Contents

List of Contributors xv
Preface xxv

I
SETTING THE SCENE, BOTANICAL, GENERAL AND INTERNATIONAL ASPECTS

1. The *Cannabis* Plant: Botanical Aspects 3
S. FARAG, O. KAYSER

2. The Biosynthesis of Cannabinoids 13
F. DEGENHARDT, F. STEHLE, O. KAYSER

3. Increasing Plant Concentrations of THC and Implications on Health Related Disorders 24
V. VINDENES, J. MØRLAND

4. Age as a Predictor of Cannabis Use 33
D. BERGEN-CICO, R.D. CICO

5. Lifetime Cannabis Use and Cognition in Psychosis Spectrum Disorders 44
M.J. CUESTA, A.M. SÁNCHEZ-TORRES, R. LORENTE-OMEÑACA, L. MORENO-IZCO

6. A Profile of Synthetic Cannabinoid Users 53
A.N. SANDERS, J.M. STOGNER

7. Dual Disorders in Cannabis Misuse 61
F. ARIAS-HORCAJADAS, N. SZERMAN, P. VEGA, I. BASURTE, B. MESÍAS

8. Cannabis Use and Cognitive Function 70
C. EVREN

9. Cannabis, Migration, and Psychosis Onset 79
A. KOKONA, I. TARRICONE, M. DI FORTI, E. CARRA

10. The Global Epidemiology and Disease Burden of Cannabis Use and Dependence 89
L. DEGENHARDT, A.J. FERRARI, W.D. HALL

11. International Aspects of Cannabis Use and Misuse: the Australian Perspective 101
D.J. ALLSOP, W.D. HALL

12. International Aspects of Cannabis Use and Misuse: Egypt 110
O.M.E. ABDEL-SALAM, A.F. GALAL, S.A. ELSHEBINEY, A.E.D.M. GAAFAR

13. Cannabis Body Packing: A Caribbean Perspective 122
S.O. CAWICH, D. DAN, V. NARAYNSINGH

II
PERSONAL, SOCIAL AND COMMUNITY ASPECTS OF CANNABIS USE

14. Gender Differences in Cannabis Use Disorders 131
R. SECADES-VILLA, S. FERNÁNDEZ-ARTAMENDI

15. The Role of Age in the Onset and Further Development of Cannabis Use Disorders 138
S. BEHRENDT

16. Effects of Cannabis Use on Neurocognition in Adolescents and Emerging Adults 151
N.E. WRIGHT, K.E. MAPLE, K.M. LISDAHL

17. Correlates and Consequences of Prenatal Cannabis Exposure (PCE): Identifying and Characterizing Vulnerable Maternal Populations and Determining Outcomes for Exposed Offspring 160
L.K. BRENTS

18. Cannabis and Clubbing: Relevance of Cannabis and Polydrug Use in the Clubbing Culture Today 171
D.A. HERZIG, S. BACHMANN

19. Cannabis and Sexual Behavior 180
G. SCIMECA, C. CHISARI, M.R.A. MUSCATELLO, C. CEDRO, G. PANDOLFO, R. ZOCCALI, A. BRUNO

20. Friendships and Cannabis Use 188
J.H. BOMAN IV, C. HECK

21. Students' Knowledge of Cannabis 198
M. DROZD, J. SOBCZYŃSKI

22. Childhood Trauma and Cannabis: Risk Factors in Severe Mental Disorders? 208
M. AAS, I. MELLE

23. Parent's Influence on Children's Cannabis Use 215
S. MILLER, J.T. SIEGEL, W.D. CRANO

24. Cannabis Users and Premorbid Intellectual Quotient 223
L. FERRARO, L. SIDELI, D. LA BARBERA

25. Cannabis and Traffic Accidents 234
R.B. DE BONI, R.P. LIMBERGER, T.R.V. SOUSA

III
CANNABIS, BEHAVIOR, PSYCHOPATHOLOGY AND NEUROPATHOLOGY

26. Drug-Related Pictures, Attentional Bias, and Cannabis Use 247
D. ASMARO

27. Cannabis Use and First-Episode Psychosis Patients (FEP) 257
I. GONZÁLEZ-ORTEGA, M. MARTÍNEZ-CENGOTITABENGOA, A. GONZÁLEZ-PINTO

28. Cannabis, Associative Memory, fMRI, and the Implicit Association Test 267
S.L. AMES, A.W. STACY

29. Stress Response in Cannabis Users and Psychosis 278
M. BIOQUE, H.-H. TSENG, R. MIZRAHI

30. Motivation in Chronic Cannabis Use 288
R. HIRST, L. SODOS, S. GADE, L. RATHKE

31. Cannabis Use and Its Association to Mental Illness: A Focus on Mood and Anxiety Disorders 298
S. LEV-RAN, D. FEINGOLD

32. Cannabis Use and Well-Being 308
J. ALLEN, M.D. HOLDER, Z. WALSH

33. Craving and Cannabis: A Potential Paradox 317
M.J. LOFLIN, M. EARLEYWINE

34. Delta-9-Tetrahydrocannabinol and Catalepsy-Like Immobilization 326
N. EGASHIRA

35. The Interactive Nature of Cannabis and Schizophrenia Risk Genes 335
T. KARL, J.C. ARNOLD

36. Neuroimaging Findings in Adolescent Cannabis Use and Early Phase Psychosis 345
C.E. CROCKER, J. COOKEY, P.G. TIBBO

37. Cannabis Smoking in Adult Schizophrenia: A Cognitive and Functional Magnetic Resonance Imaging Perspective 357
K. PAQUIN, T. LECOMTE, S. POTVIN

38. The Long-Lasting Effects of Cannabis Use on Movement and Brain Regions that Control Movement 372
G. TODD, J.M. WHITE

39. Assessment of Cannabis Acute Effects on Driving Skills: Laboratory, Simulator, and On-Road Studies 379
P. BONDALLAZ, H. CHTIOUI, B. FAVRAT, E. FORNARI, C. GIROUD, P. MAEDER

40. Chronic Cannabis Use and Axonal Fiber Connectivity 391
N. SOLOWIJ, A. ZALESKY, V. LORENZETTI, M. YÜCEL

41. Microglial Activation and Cannabis Exposure 401
L. CUTANDO, R. MALDONADO, A. OZAITA

42. Cannabis and Psychosis: Correlation, Causality, and Consequences 413
D. BASU, P. PARAKH

43. Cannabis Use in Bipolar Disorder 422
T.V. LAGERBERG

44. Cannabis Use in Epilepsy—Risks and Benefits 431
M. HOLTKAMP, M. HAMERLE

45. Cannabis, Cannabinoids, and Visceral Pain 439
R. ABALO, M. ISABEL MARTÍN-FONTELLES

46. Cannabis and Postoperative Analgesia 450
S.O CAWICH, U. DEONARINE, H.E. HARDING, D. DAN, V. NARAYNSINGH

IV

CANNABIS, ORGANS, TISSUES AND NON-CNS ASPECTS

47. Chronic Cannabis Abuse and Thyroid Function 461
U. BONNET

48. Cannabis Hyperemesis Syndrome 466
U. BONNET

49. Cannabis and Cannabinoids and the Effects on Gastrointestinal Function: An Overview 471
M. SAŁAGA, R. ABALO, J. FICHNA

50. Cardiovascular Effects of Cannabis Usage 481
S. MENAHEM

51. Cannabis and Stroke 486
P.A. BARBER

52. Cannabis Smoking and the Lung 494
D.P. TASHKIN

53. Cannabis and Hepatic Injury 505
S.A. NADA, O.M.E. ABDEL-SALAM, A.A. SLEEM

54. Cannabis Allergy: More Than a Bad Trip 517
A.L. VAN GASSE, V. SABATO, M.M. FABER, C.H. BRIDTS, D.G. EBO

55. Marijuana and Breastfeeding 527
M.G. HILL, K.L. REED

56. Hypocretins/Orexins and Addiction: Role in *Cannabis* Dependence 533
Á. FLORES, R. MALDONADO, F. BERRENDERO

57. Regulatory Role of Cannabinoids for Skin Barrier Functions and Cutaneous Inflammation 543
T. TÜTING, E. GAFFAL

V

PHARMACOLOGY AND CELLULAR ACTIVITIES OF CANNABINOIDS AND ENDOCANNABINOIDS

58. Cannabinoids and the Cannabinoid Receptors: An Overview 553
D. LU, D.E. POTTER

59. Signaling and Regulation of the Cannabinoid CB_1 Receptor 564
M.R. HUNTER, D.B. FINLAY, M. GLASS

60. Allosteric Modulation of the Cannabinoid CB1 Receptor 573
E.E. CAWSTON, M.R. HUNTER, M. GLASS

61. Polymorphisms of the CB2 Cannabinoid Receptor 584
P. KUMAR, Z.-H. SONG

62. Chemistry of Cannabinoid Receptor Agonists 592
M. AGHAZADEH TABRIZI, P.G. BARALDI

63. The Endocannabinoid System as a Target for New Antiseizure Drugs 606
L.R. VILELA, A.C.P. DE OLIVEIRA, M.F. MORAES, F.A. MOREIRA, R.N. TAKAHASHI

64. Pharmacological Aspects of Anandamide and 2-Arachidonoyglycerol as Bioactive Lipids 616
M. ALHOUAYEK, G.G. MUCCIOLI

65. Pharmacological Aspects of NMDA Receptors, mGluR5, and Endocannabinoids 630
Y. IZUMI, C.F. ZORUMSKI

66. Peripheral CB1 Receptors and Ghrelin in Feeding Regulation: Pharmacological Implications 639
L. ORIO, R. GÓMEZ DE HERAS, F. RODRÍGUEZ DE FONSECA

67. Pharmacological Aspects of Novel Antiobesity Agents Related to Cannabinoids 649
L. HERNANDEZ-FOLGADO

68. Cannabinoid Reward and Dependence: Focus on the Main Psychoactive Ingredients of Marijuana in Preclinical Studies 659
G. PANAGIS

69. Peroxisome Proliferator Activated Receptors and Cannabinoids 671
E. MUÑOZ, F. POLLASTRO, O. TAGLIALATELA-SCAFATI, G. APPENDINO

70. The Protein–Protein Interactions of Cannabinoid Receptor Interacting Protein 1a (CRIP1a) and Cannabinoid 1 Receptor: The Molecular Mechanism Study Through an Integrated Molecular Modeling Approach 680
M.H. AHMED, Y. ZHANG

71. Synthetic Cannabinoids: a Summary of Selected Phenomena with Respect to Behavioral Pharmacology and Abuse Liability 691
B.T. BURROWS, L.R. WATTERSON, J. EGNATIOS, M.F. OLIVE

VI

EFFECTS OF SPECIFIC NATURAL AND SYNTHETIC CANNABINOIDS

72. The Role of 5-HT_{1A} Receptor, and Nausea and Vomiting Relief by Cannabidiol (CBD), Cannabidiolic Acid (CBDA), and Cannabigerol (CBG) 703
E.M. ROCK, L.A. PARKER

73. Genetic and Molecular Aspects of Addiction with Tetrahydrocannabinol 713
T. JANUS, A. MACHOY-MOKRZYŃSKA, K. BOROWIAK

74. Effects of Δ^9-Tetrahydrocannabinol in Human Breast Cancer 722
S. TAKEDA, E. IKEDA, H. OKAZAKI, K. WATANABE, H. ARAMAKI

75. Δ^9-THC and COX-2 Signaling 729
J. ZHANG, C. CHEN

76. Cannabinoids and the Addictive Effects of Nicotine 739
L.V. PANLILIO, S.R. GOLDBERG

77. Cannabinoid Regulation of Intraocular Pressure: Human and Animal Studies, Cellular and Molecular Targets 748
A. ALOWAY, A. KUMAR, A.S. LAUN, Z.H. SONG

78. Ocular Delivery of Tetrahydrocannabinol 760
G.R. ADELLI, P. BHAGAV, M.A. REPKA, W. GUL, M.A. ELSOHLY, S. MAJUMDAR

79. The Role of γ-Aminobutyric Acid in the Interoceptive Effects of Oral Δ^9-Tetrahydrocannabinol in Humans 770
J.A. LILE, J.S. FOGEL, T.H. KELLY

80. The Role of Δ^9-Tetrahydrocannabinol in Diabetes Mellitus 779
Z.M. COSKUN, S. BOLKENT

81. Cannabidiol: An Overview of its Antipsychotic Properties 787
F.F. PERES, V. ALMEIDA, V.C. ABILIO

82. Cannabidiol for the Treatment of Epilepsy: An Overview of Possible Mechanisms of Action and Preclinical and Human Studies 795
R. GUIMARÃES DOS SANTOS, J.E.C. HALLAK, A.W. ZUARDI, A.C. DE SOUZA CRIPPA, J.A. DE SOUZA CRIPPA

83. Cannabidiol and Neuroprotection: Evidence from Preclinical Studies 802
N. SCHRÖDER, V.K. DA SILVA, J.E.C. HALLAK, A.W. ZUARDI, J.A. DE SOUZA CRIPPA

84. Cannabinoids as Potent Inhibitors of Human CYP1 Enzymes 813
K. WATANABE, S. YAMAORI, K. MASUDA, T. KATSU, S. NARIMATSU, I. YAMAMOTO

85. The Synthetic Analog of Δ^9-Tetrahydrocannabinol (THC): Nabilone. Pharmacology and Clinical Application 821
R.E BALTER, M. HANEY

86. Synthetic Cannabinoids in Dementia 828
S. AMANULLAH, K. SHIVAKUMAR, S. HASSAN, A. CANFIELD, J. COLE

87. Synthetic Cannabinoid Receptor Agonists (Spice) as New Recreational Psychoactive Substances 839
A. HELANDER

88. Accidents and Synthetic Cannabinoids in Blood of Drivers 848
S.S. TUV, V. AUWÄRTER, V. VINDENES

VII
MEDICINAL CANNABIS USE

89. Cannabis and Synthetic Cannabinoids for Cancer Patients: Multiple Palliative Indications Together With Promising Laboratory Antineoplastic Effects 859
D. ZALMAN, G. BAR-SELA

90. The Use of Medical Marijuana in the Treatment of Psychiatric Disorders 869
T. TELLIOĞLU, Z. TELLIOĞLU

91. Beneficial Effects of Cannabis and Related Compounds on Sleep 877
I.M.P. LINARES, J.A.S. CRIPPA, M.H.N. CHAGAS

92. Cannabinoid-Based Medicines for the Treatment of Gilles de la Tourette Syndrome 883
A.S. KANAAN, K.R. MÜLLER-VAHL

93. Cannabidiol and Multiple Sclerosis 893
M. MECHA, A. FELIÚ, F.-J. CARRILLO-SALINAS, C. GUAZA

94. Cannabinoids and Their Effects on Painful Neuropathy 905
D. SELVARAJAH, R. GANDHI, S. TESFAYE

95. Cannabis for Basal Ganglia Disorders (Parkinson Disease and Huntington Disease) 917
O.M.E. ABDEL-SALAM

96. Medical Cannabis for the Treatment of Inflammatory Bowel Disease 931
A. LAHAT

97. Cannabidiol for the Treatment of Drug Use Disorders 939
R.G. DOS SANTOS, J.E.C. HALLAK, A.W. ZUARDI, J.A. DE SOUZA CRIPPA

98. Cannabinoids and Effects on the Gastrointestinal Tract: A Focus on Motility 947
G. VERA, J. FICHNA, R. ABALO

99. Potential Medical Uses of Cannabigerol: A Brief Overview 958
S. DEIANA

VIII
SCREENING, DIAGNOSIS, AND TREATMENT

100. The Cannabis Abuse Screening Test (CAST) and Its Applications 971
L. BASTIANI, R. POTENTE, M. SCALESE, V. SICILIANO, L. FORTUNATO, S. MOLINARO

101. Screening of Synthetic Cannabinoids 981
E.L. ØIESTAD, R. KARINEN, K. HAUGLAND, Å.M.L. ØIESTAD

102. On-Site Drug Testing for Cannabis 998
A.A. FERNÁNDEZ

103. Cannabinoids in Oral Fluid: Identification and Interpretation of Analytical Results 1007
C. MOORE

104. Cannabinoids in Exhaled Breath 1018
O. BECK

105. Barriers to Treatment Seeking for Cannabis Dependence 1025
P. GATES, J. COPELAND

106. Pharmacotherapies for Cannabis Use Disorders 1030
A.L. McRAE-CLARK

107. Self-Initiated Cannabis Use Cessation in Adolescents and Emerging Adults 1036
J. TSAI, M. LITTLE, S. SUSSMAN

108. Treating Cannabis-Dependent Adolescents with Family Therapy: The Case of Multidimensional Family Therapy 1047
H. RIGTER

109. Cognitive Behavioral Therapy in Cannabis Use Disorder 1056
F.M. GUVEN, U.M. CAMSARI, O. SENORMANCI, G. OGUZ

110. The Cannabis Withdrawal Syndrome—Symptoms and Time Course 1066
M. HESSE, B. THYLSTRUP

111. School-Based Cannabis Prevention Programs 1074
C. ARIZA, F. SÁNCHEZ-MARTÍNEZ, A. PÉREZ

112. The CapOpus Trial for Cannabis Use Disorders 1086
C.R. HJORTHØJ, M. NORDENTOFT

113. Treating Cannabis Use Disorders Through Technology-Assisted Interventions: The Telephone and Internet 1093
P. GATES, J. COPELAND

114. Reducing Cannabis Use With a Real-Time Intervention Using Mobile Technology 1101
M. KELLS, L.A. SHRIER

Cannabis Neuropathology Resources and Recommended Reading 1111
R. RAJENDRAM, V.B. PATEL, V.R. PREEDY

Index 1115

Online Contents

I

SETTING THE SCENE, BOTANICAL, GENERAL AND INTERNATIONAL ASPECTS

e1. Tetrahydrocannabinol Concentration and Genetic Characterization of Cannabis e1
F. CASCINI, I. BOSCHI

II

PERSONAL, SOCIAL AND COMMUNITY ASPECTS OF CANNABIS USE

e2. Cannabis Use in Youth Subcultures e11
M. PAWSON, B.C. KELLY

III

CANNABIS, BEHAVIOR, PSYCHOPATHOLOGY AND NEUROPATHOLOGY

e3. Aggressive Behavior and Cannabis Use e19
W. LIU, H. PETRAS

e4. COMT Genotypes, Cannabis Use, and Psychosis: Gene-Environment Interaction Evidence from Human Populations, and Its Methodological Concerns e29
M. FATJÓ-VILAS, C. PRATS, L. FAÑANÁS

e5. Neuroimaging and Genetics of the Acute and Chronic Effects of Cannabis e42
R. MARTÍN-SANTOS, J.A. DE SOUZA CRIPPA, S. BHATTACHARYYA

e6. Gray Matter, Lateral Ventricle Volumes, and Executive Functioning in Cannabis Users with First-Episode Psychosis e53
P.J. CUNHA, P.G.P. ROSA, F.L.S. DURAN, L.C. SANTOS, J.A.S. CRIPPA, G.F. BUSATTO, M.S. SCHAUFELBERGER

e7. Cannabis Use and Attention-Deficit/Hyperactivity Disorder: Potential Moderators e64
K.E. MAPLE, N.E. WRIGHT, K.M. LISDAHL

IV

CANNABIS, ORGANS, TISSUES AND NON-CNS ASPECTS

e8. Cannabis and Oral Health: Deleterious Effects on Periodontitis and Dental Implants e72
G. NOGUEIRA-FILHO

e9. Does Cannabis Use Increase the Risk of Developing Cancer in Humans? e80
R.C. CALLAGHAN, M. VERDICHEVSKI, T.M. FYFE, J.M. GATLEY

e10. Cannabis and the Use of Amphetamine-Like Substances e101
A. PORCU, M.P. CASTELLI

V

PHARMACOLOGY AND CELLULAR ACTIVITIES OF CANNABINOIDS AND ENDOCANNABINOIDS

e11. Cannabinoid Signaling in Glioma Cells and Therapeutic implications e111
A. ELLERT-MIKLASZEWSKA, I. A. CIECHOMSKA, B. KAMINSKA

VI

EFFECTS OF SPECIFIC NATURAL AND SYNTHETIC CANNABINOIDS

e12. Cannabidiol as an Antioxidant e122
R.S. BORGES, A.B.F. DA SILVA

e13. The Anxiolytic Effects of Cannabidiol (CBD) e131
A.W. ZUARDI, J.A. DE SOUZA CRIPPA, J.E.C. HALLAK, A.C. CAMPOS, F.S. GUIMARÃES

e14. New Ethological and Morphological Perspectives for the Investigation of Panicolytic-Like Effects of Cannabidiol e140
N.C. COIMBRA, J. MENDES-GOMES, J.A. DA SILVA, T. DOS ANJOS-GARCIA, F. ULLAH, R.C. ALMADA

e15. Spice Use Among United States Military Personnel e150
H.A. MORRIS, J.M. STOGNER

VII

MEDICINAL CANNABIS USE

e16. Cannabis Use in Fibromyalgia e158
M. FARRÉ, A. FARRÉ, J. FIZ, M. TORRENS

VIII

SCREENING, DIAGNOSIS, AND TREATMENT

e17. Short Instruments to Screen for "Problematic" Cannabis Use in General Population Surveys e168
B. ANNAHEIM, S. LEGLEYE

e18. Self-report of Cannabis Use e185
T. VAN DER LINDEN

e19. CANDIS Program: Modular Treatment of Cannabis Use Disorders e193
E. HOCH, H. ROHRBACHER

e20. Engaging Cannabis Users in Treatment e202
F. KAY-LAMBKIN, A. HEALEY, A. BAKER, W. SWIFT, L. THORNTON, A. TURNER

Preface

Cannabis is probably one of the most commonly used drugs of misuse. It has a wide range of adverse effects including impairing learning and memory. At the same time, the medical use of cannabis has been advocated due to its ability to relieve pain as an example. Understanding the nature of the pleasure-seeking, disinhibition, and other effects have also paved the way for the specialized field of cannabis pharmacology. This includes elucidating the nature of cannabinoid receptors, which has led to the development of synthetic cannabinoid agonists. However, the aforementioned is a rather simplistic synopsis. The long-term use of cannabis may also increase the risk of schizophrenia, paranoia, and other psychoses. Its use can affect cells, organs, individuals, families, subcultures, groups, and communities. This is because the interrelationships between cannabis and individual components, diagnosis, screening, social and community effects, psychopathology, neuropathology, non-CNS effects, polydrug use, medicinal applications, treatments, and pharmacology are complex. Furthermore, although the active agents in cannabis are known, the individual steps between exposure by ingestion or inhalation and effects on cells and the body are multifactorial, and cut across many scientific disciplines. It is thus important to learn from these interrelationships to embrace a multidisciplinary approach to understand all the threads and ramifications of cannabis use, misuse, and applications. For example, some cellular mechanisms elucidated by studying one anatomical CNS component may also be relevant to other areas of the CNS, or other fields of cannabis toxicity and pharmacology. Another example relates to the impact of cannabis on social dysfunction, which may also be relevant to other psychosocial scenarios, or useful in devising new treatment strategies. An additional example relates to preclinical studies which may be relevant to understanding clinical pathologies, psychomorbidities, or therapeutic drugs. Unraveling these complex relationships is difficult, as there is a wide myriad of material related to cannabis. In simple terms, the material on cannabis use and misuse has hitherto been either scattered, diffused, or crosses different disciplines. These limitations are, however, addressed in *The Handbook of Cannabis and Related Pathologies: Biology, Pharmacology, Diagnosis, and Treatment* which embraces all aspects of cannabis in a one-stop-shop approach. Where appropriate, positive aspects of cannabis and related metabolites are described.

The book is divided into eight major parts as follows:

1. Setting the Scene, Botanical, General, and International Aspects
2. Personal, Social, and Community Aspects of Cannabis Use
3. Cannabis, Behavior, Psychopathology, and Neuropathology
4. Cannabis, Organs, Tissues, and non-CNS Aspects
5. Pharmacology and Cellular Activities of Cannabinoids and Endocannabinoids
6. Effects of Specific Natural and Synthetic Cannabinoids
7. Medicinal Cannabis Use
8. Screening, Diagnosis, and Treatments

The Editor recognizes the difficulties in ascribing chapters to particular sections, and even their location within separate sections. This is because some chapters can be categorized in many ways. However, this issue is resolved with the excellent indexing carried out by Elsevier.

The Handbook of Cannabis and Related Pathologies: Biology, Pharmacology, Diagnosis, and Treatment transcends both multiple disciplinary and intellectual divides, as each chapter has:

- *Key Facts*
- *Mini-Dictionary*
- *Summary Points*

Finally, there is a chapter on Resources and Recommended Reading, suggested by some of the book's contributors.

The Handbook of Cannabis and Related Pathologies: Biology, Pharmacology, Diagnosis, and Treatment has been designed for those working in the field of cannabis and cannabinoids, drug abuse workers, neurologists, specialists in addictive behaviors, health scientists, public health and community workers, doctors,

pharmacologists, research scientists, and other specialists. The book is valuable as a personal reference book, and also for academic libraries that cover the domains of health sciences or addictions. Contributions are from leading national and international experts, including those from world renowned institutions. It is suitable for undergraduates, postgraduates, lecturers, and academic professors.

Professor V.R. Preedy, BSc, PhD, DSc, FRSB, FRSH, FRIPHH, FRSPH, FRCPath, FRSC
King's College London, London, United Kingdom

PART I

SETTING THE SCENE, BOTANICAL, GENERAL AND INTERNATIONAL ASPECTS

1	*The cannabis plant: Botanical aspects*	*3*
2	*The biosynthesis of cannabinoids*	*13*
3	*Increasing plant concentrations of THC and implications on health related disorders*	*24*
4	*Age as a predictor of cannabis use*	*33*
5	*Lifetime cannabis use and cognition in psychosis spectrum disorders*	*44*
6	*A profile of synthetic cannabinoid users*	*53*
7	*Dual disorders in cannabis misuse*	*61*
8	*Cannabis use and cognitive function*	*70*
9	*Cannabis, migration, and psychosis onset*	*79*
10	*The global epidemiology and disease burden of cannabis use and dependence*	*89*
11	*International aspects of cannabis use and misuse: the australian perspective*	*101*
12	*International aspects of cannabis use and misuse: Egypt*	*110*

CHAPTER

1

The *Cannabis* Plant: Botanical Aspects

S. Farag, O. Kayser

Technical University Dortmund, Technical Biochemistry Dortmund, Dortmund, Germany

SUMMARY POINTS

- This chapter focuses on the botanical aspects of *Cannabis*.
- *Cannabis* trichomes can come in glandular and nonglandular shapes, including oil resin.
- Resin glands are the main producer of cannabinoids.
- Recently, hybrid cannabis strains have been developed.
- Modern hydroponic techniques, coupled with selective artificial lighting, are used in order to solve the issue of low-potency cannabis.
- However, we argue that it is necessary to apply transgenic *Cannabis* plants to facilitate the metabolic pathway for cannabinoid production or agronomic traits.

KEY FACTS

- Most popular varieties of *Cannabis* are a combination of two or three of *C. sativa*, *C. indica* or *C. ruderalis.*
- *Cannabis* cultivated for fiber or oil, or narcotics production.
- Cannabinoids are the main active ingredient.
- Cultivation and breeding of narcotic strains is not permitted in most countries.
- Only female plants are economically important for producing resin in narcotic strains.
- Indoor horticultural lighting is a new system to mimic sunlight.
- Indoor hydroponic technology is used for maximizing cannabinoids.

LIST OF ABBREVIATIONS

CBD	Cannabidiol
CBDA	Cannabidiolic acid
CBN	Cannabinol
GPP	Geranylpyrophosphate
GRIN	Germplasm Resources Information Network
ISSR	Inter simple sequence repeat
NPGS	National Plant Germplasm System
RAPD	Random amplified polymorphic
RFLP	Restriction fragment length polymorphism
RH	Relative humidity
RFLP	Restriction fragment polymorphisms
THCA	Tetrahydrocannabinolic acid
THC	Δ^9-Tetrahydrocannabinol
USDA	United States Department of Agriculture

INTRODUCTION

Cannabis sativa L. (marijuana; Cannabaceae) is an annual dioeciously flowering plant. The first appearance of *Cannabis* was believed to be central Asia about 5000 BC. For millennia, the plant has also been used for fiber, oil production, and traditional uses. It contains a number of medicinally important compounds, such as, cannabinoids (Appendino, Chianese, & Taglialatela-Scafati, 2011), terpenoids (Ross & ElSohly, 1996), flavonoids (Vanhoenacker, Van Rompaey, De Keukeleire, & Sandra, 2002), alkaloids (Turner & Elsohly, 1976), and others (Brenneisen, 2007). Cannabinoids are a unique class of terpenophenolic compounds to *Cannabis* plants, accumulated mainly in the cavity of trichomes (Kim & Mahlberg, 1997). More than 80 cannabinoids have been isolated from *C. sativa* (Elsohly & Slade, 2005). The main psychoactive compound is Δ^9-tetrahydrocannabinol (THC), with well-known medicinal effects (Elbatsh,

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00001-6

Moklas, Marsden, & Kendall, 2012). At present, cultivation and breeding of *Cannabis* is prohibited in most countries, except by permission for purposes of research and pharmaceutical uses (ElSohly, 2002). *Cannabis* plants are usually propagated through the seed (sexual reproduction; outdoor cultivation) or by vegetative propagation, using stem cuttings (asexual reproduction; indoor cultivation) (Potter, 2004). However, both techniques have advantages and disadvantages. This chapter is dedicated to botanical aspects, including morphology, taxonomy, genetics, conservation, geographical distribution, and cultivation forms.

BOTANY OF *CANNABIS*

Macroscopical Features

Information was published elsewhere, giving detailed technical descriptions of *Cannabis* morphology (Clarke, 1981; UNODC, 2009) Fig. 1.1. However, this information has been simplified in the present text. *C. sativa* is an annual, dioeciously (ie, male and female flowers are found on separate plants), pollinated plant with strong taproot, erect stems. The stems are usually angular, furrowed, branched, with woody interior, sometimes hollow in the internodes, and vary from 1 to 6 m in height. The branching is either opposite or alternate. The roots are advantageous, with branched taproot, generally 30–60 cm deep, up to 2.5 m in loose soils, very near to the surface, and more branched in wet soils. Leaves are green and palmate (seven lobes). However, the size and shape of the leaflets differs markedly, according to genetic origin. The leaf arrangement is either opposite, or alternate or spiral. The leaflets are 6–11 cm (length) and 2–15 mm (width). Leaf margins are coarsely serrated. The adaxial and abaxial surfaces are green, with scattered, resinous trichomes. Inflorescences consist of numerous flower heads that can be found on long, leafy stems from each leaf axil. The staminate (male flower) consists of five pale-green, hairy sepals about 2.5–4 mm long, and five pendulous stamens, with slender filaments and stamen. The pistillate (female flowers) are almost sessile, and are in pairs. The fruit (seed), is an achene, contains a single seed with a hard shell tightly covered by the thin wall of the ovary, and it is ellipsoid, slightly compressed, smooth, about 2–5 mm long, generally brownish and mottled.

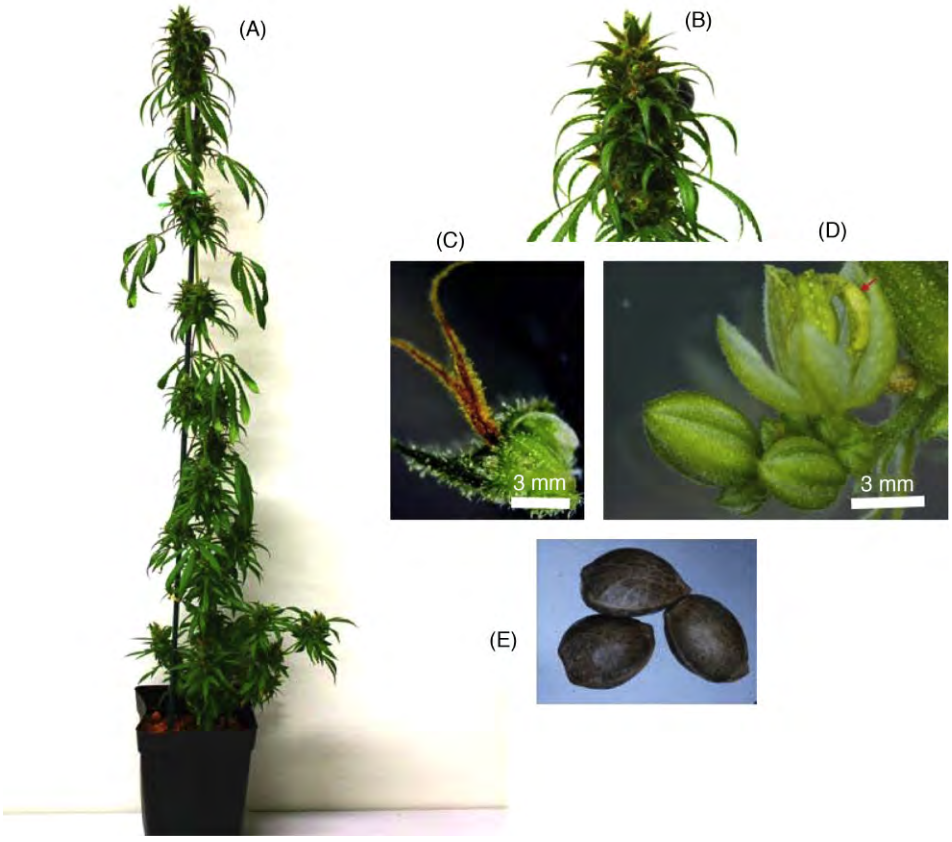

FIGURE 1.1 (A) female *C. sativa*; (B) portion of the female flowers; (C) pistillate female flower (stigmas, style, perigonal bract, and stipule); (D) portion of the female flowers show anther; (E) mature seed.

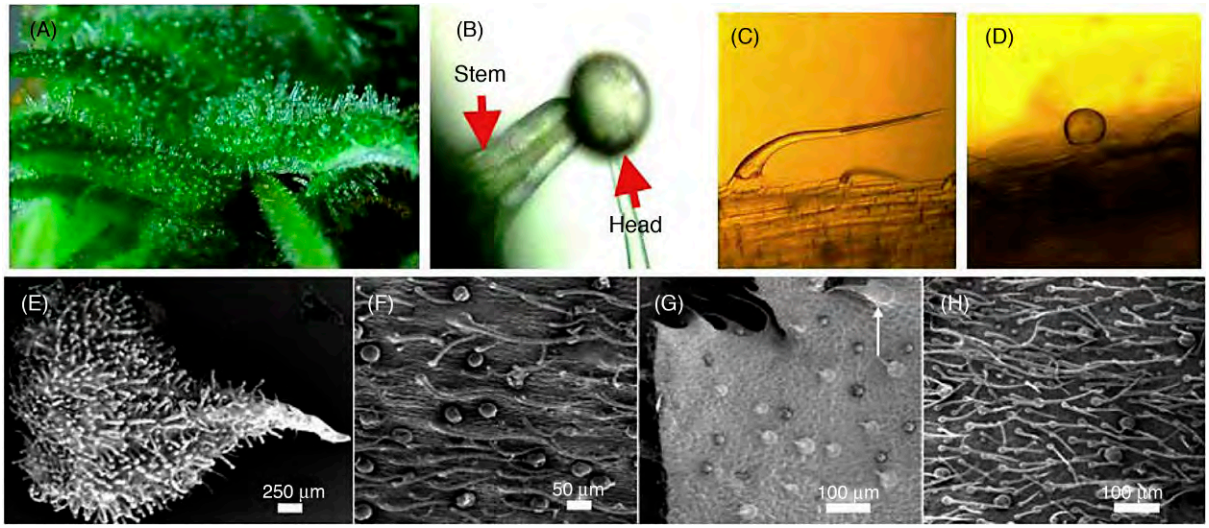

FIGURE 1.2 Microscopic photographs of *C. sativa* trichomes. (A) Trichomes on the flower; (B) capitate-stalked trichome; (C) capitate-sessile trichome; (D) bulbous trichome; (E) trichomes on the bract; (F) trichomes on the stem; (G) trichomes on the adaxial surface of a floral leaf. A big capitate-sessile trichome is indicated with an arrow; (H) trichomes on the abaxial surface of a leaf. Present abundant small capitate-sessile and bulbous trichomes. *Source: Adapted from Happyana et al. (2013).*

Microscopical Features

In general, *Cannabis* trichomes comprise a diverse set of structures and different types of trichomes (eg, glandular and nonglandular) on a single leaf, when viewed through a hand lens (Fig. 1.2). *Cannabis* trichome researchers have commonly described two types of the nonglandular trichome that have not been associated with terpenoid development (Table 1.1). Three types of glandular trichome have been described on female plants, namely bulbous, sessile, and capitate stalked (Happyana et al., 2013). Male plants have been found to exhibit a fourth type—the antherial glandular trichome, which has only been found on anthers (Fairbairn, 1972). Glandular trichomes are made from a series of differentiated cells with different functional properties, namely the secretory cells, and stalk cells (Kim & Mahlberg, 1991).

Classification of Cannabis

The first official publication which recorded the use of Latin binomials is Linnaeus's *Species Plantarum*, and it can be dated back to the year 1753. Afterward, the international community acknowledged it as the starting point for modern botanical nomenclature. The species name *Cannabis* means "*cane-like*," while the genus name "*sativa*" has the meaning "*planted or sown*," and signifies that the plant is propagated from seed, and not from perennial roots (Raman, 1998). According to the modern system of classification, *Cannabis* belongs to the family of *Cannabaceae*, along with the *Humulus* genus (hops) (Turner, Elsohly, & Boeren, 1980a,b). Different varieties of *Cannabis* have been developed over the course of many centuries, as the result of breeding and selection. However, the *Cannabis* processed by these methods creates many debates about further botanical classification. So far, there is no general agreement about the taxonomic rank of various groups within the genus *Cannabis*, and consequently its monospecific or polyspecific character, since the time of Linnaeus (late 18th century) (Hazekamp, Justin, Lubbe, & Ruhaak, 2010). UNODC (1956) divided domesticated *Cannabis* into three different groups:

- fiber hemp, long, unbranched plants, with poor seed production
- oil seed hemp, short, early maturing plants, with rich seed production
- drug hemp, short, strongly branched plants, with small dark green leaves.

Schultes, Klein, Plowman, & Lockwood (1974) distinguished three species within the genus: *C. sativa* L., *C. indica* Lam., and *C. ruderalis*. Other authors referred to the same taxa only at subspecific level within one single species, *C. sativa* (Hoffmann, 1961). Small and Cronquist (1976) divided the single species *C. sativa* into the subspecies *sativa* and *indica*, each consisting of a domesticated (Table 1.2) and wild varieties. Within the subspecies *sativa*, the domesticated and the wild varieties are *C. sativa* subsp. *sativa* var. *sativa* (domesticated), *C. sativa* subsp. *sativa* var. *spontama* (wild), *C. sativa* subsp. *indica* var. *indica* (domesticated), and *C. sativa* subsp. *indica* var. *kafiristanica* (wild). However, it is commonly accepted that *Cannabis* is monotypic, and consists only of a single species: *C. sativa* (Brenneisen, 1983; Beutler & Dermarderosian, 1978).

TABLE 1.1 A Summary of *Cannabis* Trichomes Classification, Structure, Distribution, Timing of Development, and Lifespan

Trichomes					
Classification	**Structure**	**Distribution**	**Timing of development/ density**	**Lifespan**	**References**
Nonglandular trichomes[a]	(1) *Noncystolithic trichomes*: long, unicellular, smooth, curved, covering trichomes (2) *Cystolithic trichomes*: more squat, unicellular, claw shape, cystolith covering trichomes, containing calcium carbonate	Lower side of vegetative leaves and pistillate bracts	Decreases with age	The viability and functioning secretion is correlated with senescence of epidermal cells	(Fairbairn, 1972; Hammond & Mahlberg, 1977; Turner et al., 1977, 1980b, 1981; Croteau, 1988; Werker, 2000; Guy & Stott, 2005; Happyana et al., 2013)
Glandular trichomes[b]	(1) *Bulbous*: with smallest gland	Vegetative leaves and pistillate bracts			
	(2) *Capitate-sessile (unstalked)*: the structure is commonly simple, and the trichomes head connected directly to the mesophyll cells.				
	(3) *Capitate-stalked*: the structure more complex, they developed resin head (also known as the glandular head) that resembles a golf ball sitting on a tee (the trichome's stalk).	Bracts and floral leaves	Increases with age		
Antherial sessile trichomes[c]	Large size, with a diameter of approximately 70–80 μm	Underside of the anther lobes			

[a] *Nonglandular trichomes lack cannabinoids.*
[b] *Glandular trichomes are the principal or sole site of storage of most cannabinoids, the content of Δ^9-THC in pistillate flowers ranged between 10 and 12%, and in leaves ranged between 1 and 2%.*
[c] *Male plants are of no consequence in medicine production because they develop few glandular trichomes and, consequently, produce few cannabinoids or terpenes.*

TABLE 1.2 Synopsis of C. *sativa* Sectional Species, Subspecies, and Varieties Recognized Based on Chemical, Genetic, and Morphological Variation

Section *sativa*	**Section *spontanea***

Species	

Other Recent Taxonomic Studies

CHEMOTAXONOMIC CLASSIFICATION

Recently, chemotaxonomic classification splits the phenotypes based on the quantitative differences in the cannabinoid ratio of tetrahydrocannabinolic acid (THC), cannabinol (CBN), and cannabidiol (CBD), in the ratio of [THC] + [CBN]/[CBD]. If the ratio exceeded 1, plants are classified as "chemo-type," otherwise as "fiber-type," and this was the first study to differentiate between the drug- and fiber-type, by Fetterman et al. (1971). Therefore, this ratio was subsequently used to discriminate chemotype, intermediate type, and fiber-type (Turner, Cheng, Lewis, Russell, & Sharma, 1979). Hillig and Mahlberg (2004) split *Cannabis* into putative species and subspecies, using multivariate data analysis. Moreover, it was reported that, depending on age, the *Cannabis* plant can be classified into different morphotypes, at different time points of its development. Although this classification was not comprehensive enough to elucidate infrageneric taxonomic structure, and does not define the contents of cannabinoids for each chemotype, it provides a usable tool for classification (Hazekamp et al., 2010).

MOLECULAR CLASSIFICATION

Several molecular techniques have been evaluated to establish the genetic relationship among different varieties of *Cannabis* plants. Some recent studies have classified and identified *C. sativa* samples that cannot be differentiated by HPLC analysis alone, by using genomic DNA, random amplified polymorphic DNA (RAPD), and restriction fragment polymorphisms (RFLP) analysis, but little work appears to have been conducted with marker types that would be usable for breeding (Gillan, Cole, Linacre, Thorpe, & Watson, 1995; Faeti, Mandolino, & Ranalli, 1996). Recently, Kojoma, Iida, Makino, Sekita, and Satake (2002) reported that different *Cannabis* were identified by means of inter simple sequence repeat (ISSR). ISSR is a technique offering the reproducibility and simplicity of RAPDs with high reliability (Galvan, Bornet, Balatti, & Branchard, 2003).

Current *Cannabis* Varieties

Recently, *Cannabis* growers have become more aware to create variations between different strains for developing new varieties. Newly hybrid varieties have been developed as a result of the crossbreds, such as, "*super-sativa*" (Clarke & Watson, 2002; de Meijer, 2004). Recently, varieties of *Cannabis* have been licensed to GW Pharmaceuticals Ltd, as part of indoor breeding programs (de Meijer & Hammond, 2005). In the United States, the majority of *Cannabis* cultivars were selected from single landrace sources, or from multihybrid progenies made from different landraces (de Meijer, 2004). The marijuana potency monitoring project at the University of Mississippi (USA) is breeding Sinsemilla, Skunk 1, Four Way, Four Way-F, Thai/Skunk, Terbag W1, K2, and MX *Cannabis* of hybrid varieties (ElSohly, Holley, & Turner, 1985; Elsohly, Holley, Lewis, Russell, & Turner, 1984). In the Netherlands, there are three different *Cannabis* varieties from *sativa*: Bedrocan, Bedrobinol, and Bediol, and one variety from *C. indica* is Bedica – all studied and registered by Bedrocan BV (Fischedick, Hazekamp, Erkelens, Choi, & Verpoorte, 2010). Nowadays, many *Cannabis* hybrid cultivars (Table 1.3) and some selected pure strains have been commercialized in many private companies, and there are up to 20 more or less well defined strains for either indoor or outdoor cultivation, in The Netherlands, but a sufficient data set is not available, due to illegal cultivation. Today, the cultivation and production of hemp is restricted and controlled because of its association with narcotic use. Most of the hemp breeders cultivate fiber hemp with the ultimate goal to reduce THC content below 0.2%, or even to get noncannabinoid plants by breeding and crossing experiments (de Meijer, 1995).

Genetics of *Cannabis*

Genome of Cannabis sativa

The genome of *Cannabis* ($2n = 18 + XX$ for female, and $2n = 18 + XY$ for male) has a karyotype composed of nine autosomes and a pair of sex chromosomes (X and Y). Sex chromosomes changes during the developmental stages are claimed to occur in many dioecious plants, as a strategy for survival (Flemming et al., 2007). The genome was measured in both female (XX) and male plants (XY) (Vyskot & Hobza, 2015). The estimated haploid genome sizes are 818 Mb for female plants, and 843 Mb for males (Sakamoto et al., 1998). The genomic resources available for *Cannabis* are mainly confined to transcriptome information: the NCBI database contains 12,907 ESTs and 23 unassembled RNA-Seq datasets of Illumina reads (Marks et al., 2009). The genetic basis of cannabinoid variation in *C. sativa* showed that the amount of THC versus CBD is likely governed by one locus with two codominant alleles, *B*(*d*) and *B*(*t*) (de Meijer et al., 2003). One possible explanation for these results is that the two alleles encode either THCA or CBDA synthase so that homozygous plants would contain either tetrahydrocannabinolic

acid (THCA) or cannabidiolic acid (CBDA) as the major cannabinoid, and heterozygotes would have an approximately equal mixture of the two (Fig. 1.3). Another explanation is that THCA and CBDA synthases are closely linked genes, perhaps produced as a result of a gene duplication event. A recent study analyzed the THCA synthase sequences from drug (high-THC) and fiber (low-THC) varieties, and found that the amino acid sequence of THCA synthase from high-THC varieties differed by 37 major substitutions, compared to low-THC varieties (Kojoma, Seki, Yoshida, & Muranaka, 2006).

Geographical Distribution

Small and Cronquist (1976) state that genus *Cannabis* geographically grows to the north of latitude 30°N and south of latitude 60°N (Hillig, 2005). The genus is believed to have originated in the Northwest Himalayas, and occurs widely in Africa.

Agricultural Status

Nowadays, fiber hemp is cultivated in a number of countries around the world, and China represents the largest producer of hemp with focus on fiber-type (Mediavilla, Bassetti, & Leupin, 1999). Nevertheless, cultivation of medicinal *Cannabis* is prohibited in most of countries, except by permission for purposes of research and pharmaceutical uses.

Conservation Initiatives

Cannabis populations are facing the threat of genetic drift—which has a direct effect on the changes to the phenotype and chemical profile, due to allogamous (de Meijer & Vansoest, 1992). The conservation of *Cannabis* germplasm is divided into two main strategies: in situ and ex situ.

Ex Situ Conservation in Gene Banks

The *Cannabis* gene bank at Vavilov Research Institute of Plant Industry (St. Petersburg, Russia) maintained about 200 accessions, for more than 50 years (de Meijer, 1998). In addition, the Hungarian gene bank at the Research Center for Agrobiodiversity (Tápiószele, Hungary) maintained about 70 accessions. Collections of up to 20 accessions are preserved in other depositories in Germany, Turkey, and Japan. In comparison with other crops, the available number of well-documented *Cannabis* accessions is limited (de Meijer & Vansoest, 1992). Nowadays, several accessions are maintained by the United States Department of Agriculture (USDA)/National Plant Germplasm System (NPGS), and associated data can be accessed from the Germplasm Resources Information Network (GRIN) database.

In Situ Conservation as In Vitro Gene Banks

In vitro conservation of encapsulated microcuttings of *Cannabis* shootlets was attempted under slow growth conditions between 5 and 15°C (Lata, Chandra, Khan, & ElSohly, 2008; Lata, Chandra, Mehmedic, Khan, & ElSohly, 2012), but adaptation to in vitro conditions could induce mutants of the offspring plants, causing genetic and chemical drift (Larkin & Scowcroft, 1981).

Cultivation Techniques of *Cannabis*

Outdoor Cultivation

Cannabis plant can be propagated from seeds, and the life cycle is completed within 4–6 months, depending on the time of the plantation and the variety. It can reach up to 5 m (16 ft.) in height, in a 4–6 months growing season (Raman, 1998; Clarke & Watson, 2002). Hermaphroditic varieties of this plant have been bred for industrial hemp production, as this allows more uniform crops (Leggett, 2006). The process of germination is usually completed in 3–7 days (Clarke & Watson, 2002). The seedling stage is completed within 2–3 months. Later, the plant is characterized by increased biomass and total growth under long day time lengths (vegetative growth). It is easy to recognize the male and female sex at this stage. Later in summer, the reproductive phase of *Cannabis* begins when the plant is exposed to short day time lengths (less light per day than darkness) of 12–14 h or less, depending on its latitude and genetic origin (Brenneisen, 1983). Once the male flowers ripened and pollinated, the female flowers died directly. The produced seeds after flowering have combinations of traits from two parents, as a result of cross fertilization (Clarke & Watson, 2002). This method is mostly used for the cultivation of *Cannabis* for hemp fiber, or *Cannabis* seed with less than 0.2% THC.

Indoor Cultivation

This method of breeding is used for increasing resin potency, and avoiding unwanted male plants (Chandra, Lata, Khan, & ElSohly, 2010). The complete growth cycle, quality, and quantity of biomass can be regulated under controlled environmental conditions (6–8 weeks). The successful indoor system requires an effective hydroponic system to deliver nutrients and oxygen, and support the plants' growth (Fig. 1.4). However, there is a number of different techniques that have been proposed for the indoor horticulture of *Cannabis*, for example, the standing aerated technique, nutrient film technique, and aeroponics technique. In hydroponic growing, the nutrient solution is best at a pH within a certain range (5.5–6.5) for maximum uptake and good plant growth (Argo & Fischer, 2002). Indoor *Cannabis* crop cultivation needs artificial light and compressed CO_2 gas for photosynthesis, and for controlling flowering and plant biomass (Jones, 1997). Here, selective vegetative female plants are used for making clones. Later, all clones are kept under standard environmental conditions (light, temperature, RH, and CO_2 concentration) in a growing room for vegetation (18 h/day photoperiod) and for flowering (12 h/day photoperiod).

In vitro Micropropagation

The micropropagation system offers a number of clear advantages, including (1) human-controlled method with fast propagation in a comparably short time, due to high potential multiplication rates, (2) it is independent of seasonal factors like climate and geography, and (3) the produced plants are usually free from microorganism-borne diseases (Zafar, Aeri, & Datta, 1992). On the other hand, in vitro propagation of *C. sativa* through the seed is possible in most of cultivars, although the greatest problem with such a method is the

FIGURE 1.4 **Indoor cultivation of *C. sativa*.** *Source: Photo provided from Bedrocan BV, the Netherlands.*

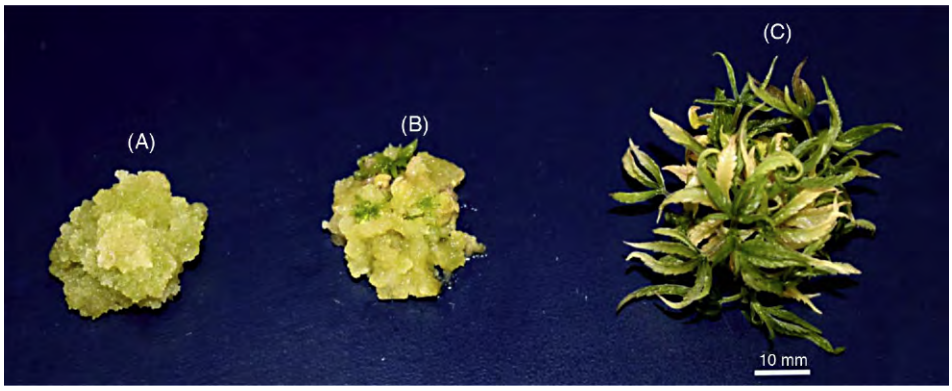

FIGURE 1.5 **In vitro micropropagation of leaf-derived calli from *C. sativa* L.** (A) Callus culture, (B) meristemoid formation, (C) shootlets multiplication on Gamborg's B5 medium supplemented with various combinations of auxins and cytokinins. *Source: Photos provided from Sayed Farag PhD project, Technische Universität Dortmund.*

high level of heterozygosity that could lead to a rapid and dramatic profile shift of secondary metabolites from one generation to the next (Chandra et al., 2010). In fact, in vitro propagation using explants or somatic embryogenesis has been reported (Lata et al., 2002). Besides the progress in the field of plant biotechnology, very little progress has been made to date toward developing an in vitro regeneration from *C. sativa*. Previous reports on de novo organogensis of *C. sativa* emerged in early 1980s (Fisse, Braut, Cosson, & Paris, 1981), and subsequently from callus of different genotypes and explant sources, including cotyledons and stem (Wielgus, Luwanska, Lassocinski, & Kaczmarek, 2008), young leaves (Lata, Chandra, Khan, & ElSohly, 2010), internodes, and axillary buds and petioles (Slusarkiewicz-Jarzina, Ponitka, & Kaczmarek, 2005), and roots (Ranalli & Mandolino, 1999). Alternatively, the use of meristematic callus for micropropagation was studied recently (Farag & Kayser, unpublished results, Fig. 1.5).

Recommendations for Future Action

Given the high therapeutic and commercial value of *Cannabis*, legal indoor breeding started in some pharmaceutical companies. The biotechnological research for genetic improvement has been minimal to date. Researches on transgenic *Cannabis* is still needed to facilitate the metabolic engineering of cannabinoids and agronomic traits.

MINI-DICTIONARY

Encapsulation In vitro technique for the production of synthetic seeds (Ca-alginate beads) for long-term storage of germplasm.
Genome The complete set of chromosomal and extra-chromosomal DNA/RNA of an organism, a cell, an organelle, or a virus.
Inter simple sequence repeats (ISSR) A molecular technique for evolutionary biology. Its simple sequence repeats (SSR), also known as microsatellites, are tandem repeats of a few base pairs distributed throughout the genome.
Micropropagation In vitro technique for multiplying plant tissues through in vitro culture, either indirectly (with intervening callus stage) or directly (without an intervening proliferative stage). This is achieved by altering the concentration of growth regulators, mainly auxins and cytokinins.
Random amplified polymorphic DNA (RAPD) A molecular technique for the rapid assignation of DNA-based character states for phylogenetic analysis. The technique uses the polymerase chain reaction (PCR) to amplify any genomic region containing single primer of nucleotide arbitrary sequence.
Restriction fragment length polymorphism (RFLP) A molecular technique for genome mapping, and variation analysis (genotyping, forensics, paternity tests, hereditary disease diagnostics, etc.). The technique uses restriction of endonucleases to cut DNA at specific (generally 4–6 bp) recognition sites.
Trichome Defined as hair-like structures that extend from the epidermis of aerial tissues; are present on the surface of most terrestrial plants.

CHAPTER

2

The Biosynthesis of Cannabinoids

F. Degenhardt, F. Stehle, O. Kayser

Laboratory of Technical Biochemistry, Department of Biochemical and Chemical Engineering, TU Dortmund University, Dortmund, Germany

SUMMARY POINTS

- This chapter focuses on the pathway which leads to the biosynthesis of phytocannabinoids in *C. sativa* L.
- CBGA is the central precursor of phytocannabinoid biosynthesis in *Cannabis*.
- CBGAS, only three enzymes—THCAS, CBDAS, and CBCAS—are involved in the biosynthesis of phytocannabinoids in *Cannabis* plants.
- Sequences of CBDAS and THCAS are known.
- The carboxyl group in CBGA seems to be essential for the enzymatic reactions catalyzed by CBDAS, CBCAS, and THCAS.
- The diversity of more than 60 cannabinoids is the result of nonenzymatic modifications.
- Propyl cannabinoids occur by the prenylation of divarinic acid (DA) with geranyl diphosphate (GPP).

KEY FACTS OF PHYTOCANNABINOIDS—BESIDES *C. SATIVA*

- Phytocannabinoids are plant-derived natural compounds that act as ligands to cannabinoid receptors (CB_1 and CB_2) or share chemical similarity with cannabinoids.
- *C. sativa* L. is intensively investigated for the presence of phytocannabinoids. To date, only a few plants are discovered that contain phytocannabinoids other than the ones known from *Cannabis*.
- The New Zealand liverwort *Radula marginata* and Japanese liverwort *Radula perrottetii* contain perrottetinene, a naturally occurring bibenzyl cannabinoid.
- Two cannabigerol-like compounds were detected in the aerial parts of *Helichrysum umbraculigerum* Less., a plant common in the eastern parts of South Africa.
- *N*-alkyl amides (cannabinomimetics), found in the medicinal plants *Echinaceae angustifolia* and *Echinaceae purpurea* (purple cornflower), are known to interact with the CB_2 receptor.

LIST OF ABBREVIATIONS

AAE	Acyl-activating enzyme
BBE	Berberine bridge enzyme
CBC	Cannabichromene
CBCA	Cannabichromenic acid
CBCAS	Cannabichromenic acid synthase
CBCVA	Cannabichrovarinic acid
CBD	Cannabidiol
CBDA	Cannabidiolic acid
CBDAS	Cannabidiolic acid synthase
CBDV	Cannabidivarin
CBDVA	Cannabidivarinic acid
CBG	Cannabigerol
CBGA	Cannabigerolic acid (3-geranyl olivetolate)
CBGAS	Cannabigerolic acid synthase
CBGVA	Cannabigerovarinic acid
CBN	Cannabinol
CBNRA	Cannabinerolic acid (*cis*-CBGA)
CHS	Chalcone synthase
CsAAE1	*C. sativa* hexanoyl-CoA synthetase 1
CsAAE3	*C. sativa* hexanoyl-CoA synthetase 2
CsHCS1	*C. sativa* hexanoyl-CoA synthetase 1
CsHCS2	*C. sativa* hexanoyl-CoA synthetase 2
DA	Divarinic acid
DABB	Dimeric α+β barrel
DMAPP	Dimethylallyl diphosphate

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00002-8

DOXP	1-Deoxy-D-xylulose-5-phosphate
GOT	Geranylpyrophosphate:olivetolate geranyltransferase
GPP	Geranyl diphosphate
HTAL	Hexanoyltriacetic acid lactone
IPP	Isopentenyl diphosphate
MEP	2C-methyl-D-erythritol-4-phosphate
MVA	Mevalonate
NPP	Neryl diphosphate
OA	Olivetolic acid
OAC	Olivetolic acid cyclase
OLS	Olivetol synthase
PKS	Polyketide synthase
SNP	Single nucleotide polymorphism
STS	Stilbene synthase
THC	Tetrahydrocannabinol
THCA	Tetrahydrocannabinolic acid
THCAS	Tetrahydrocannabinolic acid synthase
THCV	Tetrahydrocannabivarin
THCVA	Tetrahydrocannabivarinic acid

INTRODUCTION

Cannabis sativa L. (hemp) is one of the oldest domestic plants in the history of mankind, and has been cultivated for at least 10,000 years (Schultes, Klein, Plowman, & Lockwood, 1974). Together with *Humulus lupulus* (hop), *C. sativa* belongs to the small family of Cannabaceae. *Cannabis* is an annual, usually dioecious, wind-pollinated herb, with both male and female flowers growing on separate plants. The plant is well known for the biosynthesis of cannabinoids, the terpenophenolic constituents that show psychoactive effects. But since other plants also have secondary metabolites that interact with the human cannabinoid receptors, a new definition had to be made. Hence, phytocannabinoids are now defined as any plant-derived natural compound that can act as a ligand to human cannabinoid receptors (CB_1 and CB_2) or share chemical similarity with cannabinoids (Gertsch, Pertwee, & Di Marzo, 2010). Interestingly, all parts of the *Cannabis* plant, with the exception of seeds, can contain cannabinoids, but they mainly accumulate in the glandular trichomes of female flowers (Gagne et al., 2012; van Bakel et al., 2011).

The following chapter focuses on the pathway that leads to the enzymatic biosynthesis of cannabinoids. For a long time, it was postulated that the key intermediate is cannabidiol (CBD) or cannabidiolic acid (CBDA), both resulting from a condensation of a monoterpene, and olivetol or olivetolic acid (OA), respectively. In 1964, Gaoni and Mechoulam postulated cannabigerol (CBG) as the key intermediate, the condensation product of geranyl diphosphate (GPP), and olivetol or OA. Based on this, they concluded that the cannabinoids CBD, tetrahydrocannabinol (THC) and cannabinol (CBN) are all derived from CBG, and just differ in the way of cyclization (Gaoni & Mechoulam, 1964). Finally, incorporation studies with ^{13}C-labeled glucose have shown that GPP and OA are indeed the precursors for formation of cannabigerolic acid (CBGA). Thus, the general structure of cannabinoids is assembled by two parts: (1) a diphenol (resorcin) carrying an alkyl chain (OA); and (2) a monoterpene moiety (GPP) (Fig. 2.1). Subsequently, Fellermeier and

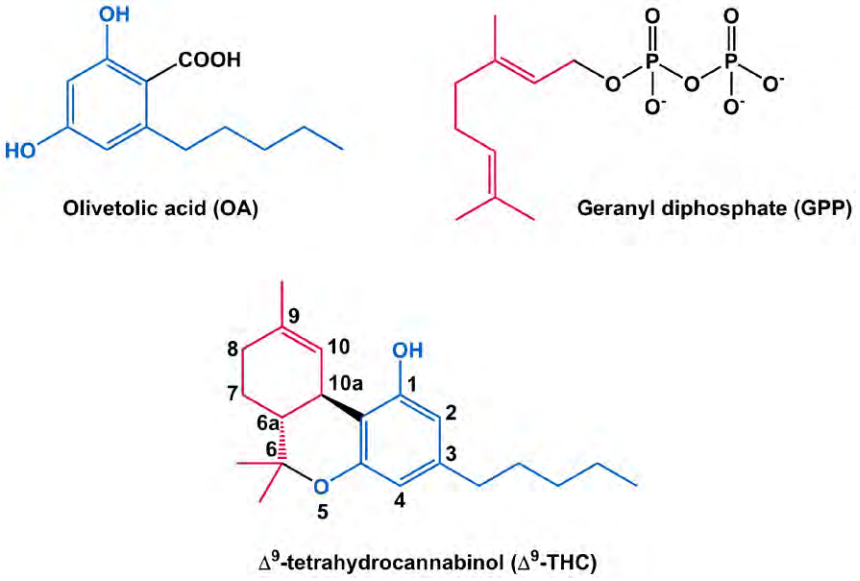

FIGURE 2.1 General structure of cannabinoids and their precursors, olivetolic acid, and geranyl diphosphate. Cannabinoids are composed of two parts: a cyclic monoterpene part *(red)*, and a diphenol (resorcin) part, carrying an alkyl chain *(blue)*. The dibenzopyran-numbering system is used.

coworkers postulated CBGA as the central cannabinoid precursor (Fellermeier, Eisenreich, Bacher, & Zenk, 2001; Fellermeier & Zenk, 1998). Interestingly, free OA has never been detected in Cannabis plant material until now.

It is worthy to note that, although more than 60 cannabinoids are known, only three enzymes, besides cannabigerolic acid synthase (CBGAS), namely tetrahydrocannabinolic acid synthase (THCAS), cannabidiolic acid synthase (CBDAS), and cannabichromenic acid synthase (CBCAS), are involved in cannabinoid biosynthesis. The resulting acidic cannabinoids are the most abundant ones accumulating in *Cannabis*. The neutral and psychoactive forms are the results of nonenzymatic decarboxylation during storage, heat or sunlight; explaining the heating of plant material (ie, smoking or baking), during *Cannabis* consumption (Fischedick, Hazekamp, Erkelens, Choi, & Verpoorte, 2010; Taura et al., 2007a). Thus, the broad diversity of the different cannabinoids is mainly due to nonenzymatic transformation or degradation of both acidic and neutral cannabinoids by the effects of light (UV irradiation) and auto-oxidation (Crombie, Ponsford, Shani, Yagnitinsky, & Mechoulam, 1968; Razdan, Puttick, Zitko, & Handrick, 1972). It is still unclear if all these forms are present in living plants as natural or artefacts, due to storage and sample preparation (ElSohly & Slade, 2005).

CANNABINOID PRECURSOR BIOSYNTHESIS

Polyketide Pathway Toward Olivetolic Acid

The origin of hexanoate in trichomes has not been elucidated so far. Suzuki, Kurano, Esumi, Yamaguchi, and Doi (2003) showed that the side-chain moiety of alkylresorcinols is formed by fatty acid units, but it remains unclear if the moiety is the result of biosynthesis or degradation of fatty acids. Studies regarding the incorporation of ^{13}C-labels into cannabinoids indicate that hexanoate is synthesized from acetyl-CoA as a starter unit, and five molecules of malonyl-CoA. These building blocks are precursors of the fatty acid biosynthesis (Fellermeier et al., 2001).

Based on this, two pathways are feasibly possible, after analysis of a cDNA/EST library generated from female flowers (glands) of *C. sativa*. First, the hexanoyl residue could be obtained by an early termination of the fatty acid biosynthesis. Subsequently, the hexanoyl moiety of the resulting hexanoyl-ACP would be cleaved by a thioesterase or transferred to CoA by an ACP-CoA transacylase. Finally, acyl-CoA synthetase would catalyze the conversion of the obtained n-hexanol to hexanoyl-CoA (Marks et al., 2009). Second, n-hexanol could be produced by the breakdown of C18 unsaturated fatty acids via the lipoxygenase pathway (Marks et al., 2009; Stout, Boubakir, Ambrose, Purves, & Page, 2012). Nevertheless, further studies are necessary to clarify the origin of the hexanol moiety.

Hexanoyl-CoA is a medium-chain fatty acyl-CoA that can be detected in high amounts in *Cannabis* flowers (Stout et al., 2012). It is synthesized by an acyl-activating enzyme (AAE) called hexanoyl-CoA synthetase (Marks et al., 2009; Page & Stout, 2013). AAEs can use short, medium, long as well as very long-chain fatty acids as carboxylic acid substrates. Two novel enzymes were identified, *C. sativa* hexanoyl-CoA synthetase 1 (CsHCS1 or CsAAE1) and *C. sativa* hexanoyl-CoA synthetase 2 (CsHCS2 or CsAAE3) that are capable of producing hexanoyl-CoA using hexanoate and CoA as substrates. Based on transcript levels, CsHCS1 seems to be trichome-specific. Although CsHCS2 exhibits lower transcript levels, in comparison to CsHCS1, it is abundant in all tissues. The gene of CsHCS1 consists of a 2163-nucleotide open reading frame, and encodes a 720-amino acid polypeptide chain. The gene of CsHCS2 is composed of a 1632-nucleotide open reading frame, and encodes a 543-amino acid polypeptide chain. Both CsHCSs generally require divalent cations for activity. This was shown by adding Mg^{2+}, Mn^{2+}, and Co^{2+} to the enzyme assays. Thus, CsHCS1 preferentially accepts Mg^{2+}, and CsHCS2 Co^{2+}. The highest enzyme activity was detected at 40°C and pH 9 for both enzymes. Furthermore, both enzymes can be inhibited by high concentrations of CoA (Page & Stout, 2013; Stout et al., 2012).

Taken together, the published data suggest that CsHCS1 is the enzyme involved in the biosynthesis of cannabinoids: (1) it is the most abundant AAE in trichomes; (2) it is highly specific for short-chain fatty acyl-CoA, particularly hexanoate (K_M value in the nM range); and (3) it is localized in the cytosol, as suggested for the olivetol synthase (see later). In contrast, CsHCS2 is localized in the peroxisomes and accepts a broad range of substrates, while showing a K_M value for hexanoate in the mM range (Page & Stout, 2013; Stout et al., 2012).

The alkylresorcinol moiety of cannabinoids is derived from OA, the product of polyketide synthases (PKSs) that catalyze the aldol condensation of hexanoyl-CoA with three molecules of malonyl-CoA (Fellermeier et al., 2001; Raharjo, Chang, Choi, Peltenburg-Looman, & Verpoorte, 2004) (Fig. 2.2). The second precursor malonyl-CoA is predominantly derived from acetyl-CoA by carboxylation. The ATP-dependent reaction is catalyzed by an acetyl-CoA carboxylase (EC 6.4.1.2). The enzyme utilizes the first step in the fatty acid biosynthesis (Chen, Kim, Weng, & Browse, 2011; Konishi, Shinohara, Yamada, & Sasaki, 1996). Taura et al. (2009) discovered a plant type III PKS in flowers and rapidly expanding leaves of *C. sativa*. The gene of olivetol synthase (OLS) encodes a 385-amino acid polypeptide chain that does

not contain a signal peptide (Table 2.1). The OLS protein has a theoretical molecular mass of 43 kDa, as confirmed by SDS-PAGE analysis. However, size-exclusion chromatography experiments revealed a molecular mass of about 89 kDa, indicating a homodimeric enzyme (Gagne et al., 2012; Taura et al., 2009). OLS (PKS-1) was preliminarily crystallized by Taguchi et al. (2008) and the structure was finally published by Yang et al. (2016). It is of interest that the enzyme does not produce OA, but olivetol, triketide pyrone, and tetraketide pyrone. Analysis of the amino acid sequence displayed a high similarity with those of *Medicago sativa* chalcone synthase (CHS), and other plant PKSs (60–70%). Additionally, the catalytic triade residues of CHS (Cys^{164}-His^{303}-Asn^{336}) are conserved (Taura et al., 2009). Since CHSs catalyze intramolecular C6 → C1 Claisen condensations, Raharjo, and coworkers were the first to suggest in 2004 (Raharjo et al., 2004) that OLS could be a stilbene synthase (STS). These enzymes catalyze C2 → C7 aldol condensations, followed by a decarboxylation step. Additionally, studies by Austin, Bowman, Ferrer, Schröder, & Noel (2004) showed that the cyclization reaction can be changed from a Claisen-type (CHS) to an aldol-type (STS) by substitution of a few amino acids in CHS (= aldol switch).

Nevertheless, since OLS alone is not capable to form OA, another enzyme/PKS might be involved in the biosynthesis. The missing enzyme should catalyze a C2 → C7 intramolecular aldol condensation upon which the carboxylate moiety is preserved. This is important since CBGAS does not accept olivetol as a prenyl donor (Fellermeier & Zenk, 1998). Gagne et al. (2012) isolated a gene encoding a 101-amino acid polypeptide chain. This small protein (12 kDa) shows similarities to a polyketide cyclase that belongs to the dimeric α + β barrel (DABB)-type protein family. Furthermore, the identified gene exhibits high expression levels in glandular trichomes. Together, this made the polyketide cyclase a promising candidate for the missing olivetolic acid cyclase (OAC).

Finally, using both OLS and OAC with hexanoyl-CoA and malonyl-CoA in one assay, the formation of OA, pentyldiacetic acid (triketide pyrone), and hexanoyltriacetic acid lactone (HTAL; tetraketide pyrone) could be demonstrated (Page & Gagne, 2013) (Fig. 2.2). It is assumed that OLS catalyzes the formation of an intermediate that is subsequently converted into OA by OAC (Gagne et al., 2012; Taguchi et al., 2008).

Biosynthesis of Geranyl Diphosphate

The monoterpene moiety of cannabinoids (Fig. 2.2) is derived from GPP. Its precursors, isopentenyl diphosphate (IPP), and dimethylallyl diphosphate (DMAPP), are predominantly (>98%) biosynthesized via the 2C-methyl-D-erythritol-4-phosphate (MEP) pathway [also termed as nonmevalonate pathway or 1-deoxy-D-xylulose-5-phosphate (DOXP) pathway] (Fellermeier et al., 2001). These results are supported by Marks et al. (2009). They isolated RNA from the glands of a tetrahydrocannabinolic acid (THCA)-producing Cannabis strain and generated a cDNA library. After sequencing, they were able to identify all but one enzyme involved in the MEP pathway. Additionally, Stout et al. (2012) found high expression of MEP pathway genes in *Cannabis* flowers. Furthermore, in higher plants the MEP pathway, mainly involved in secondary metabolism, is localized in plastids (described in detail elsewhere, for example, Eisenreich, Bacher, Arigoni, & Rohdich, (2004), or Hunter (2007), whereas the mevalonate (MVA) pathway, predominantly contributing to primary metabolism, is localized in the cytosol. The compartmental separation between these two pathways is not absolute. The metabolites of both pathways can be transported bidirectionally across the plastid membranes (Eisenreich et al., 2004).

Subsequently, the head-to-tail condensation of IPP and DMAPP to form GPP is catalyzed by geranyl diphosphate synthase (Fig. 2.2) (Burke et al., 1999).

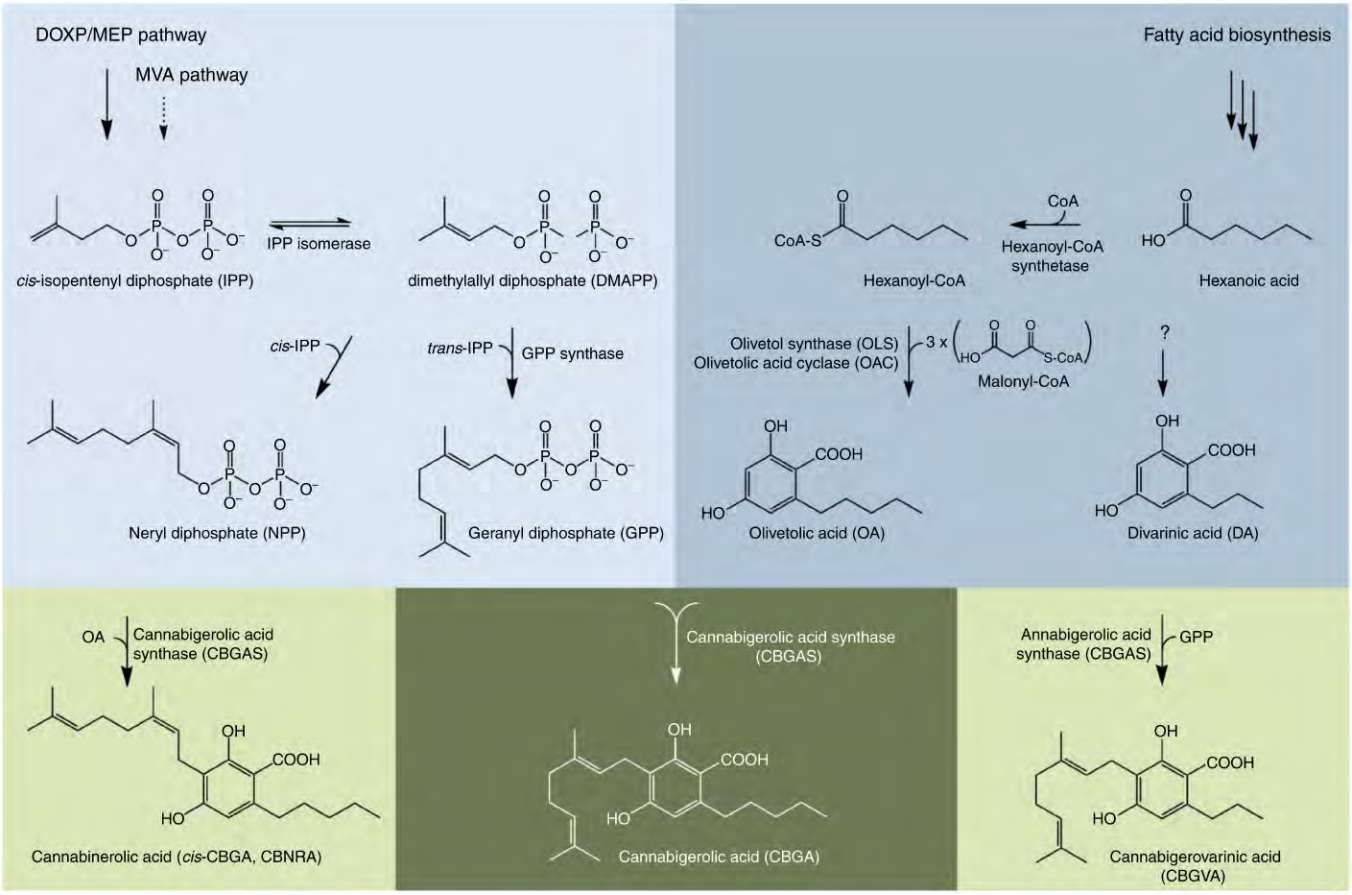

FIGURE 2.2 **Biosynthesis of cannabigerolic acid (CBGA).** The biosynthesis of the central intermediate CBGA is colored in dark green. The minor products CBNRA and CBGVA are shaded in light green. The precursor pathways are highlighted in light blue *(GPP)* and blue *(OA)*. MEP, 2C-methyl-D-erythritol-4-phosphate; DOXP, 1-deoxy-D-xylulose-5-phosphate; MVA, mevalonate (Burke, Wildung, & Croteau, 1999; de Meijer et al., 2009; Fellermeier & Zenk, 1998; Page & Gagne, 2013; Taura et al., 2009).

Cannabigerolic Acid Biosynthesis

Cannabigerolic acid synthase (CBGAS) or geranylpyrophosphate:olivetolate geranyltransferase (GOT) predominantly catalyzes the C-prenylation of OA by GPP to form CBGA (Fig. 2.2). CBGA is presumed to be the central precursor for cannabinoid biosynthesis, since different cyclization of the prenyl moiety leads to THCA or its isomers cannabichromenic acid (CBCA) and CBDA (Page & Boubakir, 2012; Sirikantaramas, Morimoto, & Shoyama, 2007).

Fellermeier and Zenk (1998) detected the enzyme in crude homogenates of rapidly expanding young leaves of *C. sativa*. This part of the plant contains the later enzymes of the THCA biosynthetic pathway (Morimoto, Komatsu, Taura, & Shoyama, 1997; Taura et al., 1995a). There are indications that CBGAS, like other prenyltransferases, is a membrane-bound prenyltransferase (Yamamoto, Kimata, Senda, & Inoue, 1997). However, Fellermeier and Zenk (1998) could not detect any enzyme activity in particulate fractions, but in the soluble fraction of the crude extract. Two major products were identified by mass spectrometry (MS) measurements as CBGA and its *cis*-isomer cannabinerolic acid (CBNRA; Fellermeier and Zenk, 1998, used CBNA instead of CBNRA). The enzyme activity was found to be Mg^{2+}-dependent. CBGAS seems to be specific for OA as a prenyl acceptor, but also accepts different prenyl donors like GPP and, to a lesser degree, neryl diphosphate (NPP) (Fig. 2.2). The production ratio of CBGA/CBNRA changes from 2:1 to 1:1 when NPP is used as a prenyl donor instead of GPP.

However, the aromatic prenyltransferase CBGAS seems to be a soluble enzyme, but Fellermeier and Zenk (1998) could not completely exclude a membrane-bound activity. Besides, two soluble hop prenyltransferases, involved in the biosynthesis of hop bitter acids, are described by Zuurbier, Fung, Scheffer, & Verpoorte (1998). Nevertheless, these are the only descriptions of soluble plant C-prenylating enzymes; until now, it was not possible to get the sequence information or to isolate the corresponding genes or enzymes.

Contradictorily, all known sequences of plant aromatic prenyltransferases belong to membrane-bound

enzymes (Yamamoto et al., 1997; Yamamoto, Senda, & Inoue, 2000; Zhao, Inoue, Kouno, & Yamamoto, 2003). This is in accordance with the second report dealing with the CBGAS (Page & Boubakir, 2012). They published a sequence of CBGAS that was mainly expressed in glandular trichomes of female flowers and young leaves of *Cannabis* plants. The gene encodes a 395-amino acid polypeptide chain showing a membrane-bound type of prenyltransferases. They were able to express the recombinant CBGAS in S*f*9 insect as well as in *Saccharomyces cerevisiae* cells, and verified the CBGAS activity in the microsomal fractions. Using MS measurements, CBGA (3-geranyl olivetolate; comparison with CBGA standard) was identified as the major product, and 5-geranyl olivetolate (identification only by LC-MS analysis) as the minor product. Furthermore, Page and Boubakir (2012) showed that CBGAS is specific only to GPP as a prenyl donor, and approves OA, olivetol, phlorisovalerophenone, naringenin, and resveratrol as prenyl acceptor. Additionally, the enzyme reaction is dependent on divalent cations, whereas the highest enzyme activity was obtained by using Mg^{2+} (Page & Boubakir, 2012).

CANNABINOID PATHWAY

CBGA, the central precursor of cannabinoid biosynthesis, is converted by three enzymes (Fig. 2.3): CBDAS, CBCAS, and THCAS. They predominantly use CBGA as substrate, and catalyze the stereoselective, oxidative cyclization of the monoterpene moiety of CBGA to CBDA, CBCA, or THCA, respectively. The THCAS and CBDAS reactions are oxygen-dependent, producing hydrogen peroxide proportional to either CBDA or THCA (Sirikantaramas et al., 2004; Taura et al., 2007b). Remarkably, the CBCAS reaction is oxygen independent, and can be inhibited by hydrogen peroxide. Thus, the enzyme seems not to be an oxygenase or a peroxidase (Morimoto, Komatsu, Taura, & Shoyama, 1998). Furthermore, all three enzymes also convert CBNRA, the

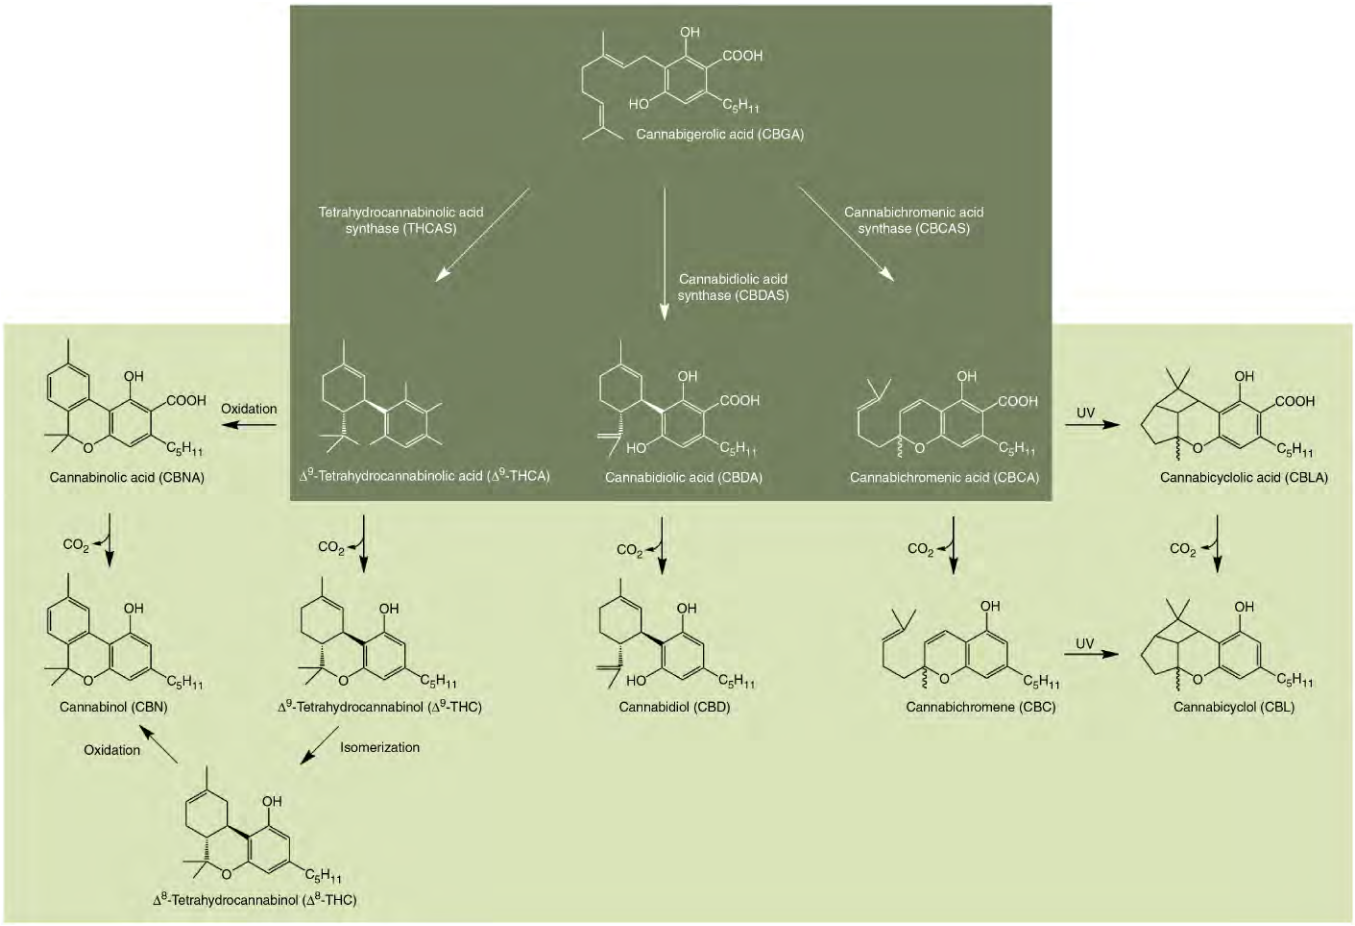

FIGURE 2.3 **Biosynthesis of cannabinoids.** The enzymatically catalyzed reactions are highlighted in dark green. All nonenzyme-dependent modifications reactions are colored in light green. Biosynthesis of C3-cannabinoids starting from cannabigerovarinic acid (CBGVA) is carried out by the same enzymes and for better clarity not shown (Crombie et al., 1968; de Meijer, 2011; Morimoto et al., 1998; Shoyama, Fujita, Yamauchi, & Nishioka, 1968; Shoyama, Oku, Yamauchi, & Nishioka, 1972; Taura et al., 1995a; 1996).

cis-isomer of CBGA, with a lower specificity (Morimoto et al., 1998; Shoyama et al., 2012; Sirikantaramas, Morimoto, & Shoyama, 2007; Taura et al., 1995b; Taura, Morimoto, & Shoyama, 1996). Since no enzymatic activity was detectable using the neutral cannabinoid CBG, the carboxyl group in CBGA seems to be essential for the enzymatic reactions catalyzed by THCAS, CBDAS, and CBCAS (Morimoto et al., 1997; Taura et al., 1995a; Taura et al., 1996).

Besides, it was postulated that THCA is biosynthesized and stored in the storage cavity of the glandular trichomes of Cannabis plants (Sirikantaramas, Morimoto, & Shoyama, 2007).

Tetrahydrocannabinolic Acid Synthase

The THCAS gene encodes a 545-amino acid polypeptide chain (Table 2.1). According to Sirikantaramas et al. (2004), a 28 amino acid long signal peptide is cleaved in the processed THCAS, leading to a protein of 517 amino acids. The mature THCAS has a theoretical molecular mass of 59 kDa. An actual mass of about 75 kDa was detected using SDS-PAGE (Taura et al., 1995b). This could be explained by posttranslational modifications, since eight possible Asn glycosylation sites were confirmed (Sirikantaramas et al., 2004). Furthermore, deglycosylated THCAS indeed showed a molecular mass of 59 kDa, and remained fully active (Taura et al., 2007b). THCAS is a monomeric enzyme with the highest activity between pH 5.5 and pH 6.0 (Taura et al., 1995b). Sequence comparison identified similarities to the berberine bridge enzyme (BBE) of *Eschscholzia californica* (Shoyama et al., 2012). BBE belongs to the family of oxidoreductases and has a covalently bound FAD (Kutchan & Dittrich, 1995). The THCAS amino acid sequence revealed a flavinylation consensus sequence (Arg^{110}-Ser-Gly-Gly-His^{114}) in which His^{114} is probably the FAD-binding site (Sirikantaramas et al., 2004). This could be confirmed by X-ray crystallography (PDB ID: 3VTE) at a resolution of 2.75Å. The results show that the enzyme is composed of two domains and one FAD binding pocket present in between. Besides His^{114}, a second residue, Cys^{176}, could be identified to be covalently bound to the FAD (Shoyama et al., 2012). Based on X-ray structure data and mutational analysis of THCAS, a possible catalytic reaction mechanism of THCAS was proposed by Shoyama et al. (2012), assigning a central role to Tyr^{484} in the catalytic mechanism (Fig. 2.5). Nevertheless, since the crystal structure was published without substrate analoga, further studies are necessary to verify the suggested mechanism.

Cannabis plants can be divided into two groups: "fiber-type" and "drug-type" plants (see dictionary). Alignment of THCAS coding sequences from "fiber-type" and "drug-type" plants showed 37 major amino acid substitutions. These substitutions seem to be the reason for decreased THCAS activity in "fiber-type" strains (Kojoma, Seki, Yoshida, & Muranaka, 2006). Minisequencing of samples from both types of *Cannabis* plants showed three different single nucleotide polymorphism (SNP) genotypes. "Fiber-type" plants are homozygous for the inactive THCAS form. "Drug-type" plants are either homozygous or heterozygous for the active form of THCAS. It seems that only a single copy of the gene encoding the active THCAS form is necessary for the biosynthesis of THCA (Rotherham & Harbison, 2011).

Cannabidiolic Acid Synthase

The gene of the wildtype CBDAS encodes a 544-amino acid polypeptide (Table 2.1). According to Taura et al. (2007b), processed CBDAS consists of 517 amino acids following cleavage of the 28 amino acid long signal peptide. The mature CBDAS has a theoretical molecular mass of 59 kDa. An actual mass of about 74 kDa was detected by SDS-PAGE that is possibly caused by posttranslational glycosylation of seven Asn residues (Taura et al., 1996; Taura et al., 2007b). CBDAS is a monomeric enzyme with a pH optimum of 5.0 (Taura et al., 1996). A comparison between THCAS and CBDAS revealed a sequence similarity of 84% (Taura et al., 2007b) (Figs. 2.4 and 2.5). Like THCAS, CBDAS is a flavinated enzyme in which His^{114} and Cys^{176} are most likely the FAD-binding sites. Since CBDAS exhibits structural and biochemical properties related to those of THCAS, it is probable that the reaction mechanism of CBDAS is similar to that of THCAS (Taura et al., 2007b).

Cannabichromenic Acid Synthase (CBCAS)

The sequence of CBCAS is still unknown. Morimoto et al. (1998) purified the enzyme to apparent homogeneity, but its sequence is not yet available in public databases. According to van Bakel et al. (2011), possible CBCAS candidates are currently analyzed biochemically.

However, CBCAS was isolated and partially purified from young leaves of *C. sativa* (Morimoto et al., 1997; 1998). In contrast to CBDAS and THCAS, CBCAS seems to be homodimer with a determined native molecular mass of 136 kDa and a maximum activity at pH 6.5. A molecular mass of 71 kDa was estimated for the monomers using SDS-PAGE. According to kinetic data, CBCAS has a higher affinity for CBGA than THCAS and CBCAS (Morimoto et al., 1998). CBCA and its neutral form CBC are both racemic. Studies of Morimoto et al. (1997) suggested that both enantiomers of CBCA are formed by a CBCAS catalyzed reaction with a molar ratio of 5:1. But it is still unknown which of the two isomers is the major product (Gaoni & Mechoulam, 1971; Morimoto et al., 1997; Taura et al., 2007a).

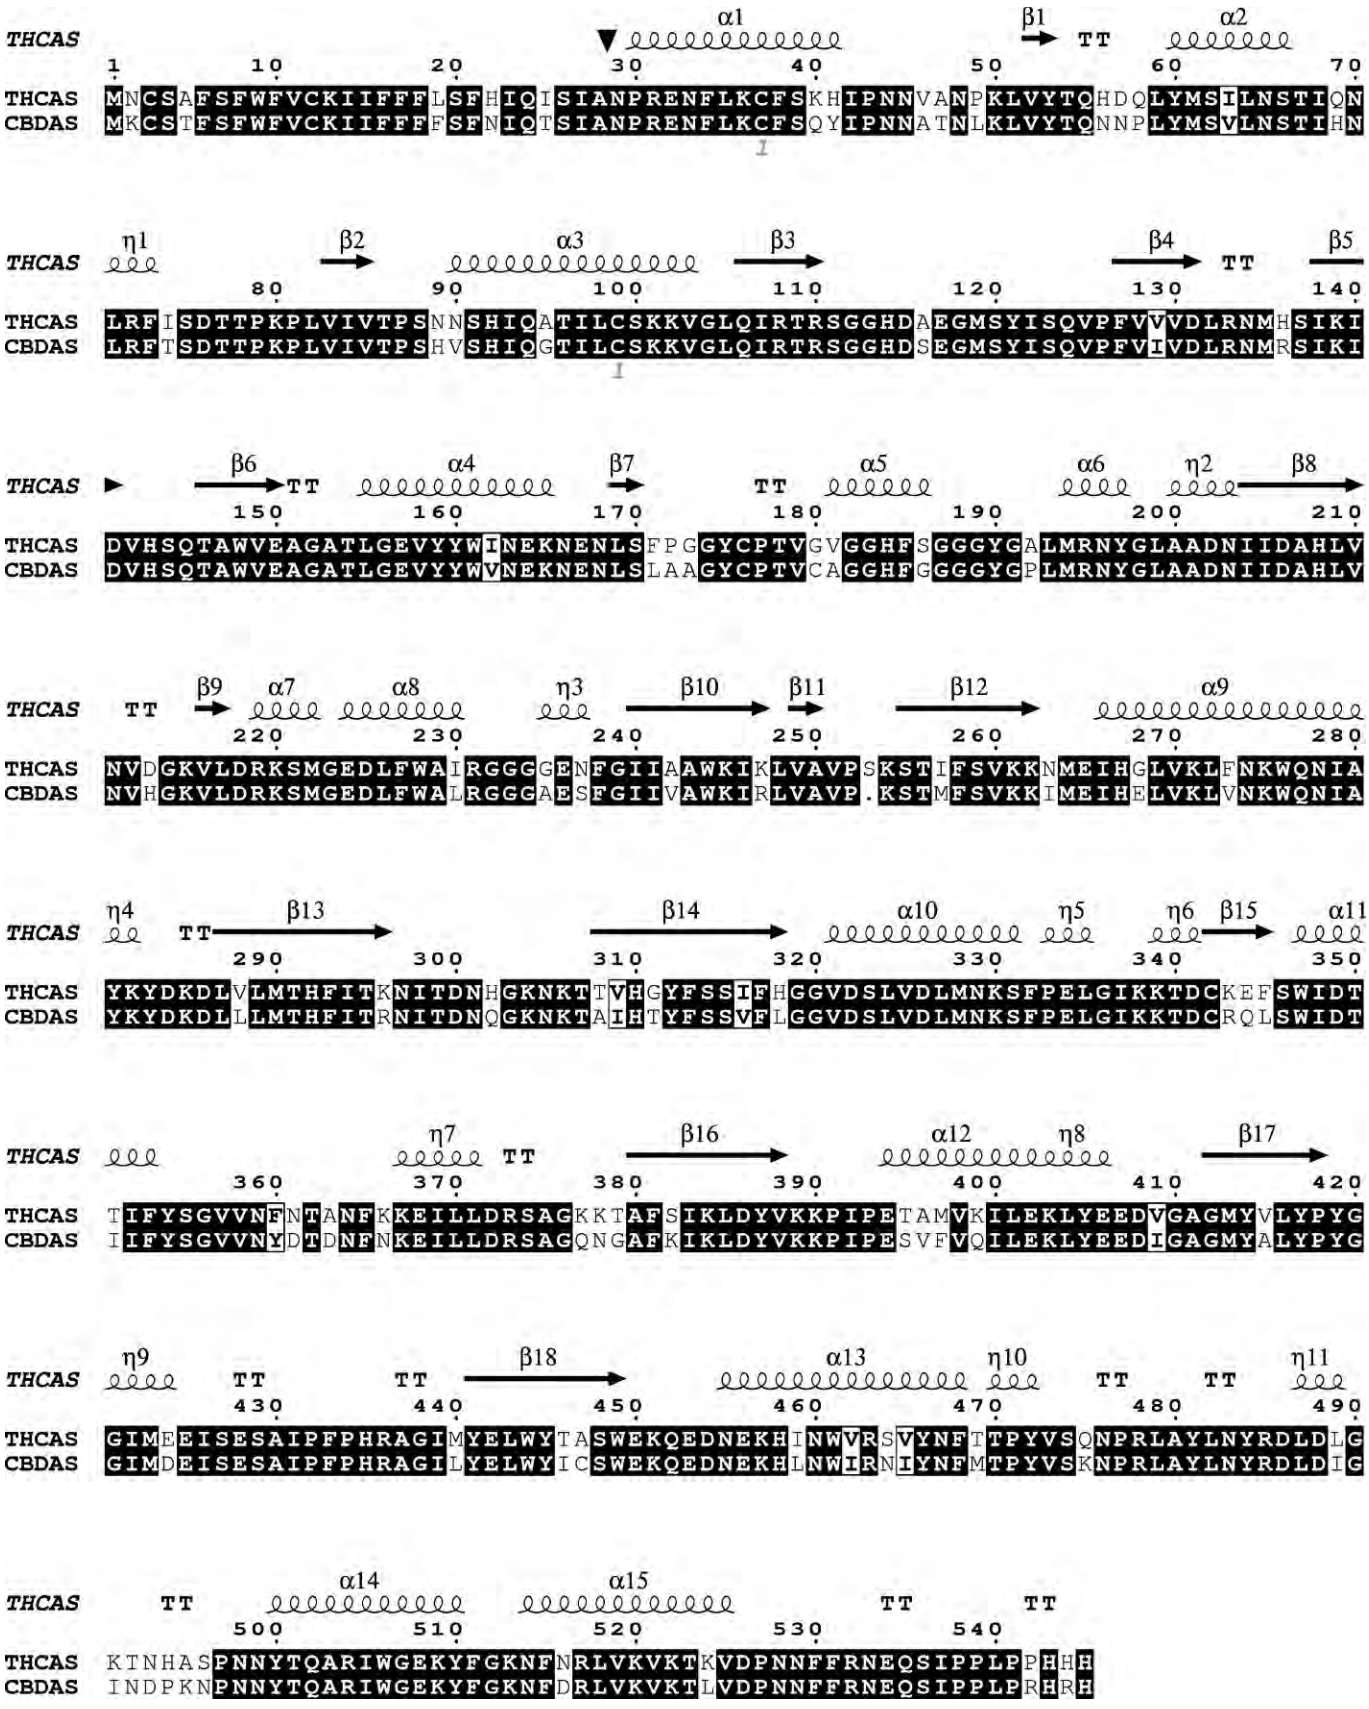

FIGURE 2.4 Alignment of amino acid sequences of THCA synthase and CBDA synthase. The alignment was performed with CLUSTAL W using the BLOSUM 62 matrix (Henikoff & Henikoff, 1992; Larkin et al., 2007). The signal peptide cleavage sites are indicated by a triangle. Secondary elements (α-alpha-helices; β-beta-sheets; TT-turns; η-3_{10} helix) are shown for the THCAS. Fully conserved residues are shaded in black. The sequences show an overall identity of 84%. The figure was made with ESPript 3.0 (Robert & Gouet, 2014). THCAS, tetrahydrocannabinolic acid synthase; CBDAS, cannabidiolic acid synthase.

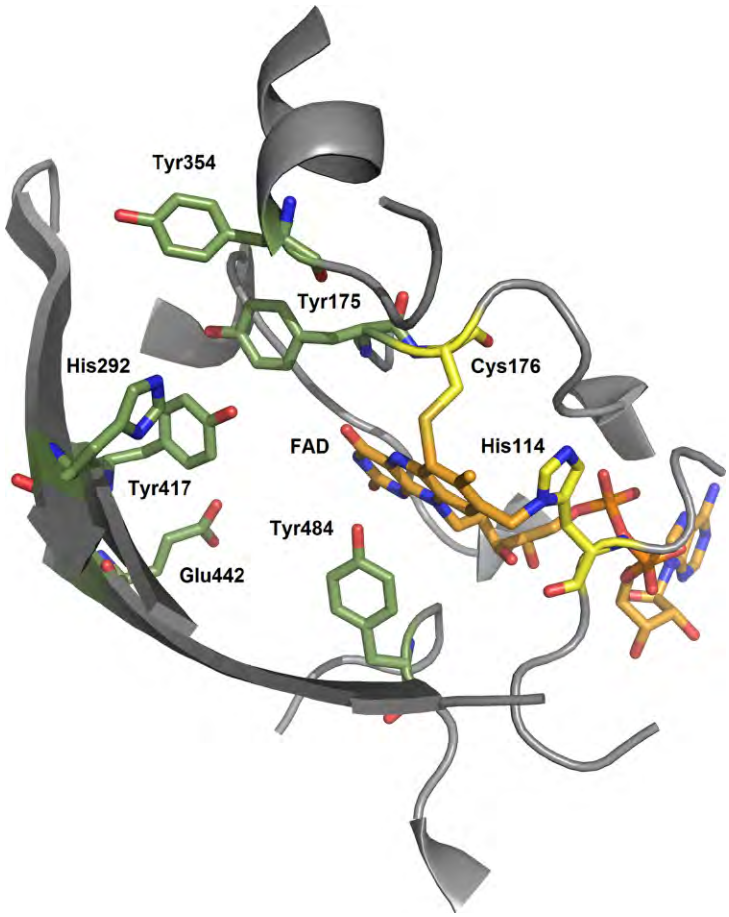

FIGURE 2.5 **X-ray structure of the active center of THCAS.** The backbone is shown as cartoon diagram (PDB ID: 3VTE). The FAD molecule *(orange)* is covalently attached to His^{114} and Cys^{176} *(yellow)*. The active site residues are highlighted in green (Shoyama et al., 2012). The close-up of active center was prepared with PyMOL. THCAS, tetrahydrocannabinolic acid synthase.

Cannabinoids with Propyl Side Chains

In contrast to the classic C5-phytocannabinoids, which contain an n-pentyl side chain, cannabinoids with an n-propyl side chain are called C3-phytocannabinoids or propyl cannabinoids. The C-prenylation of divarinic acid (DA) instead of OA by GPP yields in cannabigerovarinic acid (CBGVA) (Fig. 2.2) (de Meijer, Hammond, & Micheler, 2009). The formation of propyl cannabinoids does not occur by shortening the side chain of pentyl cannabinoids (Kajima & Piraux, 1982). CBGVA is the central branch-point intermediate in the biosynthesis of C3-cannabinoid acids, like CBGA for pentyl cannabinoid acids. The enzymes CBDAS, CBCAS, and THCAS are not selective for the length of the alkyl side chain, and can use both as a substrate. The resulting cannabinoids are called cannabidivarinic acid (CBDVA), cannabichrovarinic acid (CBCVA), and tetrahydrocannabivarinic acid (THCVA). The diverse amount of 2-carboxylic acids in different *Cannabis* strains is caused by dissimilar enzyme specificities at the level of CBGA or CBGA-analogs formation (de Meijer et al., 2009; Shoyama, Hirano, & Nishioka, 1984). Relatively high amounts of tetrahydrocannabivarin (THCV) and/or cannabidivarin (CBDV) are usually only detectable in *Cannabis indica* (de Zeeuw, 1972).

MINI-DICTIONARY

Cannabinoids Cannabinoids are a group of terpenophenolic compounds. They show affinities to cannabinoid receptors (CB_1, CB_2) or are structurally related to tetrahydrocannabinol (THC). Cannabinoids can be differentiated into phytocannabinoids, synthetic cannabinoids, and endocannabinoids.

CBGA Cannabigerolic acid (CBGA) is the central precursor of phytocannabinoid biosynthesis. It is nonpsychoactive.

"Drug-type" plants These are THCA-rich plants. The THCA is converted into psychoactive Δ^9-THC by a nonenzymatic decarboxylation that enables the plants to be labelled as THC-rich.

"Fiber-type" plants "Fiber-type" plants are also known as "nondrug" plants. These plants have a low (<0.2%) or no THCA content, but they contain a high amount of cannabidiolic acid (CBDA).

Phytocannabinoids Phytocannabinoids are a unique group of secondary metabolites (cannabinoids) occurring naturally in plants. Other names include natural cannabinoids or herbal cannabinoids (see Key facts).

Δ^8-THC In *Cannabis* plants, Δ^8-tetrahydrocannabinol (Δ^8-THC) is detectable in low amounts (<1% of the present Δ^9-THC). Like

Δ^9-THC, it is also psychoactive. Maybe Δ^8-THC is an artefact of extraction and/or analysis process. The term THC includes a combination of Δ^8-THC and Δ^9-THC.

Δ^9-THC Δ^9-Tetrahydrocannabinol (Δ^9-THC) and Δ^1-THC describe the same compound, differing in the numbering system used (dibenzopyran-numbering and monoterpene-numbering system, respectively). Δ^9-THC is responsible for the psychoactive effects of *Cannabis* products. It binds to the human cannabinoid receptors located in the central and peripheral nervous system. Misleadingly, Δ^9-THC is termed as the main component of drug-type *Cannabis* plants (see THCA).

Δ^9-THCA Δ^9-Tetrahydrocannabinolic acid (THCA), not THC, is the main component of drug-type *Cannabis* plants. It is nonpsychoactive. THCA is converted into neutral psychoactive Δ^9-THC by a nonenzymatic decarboxylation during heating or storage.

CHAPTER

3

Increasing Plant Concentrations of THC and Implications on Health Related Disorders

V. Vindenes, J. Mørland

Department of Drug Abuse Research, Division of Forensic Sciences, Norwegian Institute of Public Health, Oslo, Norway

SUMMARY POINTS

- Increased cannabis-related problems have been reported in several countries.
- Several studies have shown that the herbal cannabis market has changed worldwide in the later years toward increasing THC content (ie, increased potency).
- Cannabis potency varies widely between and within countries, and between different products.
- The literature does not support the theory that cannabis users titrate the dosage of cannabis according to their experience of THC-related "high." As a consequence, the THC exposure seems to increase when more potent cannabis is available.
- Increased concentrations of THC over the last decade have been found in blood samples from apprehended drivers and victims of fatal aviation accidents.
- In addition to THC, the content of other cannabinoids, like CBD, might influence the THC-effects.
- High-potency cannabis with low concentrations of CBD might be the reason for the increase in cannabis-related problems, but the causality has not been proven.
- The increase in cannabis-related problems might also be due to the earlier onset of cannabis use, leading to both exposure during a possible more vulnerable period, and increased life-time exposure to THC.

KEY FACTS OF EMCDDA

- The European Monitoring Centre for Drugs and Drug Addiction (EMCDDA) is an agency of the European Union.
- EMCDDA was established in 1993 and is located in Lisbon, Portugal.
- The role is to gather, analyze, and disseminate "factual, objective, reliable and comparable information" on drugs and drug addiction.
- EMCDDA provides evidence-based knowledge regarding the drug situation in Europe

KEY FACTS OF PANSS

- Positive and negative syndrome scale (PANSS) is used for measuring the symptoms associated with schizophrenia.
- Positive symptoms include paranoid and grandiose delusions, suspiciousness, fragmented thinking, conceptual disorganization, and perceptual alterations.
- Negative symptoms include lack of spontaneity, blunted affect, emotional withdrawal, and psychomotor retardation.
- The rating of the patients symptoms, using PANSS, is conducted through a brief interview.

THC	Tetrahydrocannabinol

INTRODUCTION

Cannabis is the most popular illicit drug worldwide, with high rates of use among adolescents and young adults (Copeland, Rooke, & Swift, 2013). In the United Kingdom, it has been reported that a higher number of the 16- to 18-year-olds have smoked cannabis, compared to those who have not (Morgan, Schafer, Freeman, & Curran, 2010). A stable or decreasing trend in cannabis use, especially among young adults, has been reported in Western and Central Europe (European Monitoring Centre for Drugs and Drug Addiction (EMCDDA), 2011). Cannabis is mainly used for recreational purposes, and is widely considered to be a safe drug, with relaxing and euphoric effects. There are, however, several specific adverse effects; for example, cognitive impairment (D'Souza et al., 2004; Bocker et al., 2010; Morgan et al., 2011), psychomotor impairment (Robbe, 2008; Schwope, Bosker, Ramaekers, Gorelick, & Huestis, 2012), anxiety attacks and paranoia (Bonn-Miller, Zvolensky, Bernstein, & Stickle, 2008), as well as development of psychosis (D'Souza, Sewell, & Ranganathan, 2009; Luzi, Morrison, Powell, Di, & Murray, 2008).

Different types of preparations are derived from the *Cannabis sativa* plant, and the main types are marijuana, resin (hash), and sinsemilla (skunk). Δ^9-tetrahydrocannabinol (THC) is the main psychoactive substance in all the different types. The plant contains almost 500 compounds, including 70 cannabinoids (McLaren, Swift, Dillon, & Allsop, 2008; Radhakrishnan, Wilkinson, & D'Souza, 2014). One of the other psychoactive cannabinoids is cannabidiol (CBD). The exact mechanisms by which CBD exerts its effects are not known (Niesink & van Laar, 2013), but it has been suggested it acts as a functional antagonist for some of the effects of THC, and may have anxiolytic and antipsychotic effects (McLaren et al., 2008; Morgan et al., 2011). CBD might thus offset some of the psychoactive effects of THC, thereby modulating the effects of cannabis intake.

Concerns have been raised regarding the currently available cannabis that is stronger than in the past. Higher-potency cannabis products have been claimed to cause increased exposure of THC and, accordingly, to have more negative health implications for the users. A higher number of unexpected adverse effects after cannabis consumption has been reported, and the number of people seeking treatment for dependence or cannabis-related problems has increased (Hall, 2009; Morgan et al., 2010; European Monitoring Centre for Drugs and Drug Addiction (EMCDDA), 2011).

CANNABIS PLANTS: HAS THE POTENCY CHANGED?

From the *Cannabis sativa* plant, different types of preparations are derived, and the main types are:

- Marijuana
- Resin (hash)
- Sinsemilla (skunk)

Previous studies have shown that the content of THC and other major cannabinoids varies widely between different illicit cannabis preparations (Potter, Clark, & Brown, 2008; ElSohly et al., 2000).

THC content in different plants varies according to a number of factors:

- part of the plant utilized (in decreasing order regarding THC potency: buds, leaves, stems, and seeds)
- the preparation and sample storage
- genetic factors
- cultivation techniques (eg, growing female plants isolated, resulting in seedless cannabis, and hence the name sinsemilla)
- outdoor versus indoor cultivation—indoor cultivation controls light, humidity, and temperature.

Several studies have shown that the herbal cannabis market has changed worldwide toward an increasing level of THC content (Mehmedic et al., 2010; Pijlman, Rigter, Hoek, Goldschmidt, & Niesink, 2005; Swift, Wong, Li, Arnold, & McGregor, 2013; ElSohly et al., 2000). The increase seen in THC concentration in some cannabis preparations is partly due to advances in growing techniques and cultivation methods, selection of the seeds, and also the domestic indoor production.

When cannabis potency is discussed, the main focus has been on the THC content in the different *Cannabis* plants, but since other substances might influence the THC effects, the concentrations of these substances must also be taken into account. CBD acts as a functional antagonist for some of the THC effects, and might have anxiolytic and antipsychotic effects (Morgan et al., 2010; Henquet & Kuepper, 2010; Luzi et al., 2008). The THC/CBD ratio is thus of major interest, when health-related cannabis effects are studied, and a large variation in the ratio between different plants has been found. CBD appears in cannabis resin, but rarely in herbal cannabis (Niesink & van Laar, 2013).

US data have indicated that herbal cannabis contained an average of 3.4% THC and 0.3% CBD in 1993, while, in 2008, THC levels more than doubled to 8.8%. CBD remained however low (0.4%) during this period (Mehmedic et al., 2010). The cannabinoid content of

Cannabis plants in Australia (2010–11) showed the same trends as expected in other countries toward the use of high-potency cannabis with very low CBD content (Swift et al., 2013). The average potency of the material in the United Kingdom has risen steadily in recent years (European Monitoring Centre for Drugs and Drug Addiction (EMCDDA), 2011). In recent years, the average THC content in a cannabis cigarette of the type sinsemilla (skunk) is reported to be between 42 and 61 mg in Western Europe (Bocker et al., 2010), and 63 mg in a cigarette in the United States of America (ElSohly et al., 2000).

From the studies reporting THC potency, it can be seen that there are large variations in THC content in the *Cannabis* plants within a given year, and also from sample to sample. There are also large variations in the content of CBD between different samples of cannabis products (Cascini, Aiello, & Di, 2012; Zamengo, Frison, Bettin, & Sciarrone, 2014). The THC/CBD ratio is, however, not examined in most of the publications. The results are mainly based on occasional analyses of cannabis seizures, and not systematical testing over years.

From the existing literature, the protective effects of CBD in real life seem, however, to be uncertain, and it is not known for sure how the THC/CBD ratio has changed over the years. Further discussions will thus focus on the concentrations of THC in the different cannabis preparations.

DOES HIGHER CANNABIS POTENCY LEAD TO INCREASED EXPOSURE TO THC?

A critical point in the discussion is if the current available higher-potency cannabis leads to increased exposure to THC. It has been suggested that cannabis users titrate the THC dosage according to their experienced "high" during smoking and, as a consequence, the plasma THC concentrations, and thus the exposure of THC, would not increase—even though more potent cannabis is smoked. There are divergent results as to whether cannabis users modify the amount of THC inhaled when smoking cannabis (Hall & Swift, 2000). It is difficult to know the precise dosing of THC during cannabis smoking, due to individual differences in smoking behavior, and most of the studies investigating this issue have not measured THC concentrations achieved in plasma.

Higher-Potency Cannabis and Plasma THC Levels

Azorlosa et al. have shown that seven moderate marijuana users who smoked 4, 10, or 25 puffs from cigarettes containing either 1.75 or 3.55% THC, obtained greater plasma THC levels with increased dosing (Azorlosa, Heishman, Stitzer, & Mahaffey, 1992). A dose-concentration relationship has also been shown for higher doses of cannabis (cigarettes containing 29.3, 49.1, and 69.4 mg THC) (Hunault et al., 2008).

Perez-Reyes et al. found no significant difference in plasma THC-concentrations when subjects smoked cigarettes containing 1.32 versus 1.97% THC (peak levels ± SEM of 100 ± 10, and 120 ± 11 ng/mL, respectively), whereas peak plasma levels of 163 ± 19 ng/mL was seen after smoking cigarettes containing 2.54% THC (Perez-Reyes, Di, Davis, Schindler, & Cook, 1982).

Titration of THC Intake During Smoking

Heishman et al. demonstrated that subjects adjusted their smoking of marijuana cigarettes according to different THC content (cigarettes with 1.3 and 2.7% THC) (Heishman, Stitzer, & Yingling, 1989). Subjects smoking the high-potency cigarette inhaled a smaller volume due to shorter duration of inhalation of each puff. Concentrations of THC in plasma were however not measured, so the actual exposure is not known. From a survey-based study, where cannabis users from Amsterdam and San Francisco were asked if they adjusted the amount smoked according to the potency of the cannabis, 70% reported that they used less cannabis when the cannabis preparations were stronger (Reinarman, 2009).

Chait (1989) instructed ten participants to smoke as much or little marijuana of low, medium, and high THC content as they wanted during 30-min smoking periods. To investigate if the dose was regulated in regard to the different marijuana products with different THC levels, heart rate, carbon monoxide levels, and the number of cigarettes were measured. All the measured parameters showed linear trends as a function of cigarette potency, and the study revealed that the participants failed to regulate their intake in response to the different THC content and, accordingly, were more exposed to THC when smoking high-potency marijuana. Plasma concentrations of THC were however not measured.

Freeman et al. (2014) investigated if cannabis users, smoking their own cannabis in a naturalistic setting,

TABLE 3.1 Changes in Concentrations of THC in Blood Samples

	Canfield et al. (2010) USA	Fatal aviation accidents	Vindenes et al. (2013) Norway	Drivers apprehended by the police; suspected of being under the influence of drugs
	Mean conc THC ± SD (ng/mL)	Post mortem whole blood samples	Mean conc. THC ± SEM (ng/mL)	Whole blood samples from living subjects
Total number		*N* = 88		*N* = 1748
Other drugs	Yes in 38% of the cases other drugs detected		No other drugs detected.	
1997	1.3 ± 2.6	9		
1998	0.9 ± 1.9	7		
1999	3.1 ± 4.3	7		
2000	3.9 ± 4.7	8	4.0 ± 0.3	167
2001	4.2 ± 7.3	9	3.7 ± 0.3	151
2002	1.0 ± 2.0	6	3.6 ± 0.3	116
2003	7.8 ± 16.3	19	4.5 ± 0.4	153
2004	9.9 ± 15.4	7	5.5 ± 0.4	127
2005	2.7 ± 2.4	7	5.6 ± 0.6	139
2006	14.8 ± 20.5	9	5.0 ± 0.5	116
2007			5.5 ± 0.4	167
2008			5.3 ± 0.4	161
2009			5.3 ± 0.3	190
2010			6.6 ± 0.4	258

Only two studies have investigated the changes of concentrations of THC in blood samples over time. In contrast to the experimental studies, where THC concentrations have been measured in serum/plasma, both these studies have reported THC-concentrations in whole blood. The plasma/blood ratio is approximately 2, and should thus be taken into account when these concentrations are compared with other studies.

titrated the amount of smoked THC/CDB according to the potency of their joint. A significant correlation was seen between higher potency products and the amount THC smoked, but not in regard to CBD. Concentrations of THC and CBD were measured in the cannabis products. Another naturalistic study where the cannabis users rolled their own joints, and the exposure of THC was measured by analyzing the THC concentrations, and the inhaling volume during smoking, revealed that the cannabis users titrate the THC intake by inhaling lower volumes of strong joints (van der Pol et al., 2014). The lower inhaled volume, however, did not fully compensate for the higher cannabis doses per joint, and the authors concluded that smoking potent cannabis will lead to increased THC exposure. Plasma concentrations of THC were not analyzed in any of the naturalistic studies, and the actual exposure to THC could not be determined.

Another study showed that cannabis smokers preferred to smoke high-potency cannabis more often than low-potency cannabis (Chait & Burke, 1994), but no concentrations were measured to reveal if the plasma THC concentrations differed after smoking the different products.

THC Concentrations in Biological Samples

Changes in THC-concentrations in biological samples, over the years, have only been measured in two studies; in whole blood samples from fatal aviation accidents, and from drivers apprehended by the police for suspicion of impaired driving (Canfield et al., 2010; Vindenes, Strand, Kristoffersen, Boix, & Morland, 2013) (Table 3.1).

The mean THC concentrations each year in whole blood samples from fatal aviation accidents were 1.3 ng/mL in 1997, and 14.8 ng/mL in 2006 (Canfield et al., 2010). Considerable fluctuations were seen, however, between the different years. The total number of the aviation accidents during the 10 years period investigated was low (between 6 and 19 each year, with a total number of 88 diseased) and, in 38% of the cases, other drugs were found concomitantly. Presence of other drugs of abuse could likely affect the amount of THC taken, and cases with other drugs are thus less suitable for monitoring changes in cannabis use patterns over time. The small number of cases investigated also indicates cautious interpretation.

A study from Norway found a significant increase in the mean THC concentrations in blood samples from

drivers apprehended by the police, suspected of driving under the influence of drugs and/or alcohol over a 10 years period (Vindenes et al., 2013). The total number of cases was 1748, with THC as the only substance detected in the blood samples. A screening of around 40 different drugs of abuse was performed in all the cases. Using the gradient of the THC concentration curve, a 58% increase in mean THC concentrations was found. The mean age of the cannabis users did not change during the study period, and the increase in THC concentrations could not be explained by a shorter time between driving and collection of blood samples or analytical changes. The THC cases were compared with cases where only alcohol or amphetamines were detected. Neither the concentration of alcohol nor that of amphetamines showed a similar increase in concentrations as THC (3% for ethanol and 16% for amphetamines during the same period).

A generalization of the results from the fatal aviation accidents and the impaired car drivers to other groups of cannabis users must be done with great caution. The drivers apprehended by the police could represent, for example, a selected group as indicated by the majority having a drug abuse problem, and a large part driving without a license (Christophersen, Beylich, Bjornboe, Skurtveit, & Morland, 1996).

The reason for the increased THC concentrations should however be discussed, or if these are just random findings. Changes in smoking habits over the years, and a desire to achieve an increased "high" after cannabis smoking might lead to increased exposure, but if this was a widespread trend, such a trend would also be expected to be seen for other drugs of abuse. Such changes were not seen, either for amphetamines or ethanol, in the study of apprehended drivers. Another explanation might be that the cannabis smoking population have become older over the years, and tolerance to the THC effects might explain the increase in THC concentrations due to higher exposure to achieve the same "high." The mean age among the impaired drivers did, however, not change over the years. The steadily increase in THC concentration in blood over the years might indicate that this finding is not random, but a probable consequence of the increase in cannabis potency seen during the investigated time period.

DOES HIGHER EXPOSURE TO THC INCREASE THE RISK OF ADVERSE HEALTH EFFECTS?

To study cannabis effects on health, and if higher exposure might increase adverse effects, the effects can be divided into those related to *short-term* use (Table 3.2) and *long-term/heavy* use (Table 3.3).

Effects of Higher Exposure to THC on Effects of Short-Term Use

- Impaired cognitive effects
- Impaired psychomotor effects
- Increased risk of psychotomimetic symptoms

A substantial number of publications have reported disruption of cognitive and psychomotor effects after cannabis exposure (Ramaekers et al., 2006; Ranganathan & D'Souza, 2006; Bocker et al., 2010; D'Souza et al., 2004), and dose response effects have been seen for several of the acute cannabis effects. Heishman et al. (1989) have showed significant memory impairment and a trend toward a dose and plasma concentration response relation (Robbe & O'Hanlon, 1993). To explore if the dose response relationship was seen also for cigarettes with high content of THC, Hunault investigated the effects of cigarettes containing approximately 60 mg THC per cigarette, corresponding to 20% THC (Hunault et al., 2008). Pharmacokinetics of THC and the metabolites were reported, in addition to heart rate, blood pressure, and subjective experiences of feeling "high," and drowsiness. No psychomotor tests were performed, however. The study revealed a trend to linear association between THC dose and THC serum concentrations, and the pharmacological effects increased with increasing

TABLE 3.2 Literature Regarding Impairment of Acute Cannabis Effects

Acute effects	Type of effect	Literature supporting impairment	Dose response relationship
Cognitive effects	Memory	Consistent	Yes
	Learning	Consistent	Yes
	Attention/time perception	Consistent	Yes
Psychomotor effects	Reaction time	Consistent	Yes
	Divided attention	Consistent	Yes
	Driving skills/increased risk of traffic accidents	Consistent	Yes
Paranoia/psychotomimetic	Psychotomimetic symptoms, for example, measured by PANSS	Consistent for high doses	Yes

The table shows if there is literature supporting a dose–response relationship for different acute cannabis effects.

TABLE 3.3 Literature Regarding Impairment After Long-Term Use of Cannabis

Long-term or heavy use	Type of effect	Literature supporting impairment	Dose–response relationship
Cognitive impairment	Downregulation of receptors, activity in different brain regions	Some	a
	Altered brain development	Some	a
	Learning deficits	Not conclusive if this is due to the acute or residual cannabis effects	
	Reduction in IQ	Some	
Psychosis	Earlier onset with increased use	Consistent	a
Addiction	According to specific criteria	Some	a

The table shows if there is literature supporting evidence for impairment of different long-term effects, and if a dose–response relationship was observed.
[a]*Higher frequency among regular cannabis users and cannabis, smoking of high-potency cannabis and early onset of cannabis use, but classical dose–response relationships have not been reported, as such relationships are difficult to study for chronic effects.*

doses of THC. Another study investigated psychomotor impairment after smoking cannabis with THC content of approximately 69.4 mg per cigarette, and found that increasing THC doses caused slower reaction time, and more variance and an increased amount of errors (Bocker et al., 2010). Due to cognitive and psychomotor impairment, in addition to altered judgment, cannabis use has been associated with increased risk of traffic accidents (Grotenhermen et al., 2007; Laumon, Gadegbeku, Martin, & Biecheler, 2005). An increased risk of accidents has been shown with increasing THC concentrations (Ramaekers, Berghaus, van Laar & Drummer, 2004).

D'Souza et al. (2004) were the first to characterize positive psychotomimetic symptoms, negative symptoms, and cognitive effects in healthy individuals after intravenous administration of THC. A dose-dependent relationship was seen when a seven-item positive symptom subscale of Positive and Negative Syndrome Scale (PANSS) was used. PANSS is used to measure the symptoms associated with schizophrenia.

A consistent body of literature supports that increased doses of THC lead to increasing serum concentrations of THC, and further to more severe short-term effects of cannabis.

Effects of Higher Exposure of Cannabis on Effects of Long-Term or Heavy Use of Cannabis

- Cognitive impairment
- Psychotic disorders (including schizophrenia)
- Addiction

Several studies have investigated the cognitive impairment after long-term use of cannabis, and the most consistently reported findings are deficits in verbal learning, and reduced memory and attention (Hall & Degenhardt, 2014). It is not clear, however, if these findings might be attributed to the acute cognitive effects of cannabis, the residual effects of chronic use, or the effects of cumulative THC exposure on brain functioning. Meier et al. (2012) have found that persistent cannabis use was the most likely explanation of reduction in IQ among cannabis users, and that the effects are more pronounced with higher exposure. There have been reported structural changes in the hippocampus, prefrontal cortex, and cerebellum in chronic cannabis users, but it has not been determined if cognitive impairments in long-term cannabis users are correlated with structural changes in brain areas implicated in memory and emotion.

Cannabis use is associated with an earlier age of onset of lasting psychosis, but the reason for this is not understood (Volkow, Baler, Compton, & Weiss, 2014; Luzi et al., 2008). Even though millions of people use cannabis, only a minor group experiences persisting psychotic symptoms, and even fewer develop a psychotic disorder. From a study conducted in the Swedish army, only 3% of heavy cannabis users developed schizophrenia (Casadio, Fernandes, Murray, & Di, 2011). Increased frequency of psychoses was associated with higher exposure of cannabis. A number of studies have reported that those who consistently consume large amounts of cannabis have an increased risk of later developing schizophrenia-like psychoses (Potter et al., 2008; Radhakrishnan, Wilkinson, & D'Souza, 2014; Kuepper et al., 2011; Moore et al., 2007). Di Forti et al. (2009) investigated 280 cases presenting a first episode of psychosis, compared with 174 healthy controls recruited from the local population, and found that the first episode of psychosis was not more likely to occur in subjects who had ever taken cannabis or had started doing so earlier than the control group. However, psychosis was associated with more frequent and long lasting use of cannabis. Their most striking finding was that patients with a first episode of psychosis preferentially had used high-potency cannabis preparations: sinsemilla. Cannabis users with their first episode of psychosis were more likely to have taken cannabis for a longer time, and every day, compared to healthy controls from the general population (Di Forti et al., 2009). Di et al. (2014) have recently

shown that subjects who had smoked high-potency *Cannabis* cannabis every day had the earliest onset of psychosis, compared to the group of subjects who had never used cannabis. The daily users of high-potency cannabis had an average onset of psychosis 6 years before the non-cannabis users. Several studies have suggested that the younger the age when first exposed to cannabis, the greater the risk of a psychotic outcome (Arseneault et al., 2002; Di et al., 2014; Sewell, Ranganathan, & D'Souza, 2009; Casadio et al., 2011). Bonn-Miller et al. (2008) have reported that marijuana users who demonstrated high use frequency and high coping motives reported the highest levels of anxious arousal, worry, and agoraphobic cognition, across the anxiety-relevant criterian variables.

The demand for treatment of cannabis dependence has increased over the years (Volkow et al., 2014; Hall, 2009). It has been investigated whether THC increases dopamine in striatum, which is a characteristic for addictive drugs (Hyman & Malenka, 2001). Such a dopamine increase has been found for THC, and it has thus been concluded that THC shares the potentially addictive properties with other drugs of abuse (Bossong et al., 2009). Among the overall cannabis users, about 9% have been classified as dependent, according to the DSM-4 criteria (Hall, 2009). In the group with adolescence onset, the percentage was 17, and it increased to 25–50% among the daily users (Volkow et al., 2014).

A dose–response effect between cannabis intake and complications has been suggested, but there are a number of limitations to this assessment. The THC content varies considerably, and, when smoking cannabis, a joint may be inhaled over several sessions or shared with others.

To be able to quantify the total lifetime exposure of THC, several studies have used estimates of numbers of episodes of smoking cannabis as proxy for the THC amount. Such estimates must be considered as a rough estimate regarding the amount of THC exposure, due to the large difference seen in THC concentrations in the various available cannabis products.

Smoking higher potency cannabis is one cause that might lead to increased total exposure of THC during the lifetime, and yet another cause is earlier onset of cannabis use—due to a longer time period with cannabis use and, thus, a higher total exposure (Casadio et al., 2011; Sewell, Ranganathan, & D'Souza, 2009).

DIFFERENT EXPLANATIONS FOR INCREASED RISK OF ADVERSE HEALTH EFFECTS

It is difficult to investigate if higher-potency *Cannabis* leads to an increased risk of adverse health effects, since large variations in potency in different *Cannabis* plants, within a given year and from sample to sample, have been found. Information regarding the THC/CBD ratio could also be important in these investigations but, as long as this ratio is mainly unknown, it is thus not possible to take into account in epidemiologic studies reporting frequencies of implications in different populations.

Age at first exposure to cannabis appears to be a key factor for vulnerability to many of the harmful effects of cannabis (Arseneault et al., 2002; Stefanis et al., 2013; Casadio et al., 2011). Greater risk of psychotic experiences in those who started cannabis use early might be due to the higher cumulative exposure to cannabis of early users. Adolescence might, on the other hand, represent a period with increased vulnerability to THC during critical phases of brain maturation, such as, in early puberty, and the specific association between psychotic experiences and young initial age of THC exposure might be reflected by this vulnerability (Casadio et al., 2011; Copeland et al., 2013). During adolescence, levels of endocannabinoids and cannabinoid receptors increase, peaking at puberty (Schneider, Schomig, & Leweke, 2008). The "window of vulnerability" hypothesis has thus been suggested; this is a critical period during early adolescence where the brain is particularly susceptible to the psychosis-inducing effects of cannabis, during a critical period of development and maturation (Radhakrishnan et al., 2014). Different processes take place during this period, like neuronal migration and differentiation, synaptogenesis, axon formation, and dendritic proliferation, myelination, pruning, apoptosis, and activity dependent changes—these begin in utero, but continue into the early 20s, or even later (Molina-Holgado et al., 2002). Cannabis may disrupt one or more of these processes.

The hypothesis that there is a particular critical period during early adolescence is, however, not supported by a retrospective study by Stefanis et al. (2013). The association between age of onset of cannabis use and worse outcomes could simply reflect that earlier use is more likely to become longstanding, thus increasing the overall exposure to cannabis. Other causes that might increase the risk of cannabis-related problems due to early onset, is that the risk of developing addiction is increased, and it has been reported that there is an increased risk of loss of intelligence, leading to a behavior that might pursue behaviors that increase the health risk (Meier et al., 2012).

CONCLUSIONS

The two studies which have measured THC in blood samples over a time period indicate that at least some cannabis users have increased their THC exposure during the later years. The limited number of studies and selected groups investigated makes it, thus, difficult to conclude if this is representative for the "general" cannabis users worldwide.

From the existing literature, the causality between increase in THC-concentrations in cannabis preparations and the increase in cannabis-related problems cannot be claimed. There are, however, several findings indicating that cannabis smokers are not able to titrate the THC concentration to achieve a certain wanted THC concentration, and a trend toward increase in THC exposure is seen, with the use of more potent products. Such an increase in THC in blood might have consequences for the health-related disorders that cannabis users might experience. However, more studies on the risks related to the use of more potent cannabis products are needed before firm conclusions can be drawn.

MINI-DICTIONARY

Cannabis potency The concentration of THC in cannabis preparations.

CBD (Cannabidiol) Acts as a functional antagonist for some of the effects of THC, and might have anxiolytic and antipsychotic effects. CBD might offset some of the psychoactive effects of THC, thereby modulating the effects of cannabis. CBD binds weakly to the CB receptors, and the exact mechanism by which CBD exerts its effects is not known.

Sinsemilla A cannabis preparation named after the Spanish word "sin semilla," meaning "without seeds." Sinsemilla is also known as "skunk," "buds," or "netherweet". It has been grown with hydroponic cultivation, with artificial control of daylight length, propagation of female cuttings, and prevention of fertilization, all this leading to cannabis with a higher potency.

CHAPTER

4

Age as a Predictor of Cannabis Use

D. Bergen-Cico, R.D. Cico***

***Department of Public Health, Addiction Studies, Syracuse University, Syracuse, NY, United States**
****Columbia University, New York, NY, United States**

SUMMARY POINTS

- This chapter examines the prevalence of cannabis use among people across all age groups.
- The largest percentage of cannabis users are people under the age of 20.
- People are most likely to first use cannabis prior to age 20; however, the number of people over the age of 30 who first initiate cannabis use has steadily increased over the past decade.
- Cannabis use spans the full life course.
- Although people are most likely to first use cannabis during their youth, their use may decline during early adulthood, and intermittently resurface in mid-to-late adulthood.
- Cannabis use among older adults may be becoming normative with the increasing prevalence of cannabis using peer cohorts who came of age during and following the 1960s.
- Cannabis use among adults over the age of 50 may reflect recreational and medicinal use.

KEY FACTS

Key Facts of *Cannabis*

Cannabis is a genus of flowering plants (*Cannabis indica*, *Cannabis ruderalis*, *C. sativa*) and psychoactive preparations derived from *C. sativa* that are commonly known as cannabis, hash, hashish, marihuana, or marijuana. *Cannabis* may be used in several forms. It is most commonly used in dried leaf form that can be smoked, vaporized, and eaten when prepared in food products such as specialty baked goods and chocolates. Extraction of resin from the *Cannabis* plant may be used to produce hashish (hash), typically a brown sticky oil or solid form that can be smoked or prepared into specialty foods. Most cannabis is psychoactive and produces a mild sense of euphoria and relaxation, at moderate doses.

Key Facts of Measuring Cannabis Use

The measurement of recreational drug use, including cannabis, is quantified with standard questions that ask respondents' to report if they have: (1) ever used cannabis (this indicates lifetime prevalence); (2) used cannabis in the past year (this indicates recent use); and (3) used cannabis in the past 30 days (this indicates current use). These recall and reporting measures are consistently used across most countries for national longitudinal trend tracking and cross-national comparison. Cannabis use or users are characterized in one of seven categories: (1) abstainers, (2) adolescent only users, (3) persistent users, (4) early adulthood decliners, (5) episodic users, and (6) late starters (Geller, Loftis & Brink, 2004; Juon et al., 2011; Patrick et al., 2011).

Key Facts of the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA)

The EMCDDA was established in 1993 to provide the European Union and its member states with regular monitoring data of drug use problems and trends in European countries. The mission of the EMCDDA is to provide practitioners, public health officials, and policymakers with objective data to support informed drug laws and strategies. The EMCDDA scientifically monitors and routinely collects country-based data using consistent methodology to enable reliable comparative data across nations and over time.

Key Facts of Medical Cannabis

Medical cannabis, also known as medical marijuana, refers to the use of cannabis for the treatment, or symptom reduction, of a range of illnesses and conditions. It is recognized as a treatment for glaucoma, wasting disease, nausea, some forms of pain, and some seizure disorders. Medicinal cannabis may be used in several forms, and the method of ingestion depends on the condition being treated, and the preference of the use. It may be extracted into an oil or tincture that can be consumed directly, orally or mixed into beverages or foods. It can also be consumed in dried whole leaf form, which may be smoked, vaporized, and eaten when prepared in specialty food products, such as baked goods and chocolates. Most forms of medicinal cannabis produce some psychoactive effects. As such, some specialty forms of cannabis are cultivated to have very low levels of psychoactive compounds.

INTRODUCTION

This chapter examines cannabis (marijuana, hashish) use by age group, across the lifespan with an emphasis on current (past 30 days) and recent (past year) cannabis use in Europe and the United States. We have focused on these countries where cannabis use is more prevalent, and reliable data is routinely collected to track trends over time. Data from Australia, Canada, and New Zealand is included where available. Lifetime cannabis use is virtually nonexistent in Asian countries, whereas it is most prevalent in the Czech Republic, Denmark, France, New Zealand, Spain, and the United States (EMCDDA, 2012; Degenhardt et al., 2008). Moreover, there is no singular pattern or trajectory of cannabis use initiation or continuation within these countries.

Although there are some differences in survey methodology between countries, there are well-established standard cannabis use questions that enable comparative analysis. Specifically, such questions that ask if the respondent has ever used cannabis (indicates lifetime prevalence), used cannabis in the past year (recent use), and/or has used cannabis in the past 30 days (current use). Furthermore, cannabis use is generally characterized within one of seven categories: abstainers, adolescent only users, persistent users, early adulthood decliners, episodic users, and late starters (Geller, Loftis, & Brink, 2004; Juon, Fothergill, Green, Doherty, & Ensminger, 2011; Patrick, Schulenberg, O'Malley, Johnston, & Bachman, 2011). Although this chapter examines age as a predictor of cannabis use among people in countries in Europe and North America, within the age groups and populations in each country there are unique patterns of use, particularly when further analyzed by gender and race/ethnicity. Case in point, examination of cannabis use among youth in the United States shows that black youths consistently use cannabis at lower rates than their white peers (Johnston, O'Malley, Bachman, & Schulenberg, 2010; Wallace, 1999); however, rates of cannabis use among black adults are equal to or higher than usage rates among white adults (age matched peers), indicating a "crossover effect" (Juon et al., 2011). What this means for the data presented here is that, although there are distinct patterns of use within age groups in each country, age alone does not indicate likelihood of cannabis use. Furthermore, there are notable differences in the prevalence of cannabis use by age group from one country to the next.

Initiation of Cannabis Use

Individuals begin using psychoactive substances for reasons that reflect individual history, as well as social, familial, environmental, and educational influences (Bachman et al., 2008; Eaton et al., 2010). Therefore, it is necessary to examine current and historical usage patterns of cannabis among people of all age groups. Much of the literature and monitoring data on cannabis use has focused on new initiates (age of first use) and use among youth and emerging adults because use has been highest among these age groups, in recent history. Moreover, the age of first alcohol intake has significant relevance to rates of initiation for cannabis use in many cultures (Arria, Dohey, Mezzich, Bukstein, & Van Thiel, 1995; Bergen-Cico and Lape, 2013; Eaton et al., 2010; Johnston et al., 2010; Kokkevi et al., 2006). Although there is no set age that marks the development or establishment of a cannabis use disorder (CUD), the younger a person is when they begin using, the greater the maturational deviation and psychological dysregulation, thereby increasing the risk of early age onset for CUDs (Kosterman, Hawkins, Guo, Catalano, & Abbott, 2000). It is noteworthy that initiation of cannabis use increases rapidly during adolescence, through age 18–20, with sharp declines after the age of 20 (SAMHSA, 2013; Schulenberg et al.,

2005). Research has shown an association between delaying the onset of first use until age 20 or later with a lower risk of cannabis abuse and dependence (Behrendt, Wittchen, Höfler, Lieb, & Beesdo, 2009; Winters & Lee, 2008). Although cannabis has relatively low addiction potential, compared to stimulant and depressant drugs, people who use cannabis frequently, particularly cannabis with increasingly high THC levels, can develop cannabis dependence (Inaba & Cohen, 2014). Research has also found that persistent regular use of cannabis is associated with higher rates of mental health problems among susceptible persons (Fergusson, Horwood, & Swain-Campbell, 2002).

Historically, research has shown that people who began using cannabis at an early age were less likely to graduate high school and go to college (Grunbaum et al., 2004); however, more recent studies have found cannabis use among college students to be on a par with peers not attending college (Bergen-Cico & Lape, 2013; Johnston et al., 2010). Despite early and continued use of cannabis, a substantial percentage of youths who use cannabis are capable of graduating from high school and gaining entry to college; however, the frequency and intensity of cannabis (and other drug) use is a significant determinant of academic retention and success in college (Bergen-Cico, 2000; Bergen-Cico, Urtz, & Baretto, 2004; Horwood et al., 2010).

Age of first use is related to cannabis use disorder risk, whereby the younger the age of first use, the higher the risk of cannabis abuse and dependence (Behrendt et al., 2009; Bergen-Cico & Lape, 2013; Chen, O'Brien, & Anthony, 2005; Lopez-Quintero et al., 2011; Winters & Lee, 2008). Early age of first use for cannabis follows similar patterns for the development of substance dependence for alcohol (Dawson, Goldstein, Chou, Ruan, & Grant 2008; DeWit, Adlaf, Offord, & Ogborne, 2000) and nicotine (Behrendt et al., 2009), with some evidence of temporal ordering whereby early onset of alcohol use may be associated with subsequent development of cannabis abuse (Bergen-Cico & Lape, 2013; Kirisci et al., 2013). Moreover, research has found a significant relationship between the age of first cannabis use and drinking alcohol by oneself (Bergen-Cico & Lape, 2013). This is of concern because use of alcohol or cannabis when alone (solitary use) is not an indicator of social use, but rather a marker of social isolation and potential indicator of dependency. However, as noted in the chapter *How Age Leads to Cannabis Use Disorders*, Dr Behrendt notes there is limited documentation of higher risk of escalating cannabis use among people who begin using at younger ages, which produces a void in important data that may pertain to the progression from early age of fist cannabis use to the development of CUDs later in life (Behrendt, 2015). Moreover, delaying cannabis use until after age 20 does not in and of itself inoculate people from associated mental health problems. A study by Washburn and Capaldi (2014) found that patterns of cannabis use among men during their 20s was associated with diagnoses of cannabis disorders in their mid-20s, and predicted antisocial behavior and deviant peer association in their mid-30s, thus concluding that differential patterns of marijuana use in early adulthood may be associated with psychopathology toward midlife (Washburn & Capaldi, 2014).

Trends in Cannabis Use Across the Lifespan

Fig. 4.1 illustrates the percentage of past year and past month cannabis use across all age groups (age 12 and older) among people in the United States, based on national monitoring data collected in 2012 (SAMHSA, 2013). The major graph lines illustrate the higher prevalence of use through about age 20. The trend lines show a general decrease in usage as people get older, with a moderate convergence between past year and past month use, as age increases. This figure illustrates a mountainous peak around age 20, with substantial use following this peak in a gradual downward slope through age 25, followed by sharp declines. Thus, it indicates that use generally decreases as people age, and their responsibilities (work, family) increase (Fig. 4.2) (Tables 4.1 and 4.2).

A 30-year longitudinal study of cannabis use among adolescents in the United States found that social norms and attitudes regarding cannabis use vary and cluster within birth cohorts. This clustering directly affects cannabis use among teens, even after controlling for individual attitudes and perceptions of norms (Keyes et al. 2011). This proclivity and peer social influence may also pertain to use among adults, as evidenced by the increasing rates of current cannabis use among older populations, most notably people over the age of 50 (Fig. 4.3). People in birth cohorts that are disapproving of cannabis use are less likely to use, independent of their personal attitudes toward cannabis use, and vice versa. Age alone does not predict cannabis use, social norms, attributes of low self-control, sensation seeking, and externalizing behavior have strong long-term predictive power with regard to distinct trajectories of marijuana use over time (Brook, Zhang & Brook, 2011).

Initiation of cannabis use continues well beyond adolescence, and people begin using across their lifespan. The data in Table 4.3 illustrate the mean age of first use for US adults aged 26–49 who began using during the corresponding phase of adulthood. Over the 10-year time period covered in this table, the mean age increases from 31.2 to 33.1, while the numbers of new users in this age group concomitantly increased more than 50% from 90,000 in 2002, to 139,000 in 2012. Moreover, people may initiate cannabis use during their teens or early adulthood, and then discontinue use in midadulthood

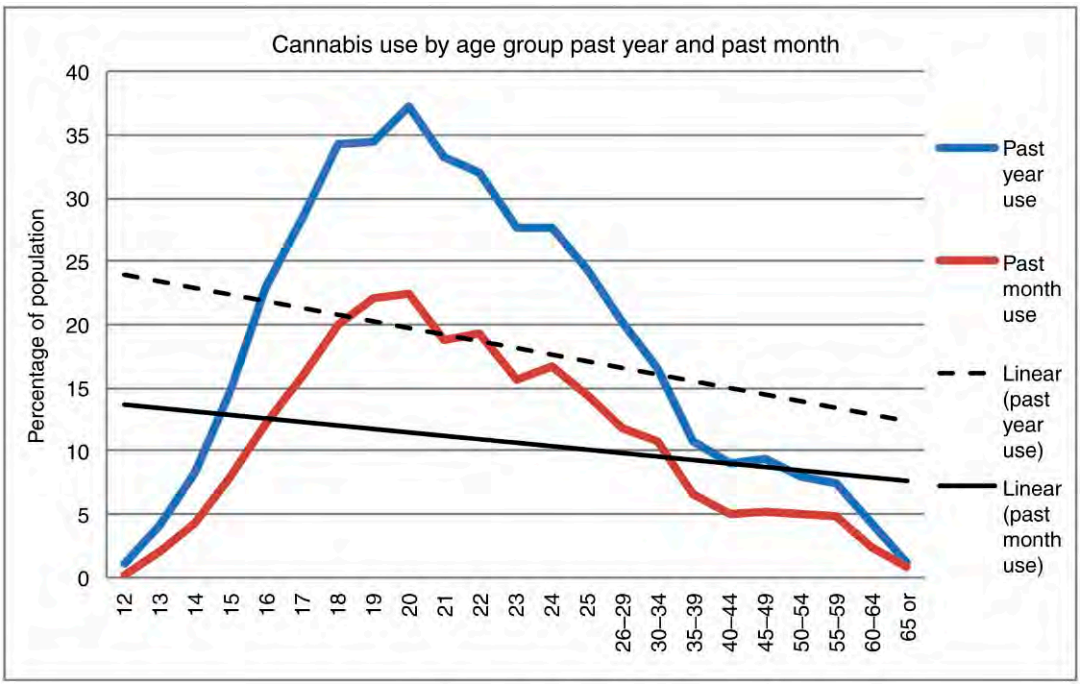

FIGURE 4.1 **Cannabis use across age groups.** This graph shows the percentage of past year and past month cannabis use across ages and age groups (age 12 and older) among people in the United States, based on national monitoring data collected in 2012 by the US Substance Abuse Mental Health Services Administration (SAMHSA, 2013). The blue and red graph lines illustrate the higher prevalence of use peaking through ~age 20. The black trend lines show a general decrease in usage as people get older, with a moderate convergence between past year and past month use as age increases (55 +).

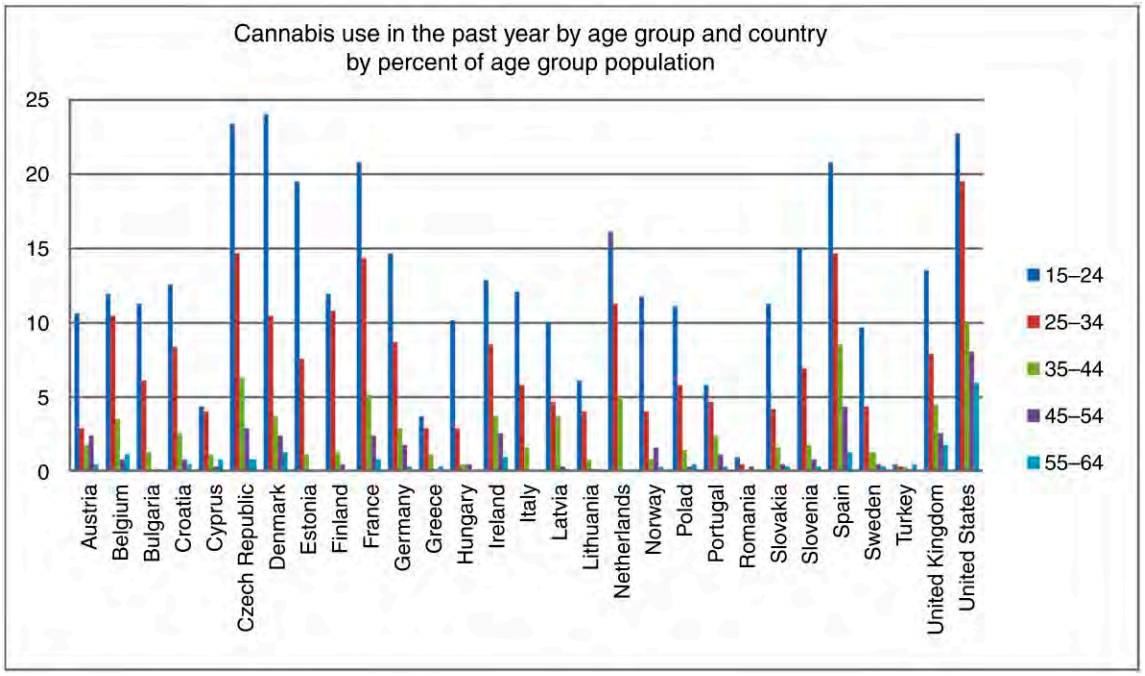

FIGURE 4.2 **Percentage of past year cannabis use by age group and country.** European data is from the European Monitoring Center on Drugs and Drug Addiction (EMCDDA, 2012), US data is from NSDUH (SAMHSA, 2013). Past year use is highest among 15–24 year olds across all countries. The highest prevalence of use among people in the 45–54 and 55–64 age group is in the United States.

TABLE 4.1 Percentage of Current Age Cohorts and Corresponding Age of First Use for Cannabis

Age of first use	Current age cohort (years)				
	12–17	**18–25**	**26–34**	**35–49**	**50 ≥**
≤ 13	6.5	7.8	7.9	7.2	1.9
14–15.	**7.3**	12.4	12.6	9.9	4.7
16–17	3.1	**15.4**	**15.4**	14	8.2
18–20	0	13.7	12.1	**10.8**	**10.7**
21–24	0	2.9	5.3	4.4	5
25 ≥	0	0	1.8	3.6	6.2

US NSDUH 2012 (SAMHSA, 2013). Note: bold data indicates highest prevalence for age of first use by current age cohort. The data in this table show that regardless of the current age group and cohort, people are most likely to first use cannabis by the age of 20.

TABLE 4.2 Cannabis Use by Age Group in US (Percentage)

Cannabis Use	12–17 (years)	18–25 (years)	26–34 (years)	35–49 (years)	50≥ (years)
Ever use cannabis	17	52.2	45.2	50	36.7
Used past year	**13.5**	**31.4**[a]	**19.5**	**10**	**4.6**
Past 30 day use	7.3	18.5[a]	11.5	5.7	3
1–5 days use past year	3.8	7.4[a]	4.5	2.6	1.2
6–10 days use past year	0.9	1.6[a]	1	0.5	0.2
11–25 days use past year	1.9	3.4[a]	1.7	1.1	0.5
26–100 days use past year	2.8	5[a]	2.8	1.8	0.8
Over 100 days of use past year	4	14[a]	8.6	4	1.9

US NSDUH 2012 (SAMHSA, 2013). Note: bold data indicates highest prevalence for use by current age cohort, when excluding lifetime use (ever used). Past year use is most prevalent.
[a]*Indicates age group with greatest prevalence by usage frequency. 18–25 year olds have the highest rate of chronic use.*

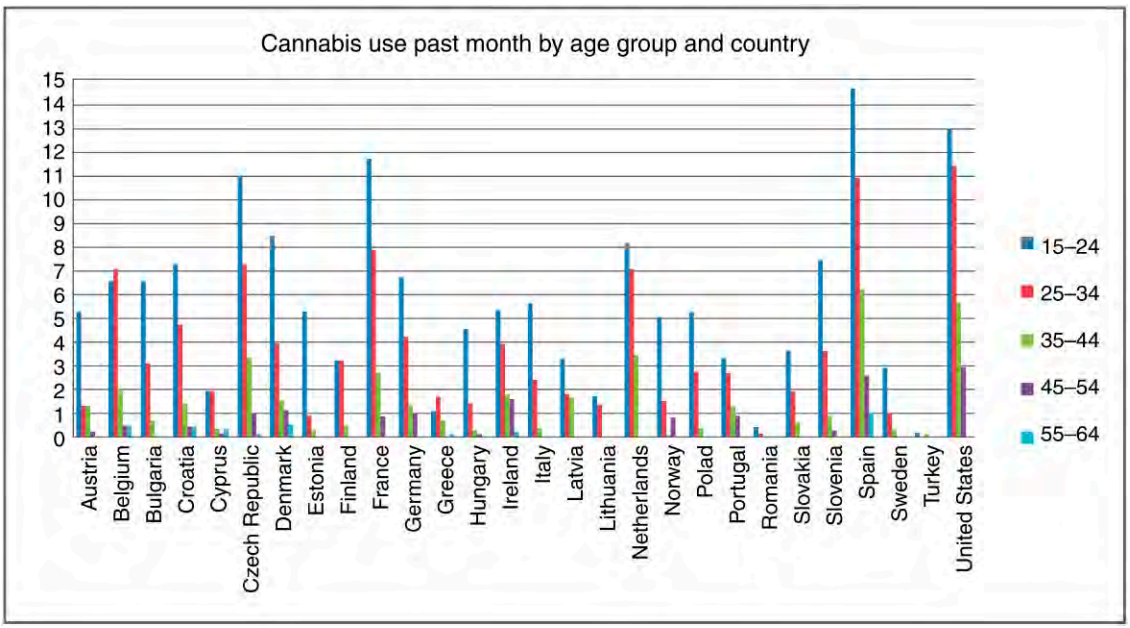

FIGURE 4.3 **Past month cannabis use by age group and country.** European data is from the European Monitoring Center on Drugs and Drug Addiction (EMCDDA, 2012), US data is from NSDUH (SAMHSA, 2013). Past month use is highest among 15–24 year olds across all countries, except Belgium, where it is greater among 25–34 year olds. The highest prevalence of use among people in the 45–54 age group is in the United States.

TABLE 4.3 Past Year Initiates Cannabis Use among US Adults Aged 26–49, 2002–2012

Mean age at first cannabis use among past year initiates in the United States, aged 26–49											
Age	31.2	29.6	29.5	30.4	29.1	32.4	32.6	32.2	36.3	29.5	33.1
Numbers	90,000	56,000	127,000	122,000	126,000	121,000	155,000	49,000	210,000	138,000	139,000
Year	2002	2003	2004	2005	2006	2007	2008	2009	2010	2011	2012

SAMHSA (2013); US NSUDH, 2002–2012.

as responsibilities (work, family) increase, and return to using again later in life (Kotarba, 2012). The mean age of first use of cannabis in Australia for persons aged 12 and older was 18.5 in 2010, indicating that youth are delaying their age of first use and/or there is an increase in older populations initiating cannabis use (AIHW, 2011).

Cannabis Use, Social Norms, and Legal Status

Over the past decade, many countries have reduced the severity of penalties for simple cannabis use or possession (Bergen-Cico, 2013; EMCDDA, 2014). European emphasis on cannabis control has focused on targeting drug supply and trafficking, rather than personal use and minor possession, and yet the number of offences related to cannabis personal possession and use have steadily increased over the past decade (EMCDDA, 2014). The legalization of cannabis in Uruguay, Colorado State and Washington State, where recreational cannabis use has been legalized with oversight and control, have been accompanied by increasing support for decriminalization and legalization of cannabis across the United States, Mexico, Central and South America, and many European countries (Uruguay, 2014; State of Washington, 2011; Amendment 64 Use and Regulation of Marijuana, 2012). Portugal and Netherlands have decriminalized cannabis use, and Switzerland is experimenting with legal recreational use. The United States reported a major decrease (~77%) in cannabis cultivation site eradication from 2011 to 2012, in conjunction with declining law enforcement efforts and increasing licit cultivation in the states of Colorado and Washington. What the change in licit supply will mean for usage across age groups is not yet known, as legal recreational use has been in place for less than a year, as of the writing of this chapter. The states of Washington and Colorado have established 21 as the minimum legal age for purchasing cannabis; how this may affect usage rates across age groups, notably people who were previously deterred by the illicit status of cannabis, has yet to be measured.

With the change in legal status comes a need to revisit the ways in which we have traditionally assessed consequences of cannabis use, and how legal consequences have delineated CUDs. Legal status aside, there is a need to examine potential risks associated with cannabis use across age groups, in the context of current use, frequency of use, and well-being. Decreases in legal consequences and increasing legal access to cannabis are reportedly part of the reason for increasing usage among older populations. Furthermore, cannabis use among older adults may be becoming normative, with increasing prevalence of cannabis using peer cohorts, as discussed in the latter part of this chapter.

Global Use

In 2012, between 125 million and 227 million people were estimated to have used cannabis, corresponding to about 3–5% of the global population aged 15–64 years (UNODC, 2014). According to the United Nations Office of Drugs and Crime (UNODC), the regions with the highest prevalence rates are West and Central Africa, Western and Central Europe, North America, and Oceania. Current cannabis usage epidemiological data is not available from Asia although the World Drug Report suggests use is increasing in Asia.

Among European nations, past year usage rate is estimated at 18.1 million, or 5.3% of the population aged 15–64 years. Whereas the past year usage rate for the United States was 7.3% of the population aged 12 and older, in 2012, this represents a notable increase from a rate of 6.2% in the United States in 2002. A closer look at this data within age groups provides some divergent trends. For example, among people aged 12–17 in the United States, the usage rates for cannabis dropped to 7.2% in 2012, from 8.2% in 2002. In fact, over this 10 year period, cannabis usage actually decreased among all age groups, for people under the age of 18 in the United States, while it increased among 18–25 year olds: from 17.3 in 2002 to 18.3% in 2012; from 7.7 to 11.3% among 26–34 year olds; and from 3.1 to 3.9% among those over the age of 35 (NCHS, 2014).

Table 4.4 presents data on current cannabis use by age group for 30 countries, and Table 4.5 includes data for 28 countries. The data illustrates the percentage of the population who currently use cannabis, where current use is defined in Table 4.4 as past year, and in Table 4.5 covers data on use in the past month. There are notable variations in the prevalence of use reported by country and by age group. It is important to note such variation because when we examine age as a predictor of use, use is contextual to the country, as well as age group. Variations

between the 15–24 years age group and the 25–34 age group for past year cannabis use are quite notable for some countries, such as, Austria (10.6 and 2.8, respectively) and Hungary (10.1 and 2.9, respectively), yet negligible for others, such as, Belgium (11.9 vs 10.5 respectively) and Finland (11.8 vs 10.7 respectively) (EMCDDA, 2012).

Cannabis Use Among Older Adults

Until recently, cannabis use and CUD among older individuals was considered rare (Compton, Grant, Colliver, Glantz, & Stinson, 2004). However, as the generation who came of age in the 1960s began to reach age 50, we have

TABLE 4.5 Past Month Cannabis Use by Age Group, Europe and the United States

seen an increase in current cannabis users among older people (Blazer & Wu, 2009; Han et al., 2009a,b). This generational shift in drug use is evident in the US National Survey on Drug Use and Health (NSDUH) data that shows increasing rates of current recreational drug use among persons aged 50–64 (SAMHSA, 2013). The current 50–64 year old cohort, comprised of baby boomers born after 1950, had higher rates of recreational drug use among youth, as compared to previous generations. By 2014, the 50–64 year old cohort consisted entirely of baby boomers who now account for the increase in cannabis use among older adults. A decade ago, researchers predicted that, by 2020, there would be a threefold increase in substance abuse problems among adults aged 50 and older (Gfroerer, Penne, Pemberton, & Folsom, 2003; Gfroerer, Wu, & Penne, 2002). In 2012, the percentage of persons in the age groups 50–54, 55–59, and 60–64 who reported using marijuana in the past year increased significantly over the prior decade (since 2002). In the United States, in 2012, 8% of those aged 50–54 said they had used

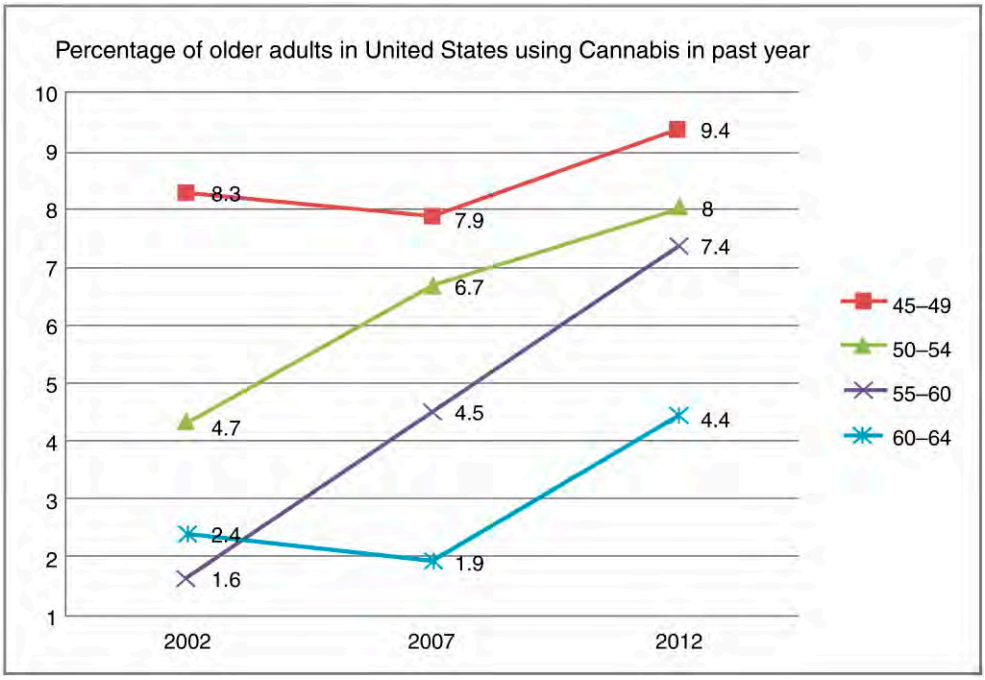

FIGURE 4.4 **Percentage of older adults in United States using cannabis in the past year.** These graphs show strong and steady upward trends in the percentage of older adults who recently used cannabis. The data represent people who came of age during and following the 1960s and, therefore, belong to a peer cohort in which cannabis use has been more normative than previous generations. *Source: NSDUH 2002, 2007, and 2012 (SAMHSA, 2013).*

marijuana in the past year, nearly double the percentage from 2002. Users aged 55–59 more than quadrupled, from 1.6% in 2002 to 7.4% in 2012. Among Americans aged 60–64, use nearly doubled, from 2.4 to 4.4% in the same period. Fig. 4.4 shows the rates of marijuana use in the previous year, by 5-year age groups (45–49; 50–54; 55–59; 60–64) for the years 2002, 2007, and 2012. Use among the older adults and the elderly varies from country to country and, upon further analysis, there are notable differences within age groups in a given country. For example, in England, current cannabis use among older adults varies widely between those in the 50–64 age group (1.8% past year use) and those over 65 (0.4%), and people over 50 living in London use cannabis at a rate 4 times higher than England (Fahmy, Hatch, Hotopf, & Stewart, 2012).

Survey data alone does not provide much context regarding current cannabis use among older adults, although they increasingly report using cannabis medically for nausea and pain (Sacco & Kuerbis, 2013). In addition to recreational use of cannabis, there is increasing use of cannabis for medical purposes. Medical use of cannabis is legal and controlled in Canada, the Netherlands, Switzerland, and several states in the United States.

Cannabis abuse or dependence is reported by very few older adults, with only 0.004% of US adults aged 50–64 reporting cannabis abuse or possible dependence in the current year. This suggests that current cannabis use among older populations may not be problematic, provided the individuals have the ability to cope with stressors, and self-regulate their emotions in the absence of cannabis and other psychoactive substances. The extent to which their use may be problematic depends on factors, such as, emotional coping strategies in the absence of cannabis use, interpersonal and social skills, and the extent to which they have been able to be active contributing members of society, regardless of their use.

MINI-DICTIONARY

Age of first use; age of initiation; age of onset These terms may be used interchangeably. The term refers to the age at which a person first used a drug. In this chapter, the drug is cannabis.
Cannabis A drug derived from certain plants in the Cannabaceae/hemp family. *Cannabis* is also commonly known as *Cannabis indica*, *Cannabis sativa*, hash, hashish, marihuana, or marijuana. *Cannabis* may be used in several forms, but is most commonly used in dried leaf form that can be smoked, vaporized, and eaten when prepared in food products such as specialty baked goods and chocolates.
Current use This term refers to use of a drug within the past 30 days and indicates a person who currently uses that drug. In this chapter, the drug refers to cannabis.
Lifetime use Reported use of cannabis in the 30 days or past month preceding the survey or similar means of data collection.
Medicinal cannabis Medical cannabis, also known as medical marijuana, refers to the use of cannabis for the treatment, or symptom reduction, of a range of illnesses and conditions. It is

recognized as a treatment for glaucoma, wasting disease, nausea, some forms of pain, and some seizure disorders.

Past 30-day use Reported use of cannabis in the 30 days or past month preceding the survey or similar means of data collection.

Past year use Reported use of cannabis in the 12 months preceding the survey or similar means of data collection.

Prevalence The proportion (usually expressed as a percentage) of a defined group (eg, age group, gender, race) or population reporting a specified behavior or outcome. In this chapter, the behavior is cannabis use.

Recent use This term refers to use of a drug at a recent point in time in a person's life, defined here as within the previous year. In this chapter, the drug refers to cannabis.

THC is the acronym for tetrahydrocannabinol, the psychoactive ingredient in cannabis. The higher the level of THC the more potent the cannabis is. Chronic use of high potency THC increases likelihood of CUD and dependency. Levels of THC vary from across types of cannabis.

Lifetime Cannabis Use and Cognition in Psychosis Spectrum Disorders

M.J. Cuesta, A.M. Sánchez-Torres, R. Lorente-Omeñaca, L. Moreno-Izco

Department of Psychiatry, IdiSNA, Navarra Institute for Health Research, Pamplona, Spain

SUMMARY POINTS

- Research concerning the association among cannabis use, cognition, and psychosis is not conclusive.
- Most of the research points to better cognitive functioning among patients using cannabis, but there are also findings supporting similar or even worse performance in cannabis users, compared with nonusers.
- Better cognition has been related to better social skills and premorbid IQ in cannabis users, as well as lower vulnerability to psychosis.
- It has also been proposed that cannabis may have neuroprotective or cognitive enhancing properties.
- Possible confounders in study designs should be controlled to obtain more robust findings.

KEY FACTS OF COGNITION AND PSYCHOSIS

- Psychotic disorders are characterized by the presence of positive, negative, disorganized, and/or cognitive symptoms.
- Cognitive deficits in psychosis are mainly related to processing speed, verbal memory, working memory, executive functions, attention, and social cognition.
- Cognitive deficits are qualitatively similar among psychotic disorders, being more severe in schizophrenia, and milder in affective psychoses.

KEY FACTS OF CANNABIS AND PSYCHOSIS

- Cannabis use is more prevalent among patients with psychosis, than in the general population.
- It is related to poorer treatment compliance, higher rates of relapse, and worse psychosocial outcomes.
- It has been associated with an increased risk of developing psychosis, and with an earlier age of onset.

INTRODUCTION

Psychosis spectrum disorders include those diagnoses that involve nonaffective psychoses, such as, schizophrenia, schizophreniform or brief psychotic disorders, and also affective psychoses, such as, bipolar and schizoaffective disorders. They are characterized by the presence of a wide range of symptoms, which may include delusions, hallucinations, disorganized behavior, blunted affect, and abulia, among others. Moreover, cognitive deficits are considered core features of psychotic disorders, and represent an important target for research because of their impact on functional outcome, treatment adherence, and risk of relapse (Carter et al., 2008).

The prevalence of cannabis use disorders among patients with a psychotic disorder is higher than in the

general population. Specifically, there is a median lifetime prevalence of 27.1% for cannabis use disorder in patients with schizophrenia (Koskinen, Lohonen, Koponen, Isohanni, & Miettunen, 2010). In addition, cannabis use has been demonstrated to be a risk factor for the development of psychosis (Henquet, Murray, Linszen, & van Os, 2005; Moore et al., 2007).

Both acute administration and long-term cannabis use have been related to cognitive impairments in healthy subjects (Fernández-Serrano, Perez-Garcia, & Verdejo-García, 2011; Verdejo-García, 2011). Global cognitive decline, which implies a lower IQ and a negative impact on everyday functioning, has been reported after 20 years of persistent cannabis use, especially among adolescent-onset users (Meier et al., 2012) (Table 5.1).

However, research on the relationship between cognition and cannabis use in patients with psychosis has produced counterintuitive results. Most studies have reported improved cognitive performance among psychotic patients who use cannabis, compared with those patients who do not. Therefore, several hypotheses have been proposed to explain these a priori striking results. In this chapter, we review the main findings regarding the relationship between lifetime cannabis use and cognition in psychosis spectrum disorders, and the hypothesis that could explain the mechanisms underlying this relationship.

COGNITIVE EFFECTS OF LONG-TERM USE OF CANNABIS IN PSYCHOTIC PATIENTS

The relationship between cannabis and cognition must be considered in regard to two main effects: the effects of acute administration, and those arising from chronic use. Here, we focus on the cognitive effects of chronic use in patients diagnosed with a psychotic spectrum disorder.

TABLE 5.2 Summary of Cognitive Areas Studied in Psychosis Related to Cannabis Use

Evidence of better performance in cannabis users	Evidence of worse performance in cannabis users
Memory	Premorbid IQ
Verbal fluency	Social cognition
Visuospatial construction	Working memory
Sequencing	Decision-making
Face recognition	Attention
Psychomotor/visuomotor speed	Verbal and visual learning
Verbal skills	Executive functions
Executive functions	
Working memory	

The effects of long-term cannabis use on cognition depend on several factors, such as, the continuity of cannabis use over time, the amount and frequency of use, the age at consumption onset and, of course, the premorbid cognitive functioning of the patient.

One might think that clinical populations would be more vulnerable to the adverse effects of cannabis on cognition. However, research on the relationship between psychotic illness and cognitive performance points to better cognitive functioning in cannabis-using patients, compared with those who do not present comorbid use (Potvin, Joyal, Pelletier, & Stip, 2008; Yucel et al., 2012). In addition, higher frequency of use and younger age at onset have been associated with higher cognitive functioning (Schnell, Koethe, Daumann, & Gouzoulis-Mayfrank, 2009).

Most longitudinal studies have reported better cognitive functioning in cannabis using patients, both in short follow-up periods (Rodríguez-Sánchez et al., 2010) and in long-term follow-up periods (Stirling, Lewis, Hopkins, & White, 2005). Specifically, Stirling, Lewis, Hopkins, and White (2005) followed a sample of patients with a first-episode of psychosis over 10–12 years, and reported that those with a history of cannabis use outperformed those who had never used cannabis in measures of memory, verbal fluency, visuospatial construction, sequencing, and face recognition. In contrast, we also followed a group of patients with a psychosis spectrum disorder and one of their siblings, over 10 years, and did not find a relationship between longitudinal patterns of cannabis use and cognitive outcomes in the patient group. Further, patients reporting longitudinal cannabis use showed poorer social cognition, and the combination of low premorbid IQ, current cannabis use, and earlier age at illness onset resulted in worse performance in the working memory domain (Sánchez-Torres et al., 2013). Cross-sectional studies have also found worse performance of some cognitive functions in patients with a history of cannabis use. Smith et al. (2014) reported cannabis-related striatal and thalamic shape abnormalities, also associated with poorer working memory performance and earlier age of cannabis use onset, both in schizophrenic patients and healthy controls who had a history of cannabis use. Mata et al. (2008) explored the influence of cannabis abuse prior to psychosis onset on executive functioning and decision-making tasks, and found that those patients who had abused cannabis showed worse performance on the decision-making task, but not in executive functioning (Table 5.2).

To interpret the results of this field, it is also important to have a healthy control group of cannabis users, because differential effects of cannabis in patients with schizophrenia and healthy subjects have been reported (Jockers-Scherubl et al., 2004). Abstinent schizophrenic patients with a history of chronic cannabis use showed better cognitive function than nonusers. However, abstinent healthy controls who were cannabis users showed impaired cognitive function compared with nonusers (Jockers-Scherubl et al., 2004, 2007).

Methodological variability in studies approaching the relationships between cannabis use and cognition in psychosis must be taken into account when interpreting the results. Factors, such as, sample size, diagnostic groups included, instruments used to assess drug use, and parameters associated with consumption, such as time since onset of consumption, frequency, and recency, should be taken into account when considering the effects of cannabis on cognition. For example, some of the studies have small samples, and this factor may reduce the statistical power by increasing type II statistical errors or false negatives (Loberg & Hugdahl, 2009) (Table 5.3).

Regarding diagnosis, most studies have focused on schizophrenia and nonaffective psychosis, and also on first-episode psychosis. Patients with bipolar disorder

TABLE 5.3 Methodological Issues to Take Into Account When Interpreting Results of the Association Between Cannabis and Cognition in Psychosis

- Sample size
- Instruments used to assess cannabis consumption
- Diagnosis included
- Variability in the duration of use
- Comorbid drug use
- Pharmacological treatments
- Illness related variables:
  - Age at psychosis onset
  - Premorbid IQ
  - Premorbid adjustment
  - Psychopathology
- History of cannabis use:
  - Age at onset
  - Frequency and amount of cannabis use
  - Potency of the substance
  - Time since last use
- Data analysis: causality of associations

have shown better performance in measures of attention, processing speed, set-shifting, and working memory (Braga, Burdick, Derosse, & Malhotra, 2012). Ringen et al. (2010) reported differential associations between cannabis and cognition in patients with schizophrenia and bipolar disorders. While schizophrenic patients who used cannabis underperformed nonusers in attention, executive functioning, and verbal memory measures, bipolar cannabis-using patients showed better verbal fluency than those patients who did not use cannabis.

How the patients were grouped according their consumption habits is another matter for discussion. They are often classified into dichotomic groups, and cognitive functioning is then compared between the two groups. The criterion to be included in these groups varies between studies, and often the frequency or amount of cannabis consumption, which should be taken into account in order to investigate dose-response relationships, is not considered (Rabin, Zakzanis, & George, 2011). Indeed, few studies use standardized instruments to assess cannabis use. Most studies establish a cutoff point to determine a positive or negative history of cannabis use, or include as consumers those patients who meet the criteria for a comorbid drug use disorder. As an example, in previous research we considered cannabis use as a continuous variable, based on information recollected with an adaptation of the Composite International Diagnostic Interview (CIDI; WHO, 1993) and explored the influence of lifetime cannabis consumption on cognition in chronic schizophrenia spectrum disorders (Sánchez-Torres et al., 2013). Rabin, Zakzanis, Daskalakis, and George (2013) also explored cumulative cannabis exposure and cognitive performance. They found an association between more years of cannabis exposure and poorer performance in tasks of attention, verbal and visual learning, and executive functions in patients with current cannabis use. Interestingly, these findings were only present in patients with current cannabis use, which has led the authors to suggest that abstinence may result in some cognitive improvement. This study also explored the differences in cognitive functioning caused by lifetime cannabis use by comparing current and former users with patients who had never used cannabis, and found that lifetime cannabis users showed better psychomotor speed. The combination of these apparently contradictory results may suggest that patients who have never used cannabis represent an etiologically different subgroup of patients, presenting worse cognitive functioning even in the absence of drug use.

One study published recently highlighted the importance of the frequency and the potency of the substance in the onset of psychotic illness (Di Forti et al., 2014). Although the latter has not been explored regarding cognitive function, it seems to be an important issue for future studies.

Another source of variability in research is the duration of cannabis consumption that is labeled as "chronic." Some studies include patients after 1 year of continued use (Rentzsch, Buntebart, Stadelmeier, Gallinat, & Jockers-Scherubl, 2011), while others include patients who have used cannabis for more than 10 years (Sánchez-Torres et al., 2013). In most studies, abstinence for at least 4 weeks (Rentzsch et al., 2011) or even as long as 6 months (Smith et al., 2014) is an inclusion criterion, to avoid the possible acute effects of consumption on cognition. For example, Mata et al. (2008) excluded patients with a current drug dependence diagnosis, and considered as patients with a history of cannabis consumption those who had at least weekly use during the year prior to illness onset.

The inclusion of patients who use other drugs may also influence the results of the cognitive assessment. Potvin et al. (2008) analyzed a pool of studies that addressed cognitive functioning in schizophrenic patients with different comorbid drug use. They concluded that this type of patient did not represent a homogeneous group, and the two factors that determined cognitive functioning were the preferred substance consumed, and the age at the assessment. In addition, substance use showed differential effects on cognition. For example, exclusive use of alcohol was related to global cognitive functioning, similar to that of schizophrenic patients without comorbid substance use, while mixed consumption including cannabis resulted in better cognitive functioning. Thus, drug interaction may have cognitive effects not comparable with the ones related to exclusive consumption of cannabis or other types of drugs. Moreover, the cognitive effects of nicotine are not considered in most studies because it is difficult to find cannabis users who do not use tobacco. However, tobacco smoking has an important impact on cognition because it has been related to enhancement of attention, working memory, and information processing (Sacco et al., 2005; Segarra et al., 2011). It has also been suggested that nicotine may interact with genes related to the risk of developing schizophrenia (Quednow et al., 2012). To avoid these confounders, Rabin et al. (2011) performed a meta-analysis including only those studies with groups of patients without current comorbid use of other drugs, but they did not include tobacco among these drugs. Their results further supported better cognitive performance in patients using cannabis, compared with nonusing patients, but the effect sizes were only in the small to medium range.

It is also of interest to account for the effects of pharmacological treatments on cognition associated with cannabis use. Most of the studies report antipsychotic doses, and some of them take this into account when analyzing the differences between cannabis users and nonusers. However, patients with psychosis usually received other

treatments, such as, anticholinergics, antidepressants, benzodiazepines, or mood stabilizers, which may also affect cognitive function, either improving or worsening performance. However, few studies report these treatments and account for them when assessing cognition (Coulston, Perdices, & Tennant, 2007).

Researchers have focused their efforts on minimizing the effect of confounding variables on the relationship between cognition and cannabis in psychotic illness. DeRosse, Kaplan, Burdick, Lencz, and Malhotra (2010) tried to control the possible clinical and demographic confounders in a large sample of schizophrenia and schizoaffective disorder patients (n = 455; 175 cannabis-using patients and 280 nonusing). Patients with comorbid cannabis abuse or dependence showed better performance on measures of processing speed and verbal skills, even after controlling for gender and global functioning, which were the only features that differed between groups. These authors emphasized the importance of studying homogeneous groups of patients to avoid the influence of possible confounders. However, this study rated lifetime clinical symptoms as present, subthreshold, and absent, which may obscure the complexity of the psychopathology in these disorders. They did not explain whether the patients used other drugs, or the amount and frequency of cannabis use.

Schnell et al. (2009) also noted the importance of understanding the history of cannabis use, including age at onset of use, time since last use, and lifetime average, as well as maximum frequency of use. Even after controlling for these variables and others such as psychopathological symptoms, education, and nicotine use, patients with schizophrenia and comorbid cannabis use disorder outperformed patients with schizophrenia without a history of cannabis use in visuomotor speed, executive functioning, and working memory tasks.

A recent study on a large sample of schizophrenic patients, conducted as part of the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) project, assessed the relationship between cognition and drug use (cannabis, cocaine, and methamphetamine), obtaining data of drug use from radioimmunoassay of hair. This test provided data on drug consumption in the last 90 days. Groups of consumers and nonconsumers were created according to these data. A key strength of this study, in addition to the implementation of the radioimmunoassay to confirm consumption, is the statistical analysis used. While most of the studies analyze the relationship between cannabis and cognition with association measures, which do not allow for the study of cause-effect relationships, this study applied moderator models to study the effects of drugs on cognition, taking into account multiple possible confounders. According to this study, patients who tested positive for cannabis use did not show better cognitive function, compared with those who tested negative. These results were consistent in nondeficit patients, for men and women, in patients in the middle and chronic phases of illness, and for those treated with lower and higher antipsychotic doses (Bahorik et al., 2014). These authors suggest that the finding of better cognitive functioning in cannabis users, compared with nonusers, may be a consequence of including first-episode patients with cannabis-induced psychosis, the heterogeneity of diagnoses, and the absence of laboratory testing to confirm drug consumption. Patients with schizophrenia tend to under-report drug use, so it would be desirable to contrast self-reports with laboratory testing to improve reliability (Bahorik et al., 2013).

In summary, most research points towards better cognitive function associated with cannabis use in psychotic patients. However, the results are inconclusive because of the methodological variability of the studies, the limited sample sizes, and the amount of research that has found no differences or poorer cognitive functioning in patients with comorbid cannabis use.

SUPERIOR COGNITIVE FUNCTIONING OF PSYCHOTIC PATIENTS WHO USE CANNABIS: EXPLICATIVE HYPOTHESIS

Findings supporting the cognitive superiority of psychotic patients who use cannabis, compared with nonusers, are inconclusive due to the methodological variability already discussed, but, to date, the majority of research points in this direction. Therefore, several hypotheses have been proposed to explain these counterintuitive findings (Table 5.4).

TABLE 5.4 Explicative Hypothesis of Cognitive Functioning Related to Cannabis Use in Psychotic Disorders

Hypothesis supporting *worse* cognitive functioning in psychotic patients using cannabis
• Cannabis use has neurotoxic effects, which are added to the brain abnormalities associated with psychosis • Sustained cannabis use is associated with striatal and thalamic shape abnormalities, which augment the brain abnormalities associated with psychosis • Animal models have demonstrated that cannabis abuse alter dopaminergic modulation in prefrontal cortex
Hypothesis supporting *better* cognitive functioning in psychotic patients using cannabis
• Cannabis users have higher premorbid IQ than nonusers • Cannabis users have superior social skills than nonusers • Cannabis induces psychosis in subjects with low vulnerability to develop a psychotic disorder • Cannabis has neuroprotective effects • Cannabis enhances cognition by stimulating prefrontal neurotransmission

One hypothesis suggests that patients with a history of cannabis use have better premorbid IQ than those who have never consumed cannabis. Leeson, Harrison, Ron, Barnes, and Joyce (2011) attributed the differences between cannabis-using and non-cannabis using first-episode patients to higher premorbid intellectual functioning in the cannabis users, prior to psychosis onset. Patients who used cannabis reported better cognitive functioning in current IQ, verbal memory, working memory span, and planning ability in the first episode. Cannabis users also showed higher premorbid IQ than nonusers; however, when controlling for premorbid IQ, the only differences in planning ability remained significant. These authors explain their results in the context of the cognitive reserve hypothesis. Higher cognitive reserve has a neuroprotective effect in patients with psychosis, which results in a later onset of psychosis, and has a positive impact on the course of the illness. Therefore, cannabis use may undermine this protective effect, anticipating the onset of psychosis. This hypothesis is also supported by the fact that good premorbid functioning is necessary to initiate and sustain illicit drug use (Rodríguez-Sánchez et al., 2010).

Better cognition in patients with comorbid cannabis use has also been related to superior social skills, compared with those patients without drug use. This hypothesis is based on the idea that the onset and maintenance of illegal drug consumption requires a set of social and personal skills. Moreover, higher interpersonal skills have been related to better cognitive functioning in schizophrenia (Harvey, Keefe, Patterson, Heaton, & Bowie, 2009), so this may be the link between cannabis use and better cognitive function. However, this idea contrasts with the findings that support poorer outcomes and a higher presence of psychotic symptoms in cannabis users with psychosis (Grech, Van Os, Jones, Lewis, & Murray, 2005; Linszen, Dingemans, & Lenior, 1994), leading to a worse course of illness. As Cohen, Solowij, and Carr (2008) proposed, the contradictory findings regarding clinical, psychosocial, and cognitive outcomes related to cannabis consumption in psychosis may be due to the differential response of brain areas responsible for psychotic, negative and cognitive symptoms to cannabis consumption.

Another hypothesis states that cannabis triggers psychosis in subjects with low vulnerability to develop a psychotic disorder. Therefore, these subjects may be more cognitively preserved than those psychotic patients who are genetically more vulnerable to psychosis and, thus, develop the illness even in absence of accumulative adverse environmental events. In fact, early onset of consumption and higher frequency of use have been related to an increased probability of developing psychosis (Di Forti et al., 2014; Moore et al., 2007). van Os, Bak, Hanssen, Bijl, de Graaf, and Verdoux (2002) demonstrated that cannabis was linked to the emergence of psychosis in up to 50% of subjects without genetic liability to psychosis. Thus, many psychotic patients would not have developed the illness if they had not used cannabis.

Relatives of psychotic patients represent a population with increased vulnerability to psychosis, but research concerning cognition and cannabis use in relatives of psychotic patients is scarce. It has been suggested that genetic risk for psychosis is associated with sensitivity to cannabis. This is demonstrated by studies of unaffected siblings who report increased psychotomimetic effects of cannabis, both regarding current and lifetime use (GROUP Investigators, 2011; van Winkel & Genetic Risk and Outcome of Psychosis (GROUP) Investigators, 2011). Our study of a group of psychotic patients and their siblings, which has already been discussed (Sánchez-Torres et al., 2013), revealed a greater influence of cannabis on cognitive performance in siblings, compared with controls. Siblings showed poorer processing speed associated with cannabis use 10 years prior, consumption over 10 years, current use, and an earlier age at cannabis use onset. Cannabis use 10 years prior and current use were also associated with poorer declarative memory. In controls, cannabis use did not predict cognitive performance independently, but was associated with other variables such as earlier age at cannabis use onset, lower IQ, and tobacco use. These results could be explained by a greater vulnerability to the effects of cannabis in siblings. On the contrary, Meijer, Simons, Quee, and Verweij (2012) did not find a differential association between cannabis use and cognitive functioning between psychotic patients, siblings, and controls. They found an association of current cannabis use with worse performance on immediate verbal learning, processing speed, and working memory in the three groups. However, current cannabis use was associated with better performance on acquired knowledge, affect recognition, and face identity recognition in all three groups. Although they used a structured interview to assess drug use, frequency of consumption was highly variable in the lifetime cannabis use group, ranging from 5 to more than 100 times in a subject's lifetime. Additionally, it is noteworthy that cannabis frequency referred only to the preceding year, which may have led to a dilution of dose-response cannabis effects.

The supposed neuroprotective effects of cannabis, which would counteract the putative neurotoxic process related to psychosis have also arisen as a possible explanation for the better cognition associated with cannabis. Many studies have attributed antioxidant, antiexcitotoxic and antiinflammatory properties to cannabinoids at the cellular level, as well as neuroprotective or neurotoxic effects in vitro and in vivo (Sarne & Mechoulam, 2005). This hypothesis is supported by studies with animal models of Parkinson's and Alzheimer's

disease (Ramírez, Blázquez, Gómez del Pulgar, Guzmán, & de Ceballos, 2005). Furthermore, studies with rodents suggest that chronic cannabis administration causes behavioral deficits in healthy animals, but also restore some functions in animals that present brain abnormalities similar to those seen in psychotic patients (Seillier, Advani, Cassano, Hensler, & Giuffrida, 2010). Thus, better cognitive functioning in cannabis-using patients may reflect the neuroprotective effect of cannabinoids in an injured brain, as this association is not found in healthy subjects.

Some authors suggest that cannabinoids may enhance cognition by stimulating prefrontal neurotransmission (Coulston et al., 2007), because the distribution of CB1 endogenous cannabinoid receptors is dense in the prefrontal cortex, specifically in the cingulated and superior frontal gyri. Cannabis use, by mediating neurotransmitter release in these brain areas, may have the capacity to enhance cognitive performance and reduce negative symptoms. However, in most studies reporting better cognitive function related to cannabis use, patients were abstinent for at least 3–4 weeks, so the acute effects of cannabis may be discarded as an explicative hypothesis.

It has been highlighted that although cannabis-using patients perform better in cognitive tasks than nonusing patients, it does not mean that cannabis improves cognition in schizophrenia (Rabin et al., 2011). On the contrary, some authors contend that better cognitive functioning represents a risk factor for cannabis abuse in schizophrenia (DeRosse et al., 2010).

CONCLUSIONS

The relationship between cannabis use, psychosis, and cognition is still a matter of debate. Research on healthy subjects has demonstrated that cannabis use entails adverse cognitive effects. Thus, it is unlikely that cannabis can improve cognition in psychotic patients who also present core cognitive deficits associated with the mental disorder. In addition, cannabis use involves worse clinical outcomes in psychotic patients, such as, higher rates of relapse, worse psychosocial outcomes, and worse adherence to treatment.

The methodological limitations already exposed should be overcome to better characterize this relationship. Prospective studies that perform exhaustive assessments of cannabis use and additional laboratory testing and control for confounding variables may help to elucidate whether cannabis is related to better cognitive functioning. In addition, statistical procedures, such as, moderation and mediation analyses would help to disentangle the cause-effect relationship between cannabis, cognition, and other confounding variables.

MINI-DICTIONARY

Comorbid Refers to a disorder that occurs simultaneously with another.
Dose-response effect The change in response (eg, higher or lower processing speed) caused by the amount of exposure to an agent, in this case, to cannabis.
Effect size A statistical concept, which refers to an index used to assess the magnitude of an event. Here, it refers to the magnitude of the differences in cognitive performance between groups (eg, patients who use cannabis and those who do not).
Executive functions The cognitive mechanisms that control the cognitive processes needed to understand complex or novel situations. This concept encompasses functions, such as, abstraction and planning, decision-making skills, initiation, self-monitoring, mental flexibility, and inhibition of immediate responses in pursuit of longer term goals.
Nonaffective psychosis Psychotic disorders in which affective or mood symptoms are not predominant, such as, schizophrenia, schizophreniform disorder, delusional disorder, brief psychotic disorder, and psychosis not otherwise specified.
Radioimmunoassay drug testing A laboratory procedure which evaluates drug metabolites deposited into growing hair shafts. This technique provides a 30-day surveillance window for detecting use for each 0.5 in. segment of hair.
Set-shifting The ability to change the focus of attention between two or more external stimuli.
Social cognition The ability to recognize, manipulate, and behave with respect to socially relevant information. It includes domains such as emotion processing, social perception, social knowledge, theory of mind, and attributional biases.
Working memory An active system for the storage and processing of information for short periods of time that is essential for other complex functions, such as, language comprehension, reading, or reasoning.

CHAPTER

6

A Profile of Synthetic Cannabinoid Users

A.N. Sanders, J.M. Stogner

Department of Criminal Justice and Criminology, University of North Carolina at Charlotte, Charlotte, NC, United States

SUMMARY POINTS

- The most commonly reported reasons for synthetic cannabinoid use are legal status, accessibility, avoiding detection in drug screening, and drug effects.
- While many demographic studies reveal that synthetic cannabinoid use may be concentrated among teenagers and young adults, use has been reported across all demographics.
- Synthetic cannabinoid users typically fall into one of four categories: the replacement user, the experimental user, the drug aficionado, or the habitual user.
- The replacement user wants to avoid legal consequences and drug detection traditionally associated with cannabis, by way of substitution.
- The experimental user wants to try synthetic cannabinoids out of curiosity, partially fueled by the media, or to adhere to a deviant social milestone.
- The drug aficionado user takes pride in their drug use repertoire, and desires the novelty of the drug experience.
- The habitual user prefers synthetic cannabinoids as their drug of choice, in comparison to other substances, for both reasons associated with other types of users but, more importantly, for synthetic cannabinoids' own unique merits.

KEY FACTS OF SYNTHETIC CANNABINOID USERS

- Synthetic cannabinoids emerged as early as 2004, but gained popularity in 2008.
- Synthetic cannabinoids are substances that imitate the effects of cannabis.
- Synthetic cannabinoid users typically want to avoid a consequence that comes with cannabis use.
- Features most appealing to users about synthetic cannabinoids include the substances' legal status, accessibility, detection in drug screening, and drug effects.
- While synthetic cannabinoid users may tend to be teenagers or young adults, demographics alone cannot describe a synthetic cannabinoid user, as reported use has been seen across age, gender, race, education, employment, and prior substance use.

INTRODUCTION

During a brief 5-year window, synthetic cannabinoids became popular within the United States and several other countries. The popularity of these compounds can largely be attributed to their initial status as a "legal high" and somewhat desirable effects. Synthetic cannabinoid use was not restricted to any one demographic, and many different types of substance users experimented with or habitually used synthetic cannabinoids. Their reported reasons for use typically included a desire to experience the psychopharmacological effects of a cannabinoid while avoiding the potential consequences associated with traditional cannabis use. Users typically reported that synthetic cannabinoids' legal status, availability in retail stores and online, and noninclusion on drug screens made it an appealing alternative to marijuana in many instances, assuming the drugs' effects were near equivalent. In addition to these highly visible reasons for engaging in synthetic cannabinoid use, users may be motivated by other factors, such as social desirability, excitement, and curiosity. Reports of user distinctive demographics, personal characteristics, and use motivations enables researchers to further develop a profile of synthetic cannabinoid users that may serve as a framework for future research and policy efforts.

This chapter presents a typology of synthetic cannabinoid users based on theory, and recent research on reasons for use, and user demographics. The presented typology divides synthetic cannabinoid users into four categories: those who use the substance as a replacement or substitute, those who use to experiment or try the substance as a social milestone, those who regularly use various substances in order to extend the breadth of their drug use experience, and lastly, those who are habitual users. Each element of the presented typology reflects common reasons for synthetic cannabinoid use, without limiting the profile to demographic characteristics. This information, in sum, suggests that the recent bans on synthetic cannabinoids will reduce use, likely redirecting would-be users to cannabis, but not eliminate synthetic cannabinoid use completely.

Reasons for Synthetic Cannabinoid Use

A common reason for synthetic cannabinoid use is that such products were at one time legal and, despite after-regulations and bans, were marketed as legal alternatives to cannabis in retail stores and online (EMCDDA, 2009; Schifano et al., 2009; Vardakou, Pistos, & Spiliopoulou, 2010; Vandrey et al., 2012; Lindigkeit et al., 2009; Barratt, Cakic, & Lenton, 2013; Fattore & Fratta, 2011). Though their intended use is readily apparent to potential consumers, synthetic cannabinoid compounds are typically labeled as "not for human consumption." Such packaging details made the drug nature of the synthetic cannabinoids less obvious. Further, the products may have been labeled "incense" or "herbal mixtures," and referred to as a "herbal smoking blend" (Auwärter, Dresen, Weinmann, Müller, Pütz, & Ferreirós 2009; Schifano et al., 2009). Many labels list herbal plants, such as, "Indian Warrior" (*Pedicularis densiflora*) or "Lion's Tail" (*Leonotis leonurus* or "wild dagga"), which are unregulated plants known to have minor psychoactive effects when smoked (EMCDDA, 2009). Despite the "not for human consumption" warning labels, these synthetic cannabinoid products were frequently purchased for use as a psychoactive substance (Vandrey et al., 2012). Some labels actually advertised products as a "legal high." Others claimed the product was solely a "herbal high" in an attempt to insinuate legal status, and that the product was primarily a natural compound (Lindigkeit et al., 2009; Zimmermann et al., 2009). The illusion that they are herbal appears to appeal to many users, as they assume that natural compounds are safer to use (Every-Palmer, 2011; Fattore & Fratta, 2011). Products were also colorfully decorated, possibly as a tool to market to younger users (Schifano et al., 2009; Fattore & Fratta, 2011) or appear legitimate. Schifano et al. (2009) points out that many of these advertising features may have made it possible for synthetic cannabinoids to be mistaken for an incense product by consumers, but this is unlikely due to the cost, packaging, and retail placement of the product. This concern, however, may be somewhat founded in that it may have assisted teenagers attempting to evade detection or suspicion from less drug-savvy adults (Table 6.1).

Synthetic cannabinoid products, either completely or seemingly legal (as some packages actually contained banned substances), were easily obtained. Products were regularly sold in head shops, convenience stores, gas stations, and over the Internet (Auwärter et al., 2009; Schifano et al., 2009; Barratt et al., 2013; Every-Palmer, 2011; Fattore & Fratta, 2011). The price of such products, while sometimes more expensive than cannabis, were affordable and sometimes accompanied by discounts, especially online (Vardakou et al., 2010; Schifano et al., 2009). Such products, especially those sold over the Internet, were sold without age restrictions (Auwärter et al., 2009; Vardakou et al., 2010; Fattore & Fratta, 2011). This enabled young adults and teenagers access to a psychoactive substance without the regulations linked to alcohol and tobacco possession/use. The Internet also seemed to help perpetuate use as several blogs and websites were available in which users could describe their intoxicating experiences, and discuss different brands and methods of use (Lindigkeit et al., 2009; Auwärter et al., 2009; Vardakou et al., 2010; Fattore & Fratta, 2011). There were also instances of Youtube videos documenting use of such products (Lindigkeit

TABLE 6.1 Various Brand Names of Synthetic Cannabinoids

Popular brand names of synthetic cannabinoids				
Spice	K2	Spice Diamond	Spice Gold	Spice Silver
Chronic Spice	Arctic Spice	Spice of Life	Spicylicious	2Spicy
Spice Mojo	Red X Dawn	Zohai	Mr. Nice Guy	Aroma
Earthquake	Space Truckin	Solar Flare	Moon Rocks	Galaxy Gold
Kamikaze	Chernobyl	Yucatan Fire	Black Mamba	Earth Impact
Dream	Stinger	Scene	Skunk	Smoke
Sence	Scence	Aroma	Bliss	ChillX
Mystery	Genie	Blue Lotus	Bombay Blue	Scope
Pulse	Kronic	Gorillaz		

This list displays frequently reported brand names of synthetic cannabinoid products. Many names reflect specific spice related products (Spice Diamond, Spicylicious), an exciting experience (Earthquake, Kamikaze), or a relaxing experience (Dream, Aroma). This list is not exhaustive, as new brands can easily emerge. Data are from the EMCDDA, as well as compiled from works referenced throughout the chapter.

et al., 2009). The Internet helped to spread knowledge of synthetic cannabinoid substances quickly, and may have fostered the false belief that experimentation was common or even normative, increasing popularity and curiosity as a result.

A common reason for individuals to choose synthetic cannabinoids over cannabis, and what allowed it to be so readily available, was its initial legal status, and the assumption that users would avoid the potential legal consequences associated with cannabis. Lindigkeit et al. (2009) discuss how a seemingly legal product can be desired by those who want to try cannabis, but are uneasy about its illegal nature and subsequent consequences. Lindigkeit et al. (2009), as well as Vardakou et al. (2010), purport that this reluctance could be particularly important for younger people. Though the actual likelihood of penalization for marijuana possession is low in many jurisdictions, individuals less familiar with drug use likely overestimate the threat and certainty of punishment. This makes products labeled "legal highs," and perceived to have few consequences, particularly appealing to novice users. The initial legal status was also important to those who expected to be subject to drug screens. Synthetic cannabinoids were not initially detectable in blood and urine tests (Schifano et al., 2009; Barratt et al., 2013) and, even if they were, carried limited penalties compared to marijuana. This makes synthetic cannabinoids desirable for people who may be subjected to such drug screens, such as, students, athletes, probationers, psychiatric patients, the military, and those in other careers subjected to workplace drug testing (Schifano et al., 2009; Dresen et al., 2010; Rosenbaum, Carreiro, & Babu, 2012; Johnson, Johnson, & Alfonzo, 2011). Many studies indicate that users engage in synthetic cannabinoid use specifically to avoid drug detection in screening tests (EMCDDA, 2009; Auwärter et al., 2009; Vardakou et al., 2010; Every-Palmer, 2011; Fattore & Fratta, 2011).

Further complicating the issues discussed previously is the "cat and mouse" game between manufacturers and policymakers. Khey et al. (2014) refer to an ongoing battle between these groups that includes a cyclical pattern of "regulate and reformulate." After a psychoactive product is manufactured and introduced, policymakers typically choose to ban that particular compound, though enacting policy is a time-consuming process. Following a ban, manufacturers tweak the chemical composition of their product in a way that leads it to retain its psychoactive properties but be chemically distinct enough to avoid regulation (often because products carrying the "not for human consumption" label are immune to regulation as an analog). For example, several US jurisdictions banned a limited list of synthetic cannabinoid compounds in 2010 and 2011. However, there was variability in which compounds were included, and none were exhaustive. On March 1, 2011, the DEA placed the five most common chemicals in the major brands (JWH-018, JWH-073, JWH-200, CP-47,497, and CP-47,497 C8 homolog) into Schedule I on an emergency basis. Other products quickly emerged and were followed by new regulation. Eventually, the broad sweeping Synthetic Drug Abuse Prevention Act of 2012 was signed into law on July 9, 2012, but even this regulation may fail to address all synthetic cannabinoids. The number of psychoactive synthetic cannabinoids is continually growing; to demonstrate the number of these compounds, a brief list follows: HU-210, O-806, JWH-122, CP-47,497, CP-47,497-C8, CP-55,950, JWH-018, JWH-200, JWH-091, JWH-250, AM694, SR-18, Anandanine, Olemide, WIN-55,212-2, WIN-49,098. The long-term efficacy of any synthetic cannabinoids regulation cannot be evaluated at this point (Tables 6.2 and 6.3).

Also helping to drive use was the positive purported experiences of users. Some synthetic cannabinoid

TABLE 6.2 Legal Responses to Synthetic Cannabinoids

Country	Date of regulation	Legal response
Australia (Queensland)	Sep. 2011 and Nov. 2011	Amends *Drugs Misuse Regulation (1987)* to include new drug analogs and substances
Austria	Jan. 2012	Passes act controlling new substances as listed in a regulation by the Minister for Health
Finland	Jun. 2011	Updates the *2008 Narcotics Act* to include new substances
Hungary	Apr. 2012	*Government Decree 66/2012* creates a new schedule of substances allowing 1 year for a drug to be risk-assessed
Ireland	Aug. 2010	*Criminal Justice (Psychoactive Substances) Act (2010)* makes it a criminal offence to advertise, sell, or supply psychoactive substances not specifically controlled under existing legislation
New Zealand	Jul. 2013	*Psychoactive Substances Act* regulates the availability of psychoactive substances
Portugal	Apr. 2013	*Decree-law 54/2013* prohibits the advertising and distribution of a new list of psychoactive substances
Romania	Nov. 2011	Passes a new law requiring a specific permit to sell products likely to provoke psychoactive effects similar to those caused by substances already controlled under drug laws
United States	Jul. 2012	*Synthetic Drug Abuse Prevention Act of 2012* amends the *Controlled Substances Act (1970)* and synthetic drugs in Schedule I
United Kingdom	Nov. 2011	*Misuse of Drugs Act* allows temporary control of new substances under drug laws for up to 1 year

Beginning in 2011, there was a wave of new legislation, particularity in Europe, in response to the growing popularity of synthetic cannabinoids. Many legal responses banned either specific synthetic cannabinoid compounds, or any related analogs. Data are from the EMCDDA, DEA, New Zealand Drug Foundation, and the National Cannabis Prevention and Information Centre.

TABLE 6.3 Timeline of Major Legal and Media Events in the United States

Major events affecting awareness of synthetic cannabinoids in the United States	
Date	**Event**
Jun. 2010	American teenager, David Mitchell Rozga, committed suicide after smoking synthetic cannabis
Jun. 2010	US Senator Chuck Grassley proposed the *David Mitchell Rozga Act* to ban the use and distribution of synthetic cannabinoids
Mar. 1, 2011	"Spice" and "K2" temporarily scheduled by the DEA
Oct. 20, 2011	Three Louisiana State University football players are suspended for testing positive for synthetic cannabinoid use
Jan. 2012	Actress Demi Moore is rushed to the hospital for issues related to synthetic cannabinoid use
Jul. 9, 2012	*Food and Drug Safety and Innovation Act* passed, permanently regulating many synthetic cannabinoids
May 16, 2013	DEA added three additional synthetic cannabinoid compounds to Schedule 1 under the *Food and Drug Safety Innovation Act*

In the United States, the first major publicized event regarding synthetic cannabinoids was the suicide of a teenager. This event prompted legal action temporarily banning such substances. More media coverage revealed popular athletes and an actress using synthetic cannabinoids, with publicized consequences. In 2012, many synthetic cannabinoids were permanently banned. As new compounds emerged after the initial ban, more compounds were subsequently added to the banned list. Data are from North Iowa Today news, CBS News, and the DEA.

users indicated experiencing more pleasurable effects than they had with cannabis. Many have even indicated a preference to the synthetic substances (Vandrey et al., 2012; Barratt et al., 2013, Every-Palmer, 2011; Fattore & Fratta, 2011), though this seems far from ubiquitous. As the effects of various cannabis strains are themselves variable and affected by setting and expectations, it is challenging to interpret users' subjective comparisons. Perhaps it is more important to stress the overall similarity noted by users, than to engage in relative ranking of experiences. Regardless, users have reported synthetic cannabinoid intoxication to be quite enjoyable, and note that it can sometimes be accompanied by pleasurable smells and taste (Fattore & Fratta, 2011; Schifano et al., 2009). Effects of synthetic cannabinoids often last for a shorter amount of time than cannabis intoxication would, an effect seemingly desirable by some users (Schifano et al., 2009; Every-Palmer, 2011). Other users have reported synthetic cannabinoid use in combination with other substances, such as, ketamine, kratom, and cannabis (Schifano et al., 2009) that alter their experience and assessment of the drug.

Additionally, some users are motivated by impulsivity and the quest to broaden their horizons. For example, as synthetic cannabinoids gained popularity and subsequent media attention in Germany, many young people characterized as "sensation-seekers" became interested in synthetic cannabinoids, due to the increased coverage (EMCDDA, 2009; Vardakou et al., 2010). This more general form of behavior is likely related to synthetic

cannabinoid use, but a more specific mindset also exists among recreational drug users, and is quite relevant. Some individuals highly value the breadth of their drug use experiences. Despite being content with cannabis, they may choose to branch out to other substances to fulfill a need to experience all that is available. The scope of their drug use may also be tied to their assumptions about respect within a drug-using group, whereby status is linked to being able to recount and reflect upon a diverse array of drug experiences. Others may simply be curious about a new substance, or use synthetic cannabinoids to partially satisfy their curiosity related to cannabis (Barratt et al., 2013). Khey et al. (2014) also note that experimental synthetic cannabinoid use may be a social, deviant milestone in some young subcultures. Such users are not acting with a specific intent, but rather for the novelty of trying a new, unknown substance, and to share an experience with the others in the group.

Demographics Associated with Cannabinoid Use

While it is critical to stress that synthetic cannabinoid use has occurred within virtually every segment of the population, use does appear to be concentrated in some groups more than others. Not surprisingly, many demographic studies indicate that young adults and teenagers are the most frequent synthetic cannabinoid users (Vardakou et al., 2010; Lindigkeit et al., 2009; Auwärter et al., 2009). National studies of substance use have recently added synthetic cannabinoids to their surveys, and have found that use is more concentrated in adults aged 19–28 (Johnston, O'Malley, Bachman, & Schulenberg, 2014a). Such studies also indicate that, among high school students, use is emerging and more frequent among male students (Johnston, O'Malley, Bachman, & Schulenberg, 2014b). While concentrated in younger populations, use is by no means exclusive to younger users.

Another developing demographic with emerging rates of synthetic cannabinoid use is the military (Walker, Neighbors, Walton, Pierce, Mbilinyi, Kaysen, & Roffman, 2014; Loeffler, Hurst, Penn, & Yung, 2012). As members of most militaries are subject to strict substance use policies, the challenges associated with synthetic cannabinoid detection makes use extremely appealing to service members (Walker et al., 2014). Military demographics associated with synthetic cannabinoid use include service members who are young, less educated, of lower income, and not married (Walker et al., 2014). For the same reason, synthetic cannabinoid use is arguably higher among probationers who have a particularly high stake in successfully passing a drug screen (Vardakou et al., 2010).

Other studies of synthetic cannabinoid users focus on university populations (Hu, Primack, Barnett, & Cook, 2011; Stephens, 2011; Stogner & Miller, 2014). Hu et al. (2011) and Stephens (2011) both found that males were more likely than females to have reported synthetic cannabinoid use, as were younger university students. Using a random sample of university students, Stogner and Miller (2014) supported prior research indicating that males were more frequent users than females, but expanded demographic findings in observing that Whites and Hispanics reported more use than other races, and that students with lower GPAs reported more use than those with higher GPAs. Use was also associated with students from higher income families and students who self-identified as LGBT. Stogner and Miller (2014) found no associations between synthetic cannabinoid use and age, class year, marital status, employment, Greek affiliation, and athlete status. As reported by *Monitoring the Future*, a United States-based national study of substance use, prevalence of synthetic cannabinoid use among college students and similarly aged young adults peaked in 2011, and have steadily decreased since then, likely in part due to federal regulation (Johnston et al., 2014a). Although providing a national look at prevalence of use, the study does not examine demographics of synthetic cannabinoid users.

Once again, case studies have revealed that synthetic cannabinoid use is not bound to any single demographic, but spans across demographics such as age, race, education, employment, and prior substance use history (Vandrey et al., 2012; Barratt et al., 2013). Specific case studies indicate that synthetic cannabinoid use has been identified in male teenagers, older adults, and women (Castellanos, Singh, Thornton, Avila, & Moreno, 2011; Mir, Obafermi, Young, & Kane, 2011; Young, Schwarz, Medina, Obafemi, Feng, Kane, & Kleinschmidt, 2012; Zimmermann et al., 2009; Barratt et al., 2013; Gunderson, Haughey, Ait-Daoud, Joshi, & Hart, 2012; Schneir, Cullen, & Ly, 2011). Furthermore, Rosenbaum et al. (2012) note that at-risk demographics are difficult to isolate due to the importance of the Internet in the spread of synthetic cannabinoid use, and its influence in both adolescents and adults. This suggests that, while use may be associated with certain characteristics, demographics alone cannot fully describe synthetic cannabinoid users.

A Profile of Synthetic Cannabinoid Users

Even among the demographic and case studies, the identified common reasons for synthetic cannabinoid use were evident among the studied populations. A clear typology of synthetic cannabinoid users, related to but not dependent on demographic factors, emerged. Recognizing that there is no single archetypal synthetic cannabinoid user, and that any framework will fail

TABLE 6.4 Summary of the Four Profiles

Profile	Characteristics of user
• The replacement user	• Uses synthetic cannabinoids as a substitute for another substance • May be attempting to avoid legal consequences • May want to avoid detection in drug screening • Typically has a history of cannabis use
• The experimental user	• Only wants to try the substance out of curiosity • May use in an attempt to adhere to perceived deviant social milestones • Uses for the sake of having used, and has no intent of using again
• The drug aficionado	• A rare group of individuals who are interested in the novelty of the experience, and adding to their drug use repertoire • May be respected among peers for their drug knowledge and experience
• The habitual user	• A frequent user of synthetic cannabinoids • Uses synthetic cannabinoids as their drug of choice, and may favor it over alternatives

In sum, the four distinct profiles of a synthetic cannabinoid user reflect the reasons for which a person engages in use. Each profile can include users from all demographics. The most common profile would be the replacement user, with the other three profiles representing a minority of synthetic cannabinoid users. Data summarize information presented in the chapter.

to encompass every user, we introduce a typology of synthetic cannabinoid user profiles that may have utility in describing, evaluating, and managing emerging drug issues. Our typology is represented by four distinct profiles: (1) those who use synthetic cannabinoids as a replacement or substitute for another substance, (2) those who experiment with synthetic cannabinoids as a social milestone or to have a single experience with a novel substance, (3) those who regularly use substances and use synthetic cannabinoids in order to extend the breadth of their drug use experiences, and (4) frequent, regular users of synthetic cannabinoids. Specific characteristics for each profile are explored in the following sections (Table 6.4).

The Replacement User

The first general category of synthetic cannabinoid user, and likely the most prevalent of the four, is composed of users who choose to substitute synthetic cannabinoids for another substance (typically cannabis). Users of synthetic cannabinoids typically have a history of cannabis use (Stogner & Miller, 2014; Hu et al., 2011), although such use is not always the case. This category is comprised of substance users who are attempting to skirt legal consequences, and turn to synthetic substances as a more legitimate alternative. Members of this group likely view marijuana more positively, but chose an alternative due to concerns regarding to the substances' psychoactive effects. While synthetics were certainly viewed as more legal prior to the bans, now in place in several countries, synthetic cannabinoids are still viewed as a substitute with fewer legal risks, by a number of individuals. Prior to recent legislation, cannabis users concerned about receiving a citation or arrest may have used synthetic cannabinoids to eliminate any risk of arrest. Probationers are one group particularly likely to have substituted due to recurrent drug screens that would identify cannabis as an illegally used drug. This same mindset likely affected the decisions of athletes and military personnel whose health is intently monitored by governing agencies (Khey et al., 2014). Following the bans, individuals may still have acknowledged risk, but still used synthetics due to perceiving that risk to be lower than what would be associated with cannabis.

Though being able to use a replacement substance without concern of arrest was critical in the spread of synthetic cannabinoid use, other factors affected its utility as a replacement. Convenience, prior to bans, also likely played a role. As synthetic cannabinoid products were available over-the-counter, consumers could directly purchase them at virtually any hour. Though the price may have been higher, individuals could obtain a product without being dependent on an illicit dealer, or having to arrange a meeting. Second, many users may have turned to synthetic cannabinoids in order to avoid detection in drug testing. Even after synthetic cannabinoids became illegal, they may not have been as easily identified on drug screens as cannabis. An individual expecting to be screened as part of their work may substitute to increase the chance of testing negative for recreational drugs. As bans were established, synthetic cannabinoids became more vulnerable to drug detections, as researchers, medical professionals, and law enforcement focused on such substances. Overall, the prevalence of this user profile is directly tied to the legal status of the drug. As synthetic cannabinoids are banned, their value as a legal alternative decreases. Once testing identifies synthetic cannabinoids as consistently as cannabis itself, the existence of this user profile will largely disappear.

The Experimental User

The second profile is that of the experimental synthetic cannabinoid user. Rather than engaging in synthetic cannabinoid as a substitute or replacement, some users possess more novel motives for use, and only want to try

a particular substance. Such experimental users act more out of curiosity than specific intent (Barratt et al., 2013). Khey et al. (2014) argue that some experimental users are attempting to simply adhere to perceived deviant social milestones. For example, using substances may be a rite of passage in some youth subcultures, in that the act of using the substance is more important than the effects. Khey et al. (2014) further postulate that these users merely want to try the substance simply for the sake of having used it, and have no intent of using again. The former legality of these substances facilitates this practice and, for some, it may have made synthetic cannabinoids an appealing substance with which to fulfill perceived peer expectations of substance use. Of course, many youth in this category may assume that both cannabis and synthetic cannabinoid experiences are expected by their peers, and experiment with both, rather than one or the other. It is possible that this mentality and practice is perpetuated by the Internet and the availability of websites, blogs, and videos depicting use of such products.

The Drug Aficionado

Within drug using groups, there seem to exist individuals that consider the scope and breadth of drug using experiences to be a valuable commodity. Individuals are respected for their ability to recount the experiences with a wide variety of drugs. While not dependent on any one substance, they claim to have experimented with substances in several categories, and selected a handful as drugs of choice. They are seen as a resource to those less experienced drug users. In Germany, there were many reports of people using synthetic cannabinoids simply because they were the new, unknown drug on the marker (EMCDDA, 2009; Vardakou et al., 2010). Khey et al. (2014) similarly describe "avid drug users" in their typology of *Salvia divinorum* users. These users are not necessarily attempting to avoid any negative consequence associated with traditional substance use, but are more interested in the novelty of the experience, and adding to their drug use repertoire. These individuals seem to exist in virtual peer networks (eg, message boards of popular drug use forums), and in local communities. For these individuals, use is about expanding their experience. Legal regulations are unlikely to dissuade them, since they typically engage in a variety of forms of substance use, both legal and illegal. Regulation is unlikely to have an effect on their experimentation, but, as noted previously, few of these individuals exist.

The Habitual User

The last profile represents the frequent synthetic cannabinoid user. Among some users, synthetic cannabinoids have become a drug choice, as opposed to a substitute or trial occurrence. While most synthetic cannabinoid users do not consider it their primary drug of choice, some users report aspects that lead them to report favoring it over alternatives. Some report experiencing stronger or more enjoyable effects from synthetic cannabinoids, as opposed to traditional cannabis (Vandrey et al., 2012; Fattore & Fratta, 2011; Barratt et al., 2013). The popularity of synthetic cannabinoid use among this group of users may be in part due to reasons discussed throughout this chapter, but are not completely encompassing, as the frequent user desires the synthetic substance over a traditional one based on the synthetics' merits alone. Overall, it does not seem to be the case that this profile describes a particularly large number. Bans likely have less effect on these individuals than the replacement users, but may decrease their occurrence if availability becomes an issue. Evidence with other synthetics suggests that a black market develops soon after a ban (Winstock, Mitcheson, & Marsden, 2010), but it has yet to be seen whether users will be able to continue to obtain a stream of the product long after the bans.

CONCLUSIONS

The categorization of substance users into a framework has utility for research, law enforcement, and policy development. A user rational-type typology allows us to better identify different types of users, than mere demographics alone. The intentions individuals have when selecting synthetic cannabinoid use are intimately tied to the ways in which they will react to legal changes. Harm reduction strategies must similarly consider that motives for use are distinct, and should be appropriately tailored to address all groups. This chapter provides four distinct profiles of a synthetic cannabinoid user not bounded simply by demographics, but rather encompassing common reasons for use. Such profiles are able to encompass a greater diversity of users, and provide insight into drug use overall.

MINI-DICTIONARY

Deviant social milestone Synthetic cannabinoid use perpetuated by a subcultural influence to meet deviant standards, in this case the use of synthetic cannabinoid products.
Instrumental drug use Substance use that is goal-oriented. This may include avoiding a specific consequence such as legal ramifications, or a positive drug test.
Recreational drug use Substance use that is for enjoyment. This type of use is for pure enjoyment and does not meet a particular goal.
Sensation seeker A person who engages in synthetic cannabinoid use as a thrill. This pattern can be perpetuated by media attention that attracts potential users with their memorable coverage of the substance.

Synthetic cannabinoid user A person who uses synthetic cannabinoid products.
The drug aficionado A person who uses synthetic cannabinoids for the novelty of the experience, and to add to their drug use repertoire. These users pride themselves on the various substances they have used, but are rare among substance users.
The experimental user A person who uses synthetic cannabinoids only to try. These users typically do not exhibit reoccurring use.
The habitual user A person who regularly engages in synthetic cannabinoid use. These users typically prefer synthetic cannabinoids as their drug of choice.
The replacement user A person whose uses synthetic cannabinoids to replace or substitute another substance, typically cannabis. These users typically want to avoid negative consequences associated with other substances.

Dual Disorders in Cannabis Misuse

*F. Arias-Horcajadas**, *N. Szerman***, *P. Vega*†, *I. Basurte***, *B. Mesías*†

**Psychiatric Department, Doce de Octubre Hospital, Madrid, Spain
**Gregorio Marañon Hospital, Madrid, Spain
†Instituto de Adicciones, Madrid, Spain

SUMMARY POINTS

- Over 75% of cannabis addicts in treatment have a dual diagnosis, and the prevalence of mood and anxiety disorders is particularly significant.
- About half of cannabis addicts have a personality disorder diagnosis.
- Cannabis-dependent subjects begin using other drugs, such as, alcohol, cocaine, and tobacco, at an earlier age than other addicts who do not use cannabis.
- Cannabis dependence is most associated with antisocial personality disorder, bipolar disorder, psychosis, and agoraphobia.
- The presence of these mental disorders is significantly associated with cannabis use beginning at an earlier age.

KEY FACTS

Key facts of eCB system as an element in emotional regulation:

- Regulation of the serotonin system (5-HT) and noradrenaline (NA).
- Regulation of hypothalamic-pituitary-adrenal axis (HPA) hyperactivity.
- Regulation of neurogenesis mechanisms in the hippocampus.

Key facts of mechanisms underlying the role of the eCB system in depression:

- CB1 agonists and FAAH inhibitors increase 5-HT.
- CB1 agonists increase NA in the locus coeruleus (LC) and the PFC.
- CB1 agonists diminish HPA axis hyperactivity, increase neurogenesis in the hippocampus, and increase the levels of brain-derived neurotrophic factor (BDNF) in the hippocampus, which have a neurotrophic role.

Key facts of eCB in PTSD:

- Alteration in eCB levels.
- Increase in CB1 density.
- Relationship with variants of the FAAH gene.

Key facts of chronic use of cannabis and cognitive effects:

- Alterations in memory.
- Alterations in executive functions, inhibitory processing, decision making.
- Alterations in attention.

Key facts of cannabis use and psychosis:

- Transitory psychotic symptoms in intoxication.
- Induced psychotic disorders after prolonged use.
- Schizophrenia after prolonged use and use at early age in vulnerable subjects (genetic vulnerability: COMT, AKT, CB1, CB2 genes; environmental factors: adverse experiences).

LIST OF ABBREVIATIONS

2-AG	2-Arachidonoylglycerol
5-HT	Serotonin
ADHD	Attention deficit hyperactivity disorder

OCD	Obsessive-compulsive disorder
PD	Personality disorder
PDQ4	Personality disorder questionnaire, version 4
PFC	Prefrontal cortex
PTSD	Posttraumatic stress disorder
SUD	Substance use disorder
THC	Δ^9-Tetrahydrocannabinol

INTRODUCTION

The comorbidity between a substance use disorder (SUD) and any other lifetime psychiatric disorder is known as dual pathology. It is a problem of great importance due to its high prevalence (in serious mental disorders, the prevalence of lifetime SUDs is over 50%), its clinical and prognostic implications (the presence of comorbidity modifies the clinical manifestations and the course), difficulties in the therapeutic approach (less scientific evidence and less adherence), and the associated healthcare costs. The underlying mechanisms of comorbidity are not well defined, and different explanatory hypotheses have been proposed: common vulnerability models, self-medication, and etiological hypotheses.

Many studies suggest that cannabis is associated with a wide variety of mental disorders. Psychiatric manifestations due to cannabis use have been extensively described in medical literature. In the 19th century, a French doctor, Moureau de Tours, was already suggesting that cannabis intoxication could mimic any psychiatric manifestation.

The description of a widely distributed cannabinoid system in our brains, and the knowledge of its implication in a broad variety of functions, such as emotional regulation, response to stress, cognitive functions, and brain development, suggest that a possible mechanism by which cannabis produces this wide variety of manifestations may be the modifications that Δ^9-tetrahydrocannabinol (THC) could produce in such system; one that may previously have been normal, or that had a dysfunction that contributed to such alterations.

Age when use begins, duration of use, and strength of the drug are relevant factors regarding the risk of developing mental disorders. Since the psychiatric manifestations only occur in a percentage of users, it is likely that there must be individual vulnerability to such development. The interaction between use, the said genetic or biological vulnerability factors, and other adverse environmental factors, such as stressful situations, seems to contribute to the development of these symptoms.

THE CANNABINOID SYSTEM IN PSYCHIATRIC DISORDERS

The Role of the Cannabinoid System in Emotional Regulation and Response to Stress

The eCB system is becoming established as a fundamental element in the regulation of our body's response to stress, and in emotional regulation. The eCB system is present in many regions of the brain that are implicated in these aspects. The eCB inhibits hyperactivation of the HPA system in response to stress, a hyperactivity related equally to depression and anxiety symptoms. It also regulates negative feedback of corticoids, reduces the release of NA, regulates the sympathetic response, and inhibits the secretion of cytokines, adopting the role of a buffer in this mechanism.

On the other hand, chronic states of stress alter the eCB system, and cause a downregulation of the CB1 receptors, which results in subsequent alteration of the response to stress. Another noteworthy aspect is that the eCB system modulates emotional response in a way that is very dependent on the context, therefore, environmental factors are relevant in the functioning of the system.

The modulation of the neurotransmission of NA, 5-HT, GABA, glutamate, and other neurotransmitters is crucial in these effects, but the implication in neuroplasticity, neurogenesis, and neurotrophic mechanisms may also be important.

The eCB System in Depression

It has been suggested that, in depression, there would be a hypofunctioning of the eCB system, based on various experimental data, although not all the information is consistent (Table 7.1). The interaction between different vulnerability factors of the eCB system and other neurotransmission systems, together with adverse environmental factors, are going to contribute to the appearance of depression. The interaction between the CNR1 polymorphisms with others of 5HTTLPR, and with environmental factors, has been described. On the other hand, stress factors related to the pathogenesis

TABLE 7.1 The eCB System is Implicated in the Pathogenesis of Depression

- Knock-out animals for the CB1 receptor (CB1KO) are more vulnerable to chronic stress and present HPA axis hyperactivity
- Chronic exposure to CB1 or THC agonists produces a depressive phenotype, and alterations in neuroplasticity. This phenomenon is found more when the exposure occurs during adolescence, with a depressive phenotype being observed in adult animals. So, adolescence is a critical period, in part because CB1 receptor activation affects the monoaminergic system
- CB1 antagonists induce depression both in animals and in humans
- Studies of genetic polymorphisms of the CB1 receptor in humans indicate that certain variants contribute to the risk of depression in response to stressful events, and have an influence on the response to antidepressants
- A reduction in the levels of AEA and 2-AG in women with depression.
- Inhibitors of the FAAH show an antidepressant effect in animal models
- Animal models of depression usually present changes in receptor expression of the eCB system, generally an increase in CB1 expression in the PFC, and a reduction in the subcortical regions
- An increase in CB1 receptor density in the PFC postmortem in suicidal depressives
- Antidepressants modify the eCB system, increase the system's limbic signal, and possibly contribute to neurogenesis through the eCB system
- Animal models with CB2 receptor overexpression also implicate this receptor in depression

of depression, such as early maternal separation, cause changes in the eCB system.

The eCB System in Anxiety

The role of the eCB system in anxiety seems to be even more complex than in depression. Attempts have been made to explain the discrepancies between the different experimental results by a biphasic effect, so low doses of cannabinoid agonists would be anxiolytic, and high doses, anxiogenic. This effect has been explained by the influence of different brain regions (PFC, amygdala, and hippocampus) or by differences in the effects of different receptors, mainly CB1 and TRPV1.

Biphasic effects of cannabinoids have been shown in processes, such as, feeding behavior, motor activity, motivational processes, and anxiety responses. Some authors found that the anxiolytic-like effects of the low dose of cannabinoids are mediated via the CB1 receptor on cortical glutamatergic terminals. On the contrary, the CB1 receptor on the GABAergic terminals is required to induce an anxiogenic-like effect under a high-dose treatment (Rey, Purrio, Viveros, & Lutz, 2012).

In addition, the response of the eCB system is very influenced by context, and that dependence on environmental factors could also explain the different results in the studies.

The CB1 receptor is highly expressed in GABA interneurons. One model suggests that the eCB system in the PFC regulates the response to stress through the GABA interneurons, which regulate regions such as the basolateral amygdala (BLA), and monoamines such as in the raphe nuclei, and this would regulate the HPA axis. Also, other neurotransmitters have been implicated, such as, the opioid system, the 5-HT1A receptors, nitric oxide, and the glutamatergic system. Likewise, other data support the role of the eCB system in anxiety (Table 7.2).

Equally, it may have a role in the pathogenesis of OCD, as can be seen in an animal model (marble burying behavior), while CBD improves compulsive behaviors in such model.

The eCB System in Bipolar Disorder

In the case of BD, the link with the endogenous cannabinoid system could be due to the modulation of GABA and serotonin neurotransmitters. In this respect, the manic episodes seem to be exacerbated by cannabis use, therefore, is it considered that a high endocannabinoid tone would cause these episodes (Agrawal, Nurnberger, & Lynskey, 2011). On the other hand, low activity of the CB1 receptors could contribute to causing depression, as we have described; however, the results have not been replicated.

TABLE 7.2 Role of eCB System in Anxiety

- The CB1 receptor is highly expressed in GABA interneurons
- FAAH enzyme inhibitors have an anxiolytic effect in animal models
- Genetic variants of FAAH in humans regulate the habituation of the amygdala to threatening situations
- The eCB system modulates the amygdala response to stress. The increase in the levels of AEA in the basolateral amygdala facilitates long-term fear extinction
- CB1 antagonists, such as, rimonabant are anxiogenic
- Anxiolytic effects of nabilone and CBD have been described. The latter possibly acts through the 5-HT1A receptors, although it may act through other mechanisms, such as, facilitation of neurogenesis in the hippocampus by boosting AEA, activation of the TRPV1 receptors, CB2 agonism, GPR55 antagonism, or PPAR-gamma agonism

In studies on genetic association, different polymorphisms have been found to be associated with bipolar disorder within the CNR1, CNR2, and FAAH genes.

The eCB System in Psychosis

In experimental studies, D'Souza et al. (2004, 2005) have found how the administration of THC to healthy subjects reproduced both the positive and negative symptoms of psychosis in a dose-dependent manner, and how it exacerbated them when it was administered to patients with psychosis. So, the agonists increase the positive symptoms, induce negative and cognitive symptoms, and induce a deficit in the PPI in the same way as seen in psychosis.

Many animal model studies confirm the role of the eCB system in psychosis, the most noteworthy being the work done with the phencyclidine model that shows the presence of positive and negative symptoms, and in which changes in the CB1 receptor and eCB levels are described.

In humans, pharmacological experimental studies, genetic studies of the eCB system, postmortem studies that analyze CB1 receptor density, studies on endocannabinoid levels, and cognitive and neurophysiological studies that compare the alterations in psychosis and those caused by the use of cannabis support the view that the eCB system has an important role in psychosis (Arias, 2007).

On one hand, THC modifying a previously normal eCB system may contribute to the appearance of psychosis. Another possible view is the role of dysregulation of the eCB system in vulnerability to psychosis, independent of cannabis use. It is possible that the consumption of THC in subjects with a vulnerable eCB system could contribute to the development of psychosis in addicts.

From the point of view of alterations in the eCB system in patients with schizophrenia, who do not use cannabis, there are several interesting findings. One is the discovery of high levels of AEA in the cerebrospinal fluid (CSF) in patients who are not taking medication, or who are being treated with atypical antipsychotics (Leweke, Giuffrida, Wurster, Emrich, & Piomelli, 1999). This increase in levels is not found in patients treated with typical antipsychotics. This seems to relate AEA levels with the D2 receptor, the main target of action for first generation antipsychotics. At the same time, and in keeping with the aforementioned, the ability of THC to reduce the activity of the D2 receptor has been observed, as well as the selective blocking of CB1 that boosts the D1 and D2 receptors. Consequently, an increase in AEA could be an indication of a compensatory mechanism for reducing D2 hyperactivity and, therefore, alleviating psychotic symptoms. On the other hand, cannabis use contributes to this increase in AEA not occurring, so this supposed protective mechanism would be lost (Leweke et al., 2007). Therefore, a dysregulation of AEA in psychosis has been suggested.

Other studies show a reduction in the levels of the CB1 receptor in the dorsolateral frontal cortex of patients. This CB1 receptor reduction has been interpreted as a compensation for the high levels of GABA. Consequently, a reduction in CB1 levels and its inhibitory action could have the effect of increasing dopaminergic transmission. Nonetheless, other studies found a high density of CB1 receptors in the anterior and posterior cingulate cortex and in the dorsolateral prefrontal cortex.

Although, once again, the studies are not consistent with each other, polymorphisms of the CB1 receptor gene have been described in relation to psychosis, but also those of the CB2 receptor that may be more related to neuroinflammatory processes. In any case, genetic variants of the dopaminergic system have been described (the COMT and AKT1 genes), or implicated in neurodevelopmental processes that could influence vulnerability to psychosis in cannabis users, as well as interact with other stress factors such as traumatic childhood experiences.

While the agonists have a propsychotic effect, CBD and rimonabant present atypical antipsychotic properties in animal models, and some clinical trials on humans have confirmed their possible clinical utility.

There are also data that suggest that the eCB system is implicated in the neurodevelopmental alterations in psychosis. The eCB system is important in this aspect, and it is considered that, in psychosis, there may be an alteration in neurodevelopment. Additionally, the fundamental role that the eCB system has in the regulation of the inflammatory response could be included. Therefore, the eCB system would be implicated in the development of schizophrenia, not only because of its regulatory function in other neurotransmitters, but also because of its function in neurodevelopment and neuroinflammatory processes.

CANNABIS DEPENDENCE AND MENTAL DISORDERS

Depression

Various cohort studies suggest that cannabis plays a moderate role in inducing depression. The possibility that the association between cannabis and depression may be due to common social or family factors, or other possible confounding factors, cannot be ruled out. The metaanalysis by Moore et al. (2007) concludes that the effects of cannabis on the subsequent appearance of

depression are moderate (odds ratio 1.3–1.6), and that such effects are dose-dependent. The most recent studies present more consistent data regarding that modest but positive effect between cannabis use and an increase in the risk of depression (Lev-Ran et al., 2014; Lev-Ran & Feingold, 2016). It is important to highlight the possible influence of the age when cannabis use began, so use during adolescence predicts subsequent depression.

In a study on twins, in each case one being a cannabis user and the other not, it was found that the twin that used cannabis had a higher risk of depression and suicide attempts (Lynskey et al., 2004). Also, cannabis use contributes to the persistence of depression and, on the other hand, the presence of depression hinders cessation of use.

Bipolar Disorder

Bipolar disorder is one of the conditions most related with cannabis dependence, as epidemiological studies on the general population confirm, such as the ECA or the NESARC, along with many clinical studies. On one hand, there is a high prevalence of use and dependence in bipolar patients. On the other, cannabis use inducing manic phases is also described. The increased risk of appearance of a bipolar disorder has been related to the dosage of cannabis and use beginning at an earlier age. Likewise, cannabis use brings forward the age of onset of bipolar disorder (Lagerberg et al., 2011), which supports the view that it has at least a role in precipitating the symptoms.

Cannabis use has been associated with clinical changes in bipolar disorder, such as more mixed episodes, rapid cycling, more suicide attempts, greater functional limitations, more psychotic symptoms, and an increase in the number of relapses. In the NESARC study, an association is indicated, and it is related to an earlier age of onset of bipolar disorder and more mixed, depressive and manic episodes (Lev-Ran, Le Foll, McKenzie, George, & Rehm, 2013a).

Anxiety Disorders

Anxiety symptoms are some of those most frequently found in cannabis users, both during periods of intoxication and abstinence. Although the majority of users mention a relaxing effect, one of the most frequently found adverse effects of intoxication is the appearance of anxiety and panic attacks. As in the disorders previously mentioned, panic disorder being induced following cannabis use has been outlined, both in longitudinal studies and in case descriptions. Cannabis use during adolescence predicted subsequent anxiety symptoms, as is the case with depression (Patton et al., 2002). Cannabis dependence has been associated with a greater prevalence of different anxiety disorders, such as, panic disorder, agoraphobia, and social phobia.

Social Phobia

It has been suggested that the relationship between cannabis and social phobia may be different from that which exists in other anxiety disorders. Social phobia usually appears earlier, therefore cannabis use as self-medication is considered to be significant. Also, the presence of both together increases functional limitations (Buckner et al., 2012).

Cannabinoid agonists are implicated in the improvement of the phobia, while rimonabant has shown a detrimental effect in experimental studies using a public speaking test. Likewise, CBD in such test produces an improvement.

Panic

The presence of cannabis use increases the risk of developing panic attacks and panic disorder, and of an earlier age of onset of this disorder (Zvolensky et al., 2008). A greater association has also been described with agoraphobia, although the relationship is not clear. In general, the relationship referred to is one in which cannabis induces panic, although occasionally the use is described as self-medication to reduce anxiety, this being influenced by the expectation that cannabis alleviates anxiety.

Posttraumatic Stress Disorder

The eCB system is implicated in the elimination of aversive memories. It regulates emotional response after a trauma, and the action of corticoids in response to the trauma, by mediating CB1 in the hippocampus and the basolateral amygdala. So, facilitation of the eCB signaling improves PTSD. In the same way, an association has been found between PTSD and cannabis use. Greater use in order to cope with aversive situations, more severe cannabis withdrawal symptoms, and more craving have been described.

Cannabis and Cognitive Deterioration

The presence of CB1 and the eCB in the hippocampus and the PFC suggest that the eCB system has a role in cognitive functioning. Acute use causes alterations in the hippocampus-PFC responsible for the processes of encoding and recuperating information. Acute cannabis use alters cognitive capacity (attention, memory, problem solving) and psychomotor performance. The effects include slowing of reaction speed, lack of motor coordination, alteration of short-term memory, concentration difficulties, and impairment of divided attention. These effects are dose-dependent.

Habitual cannabis use may cause more persistent neuropsychological deficits. Chronic use affects episodic memory, decision-making and response inhibition processes, and causes learning and executive function deficits, mainly in working memory. Above all, alteration in memory has been found.

There are discrepancies regarding the severity of the changes, and whether or not they are reversible. Longer duration of use and higher doses cause more cognitive alterations. The age when use began is also a relevant factor. Data seem to indicate that those deficits exist in the short term but, after prolonged abstinence, such changes do not persist. These are more serious when use has begun at an earlier age, implicating processes of brain maturation.

Amotivational Syndrome

Smith (1968) and McGlothlin and West (1968) described the amotivational syndrome. At that time, there was a rapid increase in descriptions of cases of apathy along with lack of concentration and memory. The majority improved with abstinence. Blunted intellectual function was described in a broad spectrum of patients in Egypt by Soueif (1976).

The description of these symptoms was widely circulated after the initial description, but nowadays they are a controversial matter. The condition is characterized by the presence of apathy, lack of motivation, lack of interest in work or education, and personal care. The majority of clinicians consider that they are symptoms that are observed in users, but what is not clear is whether they form a condition in itself, or whether they are the result of a chronic state of intoxication. In any event, they have been found to remit when use stops, although they may continue in a small percentage of users, despite withdrawal. The lack of improvement with antidepressants, and the frequent concurrence of lapses of memory and attention, suggests that the symptoms may be more related to the cognitive deterioration caused by cannabis, affecting motivation as well as other cognitive areas, rather than to a depressive disorder.

Cannabis and Psychosis

In the last few decades, various cohort studies have been carried out with the aim of investigating the relationship between cannabis use and schizophrenia. After the initial study by Andréasson, Allebeck, Engström, and Rydberg (1987), there followed others. These studies show that cannabis use at an early age is associated with a greater risk of suffering from psychosis as an adult. It has also been proved that such risk is greater than with other drugs, and that it is the only drug regarding which there is evidence that it brings forward the age of onset of psychosis.

However, this hypothesis has been criticized. It has been suggested that although cannabis use precedes the onset of psychotic symptoms, there could already be a greater susceptibility to cannabis dependence in subjects who are vulnerable to developing psychosis.

In general, the majority of authors consider that cannabis use would be a precipitating factor that would cause the development of schizophrenic disorder in individuals vulnerable to suffering from it. As such, the potential interaction between genetic vulnerability and cannabis use for the development of schizophrenia has been suggested in studies that found a higher risk of experiencing psychotic symptoms after cannabis use, among carriers of the 158 valine allele of the COMT gene, although other studies have not corroborated this. Nonetheless, other genes have been implicated, as well as the existence of epistasis between genes from different neurotransmission systems, or that are implicated in neurodevelopment and, most interestingly, the interaction between these genetic variants and environmental factors, such as, adverse experiences during childhood, or stressful life events.

Therefore, we can consider that psychosis is one of the most serious effects associated with cannabis use, and is possibly the adverse consequence about which we have the most scientific evidence. An effect influenced by the age when use began, possibly the amount and duration of use, the strength of the drug (perhaps in relation to the amount of CBD content), and for which a vulnerability that has not yet been established, is required. Likewise, it is described as an effect of synthetic cannabinoids, and psychotic symptoms have been outlined as an adverse effect in clinical studies focused on the therapeutic utility of cannabinoid agonists.

Considering that schizophrenia is a neurodevelopmental illness, and the extensive evidence that the eCB system modulates such neurodevelopment (cellular proliferation, neurogenesis, neuronal migration, axonal projections), cannabis use at an early age affecting this neurodevelopment could provide quite a plausible explanation for this adverse effect.

Personality Disorders

Personality disorders are highly prevalent in cannabis-dependent subjects. Approximately half the addicts in clinical samples have some personality disorder diagnosis, the most prevalent being antisocial, borderline, paranoid, depressive, or avoidant personality disorders. In the NESARC study, the high prevalence of these personality disorders is confirmed, above all, antisocial, dependent, and histrionic (Lev-Ran, Le Foll, McKenzie, George, & Rehm, 2013b).

MADRID STUDY ON THE PREVALENCE OF DUAL PATHOLOGY IN CANNABIS ADDICTS IN TREATMENT

The sample consisted of 837 subjects in treatment in the Community of Madrid mental health or drug network. Of the total of 837 patients assessed, 710 had some diagnosis of a lifetime SUD (including alcohol, and excluding tobacco). Regarding cannabis, 353 patients had a lifetime diagnosis (abuse or dependence), of which 133 misused at the time, and 357 had substance use disorders involving drugs other than cannabis. Only 20 subjects had a lifetime diagnosis of cannabis misuse without other associated SUDs, therefore, in the analysis, all subjects with a diagnosis of cannabis use disorder were included, even if they had other associated SUDs (Arias et al., 2013).The MINI interview was used to diagnose axis I mental disorders, and the PDQ4 questionnaire for the assessment of personality disorders.

Table 7.3 shows the distribution of lifetime comorbid mental disorders. It was considered that a dual pathology existed if there was a current mental disorder diagnosis established through the MINI and/or a personality disorder diagnosis according to the PDQ4. Table 7.4 indicates the distribution of personality disorders in patients with lifetime cannabis misuse. Table 7.5 shows the current diagnoses of axis I disorders assessed by the MINI in subjects with current cannabis misuse. 76.5% had an axis I diagnosis established through the MINI and/or a personality disorder. The high comorbidity in cannabis addicts concurs with other studies (Stinson, Ruan, Pickering, & Grant, 2006).

The most prevalent disorders were different mood and anxiety disorders. The high prevalence of manic

Bulimia	2	1.5
Generalized anxiety disorder	32	24.1

or hypomanic symptoms should be highlighted. It is possible that a high percentage was induced by use, as has been previously explained (Henquet, Krabbendam, de Graaf, ten Have, & van Os, 2006). Likewise, suicide risk, assessed by the MINI, was found in one third of the cannabis addicts. Cannabis use is considered to increase such risk (Lynskey et al., 2004). This suicide risk is higher in dual pathology patients than in those who do not present dual pathology (Szerman et al., 2011).

There were no significant differences in the prevalence of mental disorders between the cannabis addicts (n = 353) and the rest of the addicts (n = 357), although there tended to be a higher presence of dual diagnoses in the cannabis group (64% vs 57.7%, p = 0.09). There was a higher number of males in the cannabis group (86.7% vs 76.6%, p = 0.001), and they were younger (35.2 vs 39.3 years of age, p = 0.001). Antisocial personality disorder was more prevalent in the cannabis group (19.5% vs 9%, p = 0.001), and obsessive personality disorder was less prevalent (15% vs 21%, p = 0.04). When considering the subgroup of current cannabis addicts (n = 133), a greater prevalence of agoraphobia (16.5% vs 9.2%, p = 0.01), psychosis (16.5% vs 9.4%, p = 0.02), and bipolar disorder (29.3% vs 21.8%, p = 0.05) was found in comparison to the rest of the addicts.

Information regarding the age of onset of the mental disorders was not collected. The age when cannabis use began in the patients with the mental disorders mentioned was compared (Table 7.6).

Therefore, we cannot conclude that cannabis misuse or dependence is specifically associated with certain mental disorders, but we can highlight that polysubstance use in which cannabis use is included is associated with serious mental disorders, such as, psychosis and bipolar disorder. Given the nature of the study, we cannot determine what type of relationship there is with these disorders. In any case, we observed that the age at which cannabis use began is earlier in patients with these comorbid diagnoses, which suggests that cannabis use may have a role in causing or precipitating such disorders. Different, recent studies indicate that cannabis use is related to an earlier onset of psychosis, and a recent metaanalysis confirms this (Large, Sharma, Compton, Slade, & Nielssen, 2011), and that the earlier cannabis use begins, the higher the risk that a psychosis may appear (Dragt et al., 2012). Likewise it has been suggested that cannabis has a causal role in inducing mania (Henquet et al., 2006), and an earlier age of onset of bipolar disorder in cannabis users (Lagerberg et al., 2011). In a study conducted on adolescents, 62% of cannabis addicts were found to have comorbid disorders, and there was an association with mood disorders (depression and bipolar disorder) and anxiety disorders (especially with panic disorder) (Wittchen et al., 2007). We found a high prevalence of panic disorder in the cannabis addicts, although when the association was compared with the rest of the addicts, there was a greater association with agoraphobia. The close association of cannabis use with bipolar disorder and psychosis has been established in many studies (Agrawal et al., 2011; Arendt, Rosenberg, Foldager, Perto, & Munk-Jørgensen, 2007).

In addition, this subgroup of cannabis users seems to constitute a more severe subgroup, given that they also began using other drugs at an earlier age. In any event, it is necessary to consider the limitations of the method used to collect data with possible memory bias.

In summary it was considered that 76.5% of the cannabis addicts had a dual diagnosis. Likewise, this subgroup was different from the rest of the addicts because of its association with antisocial personality disorder, bipolar disorder, psychosis, and agoraphobia.

Therefore, the presence of dual pathology is very high in addicts in treatment who are cannabis dependent, and such use, possibly in the context of a polysubstance use pattern, is associated with serious mental disorders such as psychosis and bipolar disorder. Beginning cannabis

TABLE 7.6 Age When Cannabis Use Began and Presence of Mental Disorders and Age When Use of Other Substances Began in Cannabis Addicts

Age when cannabis use began in years (s.d.)			
	Presence of disorder	**Absence of disorder**	***p***
Agoraphobia	14.9 (3.3)	16.3 (4.4)	0.05
Bipolar disorder	15.5 (3.3)	16.4 (4.5)	0.05
Psychosis	14.6 (3.6)	16.4 (4.4)	0.02
Antisocial personality disorder	15.0 (4.25)	16.4 (4.3)	0.01
Age when use of other substances began in cannabis addicts (in years)			
	Cannabis addicts	**Addicts not addicted to cannabis**	
Alcohol	15.1 (4.1)	17.5 (6.9)	0.001
Cocaine	19.8 (5.5)	22.6 (7.4)	0.001
Tobacco	13.9 (2.9)	14.9 (3.6)	0.001

use at an earlier age is associated with a higher risk of presenting such mental disorders.

MINI-DICTIONARY

Cannabidiol Another component of the *Cannabis sativa*, but which has different effects from THC, and a different mechanism of action, which has been investigated for its therapeutic use in some mental disorders.
Dual disorder The comorbidity between a substance use disorder (SUD) and any other lifetime psychiatric disorder.
Endocannabinoid system A neurotransmission system, the fundamental role of which is as a modulator of other systems, such as, the glutamatergic or the GABAergic systems. Up to now, the CB1 and CB2 receptors and two endogenous compounds, anandamide and 2-AG, have been described, as well as the enzymes implicated in the synthesis and degradation of such compounds.
FAAH Fatty acid amide hydrolase, the main enzyme that degrades anandamide.
Δ^9-Tetrahydrocannabinol The main psychoactive component of the *Cannabis sativa*, implicated in the mental effects of cannabis use.

CHAPTER

8

Cannabis Use and Cognitive Function

C. Evren

Research, Treatment and Training Center for Alcohol and Substance Dependence (AMATEM), Bakirkoy Training and Research Hospital for Psychiatry, Neurology and Neurosurgery, Istanbul, Turkey

SUMMARY POINTS

- This chapter gives an overview of studies that evaluated the impairments in cognitive functions related with cannabis use.
- Risk factors that may mediate the relationship between cannabis use and impairments in cognitive functions are reviewed.
- Adolescents are more vulnerable than adults to neurocognitive abnormalities associated with chronic heavy cannabis use.
- Cognitive deficits may differ in severity, depending on the quantity, recency, age of onset, and duration of cannabis use.
- Although some studies reported recovery with prolonged abstinence, others reported persisting impairments in several cognitive domains, such as, attention, working memory, and executive functioning.
- Further research on cognitive deficits associated with cannabis use will enhance our understanding of underlying pathophysiology and improving treatments for substance abuse.
- Future studies must control the effects of potentially confounding axis I disorders and use of other substances, and consider gender differences.
- Recognition of cognitive problems related to cannabis use can help to select a proper treatment that will be beneficiial for the subject.
- Combinations of behavioral therapies and pharmacotherapies for cognitive impairments may be more effective than single approaches.

KEY FACTS OF COGNITIVE FUNCTIONS

- Cognitive functions involve all aspects of perception, thinking, reasoning, and remembering.
- The regions of the brain primarily involved with the cognitive functions include the hippocampus, prefrontal cortex, and cerebellum.
- Δ^9-Tetrahydrocannabinol is thought to be responsible for the cognitive effects of smoked cannabis.
- Cannabis use during critical developmental periods in the still maturing brain may induce persistent alterations in brain structure and brain function.
- Heavy cannabis users may develop tolerance to the impairing effects of this drug on cognitive functions.
- Cognitive deficits were found in working and episodic memory, as well as in executive and attentional functions.
- Cognitive impairments related with cannabis use predict poor treatment retention and outcome.

LIST OF ABBREVIATIONS

AT	Attention
CB	Cannabis
CBUrs	Cannabis users
CF	Cognitive functions
CU	Cannabis use
DM	Decision-making
EF	Executive functions
HCU	Heavy cannabis users
THC	Δ^9-Tetrahydrocannabinol
VF	Verbal fluency
VLM	Verbal learning and memory
WM	Working memory

INTRODUCTION

Prevalence rates for cannabis use (CBU) is increasing, particularly among adolescents and young adults, alongside a decreasing perception of harm, and less disapproval of its use (Johnston, O'Malley, Bachman, & Schulenberg, 2013). Unfortunately, cannabis (CB) has become the most widely used illicit substance in both developed and developing countries, and constitutes a major health concern.

Over the past two decades, an extensive, growing body of research has demonstrated that CBU adversely affects cognitive functions (CF) (Table 8.1). In particular, deficits were found among heavy cannabis users (HCU) in working memory (WM) and episodic memory, as well as in attention (AT) and executive functions (EF) (Bolla, Brown, Eldreth, Tate, & Cadet, 2002; Messinis, Kyprianidou, Malefaki, & Papathanasopoulos, 2006; Solowij et al., 2002).

TABLE 8.1 Examples of the Studies that Evaluated Different Domains of Cognitive Functions With Cannabis Use

Cognitive functions (CF)	Examples of the studies
Attention (AT)	Medina et al. (2007); Solowij et al. (2002)
Working memory (WM)	Day et al., 2013
Verbal fluency (VF)	Morrison et al. (2009)
Verbal learning and memory (VLM)	Hanson et al. (2010); Harvey et al. (2007); Lisdahl and Price (2012); Medina et al. (2007)
Executive functions (EF)	Gonzalez et al. (2012); Grant et al. (2012); Lisdahl and Price (2012); Ranganathan and D'Souza (2006); Schuster, Crane, Mermelstein, & Gonzalez (2012); Solowij et al. (2012)

Although some studies reported recovery with prolonged abstinence (Pope, Gruber, Hudson, Huestis, & Yurgelun-Todd, 2001, 2002), others reported persisting impairments in several CF, such as, AT, WM, and EF (Bolla et al., 2002; Grant, Gonzalez, Carey, Natarajan, & Wolfson, 2003; Solowij et al., 2002). Consistent with this, in a recent study we conducted, the scores of the Adult Memory and Information Processing Battery Form A and B increased during one month remission follow-up, compared to baseline evaluation (Fig. 8.1). The auditory reaction time of the sample decreased significantly after a month, whereas there was no significant difference in the visual reaction time (Fig. 8.2). These findings supported the previous literature suggesting that some impairment may last longer than a month (Umut et al., 2016).

Δ^9-Tetrahydrocannabinol (THC), is thought to be responsible for the cognitive effects of smoked CB (Thames, Arbid, & Sayegh, 2014). The endogenous cannabinoid system is involved in regulatory neural mechanisms that modulate processes underlying a range of CF that are impaired by CB (Solowij & Pesa, 2010). The regions of the brain primarily involved with the CF include the hippocampus, prefrontal cortex, and cerebellum, which are regions of the brain responsible for decision-making (DM), EF, and memory (Hanson et al., 2010).

EFFECTS OF CANNABIS ON COGNITION

Pope et al. (2001, 2002) have tested AT among current HCU, former HCU, and control subjects on days 0, 1, 7, and 28 of abstinence. On all four occasions, no significant differences between the groups were found in AT performance, despite impairments in VLM, which persisted

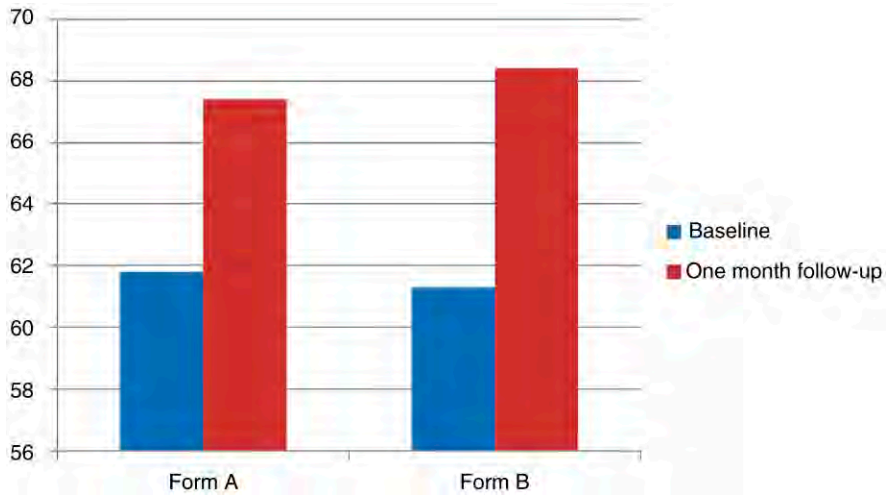

FIGURE 8.1 Comparing baseline and follow-up adult memory and information processing battery form A and form B scores. Adult Memory and Information Processing Battery (form A: z, = –2.31, p = 0.02; form B: z = –3.69, p = < 0.01).

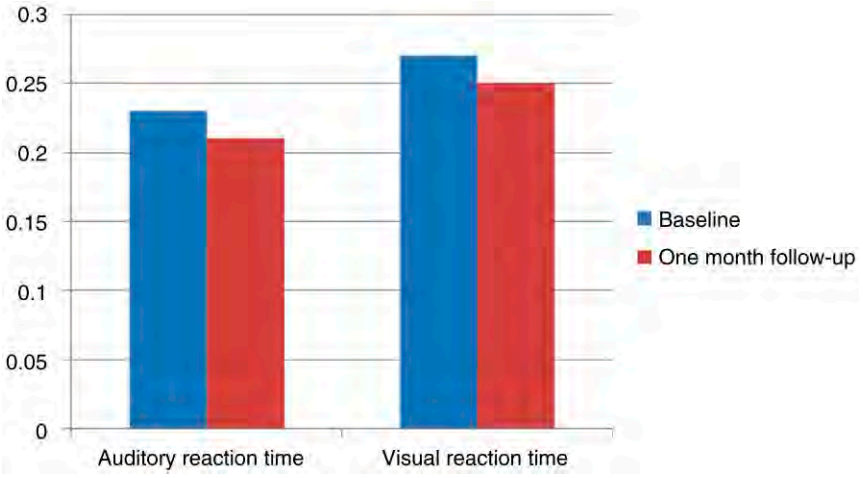

FIGURE 8.2 Comparing baseline and follow-up simple reaction time test (auditory and visual) scores. Auditory reaction time: z = –3.02, $p = 0.03$; visual reaction time: z = –1.78, $p = 0.07$).

up to 7 days of abstinence. After 28 days of abstinence, VLM impairments were no longer found. In a study that used a shorter abstinence period (ie, 24 h), cannabis users (CBUrs) showed both longer reaction times and delayed processing speed, compared with controls (Solowij et al., 2002).

Acute CB intoxication may interfere with time estimation, suggesting a "speeding up of an internal clock" (Hanson et al., 2010). Within several hours of intake, regular CBU in human adolescents or young adults appears to negatively affect VLM, AT, and spatial WM (Fried, Watkinson, & Gray, 2005; Harvey, Sellman, Porter, & Frampton, 2007). THC intoxication has been shown to impair CF on a number of levels, such as, the ability to plan, organize, solve problems, DM, remember, and control emotions and behavior (Crean, Crane, & Mason, 2011).

These impairments in CF can increase the likelihood of accidents, have been linked to the problematic risky behaviors (Romer et al., 2011; Day et al., 2013) and have been found to have hindered ability to make the best use of behavioral therapies, and trouble learning and applying the skills required for successful recovery, putting them at increased risk for relapse to CBU (Aharonovich, Brooks, Nunes, & Hasin, 2008; Crean et al., 2011).

There are reviews that compared cognitive consequences between CB and other substances (Table 8.2) and that considered CF among CBUrs (Table 8.3). These reviews generally support the adverse acute effects of CB on cognition; however, nonacute effects remain less clear.

Tolerance to Effects of Cannabis on Cognitive Functions

Some researchers have reported CB-related impairments in multiple CF (Hunault et al., 2009), while others have failed to observe such effects (Hart, van Gorp, Haney, Foltin, & Fischman, 2001; Ramaekers, Kauert, Theunissen, Toennes, & Moeller, 2009). One potential source of inconsistent findings is the type of tasks used to assess CF. Other source of the apparent incongruent findings may be the CBU histories of the research participants studied.

While Hart et al. (2001) demonstrated that HCU showed only minimal impairment on CF after acute CB administration, the lack of impairment may be due to the fact that subjects were still impaired in the placebo condition, as a result of residual effects. A plausible hypothesis is that infrequent CBUrs are more susceptible to the cognitive-impairing effects of CB than frequent users, who are tolerant to many CB-related performance

TABLE 8.2 Reviews that Compared Cognitive Consequences of Cannabis and Other Substances

Lundqvist (2005)	When compared with stimulants and heroin, CB induces loss of internal control and cognitive impairment, especially of AT and memory, for the duration of intoxication. HCU is associated with reduced function of the attentional system, as exhibited by decreased mental flexibility, increased perseveration, and reduced learning, to shift and/or sustain AT.
Holst & Schilt (2011)	This study reported that all substances of abuse, except CB, were associated with sustained deficits in EF, especially inhibition. Also, there was little evidence for sustained cognitive impairments in adult abstinent CBUrs.
Solowij et al. (2011)	This study suggested that adolescent CBUrs performed significantly worse than alcohol users and nonusers on all measures of learning and memory. They recalled significantly fewer words overall, demonstrating impaired learning, retention, and retrieval.

TABLE 8.3 Some Comprehensive Reviews for the Cannabis and Cognitive Functions

Gonzalez, Carey, & Grant (2002)	From the 40 articles, 22 reported at least some subtle impairments in CF.
Grant et al. (2003)	A metaanalysis identified selective deficits in VLM among chronic users with a range of abstinence, while other CF appeared unaffected.
Ranganathan and D'Souza (2006)	CB impairs all stages of memory, including encoding, consolidation, and retrieval.
Gonzalez (2007)	There are some methodological limitations across studies examining the nonacute effects of CB that include heterogeneous participant samples, and differ in factors, such as, severity of substance use, length of abstinence, and the presence of comorbid substance abuse and psychiatric disorders.
Schreiner and Dunn (2012)	Conducting two metaanalyses, they found that any negative residual effects on CF, attributable to either CB residue or withdrawal symptoms, are limited to the first 25 days of abstinence. Furthermore, there was no evidence for enduring negative effects of CBU.
Schoeler and Bhattacharyya (2013)	Relatively consistent findings have been reported regarding the acute impairments induced by a single dose of THC on verbal and WM. It is unclear whether they may persist beyond the intoxication state. In the long-term, these impairments seem particularly likely to manifest, and may also persist following abstinence, if regular and heavy use of CB strains high in THC is started at an early age.

impairing effects (Ramaekers et al., 2009; Hart et al., 2010; Theunissen et al., 2012). Nevertheless, although HCU develop tolerance to the impairing effects of THC on neurocognitive task performance, they do not develop cross-tolerance to the impairing effects of alcohol, and the presence of the latter even selectively potentiates THC effects on measures of divided AT (Ramaekers et al., 2011).

Duration, Frequency, and Amount of Cannabis Use

Duration, frequency, and amount of regular CBU have been associated with CB-related impairment, and recovery of CF in some studies (Grant et al., 2003). Studies have found that THC levels in urine are associated with the severity of cognitive impairment (Fried, Watkinson, James, & Gray, 2002; Pope et al., 2001). A study that evaluated the dose/frequency-effect relationship suggested that HCU is associated with persistent decrements in CF, even after 28 days of abstinence (Bolla et al., 2002). The other study demonstrated that the THC dose was linearly related to cognitive performance (Hunault et al., 2009), although it is unclear if these decrements will resolve with continued abstinence, or become progressively worse with continued HCU. Nevertheless, specific CF may deteriorate with increasing years of HCU (Messinis et al., 2006; Coullaut-Valera, Arbaiza-Diaz Del Río, de Arrúe-Ruiloba, Coullaut-Valera, & Bajo-Bretón, 2011). Together, these studies suggest that the magnitude of adverse effects of CB on cognition varies, depending upon the frequency of use, and length of abstinence.

Early Onset Cannabis Use

Adults who initiated use in early adolescence show greater dysfunction than those who began use later (Schweinsburg, Brown, & Tapert, 2008). Individuals who initiate CU at an early age, when the brain is still developing, might be more vulnerable to lasting neuropsychological deficits than individuals who begin use later in life. In a study conducted among 28-day abstinent CBUrs, it was shown that CU before the age of 17 has been associated with poor neurocognitive performance on tasks involving verbal ability (Pope et al., 2003). Adolescents who started using CB between the ages of 14–22 and stopped by the age of 22 had significantly more cognitive problems aged 27, than their nonusing peers (Brook, Stimmel, Zhang, & Brook, 2008). In a study examining the EF, individuals who started chronic CBU before the age of 15 showed significantly poorer cognitive performance on tasks assessing sustained attention, impulse control, and EF, compared with the controls and the late-onset group (Fontes et al., 2011). Finally, in a prospective study, individuals were followed from birth to the age of 38, and neuropsychological testing was conducted at the age of 13, before initiation of CU, and again at the age of 38, after a pattern of persistent CU had developed. Neuropsychological decline was concentrated among adolescent-onset CBUrs, with more persistent use associated with greater decline. Further, cessation of CBU did not fully restore neuropsychological functioning among adolescent-onset CBUrs (Meier et al., 2012). These suggest that, if regular CBU starts during early and middle adolescence, it might produce permanent or at least long lasting alterations in CF.

EFFECTS OF CANNABIS ON EXECUTIVE FUNCTIONING

A recent synthesis of studies on CU and EF suggest that findings vary substantially, depending on the specific measures employed, and whether CBUrs are tested while acutely intoxicated or when abstinent (Crean et al., 2011). Studies showing the greatest deficits in EF are the subjects who had been smoking heavy amounts of CB for long periods of time (Crean et al., 2011). Fried et al. (2005) suggested that residual CB effects are evident

beyond the acute intoxication period in current heavy users, after taking into account predrug performance, but similar deficits are no longer apparent 3 months after cessation of regular use, even among former heavy using young adults. Nevertheless, according to Crean et al. (2011) CB seems to continue to exert impairing effects in EF even after 3 weeks of abstinence and beyond.

In the following sections, acute effects denote 0–6 h after last CU, residual effects denote 7 h to 20 days after last CU, whereas long-term effects denote 3 weeks or longer after last CU.

Attention

In their review, Crean et al. (2011) suggested that evidence of the impairing effects of CB intoxication on AT is stronger in less experienced CBUrs, than those with established drug tolerance; AT in the latter group is disrupted more by acute abstinence than acute CB administration, probably as a function of neuroadaptation to chronic HCU. Investigations on the residual effects of CB on EF show that AT may or may not continue to be impaired during the interval associated with the elimination of THC and its metabolites from the brain. A recent study found that sustained CB abstinence for 3 weeks moderately improved critical tracking, and divided AT performance in chronic, daily CBUrs, but impairment was still observable compared to controls (Bosker et al., 2013). When long-term effects of CB were evaluated, basic attentional abilities are largely restored (Crean et al., 2011).

Planning and Decision-Making

Acute CBU has been generally found to impair aspects of planning and DM, for example, response speed, accuracy, and latency (Crean et al., 2011). A single study evaluating DM during the period of time from 7 h to 20 days since last use suggests that this ability is impaired (Whitlow et al., 2004). A study of Grant, Chamberlain, Schreiber, & Odlaug (2012) identified deficits on the quality of DM and executive planning in CBUrs, even in the absence of axis I disorders and a history of using other illicit drugs. A study conducted among nontreatment seeking young adult CBUrs, suggested that DM deficits may be more strongly associated with problems experienced from CBU, rather than solely being a consequence of CBU, per se (Gonzalez et al., 2012). When long-term effects of CB were evaluated, the most enduring and detectable deficits are seen in DM, concept formation, and planning (Crean et al., 2011).

Verbal Fluency

Morrison et al. (2009) studied verbal fluency (VF) among recreational CBUrs and, among this sample, compared those who were administered placebo or moderate (2.5 mg) THC, and found no impairing effects on VF abilities. The findings for VF are somewhat mixed for residual and long-term CB effects, but may be due, in part, to sample differences in the degree of CB exposure (Crean et al., 2011).

Working Memory

Although, according to some authors, there is mixed evidence regarding whether CBU leads to deficits in WM (Solowij & Pesa, 2010), Crean et al. (2011) suggested in their review that these impairments in aspects of WM are well established. In contrast to the acute effects of CB on WM, deficits resulting from residual and long-term CB effects have not been found.

Verbal Learning and Memory

VLM are two of the most extensively examined impaired CF in CBUrs. A growing number of studies suggest performance deficits in acutely intoxicated subjects, in terms of immediate and delayed recalls of words, intrusion, and learning (Solowij & Battisti, 2008; Gonzalez et al., 2012). A review focused on the long-term effect of CBU use on memory suggested that impairments are not dissimilar to those associated with acute intoxication, and have been related to the duration, frequency, dose, and age of onset of CBU (Solowij & Battisti, 2008). A study on CBU and VLM found significant associations between certain components of VLM and frequency of use, cumulative lifetime dose, and duration of regular use (Wagner, Becker, Gouzoulis-Mayfrank, & Daumann, 2010).

Finally, recent CBUrs demonstrated significantly worse performance than nonusers, across cognitive domains of AT/WM, information processing speed, and EF (Thames et al., 2014). There were no statistically significant differences between recent users and past users on neurocognitive performance. Frequency of CBU in the last 4 weeks, and the amount of daily CBU, were negatively associated with neurocognitive performance. Although some of these widespread adverse effects of CBU on neurocognitive functioning appear to attenuate with abstinence, past users' neurocognitive functioning was consistently lower than nonusers.

CANNABIS USE IN ADOLESCENTS

CB is a popular drug of abuse among adolescents, and previous reports show that fewer adolescents believe that regular CBU is harmful to health. Evidence from studies suggests that the severity of the effects

of CBU on cognitive development is dependent on the age when CBU begins. One possible explanation is that those who begin CBU early in adolescence are more likely to become heavily dependent. It is also plausible that chronic CBU will then interfere with educational and vocational training. From a more biological perspective, however, CBU during critical developmental periods in the still maturing brain may induce persistent alterations in brain structure and brain function (Shrivastava, Johnston, & Tsuang, 2011). Although fundamental CF evolve during childhood, existing CF refine throughout adolescence. A study suggested that CBU has a detrimental effect on prospective memory ability in young adults, but users may not be aware of these deficits (Bartholomew, Holroyd, & Heffernan, 2010).

A study suggested that, after 12 h of abstinence from CB, aspects of adolescent CF are independently related to the frequency of CBU, beyond acute intoxication (Harvey et al., 2007). A review reported that studies of adolescent heavy users have identified impairments in learning, memory, and WM up to 6 weeks after cessation, suggesting persisting effects, yet raise the possibility that abnormalities may remit with a longer duration of abstinence. Given ongoing neuromaturation during youth, adolescents may be more vulnerable to potential consequences of CBU than adults (Schweinsburg et al., 2008). As in adults, the degree of impairment on learning and memory, in adolescents, was associated with the duration, quantity, frequency, and age of onset of CU, but was unrelated to alcohol exposure or other drug use (Solowij et al., 2011).

The results of the study by Medina et al. (2007) suggested that, even after a month of monitored abstinence, adolescent CBUrs demonstrate subtle neuropsychological deficits, compared with nonusers. Since the number of lifetime CBU episodes was associated with poorer CF in this study, it is possible that frequent CBU during adolescence may negatively influence neuromaturation and cognitive development. A study conducted by Hanson et al. (2010) detected poorer VLM and verbal WM among adolescent CBUrs that improved during 3 weeks of abstinence, while AT deficits persisted. Another study found that impaired short-term recall memory distinguished adolescent CBUrs from nonusers (Dougherty et al., 2013). Nevertheless, a recent study suggested that abstinent (for at least 30 days) adolescents with CBU disorder history did not differ from the controls, according to CF, suggesting that previously reported deficits may be related to other factors, including residual drug effects, preexisting cognitive deficits, concurrent use of other substances (eg, nicotine), or psychopathology (Hooper, Woolley, & De Bellis, 2014).

ADDITIONAL EFFECT OF POLYSUBSTANCE USE AND PSYCHIATRIC COMORBIDITY

Additional to using different cognitive paradigms, other main limitations for the research of CBU and CF are recruitment of CBUrs with potentially confounding axis I disorders and/or with a history of using other illicit drugs (Hart et al., 2010; Solowij & Pesa, 2010).

Polysubstance Use

Nowadays, CBU as a single drug is becoming rare, whereas polysubstance use is becoming more common. A study that compared subjects only using CB and subjects using ecstasy and CB found no difference on any of the neuropsychological tests but, apart from speed of processing, where higher ecstasy consumption predicted slower processing, the deficits were more closely related to CB than ecstasy usage (Croft, Mackay, Mills, & Gruzelier, 2001). Another study that investigated the consequences of prolonged patterns of alcohol and CBU on CF in late adolescence suggested a poorer CF in alcohol users with HCU by the 18-month follow-up (Jacobus, Squeglia, Bava, & Tapert, 2013).

Psychiatric Comorbidity

The additive effects of CB dependency and depression may not extend to CF (Secora et al., 2010). Earlier initiation of CBU may be linked to poor cognitive outcomes and a significantly greater proportion of the attention deficit hyperactivity disorder patients began using CB before the age of 16 (Tamm et al., 2013).

One would expect that regular CBU will further worsen the impaired CF in patients with schizophrenia or bipolar disorder. Surprisingly, a number of recent studies reported similar or even better CF in CBUrs with schizophrenia (Shrivastava et al., 2011) or bipolar patients (Braga, Burdick, Derosse, & Malhotra, 2012), compared to patients without comorbid drug use. CB using patients who develop psychosis have less neurodevelopmental impairment, and better cognitive reserve than other psychotic patients—perhaps reflecting different etiological processes (Cunha et al., 2013).

Other Comorbidity

The patients with multiple sclerosis who smoke CB are more cognitively impaired than nonusers (Pavisian et al., 2014). Finally, although there is a minimal impact of CB on CF among uninfected individuals, or those at early stages of HIV infection, there is a synergistic effect (due to performance on memory task) of HIV and

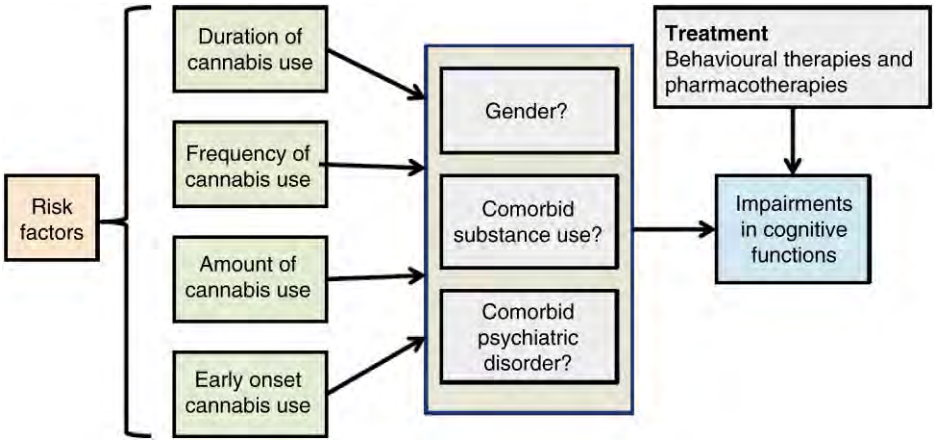

FIGURE 8.3 Risk factors and treatment of impairments in cognitive functions related with cannabis use. Duration, frequency, amount of cannabis use, and early onset cannabis use are related with impairments in cognitive functions. Effects of gender, comorbid psychiatric disorders, and use of other substances are not well known. Treatment of cognitive impairments should include both behavioral therapies and pharmacotherapies.

CBU in patients with advanced HIV disease (Cristiani, Pukay-Martin, & Bornstein, 2004).

GENDER DIFFERENCES FOR THE EFFECT OF CANNABIS USE ON COGNITIVE FUNCTIONS

As previous research identifying cognitive deficits in CBUrs employed samples that were largely male (Bolla et al., 2002; Messinis et al., 2006; Solowij et al., 2002), the CF of female CBUrs is largely unknown. Although Anderson, Rizzo, Block, Pearlson, and O'Leary, 2010 did not find gender differences in effects of CB on cognition, women requested to discontinue the smoking session more often than men, likely leading to an underestimation of differences. Lisdahl and Price (2012) examined how the amount of CBU may differentially affect CF in male and female CBUrs. Although they found that CBUrs had poorer immediate recall and interference inhibition than controls, sex did not moderate these relationships. Nevertheless, in another study, more CBU was more consistently associated with poorer episodic memory performance in females than males, whereas, conversely, it was associated with poorer DM performance in males than females (Crane, Schuster, & Gonzalez, 2013). These results suggest the importance of examining the impact of CB on neurocognition separately for males and females (Fig. 8.3).

TREATMENT

Among adults with CBU disorder, dropouts from combined motivational enhancement therapy and cognitive behavioral therapy scored significantly lower than completers on measures of abstract reasoning and processing accuracy, providing initial evidence that cognitive functioning plays a role in treatment retention in this population (Aharonovich et al., 2008). Abstinence rates following behavioral therapies have been modest, and there are no effective or approved pharmacotherapies for the treatment of CBU disorder. Therefore, targeting cognitive impairment associated with chronic CBU may be a promising novel strategy for the treatment of CB addiction (Sofuoglu, Sugarman, & Carroll, 2010). The bulk of the literature on treatments for addictive disorders suggests that combinations of behavioral therapies and pharmacotherapies may be more effective than single approaches. Thus, medications and behavioral approaches, including cognitive remediation, which target these CF may have utility for the treatment of CBU disorder. One potential area for the future research may be to evaluate specific CF that is most strongly related to improved treatment outcome.

MINI-DICTIONARY

Attention Attention is a process of selectively attending to one aspect of the environment while ignoring other things; includes divided and sustained attention to target stimuli, and it is mediated by the frontal lobes.
Cannabis Cannabis (marijuana) is a green or gray mixture of dried, shredded flowers and leaves of the hemp plant *Cannabis sativa*.
Cognitive functions An intellectual process by which one becomes aware of, perceives, or comprehends ideas. It involves all aspects of perception, thinking, reasoning, and remembering.
Decision-making A process of selecting a course of action among several alternatives.
Executive functions The term executive function describes a set of cognitive abilities that control and regulate other abilities and behaviors. They include the ability to initiate and stop actions, to monitor and change behavior as needed, and to plan future behavior when faced with novel tasks and situations.
Heavy cannabis users Usually defined as using cannabis on at least 10 occasions per month.

Memory The mental capacity or faculty of retaining and reviving facts, events, impressions, etc., or of recalling or recognizing previous experiences.
Δ^9-Tetrahydrocannabinol (THC) The primary psychoactive agent of the *Cannabis sativa* plant that is a partial agonist of the Cannabinoid Type-1 receptors.
Verbal fluency Generating multiple, verbal responses associated with a specified conceptual category.
Verbal learning The acquisition and retention of verbal information.
Working memory Working memory is an ability to hold and manipulate information, and remember it after a short delay.

Cannabis, Migration, and Psychosis Onset

A. Kokona[*], *I. Tarricone*[*,**], *M. Di Forti*[†], *E. Carra*[†]

*Department of Medical and Surgical Sciences, Bologna University, Bologna, Italy
**Department of Mental Health, Bologna, Italy
†Department of Psychosis Studies, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom

SUMMARY POINTS

- Psychotic disorders have a multifactorial etiology, characterized by risk factors operating at various stages of life.
- The use of cannabis is associated with a risk of developing psychosis of about 2 times greater, and provokes also an earlier age of onset of schizophrenia.
- The best cannabis use related predictors of psychotic symptoms are: (1) early adolescence age at first use; (2) high-potency cannabis; (3) genetic vulnerability; (4) heavy use, and (5) individual psychosis vulnerability at baseline.
- Cannabis use can make antipsychotic treatment less effective, and the remission of psychotic symptoms more problematic, and is associated with a higher rate of relapse and greater number of hospitalizations, likely in combination with lower adherence to therapy.
- Considerable evidence indicates that the incidence of schizophrenia, and psychotic disorders in general, are higher in migrant populations and ethnic minorities, compared to the general population.
- There are substantial variations in incidence rates of psychotic disorders across both places and minority groups.
- Environmental factors at the individual and area levels play an important role in the genesis of psychotic disorders among migrant populations.
- The higher risk of psychosis in first generation migrants could not be explained by substance abuse, but some studies have observed a relationship between cannabis use and psychotic onset among second generation migrants.
- Further studies are needed to emit light on the correlation of migration and cannabis use on the development of psychotic disorders.

KEY FACTS OF CANNABIS

- Cannabis is the world's most widely used illicit substance.
- Cannabis contains several cannabinoids, the two best described are: Δ^9-tetrahydrocannabinol (D9-THC) and Cannabidiol (CBD).
- The main types of cannabis available on the "street" were marijuana (grass) and resin (hash), but, in recent years, a more potent variant termed sinsemilla or skunk has become available in many countries.
- The main difference between these substances is that skunk contains a very high concentration of D9-THC (12–18%) and virtually no CBD, while grass and hash are known to contain a similar percentage of D9-THC and CBD (2–4%).
- The use of cannabis is associated with a risk of developing psychosis of about 2 times greater, and the use provokes also an earlier age of onset of schizophrenia

KEY FACTS OF MIGRATION AND PSYCHOSIS ONSET

- There are about 232 million international migrants in the world.
- It is expected that the number of international migrants worldwide will increase in the future.
- The migratory movements are determined by many reasons, with demographic factors, economic disparities, and environmental change, continuing to be major drivers of migration.
- The intense urbanization of developed countries determines also *internal migration*: many people move from rural areas to urban areas in search of higher profits and better services.
- Rates of schizophrenia are higher among migrant and ethnic minority groups.

LIST OF ABBREVIATIONS

AC	African-Caribbean
AOP	Age of psychosis onset
CB1 receptor	Cannabinoid receptor type 1
CB2 receptor	Cannabinoid receptor type 2
CBD	Cannabidiol
CNS	Central nervous system
D9-THC	Δ^9-Tetrahydrocannabinol
DSM	Diagnostic and Statistical Manual of Mental Disorders
DUP	Duration of untreated psychosis
EU-GEI	European Network of National Schizophrenia Networks Studying Gene–Environment Interactions
FEP	First episode psychosis
RR	Relative risk
OR	Odds ratio

INTRODUCTION

The term "Psychosis" indicates a mental state characterized by a set of positive and negative "psychotic" symptoms. Positive symptoms are represented by delusions (false and immutable ideas characterized by extraordinary conviction and subjective certainty, not subject to criticism, and not arising from the cultural context of origin of the subject), hallucinations (perception disorders in any of the five sensory modalities), and disorganization of speech and thinking, described as thought disorders. Negative symptoms include flattening of affect, volition, and mental capacity. Other typical features are alogia (understood as poverty of speech) and apathy (loss of energy, interests, and initiative). The presence of all psychotic symptoms is not necessarily indicative of a disorder. These symptoms have been consistently reported as experienced even by individuals from nonclinical populations (van Os & Linscott, 2009). Why someone, who experiences psychotic symptoms, crosses over the threshold into frank disorder can depend on how frequent and intrusive the psychotic symptoms are, on how they interfere with the person's life, and on how they are tolerated by the person's social context (Johns & van Os, 2001).

The rates of schizophrenia range from 7.7 to 43.0 per 100,000 with a worldwide variation up to fivefold (McGrath, 2006). Schizophrenia is commoner in men than women (male to female ratio = 1.4; McGrath, 2006), with a peak incidence in males between the ages of 20 and 24 years, and in females between 29 and 32 years (Hafner, 2003).

Psychosis in general and schizophrenia in particular, have a multifactorial etiology. The strongest and most replicated risk is a family history of psychotic disorders. The heritability for schizophrenia has been calculated as between 66% and 85% (Cardno et al., 1999). Despite major progress, genetics have not been able to fully clarify the pathophysiology of psychotic disorders. Many authors have started to focus their attention on the role of environmental factors in determining the onset of psychotic disorders (Brietzke et al., 2012). Epidemiological studies have reported how rates of substance misuse, especially cannabis, are consistently higher in first episode psychosis patients, compared to the general population. Two metaanalyses have consistently indicated that cannabis use is associated with an increased risk (about twofold) of developing psychosis (Henquet & Murray, 2005; Moore & Zammit, 2007). Another very important predictor of psychosis is migration history. It has been widely replicated that rates of schizophrenia are higher among migrant and ethnic minority groups, with a mean weighted relative risk among migrants (first and second generation) of 2.7 (95% CI 2.3–3.2) (Cantor-Graae & Selten, 2005).

We aim to summarize, in this chapter, the available evidences about the role of cannabis use and migration in the onset of psychosis, and about their possible convergence in increasing the risk of psychosis.

CANNABIS AND PSYCHOSIS

What We Know About Cannabis

The name cannabis refers to the plant *Cannabis sativa*, used to obtain different preparations. Actually, cannabis has been known for about 4000 years for its effects over the mind, and is now the third most widely used substance in the world, after alcohol and tobacco (Murray & Morrison, 2007). Cannabis contains several cannabinoids,

TABLE 9.1 Physical Effects of Acute Cannabis Intoxication

Acute cannabis intoxication: physical effects
Decreased salivation
Dry mouth
Conjunctival redness
Accelerated pulse and tachycardia in acute dosage
Orthostatic hypotension
Reduction of intraocular pressure
Reduced motor skills and concentration
Appetite stimulation

TABLE 9.2 Psychological Effects of Acute Cannabis Intoxication

Acute cannabis intoxication: psychological effects
Intensification of perceptions • Visual perceptions are more acute in the contours, colors, and depth of the images • There is a greater extent of perception of the spatial separation of sound sources • Synesthesia: the sounds take visual and color quality • Perceptions of touch, taste, and smell are increased
Space–time references (may appear longer or shorter than normal)
Mental processes and emotions • Positive effect on mood: relaxation, serenity, tendency to laugh • Greater receptivity to the funny side of situations • Different and profound meanings in ordinary situations • Tendency to introspection • Wandering thoughts • Increased imagination and creativity • Slight tendency to disinhibition • Anxiety, panic, dysphoria • Paranoia • Depression, apathy • Auditory and visual hallucinations • Persecutory ideas
Behavioral effects • Impairment of driving ability • Motor incoordination • Impairment of depth perception • Impairment in the sense of time • Impairment in the peripheral vision • Damaged reaction time and attention span • Deficits in short-term memory • Difficulty concentrating • Deterioration of the essential skills of leadership • Altered judgment, with high risk sexual behaviors

the two best described are: Δ^9-tetrahydrocannabinol (D9-THC) and Cannabidiol (CBD) (Gul et al., 2008).

Until recently, the main types of cannabis available on the "street" were marijuana (grass) and resin (hash), but, in recent years, a more potent variant termed sinsemilla or skunk has become available in many countries. The main difference between these substances is that skunk contains a very high concentration of D9-THC (14–16%), and virtually no CBD, while grass and hash are known to contain a similar percentage of D9-THC and CBD (2–4%) (Potter, Clark, & Brown, 2008; Hardwick & King, 2008). The main effects of cannabis are summarized in Tables 9.1–9.3.

The Endocannabinoid Systems

D9-THC and CBD bind to the CB1 receptor, mainly expressed in the nervous system (especially in the hippocampus, amygdalae, cerebellum, basal ganglia, and prefrontal cortex) and in some peripheral tissues and CB2 receptor, expressed on cells of the immune system of mammals, and in CNS neurons, but at lower levels than the CB1 receptor (Onaivi et al., 2006). The CB1 and CB2 receptors are part of the endocannabinoid system (Piomelli, 2003) (Fig. 9.1). The endogenous agonists to the CB1 and CB2 receptors are anandamide (Devane et al., 1992) and 2-arachidonoylglycerol (2-AG) (Sugiura et al., 1995). Endocannabinoids act presynaptically to inhibit the release of amino-acid neurotransmitters on the terminals of neighboring GABAergic and glutamatergic neurons (Fig. 9.1). The endocannabinoids are involved in: (1) the regulation of cognitive functions in neuronal circuits of the cortex, memory in hippocampal neurons, and emotions in neurons of the amygdala; (2) the modulation of motor activity in striatal projections neurons; (3) the influence of central processing of pain; (4) the reinforcing effects of substance of abuse in the mesolimbic system (Di Marzo, Bifulco, & De Petrocellis, 2004; Piomelli, 2003).

TABLE 9.3 Chronic Cannabis Abuse Effects

Chronic cannabis abuse effects
Addiction
Altered brain development
Cognitive impairment: with lower IQ among those who are frequent users during adolescence
Early loss of memory
Amotivational syndrome • Loss of interest in activities and things in general, associated with apathy and passivity • Loss of desire to work and indifference to successes and/or failures at work • Loss of energy, fatigue, easy fatigability • Melancholy and irritability • Reduced concentration • Neglect in appearance and personal hygiene • A lifestyle that prioritizes how to obtain and consume cannabis
Decline in school and/or work performance
Decline in information processing
Onset of depressive and/or psychotic symptoms and/or disorders
Chronic bronchitis

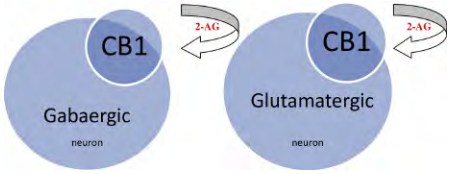

FIGURE 9.1 The endocannabinoid system. Endocannabinoids (2-AG) act presynaptically to inhibit the release of amino-acid neurotransmitters on the terminals of neighboring GABAergic and glutamatergic neurons.

The Epidemiology of Cannabis and Psychosis

The United Nations' 2012 report on drug abuse showed an annual prevalence of cannabis use, in 2010, ranging from 2.6% to 5% of the adult population (between 119 million and 224 million estimated users aged 15–64); cannabis remains the world's most widely used illicit substance (UNODC, 2012).

The use of cannabis is also associated with a risk of developing psychosis of about 2 times greater (Henquet & Murray, 2005; Moore & Zammit, 2007), and generally the use precedes the development of these disorders, and provokes also an earlier age of onset of schizophrenia: cannabis users are 2.7 years younger than noncannabis users (Donoghue et al., 2014), and 6 years younger, if we consider a daily use of high-potency cannabis (Di Forti et al., 2014). The earlier is the age of onset of cannabis use, the greater is the risk of developing a psychotic disorder (Arseneault & Cannon, 2002).

Comparing subjects with and without lifetime cannabis use, it results that the mean age at first psychotic symptoms for the first group is 25.7, while for the second group is 29.2 (Donoghue et al., 2014). The age of onset of psychotic symptoms for cannabis abusers is similar both in males and females, showing than a bigger impact on females than in males (Allegri et al., 2013).

Some authors have suggested that early age of onset of psychotic disorders (AOP) among cannabis users is not associated with the early age of use onset, but with a longer period of use (Stefanis et al., 2013). Daily use (frequency of use) and high-potency (skunk) cannabis have an independent effect both on a greater risk of psychosis onset, and in bringing further forward the AOP, compared to those who use infrequently and or low-potency (hash) cannabis (Di Forti et al., 2014).

The best cannabis use-related predictors of psychotic symptoms can be summarized as follows: (1) early adolescence age (15 years or younger) at first use; (2) frequent use and use of high-potency cannabis (skunk-type) (Di Forti et al., 2009, 2015); (3) genetic vulnerability (Henquet & Murray, 2005; Caspi et al., 2005; van Winkel, van Beveren, Simons, & Genetic Risk and Outcome of Psychosis (GROUP) Investigators, 2011; Di Forti et al., 2014).

Finally, several evidences indicate that cannabis plays a causal role in the onset of psychosis (Ferdinand et al., 2005) Moreover, patients suffering from schizophrenia are more likely to use cannabis than the general population (Thornicroft, 1990). Cannabis use is also associated with poor outcome in individuals with established psychosis vulnerability (Tarricone et al., 2014). In fact, cannabis is associated with a higher rate of relapse, and greater number of hospitalizations, likely in combination with lower adherence to therapy (Caspari, 1999). In addition, these patients have a worse outcome in social-working terms (Barbeito et al., 2013), and a more difficult social reintegration: the rate of unemployment is twice as high in schizophrenics with abuse as nonabusers (Pencer, Addington, &, Addington, 2005).

Why Cannabis Causes Psychosis

Cannabis use is a risk factor for the development of schizophrenia-like psychotic disorders (Henquet & Murray, 2005; Moore & Zammit, 2007), but only around 3% of those who are regular consumers develop psychosis (Murray & Morrison, 2007).

The most useful model to explain how and why a subject develops schizophrenia seems to be the "gene x environment" (GxE) interaction model. This model includes genetic and environmental risk factors, which combine to influence the risk of developing schizophrenia and psychotic disorders (van Os, Rutten, & Poulton, 2008; Schizophrenia working group of the Psychiatric Genomics, 2014). Several drugs, such as, LSD, amphetamine, ketamine, and cannabis, have been studied to explain different actions of, respectively, serotonin, dopamine, and endocannabinoids actions in the development of psychotic symptoms (Paparelli, Di Forti, Morrison, & Murray, 2011).

Neuroimaging studies have suggested that the active ingredient in cannabis, D9-THC, might increase dopamine release in the nucleus accumbens, inhibiting, via CB1 activation, the release of glutamate onto GABAergic neurons that project from the nucleus accumbens to the ventral tegmental area. This lifts the inhibitory effect on the firing of dopaminergic neurons which project back to the nucleus accumbens (Pertwee, 2008). This model explains how D9-THC might affect dopamine levels in cerebral regions, including the striatum, implicated in the pathogenesis of psychotic symptoms, and offering a possible key to the understanding the biology of cannabis-induced psychosis (Morrison & Murray, 2009).

In addition, it seems that D9-THC can exert opposite effects, stimulating or inhibiting the central nervous system transmission via activation or blocking of CB1 (Berrendero et al., 1999).

This model fits with the evidence that genetic variation at the AKT1 gene, which influences post–D2 receptor signaling, renders some individuals more vulnerable to cannabis-induced psychosis (van Winkel, van

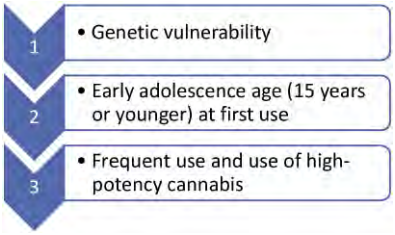

FIGURE 9.2 The best cannabis use related predictors of psychotic symptoms. **Fig. 9.2** shows the best three cannabis use-related predictors of psychotic symptoms. *Source: Henquet and Krabbendam (2005).*

Beveren, Simons, & Genetic Risk and Outcome of Psychosis (GROUP) Investigators, 2011; Di Forti et al., 2012).

On the contrary, CBD seems to ameliorate the cognitive impairment and psychotogenic effects caused by D9-THC (Murray, Morrison, Henquet, & Di Forti, 2008). A recent study has shown that, if we pretreat healthy subjects with CBD, it reduces the THC-induced paranoia, and inhibits the detrimental effects of THC on episodic memory (Englund et al., 2013).This might explain why the use of skunk, high-potency cannabis, which contains high levels of D9-THC and almost no CBD, is associated with the highest risk of psychosis (Di Forti et al., 2009, 2015) (Fig. 9.2).

Among the protective factors, it has recently been investigates as well the role of anandamide, an endo which seems to be protective against psychotic-like symptoms, whom levels are lower in heavy cannabis users compared with light cannabis users (Morgan et al., 2013).

MIGRATION AND PSYCHOSIS

The Migration Phenomena

The term migration indicates the displacement of one or more individuals from one place to another. Migratory movements bring with them, from one continent to another, different cultural patterns, and they allow people to discover environments other than those of belonging, putting in touch with each other different kinds of populations. The 21st century has been called "the age of migration," because there are about 232 million international migrants in the world, and it is expected that the number of international migrants worldwide will increase in the future, with demographic factors, economic disparities, and environmental change continuing to be major drivers of migration (United Nations, 2013).

Types of Migrations

Only a small portion of migrants moved by choice. The migratory movements are determined by many reasons: occupational, family (marriage, reunions), health, study, political, ethnic and religious reasons, and catastrophic events. Surely, the main force that drives people to migrate is poverty, understood not as being poor by itself, but as the poverty of the context in which the individual lives. The model of migrant, outlined by researchers in the field, is that of an individual who has some economic availability and, at the same time, is in good physical condition, and has a high level of education. This is the so-called model of the "healthy migrant": any family or community "invests" on that member that is more likely to accomplish successfully the migratory venture. The intense urbanization taking place in the majority of developing countries acts in a decisive way on *internal migration*: many people move from rural areas to urban areas, in search of higher profits and better services. Also, the search for a better education leads many young people to leave their homeland and go elsewhere, or move within it. There are also many people who emigrate because, within their country, they wouldn't realize their own projects, and would not be able to carry out the activities for which they were formed (Table 9.4).

Epidemiology of Migration and Psychosis

Considerable evidence indicates that the incidence of schizophrenia and psychotic disorders in general, are higher in migrant populations and ethnic minorities, compared to the general population. The first study that has shown a relationship between psychotic disorders and migration was that of Ødegaard (1932). The results of this work have shown a marked increase in the incidence of schizophrenia in Norwegian immigrants in the United States, compared to nonimmigrant Norwegians. To give an explanation for these observations, Ødegaard hypothesized that people who travel bring with them a predisposition to psychotic disorders greater than nonmigrants. This theory was called "selective migration." The recent literature on the subject has confirmed this increased risk among migrant populations, but, by studying the incidence rates of psychotic disorders in second generation migrants, an unexpected subsequent increased risk of psychotic onset in the second generation migrants was shown, compared to those of the first generation (Cantor-Graae & Selten, 2005; Bourque, van der Ven, & Malla, 2011). In a metaanalysis of Cantor-Graae and Selten (2005), the RR of developing schizophrenia in first generation migrants is 2.9, and increases to 4.5 in the second generation migrants (Cantor-Graae & Selten, 2005). The work of Bourque, instead, shows a similar risk between the two generations of migrants: OR of 2.3 for the first generation, and 2.1 for the second generation of migrants (Bourque et al., 2011). From these considerations, the hypothesis of "selective migration" has been questioned, and it has been suggested that social and environmental factors could play an important role in the genesis of these disorders among migrant

TABLE 9.4 Classification of Types of Migrations

Migration types	
According to the extent	Mass migration: movement, both voluntary and forced, of ethnic groups
	Migration by infiltration: changes of residence of individuals, families or small groups
According to the voluntary nature	Voluntary: are determined by the free choices made by the people who move
	Organized: related to the intervention of political or administrative authorities aimed at stimulating or at least to regulate and control the movement
	Forced: made obligatory by the authorities
According to the duration	Permanent: the transfer is definitive
	Temporary: do not involve the permanent transfer of the individuals who, after a more or less long period, return to their place of origin
	Commuting: shifts on daily or weekly basis, related to the periodicity of certain activities
According to the distance	External: movements that occur from one state to another
	Internal: movements that take place within the political boundaries of a state
According to the place of birth	First generation: individuals born in the places of origin and immigrated in a new one
	Second generation: a naturally born citizen of a country, whose parents are foreign born
	Ethnic minorities: groups born in a country that stand for certain traditions, customs and costumes, consisting of a small number of people

populations, and may explain the so-called "excess of psychosis" among immigrants. Another point that supports the theory of socio-environmental factors, as discussed by van Os in 2010, is the substantial variation in the incidence rates of psychotic disorders across both places and minority groups (van Os, Kenis, & Rutten, 2010). Indeed, Bourque et al. (2011) have identified differences in the risk of psychosis related to the specific meeting between ethnicity and host community: in the United Kingdom, black minorities have shown a higher risk, while in the Netherlands a greater risk was associated to the North Africans immigrated recently, and with a lighter skin color (Bourque et al., 2011). In France, a recent study has identified migrants from Sub-Saharan Africa as the most vulnerable group in this country (IRR 7.1, CI 95% 2.3–21.8) (Tortelli et al., 2014).

Why Does Migration Cause Psychotic Disorders?

Although migration is now increasingly recognized as a risk factor for psychosis, the relationship between migration and psychotic disorders is still unclear.

Some studies have suggested a role of genetic susceptibility to the increased risk of first episode psychosis (FEP) in migrant populations. Two studies conducted in the United Kingdom and one in the Netherlands found no difference in risk between the parents and siblings of migrant patients, compared to those of natives (Sugarman & Craufurd, 1994; Hutchinson, Takei, & Fahy, 1996; Selten et al., 2008). This indicates a similar genetic susceptibility for migrants and native populations, where an important role in the onset of psychotic disorders is played by environmental factors (Morgan, Charalambides, Hutchinson, & Murray, 2010).

The hypothesis of a possible role of obstetric complications in the increased risk of development of FEP in migrants was excluded, finding in some cases even lower rates of obstetric complications among migrants, compared to native populations (Hutchinson et al., 1997; McKenzie & Murray, 1999).

The risk of developing a psychotic disorder is greater the earlier is the age of migration. The risk is greatest at the ages between 0 and 4 years, and gradually decreases with the increase of the age of migration (Veling, Hoek, Selten, & Susser, 2011).

Some social factors have been identified as risk factors for psychotic onset in migrants, such as, unemployment, living alone, separation from a parent in childhood, being single, poor education, and limited social networks (Mallett, Leff, Bhugra, Pang, & Zhao, 2002; Morgan et al., 2007, 2008).

A study has associated a higher risk of FEP for the cases where a history of migration was associated with a family dysfunction (RR = 4), compared to the cases with only a migration history (RR = 2) (Patino et al., 2005) (Table 9.5).

It is very interesting to understand what are the specific characteristics of each host society that interact with a specific type of migrant and ethnic minority to increase the risk of psychosis. Today, therefore, it is necessary to speak of "migrant status" indicating the special meeting between the migrant and the host country. The nature of this meeting could explain the increased risk of psychosis in migrants in different countries. Perceived disadvantage, perceptions of discrimination, negative ethnic identity (lack of affinity to own ethnic group), and less identification with the culture of origin are some social factors associated with the development of psychotic disorders among migrants (Cooper et al., 2008; Veling et al., 2008a; Veling, Hoek, Wiersma, & Mackenbach, 2009; Bhugra, Leff, Mallett, Morgan, & Zhao, 2010).

TABLE 9.5 Risk Factors for First Episode Psychosis in Migrants

Reason for migration: refugees
Early age of migration
Past history of migration before age of 15
Parental separation before age 16
Unemployment
Living condition (far from family, alone)
Low employment level
Low education
Loss of cultural identity
Perceived discrimination
Self-esteem and self-concept
Mismatch between expectation and achievement
Social defeat
Low ethnic density
Economic crisis and intolerance

(Adapted from Bhugra, D., 2000.)

The RR of schizophrenia in migrant and minority ethnic groups is highest in those areas where they form a smaller proportion of the local population. In other words, the less ethnically dense an area, the higher the RR (Boydell et al., 2003; Veling et al., 2008a,b). In a study conducted in the United States, acculturative stress has been proposed as a risk factor for the development of psychotic disorders in migrants (Devylder et al., 2013).

Almost all of the studies conducted so far on this topic have only dealt with the phenomenon of external migration. That is, they considered only the people who migrated from one state to another. Very few and very old are the studies that have considered the phenomenon of internal migration, meaning that people who migrate from one region to another within the confines of the same country (Tarricone et al., 2016). A more detailed study on the phenomenon of internal migration may be useful in elucidating more comprehensively the association between migration and psychotic onset, and giving additional elements to understand the risk factors that underlie this correlation.

MIGRATION, CANNABIS USE, AND PSYCHOSIS ONSET

The use of substances, particularly cannabis, and immigrant status are well known risk factors for psychotic onset. Yet little is known on the association between these two risk factors in the development of new-onset psychosis: how cannabis use affects the onset of psychotic disorders in immigrant populations and ethnic minorities groups. The studies that focus on specific risk factors of psychosis in migrants are growing in number. The first population-based study conducted in the United Kingdom on FEP patients is by Harrison et al. (1997) in Nottingham which found a strikingly high rate of schizophrenia in African-Caribbean (AC) first and second generation, compared to the general population. Studying the use of substances, a higher use of substances was shown in white patients, compared with AC (Harrison et al., 1997). Therefore, according to this study, the higher risk of psychotic onset in AC could not be explained by the use of substances. Another study conducted in the Netherlands has observed a similar cannabis use among patients with schizophrenia, regardless of whether they were native Dutch or different migrant groups with high rates of psychotic disorders, such as, Moroccans and Surinamese (Veen, Selten, & Hoek, 2002). In Italy, our previous study showed higher incidence rate of psychosis among migrants, compared to natives; migrants showed a lower substance abuse rate compared to natives (Tarricone et al., 2012). Even in these cases, the higher risk of psychosis in migrant populations could not be explained by substance abuse. By further investigating second generation migrants, some studies have observed a relationship between cannabis use and psychotic onset. In a study conducted in South London, a greater use of cannabis for the black migrants born in the United Kingdom was found, compared to the natives (OR = 4.8), and a minor use for black migrants born abroad (OR = 0.8) (Afuwape, Johnson, & Craig, 2006). Further studies are needed to shed light on the correlation of these two risk factors on the development of psychotic disorders, in order to refine the understanding of the etiology and pathogenesis of psychosis. We cannot rule out that the lack of association between cannabis use and immigrant status in the development of psychotic disorders up to this day is due to a lack of studies that focus on specific risk factors, such as, cannabis and other substance use, of psychosis in migrants. The EU-GEI study (European Community's Seventh Framework Program, grant agreement No. HEALTH-F2-2009-241909, Project EU-GEI: European Network of National Schizophrenia Networks Studying Gene–Environment Interaction) coordinated by the University of Maastricht, a multicenter study that investigates the interplay between genetic and environmental factors in causing schizophrenia and other psychotic disorders, will be crucial to enable a clearer understanding of the correlation of migration and cannabis use in psychosis onset.

MINI-DICTIONARY

Endocannabinoid system A signaling system of the brain composed by neuromodulator lipids and specific receptors, involved in the control of many functions, such as, the immune response, appetite, gastrointestinal function, pain sensation, mood and differentiation, proliferation, and apoptosis of cells.
Environmental risk factors Factors and circumstances (such as early life adversity, growing up in an urban environment, minority group position and cannabis use) that interact with genetic predisposition to influence the risk of psychosis development through life.
Ethnic density The amount of people belonging to the same ethnic group in a specific area, neighborhood, or city.
Ethnicity The fact of belonging to a social group that has in common traditions, customs, beliefs, and language.
Etiology The term derives from the Greek αἰτιολογία (aitiologia), "giving a reason for." In the medical field, it indicates the study of different genetic, environmental, and social factors that stand behind the different medical disorders.
First episode psychosis Presence of hallucinations, delusions, thought disorder, bizarre or distorted behavior, negative symptoms, mania, or clinical suspicion of psychosis; absence of an organic cause or profound learning disability; no previous contact with psychiatric services for psychotic symptoms.
Migration The process of going from one country (external migration), region or place (internal migration) of residence to settle in another, for the purposes of settling down either permanently or for a prolonged period. The migratory movements are determined by many reasons: pull factors, as educational or economic growth, or personal factors, and push factors, such as, political, poverty, terrorism, and war.
Psychosis Group of severe mental disorders characterized by impaired contact with reality, and the ability to critique and judge, by the presence of thought, perception, and affectivity disorders, and the impairment of skills and social relationships.
Psychosis onset The time between the first reported/observed change in mental state/behavior to the development of psychotic symptoms.
Psychosis vulnerability The genetic predisposition of developing a psychotic disorder, regardless of the presence or absence of environmental risk factors for psychosis.

SUMMARY POINTS

- This chapter discusses the estimated prevalence of cannabis dependence, and its contribution to the global burden of disease.
- The Global Burden of Disease Study 2010 estimated 13.1 million cannabis dependent people globally in 2010 (point prevalence 0.19%)
- Prevalence peaked between 20 and 24 years, was higher in males than females, and in high income regions.
- Cannabis dependence accounted for 2 million disability-adjusted life years (DALYs) globally in 2010; a 22% increase in crude DALYs since 1990, largely due to population growth.
- Countries with statistically higher age-standardized DALY rates included the United States, Canada, Australia, New Zealand, and Western European countries; those with lower rates were from Sub Saharan Africa West, and Latin America.
- Regular cannabis use as a risk factor for schizophrenia accounted for an estimated 7000 DALYs globally.
- Cannabis dependence is a disorder primarily experienced by young adults, especially in high income countries.
- Our estimates suggest that cannabis use as a risk factor for schizophrenia is not a major contributor to population-level disease burden.

KEY FACTS OF CANNABIS DEPENDENCE

- Cannabis is a generic term for preparations (eg, marijuana, hashish, and hash oil) derived from the *Cannabis sativa* plant.
- Cannabis dependence is a substance use disorder primarily experienced by young adults, from high income countries.
- Cannabis dependence causes disability and burden across the globe.
- There were an estimated 13.1 million cannabis dependent people globally in 2010.
- Although it is an established risk factor for schizophrenia, it was not a major contributor to the overall burden attributed to schizophrenia in our study.

INTRODUCTION

Cannabis is a generic term for preparations (eg, marijuana, hashish, and hash oil) derived from the *Cannabis sativa* plant (Hall & Degenhardt, 2009). The cannabinoid primarily responsible for the psychoactive effects that cannabis users typically seek is Δ^9-tetrahydrocannabinol or THC (Gaoni & Mechoulam, 1964; Martin & Cone, 1999; Iversen, 2000), found in a resin on the flowering tops and upper leaves of the female plant. THC acts upon a specific cannabinoid receptor (CB_1) in the brain (Hall, Degenhardt et al., 2001).

Cannabis is widely used in developed and developing countries (Hall, Johnston et al., 1999; Hall & Degenhardt, 2007). Global patterns of cannabis use have been estimated by the United Nations Office on Drugs and Crime (UNODC) (UNODC, 2008), but there has not been a systematic review of global, regional and country-level patterns of cannabis dependence and disease burden.

The global burden of disease (GBD) framework uses information on mortality and disability associated with a given disease to estimate the years lost due to premature mortality (YLLs), and the years lived with disability (YLDs). YLLs and YLDs can be summed into disability-adjusted life years (DALYs), an overall summary measure of disease burden.

The Global Burden of Disease Study 2010 (GBD 2010) updated the burden estimation methodology, and estimated the burden of 291 diseases and 67 risk factors, by age, sex, 187 countries, and 21 world regions, for 1990, 2005, and 2010. GBD 2010 estimated both the direct burden attributable to cannabis dependence, and the additional burden arising from cannabis dependence as a risk factor for other health outcomes. As part of GBD 2010, we conducted systematic reviews of the literature to capture all the available data since 1990 on the prevalence and consequences of cannabis dependence. Other methodological improvements included: the use of a Bayesian meta-regression approach to model the epidemiological data and propagate uncertainty around final burden estimates; the quantification of disability for a more comprehensive list of health states using survey data from a more representative sample; and adjusting burden estimates for the effects of comorbid disorders (Murray, Vos et al., 2012; Vos, Flaxman et al., 2012).

This chapter draws heavily on a paper we recently published (Degenhardt, Ferrari et al., 2013) that summarized the GBD 2010 methodology and burden estimates for cannabis use and dependence. It built on our systematic reviews of the epidemiology of cannabis use and dependence (Calabria, Degenhardt et al., 2010a,b,c; Degenhardt, Bucello et al,. 2011), and the relationship between cannabis use and schizophrenia (Degenhardt, Hall et al., 2009; Calabria et al., 2010c; Degenhardt & Hall, 2012), and expanded on previous analyses of the contribution of illicit drug use to the global burden of disease (Lim, Vos et al., 2012; Lozano, Naghavi et al., 2012; Murray et al., 2012; Salomon, Vos et al., 2012; Vos et al., 2012).

DETAILS OF THE BURDEN OF DISEASE STUDY METHODS

Case Definition

The case definition of cannabis dependence was based on the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) (American Psychiatric Association, 2000) and *International Classification of Diseases (ICD)* (World Health Organization, 1993) diagnostic criteria for cannabis dependence (DSM:304.30; ICD:F12.2).

Systematic Reviews

Systematic searches were conducted for studies published since 1990 to identify data sources for the prevalence, incidence, remission, and all-cause excess mortality attributable to cannabis use and dependence. Full detail of these searches has been published elsewhere (Calabria, Degenhardt et al., 2008; Calabria et al., 2010a,b,c; Degenhardt et al., 2011).

All extraction and quality assurance procedures were as recommended by the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) guidelines (von Elm, Altman et al., 2007). Studies were excluded if they did not contain primary data (eg, review articles) or they contained data collected before 1990. We extracted estimates of annual incidence, current, and period (past year, past-month) prevalence. Remission from cannabis dependence was defined as no longer

fulfilling the diagnostic criteria for the disorder. For remission studies, we included prospective studies that reported on a follow-up of at least 3 years (Calabria et al., 2010a). For excess-mortality studies, we included case-control or cohort studies reporting relative-risk estimates or standardized mortality ratios.

An additional literature search identified any evidence of drug use within other regions such as reports of use (UNODC, 2008), sample estimates, drug-related treatments, drug seizures, drug-related arrests, or other qualitative information related to the use of illicit drugs. Sources included UNODC reports, government reports, surveys, news reports, and journal articles. We located evidence of cannabis use or dependence for almost all of the world's population aged 15–64 years (201 countries/territories; 99.8% of the world's population aged 15–64 years). There were estimates of the prevalence of cannabis use in 108 countries. We identified 13 studies (60 data points) from four GBD regions that reported on the prevalence of cannabis dependence. We found an additional 7 studies (57 data points) from 5 GBD regions reporting on weekly cannabis use and 80 studies (1313 data points) from 17 GBD regions reporting on past year cannabis use. We found only three general population cohort studies that reported on the incidence of cannabis use or dependence. We found no epidemiological evidence of elevated mortality risk attributable to cannabis dependence (for full details see Calabria et al., 2008; Calabria et al., 2010b; Degenhardt et al., 2011)

DisMod-MR Modelling

We pooled these epidemiological estimates in a disease model that was judged to have face validity by the GBD 2010 Expert Group and additional experts in cannabis use epidemiology. For these estimates, we used DisMod-MR (a Bayesian meta-regression tool) (Vos et al., 2012; Flaxman, Vos et al., 2013) to ensure internal consistency between separate estimates of prevalence, incidence, remission, and excess-mortality. DisMod-MR was also used to predict epidemiological estimates for regions with no available data. We preferred high quality, direct epidemiological estimates. In their absence, we used predicted estimates, rather than exclude regions with no epidemiological data from GBD 2010 estimates (Vos et al., 2012; Flaxman et al., 2013).

Disability Weights

To estimate disability weights, a lay person description of cannabis dependence was formulated by the Expert Group as one of 222 lay descriptions that reflected the 291 diseases and their sequelae in GBD 2010. Full details of this process have been reported elsewhere (Salomon, 2010; Salomon et al., 2012). The survey was completed by community samples in five countries (Bangladesh, Indonesia, Peru, the United Republic of Tanzania, and the United States of America), and by respondents to an open-access internet survey. In both, a pair-wise comparison method, asking respondents to nominate the healthier of a pair of health states, was used to arrive at an estimate of the level of disability for each GBD health state.

Full details of the process have been reported elsewhere (Murray et al., 2012; Vos et al., 2012). After adjusting the disability weight for an estimated 51% (47–54%) of cases who had no disability after accounting for comorbidity, the average disability weight for cannabis dependence was 0.162 (0.109–0.224).

Comorbidity Adjustments

In order to correct YLDs for comorbidity, separate microsimulation methods were used to generate hypothetical populations by age, sex, year, and country. Details are reported in full elsewhere (Murray et al., 2012; Vos et al., 2012).

Calculation of YLDs, YLLs, and DALYs

GBD 2010 estimated "prevalent" YLDs by multiplying prevalence estimates from DisMod-MR by the disability weight. DisMod-MR prevalence and burden estimates were stratified by sex, age, country, and 21 GBD regions (see http://www.globalburden.com.au/docs/Regions.pdf for country groupings), and for the years 1990, 2005, and 2010.

We explored time trends in burden by breaking down the change in DALYs between 1990 and 2010 into changes that were attributable to: population growth, population ageing and sex structure, and changes in the epidemiology of cannabis dependence. As we found no evidence of excess deaths (Calabria et al., 2010b) (and therefore YLLs) directly attributable to cannabis dependence, the YLDs comprised all of DALY estimates (Vos et al., 2012).

COMPARATIVE RISK ASSESSMENT (CRA): CANNABIS USE AS A RISK FACTOR FOR SCHIZOPHRENIA

We reviewed existing literature on cannabis use as a risk factor for other health outcomes (Degenhardt et al., 2009; Calabria et al., 2010c; Lim et al., 2012). We concluded that there was sufficient evidence to consider cannabis use as a risk factor for schizophrenia. We decided that cannabis and schizophrenia were most plausibly causally linked as follows: (1) there was greater disorder severity among those using cannabis regularly who have already developed the disorder; and (2) the association reflected earlier onset of schizophrenia among those

who would have developed the disorder (Degenhardt et al., 2009).

Two systematic literature reviews were conducted on the global epidemiology of regular (weekly) cannabis use (Calabria et al., 2010c; Degenhardt et al., 2011), and schizophrenia (Saha, Chant et al., 2005; Ferrari, Saha et al., 2012), respectively. Details are provided below. More information on the methodology is provided elsewhere (Lim et al., 2012).

Data on Regular (Weekly or More Frequent) Cannabis Use in the Past Year

We defined the exposure as weekly or more frequent cannabis use in the previous year because regular use is most consistently associated with this outcome. We found 7 studies reporting prevalence of weekly or more frequent cannabis use in the past year, from 15 countries and 5 GBD world regions; and 80 studies on the prevalence of past-year cannabis use, from 82 countries and 17 GBD world regions (Calabria et al., 2010c; Degenhardt et al., 2011).

The epidemiological data for regular cannabis use were modelled using DisMod-MR to estimate prevalence by country, region, age, sex, and year, using a similar method to that used to model cannabis dependence.

Modelling Earlier Age of Onset of Schizophrenia

The effect of cannabis use on schizophrenia was modelled via two pathways: the first by bringing forward the average age of onset in persons with no cannabis use, and the second by increasing the severity of schizophrenia. To account for the effects of the first pathway, we calculated the counterfactual average duration of schizophrenia across all ages, under a scenario of no cannabis use, and compared this to the observed duration. To determine the counterfactual average duration of schizophrenia, we brought forward incident cases of schizophrenia who used cannabis by 2.70 (95% CIs: 1.96–3.43) years, based on a metaanalysis (Large, Sharma et al., 2011).

We used the estimates of cannabis use by age (in single years), sex, country, and year described above, assuming that the prevalence of regular cannabis use was the same among individuals with and without schizophrenia. Estimates of the number of incident cases and the corresponding duration of schizophrenia by age, sex, country, and year were based on the DisMod-MR model for schizophrenia.

Modelling Increased Severity of Schizophrenia

To calculate the burden associated with the second pathway of shifting severity, we used the odds ratio (OR) from Foti, Kotov et al. (2010) of psychotic symptoms of 1.64 (95% confidence intervals: 1.12–2.34) in people with schizophrenia who regularly use cannabis, compared to those who do not. The percent of time spent in acute psychosis was 63% (38–82%), based on a metaanalysis of six studies covering five GBD world regions (Ferrari et al., 2012).

We used the estimates of cannabis use by age (in single years), sex, country, and year described above, and assumed that the prevalence of regular cannabis use was the same among individuals with and without schizophrenia. Estimates of the number of incident cases and the corresponding duration of schizophrenia by age, sex, country, and year were based on the DisMod-MR model. We used the linear relationship between the estimated change in disability weight (based on the proportion of time spent in a psychotic state) and the prevalence of regular cannabis use to calculate the percent of schizophrenia disability attributable to regular cannabis use. Where we report comparisons of prevalence and DALYs by country or region we use age-standardized values, using direct standardization to the global standard population proposed by the World Health Organization (WHO) in 2001 (http://www.who.int/healthinfo/paper31.pdf).

PREVALENCE OF CANNABIS DEPENDENCE

There were an estimated 11 million cases of cannabis dependence globally in 1990, and 13 million cases in 2010. These translated into pooled point prevalence estimates of 0.20% (95% uncertainty interval: 0.17–0.22%) in 1990, and 0.19% (0.17–0.21%) in 2010. These prevalence estimates were pooled across all regions and standardized by the 2010 global population age and sex. Fig. 10.1 plots the point prevalence in 2010 by region, age, and sex.

Prevalence was higher in males [0.23% (0.2–0.27%)] than females [0.14% (0.12–0.16%)], producing a sex ratio of 1.8 (1.7–1.9). Prevalence peaked in the 20–24 years age group between 0.4% (0.3–0.6%) and 3.4% (2.8–4.2%) in males across regions, and between 0.2% (0.16–0.4%) and 1.9% (1.5–2.4%) in females. It decreased steadily with age, thereafter.

The regional variation in prevalence is summarized in Fig. 10.2 and Table 10.1. Prevalence in high income regions was much higher than that in low to middle income regions, and the global average. Cannabis dependence in Australasia (the region with the highest prevalence, 0.68%) was about 8 times higher than prevalence in Sub-Saharan Africa West (the region with the lowest prevalence, 0.08%). The wide and overlapping 95% uncertainty intervals around some country and regional prevalence estimates indicate that not all variations in prevalence were statistically significant.

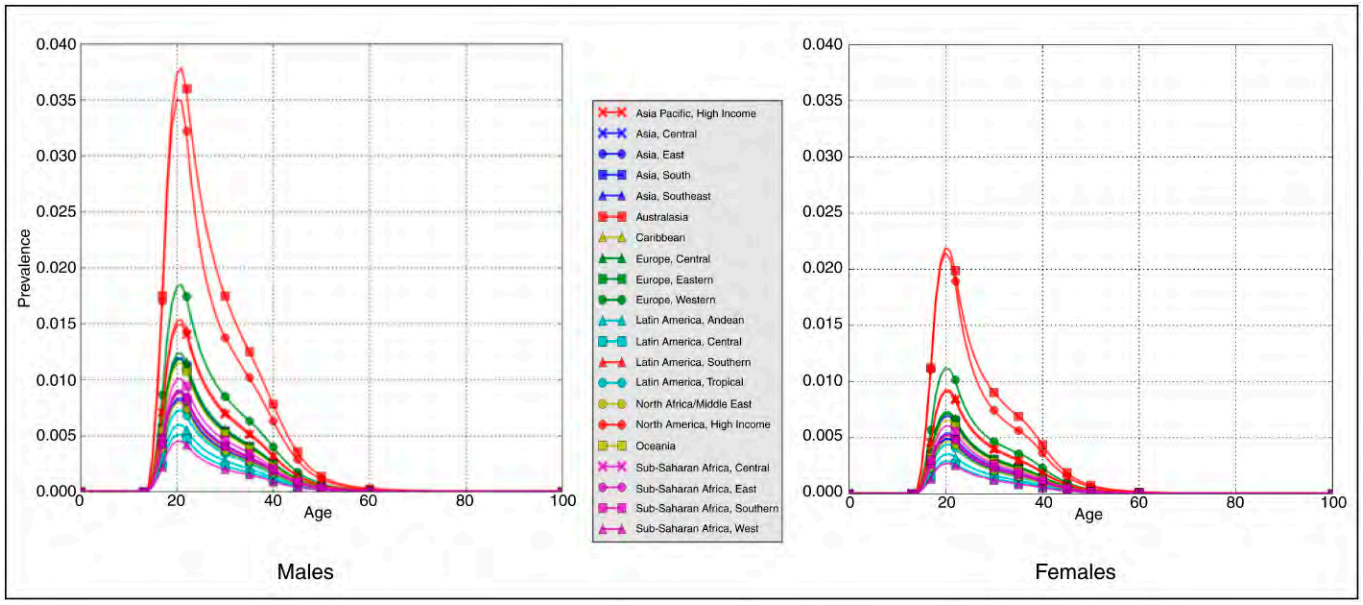

FIGURE 10.1 Estimated prevalence (proportion) of cannabis dependence by age, sex and region, 2010. Shows the prevalence of cannabis dependence (as a proportion of the general population) separately by age, sex, and region for the year 2010.

BURDEN OF CANNABIS DEPENDENCE

Cannabis dependence accounted for 0.07% (0.05–0.1%) of global DALYs in 1990, and 0.08% (0.05–0.12%) in 2010. Although there was no change in the estimated contribution of cannabis dependence to global DALYs, there was an increase in crude DALYs across this period that was attributable to a 25% increase in population, a 6% decrease due to population aging, and a 1% increase in the prevalence rate of cannabis dependence. The net effect was a 22% increase in absolute DALYs attributable to cannabis dependence between 1990 and 2010.

The remainder of the results focuses on 2010 data. There were 2 million DALYs attributable to cannabis dependence in 2010, all YLDs. This accounted for 12.5% of YLDs attributable to illicit drug use, and 0.27% (0.17–0.4%) of global all-cause YLDs. The majority of cannabis dependence YLDs occurred between 20 and 24 years (33.5% of cannabis dependence YLDs). In males, this age group accounted for 64.3% of cannabis dependence YLDs. Fig. 10.3 presents YLDs by age and sex.

Table 10.2 presents the regional estimates of DALYs attributable to cannabis dependence; and Fig. 10.4 presents age standardized DALY rates by country. There was substantial variation in DALYs between regions (Table 10.2) and between countries (Fig. 10.4 (Plot 1)), but most of this variation occurred within wide and often overlapping bounds of uncertainty (Fig. 10.4 (Plot 2)). There was considerable uncertainty around estimated rates for some countries and regions. The countries with statistically higher DALY rates than the global average were all from North America, high income, Australasia, and Europe Western regions. The countries with lower DALY rates than the global average were from Sub-Saharan Africa West, and Latin America Central and Andean.

Fig. 10.5 compares the burden of cannabis dependence to other substance use disorders in GBD 2010. Cannabis dependence was the only substance for which there were no attributable deaths and, hence, zero YLLs. Globally, it accounted for more DALYs than cocaine dependence, but fewer than the other drug use disorders.

In high income regions, such as Australasia, North America, high income, and Europe Western where we had better quality epidemiological data available, the DALY rate (per 100,000) of cannabis dependence surpassed that attributable to amphetamine dependence 93.2 (61.7–134.2) versus 58.5 (31.2–98.1) in Australasia; 43.03 (27.0–62.3) versus 34.5 (19.6–55.2) in Europe Western; and 81.5 (53.6–116.6) versus 33.4 (18.4–52.8) in North America, high income).

ADDITIONAL BURDEN ATTRIBUTABLE TO CANNABIS USE AS A RISK FACTOR FOR SCHIZOPHRENIA

Regular cannabis use as a risk factor for schizophrenia was estimated to account for 7,000 DALYs (3,000–13,000) or 0.04% (0.03–0.06%) of schizophrenia DALYs globally (Table 10.3). Overall, North America high income was the region with highest number of attributable DALYs

Summarizes the burden of cannabis dependence as disability-adjusted life years (DALYs) by sex and region for the year 2010.

(2,000 DALYs). Males were responsible for over twice as many attributable schizophrenia DALYs (5,000 DALYs; 2,000–10,000) than females (2,000; 1,000–4,000); and attributable DALYs peaked between 25 and 30 years, and decreased thereafter. When the additional burden attributable to cannabis use as a risk factor for schizophrenia was added to that of cannabis dependence, cannabis use still accounted for 0.08% of global DALYs in 2010.

WHAT ARE THE IMPLICATIONS OF THESE FINDINGS?

An estimated 13 million people were cannabis dependent in 2010, an age and sex-standardized prevalence of 0.2% (0.17–0.22%). Prevalence was not estimated to have changed significantly from 1990, although increased population size produced an increase in the

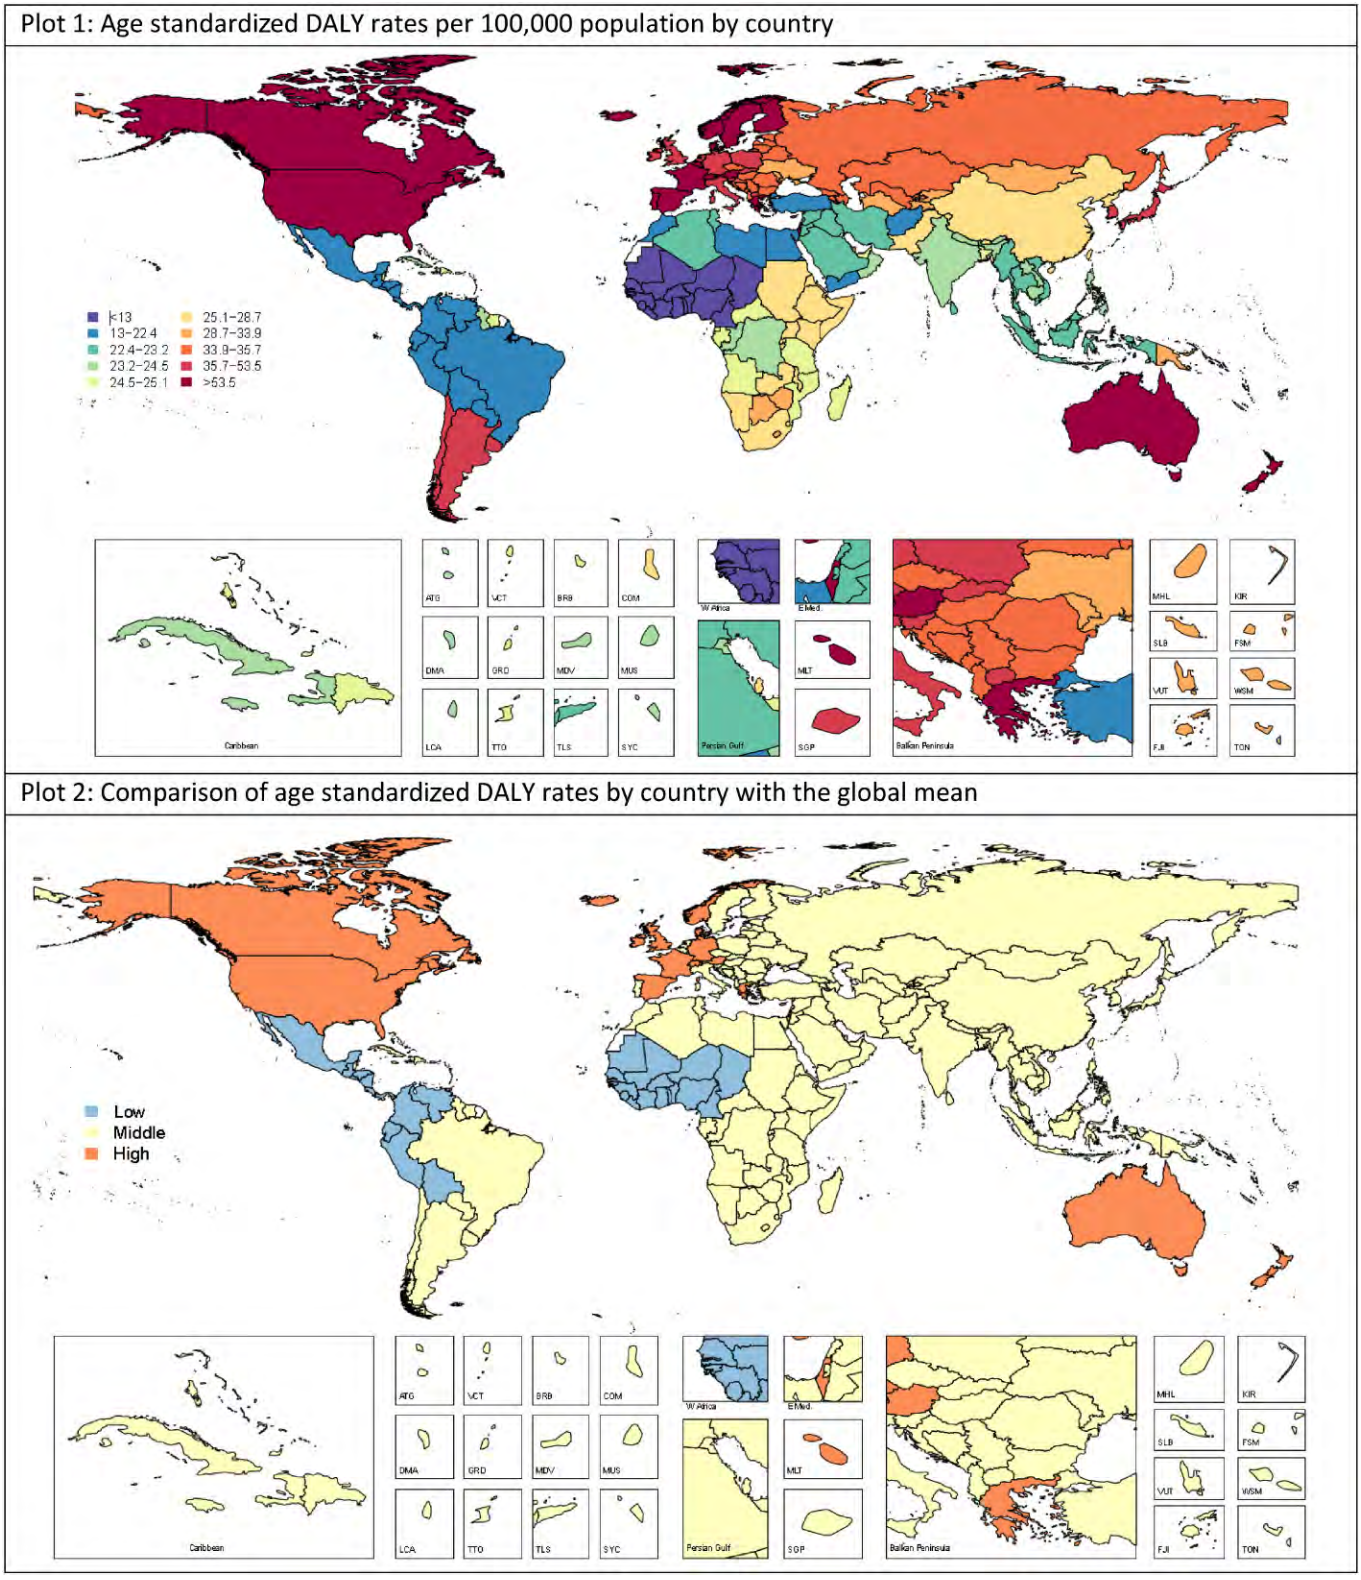

FIGURE 10.4 **Country-level DALYs per 100,000 population for cannabis dependence, age-standardized, for 2010.** Shows the burden of cannabis dependence as disability-adjusted life years (DALYs) by country, for the year 2010. Note that DALYs are age standardized, and presented as a rate per 100,000. Note: *Low*, shows countries with statistically lower DALY rates than global mean; *Middle*, shows countries with DALY rates that are not statistically different to global mean; *High*, shows countries with statistically higher DALY rates than global mean.

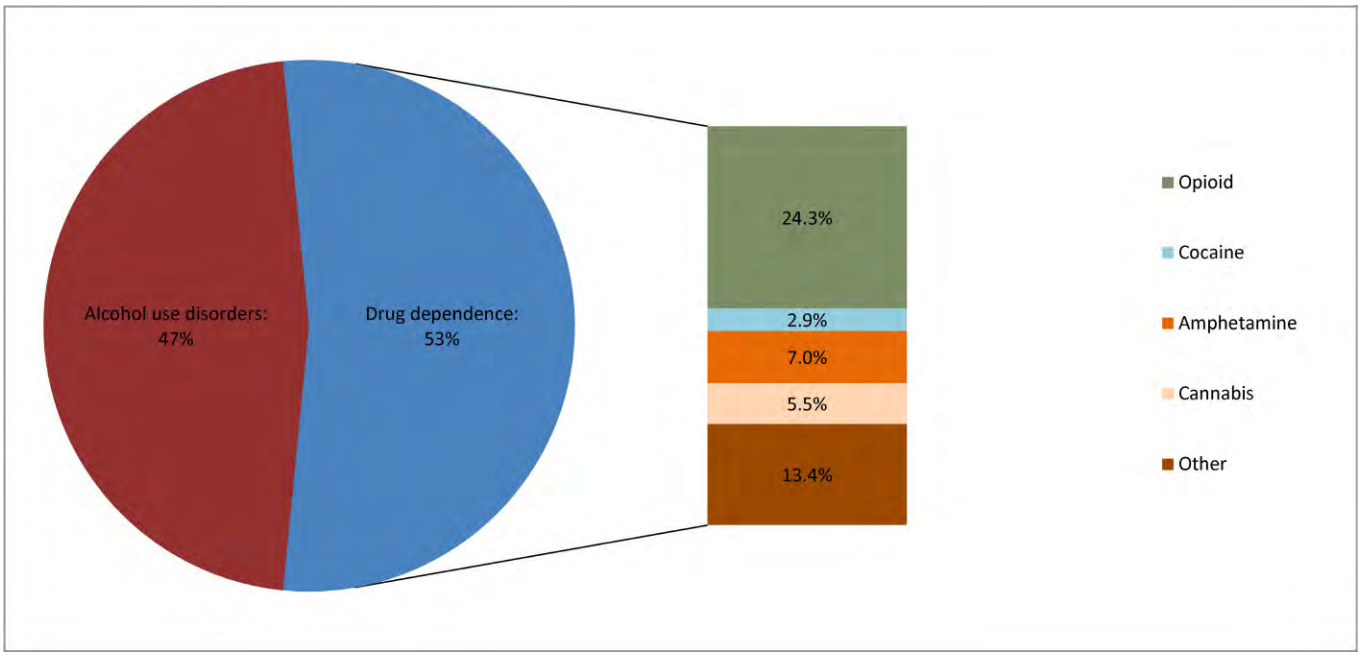

FIGURE 10.5 **The proportion of DALYs due to cannabis dependence relative to other substance use disorders in GBD 2010.** Shows the proportion of burden of cannabis dependence as disability-adjusted life years (DALYs) relative to the proportion of burden due to other substance use disorders. Note: Alcohol use disorders included alcohol dependence and foetal alcohol syndrome; other drugs, burden attributable to illicit drug types other than cannabis, opioid, amphetamine, and cocaine dependence were estimated under residual categories in GBD 2010.

number of cases of cannabis dependence over the period. Levels of cannabis dependence were significantly higher in a number of high income countries including Australia, New Zealand, the United States, Canada, and a number of Western European countries including the United Kingdom. Cannabis dependence caused 2 million DALYs in 2010. DALY rates also varied considerably geographically, with the highest rates again in North America high income, Australasia, and Western Europe.

There is clearly scope to reduce the burden associated with cannabis dependence. Although cannabis dependence was estimated to be a smaller contributor to the overall disease burden than alcohol or opioids dependence, nonetheless some 2 million YLDs were attributed to the drug. Behavioral interventions are effective in the treatment of cannabis dependence (Denis, Lavie et al., 2006; Knapp, Soares et al., 2007), with cognitive behavioral therapy and contingency management showing the greatest promise. Public health campaigns may also be necessary to advise young people of the risks of developing dependence on cannabis because this risk may be underappreciated by many users.

Based on the best available evidence, and models making reasonable assumptions, we found that only 0.04% of the DALYs attributed to schizophrenia were linked to regular (weekly or more frequent) cannabis use. Although epidemiological studies make a consistent case that early and/or heavy cannabis use is linked to a significantly increased risk of schizophrenia (Degenhardt et al., 2009), the modest increase in risk, and the low prevalence of schizophrenia, mean that regular cannabis use accounts for only a very small proportion of the disability associated with schizophrenia.

TABLE 10.3 Estimated DALYs Attributable to Regular Cannabis use as a Risk Factor for Schizophrenia, 2010

	Persons			Males			Females		
	Lower CI	**Mean**	**Upper CI**	**Lower CI**	**Mean**	**Upper CI**	**Lower CI**	**Mean**	**Upper CI**
Attributable YLLs	—	—	—	—	—	—	—	—	—
Attributable YLDs	3,000	7,000	13,000	2,000	5,000	10,000	1,000	2,000	4,000
Attributable DALYs	3,000	7,000	13,000	2,000	5,000	10,000	1,000	2,000	4,000

Summarizes the burden as disability-adjusted life years (DALYs) that can be assigned to cannabis use as a risk factor for schizophrenia, for the year 2010.

LIMITATIONS

We generated estimates based on the best available epidemiological data, and used sophisticated modelling methodology to adjust for known sources of uncertainty in the data. However, our reviews identified clear gaps in existing epidemiological data on cannabis dependence. A significant amount of research is needed to document even the most basic epidemiological parameters for cannabis dependence in most countries. Until such work is done, considerable uncertainty will remain around the exact size of global burden attributable to cannabis and other illicit drugs. This is particularly the case for low income countries, where there is typically limited information on use, less on levels of use, and usually no data on the prevalence of dependence. It is imperative to better assess levels of dependent drug use in these countries, whose populations may be experiencing higher levels of burden than were estimated here.

Further, a range of potential health outcomes of cannabis use were not included in our estimates. We considered including suicide, cancer, and accidental injuries but the evidence for a causal relationship for these outcomes was considered to too weak to generate defensible global estimates (Calabria et al., 2010c).

We also note that we assumed that levels of cannabis use among people with schizophrenia were the same as the general population. This was a conservative assumption. There are data from clinical studies that very high levels of cannabis use are found among patients with schizophrenia (Green, Young et al., 2005). However, a systematic review found that available data on the extent of this elevation were limited (Green et al., 2005) to high income countries. It is also useful to be mindful of the impact of this assumption on the magnitude of the burden we are considering. This particular aspect is only relevant for the "increased severity" analysis. The overall global attributable burden was only 7000 DALYs. Even if levels of cannabis were several times higher among people living with schizophrenia, the estimate of attributable burden would remain very small.

It is also important to acknowledge that, although improved, GBD 2010 disability weights (Salomon et al., 2012), derived from surveys of the general population, have their limitations. As discussed elsewhere (Salomon et al., 2012), it is unclear whether brief lay descriptions can accurately capture the complexity of disability due to drug use disorders. There is also the possibility that considerations other than health status may have influenced respondents' views of "which state was healthier," because it was hard to describe the disability due to cannabis use without mentioning it. Nonetheless, this study has made significant improvements in methods, and in the transparency with which burden estimates have been made.

CONCLUSION

Cannabis dependence causes disability across the globe. It is a disorder primarily experienced by young adults, and our estimates suggest that burden is higher in high income countries. It has not been shown to increase mortality as opioid and other forms of illicit drug dependence do. Nonetheless, in some countries, cannabis dependence produces more years lived with disability than drugs like amphetamines and cocaine, largely because rates of cannabis use are higher than for the stimulant drugs. Our estimates suggest that, although cannabis use is a risk factor for schizophrenia, it is not a major contributor to population level disease burden for that disorder.

MINI-DICTIONARY

Comparative risk assessment (CRA) CRA methods are used in GBD 2010's risk factor analysis to investigate the proportion of burden that could be averted, given a hypothetical absence of a risk factor in the population.

Disability-adjusted life year (DALY) DALYs were the main metric used in GBD 2010 to measure the burden associated to different diseases and injuries. A DALY is equivalent to one healthy year of life lost to a disease or injury, and combines in the one metric both fatal and nonfatal burden.

Global Burden of Disease Study 2010 (GBD 2010) GBD 2010 is the latest iteration of burden of disease studies, published in late 2012. The aim of the study was to quantify and systematically compare the proportion of health loss (or disease burden) associated with 291 diseases and injuries, and 67 risk factors.

Years lived with disability (YLD) YLDs make up the nonfatal component of DALYs, and are estimated by multiplying disease prevalence by the general public's evaluation of the severity of health loss associated to the disease.

Years lost to premature mortality (YLL) YLLs make up the fatal component of DALYs, and are estimated by multiplying deaths due to a disease by the standard life expectancy at the age death occurred.

International Aspects of Cannabis Use and Misuse: the Australian Perspective

*D.J. Allsop**, *W.D. Hall***

***Psychopharmacology Laboratory, School of Psychology, University of Sydney, Sydney, NSW, Australia**
****Centre for Youth Substance Abuse Research, The University of Queensland, Herston, QLD, Australia**

SUMMARY POINTS

- This chapter gives an overview of patterns of cannabis use, their consequences, and policies relating to cannabis use in Australia.
- Australian cannabis use is placed in its cultural and historical context, and the evolution of cannabis policy is reviewed.
- Cannabis use is common in Australia, and there is tension between the federal government and states on the penalties for cannabis use and possession.
- Australia has well-developed illicit drug monitoring systems that enable drug trends, including availability, purity, and price to be tracked.
- Cannabis accounts for the most treatment episodes of all of the illicit drugs in Australian Drug and Alcohol treatment centers, and is second only to alcohol.
- Australasian cohort studies have reported associations between regular cannabis use, poor educational achievement, and psychotic symptomology.

KEY FACTS OF CANNABIS LAW IN AUSTRALIA

- Australia is a signatory to the United Nations Single Convention on Narcotic Drugs (1961) that requires the government to prohibit and criminalize cannabis use.
- Australia's Federal political system allows individual states and territories to set and enforce their own criminal laws.
- Cannabis use is illegal in all Australian states and territories, but the penalties vary across the country.
- Minor cannabis offences are decriminalized in: the ACT, South Australia, and the Northern Territory. In all other states, criminal penalties apply, but, in reality, police have discretion under some circumstances to divert people into treatment.

KEY FACTS OF CANNABIS AVAILABILITY, PRICE, AND PURITY

- A gram of hydroponic or bush cannabis typically costs AUD$20 in Australia, although an ounce of bush is cheaper ($240) than an ounce of hydroponic ($300).
- In 2013 cannabis in the state of NSW was quantified as containing 15% THC and 0.14% CBD.
- The majority of Australian cannabis growers surveyed in 2014 grew outdoors, and for personal use.

INTRODUCTION

Cannabis has been cultivated in Australia ever since Sir Joseph Banks sent hemp seeds with the first fleet. Cannabis used as a recreational drug gained its foothold during the Vietnam War, when US soldiers brought cannabis and heroin use to Sydney and Melbourne (Manderson, 1993). Cannabis use spread to Sydney's suburbs throughout the 1960s and 1970s, as part of the surfing culture (McCoy, 1980), extending beyond the criminal milieu, to represent rebellion against established authority, particularly among young people (Penington, 1999).

Cannabis use steadily rose among young adults over the next two decades (Donnelly & Hall, 1994a; Hall & Pacula, 2003). National surveys indicated that less than 20% of young Australians had tried cannabis in the early 1970s; by 1993, 60% had done so (Donnelly & Hall, 1994a). Increased cannabis use among successive birth cohorts normalized its use, increased availability, and reduced the age of first trying cannabis (Degenhardt, Lynskey, & Hall, 2000; Donnelly & Hall, 1994a). A survey of Australian attitudes toward cannabis in 1994 revealed that most interviewees (75%) advocated no criminal penalties for personal use (Bowman & Sanson-Fisher, 1994), and just over half also thought that there should be no criminal penalties for cultivating cannabis for personal use. Strong support remained for criminalizing the commercial production and sale of cannabis (Bowman & Sanson-Fisher, 1994).

National media outlets have also played a role in influencing cultural attitudes toward cannabis in Australia. The media characterization has polarized between two policy choices: legalization or decriminalization, supported by the argument that cannabis use causes few if any harms; and on the other hand, the claim that cannabis use should remain illegal because it causes significant harms to individuals and public health (Hall, 1997).

Since the mid-1990s, cannabis has been the most commonly used illicit drug in Australia. Australasia has one of the highest prevalence rates in the world, with over one-third of the adult population having used, and one in ten have done so in the past year (AIHW, 2011). Cannabis use is most common in young men in their 20s, in Australia (AIHW, 2011). A substantial minority of 14–19 year olds have smoked cannabis in the previous 12 months, according to the 2010 National Drug Strategy Household Survey (NDSHS) (Fig. 11.1), and about one in five Australians reported that they had the opportunity to use cannabis in the previous 12 months.

The tide of public opinion has now swung in favor of removing criminal penalties. A recent discrete choice experiment suggested that the majority of people preferred civil penalties or legalization, compared to cannabis cautioning (current policy) or criminalizing possession and use (Shanahan, Gerard, & Ritter, 2014).

Patterns of Cannabis Use in Relation to Other Substance Misuse

The rise of cannabis use in Australia paralleled a general increase in the use of other psychoactive substances, including amphetamines, heroin, and hallucinogens. In more recent years, party drugs, particularly ecstasy, have increased in prevalence in Australia as cannabis (and heroin) use have declined (Roxburgh, Ritter, Grech, Slade, & Burns, 2011).

Cannabis is frequently used in combination with other psychoactive substances. A 2014 Australian study followed a group of regular nontreatment-seeking cannabis users through 2 weeks of monitored abstinence in the community. It found robust substitution effects, with alcohol (Fig. 11.2) and cigarette (Fig. 11.3) consumption increasing during the 2-week cannabis abstinence, and only returning to baseline levels after resumption of cannabis use (Allsop et al., 2014b).

Cannabis has also been associated with increased nicotine dependence, in a so-called reverse gateway effect. Up to three-quarters of dependent cannabis smokers in Australia mix their cannabis with tobacco, thereby increasing their tobacco exposure (Patton, Coffey, Carlin, Sawyer, & Lynskey, 2005; van Beurden, Zask, Passey, & Kia, 2008).

Cannabis use in Australia is higher amongst those who regularly use other illicit drugs, than in the general

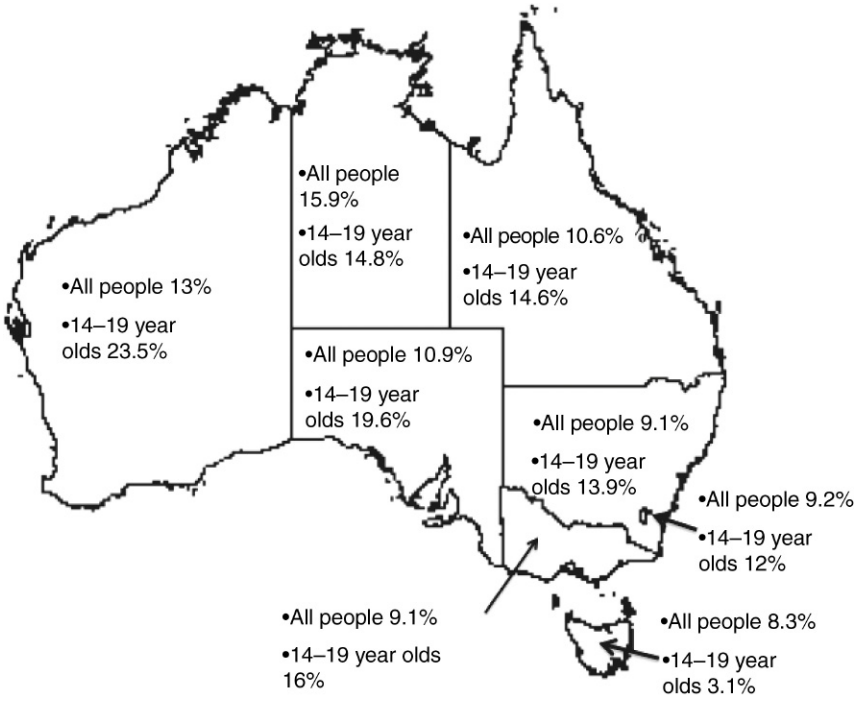

FIGURE 11.1 **Cannabis use prevalence in the Australian States and Territories.** The proportion of each state's population who have smoked cannabis in the previous 12 months split by (1) the average across all age groups (all people); and (2) the 14–19 year age group. *Source: Data from the 2010 National Drug Strategy Household Survey, Australia.*

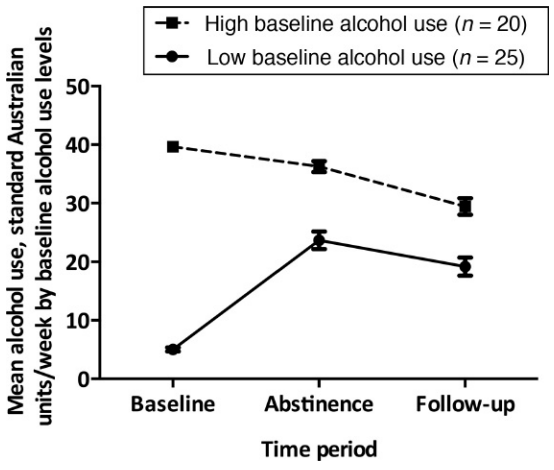

FIGURE 11.2 **Alcohol use increases during cannabis abstinence for those with low baseline alcohol consumption, and decreases with resumption of cannabis use.** The interaction of baseline alcohol use group with time is significant at $F_{2,87.11} = 13.49$, $P < 0.0001$. *Source: Adapted from Allsop et al. (2014b). Changes in cigarette and alcohol use during cannabis abstinence.* Drug and Alcohol Dependence, 138, *54–60.*

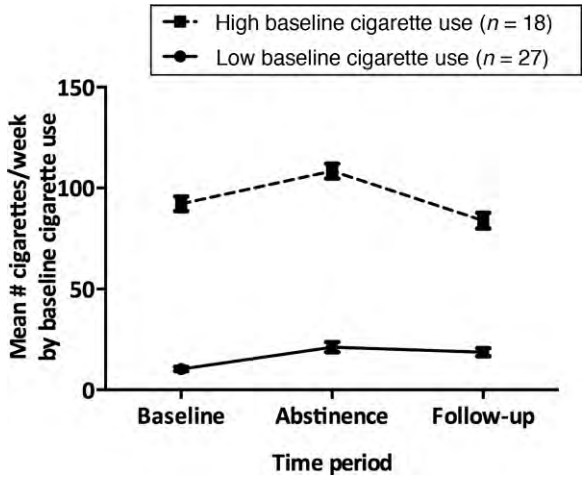

FIGURE 11.3 **Cigarette use increases during cannabis abstinence, and decreases with resumption of cannabis use.** The interaction of baseline cigarette use group with time is significant at $F_{2,89.06} = 4.58$, $P = 0.01$. *Source: Adapted from Allsop et al. (2014b). Changes in cigarette and alcohol use during cannabis abstinence.* Drug and Alcohol Dependence, 138, *54–60.*

population (McLaren & Mattick, 2007). Whilst the majority of cannabis users will not go on to use other illicit drugs, the majority of people who use other illicit drugs (eg, heroin, amphetamines) used cannabis first, and are more likely to be regular cannabis users (McLaren & Mattick, 2007).

Most regular Australian cannabis users are polydrug users. The majority (~86%) of recent cannabis users report using alcohol, 28% report using amphetamines, and 24% report using ecstasy at the same time as cannabis (McLaren & Mattick, 2007). Approximately 20% of Australian dependent cannabis users were also dependent upon opioids, stimulants, or sedatives, compared to only 1% of noncannabis users (Swift, Hall, & Teesson, 1999). Importantly, heavy cannabis users are

more likely to be polydrug users, especially of alcohol, tobacco and stimulants (Swift, Hall, & Copeland, 1997).

Types of Cannabis Products: Availability, Price, and Purity

Australia has well-developed drug use monitoring systems providing useful information about the availability and price of street drugs. The Illicit Drug Reporting System (IDRS) is a strategic early warning system for identifying emerging trends of local and national concern in illicit drug use. IDRS data are gathered from interviews with people who inject drugs (PWID), interviews with key experts, and analysis of indicator data sources related to illicit drug use. In the 2013 IDRS report, hydroponic cannabis was rated as very easy to get (53%) or easy to get (40%), and its potency was rated as high (58%), or medium (30%). Bush cannabis was rated as easy (47%) or very easy (27%) to get, with 25% rating it as difficult to get. The potency of Australian bush cannabis was rated as medium by 54% of PWID interviewed. The price of Australian cannabis was AUD$20 per gram nationally, for hydroponic cannabis, and the same for bush grown cannabis [although bush cannabis (AUD$240) was cheaper than hydroponic ($300), when purchasing an ounce of plant matter].

Claims have been made since the 1990s that the THC content of cannabis produced in Australia has greatly increased, but there has been no data to evaluate this claim (Hall & Swift, 2000). The first systematic analysis of cannabis potency in Australia was conducted in 2013, analyzing the cannabinoid content of 206 different cannabis samples confiscated by police from recreational users, under the New South Wales "cannabis cautioning scheme" (Swift, Wong, Li, Arnold, & McGregor, 2013). The study found high THC content (~15%; Fig. 11.4) and low CBD content (~0.14%; Fig. 11.5). The study also found that there were no significant differences in potency (THC or CBD levels) between indoor (typically hydroponic) or outdoor grown varieties of cannabis (Swift et al., 2013).

Australia has a well-established tradition of domestic cannabis cultivation. Herbal cannabis is most frequently consumed, and there is negligible use of hash (resin), compared to other countries (Potter et al., 2015). A 2014 survey of 491 Australian cannabis growers shows that the majority (41%) cultivated for personal use, and grew outdoor (Potter et al., 2015).

The most visible incorporation of cannabis into Australian culture is seen in the state of New South Wales (NSW), which nominally retains criminal penalties. The North of NSW (known as the Northern Rivers) has a long history of alternative cultural expression, dating back to the early 1970s. The area has long been associated with high rates of cannabis use, normalizing cannabis in the community (Reilly, Didcott, Swift, & Hall, 1998). An annual "Mardi Grass" festival is held in the Northern Rivers in peaceful protest against cannabis prohibition. The primary political organization for cannabis legalization is the Hemp Party (Help End Marijuana Prohibition), founded in 1993. The region also has the highest rates of convictions for cannabis cultivation, use, and possession in the state (Helliwell, Reilly, & Rippingale, 1992; Reilly et al., 1998; van Beurden et al., 2008).

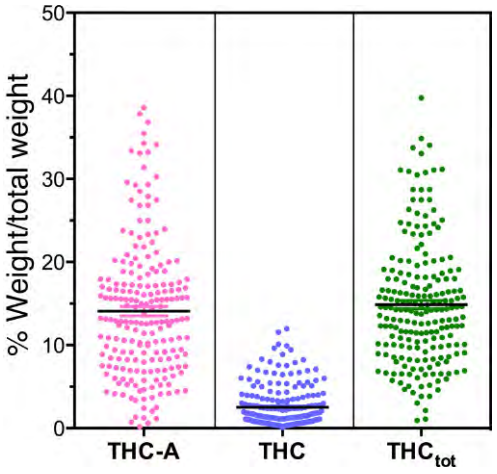

FIGURE 11.4 The levels of THC(A), THC, and THC$_{tot}$ measured in n = 206 Cannabis Cautioning seizures from NSW. Levels of cannabinoids are expressed as a percentage of total weight of sample. THC$_{tot}$ is obtained from adding free THC in the cannabis to the nonpsychoactive form of THC(A), adjusting for their differing molecular weights. *Source: From Swift et al. (2013). Indigenous Cannabis Use

Aboriginal and Torres Strait Islanders (ATSI) use cannabis at higher rates than the general population: with 50 and 27% reporting lifetime and past year use of cannabis, respectively, in 2011 (Clough et al., 2006). Cannabis smoking is often associated with tobacco smoking (van Beurden et al., 2008), the primary cause of chronic disease among ATSIs (Ministerial Council on Drug Strategy, 2011). Cannabis use occurs at higher rates in ATSIs than in the general population (AIHW, 2008; Clough et al., 2004; Forero, Bauman, Chen, & Flaherty, 1999; Perkins et al., 1994).

One longitudinal study has demonstrated that the practice of petrol sniffing in remote Aboriginal communities was a strong predictor of later heavy cannabis use (Lee et al., 2009a). This is part of a broader picture of poorer health and well-being, stemming from the experience of alienation and dispossession. Many of the social determinants of harmful substance use are disproportionately common in ATSI communities. There has been very little research on cannabis dependence in this population, until relatively recent studies of the epidemiology of use and harms (Bohanna & Clough, 2012; Lee, Conigrave, Patton, & Clough, 2009), psychiatric consequences (Lee, Clough, Jaragba, Conigrave, & Patton, 2008), and the indigenous experience of cannabis withdrawal (Rogerson & Clough, 2013).

A BRIEF HISTORY OF CANNABIS LAW IN AUSTRALIA

Australia has a Federal political system that arose when the six separate colonies formed a Federal system of government at the beginning of the 20th century (Singleton, Aitken, Jinks, & Warhurst, 2000). Under the constitution, the states have the powers to set and enforce criminal laws, including those relating to drug use. The Commonwealth Government has the responsibility for ensuring compliance with international treaties.

International drug control treaties, such as the Single Convention on Narcotic Drugs (UN, 1961), require signatory states, which include Australia, to prohibit and criminalize cannabis use by adults. Since the late 1970s, rising rates of cannabis use have prompted policy debates in Australia about the appropriateness of these criminal penalties (Hall, 2001). Australian cannabis policy is interesting because it claims to be evidence-based (Fitzgerald & Sewards, 2002), whereas, as in other countries, research is often used to support policies adopted for other reasons (Hall, 2008).

Since cannabis use was prohibited in Australia in the early decades of the 20th century (Manderson, 1993; McCoy, 1980), the initial response to rising rates of recreational cannabis use in the 1960s was to increase enforcement of prohibition. Criminal prosecutions for cannabis offences increased by nearly 1000% between 1966 and 1969. Criminal penalties were also raised, and police were given more funding to disrupt the illicit cannabis market (Manderson, 1993). These efforts had minimal effects on rates of cannabis use which rose steadily between 1970 and the mid-1990s (Hall & Pacula, 2003).

Cannabis Law Reform in Australia

More liberal cannabis policies were first advocated in the late 1970s, when cannabis prosecutions increased among middle class youth (Manderson, 1993). The argument was that having a criminal record caused more harm than cannabis use [Royal Commission into the Non-medical use of Drugs, 1979; Senate Standing Committee on Social Welfare (Baume Committee), 1977], and that a more appropriate penalty for personal possession and use was a civil penalty, such as a fine [Senate Standing Committee on Social Welfare (Baume Committee), 1977]. The Baume Committee also argued that Australia needed to develop a national policy to: reduce cannabis use; discourage cannabis users from driving while intoxicated; and reduce cannabis users' contact with the suppliers of other illicit drugs. State governments generally ignored recommendations for more liberal cannabis policies (Manderson, 1993).

The first Australian state to decriminalize cannabis use was South Australia, in 1987. Under the new law, persons found to possess and use cannabis, or to cultivate up to 10 cannabis plants for personal use, received only a civil fine. There was no criminal conviction recorded, if the fine was paid (the law was termed the Cannabis Expiation Notice System Act, or CEN). Following an inquiry into illicit drug use by the Australian Capital Territory (ACT) in 1991, similar changes in penalties were introduced there (ACT Legislative Assembly Select Committee on HIV, Illegal Drugs and Prostitution, 1991).

The National Task Force on Cannabis

A National Campaign against Drug Abuse (NCADA) was established by Federal and State Ministers in 1985, in response to rising heroin use (Hall, 2004). Cannabis decriminalization was off the agenda (Manderson, 1993). NCADA did, however, establish "harm minimization" as a central principle of Australia's national drug policy. It also initiated regular surveys of drug use in the Australian population that documented the steady rise in cannabis use over subsequent decades.

In 1993 the Federal Labor government established a National Task Force on Cannabis to encourage the states to develop a nationally consistent policy. The Task Force comprised State and Federal health and law enforcement

officials. It commissioned reviews of: patterns of cannabis use (Donnelly & Hall, 1994b), the health and psychological effects of cannabis (Hall, Solowij, & Lemon, 1994), legal options for dealing with cannabis (McDonald, Moore, Norberry, Wardlaw, & Ballenden, 1994), and public attitudes towards these options (Bowman & Sanson-Fisher, 1994).

The Task Force's report recommended that the "possession, unsanctioned cultivation, sale, and nontherapeutic use of cannabis in any quantity remain illegal" (p. xii) but that state governments "consider discontinuing … criminal penalties for the simple personal use or possession of cannabis" (Ali & Christie, 1994, p. xii). It also recommended that the Ministerial Council on Drug Strategy should develop a "comprehensive national policy on cannabis, based on the Task Force research and recommendations" (Ali & Christie, 1994, p. xi). State governments did not accept these recommendations.

In the decade after the National Task Force reported, several states and territories had debates about whether they should change penalties for cannabis use. In 1995 the Northern Territory passed legislation modeled on South Australia's, imposing civil penalties for personal use, possession, and cultivation for personal use. Attempts to legislate for lower cannabis use penalties were unsuccessful in Victoria and New South Wales (Hall, 2008). In 2004 the Western Australian Government decriminalized cannabis use, citing local research that cannabis users prosecuted under that state's laws suffered greater social harm than cannabis users who had been dealt with under the CEN system in South Australia (Lenton, 2004). This law was repealed, and criminal penalties reinstated in 2008, when a conservative government was elected.

The National Cannabis Policy

In Nov. 2004 the Ministerial Council on Drug Strategy commissioned an expert group to develop a National Cannabis Policy (NCP). The issue of penalties for cannabis use was excluded from the brief. The NCP had four aims: to educate the community (and young people in particular) about the adverse health effects of cannabis, and the penalties for using cannabis; to prevent the uptake of cannabis among young people by reducing its availability, and addressing the social vulnerabilities predisposing some young people to its use; to reduce problems related to cannabis use among young people by encouraging users to desist, and reducing the number of users who became regular users; and to respond more effectively to the increasing numbers of problem users seeking help to stop using cannabis. The NCP also advocated more research on cannabis use among young people, and more rigorous evaluations of the effects of different penalties for cannabis use in different Australian jurisdictions on rates of use and harm.

Medicinal Cannabis in Australia

Medicinal use of cannabis was advocated in the early 1990s in Australia, in the first decade of the AIDS epidemic. It was considered by the National Task Force which recommended funding clinical trials. In August 1999, the NSW Premier appointed a Working Party to advise: (1) whether cannabis and cannabinoid drugs had any medical uses, and (2) if they did, how cannabis or cannabinoids could be made available for medical use, without decriminalizing recreational cannabis use. The Working Party concluded that THC was useful in treating HIV- and cancer-related wasting and nausea caused by cancer chemotherapy (Hall, Degenhardt, & Currow, 2001; NSW Working Party, 2000). It also noted suggestive evidence that THC may relieve painful muscle spasms in neurological disorders, and pain that has not responded to conventional analgesics. It recommended further research on the therapeutic use of cannabis and cannabinoid drugs in all of these conditions.

The Working Party also concluded that smoked cannabis would not meet criteria for registration as a therapeutic good (a precondition for any medical use in Australia). It suggested that the best prospects for medical use lay in developing new synthetic cannabinoids, or ways of delivering THC that did not involve smoking cannabis. In the meantime, it recommended that patients be given compassionate access to cannabis by means of an exemption from criminal prosecution for those who were medically certified as having: HIV- or cancer-related wasting; nausea caused by cancer chemotherapy; muscle spasm in neurological disorders or spinal cord injury; and pain unrelieved by conventional analgesia. The government appointed a committee to advise on implementation of the recommendations, but no legislation was introduced.

The medical cannabis debate changed with the advent of Sativex, a botanical extract of *Cannabis sativa* comprising 50% THC and 50% CBD. Prior to May 2009, Sativex was classed as a Schedule 9 drug in Australia, which are prohibited substances for research use only. In May 2010 the Therapeutic Goods Administration (TGA) rescheduled Sativex to Schedule 8 (eg, like methadone), and made it available for use under the TGA's special access scheme. In Nov. 2012 the TGA registered Sativex for use in the treatment of severe spasticity in MS. However, changes are required to the Poisons Act to make prescribing Sativex a practical reality in Australia.

Australian scientists have explored the possibility of using Sativex as a potential Cannabinoid Replacement Therapy (CRT) for treating cannabis withdrawal in dependent cannabis users (Allsop et al., 2014a). This work demonstrated that high-dose Sativex suppressed more of the most clinically relevant symptoms of cannabis withdrawal than placebo (Fig. 11.6). The lack of intoxication suggests that this may be a viable route for future

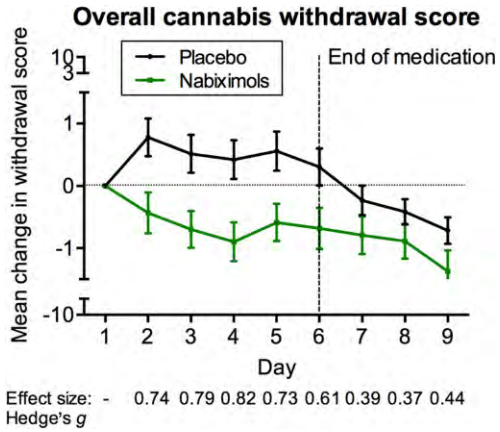

FIGURE 11.6 **Cannabis withdrawal symptoms were suppressed during inpatient cannabis detoxification, when medicated with Sativex (Nabiximols), compared to placebo.** Withdrawal scores are shown relative to baseline (day 1) scores. The interaction of treatment group with time is significant at $F_{8,325.1} = 2.83$, $P = 0.01$. *Source: Adapted from Allsop et al. (2014a). Nabiximols as an agonist replacement therapy during cannabis withdrawal: a randomized clinical trial.* JAMA Psychiatry, *71, 281–291.*

treatment of cannabis dependence. However, there remains much clinical work and policy translation before such an approach can be implemented as standard clinical practice.

A 2013 NSW medicinal cannabis enquiry recommended that medically prescribed cannabinoids (not raw cannabis) be made available for terminally ill patients, as well as allowing terminally ill patients to possess up to 15 g of cannabis. Both patient and carer would need a certificate from a specialist, need to be registered with the Department of Health, and would need photo identification. Recent media articles suggest that the Commonwealth Government has rejected the recommendations due to insufficient evidence of efficacy for cannabis.

EFFECTS OF CANNABIS USE ON AUSTRALIAN COMMUNITIES

Regular cannabis use is associated with a range of social harms. Perhaps the most prevalent and easily recognizable harm in the Australian community is the increased prevalence of adults seeking treatment for cannabis dependence. Examination of the NSW Minimum dataset, a collection of data cataloguing medical treatment episodes in NSW, shows that cannabis is the second most prevalent primary drug of concern (19%) after alcohol (49%), with heroin (17%) and amphetamines (10%) also problematical (Copeland & Allsop, 2014). Cannabis was also the most prevalent "other" or secondary drug of concern (25% of treatment episodes), followed by nicotine (17.6%), amphetamines (8.6%), alcohol (6.2%), benzodiazepines (4%), heroin (3.2%), and ecstasy (2%) (Copeland & Allsop, 2014). These trends are mirrored in other Australian jurisdictions (AIHW, 2013).

Poorer educational outcomes have also been reported in Australasian cannabis smokers who commenced cannabis use at younger ages (Horwood et al., 2010). The worst rates of high school completion, university enrolments, and degree attainment were found to be amongst those who commenced cannabis use prior to age 15, even after controlling for a range of possible confounders, such as socioeconomic status and gender (Horwood et al., 2010). Heavy users who persist in using throughout their 20s report lower life satisfaction, and poorer social outcomes, than those who do not use or who do not persist in using.

Regular cannabis use may impair memory and attention in ways that adversely affect academic performance. Indeed, a longitudinal prospective cohort study from New Zealand, following over a thousand people from birth to age 38, found that persistent cannabis use was associated with IQ decline, after controlling for years of education and other confounding variables (Meier et al., 2012). The largest declines in IQ were found in those who commenced cannabis use during adolescence, and continued to use daily throughout young adulthood.

Regular cannabis use has also been associated with increased prevalence and severity of psychotic illness in the Australian population (McGrath et al., 2010). A younger age at initiation predicts a younger age of onset for psychotic symptoms (Castle, 2013; Large, Sharma, Compton, Slade, & Nielssen, 2011; Stefanis et al., 2013).

STRATEGIES FOR REDUCING MISUSE

Supply control efforts include attempts to detect illicit cultivation, and local policing initiatives, such as the use of sniffer dogs (Dunn & Degenhardt, 2009). Border protection is less of an issue in Australia because most cannabis is domestically cultivated (McLaren & Mattick, 2007; UNODC, 2013).

Cannabis use offences remain the most common drug offences. A significant proportion of people entering the criminal penalty system in Australia for cannabis offences are problematic cannabis users (AIC, 2008). Many of these offenders are diverted into counseling and treatment.

Cannabis Public Information Initiatives

The National Cannabis Policy funded a National Cannabis Prevention and Information Centre (NCPIC) that began in 2008. The NCPIC was established in response to growing community concerns about cannabis use, with the mission of preventing cannabis use, and providing

the community with evidence-based information and interventions. Its key services included: a website providing evidence-based cannabis information; a free cannabis telephone information and help line; regular reports on the latest cannabis research findings; and national training in interventions for cannabis-related problems.

Preventative drug education, including material on cannabis, is included in secondary school health curriculums in all Australian states and territories. An educational resource, *Cannabis and Consequences*, was developed as part of the National School Drug Education Strategy to educate students from an early age about the potential harms of cannabis use, to prevent the uptake of cannabis use, and to develop resilience (Midford, Lenton, & Hancock, 2000). More recently, an interactive computer-based intervention for school children has been developed, CLIMATE Schools: Alcohol and Cannabis course (Newton, Teesson, Vogl, & Andrews, 2010). The program has been tested in a cluster randomized controlled trial, and found to significantly improve knowledge of cannabis (and alcohol) 12 months after the program was delivered, and to reduce alcohol and cannabis use (Newton et al., 2010).

The Australian government has also conducted national media campaigns on cannabis, as part of the National Drugs Campaign (NDC). The most recent campaign, in 2010, focused on ecstasy, marijuana, and methamphetamine, using the Internet, print, and in-venues advertising, a dedicated website, and an information telephone line. Some state governments have also funded cannabis-based public health initiatives.

MINI-DICTIONARY

Bush cannabis Australian vernacular for outdoor grown cannabis. Sometimes can be used to represent cannabis grown indoors that is cultivated in soil, as opposed to hydroponically grown cannabis.
Cannabidiol (CBD) Cannabidiol is a nonpsychotropic phytocannabinoid. CBD has antipsychotic and anxiolytic effects, and may dampen the psychotomimetic actions of THC.
Cannabinoid replacement therapy Using cannabinoid medications (phytocannabinoids or synthetic cannabinoids) to occupy cannabinoid receptor sites in the brain and body, in place of illicit cannabis, or potentially to replace dysfunctional endocannabinoid signaling.
Cannabinoids A diverse group of receptor proteins that activate the endogenous cannabinoid system. They include endogenous substances (eg, anandamide) and synthetic or plant based cannabinoids (THC).
Cannabis decriminalization The abolition of criminal penalties for the use and possession of small amounts of cannabis.
Cohort study An observational study used in medicine, social sciences, and ecology that gathers data on a defined group of people, over a long period of time, in order to elucidate relationships between risk factors (eg, cannabis use) and particular medical conditions or diseases.
Diversion A policy lever for channeling cannabis users away from criminal sanctions and into treatment.
Harm minimization The concept of reducing the harmful effects of alcohol and other drugs using policy levers and educational resources, on the basis of research evidence.
Tetrahydrocannabinol (THC) The main psychoactive component of the cannabis plant that is a partial agonist of the Cannabinoid Type-1 (CB1) receptors in the brain and central nervous system.

SUMMARY POINTS

- This chapter provides a concise review on the history, as well as the present status, of cannabis use and/or abuse in Egypt.
- Cannabis was neither cultivated, nor it was known in Ancient Egypt.
- From the 12th to the 19th century, Egypt was affected by large scale cannabis abuse.
- At the beginning of the 20th century, Egypt called for international restrictions on the cultivation and commerce in cannabis.
- Hashish and herbal cannabis (bango) are the most commonly abused drugs nowadays.
- Hashish is smuggled through the eastern and western borders of Egypt, while the plant is increasingly widely cultivated in Egypt, especially in the Sinai Peninsula and in Upper Egypt.
- Since 1998, seizures of hashish and cannabis herb went up, possibly reflecting increased market demand and/or successful efforts of Egyptian law enforcement officials.

KEY FACTS OF THE DRUG CONTROL AND TREATMENT OF ADDICTION FUND

- Belongs to the Ministry of Insurance and Social Affairs.
- Works in collaboration with the National Council for Addiction Treatment and Prevention.
- Its targets are the prevention and treatment of addiction.
- Performs a range of training programs to educate young people about the issue of drugs, and problems arising from them.
- Establishes clinics and treatment centers for drug addicts.
- Coordinates between the various parties concerned with the problem of drugs of abuse, in cooperation with the authorities and other relevant ministries.
- Works to develop a database on the problem of drug addiction in Egypt.

KEY FACTS OF UNITED NATIONS OFFICE ON DRUGS AND CRIME (UNODC)

- A United Nations agency (in Vienna).
- Was established in 1997 as the Office for Drug Control and Crime Prevention.
- Was renamed the United Nations Office on Drugs and Crime in 2002.
- Deals with the problems of illicit drugs, crime, corruption, terrorism, HIV, and AIDS.
- Works with member states to combat these problems.

INTRODUCTION AND HISTORICAL PERSPECTIVES

Ancient Egypt

The history of herbal medicine can be traced back to ancient Egypt. The Ebers medical papyrus dates to ~ 1550 BC, and lists many herbal prescriptions for treating numerous medical conditions. The Edwin Smith papyrus, the oldest known surgical textbook (~ 1600 BC) describes 48 typical cases, from injuries of the head to the lower spine (Leake, 1952). There is no convincing evidence that the cannabis plant was known to the ancient Egyptians. Wall paintings, tomb reliefs, plant remains in tombs, or papyri constitute our source of information concerning the plants of ancient Egypt. Tomb paintings of private gardens show sycamore fig, *doum* palm, date palm, pomegranates, olives, willows, and *persea*. Flower gardens included cornflowers, water lilies, poppies, mandrakes, hollyhocks, and mallows (Bigelow, 2000). In the ninth year of her reign, Queen Hatshepsut (1473–1458 BC), daughter of Thutmose I, commissioned an expedition to the land of Punt, and which returned laden very heavily with heaps of myrrh-resin, of fresh myrrh-trees, with ebony and pure ivory, and with cinnamon-wood, among many other things. Thutmose III followed queen Hatshepsut and, during his reign, Egypt stretched to Palestine and Syria. From there, plants and trees were brought to Egypt (Breasted, 1945). *Cannabis sativa* was not mentioned in any hieroglyphic texts or paintings, and no cloth made of hemp was found in ancient Egyptian tombs (Peters & Nahas, 1999) (Fig. 12.1).

In 1992, however, the presence of cannabis (tetrahydrocannabinol), nicotine (the main alkaloid in tobacco), and cocaine have been reported in samples from soft tissues, hair, and bone from Egyptian mummies dating back to 1070 BC–395 AD (Balabanova, Parsche, & Pirsig, 1992). In an Egyptian mummy dating to ~ 950 BC, Parsche and Nerlich (1995) detected amounts of the above drugs in internal organs, as well as in hair, bone, skin, muscle, and tendons. Since cannabis, tobacco, and coca plants were not native to Egypt or Africa, their finding in mummies was surprising, and suggested a transoceanic pre-Columbian contact between the Americas and the rest of the world. It might also be that these plants have been available in limited supply for the more prosperous elite of Egyptian society, whose bodies were mummified (Wills, 1998).

Cannabis in Arabic Medicine

Only in the ninth century did Arab scholars become familiar with the medicinal properties of cannabis, after translating the Greek texts of Dioscorides and Galen (Nahas, 1982). Cannabis seemed to have been introduced into Arab culture from India, through Persia; hence it was known as Indian hemp (Hamarneh, 1972). Medicinal uses for oil obtained from hemp seeds first appeared in Arabic literature by al-Razi (857 AD), who proposed its use for the ear, dissolving flatulence, and to cure epilepsy. Hashish is the Arabic name for the cannabis extract used in the Middle East. The word also means "grass." Another Arab physician, al-Badri (1251 AD), recommended hashish to stimulate the appetite and produce a craving for sweets (Peters & Nahas, 1999).

Cannabis in Medieval Arab World

The word "hashshashins," meaning hashish consumers, refers to followers of an 11th century Persian leader, who committed secret assassinations of some of the regional leaders (Nahas, 1982). Hence the word "hashshashins" might have formed the root for the derivation of the English word "assassin" (Raman, 1998; Roffman, Schwartz, & Stephens, 2006). Sufis (a mystical movement of ascetics) in the 12th century had possibly encouraged the use of hashish for seeking spiritual insights, and spread its consumption to Syria and Egypt (Rosenthal, 1971). The Spanish botanist, Ibn Baitar, on his trip to Egypt in 1413, noted that cannabis use in Egypt was public (Iversen, 2000). Egypt was particularly affected by large-scale cannabis abuse since the 13th century (Nahas, 1982, 1985; UNODC, 2008).

Hashish during 18th–20th Centuries

It seems that fear of the influence of hashish on French soldiers in Napoleon's army led, in 1798, to the issuing of a decree that prohibited the preparation and use of hashish as a beverage, as well as the smoking of its seeds throughout Egypt. Nevertheless, it is said that samples of the material, as well as many colorful tales of hashish and its intoxicating effects, were carried back to France by French soldiers (Kalant, 2001; Iversen, 2000).

Hashish use also seemed to have been widespread in Egypt during the 19th century. In 1893, Peterson, a Professor of Nervous Diseases at the University of Vermont, wrote on the toxic effects resulting from the excessive use of "hasheesh" which he observed in 60 men and 4 or 5 women, and described the resulting "insanity." He described the presence of several hasheesh joints in Cairo, and also his visit to one of them: "there were two or three rooms full of men enjoying their pipes and chibouques" (Peterson, 1893).

It is not surprising, therefore, that in 1925, in the Geneva Opium Convention, the Egyptian delegate, M. El Guindy, took a leading role to add international trade in cannabis into the agenda. In his speech, El Guindy claimed that "the illicit use of hashish accounted for 30–60% of the total number of cases of insanity occurring in Egypt" (Zimmer, 1997; UNODC, 2008).

FIGURE 12.1 (*cont.*) (D) agriculture in ancient Egypt. Cannabis was neither cultivated nor known in Ancient Egypt. Tomb paintings and reliefs depicted only papyrus flowers, water lilies or lotus flowers, mandrakes, and date palm.

CURRENT STATUS OF CANNABIS USE IN EGYPT

Egypt is a country with a population of about 80.72 million. The proportion of population under the age of 15 years is 34%. The country is a lower middle income group country (World Bank, 2012). Illegal drugs have made their entry into the Egyptian society, and the most common form of drug abuse is that of cannabis. There are no reliable statistics on the extent of drug abuse, but it is clear that there is a general increase in it, especially in young age (15–25 years) (WHO, 2005).The cannabis products being used in Egypt include "hashish" and marijuana, or "bango." Hashish is usually smoked in a water pipe, known as "goza" or "shisha," while bango is usually smoked in the form of a cigarette, or added to a cigarette. Cannabis is of relatively low price, can be easily obtained, and cultivated illegally in many areas in Egypt (Okasha, 2004). In 2005, the average price of herbal cannabis in Egypt was ~ 2.6 US$ per gram, compared with 5 and 15 US$ in the United Kingdom and the United States, respectively. Meanwhile, the price of hashish was 2.6 US$ per gram, compared with 3.7 US$ in the United Kingdom (UNODC, 2007).

SOURCE OF CANNABIS

Cannabis is one of the most widespread drugs on the illicit trafficking market. There are no registered cases of local production of hashish. This appears to be due to the tight security measures that prevent such activity. Thus, the hashish market depends mainly on importation from producer countries. The main source of hashish smuggled into Egypt is West Africa. Morocco was regarded as the biggest source country. There are also some attempts to smuggle hashish from Pakistan and Afghanistan, through the eastern borders of Egypt (UNODC, 2013). Cannabis herb is widely cultivated year-round in Egypt, especially in Sinai Peninsula and Nile islands, in Upper Egypt. Preventing the cultivation of cannabis presents a challenge, since this requires very costly human, material, and technical capabilities. In the year 2002, Egyptian law enforcement officials eradicated 162.8 hectares of cannabis, and in 2011 control efforts resulted in the eradication of a surface of 65.25 feddans (UNODC, 2012, 2013). Egypt accounted for 90% or more of the annual total cannabis seizures for Africa each year, from 2000 to 2009. In general, seizures of both cannabis resin ("hashish") and herbal cannabis increased

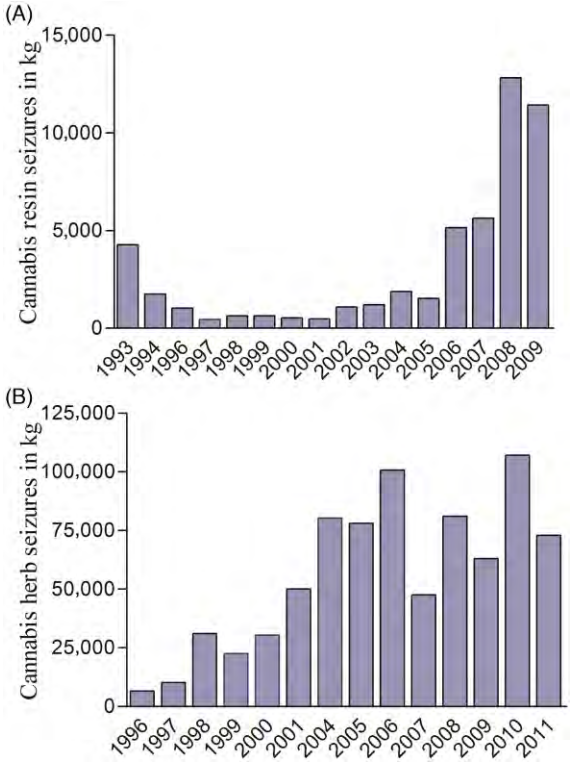

FIGURE 12.2 (A) Cannabis resin (hashish) seizures in Egypt. The columns represent the amount seized in kg during 1998-2009. (B) Cannabis herb (marijuana or bango) seizures in Egypt. The columns represent the amount seized in kg during 1998–2011. *Source: UNODC, 1999, 2000, 2006, 2007, 2008, 2009, 2011; UNODC, 2006, 2007, 2008, 2009, 2011, 2012, 2013.*

markedly since 1998. This might indicate a growing market demand. The rise in seizures in North African countries in 2006, despite the decline in cannabis production in Morocco, might also reflects growing shipments of cannabis resin from Morocco toward Egypt and other countries in North Africa (UNODC, 2008) (Fig. 12.2). Abdel Aal, Abdel Maaboud, and Aly, (2011) found that the percentage of seizures increased in Upper Egypt governorates during the period from 2003 to 2009. Cannabis, as a plant or hashish, was the most widely seized drug. The quantity of seized cannabis plants exceeded that of hashish. In this context, it should be noted that it is generally agreed that drug seizures represent a fifth of drug use in society (Okasha, 2004).

PREVALENCE OF FACTORS ASSOCIATED WITH, AND AFFECTING, CANNABIS ABUSE

In the 1980s, estimates of substance addiction showed that the most commonly abused drug was cannabis. This was followed by opium, solid and liquid hypnosedatives, heroin, and finally cocaine (Okasha, 1996). In 1982, hashish constituted 91% of the mass of drug dealing in Egypt, while opium and its derivatives did not exceed 7% (Darweesh, 1982). Soueif, Yunis, & Taha (1986) indicated that, apart from alcohol and tobacco, cannabis remained the most widely abused psychoactive substance. This was based on a series of large scale field surveys conducted since 1957. The authors reported that 30% of male industrial workers, and 20% of male students, had used drugs at some point in their lifetimes, and that approximately 25% became chronic users. In 1985, Okasha reported that 34% of University students in Egypt, who had succeeded in their studies, and 42% of those who had failed, used drugs. In the 1990s, there was an exponential increase in synthetic psychoactive drug use, these becoming the third most commonly available drug following cannabis and alcoholic beverages (Okasha, 1996, 2004). One study found that 21.4% of experimenters in secondary schools admitted continuing to take synthetic drugs (Soueif et al., 1990). But toward the second half of the same decade, marijuana (bango) became the most prevalent form of cannabis abused (Okasha, 1996, 2004). Studying drug abuse as a risk factor affecting juvenile delinquency showed that 12.7% had cannabinoids on urine testing (Moustafa, El-Defrawi, Kheder, & Hagras, 2001).

In a recent study on the lifetime prevalence of alcohol and substance use in Egypt, cannabis was the most misused drug, while alcohol was a distant second. The sample comprised 44,000 subjects from eight governorates. The lifetime prevalence of any substance abuse varied between 7.25 and 14.5%. Substance abuse was more prevalent in males (13.2%) compared with females (1.1%). Youth (15–19 years), males of Bedouin origin, seaside governorates, low levels of education, and certain occupations experienced far more substance abuse (Hamdi et al., 2013).

In a study on 457 patients with drug dependence (from the neuropsychiatry department in Tanta University Hospital), the majority of addicts were males (70.0%), aged 20–40 years (81.4%), from urban areas (75.7%), current smokers (95.6%), not married (single, divorced, and widowed) (70.0%), and of low educational level (El-Sawy, Abdel Hay, & Badawy, 2010). In a study on hired hospital cleaners, substance abuse, particularly tramadol and marijuana (bango), was significantly higher in temporary compared to permanent cleaners. Urine-based screening tests were positive for tramadol (39.7% vs 20.6%), amphetamine (1.2% vs 0.96%), marijuana (bango) (35.9% vs 24.4%), morphine (8.7% vs 4.3%), and benzodiazepines (17.8% vs 14.8%). The study also suggested that being unmarried, of male sex, with family history of mental disorder, aged ≥40 years, smoking, and with length of service of ≥8 years, were the factors associated with substance abuse (Abbas, Hammam, El-Gohary, Sabik, & Hunter, 2013).

In a survey on drug use in young people (15–29 years), 1.5% had tried drugs, representing 2.7% of all male

respondents, and 0.1% of all female respondents. These figures were probably underreported because more respondents reported that their family members had tried drugs (2.9% overall, 3.6% male, and 2.1% female), and even more reported that their friends had tried drugs (5.3% overall, 9.6% male, and 0.8% female) The most commonly used drug was hashish, which 89.2% tried, followed by marijuana (bango) (23.1%), pills (10.3%), stimulants (3.1%), and sedatives (3.2%) (SYPE, 2011).

CANNABIS ABUSE IN SELECTED POPULATION GROUPS

Cannabis Use in Patients with Drug Overdose

Studies among patients admitted to the Mansoura emergency hospital (Eastern Nile Delta) showed cannabis to be the most commonly abused drug. In a study conducted on 150 patients presenting with drug overdose over the period of 2002–2004, AbouEleinen, Mostafa, Ghanem, Elnaggar, and Elbayomy (2008) reported the presence of cannabis in urine samples of 68% of cases (followed by opiates, and barbiturates, in 42.7% and 26.7% of samples, respectively). The diagnosis of polysubstance abuse was more prevalent than single substance abuse. In 2010, Ghanem, Abdel Rahman, Mandour, and Attia, (2010) detected the presence of substance abuse in 65% and 43.8% of urine samples from 399 patients with drug overdosage. Fifty-six percent of these patients were aged between 20 to 30 years. Cannabis accounted for 16.1%, benzodiazepines for 10.2%, opiates for 8.5%, and barbiturates for 9% of samples, respectively. Amr, El-Gilany, El-Mogy, and Fathi (2014) examined 1317 patients attending the same hospital, and found cannabis to be the most common drug of abuse (3.6% of patients); being of young age (<30 years), male and single, with unsatisfactory income, or having a psychiatric illness (mainly anxiety disorders in 60.7%) were predictors of drug abuse. Tramadol and polysubstance abuse followed with a prevalence of 1.8 and 1.9%, respectively. Substance abuse was present in 63.8% of those with low educational level (below secondary school) versus 31.7% in those with a higher level of education.

Cannabis Use in School and University Students

Cannabis abuse is a problem among school and University students. Alcoholic beverages were used by 18.4% of high school students, hashish and opium by 36%, and psychiatric drugs (tranquilizers 51%) by 5.2%. Hashish abuse accounted for 81.4% of natural drug abusers (Darweesh, 1982). One study that included 14,656 male secondary school students showed that users tended to see drug consumption as either harmless or even useful, and that significantly more urban than rural students smoked tobacco, and tried cannabis and alcoholic beverages. Arts students were more likely to smoke tobacco, ever use prescription psychotropic substances, narcotics, and alcohol, compared with their science and mathematics studying counterparts (Soueif et al., 1990). In another survey, 5.1% of male technical secondary schools students have used natural narcotics at some time in their lives. The respondents ranked cannabis as the most abused (84.3%) or coabused with opium (3.4%). Age onset was 16 years for all natural narcotics. Regarding continuing or ceasing abuse, 20.8% admitted to continue abuse, while 74% stopped after the first trial for different reasons; the most important factor was a general consensus that these substances had an overall damaging effect (51.1%). Other factors were religious (11.8%), financial (9.4%), and social (6%) factors (Soueif et al., 2000).

In a study among students of secondary schools in Assuit province (south of Cairo), 11.6% tested positive for cannabis in urine; being a male, higher income, large families, and parental problems were among risk factors in this group. Cannabis addiction was reflected in decreased school activities, and increased aggressive behavior among students. The same study reported cannabis abuse in 12% of a sample of drivers, especially the younger aged (21–41 years). In students and drivers, cigarette smoking played an important role as a gateway for cannabis abuse; those who abused cannabis were also shisha smokers (Yassa, Dawood, Shehata, Abdel-Hady, & Abdel-Aal, 2009).

Studies among male University students showed that cannabis remained the most widely abused psychoactive substance, where 9.05% of students had tried it at least once. Abusers started experimentation at 18–20 years of age. The first use of cannabis most often occurred during social occasions, or in the company of friends. In all cases of "ever using" cannabis, those who stopped the practice (81.42%) were mainly motivated by fear of expected physical as well as psychological harm (38.61%). Another factor was religious prohibition of these substances, while fear of legalization was almost an ineffective reason. Approximately 30% continued cannabis consumption for pleasure and euphoria, and only 9.3% continued abuse to cope with social stress, while 5.23% continued as a result of addiction (Soueif, 1995).

Another study by Refaat (2004) found that 6.8% of University students had tried marijuana, and 2.5% were current users of marijuana. ElShair & Shafik (2012) found that one-quarter of student hostels in Cairo University were smokers who showed significantly higher use of shisha, cannabis (bango), and alcohol, compared with their nonsmoker counterparts. AbouSeif, AbouElezz, Elgaafary, Ibrahem, and El Sotohy (2011) reported drug addiction in 7.9% of 419 students from Ain Shams University (Cairo). Smoking and alcohol intake were present in 20.9% and 11.6%, respectively.

TABLE 12.1 Prevalence of Drug Abuse in Different Studies

Category	Prevalence (%)	Study
Industrial workers	30	Soueif et al. (1986)
Students	20	Soueif et al. (1986)
University students	42	Okasha (1985)
University students	2.5–6.8	Refaat (2004)
Experimenters in secondary schools	21.4	Soueif et al. (1990)
Juvenile delinquents	12.7	Moustafa et al. (2001)
General population	7.25–14.5	Hamdi et al. (2013)
High school students	36	Darweesh (1982)
Secondary school students	5.1	Soueif et al. (1990)
Secondary school students	11.6	Yassa et al. (2009)
Drivers	12	Yassa et al. (2009)
University students	9.05	Soueif (1995)
University students	7.9	ElShair & Shafik, (2012)
Psychiatric patients	26	Asaad et al. (2003)
Patients with organic erectile dysfunction	16.8	El-Bendary et al. (2009)

The table shows the proportion of those who have abused drugs reported by different studies. The drugs abused were mostly cannabis.

Cannabis Use in Psychiatric Patients

In a study on 100 schizophrenic outpatients (Ain Shams University Psychiatric Institute, Cairo), drug abuse was prevalent in 26% of patients; antiparkinsonian drugs ranked first, followed by cannabis, opioids, and benzodiazepines. The authors found no significant association between drug abuse and schizophrenia subtype or neuroleptic drug dosage. In contrast, male gender, high level of depression, smoking, and premorbid personality were strong risk factors (Asaad, Okasha, El-Khouly, & Abdel Azim, 2003). Another study on 120 inpatients of the addiction center and outpatients of the psychiatric clinic (Menoufia University Hospitals) found tramadol the most prevalent drug (20%). Other important drugs were cannabis (10%), sedative tablets (10%), and alcohol (10%), while polysubstance abuse accounted for 38.3% (Mohamed et al., 2013). Psychiatrically ill patients who abused cannabis exhibited worsened symptoms of schizophrenia, major depressive disorder, and generalized anxiety disorder, as well as decreased quality of life, compared with those patients not abusing cannabis (Sehlo, 2008).

Cannabis Use in Patients with Other Medical Conditions

The use of recreational drugs was reported in 16.8% of Egyptian patients (<40 years) complaining of organic erectile dysfunction; marijuana (bango) being the most common (8.8%), followed by hashish (4.1%), street drugs (codeine containing antitussives, and narcotic analgesics, eg, tramadol). In this sample, smoking and the use of recreational drugs were the most significant risk factors for the erectile problem (El-Bendary, El-Gamal, & Salem, 2009). Among 109 drug addicts at Abbasia chest hospital (Cairo), Saeed, Riad, & Kamel (2011) found cannabis the most commonly abused drug (67% of abused substances). Cigarette smoking was frequent in all patients (Tables 12.1 and 12.2).

GENDER AND DEMOGRAPHIC DIFFERENCES IN CANNABIS ABUSE

In a survey made in 2000, hashish abusers constituted 61.5% and 80.5% of the total male drug users in Lower and Upper Egypt, respectively. Meanwhile, 19.3% and 3.7% tended to use marijuana (bango) in Lower and Upper Egypt, respectively (together with other substances, such as opium or heroin), indicating the high prevalence and preference for hashish. Females constituted 17% and 35.6% of hashish users in Lower and Upper Egypt, respectively. In Lower Egypt, most drug abusers were males (83%), the majority of male abusers (64.3%) were 18–40 years old, while 26.6% fell in the age group 40–55 years. On the other hand, 82.1% of female abusers in Lower Egypt were in the age group of 18–40 (Abdel-Gawad, 2000). In Upper Egypt, there were less female abusers reported, where the culture plays a role in starting or experimenting with abuse. Low prevalence

TABLE 12.2 Factors Associated With Cannabis Abuse

Category	Factor	Study
Students	Unhealthy family environment	Soueif et al. (1990)
Students	High monthly income	Soueif et al. (1990)
Students	High daily funds	Yassa et al. (2009)
Students	Family problems (eg, divorce)	Yassa et al. (2009)
Students	Large families	Yassa et al. (2009)
University students	Coping with psychological or physical discomfort, or stress-triggering situations	Soueif et al. (1986)
Students	Entertainment on happy social occasions	Soueif (1994)
Workers	Difficult working conditions	Soueif (1994)
Subjects attending outpatient neuropsychiatry clinic	Coping with anxiety disorders or depressive disorders.	El-Sawy et al. (2010)

Studies point to social and economic factors as important factors associated with cannabis abuse.

of drugs among females is mainly attributed to society's values, together with higher exposure of males to drug during marriage celebrations, which constitute a major circumstantial cause of engagement of men in drug abuse (Hegazy, 1994).

El-Sawy, Abdel Hay, and Badawy, (2010) found that males started drug abuse at an earlier age than females, with a longer duration of addiction, and that single males were more vulnerable to abuse than females. Gad, El-Dod, Eissa, El-Sawi, and El-Fadaly (2004) found that female marijuana addicts were similar to males in causes of first use, negative consequences, and mood disorders, except that cognitive decline was higher in males than females. Demographics play such an important role in the discrepancy of drug abuse trends because of the kind of schools, financial level, and clubs availability are important factors in limiting the spread of drugs in the countryside among the young (Albaghdady, 2002).

Soueif and Abdel-Monem (2004) found that the percentage of males who abused cannabis was higher in urban (55.3%) than in rural areas (44.4%). The percentage increased in married persons, rather than in single ones. The authors suggested that marriage involves some kind of hardship. It involves new events and responsibilities that might make married couples more prone to abuse. Skillful workers and commercial workers constituted the highest percentage of abusers (45.3%), whereas the number of agricultural workers who abuse cannabis was significantly lower (23.8%). Finally, cigarette smoking appeared to increase the likelihood of drug abuse, especially at early ages, as 79.7% of abusers were intensive cigarette smokers (of which 18.4% smoke 40 cigarettes or more), compared to 49% of nonabusers. Smokers were thus more vulnerable to drug culture than nonsmokers (Fig. 12.3)

INITIATION OF DRUG/CANNABIS ABUSE

Marijuana use typically starts in adolescence. The mean age of first use in the 1993 survey done among the Egyptian population was 16 years, among them 11.2% reported using cannabis only, while 12.4% used alcohol, and 32.7% turned to psychiatric drugs, where 26% of them preferred to use sedatives and tranquilizers. In the survey performed in 2000 on a representative sample of general population, the mean age of starting abuse was 19.8 ± 6.9 years for the male population in Lower Egypt, and 21.6 ± 6.7 years for males in Upper Egypt. Meanwhile, the females in Lower Egypt usually started drug abuse at the age of 22.3 ± 6.8 years (Soueif et al., 1990).

The drug experience usually begins out of curiosity, in addition to peer-pressure, which plays a major role. Obtaining the information about drugs and their effects through schoolmates, friends, and relatives increases the urge to undergo the experience. Furthermore, giving the sons a high monthly stipend, besides the prevalence of smoking as a socially accepted behavior, encourages the experimentation of drugs, especially cannabis, in the form of smoked marijuana (bango) joints commonly found between teenagers (Soueif et al., 1990). Social occasions or the company of friends mostly accounted for the first use of cannabis, but coping with psychological or physical discomfort, or stress-triggering situations were the reasons for initiating psychotropic substance use (Soueif et al., 1986). Entertainment on happy social occasions was the main reason for drug use (mostly hashish) among secondary school students. Sedatives and hypnotics were next to hashish, but used to overcome physical exhaustion, fatigue, and to cope with psychosocial problems, the stress of studying and examinations, or difficult working conditions (Soueif, 1994).

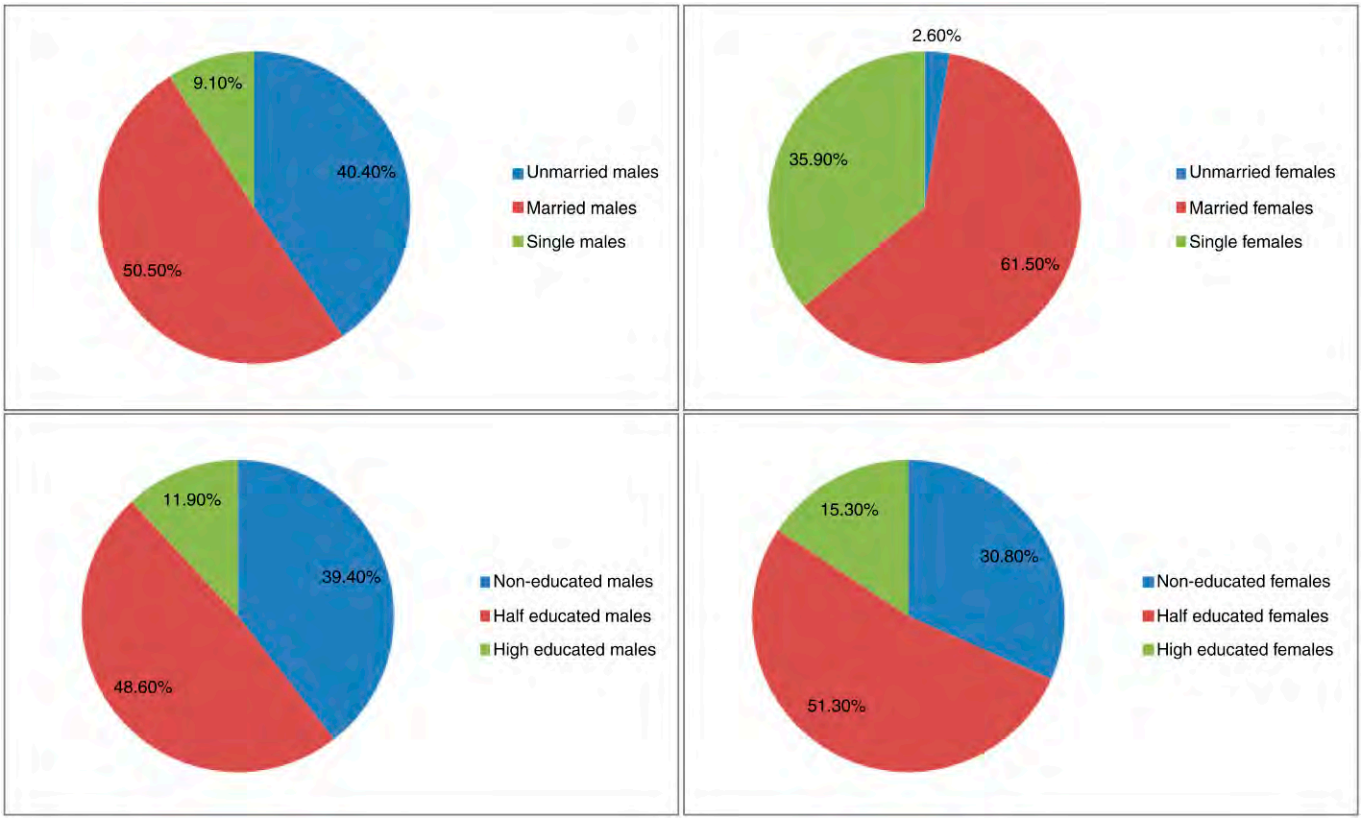

FIGURE 12.3 Relevance of cannabis use to educational level and marital status in Lower Egypt. Cannabis use increases in married and in medium educated subjects. *Source: Data from Hegazy (1994) and Albaghdady (2002).*

Among technical secondary schools students, the first experimentation with narcotics was during social occasions (51.6%) or friends' gatherings (23.6%). Other reasons were satisfying certain motives (experience, imitating, and outlook), and facing psychological stress (Soueif et al., 2000). Among university students, pleasure and euphoria, but also in order to cope with social stress, were the reasons for continuing drug abuse (Soueif, 1995). Other workers found that peer pressure was the most common motivating factor for drug abuse in males, in contrast to family troubles and sexual abuse in females. Other motivations, such as anxiety disorders, were more common in males while depressive disorders were more common in females (El-Sawy et al., 2010). There was also a strong association between exposure to drug culture and drug taking (Soueif et al., 1990) (Table 12.3).

CIGARETTE SMOKING AND CANNABIS

The rate of cigarette smoking among high school students reached 11.4% (16% in urban areas and 8% in rural areas), and 18.4% of technical high school students. The rate of cigarette smoking seemed relatively constant since 1987, which had a ratio of 10.77, and reached 10.8% in 1993 (Soueif, Taha, Gomaa, Makarem, & Amer, 2000). This established fact explains how teenagers and high school students could be easily drawn to cannabis use having the acquaintance of cigarette smoking. Tobacco cigarette smoking was the main entrance to drug abuse, where studies have shown that the percentage of drug addicts among cigarette smokers is higher than that of nonsmokers (Darweesh, 1982).

SOCIAL AND ECONOMIC FACTORS

The social and economic disruptions that took place in the 1990s in Egypt, where certain social categories rose up, together with the deterioration of the economic status and decreased standard of living of other categories, have resulted in alterations of the prevailing values in society, where the moral inherent values were replaced by luxury consumptive values (Helal, 2002). This disruption evoked psychological and social conflicts that encouraged pathological behavioral patterns, such as addiction, and ultimately contributed to increased mobility of the drug market among young people in Egypt (Albaghdady, 2002).

Social studies have also suggested that the economic crisis and the growing unemployment among youth in general, and the well-educated ones in particular, caused negative feelings and frustration that stimulated the

TABLE 12.3 Drug Abuse Pattern Among Different Categories in Egypt

Category	Hashish (%)	Bango (%)	Opiates (%)	Tramadol (%)	Heroin (%)	Stimulants (%)	Sedatives (%)	Alcohol (%)	Study
University students	34.4		7.9	10.8	5.5	11.5	9.6	18.4	Soueif (1995)

Patients with drug overdose	3.6			1.8					Amr et al. (2014)

Hashish and bango (marijuana) account for high proportion of abused drugs, though tramadol abuse is increasingly growing.

resort to another world, where dreams come true, and where they seek the absent happiness (Helal, 2002).

Soueif (1995) identified unhealthy family environment as a major factor for hashish addiction. There was also a positive correlation between high monthly income (and consequently high student pocket money) and abuse. High income encouraged families to respond to all financial demands of their children, encouraging them to break ethical standards. Studies among drug abusers and addicts in prisons and hospitals revealed a correlation between drug abuse and some family problems, such as the mother's work, and failure of the father to satisfy the family's needs, thus thinking of drugs as a means of escape (Soueif et al., 1990). Studies have suggested, in addition, an important role for the media in spreading drugs, with drug dealers and takers are portrayed as glamorous and living in luxury while negative effects are ignored (Hegazy, 1994).

MINI-DICTIONARY

Chibouque A Turkish tobacco pipe with a mouthpiece often made of amber
Feddan Land unit that equals about 4200 square meters.
Goza A water pipe where the tobacco smoke passes through water prior to inhalation.
Hashish or hasheesh The dried resinous exudate of the tops of the cannabis plant.
Lower Egypt Northern Egypt, from Cairo and Giza to the Mediterranean Sea.
Marijuana or bango The dried leaves and flowering tops of the cannabis plant.
Shisha A waterpipe that differs slightly in design from goza, with a longer tube.
Upper Egypt South of Cairo and Giza to the border with Sudan.

Cannabis Body Packing: A Caribbean Perspective

S.O. Cawich, D. Dan, V. Naraynsingh

Department of Clinical Surgical Sciences, University of the West Indies, St Augustine Campus, St Augustine, Trinidad and Tobago

SUMMARY POINTS

- This chapter gives an overview of cannabis body packing, including its consequences and complications.
- There has been a change in the demographics of the body packer in the Caribbean, with the majority of packers being young males.
- The practice brings significant potential earnings, with earnings of up to US$10,000 per successful trip.
- There are several potential complications recorded, including bowel obstruction, intestinal perforation, and potential mortality, although no deaths from acute toxicity have been reported.
- There is an urgent need for legislation to be developed to protect healthcare workers in these environments when treating body packers.

KEY FACTS OF CANNABIS BODY PACKING IN THE ANGLOPHONE CARIBBEAN

- The Anglophone Caribbean consists of 17 English-speaking nations in the Caribbean basin, with a cumulative estimated population of 6,426,914 persons.
- All Anglophone Caribbean nations adhere to the United Nations Convention on Narcotic Drugs (1961) that requires the government to criminalize cannabis.
- To meet the demand for the drug in developing countries smuggling is commonplace.
- Body packing is a common method of smuggling cannabis across international borders, and is epidemic in the Caribbean.
- The average body packer transports 1 kg of a drug, and can earn up to US$10,000 for each successful trip.
- The practice is accompanied by several potential complications, including intestinal obstruction, and colonic perforation.

LIST OF ABBREVIATION

Δ^9-THC Δ^9-Tetrahydrocannabinol

INTRODUCTION

Cannabis consumption is commonplace across the globe. It has been estimated that up to 40% of persons in the Caribbean have used some form of cannabis, with usage transcending all gender, social, economic, and educational groups (Jefferson, Harding, Cawich, & Jackson-Gibson, 2013; Boekhout van Solinge, 1996). It is commonly used to induce euphoria (Iversen, 2003; Chait & Pierri, 1992), promote meditation (Jefferson et al., 2013), heighten perception and cognition (Hollister, 1986), increase visual acuity (Jefferson et al., 2013), enhance physical performance (Hollister, 1986), temper anxiety (Jefferson et al., 2013), and relieve chronic pain (Hohmann & Suplita, 2006; Mackie, 2008).

Although there has been a thrust to legalize cannabis over the past few decades, it is still considered illegal

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00014-4

in many nations across the globe. The high demand for cannabis and simultaneous prohibition of its distribution by most legal systems fuels the illegal drug trade, and increases the opportunities for smuggling (Cawich, Williams, Simpson, Evans, & Johnson, 2008; Traub, Hoffman, & Nelson, 2003; East, 2005).

BODY PACKING AS A MEANS OF SMUGGLING

A common method of drug transportation is for smugglers to ingest packages containing contraband drugs in order to avoid detection by authorities (Cawich et al., 2008; Traub et al., 2003). Most ingest multiple packages, usually averaging about one kilogram net weight (Traub et al., 2003). In the early years, crude packaging methods were encountered, including plastic wrap (Traub et al., 2003; East, 2005), aluminum foil (Cawich et al., 2008), and condoms (East, 2005). But as the trade matured, we have encountered more sophisticated packaging in our practice in the Caribbean (Fig. 13.1).

Several names have been ascribed to this practice including "body stuffing," "body packing," or internal concealment. The smugglers are commonly called "body packers," "swallowers," or "drug mules." The packers transport their cargo to the delivery points, often using commercial transportation (Cawich et al., 2008). Upon arrival at their destination, laxatives, cathartics and/or enemas are used to expedite delivery of the cargo (Cawich et al., 2008; Traub et al., 2003; East, 2005).

DEMOGRAPHICS OF THE DRUG TRADE

The tropical climate in the Caribbean and Latin America is conducive to outdoor growth of cannabis. Although it is consumed in these developing nations, cannabis has significantly greater resale value in developed countries. Therefore, there is a steady stream of cannabis and other illegal drugs flowing toward developed countries in North America and Europe (Cawich et al., 2008). The developing countries in the Caribbean and Latin America make ideal transshipment points (East, 2005; Simon, 1990; De La Haye, 2004a; Cawich, Valentine, Evans, Harding, & Crandon, 2009; De La Haye, 2004b) along this drug stream because they offer opportunities for: (1) restocking/refueling when traversing long distances, (2) convenient redistribution of product, (3) increased availability of packers, and (4) reduced detection if packers are seemingly originating from "safer" destinations.

Although they are encountered across the globe, most packers originate from underdeveloped countries with high poverty rates (East, 2005). The practice has reached epidemic proportions in the Caribbean, as evidenced by the British High Commission's report that there are approximately 30 body packers traveling on every flight from Kingston to London (Cawich et al., 2008), and the

FIGURE 13.1 **Multiple types of packaging from pellets extracted from drug packers.** The figure demonstrates the range of packaging used by body packers.

United States Drug Enforcement Agency's report that Jamaica alone is responsible for 30% of cocaine smuggled into the United States (Cawich et al., 2009a).

Several factors contribute to the popularity of body packing in the Caribbean. Many of the territories are classified as low- or middle-income countries, and they do not have sufficient resources to devote to continuous drug surveillance. Many are underpopulated, or have their populations concentrated in clusters, leaving abundant isolated land space for unimpeded drug-related activities. Additionally, Latin American and Caribbean countries are notorious for administrative corruption (Collier, 2002) and gang activity, making the atmosphere ripe for drug-related activities.

These countries have a large population of impoverished persons, with high levels of unemployment (Cawich et al., 2008). The drug trade organizations target these individuals using the lure of enormous financial rewards (Cawich et al., 2008; Traub et al., 2003; East, 2005; Simon, 1990; De La Haye, 2004a). For obvious reasons, accurate figures are not available, but it has been reported that body packers can earn between US$2,000 and US$10,000 for one successful trip (Cawich et al., 2008; De La Haye, 2004a; Cawich et al., 2009a; De La Haye, 2004b). The lure of rapid, large earnings is sufficient for impoverished individuals to volunteer as packers, despite the knowledge of legal consequences if caught (Cawich et al., 2009a).

DEMOGRAPHICS OF THE BODY PACKER

The typical demographics of body packers have been extensively researched. The information is commonly used by antidrug task forces to facilitate passenger profiling in order to select suspicious individuals at airports and borders, for detailed searches (Cawich et al., 2009a).

In the latter 20th century, the majority of the detained body packers were single females from underprivileged backgrounds, usually with multiple dependents (Traub et al., 2003; East, 2005; De La Haye, 2004a). Once drug traffickers appreciated that authorities were utilizing passenger profiling as one means of detecting body packers, they responded by hiring packers who did not fit these profiles. We then saw a change in packer demographics in the Caribbean, with more young men (mean age 34 years) becoming body packers (Cawich et al., 2009a). Male offenders have now become significantly more prevalent, with a 4:1 male to female ratio (Cawich et al., 2009a).

LEGAL CONSIDERATIONS

Body packing is an illegal practice. Even the body packers are aware of the potential of legal consequences, including incarceration (Cawich et al., 2008). However, they may choose to take the risk because they view the likelihood of being detected lower that the potential for large earnings after they deliver the drug. Antidrug task forces are fully aware of this practice, and maintain surveillance programs at many points of emigration, in an attempt to stem trafficking (Lancashire, Legg, Lowe, Davidson, & Ellis, 1988). They heavily publicize all antidrug trafficking efforts, in an attempt to make the population aware of their activity, and of the likelihood of detection (Cawich et al., 2009a). This resulted in a consistent decline in the number of body packers detected at ports of origin in Caribbean countries, as well as their destination in countries at the turn of the 21st century (Cawich et al., 2009a).

On the other hand, many packers are aware that the impact of cannabis possession and trafficking may not be taken as seriously as other contraband drugs. To illustrate the point, Wikipedia reported that in several countries possession is "illegal but tolerated" (Wikipedia Reports, 2014). To further illustrate the point, many Caribbean countries have laws that are so antiquated that it may actually be worth the risk even if a packer is caught. Currently, any person convicted of "exporting or taking steps preparing to export ganja" before a Circuit Court in Jamaica is liable to "a fine not less than $500.00" (US$5.65 equivalent) per ounce of marijuana, "or imprisonment for a term not exceeding 35 years," Laws of Jamaica; Section 7A;1(b):1994(30)S3b (Government of Jamaica, 2014). Considering that the average drug mule ingests 1 kg (35.27 ounces) of marijuana, the monetary penalty for a convicted marijuana drug mule will only be US$199.28.

CLINICAL CONSIDERATIONS: SYMPTOMATIC PATIENTS

Apart from being illegal, body packing may be dangerous from a clinical perspective. Several complications may occur, including mechanical bowel obstruction from impacted pellets, intestinal perforation, or acute drug toxicity from ruptured packaging. These are all potentially fatal conditions.

Body packing is not unique to cannabis. In fact, reports of cannabis body packing are much less common (Cawich et al., 2010) than with heroin (Jill & Graham, 2002; Hutchins et al., 2000; Sribanditmongkol, Supasingsirpreecha, Thampitak, & Junkuy, 2006; Soriano-Perez, Serrano-Carrillo, Marin-Montin, & Cruz-Caballero, 2009) and cocaine (Traub et al., 2003; East, 2005; Khan, 2005; Simon, 1990; Cawich et al., 2009a). The reason is simple economics. The potential financial return from the same quantity of drug is significantly greater with cocaine and heroin, than it would for cannabis (Cawich et al., 2009a). Consequently, more reports of complications from heroin and cocaine body packing exist.

Acute Toxicity

Although it has become less common with the use of second-generation packaging (Cawich, Williams, Evans, & Johnson, 2009; Pidoto et al., 2002), there is still a risk of acute drug toxicity if the ingested packets rupture, exposing the drug to the large absorptive mucosal surface of the gut. Rupture is potentially fatal when the packages contain cocaine (Jill & Graham, 2002; Koehler et al., 2005; Norfolk, 2007) or heroine (Hutchins et al., 2000; Sribanditmongkol et al., 2006), but we could find no reports of deaths from acute toxicity with cannabis packet rupture, in medical literature. Even in medical literature, many consider cannabis a "soft drug" (Nahas & Latour, 1992) because of the absence of "life-threatening effects no more damaging than coffee or tobacco" (Hollister, 1986).

Package rupture will expose the packer to the psychoactive constituent of cannabis, Δ-tetrahydrocannabinol (THC). This compound produces many central nervous system effects: altered behavior, cognition, perception, and performance (Stadmauer, Beyer, Bardina, & Sicherer, 2003), heightened senses resulting in euphoria with distorted time–space perception (Boekhout van Solinge, 1996), impaired memory, complex problem solving, and motor function (Hollister, 1986; Stadmauer et al., 2003). There are also cardiovascular effects including transient sinus tachycardia and orthostatic hypotension (Jones, 2002; Wu, Tashkin, Djahed, & Rose, 1988). The effect of THC on an individual is unpredictable (Jefferson et al., 2013; Hollister, 1986; Aggarwal et al., 2009). Many factors determine the individual user's response, including the user's baseline personality, current psychological state, previous cannabis use, and the quantity of THC ingested (Hollister, 1986), but there has never been a reported case of fatality that can be directly attributed to THC overdose.

Bowel Obstruction

Bowel obstruction is the commonest complication encountered with cannabis body packing. This occurs when large indigestible pellets become impacted at areas of luminal narrowing, especially at the pylorus and the ileocecal valve (East, 2005). These patients present with cardinal features of mechanical bowel obstruction: colicky abdominal pain, abdominal distention, vomiting, constipation, and/or obstipation.

The diagnosis may be suspected when patients divulge the history of "packing," but it is well recognized that these patients are unreliable and deceptive historians (Cawich et al., 2008). Many cases, therefore, are only detected when obturated pellets are seen on imaging. The pellets are easily detected on plain radiographs in 80–90% of cases (Traub et al., 2003; Hergan, Kofler, & Oser, 2004; Beerman, Nunez, & Wetli, 1986), as demonstrated in Fig. 13.2. Contrast studies and computed tomographic scans (Hierholzer et al., 1995; Marc et al., 1990) are reserved only for cases with diagnostic uncertainty.

FIGURE 13.2 **Plain abdominal radiograph of the abdomen of a confirmed cannabis body packer.** This X-ray shows the classic findings seen in body packing: multiple elongated sausage shaped radioopacities with regular, smooth, rounded edges.

Mechanical obstruction from pellet obturation should be treated operatively. The pellets are extracted through enterotomies by a laparoscopic or open approach. Many authorities frown on the prospect of endoscopic retrieval (East, 2005; Mandava, Chang, & Wang, 2011) since there is a greater risk of package rupture when they are handled with endoscopic instruments. While there are no documented cases of deaths from THC toxicity, there is no way to tell what the pellets contain until they are retrieved and forensically examined. And, with "packers" recognized to be deceptive historians (Cawich et al., 2008), surgeons should be wary of the packer's account of the content.

Intestinal Perforation

Impacted pellets may place mechanical pressure on the intestinal wall leading to perforation and intraabdominal sepsis. This is the rationale behind emergent surgical management in cases of mechanical obstruction. Intraabdominal sepsis is not uncommon because many "packers" present to hospital late. These patients require emergent laparotomy to achieve peritoneal toilet, control contamination, and seal the perforation. Supplemental antibiotics and supportive management are also required.

Medical literature contains several reports of mortality from intestinal perforation when body packers attempted to transport heroin (Hutchins et al., 2000; Sribanditmongkol et al., 2006) and cocaine (Jill & Graham, 2002; Koehler et al., 2005; Norfolk, 2007), but there have only been two reported deaths from colonic perforation due to cannabis body packing (Cawich et al., 2010; Barnett & Codd, 2002). Although most authorities suggest that colonic pellets are less dangerous than small bowel and gastric pellets (East, 2005), it is interesting that both reported deaths from intestinal perforation with cannabis body packing were due to colonic perforations (Cawich et al., 2010; Barnett & Codd, 2002).

ETHICAL CONSIDERATIONS

Cannabis body packers may present to clinicians in one of three ways (Cawich et al., 2008):

- symptomatic packers with one of the complications detailed previously;
- asymptomatic packers detained by law enforcement agents;
- asymptomatic packers seeking medical attention on their own.

Persons who engage in body packing are usually fully aware of the potential medical and legal consequences, and take a calculated risk to engage in this practice (Cawich et al., 2008). The symptomatic packers are usually very cooperative with medical personnel because they are fearful of the potential mortality that they believe the medical team may be able to prevent. Admittedly, mortality from acute overdose has never been reported from THC, but multiple deaths from acute overdose with cocaine have been reported (Cawich et al., 2008; East, 2005; Marc et al., 1990; Ambre et al., 1988; Gay, 1982) and >50% of the patients with free rupture dying before reaching hospital (East, 2005; Cawich et al., 2009b; Schaper, Hofmann, Ebbecke, Desel, & Langer, 2003). The patients are not aware of the difference, and are only cognizant of the fact that complications during packing can cause death. Patients who seek medical attention on their own tend to be cooperative as well because they have presented to hospital with a genuine desire for medical assistance.

On the other hand, packers who are asymptomatic when detained tend to be uncooperative with medical teams (Cawich et al., 2008) because they are cognizant of the legal consequences, and wish to conceal the evidence as long as possible. Ironically, these are the easiest patients to manage from an ethical perspective because it is clear that they have already been identified, detained, and will face legal consequences. This removes any potential for blame from being ascribed to the physician teams. In this case, the physician's responsibility is to confirm the diagnosis with imaging (Cawich et al., 2008; Traub et al., 2003; Hergan et al., 2004; Beerman et al., 1986; Hierholzer et al., 1995; Marc et al., 1990), and to be vigilant in the event that a complication occurs (Cawich et al., 2008; East, 2005). Body packers have the right to refuse any examination or investigation (Cawich et al., 2008), and when this occurs they are treated expectantly until the pellets spontaneously pass. Laxatives, high fiber diets, clear fluid diets and suppositories can be administered, but their benefit remains unproven (Das, Baha, & Mackway-Jones, 2003).

While the detained patients are straightforward to manage, it is the asymptomatic body packers that pose a serious ethical dilemma from two points of view: reporting and drug disposal. Most countries do not have legislation in place to mandate reporting body packers to the authorities. The decision is many times left up to the attending physicians (Cawich et al., 2008), who often have mixed views on reporting. Many persons believe that there is insufficient reason to override patient–physician confidentiality solely on the basis of the crime committed, or the amount of illicit drugs involved (Traub et al., 2003; Khan, 2005; East, 2005), unless there has been a credible threat of violence (Cawich et al., 2008).

In 2003 the United States Department of Health and Human Services implemented the Health Insurance Portability and Accountability Act, Public Law 104-191 (Kreismann, Gang, & Goldfrank, 2006). It states that "healthcare providers are permitted, but not required

to, disclose protected health information without the patient's permission" to the authorities, in order to "undertake an enforcement action." This includes data regarding "federally regulated products or activities," and "to inform law enforcement about the commission, nature, location, victims, and perpetrator of any crime" (Kreismann et al., 2006). This is still subject to interpretation.

There are no comparable regulations in Caribbean countries where body packing is rampant (Cawich et al., 2009b). The decision to disclose is made on an individualized basis, depending on the physician's ethical viewpoint, and guided by hospital policies. This places the physician in a precarious position because, in small communities, as would exist in Caribbean countries, it is known that reporting is not mandatory (Cawich et al., 2009b). The drug lords are usually aware of this fact, and they may view sporadic reporting as a hostile action deserving violent protest (Cawich et al., 2009b). Motive is easy to appreciate, since the healthcare team's actions separate the drug lord from their valuable product. This type of intimidation puts enormous pressure on the healthcare team, who are usually unprepared (Cawich et al., 2009b). The importance of this is highlighted by recent reports that some Caribbean countries rank among the top ten countries worldwide for homicides, 50% of which were reprisal and drug related murders (Lemard & Hemenway, 2006).

Another problem arises with unreported cases when it comes to handling the extracted drugs. Many hospitals have policies to address the issue that usually involve hospital security officers confiscating the drug, and their disposal by a pharmacist (East, 2005; Cawich et al., 2009b). But the "unauthorized" disposal of this expensive product may again be viewed as antagonistic, especially in small developing countries where drug lords can monitor these actions (Cawich et al., 2009b).

SECURITY CONSIDERATIONS

Incarcerated offenders pose the least security concerns as they are already guarded by police officers. Asymptomatic patients who have not been detected by law enforcement, however, pose a security concern. Although hospital security officers guard these patients in the absence of law enforcement agents, they are not equipped for this. Often they cannot prevent the packers from leaving the hospital, or protect hospital staff from intimidation by drug lords (Cawich et al., 2009b).

There have been instances of healthcare worker intimidation from drug lords and their affiliates. Obviously, this has great impact on the doctors' management decisions, as well as any decision to report to the authorities, and even handling of the extracted drugs. The medical teams can find themselves in a moral dilemma between being coerced to comply with drug lords' instructions (Cawich et al., 2008), and taking the decision to follow the law at the risk of their personal security. This is put into perspective when we consider that some Caribbean territories are among the world's top five countries for homicide rates, 50% of which were reprisal or drug-related killings (Lemard & Hemenway, 2006).

MINI-DICTIONARY

Body packing The practice in which a smuggler ingests drug-filled packages in order to transport the drug without detection by authorities.
Body stuffing The practice in which a smuggler ingests drug-filled packages in order to transport the drug without detection by authorities.
Drug toxicity Rapid exposure to the median lethal dose of a drug.
Internal concealment The practice in which a smuggler ingests drug-filled packages in order to transport the drug without detection by authorities.
Intestinal perforation Rupture of the wall of the intestine resulting in contamination, intraabdominal sepsis, and potential mortality.
Mechanical bowel obstruction The absence of aboral flow of intestinal contents due to the presence of a mechanical blockade.
Smuggling Transportation of illegal substances across an international border, in violation of regulations.
Tetrahydrocannabinol (THC) The main psychoactive component of the cannabis plant.

CHAPTER

e1

Tetrahydrocannabinol Concentration and Genetic Characterization of Cannabis

F. Cascini, I. Boschi

Public Health Institute, Department of Forensic Medicine, Università Cattolica del Sacro Cuore, Rome, Italy

SUMMARY POINTS

- The species *C. sativa* L. includes varieties suitable for recreational and therapeutic purposes (commonly named marijuana or simply cannabis), as well as varieties appropriate for industrial use only (usually named hemp).
- Published studies show the total content of THC or CBD found in the plant material generally corresponds to the sum of its free form, and its respective acidic precursor.
- According to total THC and total CBD contents, three main chemotypes (chemical phenotypes) of cannabis have been recognized.
- The absolute THC content (quantitative chemotype) reflects polygenic genetic mechanisms showing Gaussian distributions in progenies and populations being strongly subject to environmental factors.
- The CBD/THC ratio (qualitative chemotype) is controlled by simple mendelian genetic mechanisms.
- Some authors found the upregulation of cannabinoid pathway genes, and the exclusive presence of functional THCA-synthase in the genome and transcriptome of high-THC plant strains/varieties.
- The correlation between the quantity of the THCA synthase gene and the production of THC appeared to be random and variable, in high and low potency varieties of *Cannabis*.
- To date, a great part of genetic research on *Cannabis* has been focused on molecular techniques and markers to distinguish high-THC (drug-type) from low/absent-THC (fiber-type) varieties.
- The function of genetic markers is threesome: evaluation and distinction of cannabis varieties, application in order to facilitate the use of *Cannabis* for therapeutic purposes and, concurrently, an effective monitoring tool of the illegal market.
- Advances in molecular genomics are providing genetic maps that could permit marker-assisted breeding.

KEY FACTS OF THC CONCENTRATION IN CANNABIS

- Different destinations and uses of *Cannabis* plants are related to the biological capacity of each variety or strain to synthesize cannabinoids, hence dividing drug-type from fiber-type varieties/strains.
- The amount of the main active cannabinoid Δ^9-tetrahydrocannabinol in the plant naturally depends on the influence that factors such as genotype, plant age, and environment have on the biosynthesis of cannabinoids.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00003-X
Copyright © 2017 Elsevier Inc. All rights reserved.

- Cannabinoids have been found in all tissues of the plant, but the amount in which they are present differs considerably among the tissues: they are most abundant in flowers (female plant), and especially in the glands.
- The storage cavity of glandular trichomes of the cannabis plant would not only be the site for the accumulation of cannabinoids, but also the site for THCA biosynthesis.
- Flowering tops and leaves of female plants belonging to drug type strains are traditionally known to have a THC level rarely exceeding 5%, while significantly higher THC concentrations in cannabis have been recently documented in the literature.
- The availability of a more THC-concentrated form of cannabis could cause an increase in the total amount of THC consumed, with foreseeable consequences for public health.
- Scientific research on *Cannabis* is trying to explain, through chemical and genetic investigations, the biological processes behind the differences in cannabinoids levels among varieties.

LIST OF ABBREVIATIONS

AFLP	Amplified Fragment Length Polymorphism
CBC	Cannabichromene
CBCA	Cannabichromene acid
CBD	Cannabidiol
CBDA	Cannabidiolic acid
CBG	Cannabigerol
CBGA	Cannabigerolic acid
ISSR	Inter-Simple Sequence Repeat
ITS	Internal Transcribe Spacer
RAPD	Random Amplified Polymorphic DNA
STR	Short Tandem Repeats
THC	Tetrahydrocannabinol
THCA	Tetrahydrocannabinolic acid

INTRODUCTION

Cannabis sativa L. (commonly called *Cannabis*) is a herbaceous plant belonging to the *Cannabis* genus, family of Cannabaceae. It is normally a wind-pollinated, dioecious herb, which means that male and female reproductive structures are on separate plants, although monoecious plants can occur in some populations (Divashuk, Alexandrov, Razumova, Kirov, & Karlov, 2014).

The *Cannabis* genus includes wild and cultivated forms that are morphologically variable, resulting in confusion and controversy over the taxonomic organization: some authors have proposed a monotypic genus, *C. sativa*, while others have argued that *Cannabis* is composed of two species, *C. sativa* and *Cannabis indica*, and some have included a third species, *Cannabis ruderalis*, in the genus (Hillig, 2005).

Beside this taxonomic uncertainty, the species *C. sativa* L. includes varieties suitable for recreational and therapeutic purposes (commonly named marijuana, or simply cannabis), as well as varieties appropriate for industrial use only (usually named hemp). This feature depends on the constitution of each *Cannabis* variety or strain to synthesize and store chemicals known as cannabinoids. They represent a group of more than 100 natural products (Elsohly & Slade, 2005; Mehmedic et al., 2010) within which tetrahydrocannabinolic acid (THCA) is the main (psycho)active compound.

CANNABINOIDS BIOSYNTHESIS

Tethraydrocannabinolic acid (THCA) and cannabidiolic acid (CBDA) are from the same precursor cannabigerolic acid (CBGA). THCA-synthase enzyme or CBDA-synthase enzyme are responsible for the synthesis of THCA or CBDA, respectively (Fellermeier & Zenk, 1998; Fellermeier, Eisenreich, Bacher, & Zenk, 2001; Raharjo et al., 2004a; Taura, Morimoto, & Shoyama, 1995, 1996; Thakur, Duclos, & Makriyannis, 2005).

Cannabinoids are actually biosynthesized in a carboxylated form in plant tissues. Then, they are progressively decarboxylated to THC and CBD by drying, and especially under intense heating, such as when cannabis is smoked (Dussy, Hamberg, Luginbühl, Schwerzmann, & Briellmann, 2005) while, in vivo, this conversion appears to be limited (Jung et al., 2009).

Almost no neutral cannabinoid can be found in fresh plant material. The carboxyl group is not very stable, and easily lost under the influence of heat or light, resulting in the corresponding neutral cannabinoids. However, the total content of THC or CBD found in the plant material generally corresponds, in published studies, to the sum of the free cannabinoid and its respective acidic precursor.

Cannabinoids have been found in all tissues of the plant, but the amount in which they are present differs considerably among the tissues (Fetterman, Doorenbos, Keith, & Quimby, 1971): these chemicals are, in fact, most abundant in flowers (female plant), especially in the glands. This raises the question of whether biosynthesis of cannabinoids occurs in all tissues but in different quantities, or only in one tissue, implying the following transfer to other tissues. In both scenarios, the expression level of the genes involved in the cannabinoids biosynthesis would be different among the tissues. On this topic, Raharjo et al. (2004b) identified that some proteins in *Cannabis* are expressed more in flowers than in the leaves.

FIGURE e1.1 Resin drops and glandular trichomes of resin-type cannabis. The drops of resin containing THC are visible in the picture, and appear at the stage of maturity of the plant. The secretory cells of glandular trichomes are believed to secrete cannabinoids that are then accumulated into the storage cavity of these glands.

However, in the comparison of the proteome of leaves and flowers they did not find proteins involved in cannabinoid biosynthesis. They moved to a more specific part of the flower, the glands, where the levels of cannabinoids are the highest. They also found that THCA synthase, CBDA synthase, and CBCA synthase enzymes, involved in the cannabinoid biosynthesis, are expressed at very low levels even in the glands. Biochemical processes concerning cannabinoids biosynthesis and storage in selective tissues then remained uncertain.

On the other hand, Sirikantaramas et al. (2005) suggested a sorting pathway for THCA synthase from secretory cells into the storage cavity, meaning that the glandular trichome (Fig. e1.1), believed to secrete small molecules such as resinous compounds or volatile oils, can also secrete biosynthetic enzyme. Therefore, the storage cavity of glandular trichomes of the *Cannabis* plant would not only be the site for the accumulation of cannabinoids, but also the site for THCA biosynthesis. This hypothesis has not been further investigated in *Cannabis*.

However, a different tissue-specific DNA banding could also be possible. It has been actually identified in plants (Donini, Elias, Bougourd, & Koebner, 1997), and this is not overly surprising, due to the selective amplification or mutation of genes during tissue development.

The studies previously cited (Fellermeier et al., 2001; Raharjo et al., 2004a; Thakur et al., 2005) demonstrate that significant efforts have been made by the scientific community to understand the cannabinoids biosynthetic pathways. This topic raises more interest and curiosities, if we consider that the cannabis market is changing worldwide toward an increasing level of drug potency. A literature review (with metaanalysis by year), based on 21 studies containing 75 total mean THC observations from 1979 to 2009 (Cascini, Aiello, & Di Tanna, 2012), have shown a significant correlation between year and mean THC in cannabis, revealing a temporal trend of increasing potency (5% above the mean THC value in the Poisson regression analysis), although this increase is not constant, and does not exceed 5% globally (Figs. e1.2 and e1.3). However, it would be right to consider a 200% increase of potency over the years, possibly due to the rising market of intensively grown indoor cannabis.

Amounts and ratios of cannabinoids determine the chemical phenotype of the plant and its unique pharmacological properties, including analgesic, antiemetic, and

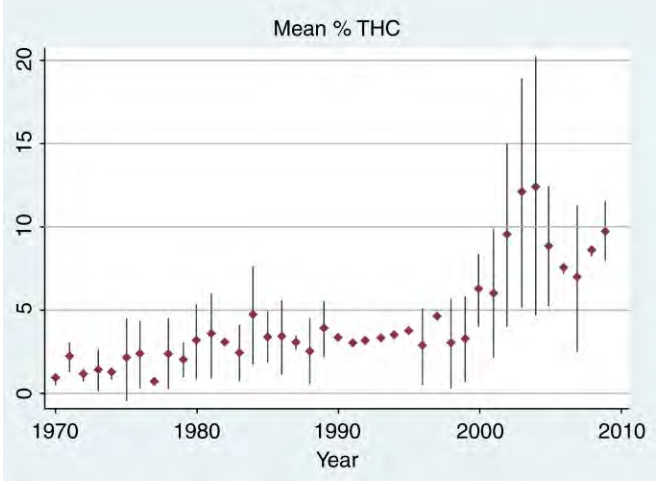

FIGURE e1.2 Per year metaanalysis graph showing the mean THC value with 95% CI. Metaanalysis was performed by year on 75 total mean THC observations from 1970 to 2009, using the random effect model. Metaregression was performed on the same dataset, using the year as the covariate. The results revealed great variability within studies (I2 = 99.91%) and a significant association (from the metaregression) (p value < 0.0001) between the mean THC in herbal cannabis and year (coef. 0.214; 95% CI = 0.163–0.266). *Source: From Cascini et al. (2012a).*

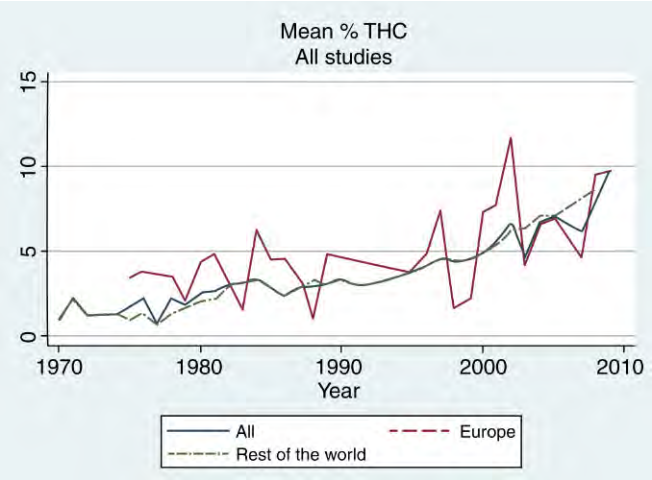

FIGURE e1.3 Time trend of the mean THC value for all samples and disaggregated by zone. The combined data from the 21 studies included in the metaanalysis indicated an increasing temporal trend in potency; the Poisson regression suggested an average increase in the mean THC value of 4.694% (95% CI 3.129–6.283). This rise in mean THC seems to have been more rapid in the last decade. Analysis of the trend, according to geographical zone, indicated a smaller increase in Europe (2.799%, 95% CI 1.157–4.467; significant at p = 0.001) compared to the rest of the world, almost totally represented by the United States (5.279%, 95% CI 3.590–6.996), but this may reflect the fact that the data from Europe started with a higher mean THC. *Source: From Cascini et al. (2012a).*

appetite-stimulating effects. The chemical phenotype naturally depends on the influence that factors such as genotype, age of the plant, and environment exercise on the biosynthesis of cannabinoids.

CANNABIS GENOME

Cannabis has a diploid genome ($2n = 20$) with a karyotype composed of nine autosomes and a pair of sex chromosomes; female plants are homogametic (XX), and males heterogametic (XY), with sex determination controlled by an X-to-autosome balance system (Ming, Bendahmane, & Renner, 2011). The genome size ranges from 0.84 to 0.91 pg: the estimated size of the haploid genome is 818 Mb for female plants, and 843 Mb for male plants, owing to the larger size of the Y chromosome (Sakamoto, Akiyama, Fukui, Kamada, & Satoh, 1998). Divashuk et al. (2014), using modern cytogenetic methods, characterized the karyotype of male and female *C. sativa*, allowing to identify it in early developmental stages of the plant. Furthermore, karyotype analysis of chromosomes suggest that the X chromosome is submetacentric, and the Y chromosome is subtelocentric, with a satellite at the terminus of its short arm.

Other lines of genetic research on *Cannabis* have also been evaluated over time to establish genetic relationships, as well as to highlight genetic differences among plant varieties (with different chemical phenotypes and different psychoactive effects).

The most investigated genes of *Cannabis* to date are related to cannabinoids biosynthesis, and concern several key enzymes, including a candidate polyketide synthase and two oxidocyclases but, in particular, THCA synthase (THCAS) and cannabidiolic acid synthase (CBDAS) (Figs. e1.4 and e1.5). (Sirikantaramas et al., 2004; Taura et al., 2007, 2009).

The gene for the enzyme THCAS responsible for the production of THC from the CBG precursor has been identified (Taura et al., 1995; Sirikantaramas et al., 2004). Several functional and nonfunctional sequence variants of this gene have been published, and sequence polymorphisms have been employed for marker application.

Kojoma, Seki, Yoshida, & Muranaka (2006) published 13 different strains of *Cannabis* plants,. distinguishing, by implementing a specific PCR marker, high-THC (drug-type) from low/absent-THC (fiber-type) varieties.

Rotherham and Harbison (2010) developed a single nucleotide polymorphism (SNP) assay, based on 4 polymorphisms of THCA synthase gene for the differentiation of drug and nondrug cannabis plants.

Other authors (Staginnus, Zörntlein, & de Meijer, 2014) have recognized three main, discrete chemotypes (chemical phenotypes) of *Cannabis* according to total THC and total CBD contents (Fig. e1.6):

1. drug-type plants (chemotype I, also known as THC predominant type) show a low CBD/THC ratio, usually 0.00–0.05 (or, alternatively, some authors prefer to consider a high THC/CBD ratio $\gg 1$)
2. intermediate-type plants (chemotype II) show an intermediate ratio, usually a CBD/THC ratio 0.5–3
3. fiber-type plants (chemotype III, also known as CBD predominant type) exhibit a high CBD/THC ratio, usually 15–25 (or, alternatively, a low THC/CBD ratio $\ll 1.0$).

Chemotype III is tipical of plants called hemp, refers to varieties that have low THC concentrations (lower than 0.2%, according to the EU legislation CE 73/2009 for Agriculture), but contain CBD as a major compound. (Hillig & Mahlberg, 2004; Pacifico, Miselli, Carboni, Moschella, & Mandolino, 2008; Staginnus et al., 2014).

The absolute THC content (quantitative chemotype) reflects polygenic genetic mechanisms showing Gaussian distributions in progenies and populations that are strongly subject to environmental factors. Total cannabinoid content of a plant is therefore a complex feature, while the relative CBD/THC ratio is fairly constant throughout the plant's life, and relatively unaffected by external factors (De Backer, Maebe, Verstraete, & Charlier, 2012; de Meijer, Van der Kamp, & Van Eeuwijk, 1992). The CBD/THC ratio (qualitative chemotype) is controlled

FIGURE e1.4 DNA sequencing electropherogram of a portion of THCA-synthase gene. The picture shows the linear nucleotide order of a segment of THCA synthase gene of a fiber-type plant (variety "Tygra").

by simple mendelian genetic mechanisms. This means that genotypes of offspring that inherit from one parent the same alleles (or a combination of alleles for the same gene or group of genes, ie, haplotype) will have the same cannabinoid ratios (CBD/THC ratio) while having different absolute THC content (quantitative chemotype). This also applies to clones of the same plant.

In particular, *Cannabis* expresses three discrete chemical phenotypes (qualitative chemotypes) depending on polymorphisms within the THCA synthase sequence. The CBD/THC ratio is determined by a single locus (B) of the THCA synthase gene having two codominant alleles (B_T and B_D). The homozygous B_T/B_T genotype underlies the THC-predominant phenotype, and B_D/B_D is CBD-predominant.

The intermediate phenotype is induced by the heterozygous state (B_T/B_D). (de Meijer et al., 2003). Expanding this line of research, Staginnus et al. (2014) tested specific polymorphisms within the THCA synthase sequence for forensic applicability have shown to be absolutely linked to either the THC-predominant (B_T/B_T) or the THC-intermediate (B_T/B_D) chemotype. The marker system they found (D589) proved to be a reliable tool to detect a B_T/B_T or B_T/B_D genotype that works independently from the developmental stage or the tissues examined.

Some *C. Sativa* L. individuals that lack the ability to form cannabinoids are known. This is generally due to a knockout factor that inhibits the metabolic pathway upstream of THCA synthase (Pacifico et al., 2006). In these plants, neither CBD nor THC can be produced, due to the absence of upstream precursors in the pathway (de Meijer, Hammond, & Sutton, 2009).

The presence of a THCA synthase gene in these individuals cannot be ruled out: the o/o genotype underlying the cannabinoid-free chemotype has been found in individuals of fiber hemp cultivars. They belonged to the B_D/B_D group, and did not show a marker signal. All this data then confirms that cannabinoid content and composition is highly variable among *Cannabis* plants, explaining distinctions between chemotypes I, II, and III.

Working on this topic, some authors (Bakel et al., 2011) found the upregulation of cannabinoid pathway genes,

FIGURE e1.5 DNA sequencing electropherogram of a portion of CBDA-synthase gene. The picture shows the linear nucleotide order of a segment of CBDA synthase gene of a resin-type plant (variety "Shiatsu Kush").

and the exclusive presence of functional THCA-synthase in the genome and transcriptome of high-THC plant strains/varieties (they studied the Purple Kush). These authors have presented a draft genome and transcriptome of cannabis, and compared the genomes and flower transcriptomes of high-THC and low-THC producing strains: Purple Kush as high, Finola as low, and USO-31 as low to absent. THCA synthase, the gene encoding the oxidocyclase enzyme that forms the THC, is found in the genome and transcriptome of Purple Kush, whereas CBDA synthase dominates in the "Finola" hemp cultivar. Moreover, they found that most of the cannabinoid biosynthetic pathway enzymes are highly expressed in flower tissues containing glandular trichomes, and that the expression of the cannabinoid biosynthetic enzymes is elevated in the high-THC strain (Purple Kush).

It has been also investigated (Cascini, Passerotti, & Martello, 2012) whether or not the THCA synthase gene, which codes the enzyme, influences the production and storage of THC in a dose-dependent manner. Quantification of the THCA synthase gene using the real-time PCR technique revealed a gene copy number that is independent of the chemical phenotype. This means that the correlation between the quantity of the THCA synthase gene and the production of THC appeared to be random and variable in high and low potency varieties of *Cannabis*. Furthermore, the same samples did not show a correlation between the THCA synthase gene expression and the THC storage in leaves and inflorescence (Cascini, Passerotti, & Boschi, 2013).

Concerning investigations on other genes involved in the cannabinoid biosynthesis, the sequence of CBDA synthase resulted to be very similar to the one of THCA synthase gene (homology 87.9%)(Yoshikai, Taura, Morimoto, & Shoyama, 2001). A total of 37 major amino-acid substitutions were detected in the alignment of the sequences from high-THC type and low/absent-THC type strains. It appeared that the amino acid substitutions induced a decrease in THCA synthase activity in the fiber-type cannabis plants.

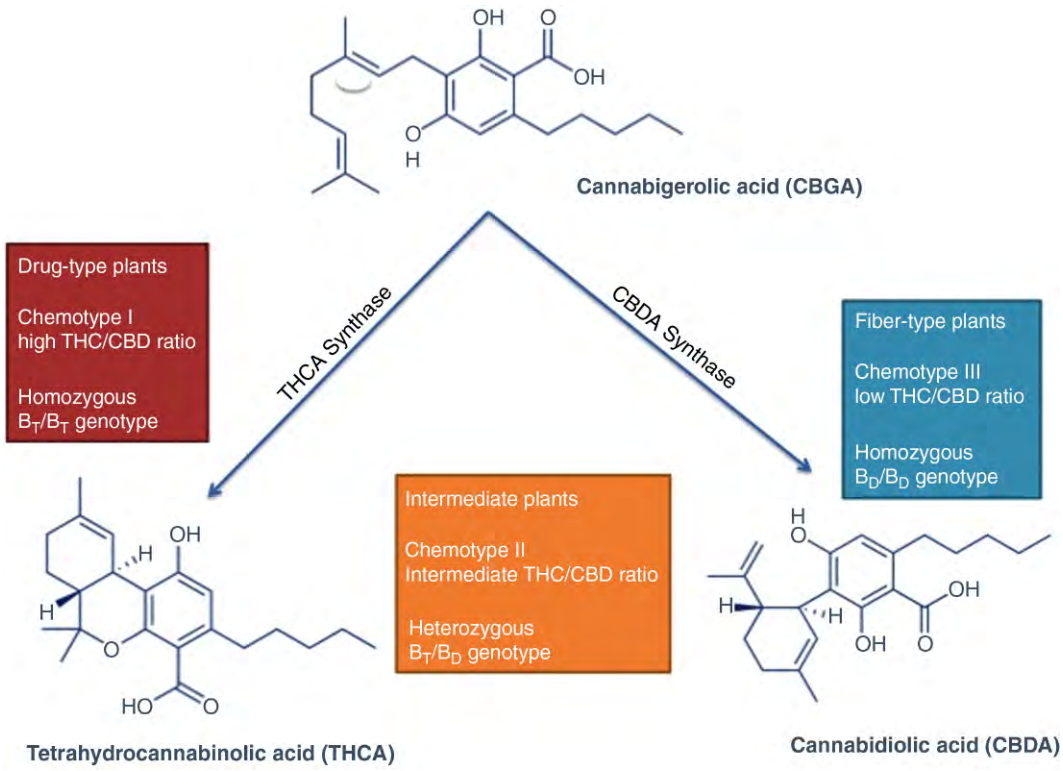

FIGURE e1.6 **Genotypes and chemical phenotypes of cannabis.** The picture shows the genetic base of cannabinoids biosynthesis. According to total THC and total CBD contents, it is possible to distinguish: (1) drug-type plants (chemotype I also known as THC predominant type); (2) intermediate-type plants (chemotype II showing an intermediate ratio); and (3) fiber-type plants (chemotype III also known as CBD predominant type). These three discrete chemical phenotypes (qualitative chemotypes) depend on polymorphisms within the THCA synthase sequence. The CBD/THC ratio is determined by a single locus (B) of the THCA synthase gene having two codominant alleles (B_T and B_D). The homozygous B_T/B_T genotype underlies the THC-predominant phenotype, and B_D/B_D is CBD-predominant. The intermediate phenotype is induced by the heterozygous state (B_T/B_D).

GENETIC MARKERS FOR FORENSIC IDENTIFICATION

To this date, beside investigations concerning biosynthesis processes, the greater part of genetic research on *Cannabis* has focused on molecular markers for forensic investigations to fight the illegal market.

Various approaches have been suggested, even if definitive conclusions haven't been reached in regard to genetic markers characterized by high levels of reproducibility and reliability.

Cannabis strains have been classified based on genomic DNA markers that revealed informative genetic diversity, such as random amplified polymorphic DNA (RAPD) (Gillan, Cole, Linacre, Thorpe, & Watson, 1995; Jagadish, Robertson, & Gibbs, 1996; de Meijer et al., 2003), amplified fragment length polymorphisms (AFLP) (Miller et al., 2003), and inter simple sequence repeat amplification (ISSR) (Kojoma, Iida, Makino, Sekita, & Satake, 2002).

Short tandem repeat (STR, microsatellite) markers have been mostly developed and widely tested (Hsieh et al., 2003; Gilmore et al., 2003; Alghanim & Almirall, 2003). Some of these STRs have been optimized for being analyzed in multiplex PCRs (Howard, Gilmore, Robertson, & Peakall, 2008; Mendoza et al., 2009; Köhnemann, Nedele, Schwotzer, Morzfeld, & Pfeiffer, 2012), but they are still scarcely used (Gilmore, Peakall, & Robertson, 2003; Howard et al., 2008; Gilmore, Robertson, & Peakall, 2009; Allgeier, Hemenway, Shirley, LaNier, & Coyle, 2011) because they are not standardized, making their results unreliable.

Valverde et al. (2014a) have recently sequenced and characterized several alleles of 15 of the most common *Cannabis* STRs, and proposed a nomenclature following forensic international guidelines.

The characterization of all these alleles has allowed the establishment of a nomenclature to be applied for standardizing the results and making comparisons between laboratories. The sequencing of every STR locus has revealed several nucleotide variations inside the repeated structure and/or in the flanking regions. This has permitted the construction of an initial SNPSTR database of all the haplotypes found, also including the previously available sequence raw data for these STR loci.

Valverde et al. (2014b) published also a new *Cannabis* STRs nomenclature proposal based on only 7 STRs and their SNPSTR data, to facilitate standardization, performance, and reliability of these analyses, thus facilitating the implementation of routine forensic investigations on *Cannabis*. Nonetheless, additional investigations concerning published STR loci in different populations and in related plants would be useful for the purpose. This would set the basis for establishing frequency databases and mutation rates for identification of varieties and strains.

In addition, because microsatellite markers are seldom located in functional genomic regions, mutations in them tend to be evolutionarily neutral. Thus, they are unaffected by selective pressure. This permits the rapid (in terms of centuries) accumulation of variations, permitting varietal (but usually not clonal) differentiation.

Among other methods to genetically characterize *Cannabis*, analysis of the organelle DNA of plants, particularly using chloroplast DNA (cpDNA) is well established as a tool to study evolutionary and population processes (Palmer, 1990; Olmstead & Palmer, 1994). It has superior attributes to nuclear DNA in discerning evolutionary trends, due to its low mutation rate and the absence of genetic recombination, which is typical of nuclear DNA. Chloroplasts and mitochondria are generally uniparentally (maternally) inherited in angiosperms, and hence have the potential to provide complementary evolutionary and biogeographic insights to nuclear DNA markers such as STRs. Numerous studies in plants have used cpDNA restriction site and sequence data to elucidate species and higher level phylogenetic relationships (Borsch et al., 2003; Soltis & Soltis, 2000). PCR amplification of cpDNA, followed by restriction fragment length polymorphism analysis of the amplicons (PCR-RFLP), has provided a rapid method of assaying information among populations, for some plant groups (Petit et al., 2002). PCR-RFLP of cpDNA has been facilitated by publication of large numbers of universal PCR primer sequences, producing amplicons that cover large tracts of the chloroplast genome (Taberlet, Gielly, Pautou, & Bouvet, 1991; Dumolin-Lapegue, Pemonge, & Petit, 1997).

APPLICATIONS OF GENOTYPING

Many researchers around the world are undergoing a mutual effort to define the genetics of *C. sativa* L. Advances in molecular genomics are providing genetic maps showing the location of interesting genes, and possibly adjacent polymorphic markers that could permit marker-assisted breeding, where the adjacent sites facilitate recognition of the desired genes.

Most of the properties associated with commercial success of cannabis are quantitative (ie, THC concentration), and depend on the accumulative action of multiple genes (maybe located on separate chromosomes), although nowadays a quantitative prediction of the final THC content in a *Cannabis* plant still cannot be made.

Genetic markers can, thus, represent a valuable tool for therapeutic and forensic purposes.

Clear indicators of gene expression are highly desirable, especially if suitable for the identification of important genetic traits at an early stage of plant development. Concerning, for example, the selection of varieties/strains susceptible to obtain a high THC chemotype, desirable for therapeutic purposes, genomic features related to chemical factors can be greatly useful in the early selection of suitable offspring. Embryos or seedlings not possessing the desirable gene(s) can be discarded early, saving time, effort, and space. The procedure also streamlines traditional breeding programs, by clearly identifying plants likely to possess the desired traits for subsequent crossing.

Also regarding forensic applications, the advantages that the genetic individualization of *Cannabis* plants could provide in the illegal trade investigations are enormous, since it offers the possibility of establishing relations between different criminal cases, and assessing their belonging to a trade network.

However, due to the illegal nature of the *Cannabis* plant in many countries, insufficient data on its genetic features has been accumulated. Then genotyping has not been yet adopted as routine beside toxicological analyses.

MINI-DICTIONARY

Allele One of different, alternative forms of a gene locus.
Autosome A chromosome that is not a sex-determining chromosome.
Genetic characterization Identification and description of some genetic structures related to certain phenotypic features.
Genotype Genetic structure of an individual/organism. It can be related to single or multiple traits.
Haplotype A group of tightly linked genes in a chromosome that are likely to be inherited together.
Heterogametic Having different gametes, sex chromosomes (X and Y).
Homogametic Having a matching pair of sex chromosomes (X and X).
Karyotype Number and appearance of chromosomes.
Phenotype The entire complex of the external (morphological, physiological, developmental) features.
Proteome The entire set of proteins expressed by a genome.
Strain Descendant/offspring produced from an ancestor (sharing uniform genotype and phenotype).
Variety One of the possible forms of a botanical taxon (subspecies/species) differing from the other forms in minor characteristics.

Gender Differences in Cannabis Use Disorders

R. Secades-Villa, S. Fernández-Artamendi

Addictive Behaviors Research Group, Department of Psychology, University of Oviedo, Oviedo, Spain

KEY FACTS

- Rates of cannabis use and CUD used to be greater among men than women.
- Males are more likely to transition from cannabis use to CUD.
- Women exhibit a telescoping effect.
- Neurocognitive effects of cannabis might be different for males and females.
- Males clearly outnumber females in treatment services for cannabis use disorders.
- Treatment demand is equally low for both genders.
- Triggers of treatment seeking, change in cannabis use, or cessation, show different patterns for males and females.
- Further research is needed to analyze gender differences in CUD.

LIST OF ABBREVIATIONS

A-CRA	Adolescent-community reinforcement approach
CBT	Cognitive behavioral therapy
CUD	Cannabis use disorders
MET	Motivational enhancement therapy

INTRODUCTION

Despite the fact that cannabis is the most widely used and misused illicit drug in the world (United Nations Office on Drugs and Crime, 2012) and is the drug with the highest rate of abuse or dependence (Compton, Grant, Colliver, Glantz, & Stinson, 2004; Stinson, Ruan, Pickering, & Grant, 2006), the gender differences among individuals with cannabis use disorders (CUD) remain poorly characterized. Nevertheless, recent research has brought to attention the important gender differences in this disorder that can lead to clinical consequences in the management of patients, and in the development of prevention strategies. The goal of this chapter is to review the main findings concerning gender differences related to development, clinical features, and treatment trends in CUD.

PREVALENCE OF CANNABIS USE AND CUD

Rates of cannabis use and CUD used to be greater among men than women. Surveys conducted in Europe indicate a cannabis use level of 4.4% for females versus 9.1% for males, among the population aged 15–64 (United Nations Office on Drugs and Crime, 2012). In all European countries, rates of cannabis use are higher for males than for females, with an increase in male-female differences from younger to older groups (Fig. 14.1). Among students aged 15–16 years old, the male to female ratio of lifetime cannabis use is 1.0–1.8, whereas it rises to 1.25–4.0 among adults (European Monitoring Centre for Drugs and Drug Addiction, 2005). These differences are even higher when the focus is switched from lifetime use toward more recent use.

These figures are very similar to those in the United States (Substance Abuse and Mental Health Services Administration, 2013). Rates of marijuana use among adolescents aged 12–17 are 9.0% for males versus 6.7% for

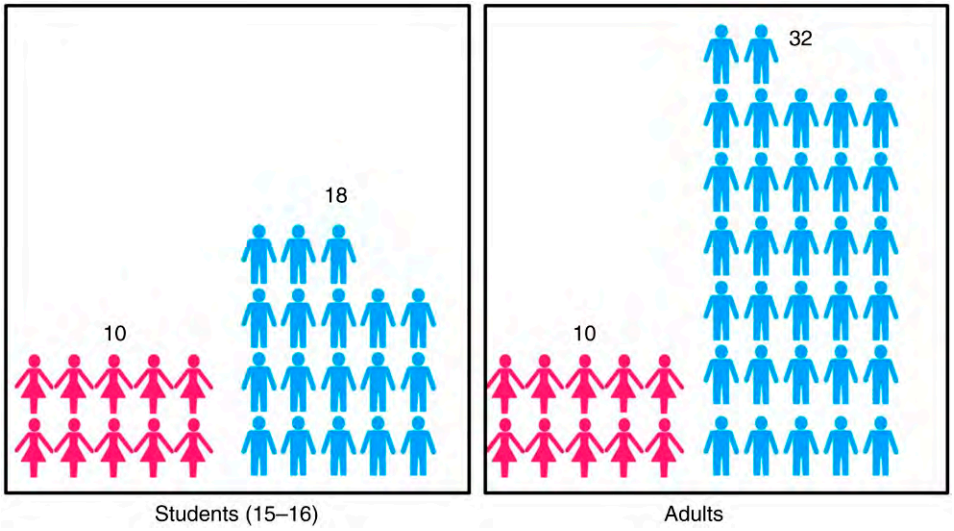

FIGURE 14.1 **Male to female ratio of lifetime cannabis use.**

females, with the difference increasing to 9.3% and 4.9% for the general population (SAMHSA, 2013).

In a nationally representative epidemiologic study of the US population, the prevalence of any 12-month and lifetime CUD was twice for men (2.2% and 11.8%) than for women (0.8% and 5.4%). The odds of both lifetime cannabis abuse and dependence were significantly greater for men than for women (Stinson et al., 2006). A nationally representative report in Australia found that the prevalence of CUD was comparable with that in the United States, and that both cannabis abuse and cannabis dependence were more common in males (Teesson et al., 2012).

In Western countries, gender differences in the rates of cannabis use seem to appear during late adolescence (Goncy & Mrug, 2013), with an increasing gender gap indicating higher consumption in males (ter Bogt et al., 2014). Recent population-based reports with young adults in the United States (Haberstick et al., 2014) have also found that rates of cannabis abuse and dependence were greater among males (5.6% and 10.9%) than among females (2.4% and 6.1%). As in the adult population, the odds for meeting diagnostic criteria for lifetime cannabis abuse and dependence were also greater among males.

Despite the higher prevalence of CUD among men than women, the incorporation of women to cannabis use has grown in recent cohorts, giving rise to gender convergence, and to the fact that the gender gap in the prevalence of CUD has been narrowing (Colell, Sánchez-Niubò, & Domingo-Salvany, 2013; Johnson & Gerstein, 2000).

An interesting issue is that even though males are more likely than females to transition from cannabis use to CUD (Looby & Earleywine, 2007), evidence also

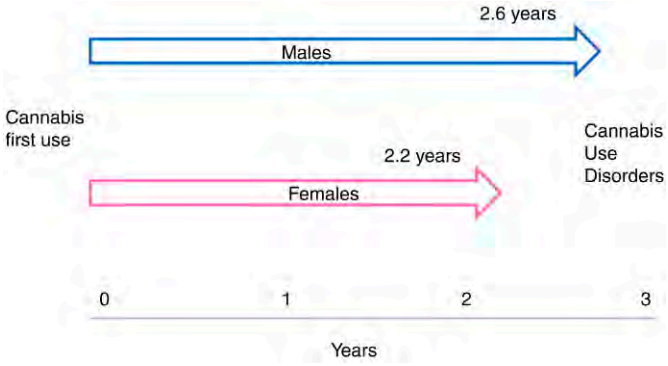

FIGURE 14.2 **Transition from cannabis first use to cannabis use disorder.** *Source: Khan et al. (2013).*

suggests the existence of a "telescoping effect" in the progression from substance use to substance use disorders in women. That is, women would experience an accelerated progression from the first stages of use toward diagnosis of a CUD. The occurrence of this phenomenon has been confirmed in the case of cannabis use by different studies (Khan et al., 2013). Women show shorter intervals between the age of first cannabis use and the onset of a CUD (Fig. 14.2). The factors that put women at higher risk of developing a CUD are not well understood, but it has been suggested that it could be a consequence of associated factors such as patterns of use, or related comorbidities.

CLINICAL FEATURES OF CUD

Results from clinical and population-based studies have shown several gender differences in the clinical features of CUD. In one clinical study with adolescent

patients, the likelihood to meet the criteria for cannabis abuse without cannabis dependence was higher for women than for men (Crowley, Macdonald, Whitmore, & Mikulich, 1998). In another clinical study with adolescents entering outpatient treatment primarily for cannabis abuse or dependence, females were more likely to be diagnosed with more severe CUD (namely dependence) than their male counterparts. The author attributed this result to the higher comorbidity of female participants. Similar results were found by Hernandez-Avila, Rounsaville, & Kranzler (2004) in a clinical study with 271 substance-dependent patients. Despite women experiencing fewer years of regular use of cannabis, they reported more severe psychiatric, medical, and employment complications. Results of a controlled laboratory study indicate that when matched for cannabis use, women are more sensitive to the subjective effects related to cannabis abuse liability, relative to men, fact that may contribute to the enhanced vulnerability to developing CUD (Cooper & Haney, 2014).

Research on the neurocognitive effects of cannabis is still scarce, but is growing rapidly. Results from a nontreatment-seeking community sample of young adults showed that cannabis use was more consistently associated with poorer episodic memory performance in females than males, and, conversely, with poorer decision-making performance for males, but not females (Crane, Schuster, Fusar-Poli, & Gonzalez, 2013). Although still nascent, the current evidence points to sex differences in the impact of cannabis on neurocognitive functioning, but more so for longer term cannabis use than acute effects (Crane et al., 2013).

Studies in community samples suggest that younger individuals and men may be more likely to use cannabis heavily and, consequently, to develop cannabis dependence (Chen, Kandel, & Davies, 1997; von Sydow et al., 2001). Fergusson et al. reported that men were 4.2 and 19.2 times more likely to be arrested and convicted, respectively, on a cannabis-related offense, even after accounting for gender differences in prevalence of CUD (Fergusson, Swain-Campbell, & Horwood, 2003). Men and women also have differences in endorsement rates for most cannabis abuse and dependence symptoms. Results from another community sample showed that the largest discrepancy occurs for hazardous use, endorsed by 53% of the men and 35% of the women, which was attributable to increased drug-taking among men as compared to women (Grant et al., 2006). An interesting result of this study was the highest endorsement of cannabis withdrawal among women in some of the subtypes of cannabis problems analyzed. Other clinical (Levin et al., 2010) and community studies (Agrawal & Lynskey, 2007) also suggest that women may be more likely to report cannabis withdrawal, although some studies find no age or sex differences (Copersino et al., 2010; Swift, Hall, & Copeland, 2000; Wiesbeck et al., 1996). Nevertheless, these findings came from samples of men and women who were not matched according to prequit cannabis use. Assessing cannabis withdrawal and relapse under controlled laboratory conditions would provide critical data to determine the clinical significance of sex in cannabis use disorders (Cooper & Haney, 2014).

Agrawal and Lynskey (2007) found that certain CUD criteria may be more potent markers for cannabis problems in one gender versus another. Specifically, two dependence criteria (quit and problems) indicated a greater level of severity for women, whereas the abuse criteria, legal and hazard, were more difficult for men. Results from a nationally representative sample of the US population (Khan et al., 2013) showed that the severity of CUD was higher in men. Men met more criteria for cannabis abuse, smoked a greater number of joints per day, had longer episodes of CUD, and were older at remission. Despite the fact that severity of CUD was higher in men, there were no significant gender differences in the age at first use of cannabis, the age at heavy use, and the age at onset of the disorder. Nevertheless, these gender differences in mean dose of cannabis smoked daily (joints per day) were not found by another previous study (Lev-Ran et al., 2012). In this study, CUD were associated with significantly poorer mental health and quality of life, and this relationship was particularly pronounced in females with CUD (Lev-Ran et al., 2012). As no significant differences existed in the cannabis smoked daily, the gender differences in mental quality of life were not attributed to a dose-response effect (Table 14.1).

While little work has focused directly on gender differences in psychiatric comorbidity, some studies have found important differences between males and females with CUD. Particularly, previous work has shown women with CUD have higher rates of comorbid mood and anxiety disorders (Grant, 1995; Khan et al., 2013), whereas men with CUD are more likely to have externalizing disorders (Khan et al., 2013). The comorbidity of internalizing disorders among women with CUD may simply reflect the higher rates of mood and anxiety disorders that occur among women in the general population, but a novel finding shows that CUD increase the risk of externalizing disorders among women, compared to

TABLE 14.1 Gender Differences in Severity Markers

Higher severity or prevalence among	
Males	**Females**
Legal and hazard DSM-IV criteria	Difficulty with quitting
Greater number of joints per day	DSM-IV criteria
Longer episodes of CUD	Associated problems
Older at remission	DSM-IV criteria
Comorbid externalizing disorders	Comorbid mood and anxiety disorders

TABLE 14.2 Clinical Features of CUD: Summary Table

- Findings about gender differences in clinical features of CUD are mixed
- Although most of the studies indicate that the severity of CUD is higher among males than among females, some of them found greater severity of cannabis use in women
- Future research is needed to extend these results, and to examine whether gender differences may be due to the inclusion of different samples (clinical vs community samples)
- These gender differences may have implications for gender-specific treatment approach

men (Khan et al., 2013). One of the most comprehensive studies analyzing the effects of cooccurring problems in 5150 adolescents receiving Adolescent-Community Reinforcement Approach (A-CRA) showed that females were overrepresented in the group with internalizing problems (40.8%) and the group with mixed problems (ie, both internalizing and externalizing; 39,5%), compared to externalizing (16.4%) and noncomorbidity groups (16.1%) (Godley et al., 2014). Although this study included users of all drugs, the majority of adolescents presented with cannabis use as the primary substance. Nevertheless, these findings should be verified in future studies (Table 14.2).

TREATMENT SERVICES

Given the higher prevalence of cannabis use and CUD among males, it is not surprising that these figures also replicate among cannabis users in treatment. In these services, males are consistently predominant. Similarly low rates of females have been reported in several studies with various populations, and from different countries. As an example, rates of males in treatment for cannabis as primary substance are above 80% among young adolescents (Battjes, Gordon, O'Grady, Kinlock, & Carswell, 2003; Tims et al., 2002; Fernández-Artamendi, Fernández-Hermida, Godley, & Secades-Villa, 2014), and above 70% for adult cannabis users (Connor et al., 2013; Copeland, Swift, & Rees, 2001; Hathaway, MacDonald, & Erickson, 2008; Hoch et al., 2014; Jungerman & Laranjeira, 2008; Mariani et al., 2011). Even though these rates are consistent with the figures of cannabis users in the general population, Hathaway et al. detected that the rate of males among users in treatment (70%) was significantly higher that among users not in treatment (62%) (Hathaway et al., 2008). Nevertheless, other studies have failed to detect such significant differences (average = 68.5%; Gates, Taplin, Copeland, Swift, & Martin, 2009).

The low presence of females in these services does not seem to be specific of CUD treatment services. Urbanosky et al. compared the characteristics of a big sample of Canadian treatment seekers (Urbanoski, Strike, & Rush, 2005), and found that the rate of males presenting with cannabis as the primary drug of abuse was not significantly different to that of cocaine, alcohol, or opiate users. Accordingly, Mariani et al. (2011) found that male/female ratios are alike among cannabis users and users with other drugs of referral. One factor that influenced the ratio of males was the use of additional drugs. In the study by Arendt and Munk-Jorgensen (2004), 78.4% of all treatment seekers with cannabis use as primary substance were males; this rate rose up to 83.9% among cannabis users who also reported using hard drugs.

What holds true for cannabis treatment services is that treatment demand is very low among both male (14.20%) and female (12.43%) cannabis users; but with no significant differences between them (Khan et al., 2013). Nevertheless, some differences have been ascertained in the sources of these treatment referrals, as well as on the motives stated for moving towards a change in their cannabis use. In the study by Urbanoski et al. (2005), men and women in treatment for their CUD, who were older than 20, were more likely to be self-referred to these services, whereas those under this age indicated family and friends as primary sources of referral. Gender differences arouse in referrals from the legal or justice system since, regardless of age, men were twice as likely to be referred to treatment by these sources. On the other hand, and also irrespective of age, women were more likely to be referred to treatment by physicians or psychiatrists. It would seem that different consequences of cannabis use are triggering treatment demand for males and females.

Among young adolescents, some studies have failed to detect significant gender differences in the factors that encourage the motivation to change (Battjes et al., 2003). However, some other longitudinal studies following this population have found differences in the factors determinant for cessation (Chen & Kandel, 1998). Among women, first-time pregnancy and parenthood were the most important social roles leading to stop cannabis use, and these events were significantly more important than for men. Although the effect of getting married for the first time did not seem to have a differential weight in males than in females, it resulted a significant predictor of cessation for boys, but not for girls. According to the aforementioned studies, external pressures or changes would be exerting greater influence on males' motivation to change and seek treatment, compared to factors, such as, health concerns or motherhood for women. Similar conclusions have been noted in previous studies with alcohol users (Blomqvist & Cristophs, 2005), but more studies are still needed before confirming such hypothesis with cannabis smokers (Fig. 14.3).

Gender differences have been found also in the attitude reported toward one's own cannabis use. In the study by Fernández-Artamendi, Fernández-Hermida, García-Fernández, Secades-Villa, and García-Rodriguez (2013) with adolescent regular cannabis users, boys were

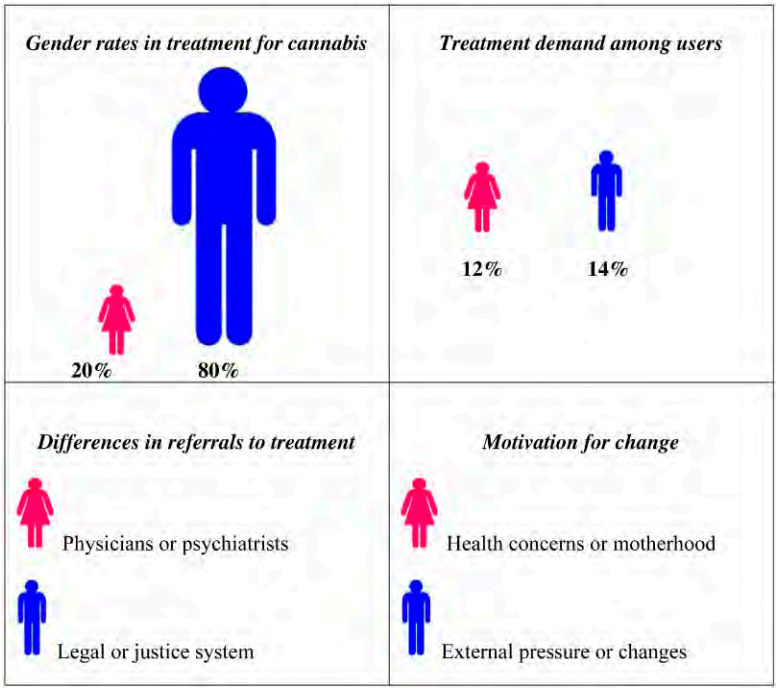

FIGURE 14.3 **Gender differences in treatment services.**

significantly more likely to express no intention to change their cannabis use, whereas girls were more likely to assert attempting a reduction on their own. In fact, Khan et al. (2013) found that rates of remission of CUD in the general population showed to be slightly higher among females (82.1%) than among males (77.8%). The age at remission was also lower for women (23.08 years old vs 25.32) than for men. In this same direction, the longitudinal study by Chen & Kandel (1998) found that, at the age of 34, 76.2% of male cannabis users had stopped using, compared to 82.3% of females. The "telescoping effect" shows that women have faster progression toward CUD. On the other hand, progression to remission, by means of treatment services or on their own, seems to happen faster and earlier, too. Some data support the idea that the telescoping effect would cause women to show a more rapid progression to treatment entry (Hernandez-Avila, Rounsaville, & Kranzler, 2004), which would also facilitate eventual remission. Once cannabis users have decided to quit, no significant differences arise in the barriers deterring males and females from attending treatment (Khan et al., 2013) (Table 14.3).

TABLE 14.3 Treatment Services: Summary Table

- Rates of males in treatment for cannabis use disorders are usually higher than those of women
- Treatment demand for cannabis use disorders is very low among both male and female
- First-time pregnancy and parenthood used to be the most important social roles leading to stop cannabis use among women

TREATMENT EFFECTIVENESS

Some gender differences in the consequences associated to cannabis use, as well as on factors influencing progress toward remission, have been found. Additionally, women seem to be more likely to speak about their cannabis use, and although they are more likely to remain abstinent after treatment, they seem more vulnerable to interpersonal problems and negative feelings that might spark relapse easier than in males (Fattore, 2013).

It remains unanswered, however, whether these differences somehow influence treatment effectiveness. To our knowledge, current research does not provide many specific studies on the possible effects of gender differences on the clinical outcomes and effectiveness of treatments for CUD. The Marijuana Treatment Research Project (2004), one of the most comprehensive clinical trials comparing Motivational Enhancement Therapy (MET) and Cognitive Behavioral Therapy (CBT), with 450 adults, found that clinical results were not influenced by gender. Pretreatment dropout rates were also similar between males and females in this study (Vendetti, McRee, Christiansen, & Herrell, 2002), and, in another brief intervention for adults, completers and noncompleters did not differ by gender either (Copeland et al., 2001). Accordingly, gender did not result to be a moderator of treatment effects in an intervention for adolescents (Hendriks, van der Schee, & Blanken, 2012).

An in-depth analysis of 1819 adolescents receiving A-CRA for their drug use (mostly cannabis use) did not

find significant gender differences in initiation, engagement, or retention (Godley, Hedges, & Hunter, 2011). Although male adolescents reported greater intake severity, rates of change after treatment were equivalent to those of females. Males also reported higher satisfaction with treatment, apparently due to their greater recognition that the staff had significantly helped them. Treatment services are often characterized by a culturally sensitive approach that deals with gender differences during treatment, and could be, therefore, preventing significant differences in clinical outcomes.

In conclusion, greater prevalence of cannabis use and CUD among males translates to greater rates of males in treatment services for these disorders. Some differences have been found in the factors that trigger treatment seeking and motivation to change, but it seems that treatment outcomes do not significantly differ between genders. Research studies on these areas are, however, relatively scarce, and more investigation is needed to determine how gender affects treatment.

MINI-DICTIONARY

Cannabis use disorders (CUD) Cannabis use and/or cannabis dependence according to DSM-IV criteria.
Cannabis withdrawal Abstinence symptoms and signs during withdrawal from chronic cannabis use.
Externalizing disorders Liability to experience substance use disorders, conduct disorder, and antisocial personality disorder.
Internalizing disorders Liability to experience mood and anxiety disorders, such as, major depressive disorder, generalized anxiety disorder, panic disorder, and social anxiety disorder.
Prevalence of CUD Percentage of the population reporting cannabis use or cannabis dependence.
Psychiatric comorbidity Cooccurrence of cannabis abuse or cannabis dependence with other psychiatric disorder.
Telescoping effect Faster progression from substance use to substance abuse or substance dependence.

CHAPTER

15

The Role of Age in the Onset and Further Development of Cannabis Use Disorders

S. Behrendt

Institute of Clinical Psychology and Psychotherapy, Technische Universitaet Dresden, Dresden, Germany

SUMMARY POINTS

- The main incidence phases for cannabis use (CU) and disorders (CUD) are in adolescence and early adulthood.
- A younger age at first CU is associated with a higher risk of CUD.
- This association might be explained by features of adolescence, susceptibility to cannabis effects, impairment of executive functions, a vulnerability for disinhibitory psychopathology, psychosocial derailment, and problematic use motivation.
- A heuristic model on the role of earlier CU onset in CUD risk integrates nonnormative risk, age-related maturational processes, and coping abilities.
- Relatively little is known about the role of earlier CU onset in the course of CUD.

KEY FACTS OF CANNABIS USE AND DISORDERS

- Cannabis is a widely used, often illegal, substance.
- Cannabis abuse refers to a CUD characterized by repeated negative psychosocial consequences of CU such as neglect of role obligations, or interpersonal problems.
- Cannabis dependence refers to a CUD characterized by clinical symptoms such as tolerance, or loss of control over consumption.
- Only a relatively small proportion of subjects who try cannabis develop a CUD.
- A substantial proportion of transitions from first use to CUD occur within a few years after first use.

LIST OF ABBREVIATIONS

CU	Cannabis use
CUD	Cannabis use disorder
EDSP	Early Developmental Stages of Psychopathology Study
NESARC	National Epidemiologic Survey on Alcohol and Related Conditions
NHSDA	National Household Survey on Drug Abuse
NSDUH	National Survey on Drug Use and Health

INTRODUCTION

Cannabis is a widely used psychotropic substance in many western countries (European Monitoring Centre for Drugs and Drug Addiction, 2012; United Nations Office on Drugs and Crime, 2012). Still, (conditional[a]) substance use disorder rates are usually lower for cannabis than for alcohol and nicotine (Compton, Grant, Colliver, Glantz, & Stinson, 2004; Grant, Hasin, Chou, Stinson, & Dawson, 2004; Grant et al., 2004b; Wagner & Anthony, 2002; Wittchen et al., 2008). Given relatively low cannabis use disorder rates (DSM-IV abuse and dependence; CUD) it is important for targeted preventive efforts to specifically identify those cannabis users who are at elevated risk of CUD. A robust predictor for substance use disorders is a younger age at onset of substance use. This has been shown for nicotine, cannabis and alcohol (Behrendt, Wittchen, Höfler, Lieb, & Beesdo, 2009; Chen, O'Brien, & Anthony, 2005; DeWit, Adlaf, Offord, & Ogborne, 2000).

This chapter focuses on the role of age in the risk of CUD. It provides an overview of high-risk age periods for incident cannabis use (CU) and CUD, and of

[a]Conditional disorder rates: rates of disorder among those who tried the substance at least once.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00016-8

empirical evidence on the association between early first CU and CUD risk. Putative explanatory mechanisms are presented and integrated in a heuristic model of early CU in CUD risk.

HIGH-RISK AGE PERIODS FOR CU AND CUD INCIDENCE

There exist several epidemiological studies—predominantly from Western countries—on age of onset distributions of CU. Contrasting differences in prevalence rates, high-risk incidence periods are relatively consistent across countries, clearly revealing adolescence and early adulthood as high-risk periods for first CU (Vega, Aguilar-Gaxiola, Andrade, Bijl, & Borges, 2002). For example, studies with samples aged between 14 and 15 years find lifetime CU rates up to about 30% (Kokkevi, Gabhainn, Spyropoulou, & Risk Behaviour Focus Group of the HBSC, 2006), and peaks of incidence rates at about the age of 14 (Monshouwer, Smit, de Graaf, van Os, & Vollebergh, 2005). These findings from young samples could, however, be influenced by right censoring.

Still, in a German representative community sample (EDSP-Study) followed until the ages of 21–34, the main incidence phase for CU were ages 14–19 (Behrendt et al., 2009). In a Swiss national survey including subjects aged 15–49 years, about 93% of CU onsets occurred up to the age of 24 (Müller & Gmel, 2002). Comparable results were shown in national epidemiological samples from the United States and Australia, including middle-aged and older adults (Lenton, Liang, & Chikritzhs, 2011; Wagner & Anthony, 2002, 2007). In contrast, late onset of CU appears rare. In an epidemiological survey (baseline age 18–99 years), only 1.9% reported first CU at a 3-year follow-up. The majority of these subjects were young adults (Agrawal & Lynskey, 2009).

Less information is available on high-risk periods for CUD onset. In the EDSP-Study, the main incidence phase for DSM-IV cannabis abuse and dependence was at the ages of 15–19 years (Behrendt et al., 2009). In the National Comorbidity Survey, the high-risk phase for DSM-III-R cannabis dependence was in adolescence and early adulthood (Wagner & Anthony, 2002). A study with a baseline age-range of 18–64 years (de Graaf, ten Have, Tuithof, & van Dorsselaer, 2013) showed 3-year follow-up CUD incidence rates below 0.4%, possibly indicating that CUD incidence in middle and later adulthood is rare.

In summary, research clearly identifies the age periods of adolescence and early adulthood as high-risk phases for incident CU and CUD. Moreover, a substantial proportion of DSM-IV CUD cases occur in the first few years after first CU (Behrendt et al., 2009; Lopez-Quintero et al., 2011), leaving little time for secondary preventive efforts.

YOUNG AGE AT CU ONSET AND ITS ASSOCIATION WITH CUD RISK

Empirical Evidence

As outlined previously, age is related to CU and CUD onset in terms of specific high-risk periods in life. Beyond this, the question arises whether the timing of first CU (a younger age at CU onset compared to an older age) is a risk factor for CUD.

Several epidemiological studies address the topic, all of which report higher CUD risk in those with earlier onset. Winters and Lee (2008) report a higher risk of DSM-IV CUD by recent CU initiation in subjects aged between 13 and 18 years, compared to subjects aged 22–26. NHSDA data revealed a higher risk of DSM-IV cannabis dependence for early CU initiation defined as, respectively, 11–13, 14–15, and 16–17 years versus initiation after the age of 20 (Chen et al., 2005). In the NESARC, CU onset before the age of 14 was associated with a higher risk of DSM-IV cannabis dependence (Lopez-Quintero et al., 2011). In the EDSP-Study, early first CU was defined by taking into account the high-incidence phase of CU in the sample. For each year of the high-incidence phase, CU onset at a later age was compared to earlier onset. Later CU onset was consistently associated with a lower risk of DSM-IV cannabis abuse and dependence (Behrendt et al., 2009).

Of note, in all studies except one, these associations remained significant after adjustment for potentially influential covariates as alcohol use, nicotine use, alcohol use disorders, and nicotine dependence prior to CUD onset (Behrendt et al., 2009), externalizing disorders, and paternal and maternal alcohol dependence (in another EDSP-analysis[b]; Behrendt et al., 2012), socio-economic status, and drug use history (Chen et al., 2005; Winters & Lee, 2008). However, the association observed in the NESARC was nonsignificant, after thorough adjustment for mental disorders and socio-economic variables (Lopez-Quintero et al., 2011).

Methodological Considerations

While these results may serve as compelling support for earlier CU onset as a risk factor for CUD, several methodological factors have to be considered:

1. A commonly agreed definition of early CU onset is lacking. Applied definitions differ by study, making comparisons difficult. It has been suggested to define early onset in consideration of the main incidence

[b]With age at onset of CU as a continuous measure.

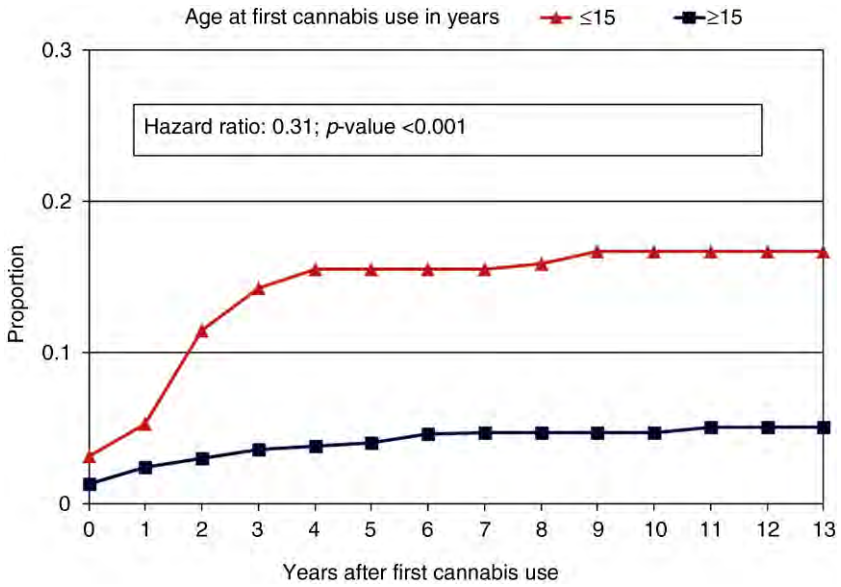

FIGURE 15.1 **Risk of DSM-IV cannabis dependence by age at first CU.** A higher age at first CU was associated with a lower risk of cannabis dependence in the EDSP-Study. *Source: Behrendt et al. (2009); unpublished figure.*

period for CU in the respective sample (Behrendt et al., 2009). This constitutes an alternative to arbitrary definitions or substitute definitions that do not apply for CU, such as, legal drinking age. Comparing several groups with early onset to the group with "latest onset" (Chen et al., 2005; Winters & Lee, 2008) may be problematic, as it can lead to extreme comparisons for those groups with very early onset. Moreover, it may not be helpful in identifying specific risk-phases within the main incidence phase of CU.

2. The association between early onset of substance use and a higher risk of substance use disorders could be an artefact, as subjects with earlier use onset simply have more time to consume the substance and to develop a disorder (Anthony & Petronis, 1995). For cannabis, two well-designed studies address this problem by investigating CUD risk by early CU onset, in subjects with recent CU onset only (Chen et al., 2005; Winters & Lee, 2008). Both find an elevated CUD risk for those with earlier CU initiation. Moreover, Winters and Lee (2008) showed that the proximity of incident CU was not influential in this association.
3. Current CUD are rarer among older individuals (Compton et al., 2004) and CUD are not necessarily stable (Perkonigg et al., 2008). Hence, two factors in combination could lead to an over-report of "late onset CU and no CUD" in older subjects: forward telescoping (the more distal the event of interest, the higher the probability to incorrectly report a higher age of onset) and forgetfulness for transient past CUD episodes. However, two studies on recent CU onset and CUD development—a study design that controls this problem—find associations between early CU and higher CUD risk (Chen et al., 2005; Winters & Lee, 2008) (Fig. 15.1; Tables 15.1 and 15.2).

Possible Explanations for the Association between a Younger Age at First CU and CUD Risk

The findings on the association between early onset CU and an elevated risk of CUD described previously agree with findings on other substances, such as, nicotine (Behrendt et al., 2009; Breslau, Fenn, & Peterson, 1993) and alcohol (DeWit et al., 2000). However, it has to be noted that these studies stem from few Western countries.

Despite this evidence, it is hard to envision how chronological age itself might contribute to CUD risk. Accordingly, Obot, Wagner, & Anthony (2001) speculated that "…early-onset drug use qualifies as a non-causal marker of special vulnerability to later drug problems…". The question arises as to which factors could underlie the association between early onset of CU and CUD risk. In the following, the role of early CU in CUD risk is discussed in the context of existing models on substance use disorder development, and related empirical evidence. For the latter, the focus will be on studies that compare early to later CU onset, instead of accepting the broader comparison category "later or no CU" when considering the effect of earlier CU on putative mediating factors in CUD risk (eg, psychosocial derailment following early CU). Studies using the broader category do not permit conclusions on specifically early versus later first CU. Evidence exists for differential results for comparisons with later onset users and nonusers (Gruber, Sagar, Dahlgren, Racine, & Lukas, 2012).

TABLE 15.1 Epidemiological Studies on Earlier Onset of CU in CUD Risk

Study	Sample	Definition of early CU onset	Result on the risk of CUD by early onset of CU	Consideration of covariates	Methodological advantages[a]	Methodological limitations[a]
NHSDA (Chen et al., 2005)	*N* = 3352 recent onset cannabis users from a representative sample from the United States (*N* = 114,241) Age: 12+ Cross-sectional survey	Early onset: 11–13 years, 14–15 years, 16–17 years, 18–20 years Late onset (comparison group): after age of 20	Higher risk of DSM-IV cannabis dependence in individuals with onset between ages of 11 and 17 *These results were also significant after covariate adjustment*	Socio-economic variables Drug use history	The design reduces the risk of • an artefact due to "more time to develop a CUD" in subjects with earlier onset of use • forward telescoping • problems remembering CUD symptoms	Comparison with "latest" onset
NSDUH (Winters & Lee, 2008)	Data from a subsample of the representative NSDUH from the United States Age: 12–26 years Cross-sectional survey	Early onset: recent onset (in past 2 years) in subjects aged 12, 13, 14, 15, 16, 17, or 18 Late onset (comparison group): recent onset in subjects aged 22–26	Higher risk of DSM-IV CUD in individuals with earlier onset (for ages 13–18) *These results were significant after covariate adjustment*	Socio-economic variables Alcohol use prior to CU	The design reduces the risk of • an artefact due to "more time to develop a CUD" in subjects with earlier onset of use • forward telescoping • problems remembering CUD symptoms	Comparison with oldest group among recent onset users Information on age at interview among recent onset users instead of information on age at onset of CU
EDSP (Behrendt et al., 2009)	Representative community sample (*N* = 3021) from metropolitan Munich, Germany Baseline age: 14–24 years; age at last follow-up: 21–34 years Longitudinal study	Early onset (for analysis on cannabis abuse): at age ≤14, ≤15, ≤16, ≤17, ≤18, ≤19 Early onset (for analysis on cannabis dependence): at age ≤14, ≤15, ≤16 Late onset: any onset occurring later	Consistently lower risk of DSM-IV cannabis abuse and DSM-IV cannabis dependence in subjects with later onset *Results were significant after covariate adjustment*	Alcohol and nicotine use before onset of CUD Alcohol use disorder and nicotine dependence before onset of CUD (separate analysis)	Early onset of cannabis is defined in reference to the high-risk phase of first CU in the sample Young sample (reduction of risk of forward telescoping and problems remembering CUD symptoms)	The assessment period covered the high-risk phase of CUD in the sample. This may reduce the risk of an artefact due to "more time to develop CUD" in subjects with earlier onset of use, but this risk cannot be excluded

(*Continued*)

TABLE 15.1 Epidemiological Studies on Earlier Onset of CU in CUD Risk (*cont.*)

Study	Sample	Definition of early CU onset	Result on the risk of CUD by early onset of CU	Consideration of covariates	Methodological advantages[a]	Methodological limitations[a]
Behrendt et al. (2012)		Continuous measure of age at first CU	Higher risk of DSM-IV CUD *Results were significant after covariate adjustment*	Externalizing disorders, paternal and maternal alcohol dependence, parental illegal drug dependence, age at onset of nicotine and alcohol use	A young sample (reduction of risk of forward telescoping and problems remembering CUD symptoms)	No cut-off for early CU applied The temporal sequence between CUD onset and covariates was not established The assessment period covered the high-risk phase of CUD in the sample. This may reduce the risk of an artefact due to "more time to develop CUD" in subjects with earlier onset of use, but this risk cannot be excluded
NESARC (Lopez-Quintero et al., 2011)	Subsample of lifetime cannabis users ($N = 7389$) of the nationally representative NESARC from the United States (participants of wave one and follow-up assessment) Baseline age: 18+	Early onset: at age ≤13 Late onset: any onset occurring later	Higher risk of DSM-IV cannabis dependence *This association was not found after covariate adjustment*	Socio-economic variables Mental disorders		Early onset not explicitely defined in reference to the high-risk phase of first CU in the sample Wide age range: possible risk of forward telescoping for first CU and problems remembering CUD in older subjects

[a]*Specific methodological advantages and disadvantages of studies on early CU onset as a risk factor for CUD as described in Table 15.2.*

Several epidemiological studies find an association between earlier onset of CU and CUD risk. CU, cannabis use; CUD, cannabis use disorder.

TABLE 15.2 Important Methodological Aspects of Studies on Early Onset of Substance Use and Substance Use Disorder Risk

Methodological obstacles	Possible solutions
There is no commonly agreed definition of early substance use onset	Definition of early onset of substance use in reference to the main incidence phase of substance use in the sample
Comparisons with latest onset of use do not permit identifying high-risk phases within the main incidence period of substance use	Consideration of other than extreme comparisons
Subjects with earlier onset of use may have had more time to develop a substance use disorder	Investigation of substance use disorder onset in subjects with first substance use within a defined and limited recent time period
Older subjects may show forward telescoping for first substance use. They may forget more distant past episodes of substance use disorders	Incidence of substance use and disorders mainly occurs in the second and third decade of life. Studies should focus on subjects from age groups for whom this phase of life is not too distant

Specific methodological aspects have to be considered in studies on early onset of substance use and substance use disorder risk.

Before focusing on the etiological models, two important features of earlier CU as a risk factor for CUD are addressed: its association with CU escalation, and its substance-specificity.

ESCALATION OF CU

Increases in CU amount and frequency after initiation are a prerequisite for CUD development. Earlier CU onset has to be linked with CUD risk via an association with a greater risk of intensified CU. Surprisingly, empirical evidence for a higher risk of such CU-escalation in early onset CU is relatively rare. In a large convenience sample aged 12–49, CU onset before the age of 16 was associated with more frequent CU (Baumeister & Tossmann, 2005). In an Australian study (Silins et al., 2013), CU before the age of 16 was associated with continued regular use in early adulthood. Of note, the studies measured CU in the 4 weeks and 12 months, respectively, prior to the assessment of the outcome, thus not reporting problematic CU that might have occurred earlier. They did not address CU duration. In both studies, the observed use patterns may have occurred in individuals who were already dependent. To summarize, there is somewhat restricted documentation of a higher risk of escalating CU in the association between earlier CU onset and CUD risk leaving an important part of the progression from earlier CU to CUD understudied.

HOW SPECIFIC IS EARLIER CU AS A RISK FACTOR FOR CUD?

It is of interest whether the association between earlier CU and CUD risk is cannabis-specific. If it was not cannabis-specific and, for example, mainly explained by a general vulnerability for externalizing behavior (Hicks et al., 2004) that manifested itself in early experimentation with different substances and lack of control over progressing use, these unspecific factors would deserve more weight in explanatory models, than cannabis-specific aspects. In a high-risk sample, earlier onset of alcohol use was associated with CUD risk (Kirisci et al., 2013), mediating the association between a heritable vulnerability for substance use disorders and CUD. In an epidemiological study, early smoking, but not drinking, was associated with CUD, even after adjustment for, for example, externalizing problems (van Leeuwen et al., 2013). Both studies are in support of cannabis-unspecific risk. Another study that considered earlier CU in the analysis (Behrendt et al., 2012) found that earlier CU, externalizing disorders, and paternal alcohol dependence, but not earlier drinking and smoking, were associated with CUD risk. In summary, findings to date indicate that cannabis-specific and nonspecific factors may underlie the association between earlier CU and CUD.

In the following, the role of earlier CU in CUD risk is presented in the context of selected models for substance use disorder development[c] (for an overview, see Tables 15.3 and 15.4).

THE ROLE OF EARLY CU IN CUD RISK IN THE CONTEXT OF ETIOLOGICAL MODELS FOR SUBSTANCE USE DISORDERS

Adolescence as a Phase of Vulnerability for Addiction

Adolescence is a period of transition from childhood into adulthood. Typical behavioral and motivational

[c]The models listed here are influential concepts on substance use disorder development in adolescents. They do not necessarily include early CU as a core factor, but permit a discussion of a role of early CU onset within the model. The core factors and mechanisms in the different models presented here are partially overlapping.

TABLE 15.3 Important Features of Earlier CU as a Risk Factor for CUD

Summary	
Is earlier onset of CU a risk factor for escalating CU?	**Is earlier onset of CU a substance-specific risk factor?**
A problematic increase of CU is a prerequisite for the development of CUD Empirical evidence from longitudinal epidemiological studies on earlier CU onset as a risk factor of problematic use progression is relatively rare This constitutes an important missing link between earlier CU onset and the risk of CUD Research is needed on earlier CU onset as a risk factor for problematic CU patterns that can lead to CUD. The specific features of these use patterns have to be identified	This question is crucial for understanding the role of earlier CU in CUD risk. It is also important for the choice of preventive efforts The association between earlier onset of CU and CUD could be either due to cannabis-specific factors (eg, THC effects) or unspecific factors (eg, impulsivity) Empirical evidence yields mixed results. It is possible that both substance-specific and unspecific factors contribute to the observed association between earlier onset of CU and CUD

It is important to understand whether earlier onset of CU is related to escalating CU and a substance-specific risk factor for CUD. CU, cannabis use; CUD, cannabis use disorder.

features of adolescence are, for example, increased novelty seeking, risk taking, and greater peer influence. These can be understood as functional in the "transition… to independence…" and new roles (Doremus-Fitzwater, Varlinskaya, & Spear, 2010). Adolescence is also a period of brain maturation, with an imbalance between slower development of the prefrontal cortex, which is important for executive functions and faster development of the motivation system (Chambers, Taylor, & Potenza, 2003; Crews, He, & Hodge, 2007; Romer et al., 2011).

It has been postulated that, while generally adaptive, these features may make adolescents vulnerable to the influence of drug using peers and rewarding substance effects, and place them at risk of undercontrolled substance use (Chambers et al., 2003; Crews et al., 2007; Doremus-Fitzwater et al., 2010; Romer et al., 2011). Following this hypothesis, tendencies of undercontrolled behavior typical for adolescence could link earlier CU to CUD.

Vulnerability for THC Effects in Adolescence

Pleasant subjective reactions to CU in adolescence are related to a higher CUD risk (Fergusson, Horwood, Lynskey, & Madden, 2003). Increased positive subjective CU-effects and reduced negative effects earlier in adolescence could influence CU-related reward learning—in terms of reduced experience of negative CU-consequences and increased rewarding effects in earlier CU—and thus lead to CUD. Results on THC-reactivity from animal studies show reduced aversive effects in adolescent, compared to adult rodents (Quinn et al., 2008; Schramm-Sapyta et al., 2007). However, in humans, subjective aversive effects were not associated with reduced CUD risk (Fergusson et al., 2003). Also, a review on animal studies found no evidence for more rewarding effects or self-administration in adolescent versus adult animals (Schramm-Sapyta, Walker, Caster, Levin, & Kuhn, 2009). Because of ethical considerations, however, objective THC-effects in younger versus older human adolescents are difficult to study.

It can be criticized that models on adolescence as a phase of vulnerability do not explain why only a small proportion of adolescents show risky CU (Romer et al., 2011).

Impairment of Executive Functions

Alternatively, it is not common features of adolescence, but individual risk factors, such as impairments in executive functions, that could link early CU with CUD risk. Such impairments and dominance of automatic over controlled cognitive processes are widely regarded as influential in substance use disorder etiology (Bühringer, Wittchen, Gottlebe, Kufeld, & Goschke, 2008; Redish, Jensen, & Johnson, 2008; Wiers, Gladwin, Hofmann, Salemink, & Ridderinkhof, 2013). Impaired cognitive functioning, such as poor regard of long-term consequences, could lead to earlier CU onset, undercontrolled CU, and CUD. It might be hypothesized, that in this process, early CU effects might disrupt maturation of executive control which could add to the risk of undercontrolled CU.

Comparing earlier and later CU, and earlier regular with later regular CU onset, respectively, studies find some indications for reduced executive functioning in earlier CU onset, but results are inconsistent over task conditions and domains of cognitive functioning (Becker, Wagner, Gouzoulis-Mayfrank, Spuentrup, & Daumann, 2010; Gruber et al., 2012; Pope et al., 2003), and two studies (Gruber et al., 2012; Pope et al., 2003) used samples with heavy CU. Importantly, available studies are often cross-sectional, obscuring the temporal sequence of executive function and early CU.

TABLE 15.4 Early CU in CUD Risk in the Context of Existing Models of Substance Use Disorder Etiology

Model	Core assumption	Important features	Important criticism or need of future research	Future research questions
Adolescence as a phase of vulnerability for addiction	Generally adaptive changes in behavior and motivation in adolescence contribute to the risk of substance experimentation, risky use, and substance use disorders An imbalance in brain maturation in adolescence (faster maturation of the motivational system vs the prefrontal cortex) is involved in these risks	Not cannabis-specific	Does not explain why only a small proportion of adolescents develop a CUD	Can the higher risk of CUD in subjects with earlier onset of use (partially) be attributed to the degree of expression of typical behavioral and motivational features and brain maturation in adolescence?
Vulnerability for THC effects in adolescence	Adolescents may be more susceptible to pleasant (rewarding), and less susceptible to unpleasant effects of THC. This could lead to frequent CU	Cannabis-specific	Does not explain why only a small proportion of adolescents develop a CUD Difficulty to obtain objective information on humans with respectively early and late onset	Which objective reactions to THC do younger and older human adolescents show? Of note: this research question is difficult to address in humans due to ethical restraints
Impairment of executive functions	A dominance of automatic over controlled cognitive processes contributes to substance use disorder etiology Lower executive functioning can lead to early first use and progression to CUD Alternatively, earlier substance use can disrupt processes of brain maturation and lead to less executive control over CU	This model considers cannabis-specific (disruption of brain maturation) or unspecific (if preexisting low executive functions lead to CU initiation) factors	Relatively little is known about executive functions in early versus late onset of CU Especially, more longitudinal studies that permit clarification of the temporal sequence of impaired executive function and early CU are needed	For which executive function can impairment predict early CU initiation and progression to CUD?
General heritable vulnerability for disinhibitory psychopathology	Substance use disorders and other mental disorders characterized by undercontrolled and impulsive behaviors share a common and unspecific heritable vulnerability Earlier onset of CU and the risk of CUD are both related to this underlying vulnerability	Not cannabis-specific	Other factors—such as THC effects—may also be of influence in the association between earlier CU onset and CUD	It would be of interest to study the vulnerability for disinhibitory psychopathology in earlier onset of use and CUD risk in relation to other factors, such as, THC effects, cognitive development or coping behavior
Psychosocial derailment	The nonnormative earlier onset of CU leads to adverse psychosocial consequences which lead to increased use and CUD	The model is cannabis-specific as it refers to the nonnormative aspects of earlier CU onset: • Cannabis is an illegal substance in many countries • Among cannabis users, early CU onset can be a deviation from the main time-period of CU initiation	Additional longitudinal-epidemiological studies that investigate possibly derailing psychosocial consequences of earlier versus later CU onset that could act as possible mediators in the link between earlier CU and CUD are needed	It would be of interest to further identify specific consequences of earlier (in contrast to later) onset of CU in the areas of, for example, cognitive, social and behavior development, mental health, and educational achievement
Problematic use motivation in earlier CU onset	Earlier CU is linked with increased CUD risk because of problematic use motives that are associated with early onset of use and increased use after initiation	Not cannabis-specific	Additional epidemiological-longitudinal studies on CU motives that are specifically related to earlier onset of CU are needed	Which CU motives are associated with earlier onset of CU? Are they also associated with the risk of CUD?

Earlier onset of CU is associated with CUD risk—but the underlying mechanisms remain to be identified. CU, cannabis use; CUD, cannabis use disorder.

General Heritable Vulnerability for Disinhibitory Behavior and Psychopathology

In this model, the core underlying factor is a heritable vulnerability that is common to substance use disorders, and other mental disorders characterized by impulsive behaviors. Twin studies including parental information support this model (Hicks, Krueger, Iacono, McGue, & Patrick, 2004; Marmorstein, Iacono, & McGue, 2009). Earlier CU onset could be regarded as an expression of undercontrolled behavior (eg, it violates norms on drug use). The link with CUD risk could then be explained by the underlying vulnerability for disinhibitory behavior that could contribute to escalating CU.

In support of this, epidemiological data showed that children with an alcohol dependent parent initiate CU earlier than controls (Obot et al., 2001). McGue, Iacono, and Krueger (2006) showed that the shared vulnerability for externalizing psychopathology is accounted for by genetic factors, as is the phenotypic link between early behavior problems and externalizing psychopathology. In a high-risk sample, earlier CU onset mediated the association between the degree of familial transmissible SUD liability, covering self-regulation, impulsive and antisocial behavior, and CUD (Kirisci et al., 2013). Moreover, an association between early CU onset and risk of current CUD in the NESARC was attenuated and nonsignificant, after controlling for covariates, including impulsivity. However, here, the outcome of the 12-month CUD may have included recurrent and stable CUD cases (Blanco et al., 2014).

One study found an association between earlier CU onset and CUD, after adjusting for early use of legal substances, externalizing disorders, and parental alcohol dependence (Behrendt et al., 2012). This finding may suggest an additional role of other factors (eg, THC effects).

Psychosocial Derailment and Problem Accumulation

One explanation for the association between earlier CU onset and CUD could be that especially earlier and thus, nonnormative CU leads to adverse psychosocial consequences, which then lead to intensified CU and CUD.

For example, in support of this, in a Latent Class Analysis, Wittchen et al. (2009) found an association between earlier CU onset and the probability of being in a class with elevated probabilities of a range of substance-related mental and social problems. However, no temporal order was established in the analysis.

No significant difference in the risk of subsequent depressive symptomatology was found for CU onset before the age of 18 (compared to age ≥ 18) in the cross-sectional NSDUH (Fairman & Anthony, 2012). To date, there are relatively few epidemiological, prospective-longitudinal studies on derailing psychosocial consequences of earlier versus later CU initiation as possible mediators in the association between earlier CU and CUD.

Problematic Use Motivation in Early Onset CU

Early CU could be linked with CUD risk via problematic use motives that are associated with early use, as well as the risk of intensified consumption and CUD. For alcohol, an epidemiological study found that subjects with adverse life events (eg, physical abuse) were more likely to report coping motives for their drinking (Rothman, Edwards, Heeren, & Hingson, 2008). Of interest, these adverse life events were associated with a higher risk of drinking before the age of 15 (compared to onset after the age of 20). This might imply that early adversity (eg, life events, mental disorders) and subsequently arising problematic use motives (coping and self-medication motives) could contribute to both earlier CU onset and escalation into CUD.

AN INTEGRATIVE MODEL OF THE ROLE OF YOUNGER AGE AT CU ONSET IN CUD RISK

Based on the existing insight discussed previously, an integrative model on putative mechanisms underlying the observed association between earlier CU onset and CUD is presented (see Fig. 15.2). The function of this heuristic model is to integrate different categories of putative underlying factors, and to model their putative relationship with age, CUD, and each other.

The model incorporates aspects of other models of CUD development, for example, the vulnerability-stress-model of mental disorder development, and the CUD development model recently presented by Blanco et al. (2014) as combined effects of different risk factors, and the relative impact of a risk factor depending on its occurrence in certain developmental periods.

A core assumption of the model is that chronological age at first CU is indirectly (not directly) connected with CUD risk, via different factors and pathways. The postulated associations between chronological age and the influential factors may vary in strength between factors and age-periods. Another core assumption of the model is that the underlying factors act on CUD risk via intensified CU, as a prerequisite for CUD. The model integrates three categories of putative influential factors. It is assumed that factors can interact within and between the three categories. These are: (1) the status of expectable

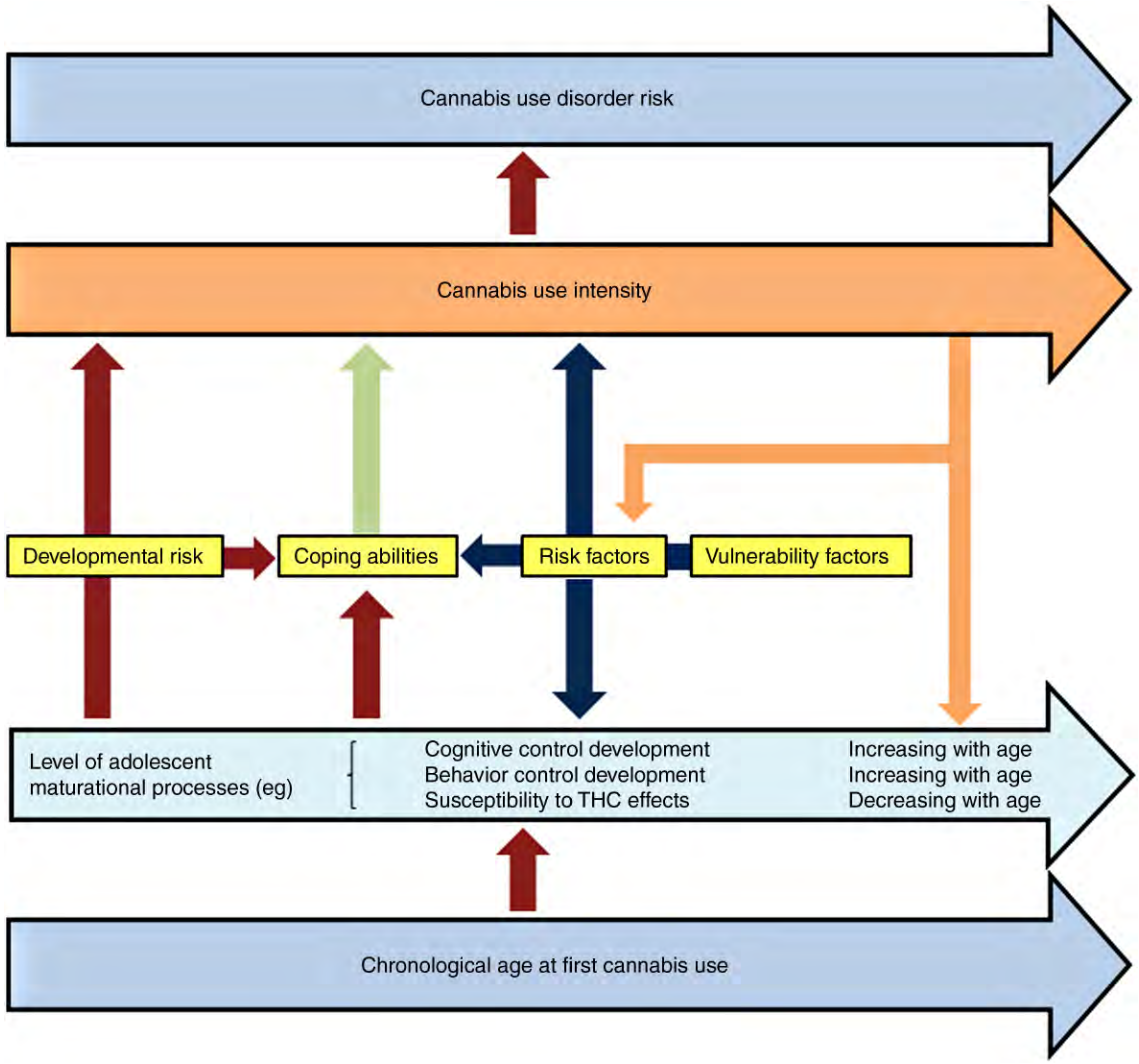

FIGURE 15.2 **What links earlier CU onset with the risk of CUD?** Putative pathways connecting early first CU with CUD risk.

age-related maturational processes, (2) nonnormative individual and social vulnerabilities and risk factors (eg, familial substance use disorders, peer use), and (3) coping abilities.

The category of age-related maturation comprises the developmental status of the individual, regarding factors that are undergoing changes during adolescence (and are thus related to age), such as, the development of cognitive control or of susceptibility to drug effects. This category is distinguished from vulnerabilities and risk factors, as it includes expectable maturational processes. In contrast, the category of vulnerabilities and risk factors comprises factors that are developmentally nonnormative, such as, an inherited vulnerability for low inhibitory control. The third category includes the ability to cope with stressors, and to limit negative consequences in critical situations (eg, ability to resist peer pressure, negative affect regulation). This ability is expected to be related to the maturational level of development. While the model focuses on factors explaining the link between earlier CU and CUD, it is also assumed that some of the factors may be involved in both the risk of earlier CU and the risk of CUD.[d]

How are these categories related to age at CU onset and intensified CU?

The status of *maturational processes* is expected to be related to age. A more immature status of such normative processes is expected in younger subjects, and expected to be linked to the risk of CU progression and CUD. For example, lower cognitive control in young subjects could contribute to a greater disregard of future risks and, thus, to intensified CU. A greater susceptibility

[d]This aspect is not included in Fig. 15.2 in order to enhance clarity of the figure.

for pleasant cannabis effects in younger subjects could also contribute to CU escalation. It is assumed that the maturational level can be directly linked with CUD risk (*direct developmental pathway*). It is also assumed that the maturational status can act via coping abilities. For example, a strong susceptibility to cannabis effects could interact with knowledge about drugs (*indirect developmental pathway*).

Risk factors can link early CU directly with increased CU, for example, via disregard for rules in conduct disorder (*nondevelopmental pathway*). Alternatively, risk factors can act via *coping abilities* or *maturational status* that are both related to age and individual development (*combined developmental and nondevelopmental pathway*). For example, peer CU could act via low social competence. Familial substance dependence could act via self-regulation development. Of note, in this pathway, the risk factor may cooccur with a certain maturational status or coping abilities, but it may also influence these factors (eg, lack of supervision could have an impact on behavior control development).

The model also includes a feedback component, assuming that, in subjects with early CU onset, CU and its escalation[e] can interfere with development, or contribute to risk factor occurrence.

AGE AT FIRST CU AND CUD ONSET AND THE COURSE OF CUD

Given the information on the high-risk incidence phases for CU and CUD and the model of adolescence as a period of vulnerability for addiction, the question arises whether age at CUD onset is related to a more severe course of CUD. Information on CUD course by earlier CU and CUD onset is relatively rare, to date. Interestingly, for alcohol, using cross-sectional data, Hingson, Heeren, & Winter (2006a, 2006b) showed that an earlier age at drinking, and alcohol dependence onset, respectively, was associated with indicators of greater course severity.

SUMMARY AND OUTLOOK

CU and CUD incidence mainly occurs in adolescence and early adulthood. A younger age at first CU is a risk factor for CUD. Putative explanatory factors are, for example, features of adolescence, psychosocial derailment, and an underlying vulnerability for disinhibitory psychopathology. As for outlook, prospective-longitudinal studies on a range of putative explanatory factors are needed.

MINI-DICTIONARY

Cannabis use disorder DSM-IV cannabis abuse or dependence.
Incidence First occurrence of an event.
Psychotropic substance Substance with effects on the central nervous system.
Right censoring When age-specific incidence risk is measured in a population, some subjects have not reached the highest age yet. For these subjects, information on age-periods above their age is unavailable (censored).
Risk factor A factor associated with an elevated risk of a subsequent outcome.

CHAPTER

16

Effects of Cannabis Use on Neurocognition in Adolescents and Emerging Adults

N.E. Wright, K.E. Maple, K.M. Lisdahl

Department of Psychology, University of Wisconsin-Milwaukee, Milwaukee, WI, United States

SUMMARY POINTS

- Significant neuromaturation occurs between the ages of 12 and 25, making adolescent and young adult brains more susceptible to damage from substances, such as, cannabis.
- Cannabis use in adolescence has been related to poorer attention, memory, inhibition, processing speed, IQ, and decision making.
- Adolescent and emerging adult cannabis users have different patterns of gray matter volumes, cortical thickness, and white matter integrity. These findings are often associated with functional deficits in neurocognitive performance.
- Functional magnetic resonance imaging (fMRI) studies reveal deficits in memory, attention, and motor tasks. Increased functional connectivity has also been found across parietal, frontal, temporal, and cerebellar regions.
- Earlier onset of use is related to worse outcomes in neurocognitive, neuroanatomical, and neurological function.
- More frequent and greater quantities of use of cannabis are related to worse outcomes.
- Gender moderates some of the effects of cannabis use.
- Future research should be directed at establishing causal, rather than correlational, relationships.
- Clinicians should be more proactive in assessing substance use in adolescence, so as to begin interventions early.

KEY FACTS OF NEUROCOGNITIVE DIFFERENCES IN ADOLESCENT AND YOUNG ADULT CANNABIS USERS

- Adolescent and young adult cannabis users have slower processing speed, poorer ability to sustain their attention, worse verbal memory, and poorer decision-making, in comparison to controls.
- These neurocognitive problems have real-world implications. Adolescent and young adult cannabis users also reported increased symptoms of inattention, depression, anxiety, poorer sleep, increased school problems, and lower grades.
- They are more likely to engage in impulsive behavior, and have less ability to inhibit inappropriate responses.
- Overall, neurocognitive problems are worse in heavy (daily) users, and in those who began using cannabis regularly (at least weekly) before they are 18 years old.

KEY FACTS OF NEURONAL DIFFERENCES IN ADOLESCENT AND YOUNG ADULT CANNABIS USERS

Structural

- These cognitive problems are related to brain structure abnormalities in areas of the brain, such as, the amygdala, hippocampus, nucleus accumbens, cerebellum, and prefrontal cortex.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00017-X
Copyright © 2017 Elsevier Inc. All rights reserved.

- Most studies point to diminished white matter integrity in cannabis users, compared to controls.
- Other factors may influence the relationship between cannabis use and brain structure, including age of use onset, gender, other substance use, and cannabis content.

Functional

- During attention and inhibition tasks, cannabis users exhibit increased activation in the motor cortex and frontal and parietal regions, but have dispersed anterior cingulate cortex activation during an inhibition task.
- During a faces memory task, greater parahippocampal gyrus activation was related to greater cannabis use; however, while engaging working memory, cannabis users have more activation in the anterior cingulate cortex, dorsolateral prefrontal cortex, and inferior frontal gyrus, compared to controls.
- A spatial working memory task elicited decreased activity in the right parietal cortex, and increased activity in the dorsolateral prefrontal cortex, while a visuospatial memory study found increased activation in the right inferior frontal gyrus, left middle frontal gyrus, and right superior temporal gyrus, in cannabis users versus controls.
- Cannabis users have greater resting state functional connectivity and task-based functional connectivity in several networks.
- Age of use onset, length of abstinence, and gender, in addition to cannabis use, may all impact brain activation patterns.

LIST OF ABBREVIATIONS

Brain Regions

ACC Anterior cingulate cortex
dlPFC Dorsolateral prefrontal cortex
IFOF Inferior fronto-occipital fasciculus
ILF Inferior longitudinal fasciculus
PFC Prefrontal cortex

Brain Imaging Terms

BOLD Blood oxygen level dependent
CBF Cerebral blood flow
DTI Diffusion tensor imaging
FA Fractional anisotropy
fcMRI Functional connectivity magnetic resonance imaging
fMRI Functional magnetic resonance imaging
MD Mean diffusivity
MRI Magnetic resonance imaging
THC Tetrahydrocannabinol

RISING RATES OF USE

The last 20 years have seen a rise in adolescent cannabis use, with 6.5% of 12th graders reporting daily use (Johnston, O'Malley, Bachman, & Schulenberg, 2013). Concurrently, as increasing numbers of US states have legalized medical use and, in two states, recreational use, perception of risk has decreased (Johnston et al., 2013). This increase in use and abuse in this vulnerable population is creating an increasing need to understand the neurocognitive effects of chronic cannabis use. The present review will summarize the neuronal consequences of regular cannabis use in adolescents and young adults (ages 12–25), while paying particular attention to unique effects by gender and other moderators. We will then discuss clinical implications, and address broader considerations for those working with and studying emerging adults who use cannabis.

THE DEVELOPING BRAIN

Neurological developmental changes are abundant in adolescence, including pruning of gray matter and cortical thinning, in conjunction with improved performance in areas associated with executive functioning, such as, the prefrontal cortex (PFC) (Gogtay et al., 2004). Further, the endocannabinoid system itself is going through vast changes that make it particularly vulnerable to exogenous cannabinoids (for review, see Schneider, 2008). These changes may lead to increased vulnerability to risky behavior, and the neurotoxic effects of drug use (for review, see Bava & Tapert, 2010). Some suggest that, due to this malleable time period of brain development, changes later in life may not be able to correct for alterations in brain development during teen years (Blakemore & Choudhury, 2006). As a result of the sensitive nature of this time period, it is important to understand the neurocognitive and neuronal consequences of cannabis abuse.

NEUROCOGNITIVE IMPLICATIONS OF CANNABIS USE

Regular (weekly to daily) cannabis use has been associated with several neurocognitive deficits, including attention (Ehrenreich et al., 1999; Medina et al., 2007a; Tapert, Granholm, Leedy, & Brown, 2002), executive functioning (Gruber, Sagar, Dahlgren, Racine, & Lukas, 2012; Fontes et al., 2011; McHale & Hunt, 2008;

Medina et al., 2007a), impulsive behavior and inhibition (Gruber et al., 2012a; Gruber, Dahlgren, Sagar, Gonenc, & Lukas, 2013; Lisdahl & Price, 2012; Solowij et al., 2012; Becker, Collins, & Luciana, 2014), psychomotor speed (Medina et al., 2007a; Lisdahl & Price, 2012), visuospatial memory (Harvey, Sellman, Porter, & Frampton, 2007; Becker et al., 2014), verbal memory (Gonzalez et al., 2012; Jacobsen, Pugh, Constable, Westerveld, & Mencl, 2007; Solowij et al., 2011; Tait, Mackinnon, & Christensen, 2011; Becker et al., 2014), and overall intelligence (Fried, Watkinson, & Gray, 2005; Meier et al., 2012; see Fig. 16.1).

These effects appear to be moderated by frequency (Fried et al., 2005; Gonzalez et al., 2012; Meier et al., 2012; Medina et al., 2007a; Lisdahl & Price, 2012), age of onset (eg, Gruber, Dahlgren, Sagar, Gönenc, & Killgore, 2012; Ehrenreich et al., 1999), and gender (Lisdahl & Price, 2012). As would be expected, heavier use of cannabis, both in frequency and quantity, has been linked to greater deficits in neurocognitive functioning (Fried et al., 2005; Gonzalez et al., 2012; Lisdahl & Price, 2012; Medina et al., 2007a; Meier et al., 2012). Further, adolescents who begin regularly (at least weekly) using cannabis when they are under 16–18 have more pronounced deficits in inhibition, attention, and executive functioning, compared to those who started using later (Pope et al., 2003; Gruber et al., 2012a; Ehrenreich et al., 1999; Fontes et al., 2011; Meier et al., 2012). When looking at gender differences, emerging adult male cannabis users tend to have more pronounced difficulty with psychomotor speed, compared to female users (Lisdahl & Price, 2012). It should be noted that analysis of interactive gender effects has been limited, though a number of studies that have assessed gender as a moderator have found null results (Tait et al., 2011; Solowij et al., 2011). Therefore, further assessment of potential interactive effects between gender and cannabis use is needed.

Importantly, differences in cognitive performance appear to remain, even after up to a month of monitored abstinence in adolescents (Hanson et al., 2010; Medina et al., 2007a), and longitudinal changes have been observed. For instance, Tapert and colleagues (2002) followed 16 year olds for 8 years, finding that cannabis use over the study period predicted poorer attention at follow-up periods. Similarly, Tait and colleagues (2011) found light and heavy users had a decline in performance across cognitive domains over an 8-year period, while former and nonusers did not exhibit the same pattern. In the largest prospective study conducted to date, Meier et al. (2012) assessed participants prior to cannabis use (7–13 years old), and followed them until they were 38 years old. They found that regular use of cannabis across 3 or more study time points resulted in a 6 point IQ decline, while those who never used cannabis had an almost one point increase. Results were maintained after controlling for childhood IQ, education, recent cannabis use, tobacco, other drug, and alcohol dependence, as well as schizophrenia diagnosis. Impairments were also found across neuropsychological domains, including memory, processing speed, verbal comprehension, and perceptual reasoning.

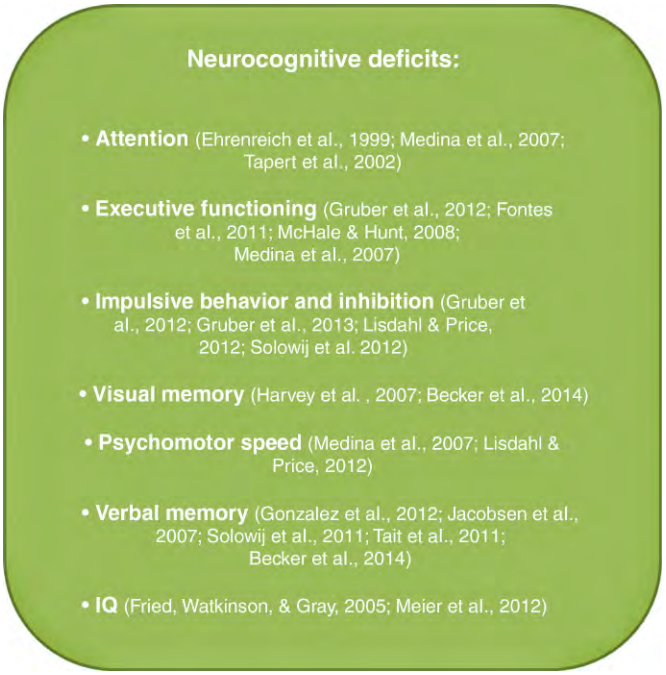

FIGURE 16.1 Neurocognitive deficits in emerging adult cannabis users. Overview of deficits in neurocognitive functioning in adolescent and young adult cannabis users, including citations for studies that have found these differences.

STRUCTURAL IMPLICATIONS OF CANNABIS USE

As function often follows structure (Greicius, Supekar, Menon, & Dougherty, 2009), it is perhaps unsurprising that neuroanatomical differences have been found between cannabis users and nonusers (see Figs. 16.2, 16.3).

Gray Matter. Converging lines of evidence suggest cannabis use in this sensitive time period may be related to differing patterns of gray matter architecture, perhaps due to immature neuronal development. Differences in gray matter volume between users and nonusers are assumed to relate to inefficient pruning of unnecessary synapses or inflammation in the case of larger regions or decreased synaptic density in smaller regions. Due to greater CB1 densities in regions, such as, the amygdala, hippocampus, hypothalamus, basal ganglia, cerebellum, anterior cingulate cortex, and prefrontal cortex (Iversen, 2003), these areas may be particularly susceptible to structural differences between cannabis users and nonusers. Increased volume has been found primarily in adolescent samples, including

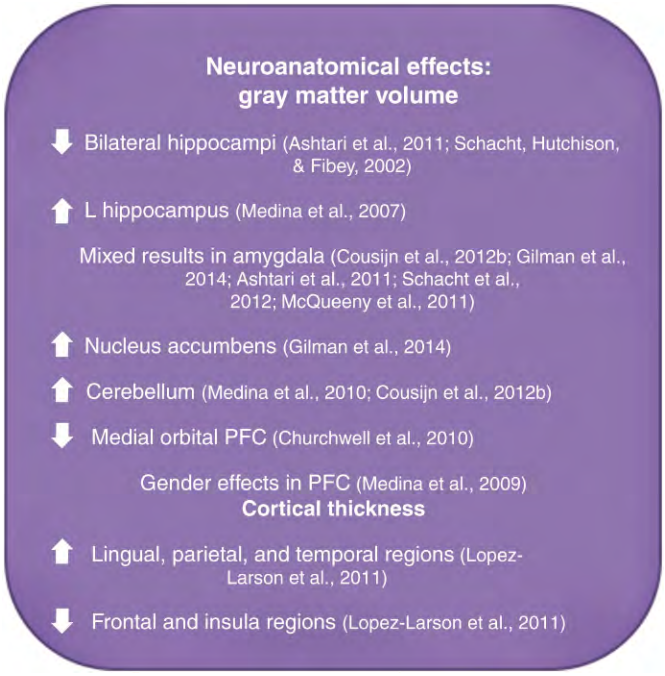

FIGURE 16.2 Differences in gray matter volume in emerging adult cannabis users. Overview of differences in gray matter volume in adolescent and young adult cannabis users, including citations for studies that have found these differences.

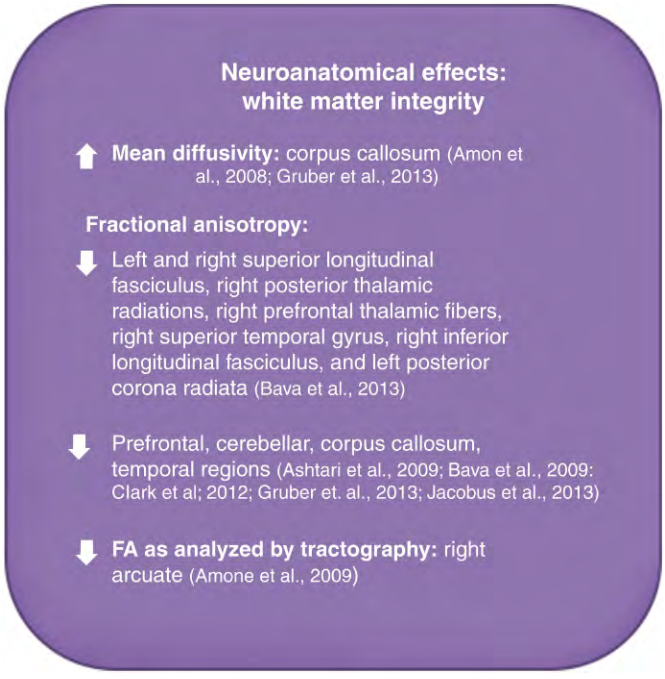

FIGURE 16.3 Differences in white matter integrity in emerging adult cannabis users. Overview of differences in white matter integrity in adolescent and young adult cannabis users, including citations for studies that have found these differences.

the right amygdala in females (McQueeny et al., 2011), left hippocampus (Medina, Schweinsburg, Cohen-Zion, Nagel, & Tapert, 2007b), nucleus accumbens (Gilman et al., 2014), cerebellum (Medina, Nagel, & Tapert, 2010; Cousijn et al., 2012b), and inferior PFC in females (Medina et al., 2009). In young adults, one study found no differences (Ashtari et al., 2011), one found increased (Gilman et al., 2014), and another decreased (Schacht, Hutchison, & Filbey, 2012) amygdala volumes. Cousijn and colleagues (2012b) found larger amygdala volumes predicted increased cannabis use problem severity. Young adult cannabis users have been found to have smaller bilateral hippocampal (Ashtari et al., 2011; Schacht et al., 2012) and medial orbital PFC volumes (Churchwell, Lopez-Larson, & Yurgelun-Todd, 2010). Patterns of cortical thickness have thus far shown decreased thickness in frontal and insula regions and increased thickness in lingual, parietal, and temporal regions (Lopez-Larson et al., 2011). Potency and content of cannabis use may impact structural findings. For example, use of cannabis with higher THC: cannabidiol ratios, two primary components of cannabis, have been found to be predictive of larger bilateral hippocampus volume, indicating that potency of THC also plays a role (Demirakca et al., 2011).

As structural studies have thus far been cross-sectional, these differences may be a result of cannabis use or, alternatively, may predispose young adults to initiate use of cannabis. For example, in a 4-year study of neuroanatomical volume, having smaller orbitofrontal volume at age 12, most specifically the right lateral orbitofrontal cortex, was found to be predictive of onset of cannabis use by age 16 (Cheetham et al., 2012). Whether cannabis is causing or reflecting neuronal differences, abnormalities in gray matter volume in areas, such as, the amygdala, cerebellum, and PFC have been found to be related to greater depressive symptoms, executive dysfunction, or increased cannabis related problems (Cousijn et al., 2012b; McQueeny et al., 2011; Medina et al., 2009, 2010), underscoring the importance of the functional implications related to neuronal differences.

White Matter. Myelinated axons, or white matter, reach within and across brain regions to convey necessary information quickly. Improved white matter integrity results in increased communication efficiency. Studies use diffusion tensor imaging (DTI), assessing mean diffusivity (MD) and fractional anisotropy (FA), or diffusion of water and coherence across white matter tracts, respectively. With few exceptions (DeLisi et al., 2006; Cousijn et al., 2012b), deficits in white matter integrity have also been reported in cannabis users. In young adult samples, findings suggest increased MD in the corpus callosum (Arnone et al., 2008; Gruber et al., 2013), as well as decreased FA in the left and right genu and left internal capsule in early regular onset (before age 16) cannabis use (Gruber et al., 2013). In adolescents, results indicate decreased FA in prefrontal, parietal, cerebellar, corpus callosum, and temporal regions (Ashtari et al., 2009; Bava et al., 2009; Clark, Chung, Thatcher,

Pajtek, & Long, 2012; Jacobus, Squeglia, Infante, Bava, & Tapert, 2013), and decreased FA in the right arcuate fasciculus, as well as increased radial diffusivity in the left and right arcuate fasciculus, as measured by tractography (Ashtari et al., 2009). Longitudinally, Bava, Jacobus, Thayer, and Tapert (2013) found deficits in FA in seven clusters: the left and right superior longitudinal fasciculus, right posterior thalamic radiations, right prefrontal thalamic fibers, right superior temporal gyrus, right inferior longitudinal fasciculus, and the left posterior corona radiata. However, in contrast to the cross-sectional studies that statistically controlled for alcohol, Bava et al. (2013) found that changes over the 18-month follow-up period were predicted by frequency of alcohol use, rather than cannabis. Additional longitudinal studies examining the relative impact of alcohol versus cannabis use on white matter microstructure are needed.

Potential Confounding or Moderating Factors. Other factors besides cannabis exposure may contribute to structural differences. As stated above, increased alcohol consumption has also been linked to worse white matter integrity in adolescents (Bava et al., 2013), although the majority of the aforementioned studies did statistically control for alcohol use. Age of regular use onset has similarly been related to poorer FA (Gruber, Silveri, Dahlgren, & Yurgelun-Todd, 2011; Gruber et al., 2013) and smaller medial orbital PFC volumes (Churchwell et al., 2010). Results regarding interactions between gender and cannabis use on brain structure have been mixed. Some have found no difference (Medina et al., 2007a; Gilman et al., 2014; Cousijn et al., 2012b), while others have found gender to significantly interact with use, especially in adolescent users. Medina and colleagues (2009) found female cannabis users had larger PFC volumes, compared to female controls, while male cannabis users had smaller PFC volumes, compared to male controls. McQueeny and colleagues (2011) found cannabis-using females had larger right amygdala volumes than male users and male and female controls.

FUNCTIONAL IMPLICATIONS OF CANNABIS USE

Various functional MRI (fMRI) tasks have found different activation patterns in cannabis users, in comparison to controls (see Figs. 16.4, 16.5). In general, adolescent and young adult cannabis users appear to compensate for deficits in functioning through overactivation of important brain regions, as well as recruiting additional regions to assist in completing tasks (eg, Abdullaev, Posner, Nunnally, & Dishion, 2010; Tapert et al., 2007). In particular, cannabis-using adolescents and young adults have less efficient functioning in attention and inhibition tasks. In an attention task, greater activation in the right PFC, motor cortex, and bilateral parietal cortex

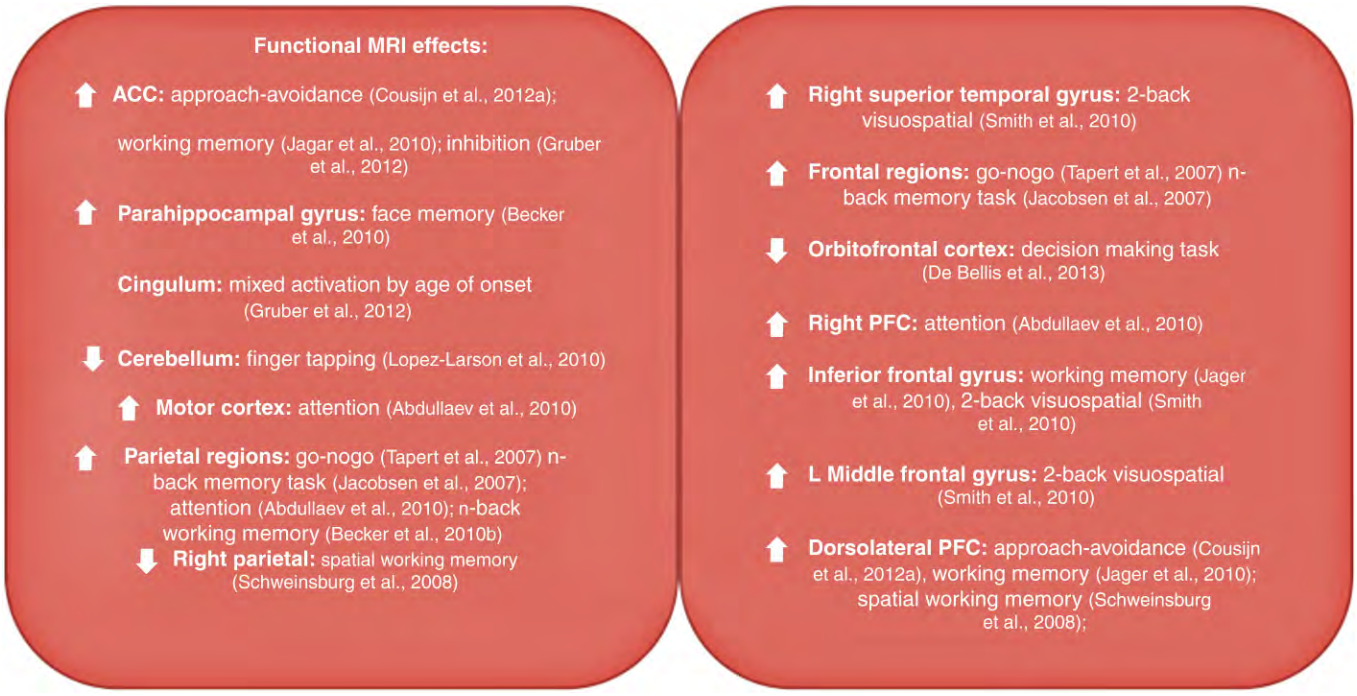

FIGURE 16.4 **Difference in neuronal function as measured by fMRI in emerging adult cannabis users.** Overview of differences in blood oxygen level dependent (BOLD) response by task and brain region in adolescent and young adult cannabis users, including citations for studies that have found these differences.

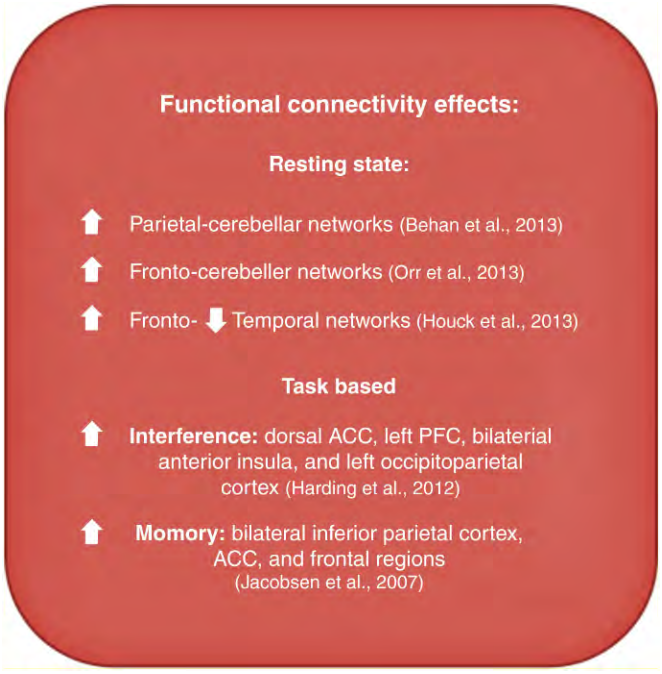

FIGURE 16.5 Differences in functional connectivity in emerging adult cannabis users. Overview of differences in functional connectivity by task and brain region in adolescent and young adult cannabis users, including citations for studies that have found these differences.

have been found and, even with this increased activation, adolescent users had worse performance over all (Abdullaev et al., 2010).

One go-nogo task found no group differences in activation in adolescent users (Behan et al., 2013). However, others (Tapert et al., 2007) have found adolescents to have increased activation in frontal and parietal regions after 28 days of abstinence during similar go-nogo tasks. In an fMRI interference task assessing inhibition, Gruber and colleagues (2012b) found cannabis use to result in broader activation of the ACC. Further, they found that the cingulum was activated differently based on early (before 16 years old) or late onset of cannabis use.

Differences in working memory function are also apparent. In a faces memory task, young adult heavy users, in comparison to occasional users, had more activation in the parahippocampal gyrus (Becker, Wagner, Gouzoulis-Mayfrank, Spuentrup, & Daumann, 2010a). Frequency of use, as well as age of onset, has been assessed in young adults, with early onset found to be predictive of greater left parietal activation during a working memory task (Becker, Wagner, Gouzoulis-Mayfrank, Spuentrup, & Daumann, 2010b). When not controlling for recent cannabis use or binge drinking through required abstinence, greater activation in the right inferior frontal gyrus, left middle frontal gyrus, and right superior temporal gyrus has been found in young adult cannabis users, in comparison to healthy controls, during a visuospatial memory task (Smith, Longo, Fried, Hogan, & Cameron, 2010). Male adolescent cannabis users have demonstrated overactivity in the ACC, dlPFC, and inferior frontal gyrus, during a working memory task (Jager, Block, Luijten, & Ramsey, 2010). Decreased activity in the right parietal cortex, but increased activity in the dlPFC, has also been found during a spatial working memory task in adolescents (Schweinsburg et al., 2008). Further, recent (2–7 days) cannabis users had greater activation in frontal regions than abstinent (27–60 days) adolescent users, but both had significantly greater activation than nonusing controls, again indicating overuse and compensation of frontal regions during spatial working memory tasks (Schweinsburg et al., 2010). Cannabis and nicotine comorbid adolescent users in nicotine withdrawal demonstrated increased activation in frontal and parietal regions, in comparison to controls during a verbal memory task (Jacobsen et al., 2007).

In adolescents, decreased activation, suggesting underutilization of important areas, has also been found in the cerebellum, in a motor skills task using finger tapping (Lopez-Larson et al., 2012), and in the orbitofrontal cortex in a decision making task (De Bellis et al., 2013). In young adults, an approach-avoidance task found no group differences, though dlPFC and ACC activation predicted cannabis problem severity at 6-month follow-up (Cousijn et al., 2012a).

Functional connectivity across and within regions has also been assessed in adolescents. Resting state functional connectivity (fcMRI) analyses have found increased connectivity in parietal-cerebellar networks, fronto-cerebellar, and fronto-temporal networks (Behan et al., 2013; Orr et al., 2013; Houck, Bryan, & Feldstein Ewing, 2013). In looking at functional connectivity in a verbal memory task, comorbid cannabis and nicotine users had increased connectivity between the right and left inferior parietal cortex, the anterior cingulate gyrus, and frontal regions, with decreased connectivity when in nicotine withdrawal (Jacobsen et al., 2007). In adults with early age of onset, greater connectivity was found within the dorsal ACC, the left PFC, the left and right anterior insula, and the left occipitoparietal cortex, during an interference task (Harding et al., 2012). Together, these findings across fMRI and fcMRI studies indicate different patterns related to use that are frequently associated with poorer performance and outcomes.

Age of onset appears to influence differences in BOLD response (Harding et al., 2012; Schweinsburg et al., 2008; Becker et al., 2010b), though this finding is not universal (Becker et al., 2010a). Gender has not often been assessed, but in the few circumstances it has, no difference has been found (Jacobsen et al., 2007). Length of abstinence is also an important issue in assessing differences. Jacobus et al. (2012) found that adolescents had decreased cerebral blood flow in four regions, including the frontal gyrus, and increased CBF in the right precuneus at

baseline; differences disappeared at 4 weeks abstinence. Therefore, there is some preliminary evidence for recovery of function with sustained abstinence.

CLINICAL IMPLICATIONS AND FUTURE DIRECTIONS

Prevalence of cannabis use and abuse is rising in the United States (Johnston et al., 2013). Rates of use are particularly disconcerting in adolescent and young adult populations, as neuromaturational changes in this time period may make them more susceptible to the neurotoxic effects of cannabis (Schneider, 2008). Adolescents demonstrate more robust and diverse cognitive (eg, working memory, verbal memory, complex attention, inhibition, decision making, processing speed) and brain structural abnormalities, compared to adult users. Other important moderators influence the impact of cannabis use, including extent of use, gender, and age of regular cannabis use onset.

Although there has been replication in cross-sectional studies that are consistent with animal models and longitudinal studies, additional longitudinal data is needed to determine the whether these neurocognitive abnormalities measured in cannabis users are risk factors for use, or directly caused by cannabis exposure. Additional research examining potential gender differences is also necessary, as few studies have adequately addressed this issue. Teasing apart alcohol and cannabis couse is also important, as cannabis users often binge drink, a fact that may be a more robust predictor of neurocognitive deficits (eg, Bava et al., 2013). Finally, while not addressed in this review, due to space limitations, greater understanding is needed regarding the specific effects of specific components of cannabis (eg, THC and cannabidiol), as well as the influence of psychiatric comorbidities on cannabis use and neurocognitive consequences.

These converging lines of evidence regarding the neurocognitive consequences of cannabis use in adolescence and young adulthood highlight the dire need to protect the developing brain through screening, prevention, and treatment. Unfortunately, the majority of physicians may not be screening for alcohol, let alone drug use (Town, Naimi, Mokdad, & Brewer, 2006). As earlier age of regular use onset is related to worse outcomes, prevention of cannabis use initiation should be a top priority. Therefore, in clinical and school settings, early screening for cannabis use is critical. For example, CRAFFT (Knight, Sherritt, Shrier, Harris, & Chang, 2002) is a brief computerized program that asks six substance use questions to provide individualized feedback on risk for developing a substance use disorder, and can be implemented in many clinical settings. Encouraging emerging adults to wait until they are *at least* 18 to begin using any substances (ideally 25) would reduce the likelihood of developing a cannabis use disorder, and reduce risk for developing negative neurocognitive effects (Meier et al., 2012; Substance Abuse and Mental Health Services Administration, 2013).

MINI-DICTIONARY

Executive functioning Executive functioning refers to higher level functioning, such as management, regulation, and goal-directed behavior, that occurs within the prefrontal cortex.
Gray matter Composed of neurons, gray matter is a major component of the cortex. It provides much of the structure for the brain, so reductions in volume, and less complex patterns of folding within gray matter are often related to functional deficits.
Inhibition The ability to prevent inappropriate or incorrect responding.
Processing speed The ability to efficiently and accurately process information.
Sustained attention The ability to maintain focus on a task over an extended period of time, typically measured through long and uninteresting tasks.
Visuospatial memory Memory related to visual stimuli.
White matter White matter refers to axons covered in a fatty sheath called myelin. Such myelinated axons increase the speed of communication within and across brain regions. Therefore, analysis of white matter integrity is used to measure how efficiently different brain regions communicate.
Working memory The ability to hold and manipulate information in your mind for a short period of time.

Correlates and Consequences of Prenatal Cannabis Exposure (PCE): Identifying and Characterizing Vulnerable Maternal Populations and Determining Outcomes for Exposed Offspring

L.K. Brents

Brain Imaging Research Center, Psychiatric Research Institute, University of Arkansas for Medical Sciences, Little Rock, AR, United States

SUMMARY POINTS

- Between 5% and 15% of pregnant women abuse illicit drugs.
- Of these women, 65–75% use cannabis during pregnancy, meaning that an estimated 5–10% of neonates are exposed to cannabis in utero.
- Prevalence estimates rely on a combination of self-report and analysis of biological samples (ie, maternal hair, urine, oral fluids, and neonatal meconium), which indicate that a small minority (<35%) of women are forthcoming about their cannabis use during pregnancy.
- Women who use cannabis during pregnancy are more likely to be younger, unmarried, of lower socioeconomic status (ie, lower education and income), and to have had unplanned pregnancies, compared to pregnant women who don't use cannabis.
- Effects of PCE are dose-dependent, with more severe negative effects occurring with heavier prenatal exposure.
- PCE is associated with lower birth weight, shorter birth length, lifelong smaller head circumference, reduced length of gestation, neonatal neurological disturbances, reduced function in specific cognitive domains (memory, verbal, and abstract/visual reasoning), but not overall intelligence, during grade school, increased impulsivity and hyperactivity, depression at age 10, poor school achievement and delinquency in adolescence, increased use of tobacco and marijuana in adolescence, and altered neural function for visuospatial working memory and motor impulse control, in early adulthood.

KEY FACTS OF CANNABIS EXPOSURE

- *Cannabis* is a plant that contains over 400 chemicals.
- The psychoactive effects of cannabis are caused by the cannabinoid Δ^9-tetrahydrocannabinol (Δ^9-THC).
- The effects of Δ^9-THC and other pharmacologically active cannabinoids are mediated by the endocannabinoid system (ECS); specifically, Δ^9-THC activates at least two G-protein coupled receptors: the Cannabinoid 1 Receptor (CB1R) and the Cannabinoid 2 Receptor (CB2R).

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00018-1
Copyright © 2017 Elsevier Inc. All rights reserved.

- The ECS is integrally involved in a variety of biological processes that are vulnerable to disruption by exogenous cannabinoid exposure: mood, cognition, appetite, energy storage and metabolism, bone formation, reproduction, and embryonic and fetal neural development.
- Acute exposure to cannabis distorts spatial and temporal perception, elevates mood, increases appetite, impairs memory and cognition, and has a suspected link to adverse cardiovascular episodes.
- Cannabis with high Δ^9-THC content can cause anxiety and/or lead to psychosis and schizophrenia onset in susceptible individuals.
- Chronic cannabinoid exposure can lead to cognition and memory problems, disrupt the function of the male and female reproductive systems, and lead to cannabis use disorder, which is characterized by dependence and withdrawal symptoms upon cessation.
- Younger individuals (adolescents) are more susceptible than adults to the adverse effects of marijuana, especially dependence and psychosis.

LIST OF ABBREVIATIONS

CB1R, CB2R	Cannabinoid Receptors 1 and 2
Δ^9-THC	Δ^9-Tetrahydrocannabinol

OPPS	Ottawa Prenatal Prospective Study
PCE	Prenatal cannabis exposure
SAMHSA	Substance Abuse and Mental Health Services Administration
SIDS	Sudden Infant Death Syndrome
UDS	Urine drug screening

INTRODUCTION

Cannabis is the most abused illicit drug worldwide (WHO, 2014) and has been used for millennia across diverse cultures for recreational, medicinal, religious, and industrial purposes (Zuardi, 2006). Because cannabis has never been documented as the primary cause of even a single death (Sidney, 2003), its use is regarded as safe by many in the public, leading to several strong movements throughout the world to legalize marijuana use for medicinal and recreational purposes (Johnson, 2014). Considering the widespread use of cannabis in the general population, it is not surprising that cannabis is used by women immediately before, during, and after pregnancy. Despite the perceived safety of cannabis throughout the general public, unnecessary use of pharmacologically active substances during pregnancy is widely discouraged, especially when their effects on the mother–fetus dyad are unknown, or suspected to potentially cause harm. The issue of marijuana's harm versus benefit in the general population is a controversial subject; similarly, reports on many of the suspected effects of prenatal cannabis exposure (PCE) are conflicted, or nuanced, and require careful consideration. This chapter aims to explore the correlates and consequences of PCE by examining the characteristics of women who use cannabis during pregnancy, and summarizing the scientific literature that describes the lifelong consequences of PCE on offspring.

PREVALENCE OF PCE AND BEHAVIORAL PATTERNS OF CANNABIS USE ACROSS PREGNANCY

With few exceptions, the possession, sale, and transport of cannabis is illegal throughout the world. Nevertheless, cannabis use is highly prevalent. In a 2013 Pew Research Center poll in the United States, 48% of respondents reported ever using marijuana, with 12% of respondents reporting use in the past year (Desilver, 2013). An estimated 17.4% of past-year cannabis users were also daily or near-daily users (SAMHSA, 2014). Consistent with these data, 51.4% of young adults in an Australian sample reported ever using cannabis; importantly, more than 21% of individuals in this sample were diagnosed as ever having a cannabis use disorder by age 21 (Hayatbakhsh, Najman, Bor, O'Callaghan, & Williams, 2009).

To determine the prevalence and impact of PCE, one should focus on drug use by women. According to the US. Substance Abuse and Mental Health Services Administration (SAMHSA), 11.4% of all women and 5.4% of pregnant women between ages of 15 and 44 were current illicit drug users in 2012–13, with rates as high as 14.6% for pregnant teenagers aged 15–17 (SAMHSA, 2014). In close agreement with the US SAMHSA data, a large Australian study (n = 25,049) from 2000 to 2006 determined that 9.3% of nonpregnant women of childbearing age self-reported regular cannabis use (Hayatbakhsh et al., 2011), suggesting that a significant proportion of women use drugs during the periconceptual period. Investigators in a London study screened 807 consecutive positive urine pregnancy tests for licit and illicit drugs, and determined that 14.5% tested positive for cannabis, confirming that there is a high prevalence of early PCE (Sherwood, Keating, Kavvadia, Greenough, & Peters, 1999).

Most women abstain from drug use during pregnancy. Upon recognition of the pregnancy, at least half of women who use illicit drugs remit at some point in their pregnancy (SAMHSA, 2014). Such women are able to progressively reduce drug consumption, and even achieve complete abstinence by the third trimester (Ebrahim & Gfroerer, 2003; Gray et al., 2010). Remission of drug use during pregnancy is associated with baseline severity of drug use, psychosocial stressors, and initiation of prenatal care (Corse & Smith, 1998). Postpartum relapse is highly prevalent, with cannabis consumption returning to prepregnancy levels within a year of birth (Fried, Barnes, & Drake, 1985).

Marijuana is, by far, the most commonly abused illicit drug during pregnancy. Of pregnant and postpartum women who use illicit drugs, an overwhelming proportion—between 64% and 75%—use marijuana (Ebrahim & Gfroerer, 2003; Falcon et al., 2012). Furthermore, prenatal marijuana consumption is reduced much less than prenatal alcohol and nicotine consumption (Fried et al., 1985). Although many women achieve abstinence during pregnancy, a significant proportion of the population is being exposed to cannabis at one or more points during early development, potentially resulting in peripartum complications, and long-term alterations in development.

PCE DETECTION METHODS AND ACCURACY OF PREVALENCE ESTIMATES

Many women are hesitant to report their drug use to health care providers, possibly due to the intense stigma of prenatal drug abuse, and to a fear of losing parental rights to their children. Estimates of prenatal drug use were derived from a combination of self-report and chemical analysis of urine, hair and oral fluids from pregnant and peripartum women, and meconium from neonates (Gray & Huestis, 2007). The prevalence of analysis-confirmed cannabis use in pregnancy can depend on participant sampling, the types of biological tissues that are analyzed, and the temporal relationship of drug use to biological sampling. Analytical results often conflict with self-report, due to underreporting or inadvertent sampling of prepregnancy biological specimens (eg, hair). One small, single site study (n = 107) in Spain detected drugs of abuse in 15.9% of the maternal hair samples obtained, with cannabis being the most prevalent (detected in 10.3% of the total sample), although less than 1% reported cannabis use during pregnancy (Friguls et al., 2012). Another study in Spain detected metabolites of cannabis in 5.3% of meconium samples, although only 1.7% of mothers disclosed cannabis use in the pregnancy (Lozano et al., 2007). These two studies suggest that less than 35% of women who use cannabis during pregnancy will disclose their drug use. The window of detection in meconium samples is restricted to the third trimester of pregnancy; therefore, a cannabis-positive meconium sample is indicative of third trimester PCE. Considering that most women who abuse drugs taper their use during pregnancy (Ebrahim & Gfroerer, 2003), third trimester use indicates that a drug was likely used throughout pregnancy, resulting in a greater overall burden of in utero exposure that occurs across most or all prenatal developmental stages. Detection of drug exposure in fetal and placental tissues is inconsistent with detection in the respective maternal hair. Less than 17% of placental and fetal tissues (gestational age 17–22 weeks) from women with a cannabis-positive hair test also tested positive for cannabis. Possible explanations of this phenomenon are that undetectable amounts of cannabis byproducts accumulate in fetal and placental tissues due to pharmacokinetic activity (ie, reduced fetal distribution, rapid metabolism, and complete excretion of cannabis from the placenta and fetus) and/or hair testing detects previous cannabis use that may have occurred only before pregnancy (Falcon et al., 2012). In contrast to hair, urine drug screening (UDS), which is the most common screening method, has a much shorter window of detection for cannabis. In a large study in the Netherlands (n = 3997), 71 pregnant women had positive cannabis UDS, even though 92 women reported use during pregnancy (El Marroun et al., 2011a). Additionally, several of these positive screens were from women who self-reported only prepregnancy cannabis use, further increasing the disparity between self-reports of drug use and UDS. Despite the advances in analytical screening, it is clear that limitations exist in determining accurate, valid information on PCE. Clinicians must rely on a combination of self-report, family report, and multiple analytical screenings across pregnancy and the postpartum period to accurately confirm maternal drug abuse.

CHARACTERISTICS OF WOMEN WHO USE CANNABIS DURING PREGNANCY

Women who abuse drugs during pregnancy tend to be younger, less educated, unemployed, and unmarried, with a history of childhood trauma, delinquency, and unplanned pregnancy (SAMHSA, 2014; Correia, Oliveria, Almeida, Sing, & Nobrega, 1995; Ebrahim & Gfroerer, 2003; El Marroun et al., 2008). Cannabis use by the biological father of the baby robustly increases the odds of a pregnant woman using cannabis (odds ratio = 38; El Marroun et al., 2008). One subgroup of prenatal drug users are women who decrease alcohol use and abstain from using some recreational drugs, specifically cocaine and ecstasy, but continue to use tobacco and cannabis at prepregnancy levels (Moore et al., 2010),

even though all of these substances are considered detrimental to the offspring. It is possible that this pattern of polydrug use is due to a misconception that tobacco and cannabis use is safer than other drugs, or to the highly rewarding or addictive properties of tobacco and cannabis. While it is presumed that most pregnant women who use cannabis do so for recreational purposes, a subset of this population reported using cannabis medicinally to treat severe morning sickness, and over 92% rated it as effective for this indication (Westfall, Janssen, Lucas, & Capler, 2006). Understanding who uses cannabis during pregnancy and their motivation for doing so is important to identifying such patients, and educating them about the potential harm of their drug use on their offspring.

THE EFFECTS OF PCE ON OFFSPRING

Drug use during pregnancy is associated with complications of childbirth (Saleh Gargari et al., 2012) and negative physical, behavioral, and cognitive effects on the offspring (Steinhausen, Blattmann, & Pfund, 2007; Day, Richardson, Goldschmidt, & Cornelius, 2000; Conradt et al., 2013), but causal relationships between specific prenatal exposures and these negative outcomes can be difficult to establish. Potentially confounding variables that often correlate with PCE, such as, socioeconomic status, age, and coexposures to tobacco products, alcohol, and other illicit drugs complicate the identification of PCE-induced effects. Another challenge is determining the dosage of maternal cannabis use during pregnancy, and the relative in utero exposures of the offspring. To circumvent these issues, three large-scale prospective longitudinal studies that are examining offspring outcomes with an emphasis on PCE have been undertaken: the Ottawa Prenatal Prospective Study (OPPS; Fried, 1995), the Maternal Health Practices and Child Development (MHPCD) study (Day & Richardson, 1991), and the Generation R study (Jaddoe et al., 2006). The populations recruited into each study differ in demographics, and thus help to discern effects that may be due to variables other than cannabis exposure; that is, consistent results across the cohorts strengthens the case that PCE plays a causal role. The OPPS cohort consists of a "low-risk," racially homogenous middle class sample of pregnant women in Ottawa, Ontario in Canada who were recruited between 1978 and 1983. The MHPCD study recruited "high-risk" urban, racially and ethnically heterogeneous pregnant women of lower socioeconomic status in the Pittsburgh, Pennsylvania area in the United States, between May 1983 and Jan. 1986. The Generation R study, which began in 2001, recruited an ethnically diverse sample of slightly higher socioeconomic status in Rotterdam, the Netherlands. Much of what is known about the effects of in utero cannabis exposure comes from these studies.

In utero cannabinoid exposure has a suspected association with minor physical abnormalities, including facial–visual system anomalies, such as, ocular hypertelorism and severe epicanthus (Fried & Smith, 2001), particularly in children who had heavy PCE. Third trimester exposure to marijuana predicted a greater risk of chest and head shape abnormalities, after controlling for covariates in one study of 6-year-olds with prenatal exposure to cocaine and marijuana (Minnes et al., 2006). As shown in Table 17.1, there are also associated cardiovascular abnormalities of the PCE offspring, including isolated simple ventricular septal defect (Williams, Correa, & Rasmussen, 2004), and smaller fetal aortic diameter. Alterations in fetal blood supply that are associated with cannabis exposure include increased pulsatility and resistance indices of the uterine artery, indicating an increase in placental vascular resistance (El Marroun et al., 2010). Interestingly, decreased uterine artery pulsatility and resistance was observed when cannabis exposure was restricted to early pregnancy (El Marroun et al., 2010), suggesting that the developmental stage at which exposure occurs is critical in determining the ultimate effects on the fetal–placental complex.

Reports on how PCE affects offspring growth are conflicted (Table 17.2). While several report no effect on birth weight (English, Hulse, Milne, Holman, & Bower, 1997), a surprisingly positive relationship between PCE and

TABLE 17.1 Cardiovascular Changes Associated With PCE

Age group	Prenatal exposure	Effects	References
All			
	Regular	Increased risk of isolated simple ventricular septal defect	Williams et al. (2004)
Prenatal			
	Regular	Decreased fetal aortic diameter	El Marroun et al. (2010)
	Regular	Increased uterine artery pulsatility and resistance	El Marroun et al. (2010)
	Early pregnancy only	Decreased uterine artery pulsatility and resistance	El Marroun et al. (2010)

PCE offspring has an increased risk of a cardiac defect and greater fetal–placental cardiovascular alterations.

TABLE 17.2 Size Effects Associated With PCE

Age group	Prenatal exposure	Effects	References
All			
	Heavy	Smaller head circumference	Fried et al. (1999), Gray et al. (2010)
Prenatal and neonatal			
	a	Small for gestational age	Hayatbakhsh et al. (2012), Hurd et al. (2005)
	a	Reduced fetal foot length	Hurd et al. (2005)
	a	No effect on birth weight	English et al. (1997), meta-analysis
	Infrequent	Elevated birth weight	Day and Richardson (1991), Fried and O'Connell (1987)
	More closely associated with regular, moderate use	Low birth weight	Hayatbakhsh et al. (2012), Sherwood et al. (1999), El Marroun et al. (2009)
	a	Decreased length	Gray et al. (2010)
Infant			
	a	Decreased body length	Barr et al. (1984)
Toddler			
	Continuous	Increased weight	Fried and O'Connell (1987)
Adolescent			
	a	No effect on height	Fried et al. (1999)

Overall associates of PCE with offspring size are conflicted. Conflicts may be due to differences in prenatal cannabis exposure (ie, low exposures are associated with increased size, and larger exposures with decreased size, resulting in no net effect when data are unstratified by exposure levels). *PCE*, prenatal cannabis exposure.
[a]*Unspecified.*

birth weight was measured in the OPPS and the MHPCD study, with exposed babies being heavier than nonexposed (Day & Richardson, 1991), and remaining heavier up to 24 months of age (Fried & O'Connell, 1987). Heavier, more frequent use of cannabis during pregnancy was associated with low birth weight in several studies (Sherwood et al., 1999; Fried & Smith, 2001), including the Generation R cohort (El Marroun et al., 2009; Huizink, 2014). Conflicting results between the older OPPS and MHPCD study and the more recent Generation R study may be due, in part, to differences in the content of the psychoactive chemical of marijuana, Δ^9-tetrahydrocannabinol (Δ^9-THC), during the two time periods. Over time, marijuana has been selectively bred to produce a higher concentration of Δ^9-THC (Cascini, Aiello, & Di Tanna, 2012), potentially resulting in greater maternal intake and in utero exposure to Δ^9-THC, in more recent studies. The size of cannabis-exposed fetuses was measured for the first time in the Generation R study. This study found that cannabis-exposed 17–22 week fetuses possessed slightly reduced foot length and body weight, with foot length decreasing in a dose-dependent manner (Hurd et al., 2005). In the OPPS cohort, PCE was negatively associated with birth length, but this relationship was not significant at 8 months, 1 year, 6 years or adolescence (Fried, Watkinson, & Gray, 1999; Fried & Smith, 2001). In contrast, prenatally exposed infants in a different cohort were still significantly shorter at 8 months (Barr, Streissguth, Martin, & Herman, 1984). Children with heavy PCE had statistically smaller head circumferences at all ages, from early infancy to early adolescence (Fried et al., 1999). As shown in Table 17.3, gestation was reduced by almost a week in heavy users in the OPPS cohort (Fried, Watkinson, & Willan, 1984), and other studies reported an association of shortened gestation and increased risk of prematurity, as well (Sherwood et al., 1999). Reports on the effects of PCE on neonate size and gestation length are conflicting, but seem to suggest a dose-dependent, negative association between PCE and two pregnancy outcomes: birth size, and length of gestation.

There is an apparent association between neonatal and infant mortality and in utero cannabis exposure (Table 17.3). A large five-site study of stillbirth determined that the presence of cannabis in umbilical cord homogenate was associated with more than a twofold increased odds of stillbirth (Varner et al., 2014), a result that may be partially confounded by concurrent tobacco use. An Australian sample of PCE offspring also had a 2.23-fold increased risk of suffering from Sudden Infant Death Syndrome (SIDS; Scragg et al., 2001); in contrast, another large study (n = 2964) found no association

TABLE 17.3 Associations of PCE With Gestation and Infant Mortality

Age group	Prenatal exposure	Effects	References
Prenatal and neonatal			
	a	Increased preterm labor or birth	Hayatbakhsh et al. (2012), Fried et al. (1984), Sherwood et al. (1999)

Toddler			
	Cannabis-positive meconium (third trimester exposure)	No increased risk of death before 2 years of age	Ostrea et al. (1997)

Reports on the association PCE with preterm labor, stillbirth, and infant mortality are conflicted. Disagreements in the literature may be due to methodological differences between studies. *PCE*, prenatal cannabis exposure.
[a]*Unspecified.*

between having cannabis-positive meconium samples and risk of infant death within the first 2 years of life (Ostrea, Ostrea, & Simpson, 1997).

There are apparent long-term effects of PCE on offspring neurological and cognitive development (Table 17.4). Markers of altered neurological function in neonates and infants prenatally exposed to cannabis include increased risk of tremors, an exaggerated and prolonged startle response, altered autonomic arousal, a high-pitched cry, less time in quiet sleep, and poorer habituation to visual, but not auditory, stimuli (Fried & Smith, 2001). There is consistently no effect of PCE on the Bayley Scales of Infant Development, except for in children of exceptionally heavy users (one or more joints per day during the third trimester). These children had reduced mental scores on the Bayley Scales at 9 months, but not at 18 months (Richardson, Day, & Goldschmidt, 1995). After the age of 3, there were distinguishable dose-dependent effects of PCE on specific cognitive domains, including short-term memory, verbal, and abstract/visual reasoning, while composite intelligence scores were not affected (Fried & Smith, 2001; Day et al., 1994; Griffith, Azuma, & Chasnoff, 1994). Although there was no association of PCE with cognitive and receptive language development in 5- and 6-year-olds that were followed by the OPPS (Fried, O'Connell, & Watkinson, 1992a), high-risk 6-year-olds in the MHPCD who were heavily exposed during the first trimester of pregnancy had significantly lower verbal reasoning scores on the Stanford-Binet Intelligence Scale than nonexposed children (Goldschmidt, Richardson, Willford, & Day, 2008). Similarly, prenatally exposed school-aged children (ages 9–12) showed deficits in specific Wechsler Intelligence Scale for Children subtests of visuospatial/visuomotor intelligence and planning, the Block Design and the Picture Completion subtests, but were equal to nonexposed children in global IQ measures (Fried, Watkinson, & Gray, 1998), and there was no effect of PCE on reading or language outcomes in this cohort (Fried, Watkinson, & Siegel, 1997). Prenatally exposed 9–12 year olds also showed poorer impulse control, and impaired hypothesis testing (Fried et al., 1998). In sum, PCE is associated with abnormal behavior in neonates, and deficits in multiple cognitive domains in preschool and school-aged children, including verbal reasoning, perceptual reasoning, memory, planning, and attentional processes, without affecting overall intelligence.

Neuroimaging studies have provided insights on the neural mechanisms underlying cognitive processing (Table 17.4). Visuospatial working memory was examined at age 18–22, in the OPPS cohort, using functional magnetic resonance imaging (fMRI) to measure neural activity while participants performed the two-back working memory task. Although behavioral performance did not differ between the prenatally exposed versus unexposed participants, there was a positive, dose-dependent relationship between PCE and neural activity in the left inferior and middle frontal gyri, left parahippocampal gyrus, left middle occipital gyrus and left cerebellum, and a negative relationship between exposure and activity in the right inferior and middle frontal gyri, during the task (Smith, Fried, Hogan, & Cameron, 2006). Similarly, a task of response inhibition that measures motor impulse, and is a correlate of drug use disorders, was measured in the 18–22 year old OPPS offspring cohort. After controlling for possible confounders, the prenatally exposed group exhibited more commission errors than the unexposed group, but both groups had similar reaction times. Brain

TABLE 17.4 Associations of PCE on Neurocognitive Development

Age group	Prenatal exposure	Effects	References
Prenatal and neonatal			
	a	Increased tremors	Fried and Smith (2001)
	a	Reduced habituation to visual stimuli	Fried and Smith (2001)
	a	Prolonged and exaggerated startle	Fried and Smith (2001)
	a	Sleep disturbances	Fried and Smith (2001)
Toddler			
	Heavy	Reduced mental scores on Bayley Scales of Infant Development (9, but not 18, months)	Richardson et al. (1995)
	Mild-moderate	No effect on Bayley Scales of Infant Development (9 and 18 months)	Richardson et al. (1995)
School-aged			
	a	No effect on cognitive development (5 and 6 years)	Fried et al. (1992a)
	a	No effect on receptive language development	Fried et al. (1992a)
	Heavy first trimester	Reduced verbal reasoning (6 years)	Goldschmidt et al. (2008)
	a	Deficits in WISC Block Design Task (spatial analysis, abstract visual reasoning) (9–12 years)	Fried et al. (1992b)
	a	Deficits in Picture Completion task (alertness to detail, visual discrimination) (9–12 years)	Fried et al. (1992b)
	a	Reduced planning (9–12 years)	Fried et al. (1992b)
	a	Impaired hypothesis testing (9–12 years)	Fried et al. (1992b)
	a	No effect on global and composite intelligence (6, 9–12 years)	Fried et al. (1992b), Goldschmidt et al. (2008)
	a	No effect on verbal fluency (9–12 years)	Fried et al. (1997)
	a	No effect on reading (9–12 years)	Fried et al. (1997)
Young adult			
	a	No effect on two-back performance (visual-spatial working memory task) (18–22 years)	Smith et al. (2006)
	Dose-dependent effect	Altered neural activity during two-back task (18–22 years)	Smith et al. (2006)
	a	Greater errors in response inhibition (18–22 years)	Smith et al. (2004)
	Dose-dependent effect	Altered neural activity during response inhibition task (18–22 years)	Smith et al. (2004)

Offspring with PCE show deficits and alterations in selective measures of neurocognitive development. *PCE*, prenatal cannabis exposure.
[a]*Unspecified.*

activity measured with fMRI during the task showed a positive dose-dependent relationship between PCE and activity in the bilateral prefrontal cortex and right premotor cortex, during response inhibition (Smith, Fried, Hogan, & Cameron, 2004). These functional neuroimaging studies indicate that PCE alters the neural strategy used in completing tasks of cognition.

PCE is also associated with alterations in emotional and behavioral development that are highly consistent between the "low risk" OPPS cohort and the "high risk" MHPCD cohort (Table 17.5). A sex-specific effect of PCE was identified in 18-month old girls in the Generation R cohort, who exhibited notably greater aggressive and inattentive behavior, but this effect was not significant at 36 months (El Marroun et al., 2011b). Depression and anxiety at 10 was predicted by PCE that was specific to exposure during the first and third trimesters (Gray, Day, Leech, & Richardson, 2005). Prenatally exposed 10-year-olds in the MHPCD cohort had higher ratings of hyperactivity, inattention,

TABLE 17.5 Behavioral Alterations in Children Prenatally Exposed to Cannabis

Age group	Prenatal exposure	Effects	References
Toddler			
	a	Aggressive, inattentive behavior (girls only, 18 months, but not 36 months)	El Marroun et al. (2011b), Generation R Study
School-aged			
	a	Reduced impulse control (9–12 years)	Fried et al. (1992b), OPPS
	Dose-dependent effect	Increased externalizing behavior and delinquency (10 and 14 years)	Goldschmidt et al. (2000), Day et al. (2011), MHPCD
	a	Increased hyperactivity, inattention, impulsivity (10 years)	Goldschmidt et al. (2000), MHPCD
	First and third trimester exposure	Increased depression and anxiety (age 10)	Gray et al. (2005), Leech, Larkby, Day, & Day (2006), MHPCD
Adolescent			
	a	Reduced academic achievement (14 years)	Goldschmidt et al. (2012), MHPCD
Young adult			
	a	Increased risk of marijuana and daily cigarette use (16–21 years)	Porath and Fried (2005), MHPCD
	a	Predictive of marijuana use (22 years)	Sonon et al. (2015), OPPS

Offspring with PCE exhibit greater behavioral and academic problems than nonexposed cohorts. *PCE*, prenatal cannabis exposure.
[a]*Unspecified.*

impulsivity, externalizing problems, and delinquency, with inattention mediating the effect between exposure and delinquency (Goldschmidt, Day, & Richardson, 2000). Heavier PCE increased odds of delinquency at the age of 14, mediated by depression at the age of 10 (Day, Leech, & Goldschmidt, 2011). Porath and Fried (2005) reported that adolescents and young adults (16–21 years) with PCE had greater than twofold increased odds of initiating marijuana and daily cigarette use. Similarly, prenatally exposed participants in the MHPCD cohort had higher rates of marijuana use at the age of 22 than nonexposed controls, even after controlling for maternal and offspring sociodemographic and psychiatric variables, as well as maternal history of drug abuse or disorder (Sonon, Richardson, Cornelius, Kim, & Day, 2015). The MHPCD study also revealed that school achievement at the age of 14 suffered in those with PCE (Goldschmidt, Richardson, Willford, Severtson, & Day, 2012). The Wechsler Individual Achievement Test Screener composite and reading scores were lower in adolescents with PCE (Table 17.4). These reduced scores were mediated by age performance at the age of 6, attention problems, depression symptoms at the age of 10, and early initiation of marijuana use (Goldschmidt et al., 2012). These results indicate that PCE is associated with adverse cognitive and behavioral outcomes that compromise offspring mental, emotional, and social development.

CONCLUSIONS

Cannabis is the most prevalent illicit drug used by pregnant women. Although most women abstain from use while pregnant, a surprisingly large proportion of women continue to use cannabis throughout pregnancy. These women tend to be younger, single, less educated, and have lower income. Definitive "diagnosis" of PCE by health-care professions relies primarily on patient self-report, and analytical detection methods, such as urine drug screening or hair analysis, which each have their own limitation, and are not always sufficiently sensitive or accurate for the time period of interest.

Long-term effects of PCE on offspring are controversial, but become more robust at higher levels of exposure, even after controlling for confounders. Although small, infrequent exposures seem to have little effect on offspring outcomes, heavier, more frequent PCE is clearly associated with negative effects. Where the line between "no effect" and "adverse effect" doses lies is unknown; therefore, pregnant women should be encouraged to quit their use of cannabis (Fig. 17.1).

MINI-DICTIONARY

Bayley Scales of Infant Development A norm-referenced assessment of early childhood development. The original version (1969) measured mental and motor development in infants aged

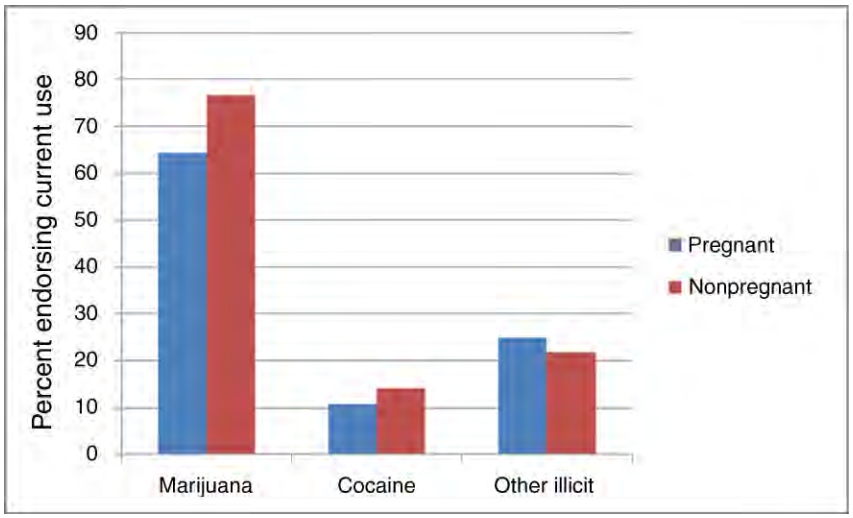

FIGURE 17.1 **Drugs used by pregnant and nonpregnant women who use any illicit drug.** This figure shows the choice of drug(s) used by women who use illicit drugs, indicating that cannabis use is highly prevalent in pregnant women in this population. *Source: (1996–1998) National Household Survey on Drug Abuse. Reproduced with permission from Ebrahim, S.H., and Gfroerer, J., 2003.*

3–28 months. The second edition (1993) extended the age range to 1–42 months, and added a behavioral rating scale. The third edition (2005) is composed of a core battery of five scales: child cognitive, motor and language interaction, and parental report of the child's social–emotional and adaptive behavior.

Cannabinoids A class of chemicals that bind to one or both known cannabinoid receptors: Cannabinoid 1 Receptor (CB1R) and the Cannabinoid 2 Receptor (CB2R). These chemicals may be isolated from the *Cannabis* plant (phytocannabinoids, eg, Δ^9-THC, the psychoactive component of cannabis), produced endogenously by a diverse array of Animalian species (endocannabinoids, eg, anandamide and 2-arachidonoylglycerol), or synthesized in laboratory conditions (synthetic cannabinoids, eg, JWH-018, WIN55, 212-2).

Cannabis A genus composed of three species of flowering plants (*C. sativa*, *C. indica* and *C. ruderalis*) that are best known for producing the psychoactive phytocannabinoid Δ^9-THC. Consumption by smoking, vaporizing or eating the Δ^9-THC-rich trichomes on the flowers of the plant results in alterations in mood, perception, and appetite. Resin extractions of the trichomes, such as, hashish and hash oil, contain high concentrations of Δ^9-THC, and are also consumed for their psychoactive effects. In addition to recreational purposes, *Cannabis* is also cultivated for industrial (eg, hemp made from the fibrous stalk of the plant), medicinal, and religious uses.

Hypertelorism A congenital facial malformation in which the eyes are abnormally spaced apart.

Meconium The earliest stools of the neonate that are composed solely of materials consumed in utero.

Pulsatility index The variability of flow velocity in a blood vessel measured by Doppler ultrasound, and calculated by subtracting the minimum diastolic velocity from the maximum systolic velocity, and dividing the difference by the mean flow velocity.

Resistance index A measure of flow in a blood vessel that is calculated by subtracting the end diastolic velocity from the peak systolic velocity, and dividing the difference by the peak systolic velocity. Abnormal umbilical or uterine artery resistance may indicate compromised fetal–placental circulation associated with adverse maternal–fetal conditions, such as, intrauterine growth restriction, or preeclampsia.

Severe epicanthus Overgrowth of the skin in the corners of the eyelids (ie, epicanthic folds).

Stanford-Binet Intelligence Scales An assessment that measures five domains of cognition in people aged 2 and older: fluid reasoning, knowledge, quantitative reasoning, visual-spatial processing, and working memory.

Wechsler Individual Achievement Test Screener An assessment of academic strengths and weaknesses in the areas of reading, math, written language, and oral language in people aged 4–85.

Wechsler Intelligence Scale for Children An assessment of cognitive abilities in children aged 6–16 that measures overall intellect ability, verbal comprehension, perceptual reasoning, processing speed, and working memory.

Cannabis and Clubbing: Relevance of Cannabis and Polydrug Use in the Clubbing Culture Today

D.A. Herzig, S. Bachmann

Clienia AG, Littenheid, Switzerland

SUMMARY POINTS

- Clubbing culture developed from raving culture in the late 1980s/early1990s.
- Drug use was and still is common during clubbing events.
- Cannabis use is elevated in users of clubbing drugs.
- Concomitant use of cannabis and clubbing drugs may have perceived short-term beneficial effects, but is associated with long-term problems.
- Since most studies to date do not address polydrug use, more research is needed on risk and resilience factors associated with concomitant cannabis and clubbing drug use.
- Certain individual (ie, variations in sensation seeking, impulsivity, and schizotypy), social (ie, variations in general communal attitude toward drug use), and biological factors (ie, variations in dopamine receptor availability) may explain the associations between cannabis and other drug use.
- More research is clearly warranted.

KEY FACTS OF CANNABIS AND CLUBBING DRUG USE

- Cannabis is often used concomitantly with clubbing drugs, especially ecstasy, amphetamines, and cocaine. For instance, in ecstasy users, rates of concomitant cannabis use range from 73% to 100%.
- Simultaneous use of clubbing drugs and cannabis may have acute perceived benefits, such as, masking or alleviating unwanted clubbing drug effects.
- Long-term problems may include higher risk for psychological, physical, and cognitive problems in polydrug users, compared to cannabis only and/or nonusers of illicit drug use.

LIST OF ABBREVIATIONS

GHB	Gamma-hydroxybutyrate
LSD	Lysergic acid diethylamide
MDMA	3,4-Methylenedioxy-*N*-methylamphetamine
NPS	New psychoactive substances

INTRODUCTION

The roots of clubbing culture go back to the first grassroot all-night dance events organized especially in the United Kingdom and United States, in the late 1980s/early 1990s, as a response of the generation X (born circa between 1960 and 1980) to economic alienation and conservatism common in mainstream culture (Anderson, 2009; Measham & Moore, 2009). As an opposition to the conservative mainstream culture and values of the time, drug use was common at rave parties, and early club studies identified higher levels of self-reported lifetime prevalence and current usage of illicit drugs among young attendees of electronic dance

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00020-X

events, than in individuals of similar age in the general population (Newcombe, 1992; Release, 1997).

These unlicensed dance events formed a threat to bureaucratic authority and conservative values of mainstream society, and political instruments (such as the Criminal Justice and Public Order Act 1994 in the United Kingdom, or the "War on Drugs" in the United States) were introduced to control noise, drug use, and handling of large amounts of people associated with these dance events revolving around electronic music (Hill, 2002; Measham, 2004). Consequently, raves were mostly transformed from unlicensed and outdoor dance events to licensed and indoor commercial venues (Measham & Moore, 2009). The definitions and terminologies to describe these events nowadays may differ (eg, electronic dance events, raves, night-time economy, clubbing, etc.), and the generalizability of drug use patterns amongst heterogeneous subcultures derived from the original rave culture has been questioned (Measham & Moore, 2009). Nevertheless, for ease of overview, we will refer to any all-night electronic dance event as "clubbing," and drugs used in the context of any of these events as "clubbing drugs" (Bowden-Jones, 2013).

Commonly described clubbing drugs include methamphetamine, cocaine, ketamine, ecstasy, GHB (gamma-hydroxybutyrate), and LSD (lysergic acid diethylamide) (Chinet, Stéphan, Zobel, & Halfon, 2007; Freese, Miotto, & Reback, 2002). Ecstasy/MDMA (3,4-methylenedioxy-*N*-methylamphetamine) is commonly used at dance clubs, techno parties, and all night raves (Parrott, 2006), and is therefore the most extensively studied drug in this context. Additionally, use of new psychoactive substances is common during clubbing events (Bowden-Jones, 2013). Cannabis is not typically listed as a clubbing drug (Moore & Miles, 2004). However, a high proportion of people using typical clubbing drugs is also likely to use cannabis, as will be outlined later. To note, cannabis may not be used during the clubbing event, but rather before or after (Moore & Miles, 2004). Some authors have also claimed that drug use during a clubbing event may be less harmful than consumption outside of these events (Forsyth, 1996), which includes problems associated with concomitant cannabis and clubbing drug use.

For these reasons, the epidemiology of, problems with, and reasons for concomitant cannabis and clubbing drug use will be elaborated in this chapter. Given the history and importance of clubbing culture, particularly in the United Kingdom, the literature cited in this chapter will be largely based on research conducted in the United Kingdom, and Europe more widely.

DRUG USE IN THE GENERAL POPULATION

Before elaborating on the rates of concomitant cannabis and other illicit drug use for comparative purposes it is useful to first establish the baseline rates (and trends, where available) for drug use in the general population.

Overall, European rates of cannabis use in the previous year seems to be relatively stable, over the past decade (Fig. 18.1), with 11.93% of young European adults (ages 15–34 years) having used cannabis in 2000, and 11.52% in 2011 (European Monitoring Centre for Drugs and Drug Addiction, 2013). In 2000 1.6% of young European adults have used ecstasy, compared to 1.68% in 2011 (Fig. 18.1). Amphetamines were used by 1.63% of young European adults in 2000, and 1.06% in 2011 (European Monitoring Centre for Drugs and Drug Addiction, 2013). Cocaine use has slightly increased in Europe (Fig. 18.1), with 1.4% of young European adults having used cocaine in 2000, and 2.4% in 2011 (European Monitoring Centre for Drugs and Drug Addiction, 2013). In 15–34 year olds, hallucinogen use in the previous year ranged between

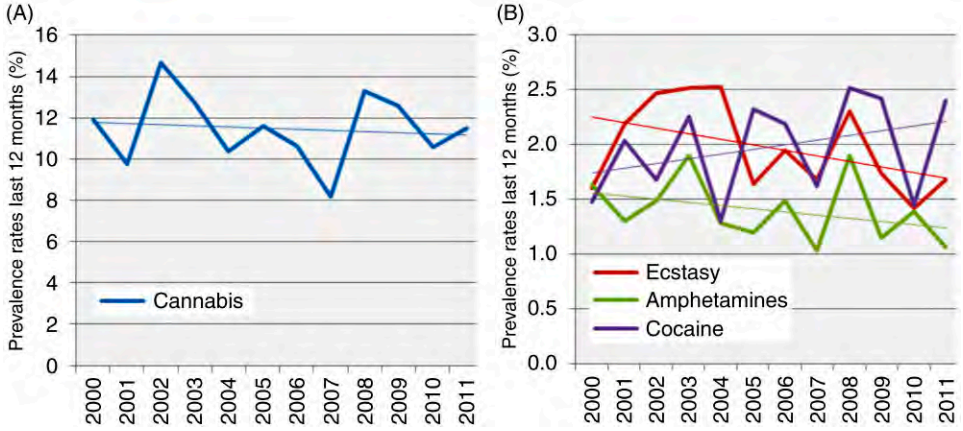

FIGURE 18.1 Prevalence rates of past 12-month use in European young adults and adolescents for (A) cannabis use, and (B) ecstasy, amphetamine, and cocaine use between 2000 and 2011. Only averages with three or more data points per year were included, based on survey data in a total of 24 European countries. The rates of cannabis and ecstasy use have remained relatively stable over the past decade, whereas amphetamine use has slightly increased, and cocaine use has increased. *Source: European Monitoring Centre for Drugs and Drug Addiction (2013).*

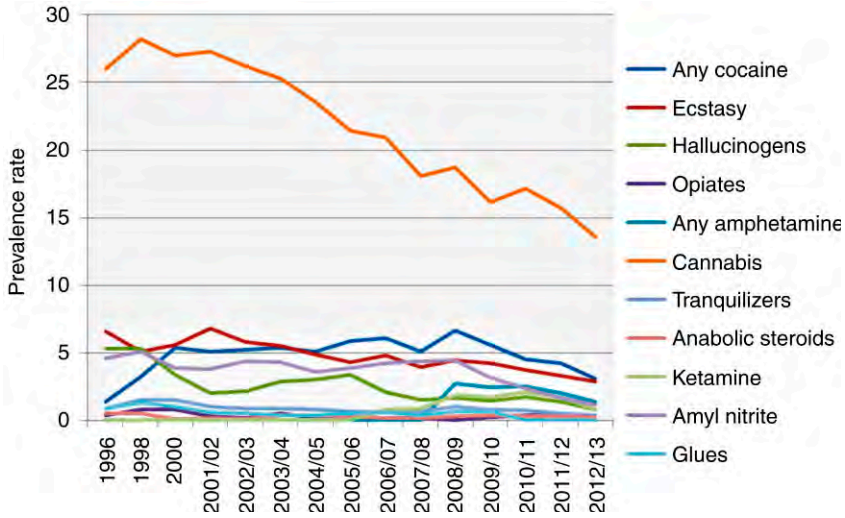

FIGURE 18.2 **Comparison to other drug trends in England and Wales in adolescents and young adults (ages 16–24).** In adolescents and young adults in England and Wales, cannabis, amphetamine, and ecstasy use have decreased between 1996 and 2013, whereas cocaine use has slightly increased. *Source: British Crime Survey (2012).*

0.2% and 5.9% in young European adults, whereas GHB use in the previous month was about 4.6% in specific surveys with preselected (and, therefore, likely more frequently using) samples (European Monitoring Centre for Drugs and Drug Addiction, 2011). The prevalence rate for opiate use (heroin) in the aforementioned sample ranged between 0.0% and 1.6% in 2011, depending on the country, with an average of 0.7% (UNODC, 2011). So far, data do not address the prevalence rates of ketamine use across young European adults yet.

In the United Kingdom, although cannabis use has steeply decreased from 26% in 1996 to 13.5% in 2012/2013 (Fig. 18.2), it is still the most commonly used illicit drug amongst young adults in the United Kingdom (British Crime Survey, 2012). Prevalence rates for amphetamine use in the previous year decreased from 2.7 in 2008/2009 to 1.4% in 2012/2013. Ecstasy was used in the previous year by 6.6% in 1996, and 2.9% in 2012/2013. Cocaine use increased from 1.4% in 1996 to 2.7% in 2012/2013. Opiate (heroin, methadone) use prevalence decreased from 0.4% in 1996 to 0.0% in 2012/2013 in young UK adults. Prevalence rates for ketamine use in the previous year in young UK adults remained stable (Fig. 18.2), at 1.8% in 2008 and 2012/2013 (British Crime Survey, 2012). No prevalence rates for GHB exist in the United Kingdom yet (British Crime Survey, 2012).

The number of identified new psychoactive substances (NPS) in the European Union rose from 14 in 2005 to 347 by the end of 2013 (UNODC, 2014). The amount of NPS has increased so much during this time that the amount of uncontrolled legal psychotropic substances (N = 347) now exceeds the amount of controlled substances (N = 234) for the first time (UNODC, 2014). On average, 5% of the European respondents admitted to having "ever" used an NPS but, in some countries, like the United Kingdom (8%), Latvia (9%), Poland (9%), and Ireland (16%), the prevalence of NPS use was considerably higher than in other countries, such as, Italy (1%), Finland (1%), Hungary (2%), Slovakia (3%), the Netherlands (3%), and the Czech Republic (4%) (van Amsterdam, Nutt, & van den Brink, 2013). The majority of currently identified NPS are synthetic cannabinoids (31%; see Table 18.1) (UNODC, 2014). Synthetic cannabinoids were used within the past 12 months by 6.5% of young

TABLE 18.1 Types and Proportion (in %) of Identified NPS Worldwide Until Dec. 2013[a]

Type	Proportion of identified NPS (%)
Synthetic cannabinoids	31
Phenethylamines	21
Synthetic cathinones	15
Others	11
Tryptamines	8
Plant-based substances	6
Piperazines	4
Ketamine and phencyclidine-type substances	3
Aminoindanes	1

NPS, new psychoactive substances.
[a]*The category with the highest rate of new psychoactive substances until Dec. 2013 was synthetic cannabinoids (ie, JWH-018 and JWH-073. JWH stands for John W. Huffman, one of the inventors of these cannabinoids), followed by phenethylamines and synthetic cathinones (ie, mephedrone, methylenedioxypyrovalerone, and methylone). Other substances included tryptamines, plant-based substances (kratom, khat, and salvia divinorum, and piperazines), piperazines [ie, m-chlorophenylpiperazine (mCPP), N-benzylpiperazine (BZP) and 1-(3-trifluoromethylphenyl) piperazine (TFMPP)], ketamine, and aminoindanes.*
UN Office on Drugs and Crime (UNODC, 2014).

adult respondents (age 19–28 years) to a worldwide online survey in 2011 (Winstock & Barratt, 2013).

While these statistics provide a baseline for drug use of a variety of clubbing drugs and cannabis, they do not indicate the rates of simultaneous or concomitant use.

RATES OF MULTIPLE SUBSTANCE USE, INCLUDING CANNABIS

Generally, this section elaborates on the rates of simultaneous or concomitant psychoactive substance use (Byqvist, 1999) in the general population, with a particular focus on cannabis and clubbing drug use (including new psychoactive substances) in young adults.

In 2009 the most frequently used additional illicit drug in the previous 12 months amongst 7178 European young adult cannabis users was cocaine, followed by ecstasy, and amphetamines (European Monitoring Centre for Drugs and Drug Addiction, 2009, Fig. 18.3).

In a similar survey of 1501 Spanish adolescents (12–17 years old) in 2007, 13.9% reported polydrug use. The majority of these polydrug users (9.4% of the total sample) indicated cannabis use together with tobacco and/or alcohol, in the past 6 months, and 0.5% used cannabis together with tobacco and/or alcohol, and cocaine, in the past 6 months (Font-Mayolas et al., 2013). The remaining adolescents either only used alcohol and tobacco (3.9% of the total sample), or consumed tobacco and cocaine, but not cannabis (0.1% of the total sample).

In 2000 a British survey of 8538 adults revealed that 32.92% (3.46% of the total sample; see Table 18.2) of those individuals using illicit drugs in the past year were polydrug users (Smith, Farrell, Bunting, Houston, & Shevlin, 2011). Interestingly, the majority of cannabis users reporting additional drug use were typically using clubbing drugs, such as, ecstasy, amphetamines and/or cocaine (Table 18.2).

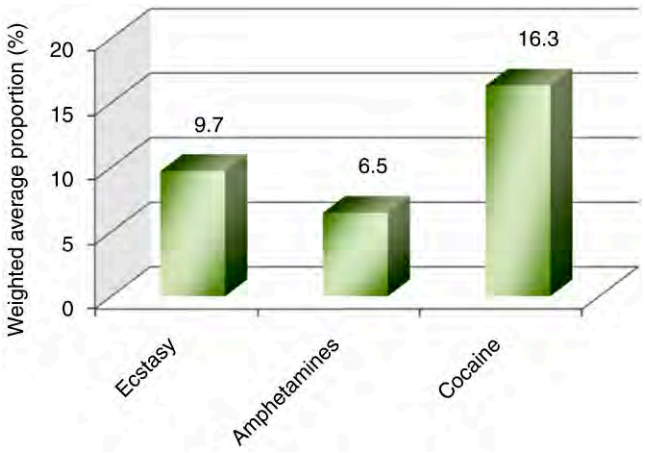

FIGURE 18.3 Average prevalence rate (based on weighted averages) of concomitant last year substance use in 7178 cannabis using European adolescents and young adults (ages 15–34) in 2009. The most popular drug used concomitantly with cannabis among European adolescents and young adults was cocaine, followed by ecstasy and then amphetamines. *Source: European Monitoring Centre for Drugs and Drug Addiction (2009).*

Rates of Cannabis Use in Clubbing Drug Users

Generally, the rates of cannabis use amongst MDMA users is vastly elevated, compared to the

TABLE 18.2 Patterns of Illicit Drug Use[a] in the Past Year[b]

Drug(s) used in the past year	#	% Total (*N* = 8538)	% CU (*N* = 683)

TABLE 18.3 Drug Use Prevalence Rates (%) Among 980 Recent Users of Synthetic Cannabis[a]

Drug types	Last year (%)	Last month (%)
Alcohol	97.8	90.5
Cannabis (any)	95	88.4
Tobacco (any)	84.2	75.2
Energy drinks	76.6	61.4
Ecstasy (any)	50.7	26.2
Magic mushrooms	36.9	12.4
Cocaine	34	14.8
LSD	32.4	12.5
Benzodiazepines	31	18.5
Amphetamine (any)	28.2	14.8
Nitrous oxide	23.4	9.8
Ketamine	17.9	5.7
Caffeine tablets	16.5	8
Mephedrone	13.3	3.7
Heroin	4.8	2.7

LSD, lysergic acid diethylamide.
[a]*In recent users of synthetic cannabis, more than half used alcohol, plant-based cannabis, tobacco, energy drinks and/or ecstasy in the past year, as well. Approximately one-third had also used magic mushrooms, cocaine, LSD, benzodiazepines, and/or amphetamines. A minority had also consumed nitrous oxide, ketamine, caffeine tablets, mephedrone and/or heroin. Winstock and Barratt (2013).*

general population (see Butler & Montgomery, 2004; Sala & Braida, 2005 for overview), with concomitant cannabis and MDMA use ranging from 73% to 100%, depending on the recruited samples and referred time-frame of use (see Sala & Braida, 2005 for overview).

Additionally, another study in 76 GHB users revealed that all (100%) had a history of cannabis use, 78% used cannabis in the past 6 months, and 26% used cannabis in conjunction with GHB (Degenhardt, Darke, & Dillon, 2002), compared to 58% concomitantly using ecstasy, 37% alcohol, 36% amphetamines, and 21% ketamine. In another sample of 189 GHB users, the most frequently reported used substances were alcohol (96.8%) and cannabis (90.5%) (Sumnall, Woolfall, Edwards, Cole, & Beynon, 2008), with 68% combining GHB with other drugs simultaneously, including ecstasy (32.4%), alcohol (17.3%), cannabis (15.6%), and amphetamines (10.4%). Additionally, of 75 inpatients treated for GHB dependence, nearly half used cannabis (45%) in the past month (Brunt, Koeter, Hertoghs, van Noorden, & van den Brink, 2013), whereas the majority used alcohol (52%).

Rates of Cannabis Use in Users of New Psychoactive Substances

Regarding new psychoactive substances, only few studies address the issue of polydrug use. Only one group investigated concomitant drug use in synthetic cannabinoids consumers. As can be seen in Table 18.3, the majority of users of synthetic cannabinoids also used alcohol, tobacco, and ecstasy in the previous year.

Given the literature, cannabis and more typical club drugs should be investigated together, as they are likely to be used concomitantly (Moore & Miles, 2004).

PROBLEMS ASSOCIATED WITH POLYDRUG USE

Most research focus on the problems associated with use of one single drug. This section will, on the other hand, cover research addressing the influence of multiple substance use (including cannabis) on a variety of issues. Again, the combination of cannabis and ecstasy is the most extensively studied, and will be reviewed predominantly.

Cumulative multiple drug use, including concomitant cannabis and clubbing drug use, is associated with greater likelihood of addiction, poorer physical health, social and mental health problems (European Monitoring Centre for Drugs and Drug Addiction, 2011). For instance, cannabis has been shown to relate to an increased risk of mental health problems in regular ecstasy users, particularly depression and anxiety (Scott, Roxburgh, Bruno, Matthews, & Burns, 2012). Psychotic-like symptoms are also more severe in polydrug users, compared

to cannabis only users, and nonusers of illicit drugs (Van Dam, Earleywine, & DiGiacomo, 2008), and the risk of an earlier onset of psychosis (Stefanis et al., 2014) and schizophrenia (Power, Dragovic, Jablensky, & Stefanis, 2013) is higher in polydrug (including cannabis) than cannabis only users, and nonusers of illicit drugs. For instance, although cannabis may lead to earlier onset of psychosis, compared to nonusers, concomitantly using cannabis and amphetamines may lead to an even earlier age of onset of psychosis (Power et al., 2014). Moreover, early cannabis use is linked with the severity of cocaine-induced psychosis (Trape, Charles-Nicolas, Jehel, & Lacoste, 2014). Cannabis, in conjunction with MDMA, may also cause more severe cognitive problems than either substance alone (see Gouzoulis-Mayfrank & Daumann, 2006 for overview).

Cannabis can also potentiate the effects of MDMA on heart rate and temperature in humans (see Mohamed, Hamida, Cassel, de Vasconcelos, & Jones, 2011 for overview). In the majority of clubbers cousing stimulants, alcohol and cannabis lead to both heart rate and blood pressure increases to levels above those related to either cannabis or alcohol alone (see Mohamed et al., 2011 for overview). MDMA and cannabis couse can also lead to disadvantageous alterations in immunological functioning, compared to cannabis use only (Mohamed et al., 2011; Sala & Braida, 2005), and concomitant cannabis use can exacerbate MDMA-induced neuroendocrine abnormalities in recreational ecstasy users (see Mohamed et al., 2011 for overview).

Unsurprisingly, compared with non-MDMA using cannabis consumers, MDMA users were significantly more likely to have used other drugs, and to report more adverse health effects due to "polydrug use" (Shimane, Hidaka, Wada, & Funada, 2013).

THE REASONS FOR CANNABIS USE IN THE CLUBBING COMMUNITY

Short-Term Effects

The reasons for concomitant cannabis and other drug use, despite the problems listed previously, may consist in the acute psychological and physiological effects of drug interactions, of which the combination of cannabis and MDMA are the most extensively studied.

First, cannabis may mask or alleviate some of the adverse effects of clubbing drugs (see Mohamed et al., 2011 for overview). Cannabis, in combination with ecstasy, is commonly used during the "coming-down" phase (George, Kinner, Bruno, Degenhardt, & Dunn, 2010), to reverse stimulant-induced insomnia (Solowij, Hall, & Lee, 1992), as well as feelings of agitation and muscular tension which can persist after using stimulants, such as, MDMA (see Mohamed et al., 2011 for overview). Cannabis can also reduce the negative side effects of stimulating drugs, for example, it has been shown to alleviate sleep problems and pain (Walsh et al., 2013), as well as modulate stimulant-induced increases in body temperature, and oxidative stress (see Mohamed et al., 2011 for overview).

Psychological benefits of cannabis and stimulant couse may exist in the alleviation of stimulant-induced anxiety and depression (see Mohamed et al., 2011 for overview; Walsh et al., 2013), and moderate use of cannabis may also alleviate stimulant-induced aggression (see Mohamed et al., 2011 for overview).

Second, cannabis seems to enhance some desirable effects of stimulant drugs. For instance, 47% of ecstasy users reported concomitantly using cannabis, partially to prolong the feeling of "high" induced by the drug (Byqvist, 1999; Solowij et al., 1992). Additionally, 36% of cannabis users consume ecstasy simultaneously to improve its effects (Boys, Marsden, & Strang, 2001).

Gateway Theory

Regarding the reasons for concomitant cannabis and other drug use, it is possible that once an individual tries an illicit drug (eg, cannabis), he/she is more exposed. and hence more likely to use other illicit drugs (Kandel, Yamaguchi, & Klein, 2006), even when active drug-seeking behavior is controlled for (ie, Wilcox, Wagner, & Anthony, 2002). In this "gateway" theory, using one class of drug is a necessary, though not sufficient, facilitator of transition to use of the next class of drug, along the trajectory (Kandel, 2002). While cannabis is nowadays often referred to as a gateway drug, this role had originally been assigned to alcohol and tobacco (see Vanyukov et al., 2012 for overview). In other words, according to this theory, there is a natural progression from legal drugs, such as tobacco and alcohol, to illegal drugs including cannabis.

Few neurobiological studies support the role of cannabis as gateway drug by suggesting that cannabis acts on reward pathways in the brain, and changes the underlying neural connections in a way that predisposes to further drug use. However, evidence that cannabis induces changes predisposing to consumption of other illicit drugs is scarce, and not unanimously supported by animal models (see Rubino & Parolaro, 2008 for review). Some studies reported that, in rats, THC-pretreatment induced opioid receptor changes in reward-sensitive limbic structures, a fact that may explain the subsequently observed enhanced opioid use (see Rubino & Parolaro, 2008 for review). Additionally, activation of the cannabinoid CB1-receptor increased the reinforcing effects of heroin in rats (Solinas et al., 2005), suggesting that cannabis potentiates the hedonistic experience of opioids. On the other hand, amphetamine sensitivity in

THC-pretreated rats was not different to placebo-pretreated rats (see Rubino & Parolaro, 2008 for review). Solely based on neurobiological grounds, this might suggest that opiate use would likely follow cannabis use, if the gateway theory is supported, and prevalence rates for concomitant cannabis and opiate use should be relatively high, compared to other combinations of drugs of abuse. However, most studies suggest a relatively low rate (if any) of cannabis with concomitant opiate use, when compared to combinations of cannabis with stimulants and/or other drugs (see review previously). Furthermore, epidemiological studies in favor of the gateway theory support a trajectory from alcohol, cigarettes, cannabis, amphetamines, ecstasy, to opiates, such as, heroin (Pedersen & Skrondal, 1999).

Additionally, in some samples, illicit drug use is high in noncannabis users (see Degenhardt et al., 2010 for overview), and any relationship between cannabis and other illicit drug use seems to be short-termed, disappearing whilst cousers transition from adolescence to adulthood (Van Gundy & Rebellon, 2010). Therefore, it seems that cannabis does not unequivocally represent a gateway to other illicit drug use.

In recent years, it has also become apparent that even though different drugs use specific mechanisms to exert their effects, they all seem to affect similar reward-sensitive (ie, dopaminergic) neurotransmitter systems (see Degenhardt et al., 2010 for overview). This makes the identification of a specific gateway drug, unlikely which induces changes predisposing to further drug use. Unsurprisingly, epidemiological studies found that reduction of one potential gateway drug does not, per se, lead to a decreased consumption of any other illicit drugs (see Degenhardt et al., 2010 for overview). Furthermore, social environment and general communal attitude toward drug use may play a more important role than neurobiological factors to explain the association between cannabis and enhanced other drug use. For instance, in societies where cannabis use prevalence is relatively low, the association between cannabis use and transition to other illicit drugs is stronger than in societies where cannabis use is relatively frequent (see Degenhardt et al., 2010 for overview).

Common Liability to General Substance Use

Certain personality traits seem to be associated with both enhanced cannabis and polydrug use. For instance, a survey of 1076 northern Italian high school students revealed that cannabis use, illicit polydrug use, and alcohol abuse were each associated with high sensation seeking (Gerra et al., 2004). These findings concur with previous studies that showed a strong link between the trait of sensation seeking, and polydrug use including cannabis (Martins, Storr, Alexandre, & Chilcoat, 2008; Pedersen, Clausen, & Lavik, 1989). Novelty seeking, a concept similar to sensation seeking, has also been associated with drug use (see Bardo, Donohew, & Harrington, 1996 for review), and has been shown to relate to lower baseline availability of the neurotransmitter dopamine (see Bardo et al., 1996 for overview). Dopamine is involved in drug reinforcement and addiction, as well (see Volkow, Fowler, Wang, & Swanson, 2004 for review). Other personality traits include higher impulsivity for cannabis and polydrug users, as compared to nonusers (Martinotti et al., 2009), and schizotypy. Schizotypy, a personality trait representing schizophrenia symptoms in milder form in the general, healthy population (Mason, Claridge, & Jackson, 1995; Meehl, 1962), has been associated with increased vulnerability to psychosis and other mental health issues (van Os, Linscott, Myin-Germeys, Delespaul, & Krabbendam, 2009), as well as higher polydrug and cannabis use (Barkus & Murray, 2010; Herzig, Brooks, & Mohr, 2013).

Interestingly, novelty and sensation seeking, as well as impulsivity and schizotypy, have been linked with the dopamine D4 receptor gene (Grant, Gabriel, Kuepper, Wielpuetz, & Hennig, 2014; Munafò, Yalcin, Willis-Owen, & Flint, 2008 for metaanalysis), which is involved in the transmission of dopamine in the brain.

It is therefore possible that the higher rates of combined clubbing drug and cannabis use reflect a common liability to substance use (Morral, McCaffrey, & Paddock, 2002). However, one should note that, despite these assumed common liabilities, the majority of cannabis users do not consume other illicit drugs (see previous sections). Therefore, other factors are likely to influence the transition from cannabis to clubbing drug use. Moreover, polydrug use is diverse (Byqvist, 1999), and different clusters of polydrug use may differ in terms of outcome (Ives & Ghelani, 2006). Clearly, more research elucidating, for example, personal, social, and biological factors representing a risk of or resilience against illicit polydrug use and associated problems are needed in future.

MINI-DICTIONARY

Clubbing Clubbing typically refers to visiting venues (ie, dance clubs) hosting electronic dance music events.

Clubbing drugs These substances are typically consumed in the context of electronic dance music events.

Cocaine This psychoactive substance is extracted from the leaves of plants called *Erythroxylum coca*. Cocaine is a potent stimulant of the central nervous system, and can lead, for example, to reductions in appetite and sleep, and increases in euphoria, feeling energetic and mentally alert, restlessness, irritability, and anxiety. At higher and frequent doses, it can also cause paranoia and hallucinations, for example.

Depressants These substances decrease central nervous system functioning, resulting in reduction of physical, psychological, or cognitive function. They can also reduce anxiety and tension,

and have muscle relaxant properties. Examples are GHB, benzodiazepines, and opioids (eg, heroin).

Ecstasy 3,4-methylenedioxy-*N*-methylamphetamine (also known as MDMA) has stimulant and mild hallucinogenic properties, and induces feelings of well-being, empathy toward others, as well as decreased anxiety, and enhanced sensory perception, for example. Undesirable effects include anxiety, panic, or confusion.

GHB Gamma-hydroxybutyrate is a neuromodulator that was first synthesized in 1960, as an alternative anesthetic because of its ability to induce sleep and reversible coma. GHB has anxiolytic, sedative, and euphoric effects and, at higher doses, can induce, for example, seizures, confusion, respiratory problems, and memory lapses.

Hallucinogens These substances result in distortion of reality perception, and can induce feelings of depersonalization and derealization, as well as auditory and visual hallucinations. Examples are, LSD, magic mushrooms, and ketamine.

Ketamine This is an anesthetic drug used by veterinarians and medical professionals, but is also used in recreational settings as hallucinogen. It can induce, for instance, feelings of euphoria, relaxation, depersonalization and derealization, hallucinations, as well as disorganization, anxiety, panic, and paranoia.

Methamphetamine Methamphetamine is a potent stimulant of the central nervous system. It can reduce fatigue, appetite, and behavioral inhibition, for example, and increase arousal, euphoria, positive mood, cognitive performance, and anxiety, as well as psychotic episodes.

New psychoactive substances These substances are usually derived from known psychoactive compounds, and mimic their effects. However, they are often not controlled under any legislation. For this reason, many of these substances are legal to consume, despite their potential harmfulness.

Stimulants These substances stimulate the central nervous system, and can enhance physical, psychological, and cognitive function. Examples are, for example, (meth)amphetamines and cocaine.

SUMMARY POINTS

- This chapter focuses on the effects of cannabis and other drugs on sexual behavior.
- Research has shown that cocaine at low doses have positive effects on sexual arousal. These effects include spontaneous erection and ejaculation, as well as multiple orgasms.
- On the other hand, chronic cocaine use is associated with erectile dysfunction and inhibited sexual desire.
- Additional research on opiates has shown that heroin has positive effects at low doses, whereas chronic use leads to reduced sexual desire, contributes to impotence, and interferes with ejaculation and orgasm.
- Methamphetamine users experience enhanced pleasure, and generally engage with many partners.
- However, long-term methamphetamine users experience sexual dysfunctions, such as, disorders of erection, ejaculation, and orgasm, as well as decreased sexual desire.
- Cannabis at low doses is associated with positive sexual effects, including improvement in the quality of the orgasm, and increased sexual pleasure and sexual satisfaction.
- Nevertheless, cannabis at high doses has been associated with erectile dysfunction, sterility, and reduction in testosterone levels.
- Additional research has also demonstrated that cannabis use was associated with slowing of temporal perception and, therefore, increased concentration on the sexual intercourse.
- Finally, it is also entirely plausible that the perceived positive effects of cannabis on sexual functioning are due to expectancy biases.

KEY FACTS OF COCAINE

- Cocaine usage increases dopamine levels, resulting in sexual excitement and pleasure, in animals and humans.
- Short-term cocaine use induces multiple orgasms, as well as spontaneous erection and ejaculation.
- Long-term cocaine use inhibits sexual arousal, as it leads to dopamine deficiency.
- Long-term cocaine use leads to delayed ejaculation, and difficulties in maintaining erection.
- Long-term cocaine use among women leads to difficulties in achieving orgasm, and diminished sexual desire.

KEY FACTS OF OPIATES

- Opiates redirect blood away from the genitals, thus contributing to sexual dysfunction.
- Heroin at low doses triggers sexual arousal, and enhances sexual performance.
- Heroine at high doses reduces sexual desire, contributes to impotence, and interferes with ejaculation and orgasm.

- Heroin suppresses testosterone production, thus inhibiting sexual desire.

KEY FACTS OF PSYCHOLOGICAL CONSEQUENCES OF DRUG ABUSE

- Drug abusers have difficulties in establishing committed and intimate relationships with their partners.
- Drug abusers are mainly characterized by instrumental sexual behavior, as they show the tendency to view the partner as a sexual object.
- Drug addicts are more prone to seek sex only for pure physical pleasure, and to appreciate masturbation and pornography rather than sexual intercourses with a partner.
- Drug addicts often experience depression, anxiety, and anger.
- Men who abuse drugs are at increased risk of inflicting sexual violence on women.

KEY FACTS OF CANNABIS

- Chronic cannabis smokers have significantly reduced plasma testosterone levels, and exhibit sterility.
- Cannabis users are more likely to get sexually transmitted diseases, such as, gonorrhea and chlamydia.
- At low doses cannabis has disinhibiting effects, and enhances sexual arousal.
- Chronic cannabis use has inhibitory effects on sexual behavior, and leads to erectile dysfunction.
- Cannabis use has anxiolytic effects, resulting in more relaxation during the sexual encounter.
- Cannabis consumption slows temporal perception.

LIST OF ABBREVIATIONS

MA Metamphetamine
THC Phytocannabinoid Δ^9-tetrahydrocannabinol

INTRODUCTION

Among a range of side effects of drug abuse, sexual behavior has been an unexplored area in the clinical care of drug addicts until recently, although highly important. On gross inspection, heavy drug use leads to impotence, painful sex, inability to ejaculate, reduced sexual interest and satisfaction, or premature ejaculation (Johnson, Phelps, & Cottler, 2004). In addition to these sexual disorders, researchers are interested in studying the effects of specific psychoactive drugs on human libido. In particular, an extensively studied drug in relation to sexual behavior that will be the main focus of this chapter is marijuana. Previously thought to be an aphrodisiac, marijuana is now recognized to be a drug that enhances sexual motivation in low doses, but that can lead to reduced libido and difficulties in reaching orgasm, in high doses (Johnson et al., 2004). Moreover, many studies have shown that marijuana consumption is also associated with health-related risky sexual behavior (Li et al., 2011).

Research on drugs, such as, stimulants suggests that these tend to increase libido and sexual satisfaction (Semple, Zians, Strathdee, & Patterson, 2009). Among them, cocaine has been fairly studied, showing mixed findings, as it can lead to both increased and inhibited sexual desire (Warner, 1993). Finally, amphetamine and methamphetamine (MA) tend to increase libido and pleasure by lowering inhibitions in both low and acute doses (Feucht, 1993). However, high and chronic doses reduce sexual motivation and satisfaction (Smith, Wesson, & Apter-Marsh, 1984).

This chapter will explore the various effects of marijuana on sexual behavior. It will describe its effects in high and low doses, and will also look at gender differences. Finally, this chapter will illustrate the effects of other drugs (cocaine, heroin, MA) on sexual behavior, in order to have a more comprehensive understanding of this area.

DRUGS AND SEXUAL BEHAVIOR

Studies looking at the relationships between specific drugs and sexual behavior have shown that cocaine, a stimulant with anesthetic features (Buffum, Moser, & Smith, 1988), increases levels of dopamine, norepinephrine, serotonin, and is often linked to sexual desire (Rawson, Washton, Domier, & Reiber, 2002) (Table 19.1). Increased dopamine levels have been found to enhance sexual excitement in animals, and are associated with feelings of pleasure (Leavitt, 1995). Research shows that short-term cocaine use causes spontaneous erection and ejaculation, as well as multiple orgasms (Buffum, 1982). However, despite the positive sexual effects associated with short-term cocaine use, many studies claim that long-term cocaine consumption results in several sexual dysfunctions. In fact, long-term cocaine use causes dopamine deficiency, resulting in inhibited sexual arousal (Cocores, Miller, Pottash, & Gold, 1988). Additionally, problems like delayed ejaculation and difficulties in maintaining an erection are common among chronic cocaine addicts. Gold (1997) argues that impotency and other sexual difficulties may continue after cocaine consumption has stopped. Additional studies have also shown that, among women, chronic cocaine use leads to difficulties in achieving orgasm and diminished sexual desire (Henderson, Boyd, & Whitmarsh, 1995).

TABLE 19.1 Type of Drug and Sexual Disorders

Type of drug	Sexual effects
Short-term cocaine use	Spontaneous erection, spontaneous ejaculation, multiple orgasms
Long-term cocaine use	Inhibited sexual arousal, delayed ejaculation, difficulties in maintaining erection, impotency, difficulties in achieving orgasm, diminished sexual desire
Heroin at low doses	Enhanced sexual arousal, enhanced sexual performance
Heroin at high doses and chronic use	Diminished sexual desire, impotence, difficulties in achieving orgasm
Amphetamine and methamphetamine at low and acute doses	Increased libido and pleasure, unprotected sex, delayed orgasm
Amphetamine and methamphetamine at high and chronic doses	Reduced sexual motivation and satisfaction, problems with erection, ejaculation, diminished sexual desire

There are different types of drugs, and these have different effects on the sexual disorders.

Studies on opiates (eg, heroin, morphine, methadone) have demonstrated that their effects on sexual function results from a complex mix of psychological, pharmacological, and sociocultural factors. Opiates are central nervous system depressants that relieve pain, acting on various neurotransmitters in the brain (Pinger, Payne, Hahn, & Hahn, 1998). Opiates also redirect blood away from the genitals, a factor that contributes to sexual dysfunction (Gay & Sheppard, 1973). Among opiates, heroin is a drug whose effect on sexual behavior has been fairly researched. Researchers suggest that small amounts of heroin enhance sexual arousal and sexual performance (Jaffe, Knapp, & Ciraulo, 1997). However, high doses and chronic use diminish sexual desire, interfere with ejaculation, and lead to impotence in men. Further, heroin also suppresses testosterone production (Buffum et al., 1988), thus inhibiting sexual desire.

Users of MA, a stimulant associated with sexual activity, reported to have numerous several sexual partners, and to engage in unprotected sex more often than other drug users (Molitor et al., 1999). Buffum (1982) also claims that MA reportedly increases sexual desire, and delays orgasm. Despite these positive effects, long-term MA users experience problems with erection, ejaculation, orgasms, as well as a decrease in sexual excitement (Buffum et al., 1988).

In addition to the physical consequences of heavy drug use, drug addicts also tend to have problems with their partners, which, in turns, affects their sexual lives (Reiss & Leik, 1989). This topic has been studied by Bruno et al. (2012), who evaluated sexual attitudes in a sample of polydrug addicted subjects (opiates, cocaine, amphetamine, inhalants, marijuana/sedatives, or hallucinogens abusers) compared with 90 nonsubstance abusing subjects. Their results showed that drug users were particularly inclined to search for sexual intercourse, and more open to different kinds of sexual experiences. However, they showed difficulties in forming emotionally close relationships with their partners, and tended to consider them as sexual objects, giving a fundamental importance to their sexual expertise. This study also showed that drug addicts did not feel the need to give love, and sought sex only for pure physical pleasure. In fact, they preferred a solitary sexual pleasure like pornography, rather than having sex with a partner (Bruno et al., 2012) (Table 19.2). Carroll, McGinley, and Mack (2001), who also studied the emotional difficulties experienced by drug users, found that maladaptive sexual behavior (eg, feeling guilty or overthinking about sex) was common in most of the examined subjects.

Additional research also reports that drug addicts often experience depression, anxiety, and anger (Liang, Chikritzhs, & Lenton, 2011), factors that dramatically affect their sexual life (Muscatello et al., 2010). Addiction has also been shown to affect self-concept (Carroll, 1982), and the ability to form intimate relationships with other people (Amaro & Hardy-Fanta, 1995).

Another documented consequence of substance abuse is also intimate partner violence (Table 19.3). Several studies have found that men who abuse drugs are at increased risk of inflicting sexual violence on women (Abbot, Johnson, Koziol-McLain, & Lowenstein, 1995). Drug abuse in females has also been associated with events of either physical or sexual violence, especially when the partners are also drug addicts (El-Bassel, Gilbert, & Rajah, 2000).

CANNABIS AND SEXUAL BEHAVIOR

Throughout history, cannabis consumption has been associated with positive effects on sexual behavior, a belief which is still present today (Abel, 1981). This relationship has been extensively studied in the last years, showing that phytocannabinoid Δ^9-tetrahydrocannabinol (THC) is the psychoactive component responsible for changes of sexual functioning in drug addicts.

The first suggestion that cannabinoids might affect sexual functioning was reported in a study on rats exposed to smoke containing radiolabeled THC

TABLE 19.2 Effect of Drugs on Sexual Behavior

Sexual behavior	Sexual effects
Sexual excitement	Enhanced easiness and degree of arousal in response to sexual stimuli
Sexual satisfaction	Reduced general satisfaction that a person derives from his/her sex life
Sexual shyness	Discomfort felt in the presence of the opposite sex
Impersonal sex	Tendency to consider the partner as a sexual object, neglecting his/her personality and the importance of establishing an emotional close relationship with him/her
Sexual nervousness	Inability to achieve sufficient sexual gratification due to disturbing thoughts, emotions, and actions coming from sex life
Pornography	Appreciation of explicit erotic images, both of verbal and graphic nature
Sexual permissiveness	A very tolerant attitude toward sexuality and its rules
Sexual disgust	Disgust of some sexual practices, even when loving the usual sexual partner
Physical sex	Giving fundamental importance to the partner's sexual expertise, ignoring other personality traits
Aggressive sex	Hostility during the sexual act

Drugs have different effects on various aspects of sexual behavior and attitudes.

TABLE 19.3 Psychological and Relational Problems Experienced by Substance Users

Psychological effects present in drug addicts	
Difficulties in establishing committed and deep relationships with their partners	Depression, anxiety, anger
Intimate partner violence	Tendency to feel guilty, worried and to overthink about sex
Self-concept instability	Tendency to neglect the importance of giving love to the partner
Tendency to neglect the partner's feelings and personality	

Drug addicts tend to have different kinds of problems with their partners that, in turn, affects their sexual lives.

(Ho et al., 1970). Tissue analysis showed a very high concentration of radiolabeled THC in the testicles, suggesting that cannabinoids play a role in testicular processes. Following this evidence, a series of intense investigations took place in the early 1970s. For instance, Kolodny, Masters, Kolodner, and Toro (1974) demonstrated that plasma testosterone levels were significantly reduced in chronic cannabis addicts (Table 19.4). Furthermore, this reduction was dose-dependent. In fact, when cannabis users were subdivided by the intensity of their usage, heavy users (more than 10 cannabis joints per week) showed a greater reduction in testosterone levels than moderate users (5–9 joints per week). In the same study, further examinations also evidenced that 35% of the sample exhibited sterility, as their sperm counts were less than 30 million per ml. However, this reduction was only present in heavy users.

Additional studies conducted among convicted adolescents (Kingree, Braithwaite, & Woodring, 2000) and in samples of homosexual men (Clutterbuck, Gorman, McMillan, Lewis, & Macintyre, 2001) showed that cannabis use was also associated with less condom use (Table 19.5). However, among young heterosexual adults (Brodbeck, Matter, & Moggi, 2006), and adults in a substance use jail diversion program (Leigh, 2002), cannabis use was not associated with condom use. Beyond condom use, a significant amount of research has been conducted to assess whether cannabis users are more likely to get sexually transmitted diseases. Evidence has shown that cannabis smokers were more likely to get sexually transmitted diseases, and adolescents who regularly used cannabis were also more likely to test positive for gonorrhea and chlamydia (Liau, Diclemente, & Wingood, 2002). Finally, it is important to stress that sexual risk behavior among cannabis users may be due to more stable personality traits that stimulate both drug use and sexual risk (Brodbeck et al., 2006).

Despite the negative effects of cannabis on sexual functioning, additional studies showed that low-dose cannabis has enhancing effects on sexual arousal. For instance, a study by Sumnall, Beynon, Conchie, Riley, and Cole (2007) revealed that over 30% of a sample of 270 adults in the United Kingdom reported using cannabis in order to improve their sexual performance.

Self-report surveys on male samples also support the notion that cannabis has a positive effect on sexual experience. Kolodny et al. (1979) interviewed 800 male subjects aged between 18 and 30; in their sample, 83%

TABLE 19.4 Main Studies Addressing Cannabis and Sexual Behavior

Authors	Year of publication	Study and result	Participants
Kolodny et al.	1974	Reduced levels of testosterone in chronic cannabis smokers	20 males
Koff	1974	In females, self-reported increase of sexual desire after smoking one marijuana joint (71%), or after smoking two or more joints (50%)	128 females and 123 males
Halikas et al.	1982	Self-reported increased duration of sexual intercourse (39%), orgasm improvement (68%), increased sexual pleasure and satisfaction (75%)	61 males and 39 females
Liau et al.	2002	Higher probability of sexually transmitted diseases (gonorrhoea, Chlamydia) in cannabis users	522 adolescent males and females
Smith et al.	2010	Recurrent cannabis use is associated with an increased number of sexual partners for both men and women, and inability to orgasm as desired	8650 people

There have been very few studies that have investigated effects of cannabis on sexual behavior.

TABLE 19.5 Positive and Negative Effects of Cannabis on Sexual Behavior

Positive effects (low doses)	Negative effects (high doses)
Enhanced sexual desire	Reduction in testosterone and sperm
Enhanced sexual pleasure and satisfaction	Sterility
Enhanced erection maintenance and ejaculatory control	Less condom use, getting sexually transmitted diseases
	Diminished sexual desire, impotence, difficulties in achieving orgasms
	Erectile dysfunction

Cannabis is associated with both positive and negative effects on sexual behavior depending on dose (low vs. high).

reported that cannabis enhanced sexual pleasure. However, it seemed that this effect was not due to changes in erection maintenance or ejaculatory control; rather, cannabis was found helpful in easing a general relaxation that allowed more attention and focus on sexual pleasure, thus making sex more enjoyable. Another study on male cannabis addicted (Halikas, Weiler, & Morse, 1982) showed that 39% of the sample reported that cannabis use prolonged the duration of sexual intercourse, 68% reported that it improved the quality of their orgasm, and 75% reported that it increased sexual pleasure and sexual satisfaction. Finally, considering the effects of drug dose on sexual behavior, Koff (1974) found that 71% of female cannabis users reported an increase in sexual desire after smoking no more than one marijuana joint. However, this number decreased to 50% for females who smoked two or more joints. As a result, Koff concluded that as the marijuana dose goes beyond one marijuana joint, the positive effects on sex decreased. In the same study, a similar pattern was also found for sexual pleasure. In fact, women reported increased sexual pleasure after smoking one marijuana joint, but decreased sexual desire with exceeding doses. Overall, these results suggest that in low-dose, cannabis enhances sexual pleasure, whereas higher doses cause a reduction in sexual pleasure. Chopra and Jandu (1976) conducted a similar study, and reported comparable results in a large Indian sample of chronic male users.

Additional research has also shown that chronic marijuana consumption leads to erectile dysfunction. In fact, evidence of erectile dysfunction caused by chronic and acute cannabis use have been reported in North African, North American, and Indian samples (Scher, 1970). Further, many have argued that cannabis facilitates sexual arousal by enhancing touch awareness, in lower doses (Halikas et al., 1982). However, this effect seems questionable because in nonsexual contexts marijuana has either no effect, or actually lowers touch sensitivity and tactile perception (Reese, 1977).

Studies exclusively conducted on women failed to show negative effect of cannabis on sexual behavior. For instance, a study by Smith et al. (2010) examined the presence of sexual difficulties in a sample of 4350 women cannabis smokers. The sexual difficulties were considered only if they lasted for more than 1 month, and included low sexual desire, orgasmic dysfunction, lack of vaginal lubrication, sexual pain, and anxiety. The results of this study did not indicate a correlation between sexual difficulties and frequency of cannabis use.

TABLE 19.6 Proposed Explanations for Positive Effects of Cannabis at Low Doses

Explanations	Sexual experience
Altered sensation and/or perception	Increased tactile sensitivity
Anxiolytic effects	Enhanced relaxation during sexual acts
Slowing of temporal perception	Sexual activities are perceived to last longer than they do
Increased awareness	Mindfully focusing on the body and its sensations during sexual intercourse
Disinhibited behavior	Lack of restrictions exhibited before and during sexual act
Placebo effects	Belief that cannabis is an aphrodisiac substance
Correlation with other psychoactive substances	Effects of other drugs taken in conjunction with cannabis during sexual intercourse

There are various kinds of explanations for the effects of cannabis on sexual behavior at low doses, ranging from psychological, to chemical, or neurological mechanisms.

Several researches have tried to assess why low-dose cannabis has positive effects on sexual behavior (Table 19.6). It has been suggested that cannabis may alter perception in a way that improves sexual experiences (Abel, 1981; Adams & Martin 1996). Halikas et al. (1982) proposed that cannabis positively impacts sexual functioning by enhancing tactile sensitivity. In support of this, Dawley, Winstead, Baxter, and Gay (1979) studied this aspect in a sample of experienced marijuana addicts. Their results show that 48% of the sample reported that marijuana had a beneficial effect on sensations during sex. Conversely, a study by Reese (1977) found that marijuana resulted in either negative or no effects on tactile sensitivity, in nonsexual situations. This leads to doubts as to whether marijuana use increases tactile sensitivity in sexual contexts.

Alternatively, sexual function may be indirectly enhanced through the effects of cannabinoids on anxiety. Given the well-known anxiolytic effects of cannabinoids (Adams & Martin, 1996), when people smoke cannabis they are more able to relax and, therefore, to enjoy the sexual intercourse more. This hypothesis has been supported by Kolodny, Masters, and Johnson (1979), who found that while 81% of their sample of 500 subjects reported that cannabis use resulted in enhanced sexual pleasure, this pleasure was attributed to the effects of increased relaxation, and not to any direct effects of cannabis on sexual desire.

Alternatively, it seems plausible that cannabis smokers perceive an improvement of their sexual activity due to a slowing of temporal perception while "high," therefore sexual activities seem to last longer than they actually do (Jarvik & Brecher 1977; Melges, Tinklenberg, Hollister, & Gillespie, 1971). Melges et al. (1971) showed that slowing of temporal perception resulted in increased concentration on the actual moment.

Another possibility is that cannabis use results in disinhibition that, in turn, leads to more relaxation and sensory focus (Dawley et al., 1979; Kolodny et al., 1979; McKay, 2005). Additionally, it is plausible that given cannabis' reputation as an aphrodisiac, its positive effects on sex are due to expectancy effects (ie, placebo effect). Several studies support the idea that the sexual experiences of cannabis addicts are influenced by their sexual expectations from the substance (Crenshaw & Goldberg, 1996; Rosen, 1991). Therefore, the perceived relationship between cannabis and sexual behavior might be purely correlational, with cannabis having neither direct nor indirect effects on sexual functioning.

Finally, it has been argued that the correlation between cannabis and sexual function may be the result of the fact that alcohol and other psychoactive substances are often taken in conjunction with cannabis. These other substances may affect sexual function, but their effects may be wrongly attributed to cannabis (Gorzalka & Hill, 2006).

MINI-DICTIONARY

Cannabinoids Family of compounds (phytocannabinoids, derivatives of *Cannabis sativa*, endocannabinoids, and synthetic cannabinoids) whose action in the CNS is mediated through specific interactions with G-protein-coupled receptors, named CB1 and CB2. CB1 receptor is predominantly located in the brain, and its activation inhibits neurotransmitter release, and modulates both excitatory and inhibitory neuronal activity in the CNS. CB2 is mainly expressed in immune tissue, and it is probably involved in cannabinoid-mediated immune responses.

Cannabis A psychoactive drug whose main constituent is Δ^9-tetrahydrocannabinol (THC). It also contains other cannabinoids, including cannabidiol (CBD), cannabigerol (CBG), Δ^9-tetrahydrocannabivarin (9-THCV), and cannabidivarin (CBDV).

Cocaine Cocaine is a central nervous system stimulant with anesthetic properties that alters the levels of dopamine, serotonin, and noradrenaline.

Dopamine A catecholamine neurotransmitter that plays a number of important roles in the human and animal nervous system. These include learning and reward evaluation, as well as sexual behavior.

Heroin An extremely addictive narcotic drug derived from morphine. Heroin is classified as an opiate.
Methamphetamine A stimulant drug included in the amphetamine family.
Neurotransmitters Chemical substances released at synapses that mediate signaling between neurons. These include dopamine, norepinephrine, etc.
Opiates Central nervous system depressants that cause sedation and relieve pain. These act on several neurotransmitters in the brain, including endorphins. Opiates include heroin, morphine, methadone, codeine, etc.
Testosterone A sex hormone and anabolic steroid found in humans and many animals. In humans, testosterone is secreted by the testicles in males, and by ovaries in females.
THC The phytocannabinoid Δ^9-tetrahydrocannabinol (THC) is the psychoactive component responsible for changes of sexual functioning in drug addicts

SUMMARY POINTS

- This chapter focuses on the impact that friends have on marijuana use.
- Friends, and particularly the marijuana use patterns of friends, have a strong impact on a person's choices to begin and continue using marijuana.
- Friends are most influential during the developmental stages of late childhood, early, middle, and late adolescence, and emerging adulthood. As a person enters their late 20s and beyond, it is likely that their marijuana use is not strongly influenced by the use patterns of friends.
- Marijuana is frequently used in small, intimate friendship groups during adolescence and emerging adulthood.
- American Courts have responded to shared usage by implementing nonassociation orders, or the situation when a court orders a person to not spend time with others who are known to use marijuana.
- With changing marijuana legislation in the United States and the world, the extent to which friends influence marijuana could potentially change going into the future.

KEY FACTS OF FRIENDS' INFLUENCE ON MARIJUANA USE DURING LATE CHILDHOOD AND ADOLESCENCE

- Late childhood is the first developmental period where there is a notable increase in the number of people initiating marijuana use.
- Most people who will use marijuana will initiate during adolescence or emerging adulthood, with the most common age being 17 years old.
- Users frequently use with their friends in small, intimate peer groups, during late childhood, adolescence, and emerging adulthood.
- Friends, and especially the marijuana use patterns of friends, are one of (if not the most) important causes of marijuana use during the late childhood, and into emerging adulthood. The impact that friends exert on marijuana use begins to fade in the early 20s.

KEY FACTS OF FRIENDS' INFLUENCE ON MARIJUANA USE DURING MIDDLE ADULTHOOD AND BEYOND

- Marijuana use becomes much less common toward the end of emerging adulthood, and is increasingly uncommon as a person ages into middle adulthood and beyond.
- Those who continue to use marijuana during the adult portions of their lives make conscious decisions to use, and are not influenced extensively by the marijuana use patterns of their friends.
- Some research suggests that there may be a resurgence of peer influence for alcohol among retired persons. With increasingly lenient marijuana use patterns in the United States and the world, a resurgence of the peer effect could potentially occur with respect to marijuana use.

KEY FACTS OF AMERICAN COURT RESPONSES TO SHARED MARIJUANA USE BETWEEN FRIENDS

- It is well understood that persons, and particularly young persons, tend to use marijuana in intimate peer groups.

Copyright © 2017 Elsevier Inc. All rights reserved.

- American courts, and particularly specialized drug courts, have implemented "nonassociation orders" in response to the fact that many people use with others.
- Nonassociation orders are court orders prohibiting a user from spending time with other marijuana users.
- With relaxing marijuana legislation that has recently begun in the United States, American courts are increasingly shying away from hearing marijuana cases. This could affect how nonassociation orders are applied in the future in marijuana use cases.

INTRODUCTION

It has long been known that the influence of friends is one of the most robust correlates of a person's own marijuana (cannabis) use. In US culture, the importance of peer influence for marijuana use was realized many decades ago, when a marijuana culture which had originally grown out of the jazz music scene in the early 1900s expanded to a much wider audience, in the 1920s and 1930s. To provide just one example, an adolescent was driven to marijuana use—and ultimately homicide—because of his choice to associate with friends who also used marijuana, in the propaganda film *Reefer Madness* (1936). Research also recognized the importance of peers on marijuana use, especially after the social movements of the 1960s in the United States (Kandel, 1978). Currently, there is no serious debate about whether peers influence marijuana use. Instead, this is accepted as a fact (Akers & Cochran, 1985; Maxwell, 2002).

Perhaps because of the extent to which personal use is influenced by friends' use, marijuana is commonly seen as a social drug. On one level, this is largely correct since marijuana is commonly used with friends and/or because of friends. One potential conclusion from this fact is that peers—and particularly the marijuana use patterns of peers—are the leading cause of marijuana use. Though this is commonly thought to be the case, we caution against such a conclusion, and instead argue that peers exert a strong impact on marijuana use only at certain ages.

In this chapter, our general focus is on the extent to which friends impact marijuana use. We begin by offering some generalizations about peer influence and discuss the importance of the construct to the scientific discipline of criminology, as well as the practice of marijuana use. Following, we emphasize that the peer effect on marijuana use is not the same at all points of a person's life-course, and keep a keen eye on how peers impact marijuana use in different ways, at different ages. Next, we discuss how the American Criminal Justice System has implemented judicial responses to shared marijuana usage among friends. Finally, we discuss some future directions, where more friend-based marijuana research is necessary.

As a point of clarification, there is a difference between "peers" and "friends" (Kreager, 2004). "Peers" describe those with whom a person is similarly situated, while "friends" describe those with whom the person shares close and affectionate ties. While we do understand that there is a difference between these two groups of individuals, this chapter is about the influence of friends on marijuana use. With this explicitly noted, we will use the terms "peers" and "friends" interchangeably at times, simply to avoid monotony.

THE NATURE OF PEER INFLUENCE

The opinions, characteristics, and behavior of friends are widely recognized as one of the leading correlates and causes of personal behavior, in a wide variety of social science disciplines, including (but not limited to) fields concerned with psychological, sociological, developmental, and criminological matters. In the criminological context, the first scholar to place a central focus on the importance of friends was Edwin Sutherland, in the 1930s. Sutherland, who has been credited with founding criminology as a distinct discipline (Cullen, 2011), was a student of the Chicago School of sociological thought (Shaw, Zorbaugh, McKay, & Cottrell, 1929). Scholars of the Chicago School were primarily focused on investigating the apparent link between criminal behavior and detrimental structural conditions, such as, community-wide socioeconomic disadvantage, a lack of legitimate opportunities for employment, and social disorganization (Shaw & Becker, 1930; Shaw & McKay, 1942).

At the time when Sutherland began writing his most influential peer-based work (the 1930s–40s), Chicago School criminologists had already acknowledged that friends may be important for behavior. However, they did not believe that friends were a central cause of crime or substance use, a point to which Sutherland strongly disagreed. Instead of continuing research within the structural-level context of the Chicago School, Sutherland developed "differential association theory" (Sutherland, 1939, 1942, 1947), a theory of individual behavior which assumed that friends could be a leading correlate and cause of deviant and conforming behavior. Though Sutherland left many of the concepts within differential association theory broad and open to

interpretation, the central hypothesis of the theory was that the more a person is exposed to peers who engage in deviant behavior, the more likely he/she is to engage in deviance him/herself. Overall, this hypothesis has received overwhelming support in research, as hundreds of studies have found that those who have deviant friends are highly likely to commit deviant behavior themselves (Pratt et al., 2010).

Perhaps due to the overwhelming empirical support of differential association theory, the notion that peers affect behavior has become engrained as a central concept to criminologists. This has been aided by scholars who have expanded upon Sutherland's theory, particularly the extension of differential association offered by Akers's "social learning theory" (Akers, 2009).

Regardless of the theoretical framework through which it is applied, the behavior of peers consistently shows a strong, positive, and significant relationship with the behavior of individuals (Pratt et al., 2010; Warr, 2002). Despite the coefficient of peer behavior nearly always being significantly related to the behavior of an individual, the magnitude by which the coefficients vary depends on the type of behavior that is under consideration. Though still significant, the weakest coefficients are typically found in the associations between peer shoplifting and peer violence, and an individual's shoplifting and violent behaviors, respectively (Warr, 2002). On the other hand, the strongest coefficients are typically found in the associations between peer substance use and vandalism, and the individual's substance use and vandalism patterns, respectively (Warr, 2002). The difference in the coefficient sizes of these relationships is likely at least partially attributable to cooffending, or the situation where the actor and his/her peers all engage in a behavior together. Stated differently, people are more likely to vandalize property and use substances with friends, than they are to steal from stores and be violent with friends.

In short, evidence strongly supports the notion that the substance use patterns of friends are overwhelmingly important for one's personal use (Warr, 2002). As such, it has been claimed that the substance use of friends is the primary correlate and/or cause of one's own substance use (Agnew, 1991).

With the importance of friends emphasized, the question then becomes "which substances are most influenced by peer use?" The short answer to this question is social drugs, which generally encompass alcohol and marijuana, but can also include other "club drugs," such as ecstasy, cocaine, and methamphetamines (DEA, 2001). But such a simple answer may be somewhat misleading, due to strong evidence that suggests that there are different causes of substance use at different stages of one's life-course. We now turn our focus to such developmental matters, with a keen eye specifically on the impact that friends have on marijuana use.

HOW DO FRIENDS INFLUENCE MARIJUANA USE?

Generally, research has demonstrated that a person's behavior is influenced by different types of people at different ages (Warr, 1993). Due to the need for care, infants and young children share close relationships with their caregivers (usually parents), and are strongly influenced by them (Hartup, 1996). However, the influence parents have on behavior wanes, as children enter late childhood and early adolescence (Hartup, 1996). By the time an actor reaches late childhood, peers replace parents as the main agent of behavioral influence (Hartup, 1996). Peers remain the primary mechanism of behavioral influence until people reach their mid-to-late 20s, at which point many people are settling down into committed relationships (Warr, 1998).

The period during which friends have the most influence on marijuana use is the period of late childhood, adolescence, and emerging adulthood (Warr, 2002). Conveniently, these are also the developmental periods when marijuana use increases rapidly (late childhood and adolescence), peaks (adolescence to emerging adulthood), and declines rapidly (emerging adulthood) in the general population (Moffitt, 1993; Nagin & Tremblay, 2005). Thus, the developmental stages during which marijuana use is the highest in the overall population are the same developmental stages when friends influence use the most.

Although there are exceptions to this general trend, most people who choose to use marijuana use at the highest rate of their lives during adolescence and emerging adulthood (Warr, 2002; Moffitt, 1993). Accordingly, the developmental time period of adolescence is extremely important for the onset and continuance of marijuana use. Additionally, the influence that peers exert on marijuana use in adolescence shifts considerably during this tumultuous time in life. As such, we review the impact that friends have on marijuana use during several distinct developmental periods—late childhood, early adolescence, middle adolescence, late adolescence, emerging adulthood, and middle adulthood and beyond.

Late Childhood and Early Adolescence

Late childhood and early adolescence are generally thought of as the time when a person is between 9 and 12 years of age (Kastenbaum, 1993). In addition to the number of physical and hormonal changes that happen during this period of life, late childhood is also marked by a very important social shift. By the time most children enter late childhood—and certainly by the time a child turns 11 or 12—the most important influence for behavior no longer comes from parents and/or caregivers, but instead comes from friends (Hartup, 1996).

This shift in social influence from caregivers to friends carries important consequences for marijuana use. Late childhood is the beginning of a period of several years when numerous people will choose to use marijuana for the first time. This "initiation" or "experimentation" with the substance almost never occurs in a manner where a child acquires marijuana and uses it on his/her own. Instead, the onset of use during this age almost always happens because of some form of peer pressure or peer influence. One common scenario is a child's friend acquires marijuana and chooses to share it with the individuals within his/her friendship group (Anderson, 1999). Another common scenario is the child, or the child's friend(s), is acquainted with a slightly older individual (including older siblings) through whom he/she is able to acquire marijuana for use immediately or later (Ellickson, Tucker, Klein, & Saner, 2004).

Regardless of the means through which marijuana is first ingested, peers play a central role in instigating the onset of use during late childhood and early adolescence. To a great extent, this observation is also true during the developmental stage of middle adolescence.

Middle Adolescence

Middle adolescence is defined as the time when a person is between 13 and 15 years old (Kastenbaum, 1993). When individuals transition from the late childhood/early adolescence time period to middle adolescence, most people who will eventually use marijuana have not yet begun using (ONDCP, 2011). However, many future users will initiate use during middle adolescence (ONDCP, 2011).

Like during the period of late childhood and early adolescence, evidence suggests that the marijuana use patterns of friends are the most important correlate of the onset of experimentation with marijuana during the ages of 13–15 (Kandel, 1978). However, marijuana use trends frequently change with the onset of the early teenage years. In particular, a common pattern of use that arises during middle adolescence is the beginning of a transition from experimentation with marijuana to steady, regular patterns of marijuana use that will persist through middle and late adolescence, and into emerging adulthood. Depending on the user, regular, steady use, which can be referred to as "use maintenance" (Ellickson et al., 2004; Gilchrist, Gillmore, & Lohr, 1990), is something that can last from a very short period of time (eg, several months) to many years (eg, a lifetime; Windle & Wiesner, 2004).

Those who enter the maintenance stage of use during middle adolescence are very likely to have friends who also regularly use marijuana (Warr, 1993), although not necessarily in similar quantities (Kandel & Davies, 1991). Most peer groups (Fig. 20.1 for an example of a social network) during this age period have individuals embedded with them who use substances frequently, those who use occasionally, and those who do not use at all (Haynie, 2002). Stated differently, peer networks in middle adolescence generally contain people who engage in a wide range of different behaviors (Haynie, 2002). Regardless, evidence routinely suggests that the use of friends is extremely highly correlated with marijuana use maintenance during middle adolescence (Kandel & Davies, 1991).

Several authors have investigated the relationship between marijuana use and/or general drug use and friendship quality, during middle adolescence. Using emerging networks of recreational drug users (including marijuana users), Kandel and Davies (1991) explored the relationship between substance use and friends' social bonds, concluding that users were more closely tied to one another than nondrug-users. Using data on adolescents who were at high risk for criminal behavior and drug use, Krohn and Thornberry (1993) reached a similar conclusion. Additionally, the authors concluded that drug users were willing to alter their friendship networks so that they were more closely tied with peers who also used drugs (also see Giordano, Lonardo, Manning, & Longmore, 2010; Piehler & Dishion, 2007). Using the Add Health Data, this latter finding was replicated by McGloin (2009), who concluded that deviant individuals will drop friends, and select into friendships with those who behave more similarly to themselves.

Despite some significant results, other studies fail to demonstrate a relationship between marijuana use and/or general drug use and friendship quality (Giordano, Cernkovich, & Pugh, 1986). Perhaps part of the reason for this is that some studies have concluded that drug users who are in middle adolescence experience more conflict with one another than those who do not use drugs (Kandel, 1978; Krohn & Thornberry, 1993). Thus, it certainly appears that there are mixed results regarding how drug use impacts friendship quality during middle adolescence. More studies focusing specifically on marijuana, use as opposed to "general" drug use, seem necessary.

Overall, the period of middle adolescence is a time when the use of friends exerts a heavy influence on the onset and maintenance of marijuana use. This is in spite of the fact that there is substantial friendship turnover during this time (McGloin, 2009; Urberg, 1999), and mixed evidence on how friendship quality is impacted by marijuana use, and vice versa (Giordano et al., 1986; Krohn & Thornberry, 1993).

Late Adolescence

Persons are considered to be in late adolescence during the ages of 16–18 years of age (Kastenbaum, 1993). During this period of time, the peak of marijuana use

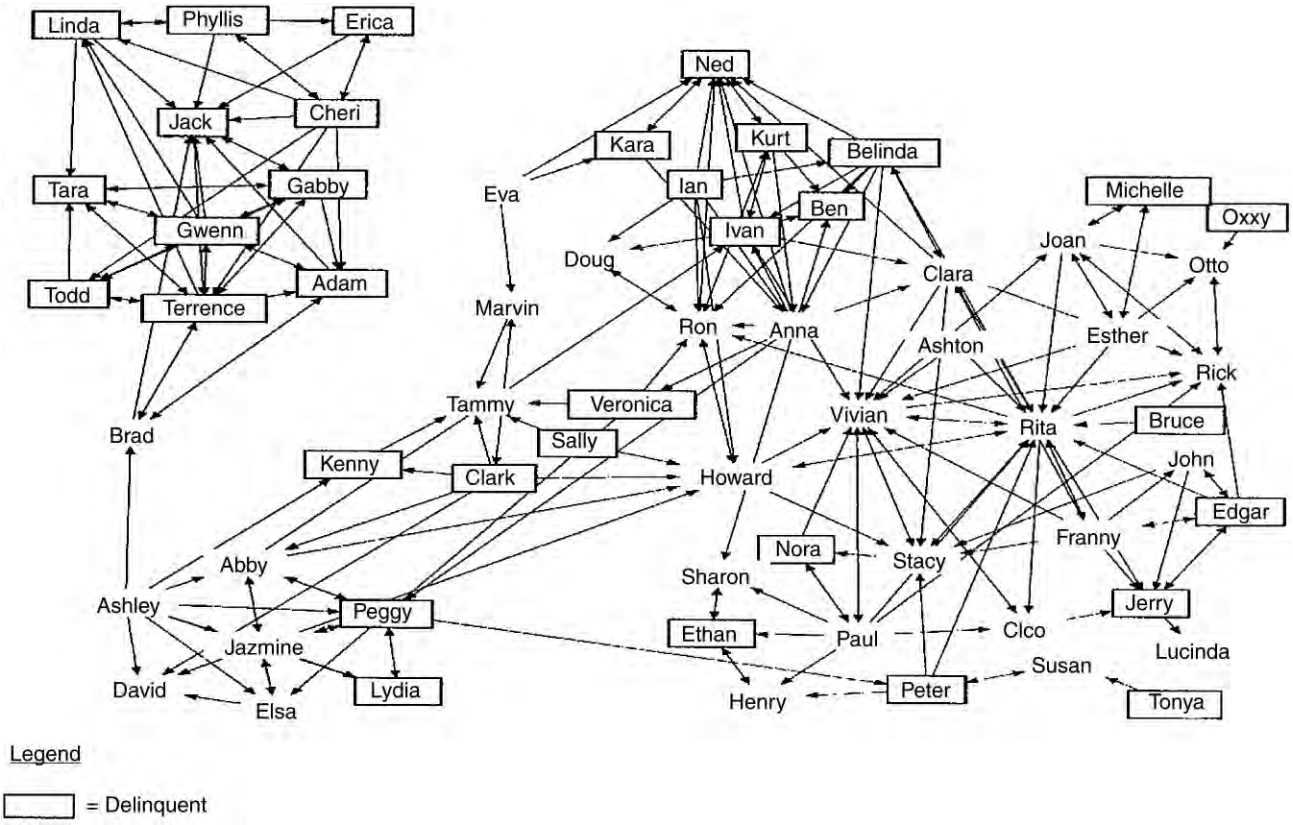

FIGURE 20.1 **An example of a social network during adolescence.** Outgoing arrows signify one nominated another as a friend. Incoming arrows mean the person was nominated as a friend by another. Double-headed arrows mean both members of the friendship nominated each other (reciprocal friendship). *Source: Taken from Haynie (2002), p. 115.*

in the overall population begins to occur, and will continue for several years into emerging adulthood (Moffitt, 1993; ONDCP, 2011; Warr, 2002).[a] Part of the reason for this is that late adolescence (17.5 years of age, in particular) is the most common time in the overall US population for people to begin experimenting with marijuana (ONDCP, 2011). Like it was in late childhood and middle adolescence, the use of marijuana is strongly influenced by the marijuana use patterns of one's friends at this time (Akers & Cochran, 1985).

Despite the marijuana use patterns of persons during late adolescence being heavily influenced by peers, the extent to which friends influence marijuana use is not getting any stronger during this time (Warr, 1998, 2002). For many people, late adolescence is the last developmental stage where peer influence is the primary social factor that relates to deviance and marijuana use (Warr, 1998).

There is mixed evidence on how friendship quality and marijuana use relate to one another in late adolescence (Giordano et al., 1986, 2010; Kandel & Davies, 1991; Piehler & Dishion, 2007). However, marijuana users in late adolescence do appear to change friendships more frequently than nonusers do (McGloin, 2009). There is ample evidence to suggest that this so called "friend shopping" is partially caused by users wanting to associate with peers who also use (McGloin, 2009). Despite this, friendship networks are still quite diverse during this time period, as the majority of them are comprised of those who do and do not use marijuana (Haynie, 2002).

Emerging Adulthood

Despite a person being considered an adult legally in the United States, and many other countries, at the time they turn 18 years old, few people at this age carry full responsibilities as an adult (eg, financial independence, full-time job, etc.). As such, developmental scholars have stressed that those who are in their late teens and early twenties cannot be fully considered adults (Arnett, 2000). Accordingly, the developmental period of emerging adulthood has been emphasized in research, and is defined as the time when a person is between 18 and 25 years of age (Arnett, 2000).

[a]Heading into the future, this age range could potentially change with the legalization movement of marijuana in the United States and other countries. We comment on this in the concluding remarks of this chapter.

In consideration of how friends affect marijuana use, emerging adulthood is the beginning of a period of great change. The reason for this is because the influence that friends exert on marijuana use dramatically decreases during this time, particularly toward a person's mid-20s (Warr, 1998). This is despite the fact that people tend to use marijuana in quite different patterns, or trajectories, during this age (Windle & Wiesner, 2004). While many persons are using marijuana steadily, others use only sporadically. Additionally, some will use solely in poly-drug contexts, some will experiment with marijuana only, and many will refrain from use entirely.

A consequence, or perhaps cause, of the decrease in peer influence during emerging adulthood is a shift in how people use marijuana that increases especially quickly as people reach their mid-20s. During the previous developmental stages of middle and late adolescence, an extremely common way for marijuana to be used was in a peer group where two or more people jointly use marijuana (Kandel, 1978; Kandel & Davies, 1991). During emerging adulthood, and particularly its latter years, there is a sharp decrease in co-use of marijuana with friends (Kandel & Davies, 1991; Warr, 1998).

Despite a drop in peer group-based usage during emerging adulthood, there is some evidence that suggests that friendship quality may be aided by marijuana use during this time. Using dyadic friendship data, Boman, Stogner, and Miller (2013) found that individuals who are in friendships in which both persons use marijuana have very high quality friendships. However, despite having higher overall quality friendships than nonusers, these individuals also experienced more conflict with one another. The latter finding is similar to other studies using general measures of substance use in adolescent samples, perhaps indicating some extent of cross generalizability across substances, and different developmental periods (Hawkins & Fraser, 1985; Kandel & Davies, 1991; Krohn & Thornberry, 1993; also refer to Haynie, 2001, 2002; McGloin, 2009 for some generalizations about deviance, peer networks, and network balance).

In sum, the amount to which marijuana use is affected by the use patterns of friends is rapidly decreasing during emerging adulthood. Users instead are becoming more independent, and use frequently occurs without some form of peer influence. However, persons who continue to use with friends tend to experience very high quality friendships, although the occasional conflictual encounter may occur.

Early Adulthood, Middle Adulthood, and Beyond

As people transition to the mid-to-late 20s, 30s, and into their 40s, the same trend that was observed during emerging adulthood is continuing, but to a greater extent. During these developmental stages, research suggests that persons who use marijuana do so for reasons that are not peer related (Warr, 1998; Nagin & Tremblay, 2005).

That is, the use of peers does not seem to contribute substantially to a person's decisions to use marijuana during their late 20s, 30s, 40s, or 50s. Despite this, individuals do still tend to use marijuana with some frequency (Fig. 20.2).

The reasons for the lack of a significant peer effect during adulthood are numerous. A major reason is that most peoples' focus shifts to nonpeer-based activities, such as, employment, finances, child rearing, and family (Warr, 1998). Additionally, adults have less free time than

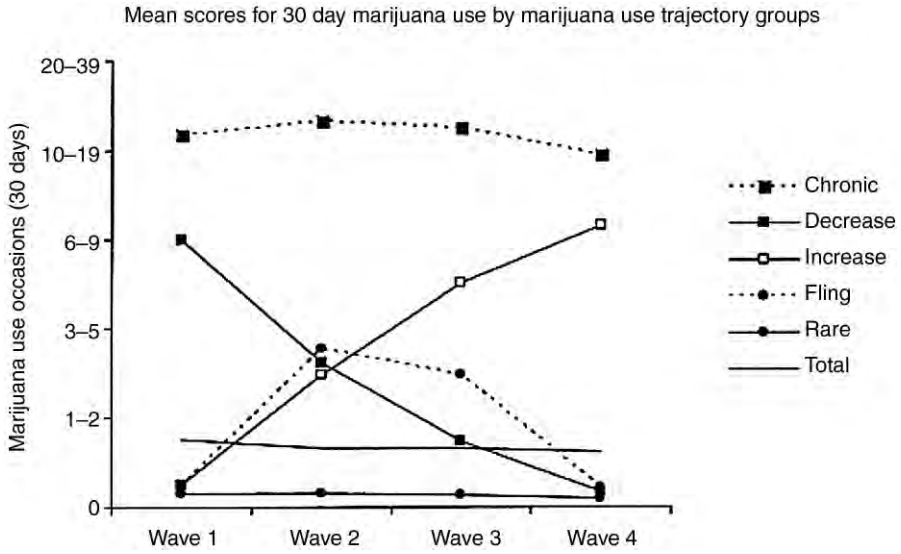

FIGURE 20.2 **Trajectories of marijuana use for those in early adulthood (ages 18–24).** *Source: Taken from Schulenberg et al. (2005), p. 263.*

Individual characteristics	Intervention	Short-term outcomes	Outcomes
Risk and need factors	Treatment, judicial oversight, intensive supervision, drug testing	Program completion, clean drug tests, employment and educational attainment	Sobriety, reduced criminality, improved social function

FIGURE 20.3 **The American drug court model which was originally developed in Dade County, Florida, United States.**

those in adolescence and emerging adulthood, meaning that finding time to gather groups of friends together for marijuana use is considerably more difficult than it was during earlier developmental stages.

Despite the peer effect dissolving during adulthood, there is some research that suggests that a resurgence in the importance of peer behavior may occur. Studying senior citizens, Akers, La Greca, Cochran, and Sellers (1989) found that the alcohol consumption patterns of same-age friends reemerge as strong and significant correlates of one's own alcohol use. Unlike those who are raising children, retirees experience a strong drop in responsibilities, and have much more discretion in how they spend their abundance of free time. Although alcohol is a much different intoxicant than marijuana, its perception as a "social drug" may suggest that this finding could cross-generalize in future research. This may be especially true, considering that many regions of the world are relaxing legislation regarding the use and sales of marijuana.

AMERICAN COURT RESPONSES TO SHARED USE

As we have discussed, marijuana is a social drug that most frequently is initiated and continued by the marijuana use patterns of one's friends. One important attempt to legally address the issue of marijuana and other drug use among friends began with some overworked professionals in Dade County, Florida, United States. These professionals came together from applied legal, criminal justice, and substance abuse treatment backgrounds, with the goal of solving the difficult issue of repeat offenders with substance abuse problems clogging the criminal justice system. The group determined that a possible solution to these problems would be a complex model linking the authority of the court, and the supervision and drug testing services provided by probation, with substance abuse treatment. This program has since become known as the "drug court model" (Fig. 20.3).

As part of the drug court program (Fig. 20.4), one of the most important elements of the drug court model relates to probation conditions that are enforced through frequent judicial contact. A commonly used condition is called the "nonassociation order." This order is frequently given to substance users who are caught by the police, and have been known to associate with other users. In essence, the nonassociation order is a court-mandated condition of probation that states that a marijuana (or other drug) user may have no contact with his/her friends who are known to also use illicit substances.

While all the courts and service agencies had worked together prior to the creation of the drug court model, its implementation called for a higher and more formalized level of cooperation. The model worked, and has continued to work, and more than 2400 programs across

Referral process	Program admission	Program activities	Graduation requirements
County attorney, judges, defense bar, law enforcement sources	Legal criteria	Intensive supervision	Completion of probation requirements
Referred for review	Substance abuse criteria/assessment	Random drug testing	Clean and sober living
Team decision to begin admission process	Community safety criteria	Intensive substance abuse treatment	Employment or educational goals
–	Participant agreement	Weekly court appearances supporting behavioral model	Stable living arrangement

FIGURE 20.4 **The program agenda for the drug court model.**

the United States and globally have been started using this model, in a way in which its core has been changed very little (Huddleston, Marlowe, & Casebolt, 2008). The drug court model has revolutionized the system of justice for many substance abusing and addicted offenders.

The intuitive appeal of the drug court model is obvious to those who work in the American Criminal Justice System. It makes sense that the authority of the court should be brought to bear on the daily activities of substance abusing offenders. The drug court model has brought effectiveness to substance abuse treatment, filling in where other historical programs—which have very low levels of retention for users—have failed (Stark, 1992).

To provide just one example of a failing treatment program, the extent to which probation services and incarceration are ineffective at changing substance abusing behaviors is well documented. The United States has been on a prison building binge that has one in every 134 residents of the United States incarcerated at midyear 2009 (West, 2009), despite reduced levels of offending in nearly every category of crime. Of these prisoners, over half report substance abuse or dependence, at the time of incarceration (Mumola & Karberg, 2004). The drug court model was designed with the goals of keeping offenders in community-based treatment, thus reducing the need for incarceration. And, after 25+ years of operation, the empirical evidence supporting the drug court model goes well beyond the initial intuitive appeal. There is a strong body of scientific research that supports the use of drug courts, as opposed to traditional criminal justice mechanisms with substance abusing offenders (Huddleston et al., 2008).

Though drug courts are tasked with controlling substance abuse generally, they have placed a considerable amount of effort into combating marijuana use, specifically. The United States' National Association of Drug Court Professionals has taken a hard line stance against marijuana use, claiming that marijuana has a negative impact on the brain, and addictive properties (NADCP Board of Directors, 2012). And, drug courts have proven to reduce marijuana use among participants, as well as those who graduate from the program (Bureau of Justice Assistance, 2010). While the intensity of the treatment model is too much for some, drug court professionals believe the drug court model has positively impacted the lives of many marijuana users, by reducing or eliminating their use of marijuana (Huddleston & Marlowe, 2011).

FUTURE DIRECTIONS OF RESEARCH AND CONCLUSIONS

Friends, and especially the marijuana use patterns of friends, exert a substantial impact on an individual's marijuana use during late childhood, adolescence, and emerging adulthood. Around the time a person enters their mid to late 20s, friend influence wanes, and those who continue to use marijuana do so for reasons other than having friends who use.

With the implementation of the drug court model and nonassociation orders, American courts have acknowledged that peers do matter for marijuana use. However, considering the increasingly dubious legal status of marijuana in the United States, the US court system finds itself at somewhat of an impasse. Several states in the United States have legalized, or have referendums that propose to legalize, marijuana. This means that marijuana can be purchased legally, and taxed, in these jurisdictions.

Given the recent push for legalization in the United States, the current state of knowledge on how friends influence marijuana could certainly change, and for a number of reasons. To provide one possibility, marijuana legalization could lead to a wider audience using the substance, since it is now legal and extremely easy to obtain (see the study by Lynne-Landsman, Livingston, & Wagenaar, 2007 on how medical marijuana legislation in the United States has changed adolescent marijuana use patterns). This may change the contexts and patterns of how people use marijuana, thus potentially altering what we know about how friends influence marijuana use. There are a number of possibilities as to what could happen. One potential implication could be that shared use becomes more common for adults, and especially for those who have some level of expendable income, and free time. If this were the case, group-based usage of marijuana could become as common among adults as it currently is for adolescents. This could mean an emergence of a significant friend effect for those who would have otherwise "aged out" of the developmental periods traditionally associated with friend influence. This could potentially also occur in a cohort effect, where adolescents who grew up regularly using marijuana continue to use in a manner where peers still influence marijuana use patterns at adult ages. Other possibilities exist too, though it is difficult to speculate on what they may be, given the absence of empirical data at the time this chapter was written.

This discussion points to perhaps the main future direction of necessary research on marijuana and friends. As marijuana becomes increasingly legally available across the United States, and other worldwide jurisdictions, what will happen to the marijuana use patterns of people of different ages? We already know that people tend to follow different trajectories of marijuana use (Windle & Wiesner, 2004), but will these trajectories—and the reasons that people follow them—change? To further complicate matters, any change in how friends impact marijuana use could depend on the actions of worldwide governments in the upcoming years.

One way or the other, research needs to focus specifically on peer relationships and marijuana use during this transition. Further, we stress the necessity for research to focus solely on marijuana. Much of the literature we have reviewed is on "drug use" or "offending" generally, and not specific to cannabis. As marijuana legislation changes, researchers must focus specifically on how marijuana affects friendships, and how these friendships in turn impact marijuana use.

Regardless of what is to come with the state of marijuana legislation in the United States, another area of research that is needed is the exploration of how friends affect marijuana use (or if they do) among elderly populations. The fact that peer influence may reemerge as a significant correlate of alcohol use among the retired (Akers et al., 1989) begs the question if this is also the case with marijuana.

Further, it would be useful to explore how friendship quality affects, and/or is affected by, marijuana use generally, but especially during the adult years. With younger populations, the two most common findings are (1) marijuana use does not affect friendship quality, or (2) improves it, but leads to conflict. The equivocal findings may in part be due to the lack of stability that friendships have in adolescence, compared to adulthood (McGloin, 2009).

In conclusion, the future of our understanding on how friends influence marijuana use could change substantially, heading into the near future. Regardless, there is enough research (Pratt et al., 2010) to suggest that the peer effect that exists during late childhood, adolescence, and emerging adulthood will not dissipate, despite what happens with legislation. Succinctly, friends are too important in causing experimentation with, and continuation of, marijuana use at a variety of ages for the effect to completely dissolve just because of legislative reasons.

MINI-DICTIONARY

Differential association An extensively supported theory of crime developed by Edwin Sutherland in the 1930s and 1940s. It generally hypothesizes that a person can be pulled in and out of crime and substance use by the definitions they develop from the extent to which their peers are involved in crime and substance use.

Drug court An American-based model that was designed to remove drug offenders from the criminal justice system, and place them in a court which only deals with drug offenses.

Friend A person with whom a target individual shares close, interpersonal ties. Peers can be friends, but not all peers are friends. Friends are perceptual; that is, if the target individual perceives they are friends with another, that other person is a friend in the mind of the target individual. Thus, the other person does not have to reciprocate the friendship label.

Friend influence Generally, also known as peer influence. The extent to which friends exert a behavioral, social, or emotional impact on a target individual.

Nonassociation order An American court order that states a target individual may not spend time with another person; the other person is generally a known substance user.

Peer A person who is similarly situated to a target individual in terms of age and social status. Not necessarily a friend, although we use the terms friend and peer interchangeably to avoid monotony.

Peer group Also known as a friendship group, or friend group. A subset of a person's social network consisting of individuals with whom he/she perceives affectionate ties, and considers a friend. Peer groups are generally smaller than social networks, though they can still be quite sizable.

Shared marijuana use Also known as co-use. The situation when a target individual engages in marijuana use in the presence of at least one other person who is also using marijuana.

Social network A person's entire group of peers with whom he/she spends time. Persons in the peer network do not need to be identified as friends. Generally consists of many individuals, especially during the time when adolescents are enrolled in school.

CHAPTER

21

Students' Knowledge of Cannabis

M. Drozd, J. Sobczyński

Department of Pharmaceutics, Medical University of Lublin, Lublin, Poland

SUMMARY POINTS

- The chapter focuses on cannabis-related knowledge among students (adolescents and young adults), as well as the role of knowledge in recreational and medical cannabis use.
- Students with broader and more nuanced knowledge on cannabis are less likely to use it, which is a basis for including cannabis-related knowledge in school prevention programs and university courses.
- Successful school-based drug prevention comprises of repeated courses that aim to present the key facts on cannabis health effects, address the issue of peer pressure, and develop the refusal skills.
- Internet, media, and friends are the most popular sources of information that students approach when seeking information on illicit drugs.
- University students know of positive, medically useful cannabis effect on human health, but don't know of specific cannabis uses in medicine.
- Evaluation of cannabis-related knowledge among nonhealth professionals may help to develop better patient education programs in order to address misconceptions on medical cannabis and, consequently, improve medication adherence.

KEY FACTS ON CANNABIS USE AMONG ADOLESCENTS AND YOUNG ADULTS

- It was estimated that 14.6 million (11.2 % of European young adults aged 15–34) used cannabis in 2013.
- Regular cannabis use in adolescence adversely affects mental health in young adults, increasing risk of psychotic disorders and symptoms.
- Adolescent regular cannabis users are more likely to use other illicit substances as compared to nonusers, and they may also experience decreased cognitive functions.

KEY FACTS ON MEDICAL CANNABIS AND CANNABINOIDS

- Cannabis has been used to treat diseases and alleviate their symptoms since antiquity, and is now approved for medical use in some American states.
- Sativex, Cemet and Marinol are cannabinoid-based medication registered for use by patients suffering from certain chronic diseases and cancer, in Europe and the United States.

KEY FACTS ON MEDICATION COMPLIANCE

- While around 20–30% of patients don't adhere to medication regimens that aim to cure diseases or relieve symptoms, 30–40% fail to follow regimens designed to prevent health problems, and 50% do not comply with long-term medication regimens.
- In 2001, it was estimated that poor adherence generates annual approximate direct and indirect health-care costs of $177 billion, in the United States.

NIDA	National Institute of Drug Abuse
THC	Tetrahydrocannabinol

INTRODUCTION

Cannabis has been widely used for recreational purposes, especially in the last 50 years. Cannabis use among adolescents and young adults gained particular scientific interest since, together with alcohol, it is the most popular psychoactive agents among youth (see the Key facts on cannabis use among adolescents and young adults; Hall & Degenhardt, 2009). Previous reports showed that cannabis use among students is associated with lower educational attainment, low religiosity, adverse life events, and increased reported use of illicit drugs other than cannabis (Engs & Mullen, 1999; Pacula et al., 2000). Moreover, low socioeconomic status in childhood, as well as various intrapersonal variables, were associated with higher cannabis use prevalence (von Sydow, Lieb, Pfister, Höfler, & Wittchen, 2002). The research identified a group of adolescents that are more likely to use cannabis in the future (vulnerable nonusers; Crano, Siegel, Alvaro, Lac, & Hemovich, 2008) that should primarily be addressed by drug prevention programs. The reader is referred to a comprehensive review, where the influence of a number of various factors on cannabis use is described (Macleod et al., 2004). However, the level of cannabis-related knowledge among students, and its impact on cannabis use prevalence and patterns of use, has rarely been studied. Geramian, Akhavan, Gharaat, Tehrani, and Farajzadegan, 2012 analyzed knowledge of cannabis and other psychoactive agents among 6998 Iranian students (aged 14–18), from both urban and rural areas (Geramian et al., 2012). They found that female students had higher knowledge on health consequences of drug use. Heckman, Dykstra, and Collins, 2011 evaluated cannabis-related knowledge as a means to assess the efficacy of a "drugs and behavior" university course (Heckman et al., 2011). Newton, Teesson, Vogl, and Andrews (2010) measured cannabis-related knowledge using a 16-questions quiz in order to determine the level of knowledge before and after students' participation in a cannabis and alcohol school prevention program (Newton et al., 2010). However, there does not seem to be one universal scale, test, or quiz to properly evaluate the level of knowledge, so each study yields results that cannot be compared.

Apart of their psychoactive properties, the active ingredients of cannabis are reported to possess a distinct pharmacological effect on the human body (see the Key facts on medical cannabis and cannabinoids; Leung, 2011; Borgelt, Franson, Nussbaum, & Wang, 2013). Medical cannabis use is approved in certain American states as a treatment modality for patients suffering from, for example, cancer, glaucoma, multiple sclerosis (MS), chronic pain, Crohn disease, Alzheimer disease, Parkinson disease (Marcoux, Larrat, & Vogenberg, 2013). As the cannabinoid administration in form of smoked herb may have negative impact on the respiratory tract, several pharmaceutical cannabinoid preparations have been developed (Machado Rocha, Stefano, De Cassia Haiek, Rosa Oliveira, & Da Silveira, 2008). While nabilone (Cesamet) is utilized in the United States to control chemotherapy-induced vomiting and nausea, in patients suffering from cancer, dronabinol (Marinol) is used for the same indications by Acquired Immunodeficiency Syndrome (AIDS) patients. Nabiximols (distributed in several European countries, Canada, and New Zealand under its brand name Sativex) is employed to relieve the symptoms of MS, for example, neuropathic pain, spasticity, and overactive bladder (Sativex, 2014). However, the use of cannabinoids is still not widely recognized in medicine, and does not correspond to their therapeutic potential. Previous studies aimed to assess cannabis-related knowledge and attitudes among health-care professionals, as it influences prescribing registered cannabis products, admission into medical cannabis programs, and affects patient care in hospice settings (Charuvastra, Friedmann, & Stein, 2005; Kondrad & Reid, 2013; Uritsky, McPherson, & Pradel, 2011). However, knowledge, attitude, and perception of medical cannabis has not been thoroughly evaluated among the general public. The only study exploring this topic is the work of Taylor (1972), and our recent paper (Sobczyński et al., 2013). Taylor (1972) examined the risk perception and attitude toward cannabis' legal status among 372 Canadian freshmen students. It was found that while the views on legal status were not affected by the responder's gender, women were more likely to recognize the risk associated with cannabis use.

CANNABIS-RELATED KNOWLEDGE, ATTITUDE, AND RISK PERCEPTION IN THE CONTEXT OF RECREATIONAL USE

It has been found that adolescents who reported higher levels of parental monitoring and control were less likely to be past or current cannabis users (Ramirez et al., 2004). However, as the influence of parental control and supervision is expected to dwindle with the student's age, high-school students are more likely to be

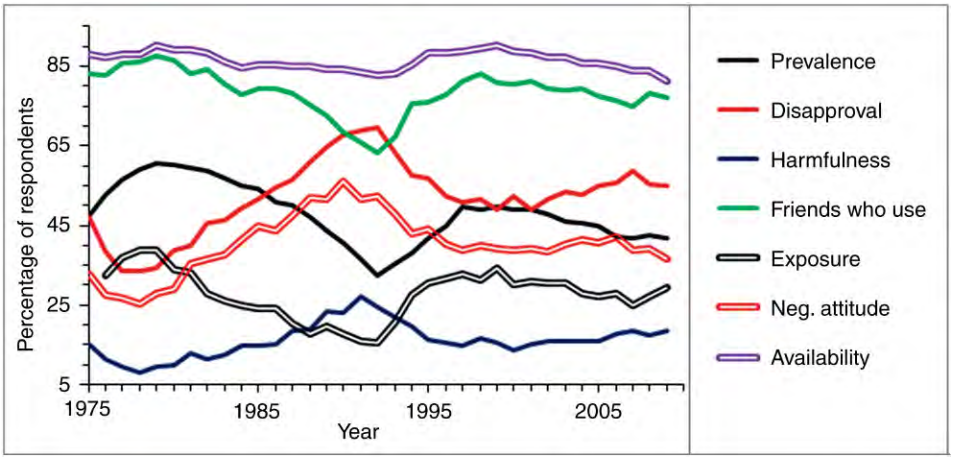

FIGURE 21.1 **Cannabis use and views.** Trends among American students in the period 1975–2009. Self-reported cannabis use, attitude, perception of risk, and exposure among American 12th graders (aged 17–18). *Availability*, percentage of respondents who considered cannabis "very easy" or "fairly easy" to get if desired; *Disapproval*, percentage of respondents who answered positively when asked: "Do you disapprove of people (≥ 18 years old) trying marijuana once or twice?;" *Exposure*, percentage of respondents who have often been around people taking cannabis during last 12 months; *Friends who use*, percentage given by respondents, when asked: "How many of your friends smoke marijuana?;" *Harmfulness*, percentage of respondents who considered that use of marijuana (once or twice) is associated with great risk; *Negative attitude*, percentage of respondents who answered positively when asked: "Do you think that people (≥ 18 years old) should be prohibited by law from smoking marijuana in private?;" *Prevalence*, self-reported lifetime use of cannabis. *Source: Based on the report of Johnston et al., 2010.*

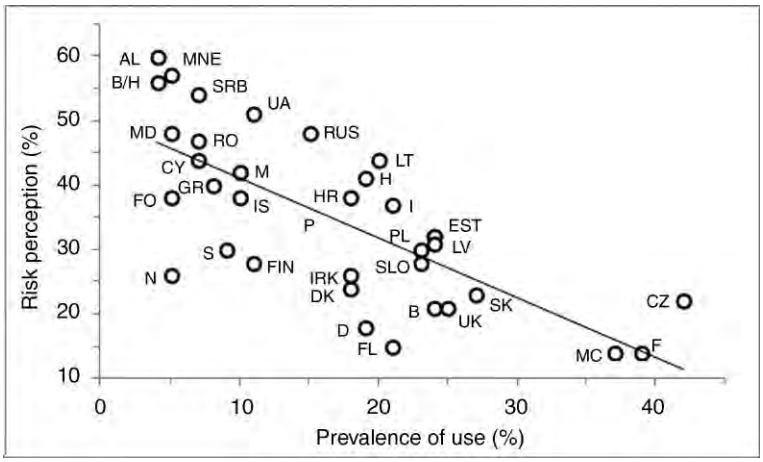

FIGURE 21.2 **The relationship between self-reported cannabis use prevalence and risk perception among European students.** Correlation between self-reported lifetime use of cannabis and the percentage of students (aged 15–16, n = 100,000) answering that use of cannabis (once or twice) is associated with great risk. A trend line was implemented using Microsoft Office Excel 2007 (correlation coefficient = 0.73). *AL*, Albania; *B*, Belgium; *B/H*, Bosnia and Herzegovina; *BG*, Bulgaria; *C*, Croatia; *CY*, Cyprus; *CZ*, Czech Republic; *D*, Germany; *DK*, Denmark; *EST*, Estonia; *F*, France; *FIN*, Finland; *FL*, Liechtenstein; *FO*, Faroe Islands; *GR*, Greece; *H*, Hungary; *IS*, Iceland; *IRL*, Ireland; *I*, Italy; *LV*, Latvia; *LT*, Lithuania; *M*, Malta; *MD*, Moldova; *MC*, Monaco; *MNE*, Montenegro; *N*, Norway; *PL*, Poland; *P*, Portugal; *RO*, Romania; *RUS*, Russian Federation (Moscow); *SRB*, Serbia; *SK*, Slovak Republic; *SLO*, Slovenia; *S*, Sweden; *UA*, Ukraine; *UK*, United Kingdom. *Source: Based on the report of Hibell et al., 2012.*

influenced by their closest friends and classmates, as previously reported (Iannotti & Bush, 1992; Lewis & Clemens, 2008). The National Institute of Drug Abuse (NIDA) study envisaged the impact of social norms among young adults on self-reported cannabis use (Johnston, O'Malley, Bachman, & Schulenberg, 2010). Cannabis use among students was elevated when the perception of exposure and cannabis consumption by friends was high (Fig. 21.1). A similar trend was observed in Europe, in a survey performed under the auspices of the European School Survey Project on Alcohol and Other Drugs (ESPAD; Hibell et al., 2012), showing a clear negative correlation between perception of risk associated with cannabis use, and self-reported use prevalence was reported (Fig. 21.2). The Eurobarometer telephone-based survey showed that the health risk associated with cannabis use was lower among young people who have previously used cannabis (one or two times; 52 % listed medium or high risk), as compared to those that never used it (94% listed medium or high risk), as similar to NIDA

and ESPAD studies (Eurobarometer, 2008). While 91% of respondents recognized the health risk associated with regular cannabis use, only 30% of study participants claimed that incidental use of cannabis posed a medium or high risk. As similar to the ESPAD report, the Eurobarometer study showed significant differences in risk perception among young people from different EU member states, arising from differences in social norms in countries more favorable to cannabis use (eg, Denmark, Netherlands, or Czech Republic), as compared to others, where even incidental cannabis use is considered harmful (eg, Cyprus and Romania). In contrary to the NIDA study, the ESPAD and Eurobarometer reports showed a positive correlation between perceived low availability and perceived high risk of cannabis use.

Ramirez et al. (2004) interviewed a group of 1094 American fourth-through 12th-grade students (Anglo Americans and Hispanic Americans), and distinguished a group of adolescents who were less likely to use cannabis. They exhibited stronger bonds with parents, and had more profound cannabis-related knowledge (presumably gained from relatives). Seeking cannabis-related knowledge from friends, especially the ones being regular cannabis users, may encourage cannabis consumption (Figs. 21.1, 21.2), as the risk perception among users is generally lower than among nonusers (Danseco, Kingery, & Coggeshall, 1999). Moreover, more frequent users considered frequent use (ie, ≥2–3 times per week) to be less harmful than nonfrequent users (O'Callaghan, Reid, & Copeland, 2006). It has also been found that even these users that are aware of cannabis risk were more likely to recognize psychological problems (30.3%; concerning, for example, concentration, memory, motivation), followed by physical and general health issues (21.5%; eg, respiratory problems, cancer, impotency), rather than legal and life issues. However, the serious social personal consequences (eg, impaired performance at university or work, and problems with relationships) were listed only when interviewees were prompted, and some issues like addiction were given more emphasis (O'Callaghan et al., 2006).

Taking into consideration the conflicting influence of parents, friends, teachers, etc. on cannabis use among students, it is important to determine the possible sources of knowledge that young people consult when seeking information on cannabis. Eurobarometer responders listed the same potential sources of information on illicit drugs, in various countries (the three most popular answers were identical), and obtained information from similar sources in the period of the previous year (Fig. 21.3). As the results showed that internet is an important source of knowledge for students (and it is becoming even more significant, as compared to previous Eurobarometer results from 2008), internet-based prevention measures may be useful in educating young people on cannabis. While adolescents were more likely to be informed on illicit drugs by school prevention programs (63%), young adults (aged 22–24) obtained information from media campaigns (54%). Whereas school campaigns showed to be an important measure in forging the students' perception of drugs, many students, especially those that tried cannabis, turned to friends.

CANNABIS-RELATED KNOWLEDGE IN THE CONTEXT OF SUBSTANCE USE PREVENTION PROGRAMS

As mentioned in the previous section, media campaigns and school-based drug prevention programs are important sources of cannabis-related knowledge for students. Different approaches have been utilized in order to address the risk factors that lead to cannabis use, on the individual adolescent's level (summarized in Fig. 21.4). Skill-based programs aim to develop resistance skills and assertiveness, among sensation-seekers, addressing, for example, stress management, communication, decision-making, and goal-setting abilities. The knowledge-centered programs will provide students with information in order to make better choices. Programs offer information on consequences of cannabis use, effects of cannabis products on the individual's health and behavior, especially in the context of polydrug use. The goal of giving a thorough description of psychological drug action is to build a negative attitude toward drugs and, consequently, decrease their use. The discussion of drugs' addictive potential and outcomes of developing an addiction may be used to dissuade students from using cannabis. Knowledge-based programs also affect students' perception of cannabis use, as the difference between perceived and real prevalence of drug use, in the context of peer pressure, is explained. It has been shown that perception of cannabis use prevalence among peers is overestimated (McCabe, 2008; Franca, Dautzenberg, Falissard, & Reynaud, 2010; Wolfson, 2000). As students that have a false impression that cannabis is very popular among the youth may be more likely to try it (see the previous section), presenting the statistics of drug use may help to clear up this misconception. Providing information on different cannabis products (eg, their potency, short- and long-term health risks), as well as the legal and financial consequences of drug use, may also discourage drug use among adolescents and young adults. Finally, the positive attitude to nonuse is enhanced by presenting alternatives to drug use in regard to situations when adolescents would typically use cannabis (Fig. 21.4). The latter approach is mostly addressed to young people taking drugs as a way to deal with bad mood, or personal problems.

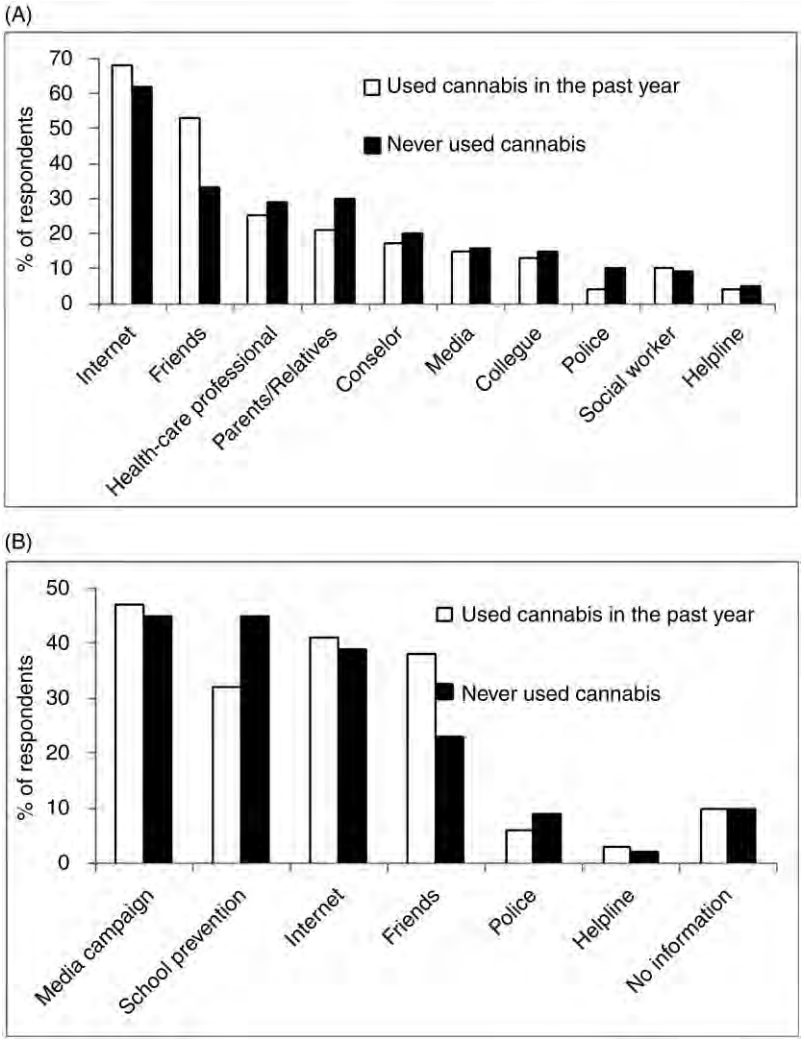

FIGURE 21.3 Sources of information on illicit drugs, reported by European young people. Potential sources of information about illicit drugs and drug use, reported by students (aged 15–24, $n = 12{,}315$) who never used cannabis and students who used cannabis at least once in the last year. A and B present answers for following questions: *A*, "If you wanted to have information about illicit drugs and drug use in general, who would you turn to?;" *B*, "Through which channels, have you been informed over the past year about the effects and risks of the use of illicit drugs?." *Source: Based on data from Eurobarometer (2011).*

It has been found that skill-base programs are somehow more efficient in discouraging drug use (Faggiano et al., 2005). However, the increased knowledge can help some students to understand the link between drug action and its harmful effect. As many factors presented in Fig. 21.4 are intertwined, the most efficient programs will integrate knowledge elements, and develop useful interpersonal skills (Coggans, 2006). There is an ongoing discussion regarding the content, as well as delivery measures, of the ideal substance use prevention program. The reader is referred to a review of school prevention programs and guidelines by Sloboda (2008). Evaluation of students' cannabis-related knowledge may be useful in the development of knowledge-based prevention programs and university courses tailor-made for a group of students, considering their socio-demographic characteristics. It may show, for example, where the gaps in education are, envisage students' understanding of the delivered content, or evaluate how much basic knowledge courses should include. Some elements that were found to play crucial role in respect to the efficacy of drug prevention programs are summarized in Fig. 21.5. An example of a drug prevention course can be found in paper by Newton et al. (2010). As similar to the development of school-oriented programs, reports concerning students' knowledge may serve as a basis for establishing and improving education tools for specialized drug counselors and health professionals, as well as internet-based drug prevention programs and media campaigns (Derzon & Lipsey, 2001; Tossman & Leuschner, 2009).

CANNABIS-RELATED KNOWLEDGE AND ATTITUDES IN THE CONTEXT OF MEDICAL USE OF CANNABIS

Since more cannabinoid-based pharmaceutical products are expected to be developed, it's interesting to look at one of the issues that has significant impact on the drugs' clinical treatment outcomes (ie, treatment efficacy and safety), namely the medication compliance (see the Key facts on medication compliance; PGEU, 2008). Medication compliance is defined as the extent to which a patient correctly follows medical advice (eg, treatment regimen, lifestyle tips, advice concerning disease management). Causes of low medication compliance include: socioeconomic factors (eg, age, economic status, treatment cost), patient-related factors (eg, forgetfulness, misunderstood instructions, treatment anxiety, fear of developing dependence on medication), drug-related factors (eg, length and complexity of treatment, adverse reactions (ADRs—see the Mini-dictionary), as well as specific, condition-related factors (Vermeire, Hearnshaw, Van Royen, & Denekens, 2001). Some problems hindering the therapeutic use of cannabis and cannabinoids (eg, patient substituting pharmaceutical cannabinoid dosage forms with a cannabis product) were mentioned by Grinspoon (2001). Moreover, patients with a history of substance use may try to induce a euphoric effect by exceeding the therapeutic dose, or polydrug use (Grant, Atkinson, Gouaux, & Wilsey, 2012). Finally, patients may undergo drug tests at their workplace, which aim to identify persons involved in illicit substance use. However, tests would not discriminate between recreational and medical cannabis use (Neavyn, Blohm, Babu, & Bird, 2014).

In order to initiate the treatment, patients must believe that (1) they suffer from the disease, (2) the disease will most likely negatively impact their wellbeing, and (3)

the severity or threat of the disease will be diminished or abolished, considering they follow health recommendations. There are many concerns and misconceptions arising from patients' inadequate knowledge on cannabis that are expected to affect medication compliance negatively. Firstly, patients may be concerned about becoming dependent on their medication, in the long run, due to the addictive potential of tetrahydrocannabinol (THC). This has previously been observed for methylphenidate, a remedy for attention-deficit hyperactivity disorder (Berger, Dor, Nevo, & Goldzweig, 2008). Secondly, patients may be worried about other ADRs associated with cannabinoids, especially when the treatment of an off-label indication is considered (Wang, Collet, Shapiro, & Ware, 2008). THC-induced intoxication and euphoria, as well as other nervous system disorders, may be particularly annoying in elderly patients (Grant et al., 2012). The most frequently reported ADRs of Sativex, that is, drowsiness, dizziness, and fatigue, have already been identified as a reason for low medication compliance in the treatment of muscle spasms with baclofen (Halpern, Gillard, Graham, Varon, & Zorowitz, 2013; Sativex, 2014). Ware, Doyle, Woods, Lynch, and Clark (2003) surveyed almost 3000 patients using medical cannabis. Out of 403 patients that discontinued the treatment, 60 reported euphoria or other ADRs as a reason for discontinuing medicinal cannabis. Moreover, cannabinoids may interact with other drugs taken by patients (eg, antidepressants, neuroleptic and analgesic agents), leading to ADR potentiation (Seamon, Fass, Maniscalco-Feichtl, & Abu-Shraie, 2007).

When faced with a necessity of adhering to a treatment regimen, patients confront the health-care professional's advice with their own set of beliefs (Vermeire et al., 2001). The proposed therapeutic schedule is confronted with perceived group and social norms, as well as the perceived social consequences regarding the behavior and its acceptability (van Dulmen et al., 2007). The opinion of patients' family and friends will influence the medication compliance in the form of negative or positive social influence. Social support to medication compliance includes increased motivation, confidence, and internalization of social norms that promote healthy choices. A nonsupportive social influence can interfere with beneficial health behavior, and discourage following the medication regimen (DiMatteo, 2004). We hypothesize that if the patient has low cannabis-related knowledge, perceives cannabis as a dangerous substance with detrimental effect on human health, and associates it primarily with drug abuse, he or she will be reluctant to initiate and follow treatment with cannabinoids. Considering the perceived risk of using given medication is high, patients would try to minimize the possible damage. Patients may postpone the treatment initiation, cease to follow the medication regimen (eg, reduce the dose or frequency), or stop using a drug. Chong et al. (2006) have previously surveyed 254 MS patients using medical cannabis (Chong et al., 2006). One-quarter of respondents expressed concerns on possible social stigma (25%), a percentage being comparable with patients who were worried by becoming dependent (31%), or suffering from drug-drug interactions (27%).

The issue of nonadherence should be addressed early on (by, for example, patient education), when introducing treatment with medical cannabis or synthetic cannabinoids, as pointed out by Grant et al. (2012) . Education programs aim to increase patient compliance, promote healthy choices, change disease and treatment perception, and improve disease management (van Dulmen et al., 2007). Evaluation of students' cannabis-related knowledge and attitude may be used to analyze the expected knowledge of a nonmedical professional, in order to build up pharmaceutical care education and counseling. It will also serve as a background for studies concerning cannabinoid medication compliance, and predicting the compliance pattern in a given country. In this regard, several issues can be addressed when developing a survey. Firstly, the level of both basic knowledge on cannabis and knowledge on specific cannabis uses, as well as sources of knowledge on cannabis, should be studied. Moreover, the knowledge on side effects and risk perception, as well as attitude toward medical cannabis, should be evaluated. Currently, there is a limited number of such reports.

Our web-based study attempted to assess the level of university students' knowledge concerning positive and negative effects of cannabis on human health, as well as sources of knowledge on cannabis (Sobczyński et al., 2013). Although respondents knew about the possible medical use of cannabis, and recognized the potentially useful impact of cannabis on human health, they were more likely to associate cannabis with its psychoactive rather than therapeutic use (Fig. 21.6). While around 40% of respondents knew that cannabis could be used by patients suffering from cancer or MS, students didn't know of registered pharmaceutical cannabinoids, probably due to lack of registered cannabis products in Polish pharmacies in 2011. There was a distinct difference in knowledge on cannabis and cannabis perception, depending on the respondents' gender (Fig. 21.6). Women were more likely to recognize the health risk associated with cannabis use, as similar to previous reports (Taylor, 1972). Men listed more different sources of cannabis-related knowledge, and were more likely to list textbooks and personal experience with cannabis. More men than women recognized the medical use of cannabis, and knew the term "medical marijuana." In a follow-up study, performed in 2014, we surveyed another sample of university students

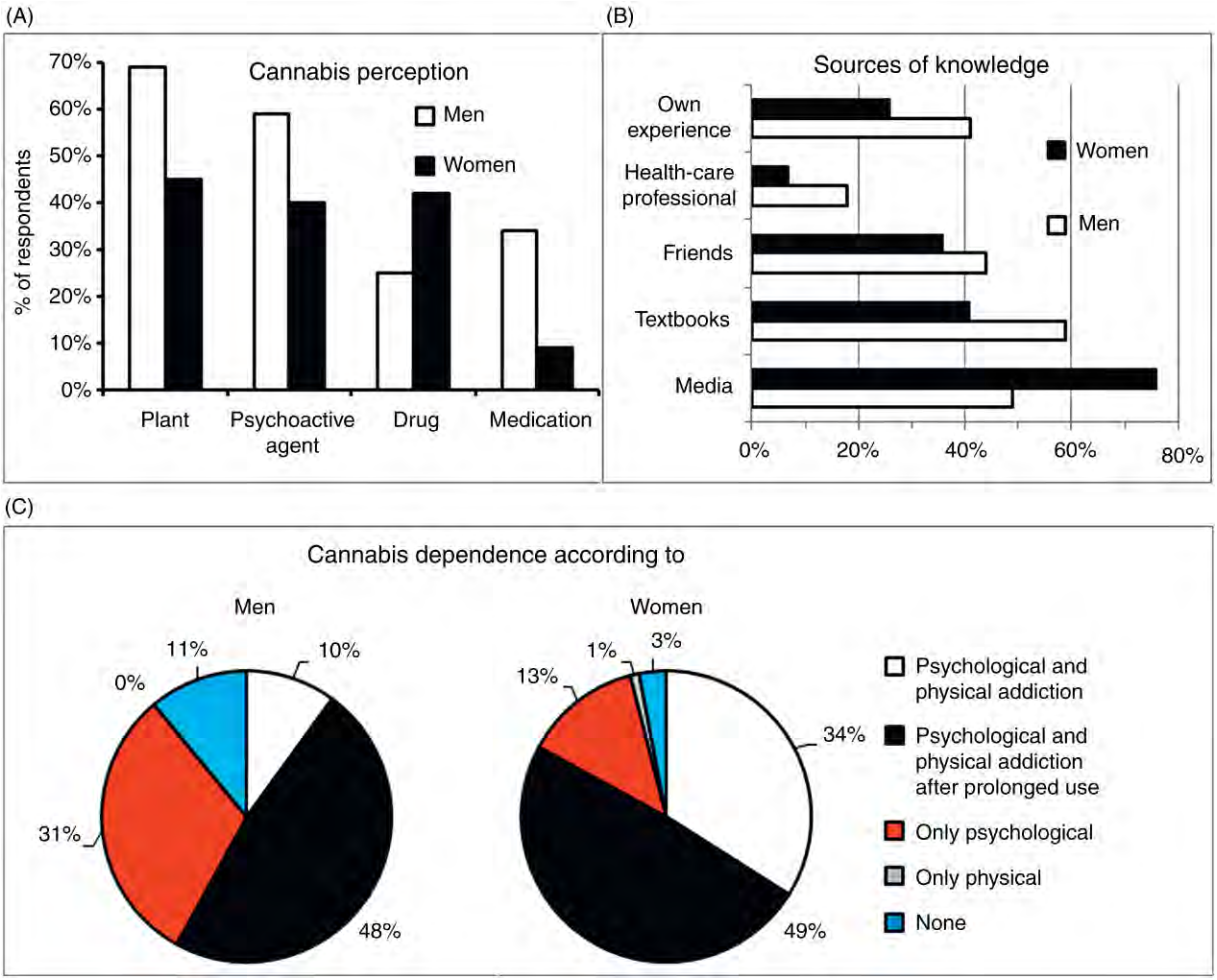

FIGURE 21.6 **Gender differences in cannabis-related knowledge and risk perception among Polish students.** Cannabis perception (A), sources of cannabis-related knowledge (B), and perception of cannabis addictive potential (C), according to male and female university students (aged 18–23, *n* =176). *Source: Based on Ostapkiewicz (2012), and reproduced from Sobczyński et al. (2013), with permission of the copyright owner.*

(Sobczyński, Drozd, manuscript in preparation). In the period of 2011–2014, Polish media addressed the topic of legalization of cannabis use in some American states, and the first cannabinoid pharmaceutical preparation, Sativex, obtained market authorization in Poland (Sativex, 2014). This was presumably the reason for an increase in self-reported positive cannabis effects on human health, and in a higher recognition rate of medical cannabis (Fig. 21.7).

MINI-DICTIONARY

Adverse drug reaction Undesired, harmful reaction, following taking medication in the prescribed dose that may be predictable, dependent (majority of cases) or independent of dose.
Cannabis product Cannabis products (eg, cannabis herbal preparation or resin) are derived from the cannabis plant; cannabis products are characterized by different composition, THC content, and subsequently different potency due to variety in plant genetics, mode of cultivation, and processing.
Cannabis-related knowledge An individual's knowledge of short- and long-term effects of cannabis on health and behavior, as well as the addictive potential of cannabis products.
Health-care professional Person who, by education, training, certification, or licensure is qualified to, and engaged in, providing health-care (eg, doctor, nurse, pharmacist).
Medical cannabis This term denotes the use of cannabis or its active ingredients—cannabinoids such as THC and cannabidiol (CBD)—in the treatment of diseases, or for alleviating symptoms.
Medication compliance The patient's conscious decision to undertake treatment medication as prescribed.
Pharmaceutical cannabinoid products Pharmaceutical product in the form in which it is intended for use (eg, a tablet, spray, capsule), with an active component—cannabinoid drug(s)—and inactive components, facilitating formulation.
Polydrug use Refers to concomitant or consecutive use of two psychoactive agents in order to potentiate their action, or lessen side effects.
School-based drug prevention program These programs may include school-day or afterschool classes delivered by school teachers or specialized personnel, and may be mandatory or voluntary. Their main goal is to deter or to delay the onset of drug use by providing students with the skills and knowledge to address the problem.

CHAPTER

22

Childhood Trauma and Cannabis: Risk Factors in Severe Mental Disorders?

M. Aas, I. Melle

NORMENT, KG Jebsen Centre for Psychosis Research, Division of Mental Health and Addiction, Oslo University Hospital & Institute of Clinical Medicine, University of Oslo, Oslo, Norway

SUMMARY POINTS

- This chapter focuses on the role of childhood trauma and cannabis as potential risk factors in severe mental disorders, focusing on schizophrenia spectrum, or bipolar illness.
- A history of childhood trauma is associated with use of cannabis in adolescence and early adulthood.
- The literature supports the additive effects of having both cannabis abuse and childhood trauma, and more severe clinical features of schizophrenia or bipolar disorders.
- This chapter has also discussed the putative idea behind the cooccurrence of cannabis use in individuals with high levels of childhood trauma, focusing on reported opposite effects on the body's stress system, the HPA axis.
- This chapter focuses on the importance of gathering information on early adverse events, as well as cannabis use, when investigating mechanisms behind severe mental illness.

KEY FACTS OF HYPOTHALAMIC PITUITARY-ADRENAL (HPA) AXIS

- The HPA axis is the main endocrine system involved in the stress response.
- The main stress hormone, cortisol, is affected by a variety of physiological and psychological stressors.
- Acute stressful experiences mobilize adaptive changes in the bodily processes and performance that help to meet the strain of environmental challenges, and protect against treats to the internal homeostasis (Sapolsky, 2000; Selye, 1975).
- While long-term stress can lead to maladaptive changes in bodily processes and performance, they also have a negative effect on health, cognition and mood (McEwen, 1998).
- Patients with severe mental illness, such as psychosis have an abnormal HPA axis. Both increased cortisol levels during the day, as well as a blunted awakening response is described in the literature (Mondelli, 2014).

LIST OF ABBREVIATIONS

CBD	Cannabidiol
CI	Confidence interval
CTQ	Childhood Trauma Questionnaire
HPA axis	Hypothalamic-pituitary-adrenal (HPA) axis
OR	Odds ratio
SCID	Structured Clinical Interview for Diagnostic and Statistical Manual of Mental Disorders (DSM)
SD	Standard deviation
THC	Tetrahydrocannabinol

INTRODUCTION

Several studies demonstrate that childhood trauma and cannabis use are associated with increased risk for schizophrenia and bipolar disorders, as well as increased symptom severity. Could it be that a history of childhood trauma increases the risk of using cannabis, which is then linked to psychopathology in vulnerable individuals? This chapter will cover the literature on childhood trauma and psychopathology, and cannabis use and psychopathology, and will aim to answer the question aforementioned. This chapter will also investigate the relationship between a history of childhood trauma and cannabis use, with the development of mental disorders, focusing on schizophrenia spectrum, and bipolar disorders.

CHILDHOOD TRAUMA AND MENTAL DISORDERS

The literature demonstrates associations between a history of childhood trauma and mental disorders in adulthood, both by increasing the risk for developing a mental disorder, and by increasing illness severity. For example, childhood trauma is well documented in the literature as a potential risk factor for developing psychosis. A recent large scale metaanalysis concluded that childhood trauma is a strong environmental risk factor for developing psychosis, with an overall effect of OR = 2.78 (95% CI = 2.34–3.31) (Varese et al., 2012). Subjects (45,441) were included in the metaanalysis gathered from case control studies, prospective studies, and cross-sectional studies. Across the different studies, it was concluded that a history of childhood trauma was more frequently reported in high-risk individuals, compared to healthy controls, and also associated with the development of psychopathology severity (Sahin et al., 2013; Thompson et al., 2010). In our own work, we have previously shown that childhood trauma is associated with reduced cognitive function, in two independent psychosis studies (Aas et al., 2011a, 2012c). We have also demonstrated a relationship between a history of childhood trauma and brain volume reduction of limbic areas of the amygdala and hippocampus (Aas et al., 2012b), as well as an interaction with genetic risk variants in psychosis (Aas et al., 2012a, 2013b).

Another recent metaanalysis also confirmed that childhood trauma is associated with bipolar disorders, both by increased prevalence, and more severe clinical characteristics (Daruy-Filho, Brietzke, Lafer, & Grassi-Oliveira, 2011). These findings are supported by two recent large studies (Aas et al., 2013a; Etain et al., 2013). The study by Etain et al. (2013; $n = 587$), demonstrated that a history of childhood trauma was associated with more than 5 years earlier age at onset, in the patients reporting three types of childhood trauma (emotional, sexual, and physical abuse), compared to those reporting no childhood abuse, in a dose-dependent manner (Fig. 22.1). Moreover, a history of childhood trauma has also been linked to a rapid cycling course (Garno, Goldberg, Ramirez, & Ritzler, 2005; Etain et al., 2013), affective lability (Aas et al., 2014; Fig. 22.2), psychotic features (Bebbington et al., 2004; Janssen et al., 2004; Shevlin, Dorahy, & Adamson, 2007), number of lifetime mood episodes (Brown, McBride, Bauer, & Williford, 2005; Nemeroff, 2004; Weber et al., 2008; Etain et al., 2013), and suicide ideation and attempts (Alvarez et al., 2011; Etain et al., 2013).

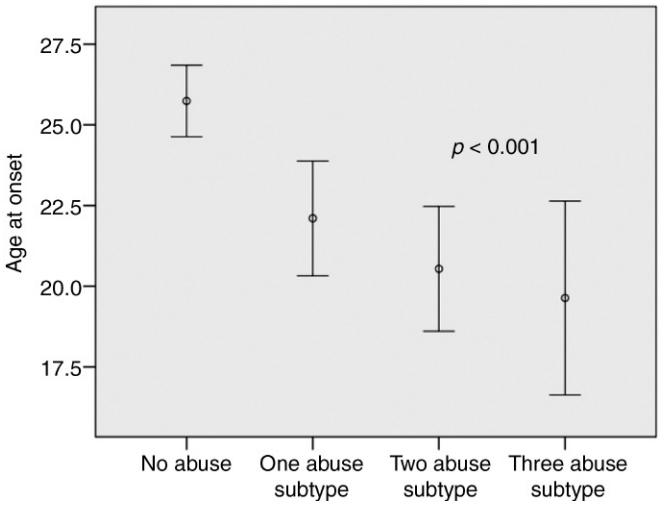

FIGURE 22.1 Age of onset in years (mean, and standard error) and childhood abuse (Etain et al., 2013). Fig. 22.1 illustrates a dose relationship between childhood abuse and earlier age at onset. The more abuse subtypes the patient report, the lower the age at onset. Kruskal–Wallis Test; $p < 0.001$; no abuse: $n = 361$, mean ± SD = 25.76 ± 10.54; one abuse subtype: $n = 114$, mean ± SD = 22.11 ± 9.49; two abuse subtypes: $n = 61$, mean ± SD = 20.54 ± 7.55; three abuse subtypes: $n = 22$, mean ± SD = 19.64 ± 7.05. *Source: Figure published in Etain, B., Aas, M., Andreassen, O. A., Lorentzen, S., Dieset, I., Gard, S., et al. (2013). Childhood trauma is associated with severe clinical characteristics of bipolar disorders.* Journal of Clinical Psychiatry, 74, *991–998.*

A history of childhood trauma has also been associated with unipolar depression (Heim, Newport, Mletzko, Miller, & Nemeroff, 2008b), including long-term changes in the hypothalamic-pituitary-adrenal (HPA) axis, as well as long-term epigenetic changes (Heim, Mletzko, Purselle, Musselman, & Nemeroff, 2008a; Heim et al., 2008b; Nemeroff & Binder, 2014). Long-term changes in the HPA axis are also found in patients with psychosis reporting high levels of childhood trauma (Mondelli et al., 2010). Therefore, there is reasonably consistent evidence that childhood trauma is associated with an increased risk for development of severe mental disorders in adulthood, by interacting with specific genes, as well as having a long-term influence on specific biomarkers, such as the HPA axis.

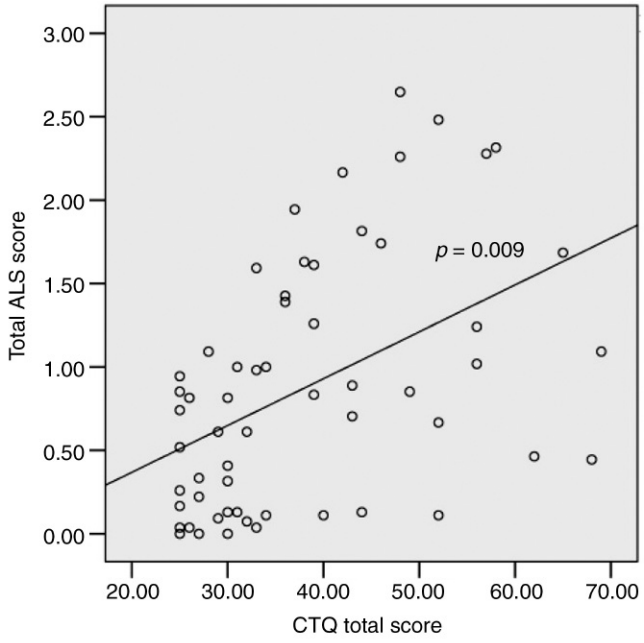

FIGURE 22.2 Affective lability score (ALS) and CTQ total score (Aas et al., 2014). Fig. 22.2 illustrates that childhood trauma is associated with higher score on the affective liability scale. Spearman's correlation: $r = 0.40$, $p = 0.009$, CTQ = Childhood Trauma Questionnaire. *Source: Figure published in Aas, M., Aminoff, S. R., Vik, L. T., Etain, B., Agartz, I., Andreassen, O. A., et al. (2014). Affective lability in patients with bipolar disorders is associated with high levels of childhood trauma. Psychiatry Research, 218* (1–2), 252–255.

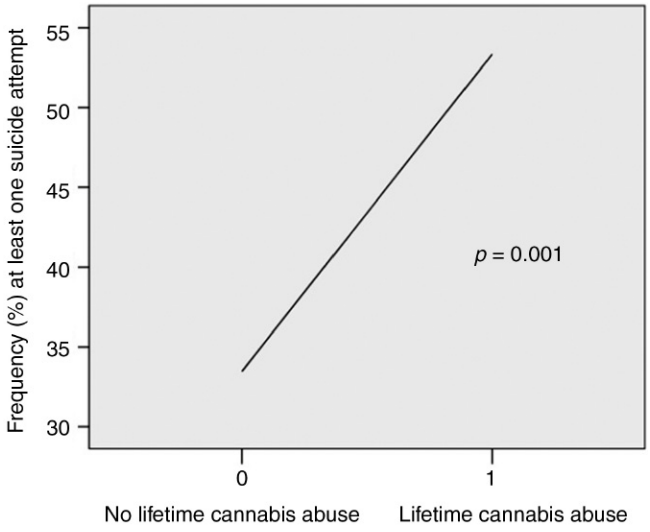

FIGURE 22.3 Cannabis abuse and suicide attempt (wish to die) (Aas et al., 2013a). Fig. 22.3 illustrates that cannabis abuse is associated with higher prevalence of having at least one suicide attempt (wish to die) in bipolar patients, compared to cases without cannabis abuse. Chi-square, $p = 0.001$ "no lifetime cannabis abuse," $n = 368$; "lifetime cannabis abuse," $n = 211$. *Source: Figure published in Aas, M., Etain, B., Bellivier, F., Henry, C., Lagerberg, T., Ringen, A., et al. (2013a). Additive effects of childhood abuse and cannabis abuse on clinical expressions of bipolar disorders. Psychological Medicine, 1–10.*

CANNABIS AND MENTAL DISORDERS

In addition to childhood trauma, one of the most consistently reported environmental risk factors for psychotic disorders is cannabis use. Several studies demonstrate that the use of cannabis increases the risk of schizophrenia (Andreasson, Allebeck, Engstrom, & Rydberg, 1987; van Os et al., 2002), with further reports of similar findings for bipolar disorders (Lev-Ran, Le, McKenzie, George, & Rehm, 2013). Moreover, cannabis has been shown to correlate with severity of illness in psychotic disorders. In addition, among both patients with schizophrenia and in bipolar disorders, those who report cannabis use have an earlier age at onset (Di Forti et al., 2014; Lagerberg et al., 2011, 2014). Moreover, in a large study of bipolar disorders (n = 471) and healthy controls (n = 1761), bipolar patients were 6.8 times more likely to report a lifetime history of cannabis abuse, than healthy controls (Agrawal, Nurnberger, & Lynskey, 2011). Agrawal et al. (2011) also reported associations between cannabis abuse and increased suicide attempts, mixed episodes, and greater disability, with similar findings found in the study by Aas et al. (2013a); see Fig. 22.3. Post (2010) supports these findings by linking drug abuse to increased sensitization, and vulnerability to recurrent episodes, thus driving illness progression in bipolar disorders. However, research on this field is sparse, and more studies are needed.

ARE PEOPLE WHO EXPERIENCE CHILDHOOD TRAUMA MORE PRONE TO ILLICIT DRUG USE, INCLUDING CANNABIS, LATER IN LIFE?

Individuals reporting a history of childhood trauma are more prone to substance abuse in adulthood (Aas et al., 2013a; Etain et al., 2013; Fergusson, Boden, & Horwood, 2008; Fig. 22.4). A 25 year-long prospective study examining the development of illicit drug use, from a birth cohort of 1265 New Zealand children, found that childhood sexual and physical abuse are the main predictors for illicit drug use at ages 16–25 (Fergusson et al., 2008). A national longitudinal study of adolescent Heath (AddHealth) of 12,748 adolescents found that maltreatment in childhood is significantly associated with increased binge drinking in adolescence, with 12.4% prevalence of binge drinking, compared to 9.9% among those reporting no maltreatment (Shin, Edwards, & Heeren, 2009).

Both illicit drug use, including cannabis use, and a history of childhood trauma are associated with increased risk of psychosis, and both should be taken into account when investigating risk factors for psychosis (Houston, Murphy, Shevlin, & Adamson, 2011). As described in the paper by Aas et al. (2013a), the possible

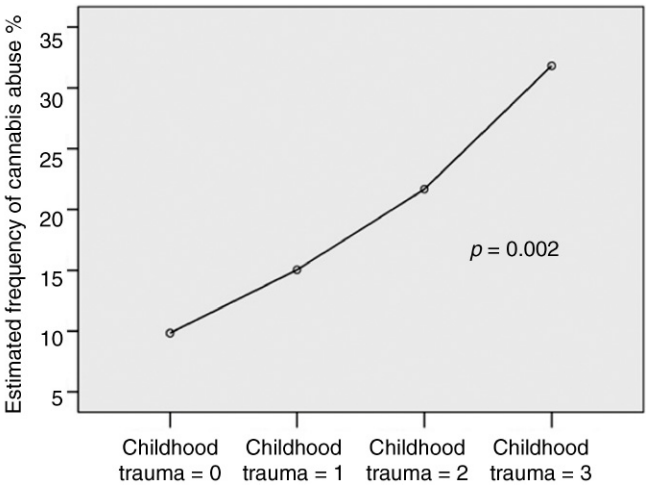

FIGURE 22.4 Substance abuse and childhood trauma abuse dose effect (Aas et al., 2013a,b). Fig. 22.4 illustrates a dose effect of number of childhood trauma experiences and use of cannabis: $X^2 = 14.52$, df = 3, $p = 0.002$. Based on Bernstein's cutoff scores for moderate to severe abuse; no abuse, $n = 366$; one abuse subtype, $n = 113$; two abuse subtypes, $n = 60$; three abuse subtypes, $n = 22$. *Source: Figure published in Etain, B., Aas, M., Andreassen, O. A., Lorentzen, S., Dieset, I., Gard, S., et al. (2013). Childhood trauma is associated with severe clinical characteristics of bipolar disorders.* Journal of Clinical Psychiatry, 74, *991–998.*

mechanism behind the cooccurrence of childhood abuse and cannabis abuse could be related to their having opposite effects on the HPA axis (Heim et al., 2008a; van Leeuwen et al., 2011). Cannabis and substance use have been linked to a reduction in HPA activity (van Leeuwen et al., 2011), whilst a history childhood trauma has been linked to increased HPA axis, specifically in depression (Heim et al., 2008a,b). Thus, it could be hypothesized that cannabis or substance use in individuals with a history of childhood trauma may be viewed as a way of "regulating" the HPA axis. Further studies here are needed.

WHAT IS THE LINK BETWEEN A HISTORY OF CHILDHOOD TRAUMA, CANNABIS USE, AND SEVERE MENTAL DISORDERS?

Both childhood trauma and cannabis use are linked to bipolar disorders, both by increased frequency, and severity of clinical characteristics. The question is whether they influence the clinical picture separately or in tandem. We have shown previously that individuals reporting childhood trauma tend to show increased risk of substance abuse in adulthood, compared to individuals without childhood trauma, thus indicating possible interactions or additive effects. It may also be that relationships to clinical expressions are driven, or mediated by, either cannabis abuse or childhood trauma. A recent paper by Morgan et al. (2014) aimed to answer this question from a dataset consisting of 1680 individuals, as part of the South East London Community Heath Study (SELCoh). The authors found a strong association between childhood abuse and other environmental risk factors for psychosis, including cannabis use, and between later life events and an increased odds ratio of psychotic experiences. Moreover, the additive effects of different risk factors were larger than when investigating them separately. The large study ($n = 7403$) from the Adult Psychiatric Morbidity Survey 1997, from the United Kingdom, supports the findings previously; the participants reporting both nonconsensual sexual experiences in childhood, and cannabis consumption, had more than a 7 times (OR 7.84) greater likelihood to be diagnosed with psychosis, compared to participants without these experiences. The OR sank to 6.10, when investigating only nonconsensual sexual experiences in childhood, without taking cannabis use into consideration (Houston et al., 2011). Another study of adolescents in an urban environment from Ireland ($n = 211$) found that combined exposure to nonconsensual sexual experiences in childhood, and cannabis use, increased the likelihood of having a diagnosis of psychosis by almost 12 times (Harley et al., 2010); however, the sample size was small, with only $n = 5$ scoring positive for psychosis and childhood trauma, and $n = 4$ scoring positive for cannabis and psychosis.

In bipolar disorders, additive effects of childhood trauma and cannabis use (here a SCID verified diagnosis of cannabis abuse) have been associated with clinical features of the disorder (Aas et al., 2013a). In a sample of 587 participants with a bipolar disorder, from France and Norway, cannabis abuse was significantly associated with childhood abuse, specifically emotional and sexual abuse. Cannabis abuse moderated the prevalence of having at least one suicide attempt in the patients with childhood sexual abuse (Aas et al., 2013a); see Fig. 22.5. Additive effects were also observed between cannabis abuse and childhood trauma on earlier age at onset, and increased prevalence of rapid cycling (Aas et al., 2013a), see Fig. 22.6.

Although a relationship is observed between increased risk of substance abuse in individuals experiencing childhood trauma, the literature does not support clear mediation effects between childhood trauma, cannabis abuse, and the development of psychopathology. The literature supports additive effects and moderation effects in the direction of having both increases in the risk of developing a mental disorder, as well as increasing severity of clinical features. More studies are required to investigate this further.

Limitations of this type of research are many: first, childhood trauma is often measured retrospectively, for example, using the Childhood Trauma Questionnaire (CTQ), with the inherent weaknesses of retrospective interviews. Ideally, when investigating childhood trauma and risk of schizophrenia or bipolar disorder,

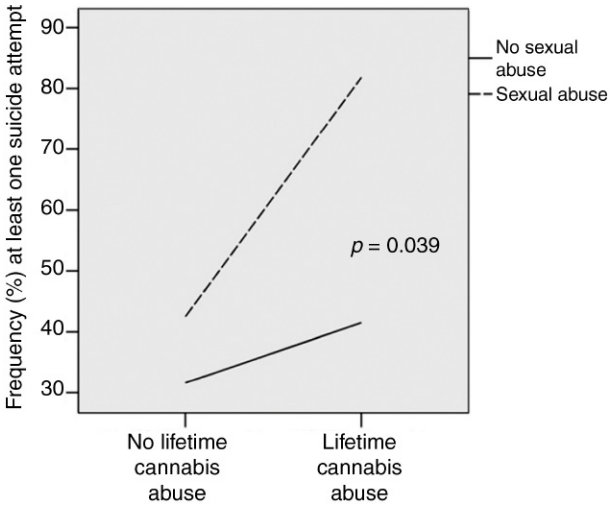

FIGURE 22.5 Interaction between childhood sexual abuse, cannabis abuse, and a history of at least one suicide attempt (Aas et al., 2013a,b). Fig. 22.5 illustrates interaction (p = 0.039) between sexual abuse, cannabis abuse, and a history of lifetime suicide attempt. Binary logistic regression. "No lifetime cannabis abuse," n = 368; "lifetime cannabis abuse," n = 211; sexual abuse dichotomized into trauma versus no trauma, based on moderate to severe cutoff scores by Bernstein et al. (2003), "no sexual abuse," n = 475; "sexual abuse," n = 104. *Source: Figure published in Aas, M., Etain, B., Bellivier, F., Henry, C., Lagerberg, T., Ringen, A., et al. (2013). Additive effects of childhood abuse and cannabis abuse on clinical expressions of bipolar disorders.* Psychological Medicine, *1–10.*

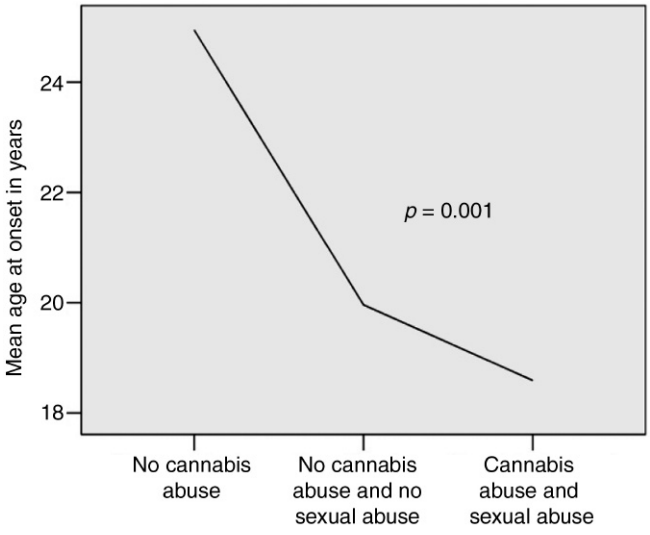

FIGURE 22.6 Age at onset, substance abuse, and childhood trauma abuse dose effect (Aas et al., 2013a). Fig. 22.6 illustrates significant additive effect for sexual abuse and cannabis abuse on earlier age at onset (p < 0.001), with the earliest age at onset in the group reporting both cannabis abuse and childhood trauma (mean ± SD of 18.6 ± 7.3 years; compared to no cannabis and no childhood abuse: mean ± SD of 25.0 ± 10.5 years). Kruskal-Wallis Test, p = 0.001, "no lifetime cannabis abuse," n = 499; "lifetime cannabis abuse and no sexual abuse," n = 53,·"lifetime cannabis abuse and sexual abuse," n = 22. *Source: Figure published in Aas, M., Etain, B., Bellivier, F., Henry, C., Lagerberg, T., Ringen, A., et al. (2013a). Additive effects of childhood abuse and cannabis abuse on clinical expressions of bipolar disorders.* Psychological Medicine, *1–10.*

prospective studies are conducted following a large cohort, over many years. The challenge here is the N required, as these illnesses are quite rare (1–3% of the population), as well as the time required, and resources in general. Second, several factors should be taken into account when investigating cannabis use, specifically the potency, frequency, and duration. The potency of cannabis is defined as the concentration of tetrahydrocannabinol (THC), the major active principle of the cannabis plant. Apart from THC, cannabis and cannabis resin contain many other cannabinoids. One of these (cannabidiol, CBD) has attracted recent interest because it is believed to show antipsychotic properties (Home Office Cannabis Potency Study, 2008). THC/CBD levels vary in the different types of cannabis, with synthetic skunk showing the highest THC levels, compared to the herbal version. The component of THC varies in the different drugs used (synthetic vs herbal), which may challenge comparisons between studies. Frequency of use is also important to take into account; is cannabis only tried a few times, or used regularly? A recent study investigated daily use, age first started (after or before the age of 15), as well as THC levels, in order to capture a broader, and more complete picture of how cannabis may increase risk of psychosis (Di Forti et al., 2014); however, most of the studies in the literature do not include such detailed information on cannabis use.

CONCLUSIONS

Childhood trauma and cannabis use are reported as risk factors in severe mental disorders, such as schizophrenia and bipolar disorder, both by increasing frequency, and by association with more severe clinical features of the disorder. Furthermore, several studies show that a history of childhood trauma is associated with cannabis use. More studies are needed to explore the association between childhood trauma and cannabis use in severe mental illness. So far, the literature supports additive affects, as well as increased odds ratio, when including both risk factors together in multivariate models, compared to measuring the risk factors independently. This chapter has also discussed the putative idea behind the mechanism of the cooccurrence of cannabis use in individuals with high levels of childhood trauma as a possible consequence of having opposite effects on the HPA axis, thus potentially related to some sort of "self-medication" aiming to normalize the HPA axis. To return to the question in the introduction, namely whether a history of childhood trauma increases the risk of using cannabis, the literature review covered in this chapter supports this link. Furthermore, this chapter supports a link between childhood trauma and cannabis use, and more severe clinical psychopathology in vulnerable individuals.

MINI-DICTIONARY

Additive effect A variable that has an additive effect can be added to other terms in a model to determine its effect on the independent variable.
Bipolar disorder Bipolar disorder is a mental illness characterized by periods of elevated mood (mania or hypomania), often followed by periods of depression.
Childhood trauma A history of childhood trauma covers different types of adverse experiences in childhood, such as: emotional abuse, physical abuse, sexual abuse, physical neglect, and/or emotional neglect. A frequently used questionnaire to capture information on childhood trauma in the literature is the Childhood Trauma Questionnaire (CTQ), a self-report retrospective questionnaire of 28 items (Bernstein et al., 2003). Another frequently used self-report measure of childhood trauma is, for example, the Childhood Experience of Care and Abuse Questionnaire (CECA.Q) (Bifulco, Bernazzani, Moran, & Jacobs, 2005). The CECA.Q includes physical abuse by the main mother and father figures (usually, but not necessarily, the biological parents), sexual abuse by any adult or an individual at least 5 years older than the recipient, parental antipathy (hostility, rejection, or coldness), and emotional or physical neglect. Both the physical and sexual abuse sections of the CECA.Q begin with screening questions, and then positive responses are followed up with more detailed questions to elicit concrete examples. Childhood trauma may also cover loss or separation of a parent.
Hypothalamic-pituitary-adrenal (HPA) axis The HPA axis is the main endocrine system involved in the stress response. The main stress hormone, cortisol, is affected by a variety of psychological stressors, including: trauma, fever, anxiety, exercise, and exposure to new situations (Pariante & Miller, 2001).
Mediation statistical analysis In statistics, a mediation model is an analysis that seeks to identify the mechanism that underlies an observed relationship between an independent variable and a dependent variable, via the inclusion of a third explanatory variable, known as a mediator variable.
Odds ratio (OR) An OR is a measure of association between an exposure and an outcome. The OR represents the odds that an outcome will occur, given a particular exposure, compared to the odds of the outcome occurring in the absence of that exposure.
Schizophrenia disorder Schizophrenia is a mental disorder often characterized by abnormal behavior, and failure to recognize what is real. Common symptoms include delusions, hallucinations, confused or unclear thinking, inactivity, and reduced social engagement and emotional expression.
Standard deviation Standard deviation measures the amount of variation from the average. A low standard deviation indicates that the data points tend to be very close to the mean; a high standard deviation indicates that the data points are spread out.
Tetrahydrocannabinol (THC) THC is the major psychoactive ingredient in cannabis, and the component of cannabis associated with psychotic illness (Di Forti et al., 2014).

Parent's Influence on Children's Cannabis Use

S. Miller, J.T. Siegel, W.D. Crano

Division of Behavioral and Organizational Sciences, School of Social Science, Policy and Evaluation, Claremont Graduate University, Claremont, CA, United States

SUMMARY POINTS

- This chapter focuses on how parental behavior can influence children's use of cannabis.
- Recent changes in public sentiment regarding the acceptability of cannabis have coincided with an increase in the level of adolescent cannabis use.
- Cannabis use in adolescence has been linked to significant cognitive developmental delay in young adults, which is all the more reason to emphasize how parents can prevent adolescent cannabis use.
- Parental use has been shown to change the expectancies children perceive regarding their own cannabis use, in such a way that they will be more likely to experiment with cannabis if their own parents are cannabis users.
- Authoritative parenting, characterized by setting high expectations and showing affection, has been shown to be the most effective parenting style for preventing adolescent cannabis use.
- Effective communication between parents and their children is based on feelings of trust and acceptance which facilitate the willful disclosure of information from the child to the parent.
- Parental monitoring is one of the most effective ways that parents can prevent adolescent cannabis use, by virtue of having knowledge about their child's activities, whereabouts, and peer groups.
- Increasing parent's feelings of competence to talk to their children about cannabis use is an area where policy makers could have an impact by designing more targeted media campaigns.

KEY FACTS OF OUTCOME EXPECTANCIES

- Outcome expectancies are the beliefs an individual has concerning what they will experience if they engage in a particular behavior.
- Expectancies are formed in a number of ways, either from previous experience, second-hand accounts, media portrayals, educational mediums, and other informational sources.
- The expectancies an individual has regarding a specific behavior can be positive, negative, neutral and, in many cases, a mix of all three.
- The more favorably a person perceives the outcomes of a behavior to be, the more likely they will perform that behavior, if given the opportunity.
- Outcome expectances are based on *perceptions* of reality and, therefore, do not have to conform to what is most likely to happen (if the behavior is performed) to be influential.

The aforementioned points outline the core facets of outcome expectancies, what they are, how they're formed, and how they function to guide behavior.

NSPY National Survey of Parents and Youth

INTRODUCTION

In the 1980s, there was a now (in)famous commercial which was part of an antidrug media campaign targeting adolescent cannabis use. A hostile parent confronts his son with a stash of cannabis he found in the child's room, and starts peppering the child with questions, trying to learn out how this could come to pass. Finally the parent demands to know, "Who taught you how to do this stuff?" The visibly distraught child shoots back with, "You, alright! I learned it by watching you!" A solemn voiceover intones, "Parents who use drugs have children who use drugs." Clearly, the commercial was trying to persuade parents not to use drugs, if for nothing else than the sake of their children. While it is true that parents who are cannabis users are more likely to have children who use cannabis (Miller, Siegel, Hohman, & Crano, 2013), what is often overlooked is why adolescent cannabis use is a bad thing. Parents should be concerned with their child's cannabis use for two main reasons. First, children who use drugs are, by that very behavior, at greater risk for delinquency, and entering into the criminal justice system, as most countries enforce a prohibition against cannabis use by minors. Second, there is mounting evidence (Dougherty et al., 2013; Gruber, Sagar, Dahlgren, Racine, & Lukas, 2012; Lisdahl & Price, 2012) indicating that children who use cannabis are at greater risk for developmental delay. Meier et al. (2012), for example, showed up to an eight points deficit in IQ scores among young adults who were regular cannabis users as children. These findings are made all the more relevant, given recent trends indicating an increase in adolescent cannabis use (SAMHSA, 2010; Fig. 23.1).

PARENTAL INFLUENCE ON ADOLESCENT CANNABIS USE

Researchers, prevention specialists, and policy makers have been concerned, for many years, with the processes by which parents influence children's illicit drug use, as exemplified by the commercial described at the start of this chapter. This concern suggests that children may infer the boundaries of substance usage from their parents' drug use behaviors. The evidence showing that parents who use cannabis are more likely to have children who themselves become cannabis users supports this possibility (Duncan, Duncan, Hops, & Stoolmiller, 1995; McDermott, 1984). This is a troubling finding. It implies that children are destined to make the same mistakes as their parents—and, further, that there is nothing the parent can do about it. However, the explanation is not so simple. Many parental factors have been shown to affect the likelihood of their children's initiating substance misuse, and these factors appear to hold, independent of parents' prior usage. Of course, current, ongoing parental drug use is a major risk factor for children (Miller et al., 2013), and may well trump the ameliorative factors that will be discussed.

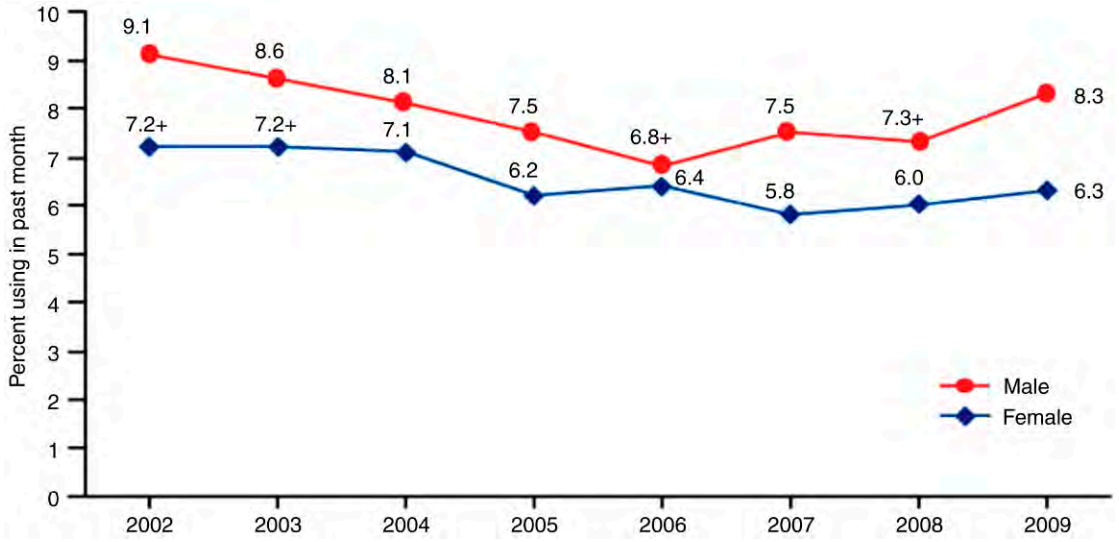

FIGURE 23.1 **Past-month marijuana use among youth, age 12–17, by gender: 2002–09.** Among youth age 12–17 in 2009, males had a higher rate than females of current marijuana use (8.3% for males vs 6.3% for females). +, Difference between this estimate and the 2009 estimate is statistically significant at the 0.05 level. *Source: From SAMHSA (2010; Fig. 2.9).* Results from the 2009 National Survey on Drug Use and Health: Vol. I. Summary of National Findings. *Rockville, MD. Reprinted with permission.*

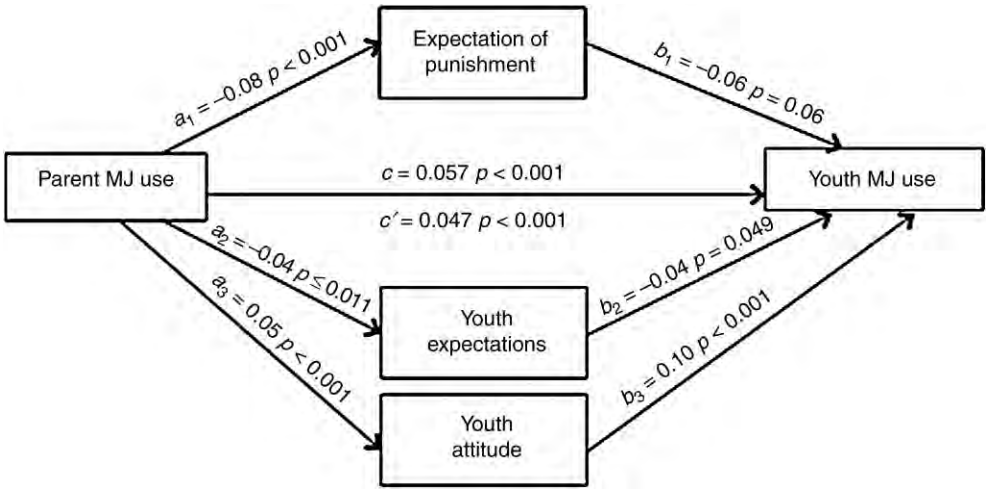

FIGURE 23.2 Multiple mediation model of parent cannabis use influencing child cannabis use. This figure shows how expectations of punishment, outcome expectations of cannabis use, and attitudes toward cannabis are influenced by the recency of parent cannabis use. *Note*. All variables were measured at R1, except youth marijuana use, which was measured at R2, and the effects were controlled for age measured at R1. *Source: From Miller et al. (2013, Fig. 1, p. 851). Copyright 2013 by the American Psychological Association. Reprinted with permission.*

Until recently, there was a dearth of good data available to examine the psychosocial processes behind this relationship. Either there were data about parental drug use that did not address the drug use habits of the child or, more likely, there were data on the child but not the parent. Even when data regarding the drug use habits of both parent and child were available, it was likely to be cross-sectional, making it impossible to test hypotheses regarding the development of the process of influence over time. This changed with the National Survey of Parents and Youth (NSPY), which included information from parents and children on their own drug use behavior (David, Hornik, & Maklan, 2010). In a recent analysis of the NSPY dataset, Miller et al. (2013) identified three key factors that mediated the relation between parental cannabis use and their adolescent children's use (Fig. 23.2).

RECENCY OF PARENTS' CANNABIS USE AND CHILDREN'S INITIATION

The research of Miller et al. (2013) was concerned with parental factors that might influence how adolescent nonusers of cannabis came to be users. It showed that the parents' substance use behaviors were associated with their children's initiation of use. Even more predictive, regarding drug use, were the child's *perceptions* of what their parents knew or did. Analysis indicated that children's attitudes toward cannabis were significantly related to parental usage. If a parent had ever used cannabis, the child was more likely to do so. Further, and more importantly, the recency of parental usage also was significantly related to children's behaviors: the more recent the parental use, the more positive were children's attitudes toward cannabis. Two other factors mediated the relation between parental usage and children's initiation. One of these had to do with the child's expectation of punishment for cannabis use. The more recent the parent's usage, the lower was the child's expectations of punishment for use. The third mediating factor between recency of parental use and children's initiation was the child's expectations regarding the effects of cannabis. Table 23.1 shows the correlations between parental use, child use, and the mediating factors associated with both. The more recent the parent's usage, the more positive were the child's expectations regarding the effects of cannabis. For more on how outcome expectancies influence behavior see Section "Key Facts of Outcome Expectancies.".

TABLE 23.1 Correlations Between Child Marijuana Use, Parent Marijuana Use, Expectation of Punishment, Attitude, and Expectations

Item	V1	V2	V3	V4
V1. Child marijuana use	—			
V2. Parent marijuana use	0.13***	—		
V3. Punish	–0.14***	–0.13***	—	
V4. Attitude	0.18***	0.08**	–0.19***	—
V5. Expectations	–0.13***	–0.07*	0.24***	0.34***

This table illustrates how each of the youth variables concerning attitudes and expectations of use (ie, V3, V4, and V5) are related to parent cannabis use at Time 1, and child cannabis use at Time 2. In essence, the variables that predicted child cannabis use at Time 2 were predicted by parent cannabis use at Time 1. All variables were measured at R1, except child marijuana use, which was measured at R2. * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$.
From Miller et al. (2013, Table 1, p. 850). Copyright 2013 by the American Psychological Association. Reprinted with permission.

Clearly, the child's impressions have implications for their own usage. Research has established that adolescents with more positive attitudes toward cannabis are more likely to try the drug (Hohman, Crano, Siegel, & Alvaro, 2014). On the other hand, expectations of punishment can be a strong deterrent to use. The analysis indicated that such expectations were attenuated as a function of recency of parental use. Expectations regarding the effects of cannabis also were shown to affect children's usage intentions. These expectations can range from the physiological (eg, feelings of euphoria, brain damage), to the social (eg, increased popularity, stoner label), and they, too, mediated the association between parental use and children's initiation.

Obviously, these results suggest that parents should never have initiated cannabis use. For many parents, of course, this admonition comes too late. However, children's *perceptions* of their parents' past usage, attitudes toward cannabis, the punishment in store for usage, and the gains and losses of cannabis usage can be affected by present (vs past, perhaps distant past) parental behaviors, and these behaviors can be learned or modified by appropriate training. How this can be done is indicated in a number of recent studies.

PARENTAL WARMTH AND MONITORING (KNOWLEDGE OF CHILD'S ACTIONS AND WHEREABOUTS)

Two parental variables that have received considerable research attention are parental monitoring, and parental warmth. Parental monitoring can mean many things, but generally is subdivided into two categories: surveillance and knowledge gained from the child's self-disclosure of actions to parents. Both appear to have protective effects on children's substance misuse, but knowledge is clearly the preferred modality, as it suggests a warm and accepting family context in which the child feels free to disclose issues to parents, whose advice is actively sought, rather than imposed. Early survey research by Ramirez et al. (2004) showed that youth (fourth through 12 graders) who perceived higher degrees of parental surveillance were less likely to use illicit substances (cannabis and inhalants). The same result was found as a function of perceived family warmth: the greater warmth perceived by the child, the less likely was he or she to use either substance. Both of these results were qualified by an interaction with knowledge; that is, effects of surveillance and family warmth were enhanced as a function of the child's knowledge of the consequences of drug use.

These results were reinforced by a meta-analysis concerned with the link between parental monitoring and cannabis use in youth. Lac and Crano (2009) found a statistically significant inverse relation between parental monitoring and cannabis use, across 17 studies with more than 35,000 independent observations. The results were strongest when monitoring was defined in terms of parental knowledge (presumably the result of children's self-disclosure). The data were unequivocal. A file drawer analysis indicated that more than 7000 studies of nil effect would be needed to render the results nonsignificant.

A formal model of the way in which parental knowledge and warmth might affect adolescents' use of cannabis, framed within the theory of planned behavior (Ajzen, 1991), was proposed by Lac, Alvaro, Crano, and Siegel (2009). This research made use of data from the restricted version of the National Survey of Parents and Youth, which was conducted to evaluate the National Youth Antidrug Media Campaign (National Institute on Drug Abuse, 2006). The sample consisted of 2141 adolescents (12–18 year olds) and their parents. The data from this archive were entered into a structural equation model. Parental warmth and parental knowledge were hypothesized to affect attitudes toward cannabis, subjective norms regarding cannabis use, and perceived behavioral control. Results showed that parental knowledge affected all three of these endogenous variables; warmth affected the first two, but not perceived behavior control. Attitudes, subjective norms, and perceived behavioral control, in turn, were significantly associated with adolescents' intentions to use cannabis, which significantly predicted actual cannabis use 1 year later. This study revealed a strong and statistically significant linkage from parental monitoring and warmth to adolescent beliefs, and consequent behaviors. It indicates clearly the importance of parents in moderating use. The research supported the majority of hypotheses. Parental knowledge predicted more negative attitudes toward cannabis, stronger subjective norms against usage, and higher levels of perceived behavioral control in avoiding cannabis. These factors, in turn, attenuated usage intentions and actual use.

A conceptual replication and extension of the research of Lac et al. (2009) was advanced by Hemovich, Lac, and Crano (2011), who were interested in the ways that family structure (single or dual parents) were associated with adolescents' attitudes and friendship patterns, and the consequent effects of these predictors on illicit substance use (alcohol, tobacco, and cannabis). The study involved 4173 child–parent pairs (adolescents ranged from 12 to 18 years of age), who were assessed over 2 years. The data were used in a path analytic model in which family structure and family income affected parental monitoring behavior, but not family warmth. Lower family income was observed in single-parent families, as were lower levels of monitoring. The authors speculated that single parents' need to be engaged in the labor force, of necessity, detracted from the time available to monitor children, but would not necessarily impinge on

the warmth they extended to their children. Monitoring and warmth, in turn, affected two critical variables: children's attitudes toward illicit substance use, and the attitudes and the choice of the friends with whom they associated. The link between attenuated parental monitoring and children's substance use was hypothesized to operate through the adolescents' social ties and attitudes toward illicit substances. This hypothesis was supported. The analysis of the path model revealed that lower monitoring and warmth predicted more drug-friendly attitudes on the part of the adolescents, and their choice of friends—who were more likely to be involved in delinquent behaviors, including substance misuse. These two factors, in turn, were significantly related to the adolescent's own use of illicit substances, 1 year later. It is important to note that only substance-free adolescents were used in the first year of the study.

Further studies on parental monitoring designed to explain *why* monitoring matters have revealed that parental monitoring affects adolescents' perceived norms regarding the acceptability of using cannabis, their attitudes toward cannabis, and their intentions to use cannabis (Yabiku et al., 2010). Further, evidence suggests that strong parental monitoring may mitigate negative peer influence (Tragesser, Beauvais, Swaim, Edwards, & Oetting, 2007), and an evaluation of a parental monitoring intervention found that parents' knowledge of adolescent activities was more accurate when exposed to the monitoring intervention (Li et al., 2002).

It stands to reason that parents who are more knowledgeable about their children and their activities will be better equipped to recognize and address potential risk factors associated with cannabis or other substance misuse. The research cited here and elsewhere supports this conclusion. However, it is important to note that the effects of parental monitoring, much like communication, do not exist in a vacuum. Monitoring is most effective when parental warmth and communication are present, as well (Fletcher, Steinberg, & Williams-Wheeler, 2004; Patrick, Snyder, Schrepferman, & Snyder, 2005).

PARENTAL WARMTH AND PARENTING STYLE: SOME CONCEPTUAL OVERLAP

Parental warmth is conceptualized in the literature as the love and affection shown to children throughout their developmental years. Warmth more broadly has to do with children's *perceptions* of parental acceptance or rejection (Khaleque, 2013). As discussed, research on the relationship between parental warmth and adolescent cannabis use has shown a negative association (Hemovich et al., 2011; Lac et al., 2009). This finding suggests that mutual trust between parent and child has a strong protective effect from substance involvement, and has received empirical support in the literature concerning child delinquency (Kerr, Stattin, & Trost, 1999). It is likely that trust, rooted in perceptions of love and acceptance, facilitates the willful disclosure of information from the child to the parent (leading to parental knowledge). With this trust also comes a greater willingness to accept the attitudes and norms of the parent, regarding cannabis use (Lac et al., 2009).

Parenting style is similar to parental warmth, but it incorporates warmth into a broader framework of parenting. In her seminal work, Baumrind (1967) identified four key elements of parenting that have to do with how controlling, demanding, communicative, and nurturing parents were with their children. This research led to the theoretical identification of three distinct parenting styles: authoritarian, authoritative, and permissive (Baumrind, 1991), and later a fourth style known as "uninvolved" (Maccoby & Martin, 1983), which primarily has to do with neglectful or absent parents. In a review of the literature on parenting styles and drug use, Becona et al. (2012) found that the authoritative style was the style most consistently associated with lower rates of adolescent drug use (including cannabis use), while the uninvolved style was linked to increased likelihood of adolescent drug use. The authoritative style is characterized by a "firm but fair" approach to parenting, in which parents have very high expectations of their children, but also show warmth, and recognize their child's need for independence.

PARENTAL COMMUNICATION AND CHILDREN'S SUBSTANCE USE

While showing love and acceptance helps to build a solid relationship between parents and their children, communicating the dangers of cannabis use before children have an opportunity to experiment on their own also has positive preventive implications. Although parents have a demonstrably important role to play in the prevention of their children's substance misuse, surprisingly little research has been devoted to enhancing parental preventive communication. The focus on parental-child substance prevention communication may provide important insights into prevention, and so it is reasonable to hope that more research on this topic will be forthcoming. A recent study that merits close consideration was performed by Huansuriya, Siegel, and Crano (2014). In this 4-year panel study, parents' exposure to an ongoing antidrug media campaign was assessed. Higher levels of ad exposure were associated with parents' attitudes toward communicating with their children about drugs, and higher levels of perceived social approval from significant others for doing so. These variables, along with perceived behavioral control, anticipated parents' intentions to discuss drug avoidance with their children.

These intentions were associated with children's reports of drug communication with parents, on a measure taken 1 year later. The frequency of communication with parents was associated with children's attenuated intentions to use drugs. This study was replicated in an analysis of the third and fourth year of the panel study, with identical results.

This study strongly suggests that adolescents view parents as a credible source on drugs. The results of Huansuriya et al. (2014), however, indicated that many parents did not know how to communicate about drugs with their children. Their perceived behavioral control to discuss drugs with their children was not affected by the ad campaign. This may be due to the fact that the great majority of the ads used in the campaign were directed toward youth, and provided little information that parents could use in gaining knowledge and confidence about drug-relevant communication with their children. The children's perceived behavioral control also was not a strong component in their substance avoidance. Both of these findings suggest the importance of providing more usable facts to parents in their conversations with children about the dangers of drug misuse. Further support for this contention was supplied by Lamb and Crano (2014), who showed that although parents were generally aware of their children's usage behavior, most children, even those engaged in marijuana use, assumed their parents would not know if they were using drugs.

The implications to be drawn from both Lamb and Crano (2014) and Huansuriya et al. (2014) are that parents are willing actors in facilitating drug prevention in their children, but may not know the most effective ways of doing so and, as such, may avoid speaking about drug prevention, even if they know or suspect their children are at risk. We know parents can be an effective source of antidrug communication for adolescents (Kafka & London, 1991; Tobler & Komro, 2010), but it is not enough to tell parents to tell their children to avoid drugs. They must be informed about the proper ways of communicating antidrug messages in ways that are informed and persuasive. Assuming that parents already know what to say is not supported by the relevant literature. Teaching parents how to communicate about the complex and ever-changing landscape of available substances may be challenging, and the job is complicated by the fact that a one-size-fits-all strategy may not be optimal. After learning the relevant facts, parents will need to modify their communication strategies, depending on the nature of the child, and their relationship with him or her.

To summarize, we have addressed four key parental behaviors shown to be related to adolescent cannabis use. They are: parental use of cannabis, parental warmth and style, parental communication, and, finally, parental monitoring. These behaviors have been shown to influence adolescent norms, attitudes, and intentions regarding cannabis use, and have further been found to yield influence synergistically, with one behavior often facilitating the efficacy of another. So, for parents who are concerned about their children experimenting with drugs, Table 23.2 summarizes "best practices" for how to raise children who remain abstinent from using cannabis.

TABLE 23.2 Best Practices for Raising Drug-Free Children

1. Refrain from using cannabis, or quit if you already do.
2. Adopt an authoritative parenting style.
3. Communicate with your child about the dangers of cannabis.
4. Monitor your children's activities and peer groups, and be aware of potential risk factors associated with cannabis use.

This table lists four of the most established research findings linking parental behavior to adolescent cannabis use. Research suggests that parents who follow these practices in their own behavior and in their interactions with their children will be less likely to have children who use cannabis.

While there is no magic bullet for preventing adolescent cannabis use, these parenting practices collectively represent the clearest evidence we have on how to mitigate the risks that lead to cannabis use in adolescents.

CONCLUSIONS

Parents can play a key role in lowering the risk of their children's illicit substance use. In fulfilling this role, parents need to understand (1) how their behavior affects their children's cannabis use, and (2) how best to communicate with their children about the potential dangers of cannabis. Research examining effective ways to teach parents how and what to communicate to their children about cannabis use may prove important in preventing adolescent substance misuse. It is important to learn which parental variables should be targeted. In addition, there are many more avenues to explore in the field of parental influence than are covered here (suggestions for "Future Directions" are outlined in Table 23.3). Many of

TABLE 23.3 Future Directions in the Field of Parental Influence

- Researchers, in conjunction with policy advisors and governmental agencies, should begin to study the impact of decriminalization and legalization of cannabis laws on adolescents.
- More neurocognitive evidence on the developmental effects of cannabis use during adolescence is needed to better inform parents and children about potential long-term, negative consequences.
- Studies on how to increase parents' perceived behavioral control to talk to their children about cannabis use are needed to better inform antidrug media campaigns, and other interventions focused on the parent.
- Continuing to adapt representative and longitudinal surveys (eg, NSPY) will be necessary to reflect the changing landscape of adolescent drug use.

This table outlines brief suggestions for expanding the knowledge base in the field of child cannabis use. The four points are based on the literature to date, and are responsive to the changing societal norms concerning the legal status of cannabis.

the constructs reviewed here (eg, parental warmth, parental style, family structure, etc.) are of theoretical interest, to be sure, but, more importantly, provide important insights into informational and attitudinal interventions that may lead to positive outcomes.

MINI-DICTIONARY

Attitude The positive, negative, or neutral evaluation of an object, where an "object" can be a person, a thing, or a behavior. Attitudes have the power to influence behavior.

Delinquency Often used in reference to adolescents, delinquency is characterized by antisocial behavior, such as, drug use, school absence (or school dropout), and other illegal or dangerous acts.

Expectancies of use The perceived beliefs surrounding the use of a particular substance, in this case, cannabis. Expectancies can be positive or negative, and will influence the likelihood a person will experiment with cannabis.

Parental monitoring The degree to which a parent has knowledge of their child's activities, whereabouts, and friend groups.

Parental preventative communication The specific conversations that parents have with their children about engaging in risky and/or illegal activities, specifically drug use.

Parental warmth The affection and acceptance shown to a child by the parent. Warmth facilitates trust within the context of the parent–child relationship.

Parenting style The manner in which parents relate to their children with regard to expectations of behavior, communication, and punishment. Parents typically adopt one of four broad categories of parenting style: authoritarian, authoritative, permissive, and uninvolved, with authoritative being the most protective against child substance abuse.

Perceived behavioral control Also known as "self-efficacy," the degree to which people feel they are able to complete a specific task.

Subjective norms Also known as "injunctive norms," subjective norms are the perceived expectations people close to us have for our behavior. For example, if a person's entire family loathes smoking, there is a strong subjective norm for that person to not smoke.

Theory of planned behavior A theory proposed by Icek Ajzen that describes how attitudes, subjective norms, and perceived behavioral control are factors that influence a person's intention to engage in a specific behavior (Ajzen, 1991).

CHAPTER

24

Cannabis Users and Premorbid Intellectual Quotient

L. Ferraro, L. Sideli**, D. La Barbera***

***Biomedical Department of Internal and Specialist Medicine; Department of Experimental Biomedicine and Clinical Neuroscience, School of Medicine, University of Palermo, Palermo, Italy**
****Department of Experimental Biomedicine and Clinical Neuroscience, School of Medicine, University of Palermo, Palermo, Italy**

SUMMARY POINTS

- The chapter focuses on premorbid Intellectual Quotient (IQ) in cannabis users, one of the most controversial topics in studies on the harmful effects of cannabis use on cognition.
- Several studies have ascertained acute and residual effects of cannabis use in the memory domain, but only a minimal general cognitive effect after a long-term period of abstinence.
- A number of longitudinal studies were able to obtain IQ measures before and after cannabis consumption, but they yielded discordant findings.
- Authors, however, observed a relationship between higher premorbid IQ and recreational or discontinued use while a lower premorbid IQ resulted as a predictor for regular or heavy cannabis use.
- Studies on cannabis use and cognitive impairment associated with schizophrenia paradoxically found better IQ among patients with cannabis use lifetime.
- At the end of the chapter, authors proposed a conceptual table to summarize the complex relationship between premorbid IQ and cannabis use in determining different outcomes, by sustaining the hypothesis of a shared genetic-early environment vulnerability to psychosis and cannabis use, which is reflected on premorbid IQ and able to influence the contact with the substance.
- In turn, cannabis may be a trigger for psychosis towards this continuum of neurodevelopmental vulnerability.

KEY FACTS OF IQ

- The Intellectual Quotient (IQ) is a standardized measure, able to estimate the intelligence of an individual starting from the assessment of verbal and not-verbal skills.
- Each person's IQ is compared to a norming sample composed of other people from the same population. The medium IQ is conventionally defined as a score of 100 and the majority of the population belong to an IQ range between 70 and 130.
- IQ scores variance is due to the interaction between genes and environmental factors.

KEY FACTS OF PREMORBID IQ

- Dementia is a well-known cause of the decline from premorbid IQ and other cognitive domains. However, also other factors, such as severe mental illnesses, traumatic brain injuries, brain cancer, stroke and hypoxia may determinate a detrimental effect on premorbid IQ.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00026-0
Copyright © 2017 Elsevier Inc. All rights reserved.

- Two principal ways in which a decline from premorbid IQ could occur were suggested: an alteration in the development of the brain linked to a genetic vulnerability that frequently appears in childhood or in adolescence and an age-related structural and functional degeneration of the brain that may be physiological or pathological.
- Premorbid IQ has been suggested as a good predictor for individuals at risk of developing psychosis and as an important prognostic factor to be taken into account.

INTRODUCTION

The harmful effects of cannabis use are a contentious debate topic in research and public health, especially in the context of its legalization and medical use. One of the most widely-studied and critical points of this issue concerns neuropsychological-specific and global impairment, that is, the impact of cannabis use on individual psychological functions (memory, attention, executive functions), and its effects on the general intellectual quotient (IQ). High efficiency, speed, and multitasking capacities are in great demand in today's world, and detrimental effects on brain functions have been identified as risk factors for different psychiatric (Bora, Yücel, & Pantelis, 2010; Hatch et al., 2007) and medical illnesses (Calvin et al., 2011). These considerations augment the significance and urgency surrounding the study of the problem, since cannabis is one of the commonly-used illegal drugs, and the rates have increased in the last few years (SAMHSA, 2013). The National Survey on Drug Use and Health has identified cannabis as the leading drug associated with the initiation of illecit-drug use (SAMHSA, 2013). It also estimates that about 2.4 million people aged 12 or older had started using cannabis by 2012, and 5.4 million use marijuana on a daily basis (SAMHSA, 2013). All this data suggests that there is a significant proportion of very young people at risk, during this most critical period of brain maturation. While several studies report an acute adverse effect of cannabis on cognition, with obvious consequences on personal and public health (Asbridge, Hayden, & Cartwright, 2012; Kalant, 2004), the long-term effects of cannabis are still unclear (Grant et al., 2003; Schreiner & Dunn, 2012). This state of uncertainty is mostly attributed to the difficulty in controlling for relevant variables—first of all, premorbid cognition—in naturalistic designs, thus preventing the drawing of firm conclusions about the casual direction of positive results. To further complicate the matter, studies on cannabis use and cognitive impairment associated with schizophrenia have yielded controversial results (Yücel et al., 2012; Potvin, Joyal, Pelletier & Stip, 2008; Rabin, Zakzanis, Daskalakis, & George, 2011). These considerations lead to the conclusion that premorbid conditions are the most appropriate indicator in determining the observed effects of cannabis on cognition among clinical and nonclinical samples.

CANNABIS AND COGNITION: APPROACHING THE "PRE" PROBLEM

The association between cannabis use and cognitive performance has been fully-studied. Table 24.1 shows a nonexhaustive summary of the principal reviews on this subject, with the authors' conclusions. It started from 1995, when Pope, Gruber, and Yurgelun-Todd (1995) first tried to distinguish between the acute and residual effects of cannabis in individuals without any psychiatric disorders.

Even differences between heavy users and controls had very modest results, or were absent in this study (Pope et al., 1995), so the authors argued that it would be very important to try to exclude the virtual continuous effect of acute intoxication, and the confounding effect of withdrawal syndrome. With this consideration in mind, they later tried to define the neurotoxicity of cannabis as its long-term residual effect lasting after 28 days of abstinence and tested people who had used cannabis on an almost daily basis (Pope, Gruber, & Yurgelun-Todd, 2001a; Pope et al., 2001b; Pope, Gruber, Hudson, Huestis, & Yurgelun-Todd, 2002). Their results suggested deficits in memory and attention present for days after discontinuing use, but mainly reversible after 4–5 weeks (Pope et al., 2001a), regardless of the cumulative amount of lifetime cannabis use (Pope et al., 2002). Gonzalez et al. (2002) examined the methodology adopted in the previous literature on the basis of the correspondence to a priori criteria, and their results were consistent with those from Pope and coworkers. Despite methodological rigor, very few studies among those considered assessed premorbid neuropsychological abilities, and they, usually, looked at vocabulary or verbal fluency tests (Table 24.2). The same group performed a metaanalysis in 2003 (Grant et al., 2003) by including 1014 subjects, and the average global neurocognitive effect was small, and was expressly observed in memory and forgetting/retrieval tests.

TABLE 24.1 Reviews and Metaanalysis on Cannabis and Cognition

Authors	Study type	Number of studies included (years of publication)	Cannabis effect targeted	Impaired domains
Pope, Gruber, and Yurgelun-Todd (1995)	Review	42 (1972–93)	RE = 12–24 HA LTE > 24 HA	RE: attention, psychomotor tasks, short-term memory LTE: minimal
Pope, Gruber, Hudson, Huestis, and Yurgelun-Todd (2001b)	Review	8 (1996–2001) RE 7 (1989–2000) LTE	RE < 28 DA LTE > 28 DA	RE: memory and selective attention LTE: minimal
Gonzalez, Carey, and Grant (2002)	Review	40 (1973–2002)	RE > 24 HA	RE: attention and working memory

Solowij and Pesa (2010)	Review	116 (2000–2010)	AE ≤ 24 HA RE = 24 HA-28 DA	AE and RE: attention, inhibition, verbal memory and other memory processes
Crean, Crane, and Mason (2011)	Review	12 (1970–2009) AE; 14 (1995–2010) RE; 11 (1995–2006) LTE	AE ≤ 6 HA RE = 7–20 DA LTE > 21 DA	AE: working memory, attention and inhibition RE: decision making and risk taking LTE: none
Schreiner and Dunn (2012)	Metaanalysis	33 (2000–2011) RE; 13 of them on LTE	RE > 4 HA LTE > 25 DA	RE: global performance, most cognitive domains LTE: none
Crane, Schuster, Fusar-Poli, and Gonzalez (2013)	Review	34 (2007–2012) AE; 61 (2007–2012) RE	AE < 8 HA RE > 8 HA	AE: learning and memory, attention, concentration and working memory RE: episodic memory, attention, concentration, risk taking and decision making

The table presents a summary of the principal reviews about cannabis use, and acute, residual, and long-term effects on cognition with authors' findings.
Abbreviations: AE, acute effect; RE, residual effect; LTE, long-term effect; HA, hours of abstinence; DA, days of abstinence.

A small effect has also been observed by Gonzalez (2007) in frequent and heavy cannabis users, and this was not necessarily matched with changes in brain functioning. However, results from Gonzalez and Grant's group appear not to be able to overcome the question about long-term neurotoxicity, given that most of the cannabis users included in their studies had been abstinent for a maximum of 2 weeks. In fact, in a recent update of Grant's work, published by Schreiner and Dunn (2012), most of the cognitive domains assessed, as well as the overall performance, resulted significantly impaired when subjects were tested within the first 25 days of abstinence, but not after. This study indicated a small negative residual effect, and no lasting effects on neuropsychological performance, regardless of the duration of use.

Besides the amount of cannabis used and abstinence length, another crucial point, when considering the harmful effects of cannabis on cognition, is the age of first cannabis use. Jacobus et al. (2009) addressed this point in a review, and concluded that adolescents who use marijuana heavily tend to show disadvantages in attention, processing speed, verbal learning, and memory that persist beyond 1 month of abstinence, but largely remit after 3 months of sustained abstinence. Once again, without any measure of premorbid IQ, it is difficult to establish whether a causal direction exists between cannabis use and cognition.

Di Forti, Morrison, Butt, and Murray (2007) addressed "the chicken or the egg" question by claiming the role of an earlier age of onset in using cannabis as a determinant in the detrimental effect of the substance on cognition and hypothesizing a gene–environment pattern of common vulnerability to cannabis effect and psychosis, where neuropsychological deficits underlay a profile of people at-risk to develop psychosis without the need for the additional risk factor of cannabis use. Other reviews have ascertained impairment in memory during the acute phase (Ranganathan & D'Souza, 2006), and in the long-term (Solowij & Battisti, 2008), together with attention and inhibition, depending on duration, frequency, dose, and onset of cannabis use in adolescence (Solowij & Pesa, 2010). Schoeler and Bhattacharyya (2013) have recently highlighted the role of the mix of different cannabinoids present in the cannabis used on cognition. Other executive functions have received more attention in recent years (Crane et al., 2013; Crean et al., 2011) as is shown in Fig. 24.1.

Most of the reviews concentrate on residual and long-term effects. Residual effects are the most-represented

TABLE 24.2 Instruments for Assessing Premorbid IQ

Type of test	Examples	Task	Strengths and limitations
Verbal subtests of the Wechsler Adult Intelligence Scale (WAIS)[a]	• Vocabulary	To provide the definition of a list of increasingly difficult words	They are considered less sensitive to the impact of age and various forms of brain damage. However, they are strongly affected by the integrity of long-term memory, and might be poorly reliable in individuals with impaired memory
	• Information	To answer a list of questions regarding general culture (ie, in what continent is Argentina?)	
Verbal fluency	• Controlled Oral Word Association Test (COWAT) from the Halstead-Reitan neuropsychological test battery[b]	To generate as many words as he/she can, beginning with a particular letter (ie, F, A, and S) or belonging to a particular semantic category (ie, animals) within a limited time	They depend on the ability to retrieve and organize information of the semantic memory, considered the most resistant memory register. However, reduced speed and a deficit in verbal memory could compromise the test
Reading test	• Wechsler Test for Adult Reading, WTAR[c] • National Adult Reading Test, NART[d]	To read aloud a list of irregularly spelled words (whose transcriptions do not correspond to their pronunciation)	Since general spelling rules cannot be applied to irregular words, the correct pronunciation mainly relies on remote simple learning of vocabulary. However, they are not available for nonirregular languages

The table provides a critical summary of the principal instruments used to assess premorbid IQ in cannabis studies. Abbreviation: IQ: intellectual quotient.

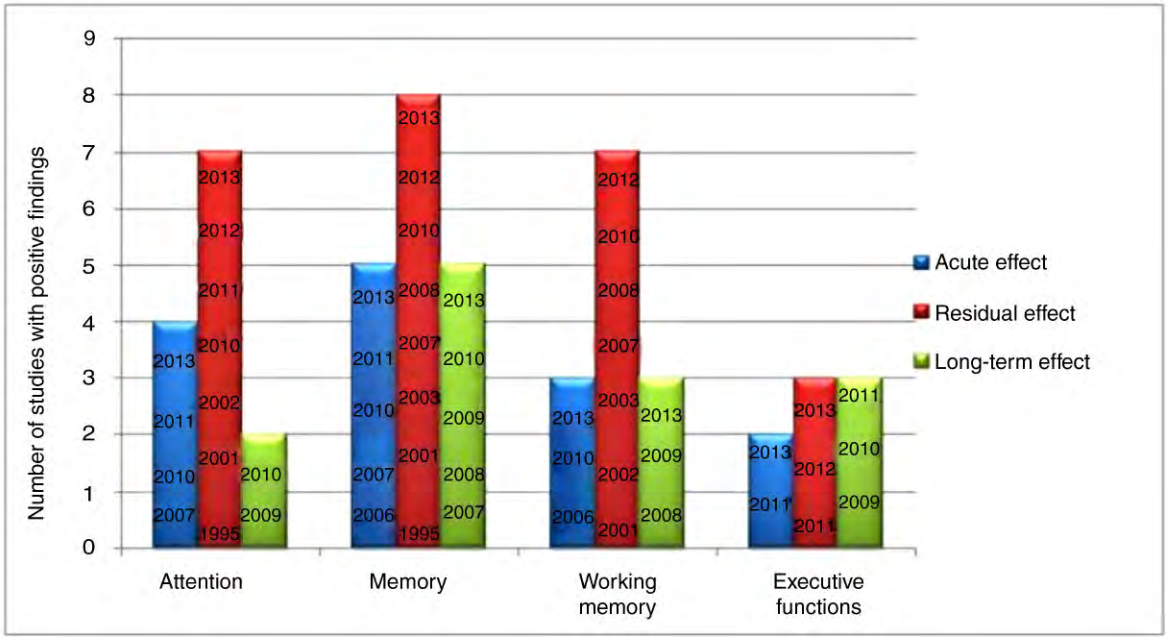

FIGURE 24.1 **Cannabis use and cognitive functioning.** This histogram provides an overview of the main findings on cannabis use and cognition mentioned in this chapter. Cognitive functions are on the *x*-axis, and the number of studies with positive findings on deterioration for each domain, divided according to acute effect, residual effect, and long-term effect, are counted on the *y*-axis. Each bar cumulates studies on the field indicated, by referring to their year of publication—from the oldest to the newest. Original material.

findings over the years, especially in the memory domain, and positive results on long-term effects of cannabis probably depend on ameliorated research designs. Very few papers from those mentioned previously considered general IQ as a measure of interest, and generally found a small residual effect on overall impairment, but not after a long-term period of abstinence (Grant et al., 2003; Schreiner & Dunn, 2012).

LONGITUDINAL STUDIES ON PREMORBID IQ: WHICH "PRE" PREDICTS WHAT "POST"

Table 24.2 provides a critical summary of the principal instruments used to assess premorbid IQ in cannabis studies.

Solowij and Battisti (2008) reported three studies showing lower vocabulary scores in cannabis users, compared to controls. Pope et al. (2001b) estimated premorbid IQ by using a vocabulary test which resulted in lower scores among heavy users than controls, additionally attenuating differences in cognitive performance between the two groups, when entered as covariates (Pope et al., 2001b).

Schreiner and Dunn (2012) indicated a similar impairment on overall performance in the verbal/language domain—assessed by vocabulary, verbal fluency, and naming tests—within the first 25 days of abstinence, but not after this period of time. These results suggest that the vocabulary and verbal fluency tests behave more as measures of actual capacities, than as an estimate of premorbid IQ. Longitudinal studies are probably the best way to address this issue, by measuring cognitive performance before and after a period of life in which cannabis is consumed. Otherwise, in the absence of these possibilities, reading tests have been suggested as a better method because they are able to estimate the general ability before eventual impairment, as opposed to other tests (Griffin, Rivera-Mindt, Rankin, Ritchie, & Scott, 2002). Table 24.3 simplifies methods and conclusions of the principal longitudinal studies on premorbid IQ and cannabis use.

In the early 1980s, Kellam, Ensminger, and Simon (1980) tested a large cohort of African-American adolescents from Woodlawn, an urban, poor community on the South Side of Chicago, at their first degree school, and retested them 10 years later, by revealing that people with higher IQ, social adaptive capacities, and readiness-for-school scores were more likely to use cannabis in their teenage years. Fleming et al. (1982) later revealed on the same population that boys with higher IQ and readiness-for-school tended to initiate substance use at an earlier age, and girls who were rated as shy or having learning problems tended to initiate use at a later age. Ensminger, Juon, and Fothergill (2002) reinterviewed 952 subjects from this original cohort at age 32, and showed that males having superior IQ scores in childhood were more likely to initiate cannabis use in adolescence, but were also more likely to discontinue this behavior as young adults, while to be shy and aggressive was a risk factor for becoming a persistent cannabis user as an adult.

Fried and coworkers (Fried, Watkinson, & Gray, 2005; Fried, Watkinson, James, & Gray, 2002) had the opportunity to follow-up on a group of young subjects, as part of the Ottawa Prenatal Prospective Study, and assessed their IQ before, during, and after cessation of regular marijuana use. Young adults with heavy actual or former use started with a lower IQ, compared to nonusers and light users, but only actual heavy use was related to a lower IQ, when compared to the other groups. However, similar deficits were no longer apparent 3 months after cessation of regular use. Opposite findings were derived from two different British cohort studies by White and coworkers (White, Gale, & Batty, 2012a). They found that a higher childhood IQ is related to an increased risk of illegal drug use in adolescence and adulthood, even when correcting for material disadvantage, antisocial behavior, social distress, and anxiety. However, the same group (White, Mortensen, & Batty, 2012b) found out the opposite result on a group of males US Vietnam veterans with IQ assessed at the time of the military service enrollment. That is, subjects with higher IQ scores had a lower probability to be habitual users of cannabis, during active service and in civilian life, with a moderating effect of socioeconomic status in adulthood.

Meier et al. (2012) had recently published a paper where people from the Dunedin Cohort Study were followed-up from childhood to the age of 38. Subjects with more persistent cannabis dependence (that had started in adolescence) presented greater IQ decline, not specific to any domains, when compared to study members who never used cannabis. This latter group experienced only a slight increase in IQ. Results stayed significant after ruling out possible confounders, such as, education, diagnosis of schizophrenia, other drug dependence, and past-week cannabis consumption. Interestingly, people who reported a lifetime recreational use of cannabis, but not dependence, started with a higher IQ than people that never used cannabis. These two groups had similar IQ levels at the age of 38. However, the authors did not test the study subjects after a period of abstinence of at least 4 weeks. Therefore, their findings are likely to be more reliable for the residual effect of cannabis, than the long-term effect. This study has raised a debate surrounding other potential confounders of the results. For example, Rogeberg (2013a) argues that socioeconomic status alone can potentially explain the IQ decline observed by Meier et al. (2012), and recalls the Flynn–Dickens model of IQ (Dickens & Flynn, 2001) that emphasizes a two-way causality between IQ and environment, with both a direct influence on IQ from the genotype, and the opposite. That is because people with

TABLE 24.3 Longitudinal Studies on Premorbid IQ and Cannabis Use

Authors	Study	Number of subjects	Pattern of cannabis use as described by authors	Measures (age in years in which measures are taken)	Conclusions

f) White and Batty (2011)	1970 British Cohort Study—UK	7,946	Occasional	IQ (5; 10)	High childhood IQ increases the risk of use in adolescence and adulthood, especially in women
g) White et al. (2012a)	1958 National Child Development Survey—UK	6,713	Recreational	IQ (11; 42)	Use in middle age is more probable in children with a greater IQ, especially women
h) White et al. (2012b)	Vietnam Experience Study—USA	14,362	Habitual	IQ (22; 40)	Subjects with higher IQ at 22 are less likely to be habitual users, during active service and in civilian life. This association is attenuated by confounding variables
i) Meier et al. (2012)	Dunedin Cohort Study—New Zealand	1,037	Persistent	IQ (7–13; 38)	A drop from childhood to adult average full-scale IQ especially in adolescent-onset users

In this table is offered an overview of longitudinal studies that expressly assess IQ before and after cannabis use. Abbreviation: IQ, intellectual quotient.

a higher IQ tend to be involved into more cognitively challenging environments that further increase IQ. Daly (2013) intervenes in the debate saying that the personality trait of "conscientiousness" may be protective for the same people. The cut and thrust of this discussion is in two successive letters in the same volume of the Proceedings of the National Academy of Science (Moffit, Meier, Caspi, & Poulton, 2013; Rogeberg, 2013b). In conclusion, all these discordant findings show that IQ is not only a complex proxy for cognitive functions, but also one for social adaptation, environmental factors, and genes. It is far from exhaustive of, or independent from, these other measures, and is determined by a consensus on conventional and standardized elements. Interestingly, all these studies present a point of consistency, as indicated in Fig. 24.2. That is, the relationship between higher premorbid IQ and recreational or discontinued use, while a lower premorbid IQ results as a predictor for regular or heavy cannabis use.

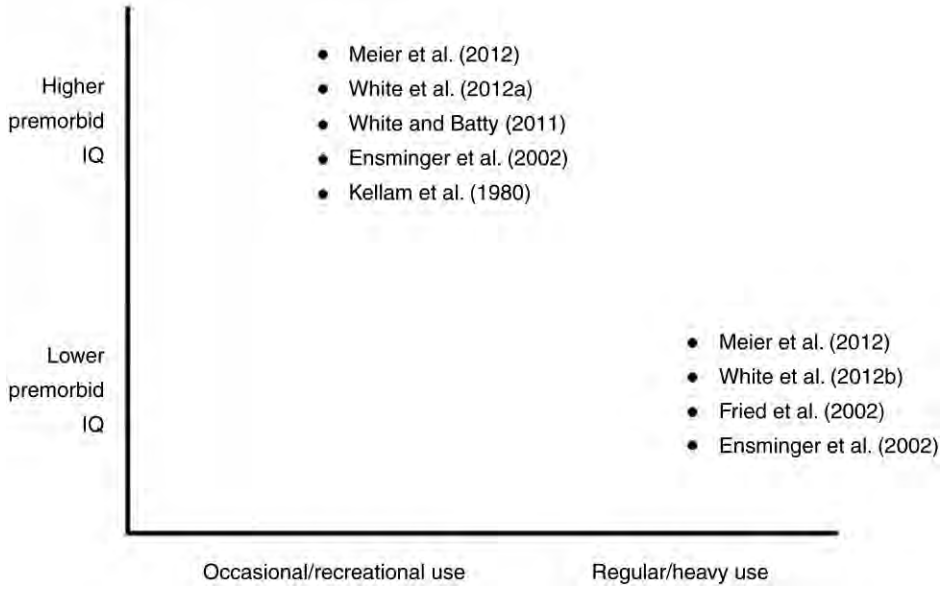

FIGURE 24.2 **Premorbid IQ and cannabis: main findings from longitudinal studies.** This graph provides a simplification of the results of longitudinal studies on premorbid IQ, categorized into "higher" and "lower" on the *y*-axis, and differentiated by patterns of cannabis use, recreational versus regular use, in the *x*-axis.

CANNABIS AND PREMORBID IQ: WHAT'S THE REAL RISK?

When looking at the previously mentioned studies, it seems less likely that cannabis use influences IQ, and more likely that premorbid IQ is linked to cannabis use, toward complex mechanisms. Nevertheless, it is very difficult to believe that a psychotropic substance acting on important neurotransmitters such as acetylcholine, dopamine, GABA, glutamate, serotonin (Grotenhermen, 2004), does not have neuropsychological effects at all, in the long run. It was suggested that its effects are so subtle that they are difficult to detect (Gonzalez, 2007), otherwise cannabis may be relatively innocuous for most people, but quite toxic for the occasional individual (Pope et al., 2001b), depending on dose, type of cannabis used, age of onset (Solowij & Pesa, 2010), and gender (Crane et al., 2013). Cannabis use has been ascertained as a risk factor for the development of psychosis (Moore et al., 2007; Potvin & Amar, 2008), and may lead to an earlier age of onset of the illness, especially if cannabis use starts in early adolescence, with a pattern of daily use of high potency cannabis (Di Forti et al., 2014). Surprisingly, three different metaanalyses on neurocognition and cannabis among schizophrenic patients found better cognitive performance among patients with a lifetime use of cannabis (Potvin, Joyal, Pelletier, & Stip, 2008; Rabin et al., 2011; Yücel et al., 2012). This counterintuitive finding, coupled with the fact that most psychotic patients suffer from cognitive impairment (Reichenberg et al., 2009) make it more difficult to understand the mismatch between this two risk factors.

In a recent study, our group (Ferraro et al., 2013) found strong evidence for a better premorbid IQ, and a minor deterioration (difference between IQ and premorbid IQ) in FEP patients who referred to have used cannabis in their lifetime. Such differences were not witnessed among controls, with a significant interaction between group and cannabis use. Cases of our group were more likely to have preferred skunk, and to have smoked on a daily basis, than controls so we suggested that the better cognitive performance of FEP patients who had used cannabis, compared with those who had not, was due to the better premorbid IQ of the former. Moreover, psychotic cannabis users reported a social use of cannabis in similar proportions to those in controls (69%). Thus, these findings are compatible with the view that, among psychotic patients, those who used cannabis were less neurodevelopmentally impaired than those who did not, and their better premorbid cognition was likely to have facilitated their use of the drug in a typical recreational way, sharing it with their friends (Ferraro et al., 2013).

Data observation suggests that cannabis is a dangerous substance because, while studies on animal models could precisely measure the proportion between tetrahydrocannabinol (THC) and cannabidiol (CBD), the types of cannabis that are encountered by real-world users have a wide range of THC:CBD ratios (see also Niesink & van Laar, 2013). Also, healthy people who smoke higher THC concentration cannabis are more likely to develop psychosis-like symptoms (such as paranoia) (Morgan & Curran, 2008), even with a recreational pattern of use (Morgan et al., 2012). Among the tiny percentage of smokers

who develop psychosis, the preferred variety used is skunk (Di Forti et al., 2009), which has a relatively high concentration of THC. Therefore, there is not enough evidence to sustain the possibility that paradoxical effects of recreational cannabis use frequently observed in naturalistic studies with psychotic patients are derived from a neuroprotective action of CBD on the brain.

So, what about premorbid IQ and cannabis use? What is the real risk that people who smoke cannabis are facing? In Fig. 24.3, the authors speculated about a possible

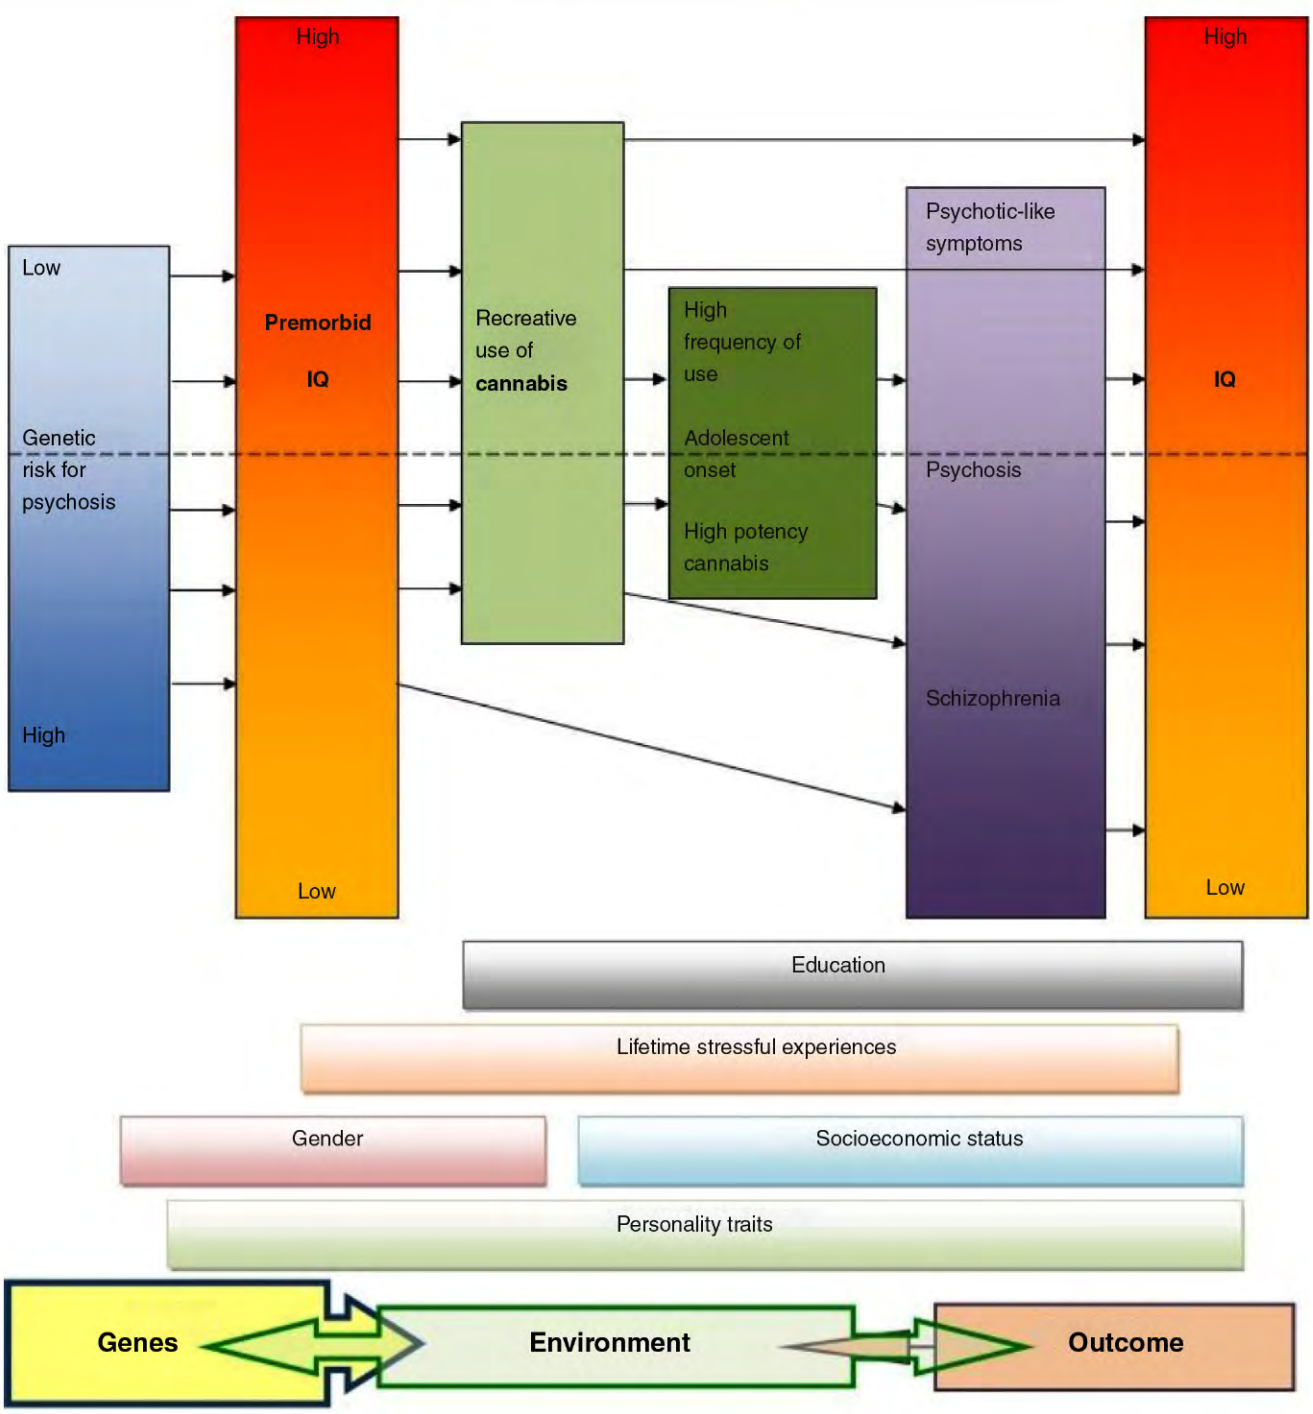

FIGURE 24.3 A possible explanation of the link between premorbid IQ, cannabis use, and psychosis. This conceptual table proposes a shared genetic vulnerability to psychosis and cannabis use that may cause psychotic-like symptoms in healthy people, or may be a trigger for psychosis in people predisposed—toward different pattern of cannabis use—on a continuum of vulnerability that involves premorbid IQ, and is reflected in actual IQ. Education, socioeconomic status, gender, and personality traits are shown as examples of moderator factors. The lower part of the figure indicates the main fields where each factor belongs.

explanation of the link between premorbid IQ, cannabis use, and the risk of psychosis.

A pattern of genetic-early environment vulnerability to psychosis could predispose subjects to cannabis use, as was suggested in a very recent study on 2082 healthy individuals, conducted by Power et al. (2014). THC may, in turn, cause psychotic-like symptoms in healthy people with some predisposition to psychosis, even if consumed in a recreational way (Morgan et al., 2012; Sideli et al., 2015). This pattern of common vulnerability could explain why cannabis users are impaired in many of the same type of cognitive tests in which people with schizophrenia are impaired (Solowij & Michie, 2007).

Going down toward the continuum, the greater the predisposition to psychosis, the stronger is the association with lower premorbid IQ. This relationship operates across the entire range of intellectual abilities, in a progression of neurodevelopmental risk (Khandaker, Barnett, White, & Jones, 2011). However, only people near to a normal premorbid IQ range (ie, lower limit of normality, 90–100) have the opportunity to stay in contact with the illegal substance, sharing it with friends (Ferraro et al., 2013) and *this* constitutes an additional risk factor for cannabis use, among patients and healthy people. *This*, coupled with a pattern that usually presents a high risk (ie, frequent use, onset of use in adolescence, preference for cannabis with high TCH concentration), but that could be harmful even in a recreational way, falling down the continuum of the neurodevelopmental impairment, perhaps because it encounters a major sensitiveness to the THC effect (Verdejo-Garcia et al., 2013). Even more neurodevelopmentally compromised individuals could develop psychosis, without the need for the additional risk factor of cannabis use (Di Forti et al., 2007), and they could also have major cognitive deterioration at their first episode because they have less cognitive reserve (Leeson, Harrison, Ron, Barnes, & Joyce, 2012). As already mentioned, other factors can moderate (and can be influenced by) the contact with an illegal substance and the outcome, in different complex ways. For example, gender, personality traits, education, and lifetime stressful experiences, including childhood trauma (Sideli et al., 2015) could play a role. However, the authors only have at their disposal the previous literature, and a point of view from which to generate this streamlined model, and they are aware that further investigation is needed in order to understand this complex mechanism.

CONCLUSIONS

Cognitive abilities of subjects who smoked cannabis are reliable only if assessed after a prolonged time of abstinence. Eventual long-term impairment observed after this period could reflect the consequence of a complex premorbid gene—early environmental predisposition. This predisposition can influence the contact with the substance, and a particular pattern of cannabis use, moderated by other environmental factors. This could be true even for clinical samples since, according to the neurodevelopmental theory of schizophrenia (Murray & Lewis, 1987), the neurocognitive impairment in psychosis remains stable after the onset of the illness (Bora & Murray, 2014). Moreover, cannabis use could be a trigger for a neurodevelopmental predisposition.

So, is cannabis safe? The answer is no. Since we do not know which special premorbid cocktail was prepared for us, cannabis could act like a "Russian roulette" placed against the brain: the more you play, the higher is the risk you are taking but, sometimes, a single game could be enough.

MINI-DICTIONARY

Acute cannabis effects Effects measured within 24 h from cannabis administration.
First episode of psychosis (FEP) An individual affected by a psychotic disorder (schizophrenia, major depression or bipolar I disorder with psychotic features) presenting for the first time to mental health services to receive medical treatment.
Intellectual quotient (IQ) An estimate of general intellectual functioning of an individual, including both verbal and practical skills. It is, usually, assessed using multidimensional tests and by comparing the individual's performance with those of the people of similar age and gender in a determinate population.
Literature review and meta-analysis A critical summary of the literature that discusses a particular research question, which may include a quantitative estimation of the evidence of interest (metaanalysis).
Long-term cannabis effect Effects lasting after at least 28 days of cannabis abstinence.
Longitudinal/prospective study A study designed to compare repeated observations of the same individuals collected at different time-points, that is before and after the exposure to a risk factor or the administration of a treatment.
Neurodevelopment impairment A pathological alteration of the primary brain function (attention, memory, learning, language, and emotion) that arises in childhood as consequence of genetic and environmental exposures.
Premorbid IQ An estimate of general intellectual functioning of an individual before the occurrence of any event potentially detrimental for his mental health, such as the onset of a mental disorder or the use of any psychoactive substance.
Residual cannabis effect Effects lasting beyond the first 24 and up to 28 days after the last cannabis administration.
Schizophrenia A severe mental disorder characterized by delusions, hallucinations, and disorganized language and behavior.

SUMMARY POINTS

- This chapter presents insight on epidemiological studies, techniques, and rationale for laboratory testing, and the legislation regarding driving under the influence of cannabis.
- Cannabis was the most common illicit drug found on the three largest roadside surveys that objectively evaluated the presence of cannabis, and used probability samples.
- The prevalence of cannabis among injured drivers varies widely, based on geographic region and epidemiological methods, but most studies have found that cannabis use is higher among men and young adults.
- A metaanalysis estimated that driving under the influence of cannabis increased the risk of fatal crashes.
- Different toxicological methods used to detect cannabis, and the interpretations of their results, are a challenge on the comparison of epidemiological findings.
- Whole blood sampling is still the most effective way to confirm the presence of tetrahydrocannabinol (THC) in the body, although the most accessible matrix for the roadside detection is oral fluid.
- The combination of immunological methods with GC/MS, LC-MS/MS, or both, seems to be the best approach for toxicological analysis.
- The laws that regulate driving under the influence of illegal drugs also regulate driving under the influence of cannabis.
- Most countries that have drug driving legislation apply zero-tolerance laws, with regard to illegal substances.

KEY FACTS

- Cannabis is the most frequent illicit drug detected among drivers.
- The prevalence of driving under the influence of cannabis ranged from 0.6% to 6.5%, but data are not entirely comparable across studies, given the methodological differences among them.
- Driving under the influence of cannabis increased the risk of fatal crashes (OR = 2.10; 95% CIs = 1.31–3.36) (Asbridge et al., 2012).
- Punishments vary, given the country in European Union, but may include suspended licenses, fines, and prison sentences (EMCDDA, 2014).

TAs Traffic accidents
THC Δ^9-Tetrahydrocannabinol
WHO World Health Organization

INTRODUCTION

Traffic accidents (TAs) are a public health problem, and the World Health Organization (WHO) estimates that they are the cause of 1.24 million fatalities worldwide each year (WHO, 2013). Certain risk factors have been well established for TAs, and these factors can be categorized as environmental, vehicular, or individual. For example, environmental risk factors include city infrastructures, climate conditions, and legislation. Vehicular risk factors include vehicular conditions, and the presence of safety equipment, such as seat belts, and air bags. Individual risk factors include driver sex and age, as well as driving experience, driving behavior, and the use of alcohol, drugs, or both. Approximately 90% of all TAs are related to individual risk factors. The use of alcohol has been associated with an increased likelihood of crashes since the 1960s (Borkenstein, Crowther, Shumate, Ziel, & Zylman, 1974; Compton et al., 2002), and, as scientific evidence has increased, the laws that restrict the use of alcohol prior to driving have also increased. According to the Global Status Report on Road Safety, 89% of the world's countries (comprising 66% of the world's population) have laws that restrict drinking and driving (WHO, 2013). This legislation and its enforcement have contributed to the decrease in the number of TAs within many high-income countries, over recent decades (Fell & Voas, 2006).

Evidence regarding how drugs other than alcohol affect driving and TAs has accrued more recently. In 2004, a comprehensive review of the scientific literature showed that few data were being obtained with regard to the prevalence of drug-influenced driving among the general population because most studies have addressed injured or deceased drivers (Kelly, Darke, & Ross, 2004). These authors also highlighted that the distribution of drugs found among injured drivers typically follows the distribution found in the general population; thus, cannabis is one of the most frequent illicit drugs detected among drivers because it is the most frequently consumed illicit substance in many countries (UNODC, 2013). More recently, Hartman and Huestis (2013) reviewed epidemiological, culpability, and experimental studies over the last two decades, and noted that most studies found a positive association between cannabis use and TAs. The authors highlighted the importance of toxicological techniques, since most studies that did not found association have used self-reports or urine samples to detect drug use.

Furthermore, experimental studies have demonstrated that cannabis use affects many driving skills, including reaction time, divided attention, and lane position. Different designs can be used to assess the effects of cannabis on driving, and its consequences for TAs. In 2008, a panel of experts proposed a set of guidelines for research on driving under the influence of drugs (Walsh, Verstraete, Huestis, & Mørland, 2008). These guidelines provide recommendations in three major areas of knowledge: behavioral, epidemiological, and toxicological, and were a landmark for research on driving under the influence of drugs. Given that the present book has a specific chapter about the effects of cannabis on behavior and the ability to drive, addressed via experimental studies, this chapter focuses on the epidemiological studies that were conducted in order to evaluate the association between cannabis use and TAs, the techniques and rationale for laboratory testing, and the legislation regarding driving under the influence of cannabis.

EPIDEMIOLOGY OF DRIVING UNDER THE INFLUENCE OF CANNABIS

This section discusses the three major types of observational studies that have been conducted to evaluate the association between cannabis and TAs: roadside surveys, hospital studies, and fatal crash studies (Walsh et al., 2008). These designs answer different research questions, and are important for exploring associations and their magnitudes. In most cases, however, they cannot determine causality due to their cross-sectional and observational natures. The prevalence of cannabis use is typically lower among the general population of drivers (according to roadsides surveys) than among injured or fatally injured drivers (according to hospital and fatal crash studies); furthermore, most case-control studies have found an increased chance of TAs among individuals who drive under the influence of cannabis. Tables 25.1–25.3 provide some examples of studies conducted over the last 10 years. These examples include studies that were published in peer-reviewed journals, employed objective measurements of cannabis use, and provided results for cannabis use alone (ie, rather than cannabis with alcohol, or other drug combinations). In addition, only one study was included per country (generally the most recent), and we searched for at least one study from low- and middle-income countries.

Roadside Surveys

Roadside surveys are an important tool for establishing the prevalence of driving under the influence of drugs within the general population of drivers. This methodology surpasses classic general population surveys because it presents the possibility of an objective

TABLE 25.1 Prevalence of Cannabis and Methods on Selected Roadside Surveys

[a] *Toxicological analysis may be performed using different techniques and cutoffs, irrespectively of the biological matrix.*

onsite measure (as opposed to self-reports), thereby reducing social desirability and recall bias. In addition, roadside surveys restrict their study populations to drivers who are actually on the road, because many people with driver's licenses do not drive, and individuals might drive without a valid driver's license, in countries with lax enforcement. However, roadside surveys are expensive and challenging to execute because they generally require the presence of police officers, and must extensively address ethical issues in order to protect participant privacy. As with any mobile population (Sudman, Sirken, & Cowan, 1988), designing representative probability samples of drivers is not an easy task, but this is a crucial step in study planning, if we are to provide valid estimates for the survey population.

The three largest roadside surveys that objectively evaluated the presence of cannabis among drivers, and that benefited from probabilistic samples, were the DRUID project (http://www.druid-project.eu/Druid/EN/Home/home_node.html), which included more than 50,000 drivers from 13 European countries; the Norwegian roadside survey, which included 10,000 drivers; and the US 2007 National Roadside Survey of Alcohol and Drug Use by Drivers (http://www.nhtsa.gov/Driving+Safety/Research+&+Evaluation/2007+National+Roadside+Survey+of+Alcohol+and+Drug+Use+by+

TABLE 25.2 Selected Hospital Studies Conducted to Evaluate Cannabis Among Traffic Crashes Victims

Drivers), which included approximately 8500 drivers. All of these studies included objective screening of multiple drugs. As expected, the drug use findings followed the patterns of consumption found among the general population. Specifically, cannabis was the most common nonprescribed drug found, and the drivers who tested positive were mostly young men. Table 25.1 provides an example of the methods and results from selected roadside surveys conducted around the world. The prevalence of driving under the influence of cannabis ranged from 0.6% to 6.5%, but these data are not entirely comparable across nations, given the methodological differences among the studies. The most important differences were the days and hours of interviews, as well as the toxicological methods used to establish cannabis use. In fact, although challenges and controversies exist, the detection of cannabis via roadside surveys is one of the greatest advances in the field, which is described in the section "Cannabis Detection and Traffic."

Importantly, some countries (eg, Australia) already test for the presence of drugs in the saliva of drivers, during routine random tests conducted by police. The results of these tests are not comparable with those from roadside surveys, because driver selection is not probabilistic, but they are important as surveillance on the trends of cannabis use among drivers. Davey, Armstrong, and Martin (2014) analyzed a dataset from the Queensland Roadside Drug-testing Program, since its implementation (from 2007 to 2012; more than 80,000 samples). They found that cannabis, after methamphetamine, was the most common illicit drug found among drivers. Because THC is the most commonly consumed illicit drug in Australia, these authors argued that their findings might have been related to differences in the detection windows for cannabis and methamphetamine.

Hospital Studies

The literature investigating the effects of substance use among individuals in emergency settings is older than roadside surveys, but challenges remain with regard to ethical issues (see Goldim, Fernandes, & Pechansky, 2011 for a review). Hospital studies are important to determine the prevalence of cannabis use among injured drivers. These studies might also be designed as case-control studies and, therefore, estimate the likelihood of TAs among drivers under the influence of cannabis, compared with drug-free drivers. In addition, they can also explore the associations between cannabis use and injury severity (from progression to death), and its economic costs.

The prevalence of cannabis use among injured drivers varies widely, based on geographic region and epidemiological methods, but most results indicate that cannabis use is higher among men and young adults (compared with women and older drivers, respectively). Most case-control designs have shown that the likelihood of TAs is higher for drivers who used cannabis, compared with nonusers (Table 25.2).

Fatal Crash Studies

Finally, the last type of observational study to be discussed includes the studies that evaluate fatally injured drivers. The prevalence of cannabis among fatally injured drivers is similar to that among those nonfatally injured. The metaanalysis conducted by Asbridge,

Hayden, and Cartwright (2012) revealed that driving under the influence of cannabis increased the risk of fatal crashes (OR = 2.10; 95% CIs = 1.31–3.36), and this effect size was higher than that found with regard to culpability in nonfatal crash studies. Table 25.3 shows some of the results from fatal crash studies. As with roadside surveys and hospital studies, however, these results are not entirely comparable, due to methodological differences.

An important piece of information that can be obtained from this design relates to trends over time, and their associations with availability and legal aspects. For example, Salomonsen-Sautel, Min, Sakai, Thurstone, and Hopfer (2014) performed a time-series analysis comparing the pre- and postcommercialization of medical marijuana in Colorado (United States), between 1994 and 2011. The authors found a significant increase in the prevalence of cannabis among fatally injured drivers (from 4.5% in 1994 to 10% in 2009). Given the possibility of evaluating such outcomes, these types of studies expand beyond drug-influenced driving, and are fundamental to monitor the social harms related to cannabis availability and its legalization.

CANNABIS DETECTION AND TRAFFIC

Epidemiological findings are difficult to compare for many reasons; some of the most important are the different toxicological methods used to detect cannabis, and the interpretation of their results. Delta-9-tetrahydrocannabinol (Δ^9-tetrahydrocannabinol or THC) is the major psychoactive constituent of cannabis, formed from multiple THC acids that are present in *Cannabis sativa* L. in vivo. THC is metabolized via hydroxylation to an active metabolite, 11-hydroxy-THC (11-OH-THC) which, in turn, is oxidized to an inactive 11-nor-9-carboxy-Δ^9-tetrahydrocannabinol (THC-COOH) (Cone & Huestis, 2007).

One of the key issues for toxicologists is to establish the association of cannabis use and the impairment on driving skills. The blood-concentration-time profile of THC shows a dose effect on driving performance; however, it is difficult to establish a relationship between THC blood concentration and impairment, once the cannabinoids possess unconventional pharmacokinetics (Armentano, 2013). Unlike other psychoactive drugs, the peak THC blood levels do not typically correspond with the participants' maximum levels of behavioral impairment. THC shows a counter-clockwise hysteresis; in other words, the effects of the psychoactive substance lag behind those observed at maximal drug concentrations (Gotenhermen, 2003; Hartman & Huestis, 2013).

In general, plasma elimination half-life (t½) is used to estimate how long it takes a drug to leave the body, but the half-life of THC differs for regular versus infrequent users. Thus, the presence of THC, its metabolites, or both, in blood, particularly at low levels, is an inappropriate indicator of impairment. Although high blood concentrations of THC (greater than 5 ng/mL) are indicative of recent use, low concentrations (below 2 ng/mL) do not necessarily suggest that cannabis use has not been recent. Naive or infrequent users of cannabis can be more severely affected at low THC blood concentrations than regular users of the drug (Poulsen, Moar, & Pirie, 2014). In addition, THC is a lipophilic compound that accumulates rapidly in body fat, where it is stored and slowly redistributed throughout the blood. Although occasional consumers of cannabis will likely test negative for the presence of THC in blood, within 12 h following inhalation, THC's lipid solubility can lead to positive test results for residual concentrations of THC, even after several days of abstinence, among certain chronic users. The potential presence of residual, low levels of THC in the blood, combined with the possibility of periodic increases in THC blood levels, absent concomitant use, might confound the ability of toxicologists to interpret whether the presence of THC in one blood sample is evidence of recent cannabis consumption by an occasional consumer, or indicative of past consumption by a more frequent cannabis user (Toennes, Ramaekers, Theunissen, Moeller, & Kauert, 2008).

Another challenge on the driving field is with regard to the choice of biological matrices. Whole blood is the gold standard for threshold setting because it relates best to the scientific evidence on driving impairment. However, THC has a rapid metabolism and, if the time between the traffic stop/accident and blood sampling is delayed, the blood concentration might decrease markedly (based on a THC t½ of 1.5 h). Small amounts of THC, as well as its metabolites, THC-COOH and 11-OH-THC, are typically found in the blood of users, and the detection of both is used to demonstrate cannabis consumption. The detection window for THC is narrow and, as it was mentioned previously, it depends on dosage, and chronic versus occasional use. The 11-OH-THC metabolite is present in the blood at low levels, almost immediately after cannabis inhalation, and possesses a relatively short detection period in blood. Thus, the presence of 11-OH-THC, particularly in substantial quantities, might indicate recent cannabis ingestion, and possible behavioral impairments (Armentano, 2013).

Most studies on the association of cannabis use and TAs that have found no association have used urine as the biological matrix to detect cannabis (Hartma & Huestis, 2013). Drug concentrations in urine are typically not relevant with regard to their effects on driving impairment, and urinary drug concentrations are not generally accepted as indicators of the effects on immediate driving safety. Although urinalyses are advantageous—because they are fairly easy to collect in large volumes, the technology for drug screening is well established,

and numerous studies have described how to interpret these drug findings (Gotenhermen, 2003)—the interpretation of urinalyses on the road safety area is often complex, and show great variability.

The use of oral fluid (of which, saliva is a key constituent) as a matrix for cannabis testing has gained increasing interest because it is easy to obtain, and the advances in technology have enabled the collection of small amounts of oral fluid using commercial devices. In comparison to urine, oral fluid has stronger correlations with blood measures and impairment (Toennes et al., 2008). However, contamination of the buccal cavity is an issue for detecting cannabis use, given the usual administration route of the drug. Following the recent use of cannabis, "shallow deposits" can accumulate in the buccal cavity, producing elevated concentrations in oral fluid, for several hours after ingestion. Unfortunately, cannabinoids do not pass readily from the blood into saliva, and the detection of THC in oral fluid may be attributed to the contamination of the oral cavity following smoking. THC and small amounts of THC-COOH may be found in oral fluid, following the consumption of smoked or orally ingested cannabis. The confirmed presence of both THC and 11-OH-THC in oral fluid is useful to substantiate use (Cone & Huestis, 2007).

In most instances, when one is looking for cannabis in biological specimens, screening tests by immunoassay are employed, or maybe a broad-based screen, such as gas chromatography mass spectrometry (GC/MS). Screening tests must be appropriate, and validated for the type of biological specimens being analyzed. For example, immunoassays used on whole blood must be appropriately validated for that purpose. If the results of preliminary, unconfirmed screening tests are included on the final report, the report must clearly state that the results are unconfirmed. As a general matter of scientific and forensic principle, the detection or initial identification should be confirmed by a second technique, based on a different chemical principle. Where possible, the use of mass spectrometry is recommended as the confirmatory technique, where possible and practical (SOFT/AAFS Forensic Laboratory Guidelines, 2006). A minimum of 5% of negative screening tests should be analyzed by mass spectrometry to evaluate false negative results (Walsh et al., 2008). Gas chromatography coupled to mass spectrometry (GC/MS) is the method of choice to assess cannabinoids. The high performance liquid chromatography coupled to mass detector (LC-MS or LC-MS/MS) makes possible the analysis of acidic and neutral cannabinoids, without requiring any derivatization (protective reactions of polar functional groups) or previous decarboxylation, and allowed the multidrug methods.

The prevalence of cannabis use reported in the literature relies on which cannabis components were analyzed, and whether the results originated from the analysis of blood, oral fluid, or urine via different techniques. Therefore, some variation in the results of different studies is to be expected. In summary, whole blood sampling is the most effective way to confirm the presence of THC in the body because it is most related to the scientific evidence regarding driving performance, given that it is more related to recent use. The most accessible matrix for the roadside detection of drugs is oral fluid because it is easy to obtain. The debate continues with regard to whether oral fluid THC concentrations are correlated with blood THC concentrations and, therefore, an indirect indicator of driving impairment (Wolff & Johnston, 2014). Hence, the choice of fluid for roadside screening is under discussion, and numerous confounds have emerged; more studies are needed to clarify toxicological aspects. The combination of immunological methods with GC/MS, LC-MS/MS, or both, seems to be the best approach for toxicological analysis. The cutoffs applied for each matrix should be carefully evaluated, based on international guidelines.

LEGISLATION

Given the difficulties in establishing impairment on driving skills based on toxicological tests, countries have struggled to enact legislation that regulates driving under the influence of cannabis. Overall, the laws that regulate driving under the influence of illegal drugs also regulate driving under the influence of cannabis. Three approaches to legislation exist, regarding drug-influenced driving: establishing the legally allowed limit, zero-tolerance laws, and impairment laws (EMCDDA, 2012, 2014; Verstraete et al., 2011).

- Establishing a maximum fixed limit for a substance. Most legislation regarding driving under the influence of alcohol establishes the allowable blood alcohol concentration (BAC) under which it is legal to drive. If a driver's BAC is above the legal limit, then he or she is considered as an offender, regardless of whether he or she shows signs of impairment.
- Zero-tolerance laws. These laws are a subgroup of legal limit laws that do not allow any substance concentrations in the blood. That is, any detectable amount of psychoactive substances in the driver's body is a violation of the law.
- Impairment legislation. In these cases, it is necessary to evaluate each case to determine whether an individual's ability to drive is compromised.

Most countries that already have drug-consumption and driving legislation apply zero-tolerance laws with

regard to illegal substances, but the toxicological approach for determining recent use is not always clearly regulated. In the next paragraphs, some examples of countries that have established drug-related driving laws are provided.

Australia

Australia was the first country to routinely assess the use of drugs among drivers. Testing began in Victoria (2003) with the amendment of the Road Safety Act (1986), which implemented random drug screenings, and created new offences for failing or refusing a drug test (Australian Capital Territory, nd; Dixon, 2007; Government of Victoria, 2014). Currently, all states and territories in Australia can legally conduct roadside drug testing. In the Northern Territory, the saliva test can be conducted when a driver is involved in a TA, driving a large vehicle, suspected to be under the influence of alcohol, drugs, or both, or is stopped for a random breath test. All other states and territories can conduct routine drug testing using oral fluid for illegal drugs (Rowden, Mazurski, Withaneachi, & Stevens, 2011; Northern Territory, 2014). Differences exist with regard to the penalties among the states, but they can include disqualification from driving, heavy fines, imprisonment, or some combination therein. Prison sentences can vary from 9 months to 2 years for driving under the influence, depending on whether it is a first, second, or additional offense. Refusing to take the test can also result in any of these penalties (Western Australia, 2014).

Canada

Impaired driving (due to alcohol or other drugs) is an offense under the Criminal Code of Canada, which added more sanctions and mandatory programs to the various highway traffic acts, in most of its provinces and territories (Canadian Center on Substance Abuse, 2013). According to Beirness and Beasley (2010), the Criminal Code of Canada was amended in July 2008 to provide police with the authority to demand that drivers submit to drug impairment testing. It is also an offense to fail or refuse a test of physical coordination (ie, standard field sobriety tests), receive an evaluation that determines a drug influence by a certified drug recognition expert, or refuse to provide samples of breath, blood, urine, or oral fluid for analysis of alcohol and drug content (Minister of Justice of Canada, 2014). The penalties can range from 10 years in prison to lifetime imprisonment, if the impaired driving results in injury or deaths, respectively. The provincial and territorial laws impose immediate short-term license suspensions, and additional sanctions can include license reinstatement fees, mandatory participation in driver rehabilitation programs, and vehicle impoundment (Ministry of Justice of British Columbia, 2014).

European Union

According to the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA, 2012), as well as Verstraete et al. (2011), a variety of legal mechanisms related to drug control and road traffic control laws, drug tolerance levels, and enforcement are used to sanction drug-influenced driving in European countries. Zero-tolerance laws for illicit drugs, such as cannabis were introduced in Belgium, Portugal, and Sweden, in 1999, and in France and Finland in 2003 (EMCDDA, 2007), but many differences exist with regard to how countries manage their legislation and enforcement. In some countries (eg, Finland), drivers with traces of illicit drugs in their systems during sobriety testing can be prosecuted for illicit drug consumption; in other countries (eg, Belgium), specific clauses exist in the road traffic laws that prohibit the results of the tests from being used in other criminal investigations. To detect drug driving, some countries (eg, Belgium, Spain, Estonia, and Denmark) randomly stop drivers to test them, whereas other countries (eg, Germany, Greece, France, and Italy) require that police officers first suspect that the driver is impaired. Punishments vary, given the country, but may include suspended licenses, fines, and prison sentences (EMCDDA, 2014).

United States

In the United States, legislation on driving under the influence of drugs varies by state, but not all states present laws addressing it. On those that present, legislation is mostly zero-tolerance for illicit substances. In California, New York, and Hawaii the law separate the driving under the influence of alcohol, under the influence of a drug, and under the combined influence of alcohol and a drug—as part of their impaired driving stature; other States have training for law enforcement programs that certifies drug recognition experts. According to the Governors Highway Safety Association (2014), the state of Washington has a specific determination on cannabis use: following the state's legalization of marijuana for recreational use, in November 2012, people with a THC blood content of 5 ng/mL or higher cannot drive (Kay & Logan, 2011; Washington State Legislature, 2014). Ohio (Ohio State, 2014) and Nevada defined 2 ng THC/mL as sufficient for impairment, whereas Pennsylvania's health department has a guideline of 5 ng that can be used in driving violation cases. Blood testing by medical professionals is used to identify THC

in Washington drivers, after the police suspect impaired driving. The penalties for drug-influenced driving in the United States differ by state, but can include imprisonment, fines, license suspension, or revocation for up to 3 years.

CONCLUSIONS

This chapter reviewed epidemiological, toxicological, and legal aspects related to the use of cannabis and driving. Most epidemiological studies have found a positive association between cannabis use and TAs. The biological matrices most appropriate for detecting cannabis use, in the context of TAs, are blood (the gold standard) and oral fluid (especially in screenings during roadside surveys). Legislation regarding driving under the influence of drugs has advanced over the last decade. Some important challenges remain in all areas. Finally, we argue that using comparable methodologies is one of the most fundamental issues for continuing with the research agenda in this field.

MINI-DICTIONARY

Biological matrices Fluids or body parts used in laboratory tests to detect diseases or substances.
Delta-9-tetrahydrocannabinol (Δ^9-tetrahydrocannabinol or THC) Principal psychoactive constituent (or cannabinoid) of cannabis.
Gas chromatography mass spectrometry (GC/MS) Analytical method that combines the features of gas-chromatography and mass spectrometry to identify different substances within a test sample.
Hydroxylation Addition or replacement of hydroxyl in a molecule.
11-hydroxy-THC (11-OH-THC) Main active metabolite of THC formed in the body after cannabis consumption.
Immunological methods Biochemical test that measures the presence or concentration of a macromolecule in a solution through the use of an antibody or immunoglobulin.
Liquid chromatography coupled to mass detector (LC-MS or LC-MS/MS) Analytical chemistry technique that combines the physical separation capabilities of liquid chromatography with the mass analysis capabilities of mass spectrometry.
11-nor-9-carboxy-Δ^9-tetrahydrocannabinol (THC-COOH) Metabolite formed in the body by oxidation of the 11-hydroxy-THC.
Screening tests by immunoassay Diagnostic kits aimed the early detection of substances by antibodies.
THC metabolites THC metabolites are the intermediates and products of metabolism of THC.

Cannabis Use in Youth Subcultures

*M. Pawson**, *B.C. Kelly***

***Department of Sociology, The Graduate Center, City University of New York, New York, NY, United States**

****Department of Sociology, Purdue University, West Lafayette, IN, United States**

SUMMARY POINTS

- Cannabis is used widely across many youth cultures.
- Cannabis use is a common and normative behavior within subcultural scenes.
- Subcultural systems influence and inform cannabis consumption practices, and the meanings associated with them.
- The use of blunts has come to be a defining feature of marijuana smoking within the hip-hop subculture, and is laden with specific symbolic meaning.
- Informed by the subculture's ethos of generosity, marijuana sharing practices play an integral role in forming and sustaining a sense of community within the jam band scene.
- The use of marijuana to modulate the effects of club drugs, within the EDM scene, highlights how specific subcultural practices like drug sequencing shape marijuana consumption.

KEY FACTS OF HIP-HOP CULTURE

- Hip-hop emerged in America among Black youth during the 1970s, and flourished during the 1980s.
- The genre is typically performed by MCs rapping over beats-driven music.
- Hip-hop culture grew to encompass other elements of Black American youth culture, including fashion, art, and dance.
- Blunts are the means by which marijuana is commonly smoked within hip-hop subcultures.

KEY FACTS OF JAM BAND CULTURE

- The jam band culture emerged from summer festivals of rock bands, such as, the Grateful Dead.
- The genre currently relies upon live performances involving extended musical improvisations.
- Subcultural participants often traveled to festivals and lived in makeshift communities.
- The jam band subculture is communally oriented.
- The sharing of cannabis is an important means of networking and enhancing solidarity within the jam band scene.

KEY FACTS OF ELECTRONIC DANCE MUSIC CULTURE

- Electronic dance music (EDM) emerged early on in the form of "house" music, and was more widely popularized following the birth of the rave scene in the United Kingdom during the late 1980s.
- The musical genre has spawned many subgenres of EDM, including techno, drum-n-bass, and dubstep.
- Dancing under the influence of drugs became a common, though not universal, routine for rave participants and nightclub attendees.
- Cannabis is often used by members of the EDM scene to influence the effects of other drugs.

LIST OF ABBREVIATIONS

EDM	Electronic dance music
MDMA	The drug methylenedioxymethamphetamine, commonly known as ecstasy

INTRODUCTION

As the most commonly used illicit drug in many Western nations, marijuana has been incorporated into the lifestyles of a wide range of individuals (Hathaway, 1997). Adolescents and young adults are among the largest group of consumers of cannabis; this remains a persistent trend across many countries. The normalization of its use is especially visible within youth subcultures (Parker, Aldridge, & Measham, 1999). This is apparent in the significant cultural accommodations toward the use of marijuana commonly found within particular subcultures, as well as the drug's pervasive availability and relatively high rates of regular recreational use.

Youth cultures are important guiding forces in the lives of many adolescents and young adults. A youth culture is essentially a cluster of young people who share activities, mindsets, tastes, and styles on the basis of their subcultural affiliation. While styles are often the most recognizable facets of these subcultures, they are merely outward representations of the symbolic system of meanings that is inherent within each subculture. In this respect, a youth culture provides a way of thinking about the world for the young people who participate in it. Yet, it also extends beyond mere psychology to the ways in which young people act and interact. The broader cultural framework of a youth culture shapes the ways in which young people who participate in them behave. Importantly, youth cultures function differently and, therefore, establish different patterns of drug use across them, both with respect to the substances used, and the meanings underlying their use (Kelly et al., 2015). Indeed, studies have shown that musical tastes—which often form a basis for youth cultures—and substance use tend to cluster (Vuolo, Uggen, & Lageson, 2013).

Many youth cultures place symbolic value on particular forms of drug use. In this regard, the use of specific substances can act as a social currency in certain subcultures. Additionally, consuming certain drugs in specific ways can shape social bonds within that scene, and influence social status. Marijuana use has been tied to many subcultures rooted in musical genres, including but not limited to reggae, rock, hip-hop, and electronic dance music scenes (Golub, Johnson, & Dunlap, 2006; Hunt, 2012; Pawson & Kelly, 2014; Perrone, 2009; Winders, 1983). Further, research has shown how specific social settings can influence the ways in which cannabis is consumed (Dunlap, Johnson, Benoit, & Sifaneck, 2005). In this regard, subcultural contexts can shape not only the patterns and practices of marijuana consumption, but also the ways in which these consumption practices unfold, as well as the meanings specific subcultures attribute to them.

Although jazz music is highly regarded as a well-established musical genre widely listened to by older adults, it was once itself the basis of a thriving youth culture, many decades ago. Descriptions of marijuana use among jazzmen form the basis of some of the earliest descriptions of drug use within subcultures. The early work of sociologist Howard Becker (Becker, 1953) highlighted the prominent role of marijuana smoking among young jazzmen, which established an early sociological examination of drug use by young people as a form of deviance. These early studies on marijuana-smoking jazzmen continue to have import for the study of drug use among young people. For the remainder of this chapter, we will focus on highlighting three current youth subcultures that prominently embrace the use of marijuana in the 21st century: the hip-hop scene, the jam band scene, and the rave scene. In doing so, we will describe the various ways in which the specific subcultural norms and values embodied within these different scenes influence and inform distinct marijuana consumption practices.

Similar to other youth subcultures, the hip-hop, jam band, and rave scenes revolve around particular tastes in music, as well as fashion. Youth cultures as nightlife scenes provide sources of entertainment and leisure activity for young adults, and substance use, whether legal or illegal, is relatively commonplace within these scenes. The use of marijuana holds particular symbolic value within hip-hop, jam band, and rave scenes, despite the fact that the subcultures surrounding these three nightlife scenes are quite distinct. The meanings underlying the shared practice of marijuana consumption can differ quite markedly across subcultures (Pawson & Kelly, 2014).

Below, we will describe the meanings and practice of cannabis use within each of these three subcultures. First, we will begin with a discussion of the historical and contextual significance of marijuana use within the hip-hop scene. We will also provide a descriptive account of the symbolic significance of smoking marijuana in the form of blunts within the hip-hop subculture. Next, we will turn to covering marijuana's entrenchment within the jam band subculture, as we highlight the key role that marijuana use plays in forming and sustaining a sense of community within the scene. Finally, we take a look at the rave scene (and the wider electronic dance music culture that grew out of it), and the ways in which marijuana is used along with popular club drugs like MDMA.

HIP-HOP

Hip-hop emerged as a new music genre during the 1970s, as deejays began to sample, mix, and scratch records to create extended breakbeats at dance parties in the South Bronx (Fricke & Ahearn, 2002). Emceeing soon

followed, as party promoters and hosts began to talk or rap over the records being played. Call and response chants were used to involve the audience in the music, and MC's would also showcase their rhyming abilities as they "battled" one another as a way to gain status within the scene (Chang, 2007).

Throughout the last several decades, hip-hop has become much more than just a new form of music, as those associated with it have developed their own unique subculture with particular forms of fashion, language, and activities being distinctly attributed to, and associated with, the hip-hop music scene (Blair, 1993; Chang, 2007; Fricke & Ahearn, 2002). Marijuana's pervasive presence within the hip-hop scene dates back several decades, and its use is considered to be a normalized aspect of the subculture.

As hip-hop music and culture flourished throughout the late 1980s and early 1990s, an inner city cultural backlash to the crack epidemic of the 1980s and heroin epidemics of the 1970s led to a decline in hard drug use, especially among young adults (Golub et al., 2006). As such, the denigration of hard drug use by inner city youth precipitated the increasing popularity of marijuana use, and its status as the drug of choice among members of the hip-hop scene (Allen, 1996; Golub et al., 2006). This affinity for smoking marijuana within the hip-hop scene is highlighted by the development of subculturally specific consumption practices and discourse. More specifically, the use of blunts, which is marijuana rolled up in cheap cigar shells, became entrenched within the cultural repertoire of the hip-hop subculture (Golub et al., 2006; Timberlake, 2009). It has come to be a defining feature of marijuana smoking in hip-hop scenes.

Blunts emerged as a nuanced form of marijuana consumption in the mid-1980s, and has its origins in the Jamaican spliff—marijuana rolled in large rolling papers or broad tobacco leaves commonly referred to as "fronto" leaves (Sifaneck, Kaplan, Dunlap, & Johnson, 2013). Using marijuana in the form of smoking blunts is an integral practice distinctly associated with the hip-hop subculture (Fig. e2.1). The blunt's overtly larger size, in comparison with joints, is commonly referenced as being aligned with hip-hop's core subcultural values of "phatness," or of "living large"—both connoting an outsized public presentation of success— and is of significant symbolic importance within the scene (Allen, 1996; Sifaneck, Johnson, & Dunlap, 2006). This particular style can also be seen in the hip-hop participant's affinity for consuming 40-ounce bottles of beer or malt liquor, as opposed to 12-ounce bottles, which not only are economical, but overtly emphasize substance consumption to onlookers.

Clothing and other apparel that either display the logos of commonly used cheap cigar brands like "Philly Blunts," or reference blunt smoking, are common symbols within hip-hop fashion (Sifaneck et al., 2013). Furthermore, the pervasive presence of blunt smoking within hip-hop media, such as, music videos, magazines, and movies legitimizes the consumption of marijuana in this form as a unique aspect of the hip-hop subculture (Sifaneck et al., 2006; Soller & Lee, 2010). Some researchers have noted that the presence of blunts in various media outlets eventually led to the expansion

FIGURE e2.1 **Blunts.**

and cooptation of smoking blunts beyond the hip-hop subculture, into broader popular culture (Sifaneck et al., 2013). Interestingly though, the use of blunts within other subcultures is believed to be relatively uncommon. For example, previous field research within the jam band scene reports a general absence of regular blunt smoking within this subculture, despite the pervasive presence of cannabis, which we will now turn to discuss (Pawson & Kelly, 2014).

JAM BAND

The jam band subculture, in many aspects, arose out of the remnants of the deadhead subculture that followed the rock band the Grateful Dead, as they toured around the United States. Throughout the 1990s, the subculture grew from a handful of bands to hundreds of bands showcasing a specific genre of music that mirrors the musical style of the Grateful Dead. Similar to deadheads, many fans of particular jam bands "tour" several different festivals, during the course of the summer (Hunt, 2008). As a result, some fans have, like the deadheads, been labeled based on the bands they follow (eg, "phishheads"). The term "head" more generally can also be used to refer to a member of this subculture, and, to some degree, may be considered a derivative of the "deadhead."

A core aspect of the jam band scene focuses on live performances involving extended musical improvisations, and the ritualistically occurring series of summertime festivals that feature various jam bands (Fig. e2.2). These festivals, similar in style to that of Woodstock, span several days in a row and, in many ways, function as the heart of the jam band subculture. These jam band festivals often involve outdoor camping, and are infused with "hippie" ideals promoting a shared sense of community, as well as embracing the recreational and spiritual use of psychedelic drugs (Epstein & Sardiello, 1990).

Furthermore, the parking lots of the venues where jam bands are performing frequently form a unique communal space, commonly referred to as shakedown streets, which is the name of a popular Grateful Dead song. Shakedown streets are essentially informal market places where scene participants who are following a particular jam band on their tour sell various wares in order to support themselves. Products like live recorded music, food, drugs, clothing, and jewelry are typically available for purchase, barter, or trade (Hunt, 2008; Sheptoski, 2000).

Both quantitative and qualitative studies have noted the ubiquitous drug use present at jam band shows and festivals (Morris, 2014; Vuolo et al., 2013). While jam band shows and festivals are often places described as being ideal for experimenting with psychedelic drugs, the scene's most pervasively used drug is marijuana, often cited as being the drug staple of the subculture (Hunt, 2008, 2010, 2012). This pervasive cannabis consumption traces back to the hippie culture in which its roots are based (Davis & Munoz, 1968; Zimmerman & Wieder, 1977). Jam band scene participants smoke mostly joints, and utilize pipes or "bowls" to smoke marijuana. Somewhat unique to the jam band scene are the presence of marijuana in various edible forms, although their use is growing elsewhere, with the rise of the medical marijuana industry. These edibles may be sold or bartered on shakedown streets, and have been referred to by some users as ganja goo balls (Fig. e2.3).

FIGURE e2.2 **Jam band performance.**

FIGURE e2.3 **Ganja goo ball.**

Furthermore, the scene's subcultural ethos of generosity can at times elevate marijuana to the status of being a pseudocommunal commodity, and its shared use within the scene illustrates participants' desire to connect with other participants. Several studies on the jam band scene have highlighted the central role and cultural importance of marijuana consumption within this context (Davis & Munoz, 1968; Hunt, 2012; Pawson & Kelly, 2014; Zimmerman & Wieder, 1977). One study in particular noted how the use of marijuana enabled a high level of sociality amongst participants, as the practice of sharing marijuana was found to function as a means to initiate interactions with others within the subculture (Pawson & Kelly, 2014). In this regard, marijuana has played a key role in forging and maintaining a sense of community and solidarity within the scene, as these publicly practiced routines enabled the reproduction of some of the key subcultural values of kindness and generosity within the scene.

RAVE CULTURE AND ELECTRONIC DANCE MUSIC

Electronic dance music (EDM) consists of a variety of musical genres that all share their historical roots in the advent of house music in the postdisco era (Reynolds, 1999). Although EDM existed prior to the development of raves, the musical form became more widely popularized among young people through rave culture. The emergence of raves as a cultural form for youth dates to the late 1980s. Raves gained a specific social currency in England during the late 1980s, with the development of the Acid House scene. The parties that showcased this particular form of house music, eventually known as raves, were typically held in desolate farm fields or abandoned factories and warehouses (Hill, 2003). These locations were typically illegally occupied, and the parties were grounded in a DIY mentality (Ingham, Purvis, & Clarke, 1999). The "Second Summer of Love" was the label applied to the birth of the rave scene, as some of the values of hippie youth culture from the late 1960s served as a foundation for the burgeoning rave scene; some of these values are articulated in the rave ideology of PLUR—short for Peace, Love, Unity, and Respect. The linkages of early rave culture to values shared with the youth cultures of the 1960s may have established a foundation for marijuana's acceptability within the rave scene (Fig. e2.4).

By the mid to late 1990s, the EDM subculture had evolved into a highly organized, commercialized, and global phenomenon. Raves themselves became more mainstream, and nightclubs routinely played EDM. As with many other incarnations of youth driven music that came before it, particular drug trends arose within this new music based subculture, as it gained popularity. MDMA, colloquially known as ecstasy, became a prominent component of the early rave scene, and was adopted in club culture more widely, as the music became more mainstream. In addition to MDMA, other substances like ketamine, GHB, cocaine, methamphetamine, and LSD have been associated with EDM scenes and, as such, have been referred to, as a group, under the category of "club drugs." The use of club drugs within the rave scene and EDM nightclubs has been the focus of many public health studies (Forsyth, 1996; Kelly, Parsons, & Wells, 2006; Lenton, Boys, & Norcross, 1997; Measham, Aldridge, & Parker, 2001), but the use of marijuana within these scenes has received less attention.

Although MDMA is the drug of choice often most readily attributed to the rave scene (and electronic dance music scenes more generally), the use of marijuana within the subculture is extraordinarily prevalent. Many studies note how rates of marijuana use are far higher than that of MDMA or other club drugs within the EDM subculture, with studies finding very high prevalence of participants reporting smoking marijuana within the last 6 months, as well as high prevalence of use within the last month (Barrett, Gross, Garand, & Pihl, 2005; Fernández-Calderón et al., 2011; McCaughan, Carlson, Falck, & Siegal, 2005). One study noted that marijuana was the most popular illicit drug used as participants leave a rave (Fernández-Calderón et al., 2011). Thus, marijuana is arguably the most commonly used illicit drug among young adults involved in these scenes, although its use within dance clubs has become complicated by

FIGURE e2.4 **Rave.**

the introduction of smoke-free air policies that prohibit smoking within bars and nightclubs.

The electronic dance music subculture is diverse, and can be divided into a number of subscenes with specific styles of electronic dance music. This has long been the case, as raves incorporated multiple genres of EDM, dating back to the 1990s. Yet, members of these subscenes often view themselves as participating in distinct scenes. The use of marijuana is highly associated with certain subgenres of EDM. For example, drum-n-bass music (also known as jungle) has been influenced by reggae and other breakbeat music, and members of this subculture also draw upon other symbolic markers from reggae and Jamaica, including marijuana. In this respect, cannabis use may be more common among members of the drum-n-bass scene than other subgenres of EDM, due to its strong symbolic representations within the scene, although cannabis use remains common across all EDM scenes. In many respects, marijuana has been widely incorporated into the drug consumption repertoires of participants in the EDM scene, although use in some subscenes remains more visible.

Commonly reported within the public health literature on EDM subcultures is the strategic use of marijuana within the scene (Boys, Lenton, & Norcross, 1997; Grov, Kelly, & Parsons, 2009; Hunt, Evans, Moloney, & Bailey, 2009; Jacinto, Duterte, Sales, & Murphy, 2008; McCaughan et al., 2005; Sterk, Theall, & Elifson, 2006); it has been reported as playing a prominent role in polydrug use repertoires for participants using club drugs (Grov et al., 2009). This notion of using particular drugs at particular times throughout the night is common to the EDM subculture, and functions as a way for participants to enhance pleasure and avoid the negative side effects of using club drugs (see the chapter by Herzig and Bachmann within this volume for more details). The role that marijuana plays with regards to modulating the effects and impacts of club drug use highlights how specific subcultural practices, such as drug sequencing, inform and influence patterns of marijuana consumption within a subcultural scene.

CONCLUSIONS

The use of marijuana continues to play a predominant role in various youth subcultures. From the overviews of the hip-hop, jam band, and EDM scenes, there are distinct symbolic values that each subculture places on the use of marijuana. More specifically, the subcultural norms and practices within these scenes inform and influence unique patterns of marijuana use. This is evident in the blunt smoking practices observed within the hip-hop scene, and its alignment with the norms and values of that subculture. Meanwhile, within the jam band scene, marijuana was used as a way in which to initiate interactions, and was a basis for experiencing notions of community within the subculture. Finally, when looking

at the EDM scene, much of the literature has focused on the specific role of marijuana use in modulating the effects or after effects of club drugs, such as MDMA, used by members of the subculture.

Youth cultures have a powerful influence on drug use practices among young people. Across all three of these music-based subcultures, these descriptions highlight not only how the use of marijuana is a normative aspect of drug consumption practices within these scenes, but also how the subcultural values embedded within these scenes inform and influence the ways in which the drug is used. Additionally, the meanings these patterns of use have for their respective participants vary across youth subcultures. These attributes of youth cultures are not merely sociological curiosities, but matter with respect to enhancing the health and well-being of adolescents and young adults. While young people are often lumped together in epidemiological studies and clinical practice, considerations of the nuances of the subcultures they participate in may provide meaningful insights for prevention and intervention efforts. Variations in these youth cultures create divergent meanings in cannabis use among youth, and thus generate different points of intervention. Strategies used in health promotion efforts may require a multifaceted approach, in order to maximize our reach to a wide-range of young people.

MINI-DICTIONARY

Blunt Marijuana rolled into the paper of a hollowed out cigar.
Club drugs Consisting of a diverse group of substances, from stimulants, depressants, and hallucinogens, the use of these substances has proliferated through the 1990s, due to a perceived association with rave and club culture. Primarily subsumed under this classification are: MDMA, ketamine, rohypnol, GHB, methamphetamine, cocaine, and LSD.
EDM Electronic dance music is a genre of music that is produced through electronic and digital means, rather than through traditional instruments. It is encapsulated by styles, such as, house, techno, trance, and drum-n-bass.
Fronto leaf Broad tobacco leaves used to roll marijuana, commonly referred to as spliffs by Jamaican and other Caribbean cultures. Spliffs rolled with fronto leaves are typically considered the predecessor of the modern blunt.
Hip-hop A genre of music most commonly including rapping over music produced by a DJ that was first generated by urban African-American youth.
Jam band A genre of rock music predicated on musical improvisation and long instrumental renditions.
MDMA The drug methylenedioxymethamphetamine, commonly known as ecstasy.

Drug-Related Pictures, Attentional Bias, and Cannabis Use

D. Asmaro

Department of Psychology, Simon Fraser University, Burnaby, BC, Canada

SUMMARY POINTS

- Presentations of drug cues to drug users have been shown to elicit both craving and neural responses, yet relatively little research has focused on cannabis use behavior.
- Using behavioral, electrophysiological, and functional neuroimaging studies, scientists have been able to characterize how cannabis users respond to cannabis cues.
- Behavioral research shows that reaction times to cannabis cues increase and that craving for the substance becomes amplified after cue exposure.
- Event-related potential research shows that early and late effects have been observed after cannabis cues are presented to cannabis users, therefore allowing scientists to better understanding the temporal processing of these cues within the brain.
- Functional magnetic resonance imaging (fMRI) research has shown that parts of the brain that are related to reward processing become activated by cannabis cues when users of the substance see images that have been conditioned to the effects of the drug.
- Understanding the behavioral and neural correlates of cannabis cue-reactivity as well as its association with increased attentional bias has important treatment implications.

KEY FACTS OF ELECTROENCEPHALOGRAM/EVENT-RELATED POTENTIALS

- An electroencephalogram (EEG) is a continuous recording of brain electrical activity that is acquired by using an array of electrodes.
- While brain electrical activity can be recorded directly from brain tissue most published findings are based on measurements that were obtained from the surface of the scalp as this is less invasive than the former approach.
- Event-related potentials are averaged electrophysiological responses that are extracted from the ongoing EEG. A researcher can choose to combine events that were flagged in the EEG signal and then extract the average waveform for that segment of the EEG across all events of a given type. For example, a researcher could look at all responses to neutral and target stimuli in the EEG, and then extract and average that data in order to create waveforms that reflect brain responses to these two types of stimuli.
- After signal averaging is completed for each participant, the researcher can create a grand-average where a group of participants' responses to different experimental stimuli are combined. These data can be visually inspected in order to determine where different responses occurred in time, and subsequent statistical analyses can be conducted to determine whether the amplitude or latency of these effects are significant.

- EEG/ERPs have exquisite temporal resolution, and this can allow researchers to see how the brain processes stimuli on a millisecond by millisecond basis.
- However, the electrical signal generated by the brain is distorted by different tissues before it reaches the electrodes that are placed on a participant's scalp. Because of this, the technique has poor spatial resolution and therefore cannot be used to answer questions that involve determining where in the brain a particular signal is coming from.

ms	Millisecond
MRI	Magnetic resonance imaging

INTRODUCTION

Human beings (as well as other animals) have been using psychoactive substances to alter conscious experience throughout the course of recorded history (Siegel, 1989). Cannabis is one such substance, and it has likely been used for thousands of years by people who inhabit a variety of different geographic regions around the world (Meyer & Quenzer, 2005). Despite the fact that use of the substance has lengthy historical roots, empirical investigations regarding its psychological effects have only been conducted in the more recent segment of human history. The advent of computers and neuroimaging methods have allowed scientists to address questions which are related to drug dependency and exploration into the effects of cannabis are certainly no exception. While some of these investigations have attempted to understand the acute effects of cannabis on human cognition and sensorimotor performance, other scientists have attempted to understand how frequent users of the drug respond to cannabis-related stimuli in their environments (Fig. 26.1). This chapter will explore the latter concept from the perspectives of behavioral and neuroscientific research, with an emphasis on how neural and behavioral effects can be measured and elucidated within laboratory environments. After a brief overview of some of the methodologies that are

FIGURE 26.1 **Cannabis cues in our everyday environments.** A store (also located on a major road) that sells cannabis-related products in downtown Vancouver, British Columbia. How might a regular cannabis user respond to a salient cue like this one?

currently being employed to study addiction processes in human beings, the chapter will provide a summary of findings that were obtained using a number of these techniques. Importantly, the research presented in this chapter will be centered around cannabis cue-reactivity and the effects of these cues on cannabis users. Research from multiple methodologies are also highlighted as the author believes that this will provide a more complete picture of how cannabis cue-reactivity influences the behavior and brain function of regular users as opposed to nonusers.

METHODS USED IN ADDICTION RESEARCH

Researchers have utilized a number of research methods to better understand how different drugs affect behavior, emotion, and other aspects of conscious experience. The use of computer-based methods has been extremely helpful in the assessment of motor and sensory effects, and the discovery of techniques that allow researchers to peer into the workings of a functioning human brain while experimental tasks are being completed have allowed for inference into the brain–behavior relationships that develop as substance use continues for prolonged periods of time. Although a variety of tasks have been used to understand the perceptual and cognitive experiences of drug users, the proceeding discussion will pertain to techniques that utilize *cue-reactivity paradigms* (where drug cues and other stimulus categories are presented to different groups of subjects). The following sections will introduce some of the of behavioral and brain-based methods that are currently being employed by those conducting research in this field.

Behavioral Methods

Reaction Times

One way that researchers have attempted to understand the effects of drug-cues on users of various substances is by asking them to respond as quickly as possible to target visual stimuli immediately after they appear on a computer monitor. Typically, experimental instructions will ask participants to respond to a colored square or other target that is superimposed on top of either a neutral, affective, or drug picture. Alternatively, instructions may specify that participants need to categorize these stimuli using different button presses. Programming tools that are used to create these computer-based tasks record the amount of time it takes for a button press response to be made and these responses can deemed correct or incorrect. For experiments that utilize these *reaction time* measurements it is usually standard practice to include only those trials that were deemed to be correct as this ensures that the participant was paying attention and was not distracted with anything that may have been happening in the testing environment. In studies, such as these, longer reaction times to drug stimuli (particularly for participants who were identified as having had past experience with the substance being investigated) may indicate that more attentional resources were allocated toward their detection and subsequent processing. This phenomenon has been termed *attentional bias* and it is frequently observed with substance users who meet criteria for substance abuse or substance dependence diagnoses (see Figs. 26.2 and 26.3).

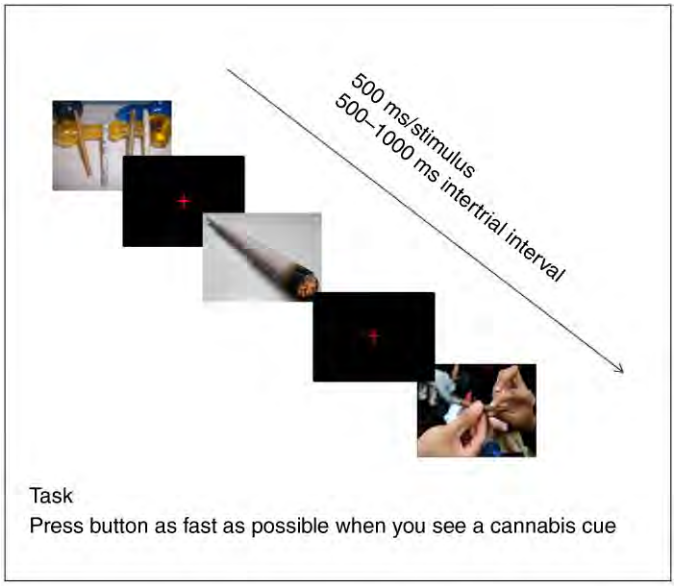

FIGURE 26.2 **Cannabis cue trial series.** A set of stimuli that might be presented in a typical cannabis cue-reactivity paradigm.

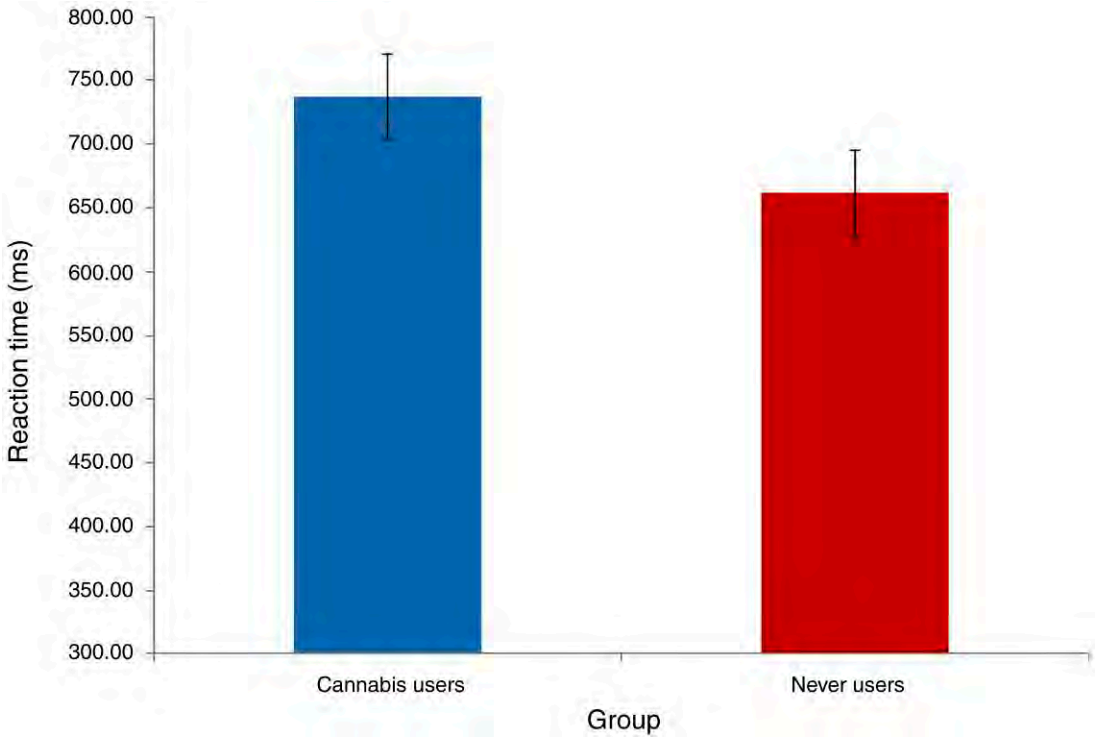

FIGURE 26.3 **Reaction times to cannabis cues.** Reaction times to cannabis-related cues for cannabis users and never users.

Cue-Induced Craving

Paradigms that present drug cues to participants typically include self-report measurements that have participants rate the degree of craving they were experiencing before, during, or after an experimental condition. These self-reports can take place before and at the very end of a task (where change in craving after viewing substance cues can be assessed by comparing pre- and postvalues), or they can be presented after every block of stimuli the participant views. A typical finding is that self-reported craving for a given drug (or even a food) is higher for those who are frequent consumers of the substance, yet these ratings remain low for those who belong to non-user/never a user groups. Furthermore, measurements of cue-induced craving may be used to assess the effects of effortful cognitive control, reappraisal, or satiety. Experimental manipulations of this kind may be especially useful for researchers who wish to understand the effects of different behavioral, cognitive, or pharmacotherapies in reducing cue-related craving as this is believed to play a significant role in relapse following serious attempts at abstinence.

Neuroimaging Methods

Event-Related Potentials

Event-related potentials (ERPs) allow researchers to measure brain responses to stimuli presented during experimental tasks by measuring voltage changes in brain electrical activity from the level of the scalp. ERPs refer to neural responses that are extracted from an ongoing electroencephalogram (EEG) and are obtained by attaching an array of electrodes to a participant's scalp. Events that are presented during an experimental task are called trials, and all trials that belong to the same category are eventually averaged together offline after the data collection session is completed. The process is repeated for each participant and averaged waveforms that depict scalp-recorded electrical activity are created using specialized computer software that allows researchers to remove artifacts and extract data from windows of time in the EEG epoch that are of interest to them. Later, a grand-average is created by averaging all participants' averaged brain responses to discrete stimulus types. Importantly, this technique has exquisite *temporal resolution* which can allow researchers to see how attention is allocated toward cues very early on, after stimulus presentation (ie, from 1 to 1000 ms after a cannabis cue was presented on screen), and also allows for other rapidly occurring cognitive effects to be detected and evaluated. Furthermore, the equipment is inexpensive relative to other technologies that are used to acquire brain data, and its maintenance is much more cost-effective compared to that seen with magnetic resonance imaging/functional magnetic resonance imaging (MRI/fMRI) technology. Despite its advantages, the electrical activity detected by the electrodes is distorted by different matter found in the head (eg, bone, cerebrospinal fluid) so detecting where brain activity occurred after drug or

FIGURE 26.4 **EEG recording equipment.** An electrode cap and some electrodes that would be attached to a subject and plugged into an amplifier for EEG recording.

neutral stimulus presentations is difficult to determine. Although some techniques have been developed to solve this problem, they currently offer a "best guess" solution and require validation using other techniques that are not subject to the same methodological constraints (eg, fMRI). See Luck (2005) for a useful discussion of the advantages and disadvantages of using the ERP technique relative to other imaging methods that are currently used by scientists (also see Fig. 26.4 for an example of recording equipment that might be found in a typical ERP laboratory).

Functional Magnetic Resonance Imaging

fMRI has been used extensively within the context of addiction research and is quite useful for determining which brain structures and neural networks are involved in the evaluation of drug cues versus other categories of stimuli. The MRI machine generates a strong magnetic field that effectively orients hydrogen atoms in our bodies to a certain orientation, and participants are asked to lie down in the scanner and remain very still during the experimental task. The MRI scan allows the researcher to take a picture of the brain after a radio pulse is transmitted through the magnetic field created by the scanner. This pulse disrupts the orientation of the hydrogen atoms, and the machine detects their realignment after the radio signal ceases (which allows for different tissue densities to be visualized). Following an MRI scan, an fMRI scan is conducted in order to map functional changes onto this previously created structural map. fMRI analyses rely on measuring the *blood-oxygen level dependent (BOLD) response* created by changes in the blood's oxygen levels. Importantly, when different regions of the brain are more active during a task more oxygen is used up by tissue in that region. When a radio wave is passed through the scanner during the presentation of different stimuli, it temporarily changes the orientation of hydrogen atoms within the blood, and blood that is deoxygenated has more magnetism that blood that is oxygenated. Deoxygenated blood will cause neighboring particles to spin more as they reorient after the radio wave pulse stops, and it is this spin–spin interaction that allows researchers to determine if a brain region was more or less active during the presentation of a given stimulus type (eg, a cannabis-related picture). This technique (when used in conjunction with a structural MRI scan) has excellent *spatial resolution*, meaning that it can detect the loci of brain activations in regions as small as 1 millimeter cube (mm^3). However, because its relies on measuring changes in blood-oxygen levels, the temporal resolution of this technique is sluggish and therefore not conducive to answering research questions that pertain to rapidly occurring cognitive/neural events (here, the ERP technique may be a more suitable apparatus). Furthermore, the equipment is quite expensive to acquire and maintain. However Despite its inherent limitations, many of the brain imaging studies that currently exist in the addiction literature have been conducted with the use of fMRI and invaluable information about the roles that different brain structures play in evaluating drug-related stimuli has been acquired by use of this method.

CANNABIS PICTURE PRESENTATIONS: BEHAVIORAL, ERP, AND fMRI FINDINGS

While a number of studies that look at drug-cue effects have been published in the addiction literature, only a small portion of this research has been dedicated to understanding the effects of cannabis cue presentations. The following sections will discuss some of these findings in detail.

Behavioral Studies

A number of studies have been conducted with the aim of delineating the effects of cannabis-related cues on craving, mood state, and attention. In one study, Lundahl and Johanson (2011) elicited cannabis cue-reactivity in their laboratory in the hope that they could accurately model what might also be seen in a real world setting. By having cannabis dependent users view video clips that depicted people smoking marijuana while also handling cannabis paraphernalia (eg, rolling papers, a pipe) several noteworthy effects were observed when these subjects were compared with cannabis-naive control participants. Within the cannabis user group, significant increases in cannabis craving were seen after these

multimodal cannabis cue presentations were delivered and this effect was not observed in the control group. Furthermore, the self-reported urge and desire to smoke marijuana was also found to be greater following cannabis versus neutral cue presentations. Wölfling, Flor, and Grüsser (2008) also used a cue-reactivity paradigm to study psychophysiological responses to cannabis, and although their study was primarily focused on cataloging ERP responses to pleasant, negative, neutral, alcohol, and cannabis cues, the behavioral component of the experiment found that cannabis dependent participants rated cannabis images as being more pleasant and more arousing than relative to control participants. Greater craving was also observed for the former group when self-report data obtained before and after cannabis cue exposure was compared. No differences in arousal or pleasantness ratings were found for other stimulus category contrasts. While the previously discussed studies have focused on cannabis cue-related responses in adults, similar effects also appear to be entrenched in adolescent cannabis users. Gray, LaRowe, and Upadhyaya (2008) presented 16–21 year old cannabis users with neutral and cannabis-related audio recordings, video clips, and in vivo stimuli (eg, marijuana cigarettes and pencils) to elicit craving and physiological responses. Craving ratings were found to be higher in the cannabis video and in vivo stimulus presentation conditions relative to their neutral counterparts. In vivo presentations of cannabis cues also evoked higher skin conductance and heart rate measurements relative to other modalities of cannabis cue presentations, suggesting that such presentations are particularly salient for cannabis users (also see Gray, LaRowe, Watson, & Carpenter, 2011 for additional evidence regarding the effects of in vivo cannabis cue exposure on craving, skin conductance, and heart rate in adolescents). Although research that looks specifically at cannabis cue-reactivity is sparse compared to the number of studies on other substances of abuse (eg, alcohol, tobacco, and cocaine), cue-induced craving does seem to be reliably observed in cannabis dependent users. The observation that presentations of cannabis cues can elicit this response in younger people also suggests that the human reward system is highly susceptible to the effects of drug-related *classical conditioning* and that this effect can take place relatively quickly. Lastly, cannabis users and nonusers have been found to differ from one another in terms of the degree of attentional bias they afford toward marijuana cues. In one study, participants were asked to view cannabis-related or neutral pictures that were presented on a computer screen while eye movements were recorded with a special set of goggles (Field, Eastwood, Bradley, & Mogg, 2006). They were also instructed to respond as quickly as possible to visual probes that replaced the different images from trial to trial. For cannabis users (but not control participants), eye gaze was directed toward cannabis cues for significantly longer periods of time relative to what was observed after neutral picture presentations. Cannabis-users also responded to the visual probes that replaced the cannabis pictures significantly faster than those that replaced the neutral pictures. Taken together, the reaction time and eye movement data again suggest that attentional bias toward cannabis cues may be present for those who use the substance regularly. Given that attentional bias is thought to play a role in the maintenance of substance addiction as well as relapse incidence following abstinence attempts, these findings may be particularly relevant for those who are trying to quit the habit. Importantly, attentional bias toward cannabis-related cues can also occur when stimuli that are less salient than vivid images are presented. For example, Field (2005) found that cannabis users took significantly more time to name the colors of visually presented cannabis-related words, therefore indicating that these words were able to elicit attentional bias despite being more subtle in nature.

Cannabis cue-reactivity paradigms have even been employed to better understand how genetic factors influence withdrawal trajectories in cannabis dependent subjects. Haughey, Marshall, Schacht, Louis, and Hutchison (2008) recruited a sample of daily cannabis users and measured cue-induced craving for cannabis before and after a 5-day abstinence period. Craving was induced by placing used bongs and pipes in a room while an audio tape instructed the participants to focus their attention on the items and imagine using them to self-administer the drug. Cheek cell and saliva samples were also collected for later DNA analysis during the initial session. After both testing sessions were completed it was found that cue-induced craving for cannabis significantly increased after 5 days of abstinence but only for cannabis users. Interestingly, cue-related craving was found to be higher for those users who had cannabis receptor CNR1 T/C gene expression (as opposed to those with a CNR1 T/T genotype), and these users were also found to be more dependent on cannabis relative to users with the latter homozygous allele pairing. When approached from a treatment perspective these findings are extremely informative given that they directly link a specific genetic makeup to heightened dependency and greater cue-related craving. Both of these factors are likely to influence treatment success, however, the researchers were careful to emphasize that additional follow-up research would need to be conducted before any firm conclusions could be asserted. Still, this research provides important ground work for future studies that aim to reduce relapse rates among cannabis users who are making abstinence attempts. In the future, these findings could also help clinicians tailor interventions to meet the needs of individual clients if they are identified as being at higher risk for future relapse.

Event-Related Potential Research

Researchers have combined cannabis cue-presentations with continuous EEG recordings in order to help understand how these cues are processed in the human brain and how neural events translate into cognition and observable behavior. One distinction that can be helpful for those trying to interpret ERP findings involves categorizing observed components as early (eg, between 100 and 300 ms after stimulus presentation) versus late occurring (eg, 300–2000 ms after stimulus presentation). This distinction is important as bottom-up (or stimulus driven) versus top-down (cognitively mediated) influences will be more or less likely depending on the window of time being examined. For instance, an ERP component that is elicited early on in stimulus processing may reflect an automatic orienting of attentional resources toward an environmental stimulus, and this may occur independently of higher-order cognitive influences or voluntary attention toward it. On the other hand, a component that is present between 400 and 700 ms may reflect more in-depth processing, where affective and cognitive appraisals will begin to exert some influence on the associated neural response. In the studies described in the following section, stimulus presentations have been delivered primarily through the visual modality.

One early occurring ERP component that is reported in the literature has been termed the EAP (early anterior positivity) effect, and it has been found over the frontal scalp in a window of time ranging between 200 and 350 ms. Although it was first reported in chocolate cravers when they viewed chocolate images (Asmaro et al., 2012), a subsequent study also found that this component was elicited after cannabis pictures were presented to participants who met criteria for cannabis dependence (Asmaro, Carolan, & Liotti, 2014). Importantly, this appeared to discriminate cannabis users from never users because the EAP effect was not observed in the latter group. This effect was thought to represent attentional bias being afforded toward the cannabis cues and may indicate that preconscious processing in the brain effectively identifies and directs attention toward craving inducing cues even before the user is aware that this is happening. Findings that pertain to neural correlates of attentional bias toward cannabis cues nicely complement findings that were presented in the previous section of this chapter, and they also provide evidence that earlier occuring attention-related processes can have a powerful influence on subjective craving.

Later occurring effects have also been observed when ERPs to cannabis cues were recorded during cue-reactivity paradigms. Of these effects, the late-positive potential (LPP) is one of the most frequently reported in the addiction literature (this is sometimes referred to as the P300/LPP complex), and has been observed in windows of time ranging from 300 ms after stimulus presentation and beyond. This component is believed to reflect a heightened arousal and greater attentional resource allocation toward affective stimuli when they are presented to participants (Polich & Criado, 2006), and cannabis dependent participants appear to have an LPP response after presentations of cannabis images (Wölfling et al., 2008; Henry, Kaye, Bryan, Hutchison, & Ito, 2014). One study has even demonstrated that the amplitude of the LPP (recorded in a window ranging between 300 and 600 ms) was found to be enhanced after cannabis dependent adolescents handled cannabis-related paraphernalia (Nickerson et al., 2011). In the latter study, LPPs elicited by cannabis cues were significantly larger those seen after presentations of other arousing cues, therefore suggesting that cannabis cues were subjectively more arousing than other stimulus types and perhaps more able to recruit attentional resources.

When information obtained from studies that reported early or late occurring ERP components is looked at holistically, one can begin to ascertain how cannabis stimulus processing occurs within the human brain at various points in the stream of perceptual processing. Early voltage enhancements to cannabis cues may alter downstream, later occurring processes that become elicited within cannabis users when they are presented with these stimuli and this may provide scientists with valuable information that ultimately helps to piece together how neural events give rise to observable behavior in the real world (Fig. 26.5). However, it is important to note that while ERPs can give us superb information about "when" different perceptual happen, they do not give reliable information about "where" in the brain these processes occur. In order to address questions related to "where," functional neuroimaging techniques need to be utilized in conjunction with cue-reactivity paradigms (Fig. 26.5).

fMRI Research

Research that utilizes the fMRI technique attempts to localize activations that are uniquely elicited by different stimuli or different tasks that participants are required to complete while they are being scanned. There have been a large number of studies within the addiction literature that report on results that were acquired with this technique, however, only a small subset of these has looked specifically at cannabis cue-reactivity. Understanding how brain structures facilitate the processing of these reward-related cues ultimately provides vital information about cannabis use behavior and the following paragraphs will discuss some of these current findings in more detail.

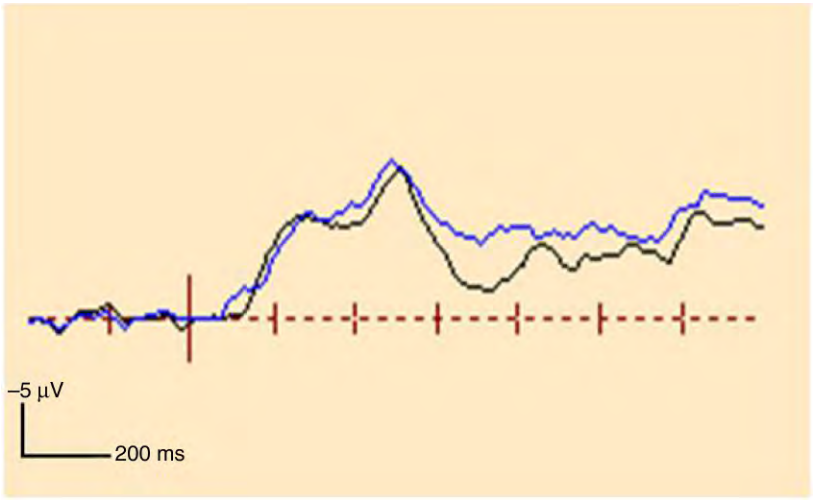

FIGURE 26.5 ERPs to cannabis and neutral cues: grand-averaged waveforms. ERPs (recorded at a frontal electrode channel) to cannabis-related *(black line)* and neutral cues *(blue line)* in a sample of cannabis users between 200 to 700 ms after visual stimulus presentation. Note the differences between the two responses and where they occur in time.

A number of fMRI studies have found that cannabis cues elicit activations in parts of the brain that are believed to play a fundamental role in allowing human beings to experience reward and process reward-related stimuli. Cousijn et al. (2013) found that frequent cannabis users and sporadic cannabis users (people who had used cannabis between 1 and 50 times during the course of their lives) showed increased activation in the medial frontal gyrus and orbitofrontal cortex (OFC) when they were presented with cannabis cues, yet this activation was not seen in nonusers. The OFC activation was particularly relevant, given that this structure is believed to play a role in triggering cue-related craving when drug users perceive drug stimuli (Koob & Volkow, 2010). Additionally, frequent users showed greater activation in a part of the brain called the ventral tegmental area (which is a part of the brain that releases a neurotransmitter called dopamine) when their cannabis cue elicited neural activations were contrasted with those of sporadic users. This is important, as the authors suggest that the processing of these reward-related cues may change as abuse of the substance becomes more frequent. Additional evidence that was acquired using fMRI also suggests that OFC activation to cannabis images becomes more pronounced as the number of years of cannabis abuse increases over time (Wetherill et al., 2014), and that greater activation in the nucleus accumbens (a dopaminergic neural region in the midbrain that projects to the ventral tegmental area) and OFC is also associated with higher frequencies of cannabis-related problems that interfere with everyday life (Filbey, Schacht, Myers, Chavez, & Hutchison, 2009) (see Fig. 26.6 for a representation of OFC location in brain space).

Lastly, fMRI research has also been used to link genetic composition to cannabis cue-reactivity. Similar to what was done in the previously discussed study by Haughey et al. (2008), Filbey, Schacht, Myers, Chavez, and Hutchison (2010) found that expression of the G allele for the CNR1 cannabis receptor and the C allele for the CAAH cannabis receptor impacted the degree of cannabis cue activation in parts of the brain that are associated with reward processing. Cannabis users who were CNR1 G allele heterozygotes had greater responses in the OFC, insula, inferior frontal gyrus, and in the dorsal anterior cingulate gyrus when cannabis cues were presented to them (as opposed to those who were A/A homozygotes). Additionally, cannabis users who were homozygotes for the FAAH C allele showed increased activation in the OFC, inferior frontal gyrus, striatum, and ventral tegmental area when cannabis versus control cue contrasts

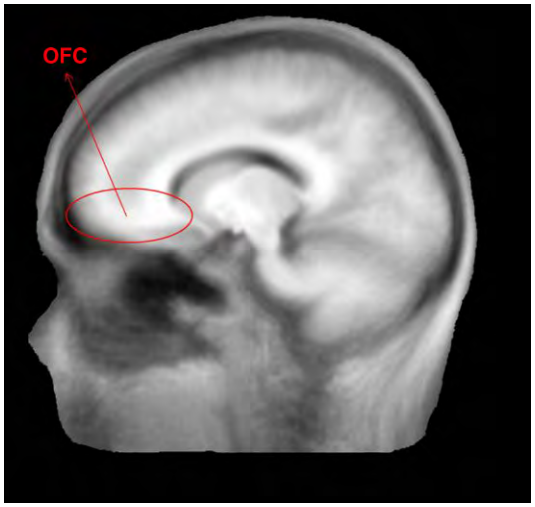

FIGURE 26.6 The orbitofrontal cortex in BESA brain space. A representation of where in the brain the OFC is located using an average brain model in BESA 5.3.

were examined. The researchers were also able to determine that cue-reactivity became more exaggerated as the number of risk alleles increased, therefore suggesting that there is a genetic basis for increased susceptibility to cannabis cue-reactivity. Findings, such as these support research that was conducted using behavioral techniques and could help focus prevention efforts that attempt to mitigate the development of cannabis abuse and dependence should such approaches be adopted in the future.

Taken together, it appears that cannabis cues can elicit activation in parts of the brain that are believed to be the neural substrates of reward processing and these activations could be used to determine genetic susceptibility for cannabis abuse/dependence. Importantly, parts of the brain that are activated by cannabis cues also appear to be activated in other paradigms that present substance users with cues related to a variety of abuse substances (which suggests that a common neural basis exists across substance abuse diagnoses).

CONCLUSIONS

Research on cannabis cue-reactivity has been conducted in a concerted effort to better understand the behavior of cannabis users and how exposure to cannabis-related cues uniquely impacts brain functioning. Using behavioral research techniques, researchers have found that greater craving and attentional bias is afforded toward cannabis cues by frequent users of the drug. Research that has employed electrophysiological techniques has found that early and late-occurring components provide information about the temporal processing of these cues by cannabis users and some of these findings appear to reflect attentional bias toward this specific kind of drug cue (which supports nicely findings that were obtained using behavioral techniques). Finally, fMRI research has been able to provide us with information about the brain regions that are involved in cannabis cue appraisal and have shown that such cues are able to activate parts of the brain that are involved in the processing of rewards. Cue-reactivity research has allowed us to better understand cannabis use and dependence and may facilitate effective treatment options in the future if such techniques are utilized within clinical settings to provide objective assessments of individual clients.

MINI-DICTIONARY

Attentional bias The exaggerated deployment of attentional resources to a salient stimulus that is present in a person's external environment. In addiction research this bias is seen in substance users and is related to increases in drug craving and longer drug stimulus fixations (which often result in increased reaction times).

Blood-oxygen level dependent response The measured changes in hemoglobin properties that are recorded during an fMRI scan. These responses characterize changes in blood oxygenation and the subsequent changes in the blood's magnetism that arise as a result.

Classical conditioning A process that takes place after a stimulus that initially had no reward value is repeatedly paired with the onset of a reward. Over time, the presentation of the stimulus (now called a conditioned stimulus) will elicit responses that are associated with the receipt of actual rewards.

Cue-reactivity paradigms Experimental paradigms that present stimuli to participants in order to elicit behavioral or neural responses to discrete categories of stimuli.

Dopamine A catecholamine class neurotransmitter that is primarily manufactured in the midbrain and in subcortical structures. Although it plays a vital role in many cognitive and motor functions it is also critically involved in signaling reward onsets.

Event-related potentials Electrophysiological responses that are observed at the level of the scalp after stimuli are presented to a participant. Although they can be derived after just one stimulus response is recorded, they are usually created by averaging all stimulus presentations of a given type together within single subjects and then across an entire sample.

Multimodal A term that denotes that a multiple sensory systems were involved in the processing of a stimulus (ie, vision and touch).

Orbitofrontal cortex A region in the brain's frontal lobe that is thought to be a core component of the human reward system. It is located at the anterior part of the brain just above where the eyes would be found.

Reaction time The amount of time it takes for a participant to respond to a stimulus that is presented to them. These are usually measured in milliseconds (ms).

Spatial resolution The ability to visualize locations in space in varying degrees of detail. A methodology that has higher spatial resolution will be able to extract more detail about a spatial location.

Temporal resolution The ability to record events that occur during varying lengths of time. A technique that has high temporal resolution will be able to discriminate events that occur very soon after each other (ie, from 1 ms to the next).

SUMMARY POINTS

- Cannabis use is a risk factor for psychosis, especially in vulnerable individuals.
- First-episode psychosis patients with cannabis abuse have a poorer clinical and functional outcome, compared with patients without cannabis abuse.
- Cannabis use is associated with cognitive deficits in first-episode psychosis (FEP) patients.
- Depressive symptoms are associated with cannabis abuse in FEP patients.
- Cannabis use is a target for the prevention and treatment of patients with first psychotic episodes.

KEY FACTS OF CANNABIS USE AND FIRST-EPISODE PSYCHOSIS PATIENTS

- Cannabis is the most widely used drug among patients with FEP.
- Cannabis use has become a target for the prevention and treatment of patients with first psychotic episodes because of its influence on the development and prognosis of the disease.

LIST OF ABBREVIATIONS

CUD	Cannabis use disorders
FEP	First-episode psychosis patients
5-HTTLPR	Short allele of the serotonin transporter gene-linked polymorphic region
THC	Δ^9-Tetrahydrocannabinol

INTRODUCTION

Cannabis is the most commonly abused substance in FEP (Koskinen, Lohonen, Koponen, Isohanni, & Miettunen, 2010). Cannabis use may play a role as a risk factor for psychosis by influencing the age at onset of psychosis (González-Pinto et al., 2008). Risk of developing psychosis has been associated with the frequency or duration of cannabis consumption, the dose of cannabis consumed, and an early age at onset of cannabis consumption (Arseneault, Cannon, Witton, & Murray, 2004), especially in vulnerable individuals (Dekker et al., 2008).

There is empirical evidence that prolonged cannabis use has a negative effect on the clinical and functional course of FEP patients. Cannabis use in FEP is associated with poor treatment adherence (Barbeito et al., 2013), more severe and chronic symptoms (Kovasznay et al., 1997), increased risk of relapse (Pencer, Addington, & Addington, 2005), and poorer long-term functioning. However, those patients who stopped using cannabis experience

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00030-2

a slow but steady improvement over time, both in functional outcome and negative symptoms (González-Pinto et al., 2011). Moreover, cannabis use is associated with cognitive deficits in patients with psychosis (Rais et al., 2008; Ayres et al., 2010; Meijer et al., 2012).

Because of the high rate of cannabis use among FEP patients, and its influence on the development and prognosis of psychosis, cannabis use has become a target for the prevention and treatment of patients with first psychotic episodes.

CANNABIS USE AS A RISK FACTOR FOR PSYCHOSIS

Substance misuse is a common comorbid problem in people presenting with a first episode of psychosis (Lambert et al., 2005). Cannabis is the most commonly abused substance in this population. The prevalence rate of cannabis use among patients with FEP ranges from 14% (Addington & Addington, 2007) to 66% (Wade, Harrigan, Harris, Edwards, & McGorry, 2006). The variation in reported prevalence rates may be due to the sample studied, and how cannabis use was defined, measured, or diagnosed (including prior, current or liftime use). In a recent metaanalysis examining the rate of cannabis use disorders (CUD) in schizophrenia and other psychotic disorders, the estimated median rate of CUD was higher in first-episode patients, than in long-term schizophrenia patients: 28.6% versus 22.0% for a current diagnosis of CUD, and 44.4% versus 12.2% for a lifetime diagnosis of CUD (Koskinen et al., 2010). These findings support the hypothesis that cannabis consumption may have a role in the etiology and evolution of psychosis. Further research has implicated cannabis use as an environmental factor associated with the development of psychotic illness (van Os, Kenis, & Rutten, 2010).

Although causal relationships are difficult to establish in psychiatry, there are important data that tip the balance in favor of a causal relationship between cannabis use and psychosis. Longitudinal studies indicate that cannabis use often precedes psychotic disorders (Kuepper et al., 2011; van Gastel et al., 2014). In a population-based cohort study in Germany, where almost two thousand people aged 14–24 years were followed up for 10 years, Kuepper et al. (2011) found that incident cannabis use increased the risk of incident psychosis 4 years later. They also found that continued cannabis use increased the risk of persistent psychotic symptoms. A major advantage of this study is that reverse causality (ie, premorbid subthreshold psychotic symptoms induce cannabis use) could be controlled for.

Other studies argue that cannabis use precipitates the onset of a psychotic episode in individuals with a pre-existing vulnerability to psychosis (Henquet et al., 2005). Research has indicated that genetic factors play a role in the development of psychotic disorders; for example, schizophrenia has an estimated heritability of 85%, and there is a 10-fold increased risk for psychotic disorders in siblings of patients with schizophrenia (Lewis et al., 2003). However, despite the research conducted in recent decades, there has been only limited progress in our understanding of the mechanisms involved in the disease. Neither genetic nor environmental variables alone appear to be sufficient or necessary to precipitate the disease (Rutten & Mill, 2009; van Os et al., 2010), making it important to study the gene–environment interaction.

It remains unclear whether the same genes that increase the risk of psychosis also increase the risk of cannabis use, or if other mechanisms are involved. Recently, investigators found preliminary evidence that some common genes are implicated in the association between psychosis and cannabis use (Power et al., 2014).

Cannabis use may play a role as a risk factor for psychosis by influencing the age at onset of psychosis. Risk of developing psychosis has been associated with the frequency or duration of cannabis consumption, the dose of cannabis consumed, and an early age at onset of cannabis consumption (Arseneault et al., 2004), especially in vulnerable individuals (Dekker et al., 2008). In a study of FEP patients, we found a strong and independent relationship between cannabis use and early age at onset of psychosis, such that the age at onset of psychosis decreased, as patients were classified as having cannabis use, abuse, and dependence versus cannabis nonusers (González-Pinto et al., 2008) (Fig. 27.1). This suggests that cannabis is a dangerous drug for young people at risk of developing psychosis to use. However, our findings are not consistent with the hypothesis that cannabis use and age at onset of psychosis are only associated because younger patients are more prone to using cannabis. The inverse dose relationship of cannabis use with age at onset of psychosis in this and other studies (Fergusson, Horwood, & Ridder, 2005) gives more strength to the hypothesis that the association between cannabis use and psychosis onset is causal, or that it is due to effect modification (ie, cannabis use is associated with the development of psychosis in people who are susceptible to developing psychotic symptoms), as discussed in previous studies of the general population (Fergusson, Poulter, Smith, & Boden, 2006). It is clear from studies that increasing use of cannabis is associated with an increasing risk of psychosis (Fergusson et al., 2006), whereas only heavy substance use (versus mild use or no use) is associated with worse symptomatic and functional outcomes in FEP patients (Wade, Harrigan, McGorry, Burgess, & Whelan, 2007).

Furthermore, although the association between cannabis use and age at onset of psychosis may be mediated or moderated by other factors, such as comorbid use of other drugs or sex (Veen et al., 2004), the results of our

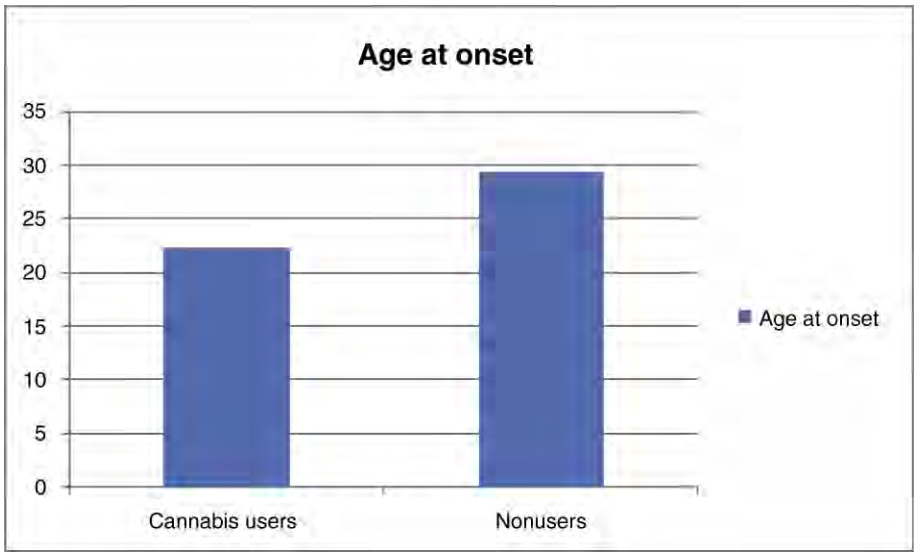

FIGURE 27.1 **Cannabis use and age at onset.** Relationship between age at onset and cannabis use in the long-term. *Source: From González-Pinto et al. (2008).*

study suggest that the effect of these variables is minimal or nonexistent (González-Pinto et al., 2008).

INFLUENCE OF CANNABIS USE ON CLINICAL AND FUNCTIONAL OUTCOMES, AND THE ROLE OF DEPRESSIVE SYMPTOMS IN FEP

There is empirical evidence that prolonged cannabis use has a negative effect on the clinical and functional course of FEP patients (Clausen et al., 2014; González-Pinto et al., 2011). Cannabis use may be a risk factor for nonadherence to treatment in FEP patients (Miller et al., 2009; Zammit et al., 2008). Longitudinal studies by our research group have shown that FEP patients who quit cannabis use during follow-up have better long-term adherence to medication (Barbeito et al., 2013), and improved clinical and functional outcomes (González-Pinto et al., 2011). Barbeito et al. (2013) demonstrated that the proportion of FEP patients using cannabis decreased from 52% at baseline to 29% at 8 years. Moreover, the majority (74%) of patients who continued to use cannabis over the 8-year follow-up period were classified as having bad adherence to medication, whereas only 17% of the patients who stopped using cannabis had bad adherence (Fig. 27.2). At the same time, patients with bad adherence at 8 years had worse functioning than those with good adherence (Fig. 27.3). There is, therefore, a relationship between long-term cannabis use, poor functionality and the pattern of adherence (Fig. 27.4). Moreover, involuntary first admission was associated with improvement in adherence during follow-up. These findings indicate that FEP patients with coexisting cannabis use are more likely to be nonadherent to medication, and suggest that interventions should aim to stop cannabis use and improve adherence.

Cannabis use is also associated with poorer outcomes in FEP patients. In our study of the influence of cannabis use on long-term outcomes, we compared FEP patients who stopped using cannabis with those who never used cannabis, and with patients who continued to use cannabis during 8 years of follow-up (González-Pinto et al., 2011). Results indicated that continued cannabis use had a deleterious effect on outcome. Specifically, patients who stopped using cannabis experienced a slow but steady improvement over time in their negative symptoms and functioning, whereas patients who continued using cannabis had a trend to increasing negative symptoms over time, and no improvement in functional outcome. All patients showed improvements in positive symptoms, over the long term.

Other studies have also demonstrated that FEP patients who use cannabis have a worse outcome than patients who do not use cannabis. In a systematic review that included seven follow-up studies of FEP patients, cannabis use was associated with worse outcomes (increased relapse and nonadherence) in the short- and medium-term, although differences in outcome between cannabis users and nonusers were more modest, when the studies controlled for use of other drugs, and baseline illness severity (Zammit et al., 2008). Similarly, other studies have shown that continued use of cannabis by FEP patients is associated with a worse functional outcome (Addington & Addington, 2007).

It is possible that the deleterious effect of continued cannabis use on symptoms and functional outcome is due, in part, to additive effects of psychosis and cannabis

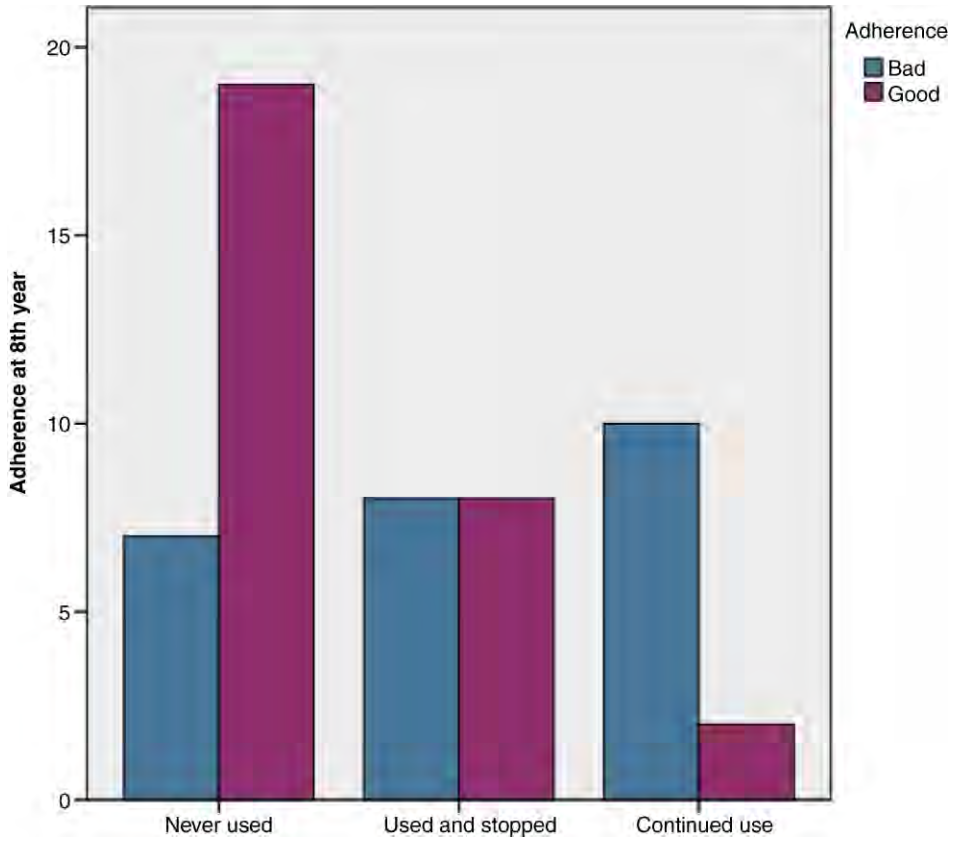

FIGURE 27.2 **Cannabis use and adherence.** Relationship between cannabis use and the pattern of adherence in the long-term. *Source: From Barbeito et al. (2013).*

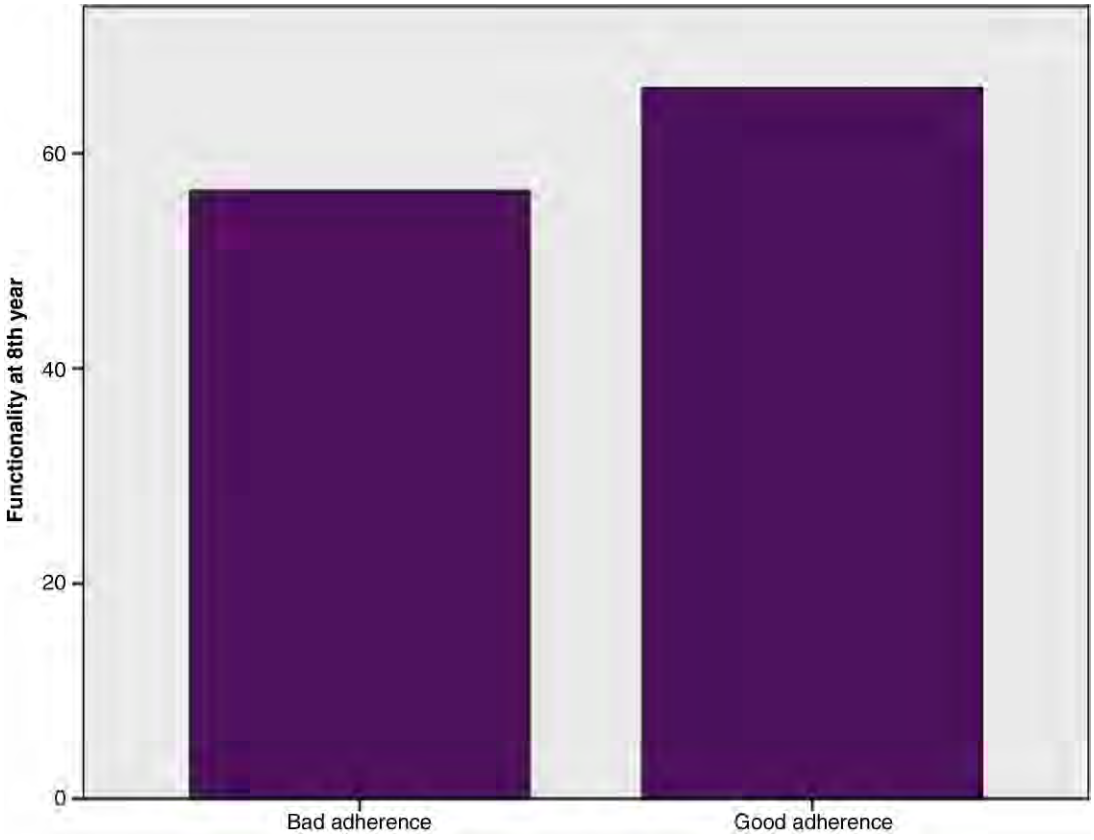

FIGURE 27.3 **Adherence and functionality.** Relationship between bad adherence and poor functionality in the long-term. *Source: From Barbeito et al. (2013).*

use. Furthermore, use of other drugs, mainly stimulants, may contribute to the worsening of functional outcomes. From our study of the impact of cannabis use on long-term outcomes in FEP patients (González-Pinto et al., 2011), it is difficult to understand why those patients who were able to quit cannabis use during follow-up had a better long-term functional outcome than those who never used cannabis. It could be that, at initial hospitalization with a first psychotic episode, cannabis users have a phenotypic presentation that is as severe as non-users (although they could have a lower genetic loading), but that quitting cannabis reveals a more benign disease after some years of follow-up, at least for functional outcome and negative symptoms. If this is true, continued use of cannabis causes even more damage than is currently thought. The progressive improvement of symptoms and functioning during follow-up, in the group who stopped using cannabis, is not consistent with the theory that cannabis causes permanent and residual effects in the long term (González-Pinto et al., 2011). In a recent metaanalysis of studies that compared outcomes in patients with psychosis who stopped using substances with those who had never used substances, the authors concluded that prior cannabis use is not necessarily a poor prognostic factor for those who stop using it (Gupta, Mullin, Nielssen, Harris, & Large, 2013). However, we have shown that stopping cannabis use is clearly beneficial (González-Pinto et al., 2011).

Cannabis use is also associated with depressive symptoms, and FEP patients with depressive symptoms have poorer long-term outcomes. In the study conducted by Sönmez, Romm, Andreasssen, Melle, and Røssberg (2013), FEP patients with persistent depression had poorer functioning and more negative symptoms at 12 months follow-up than patients with no depression. Birchwood, Iqbal, and Upthegrove (2005) have suggested that persistent depression is an integral aspect of schizophrenia that is associated with disease severity and negative symptoms. This link between depression and negative symptoms is particularly important in patients with comorbid cannabis use, although the etiology of the association remains unclear (Hartley, Barrowclough, & Haddock, 2013).

Some studies have found an association between cannabis abuse and the presence of fewer or less severe depressive symptoms (Tosato et al., 2013), suggesting that cannabis may alleviate some of these symptoms. According to the self-medication hypothesis, patients with depression often show a poor repertoire of behaviors, with a lack of rewarding activities in their daily life, except for the use of addictive substances (Arendt et al., 2007); these facilitate the appearance of a depressed mood which, in turn, is associated with an increased risk of cannabis

consumption in an attempt by patients to relieve their negative emotional state (Schofield et al., 2006). Thus, one factor that may contribute to the difficulty in stopping cannabis use among patients with depressive symptoms is the anxiolytic effect of its two main constituents, Δ^9-tetrahydrocannabinol (THC) and cannabidiol (Campos, Moreira, Gomes, Del Bel, & Guimarães, 2012).

The presence of depressive symptoms has also been associated with the effects of chronic use, or subacute intoxication with cannabis; this is referred to as the "amotivational syndrome," and includes symptoms of anhedonia, apathy, passivity, lack of interest, or difficulties in functioning (Arendt et al., 2007). In fact, some studies have observed an increase in negative symptoms (D'Souza et al., 2005) or depressive symptoms (Lev-Ran et al., 2014), when THC is administered to patients with schizophrenia. On the other hand, recent findings suggest that the effect of cannabis use on depressive symptoms might be moderated by genetic factors, specifically the short allele of the serotonin transporter gene-linked polymorphic region (5-HTTLPR) genotype; that is, cannabis use increases the risk for a worsening of depressive symptoms in individuals with this genetic vulnerability (Otten & Engels, 2013). Therefore, the association found between depressive symptoms and cannabis use is inconsistent, which raises the question of whether cannabis use could be the result of depressive symptoms. Thus, there are at least three hypotheses that could explain the relationship between depressive symptoms and cannabis abuse: (1) depressive symptoms are a consequence of cannabis abuse (Lynskey et al., 2004); (2) the self-medication theory (Arendt et al., 2007; Degenhardt, Coffey, Moran, Carlin, & Patton, 2007); and (3) patients have a common genetic or environmental vulnerability for both disorders (Lynskey et al., 2004).

Depressive symptomatology may contribute to a greater difficulty in stopping cannabis use, and predict a worse clinical and functional outcome of psychosis. Depressive symptoms, therefore, should be a therapeutic target in patients with first psychotic episodes, especially those who use cannabis, with the aim of improving the clinical and functional course of the disease.

In conclusion, cannabis use in FEP patients is associated with poor treatment adherence (Barbeito et al., 2013), more severe and chronic symptoms (Kovasznay et al., 1997), increased risk of relapse (Pencer et al., 2005), and poorer long-term functioning (González-Pinto et al., 2011).

IMPACT OF CANNABIS USE ON COGNITIVE FUNCTIONING IN FEP

Cannabis use among healthy individuals has been associated with cognitive deficits in multiple domains, such as, memory, attention, inhibitory control, executive function, and decision making. Cognitive impairment has also been associated with the frequency, duration, and age at onset of cannabis use (Meier et al., 2012).

The association between cannabis use and cognitive deficits in patients with psychosis is less clear, and more difficult to demonstrate because cognitive deficits are also present in patients with psychosis who do not use cannabis. Some studies have shown cognitive impairment in FEP patients, compared with control subjects (Ayres et al., 2010), and cognitive deficits which decreases in gray matter volume, lateral ventricle enlargement, and other structural brain abnormalities (Minatogawa-Chang et al., 2009; Rosa et al., 2010; Schaufelberger et al., 2011; Trzesniak et al., 2012), in FEP cannabis users (Rais et al., 2008).

Moreover, D'Souza et al. (2005) found that acute administration of THC causes more deleterious cognitive effects in patients with psychosis than in healthy control subjects. A recent cross-sectional study has shown that current cannabis users have deficits in processing speed and verbal memory (Meijer et al., 2012). In contrast, other authors have reported that patients with psychosis, who use cannabis, have better cognitive functioning in some domains than patients who do not use cannabis (Leeson et al., 2009; Leeson, Harrison, Ron, Barnes, & Joyce, 2012; Loberg & Hugdahl, 2009). Moreover, Cunha et al. (2013) recently found that FEP patients with a history of cannabis use not only had less brain abnormalities (ie, gray matter and lateral ventricle volume was preserved), but also had less attentional and executive impairment, compared to patients who never used cannabis.

These conflicting findings are probably due to methodological limitations of the studies, and the effects of different moderators in the samples analyzed. Yücel et al. (2012) considered that there is probably a subgroup of cannabis users with psychosis who have better premorbid adjustment and cognitive performance. Similarly, Meijer et al. (2012) found that current cannabis use is associated with poorer cognitive performance, but that lifetime cannabis users may have a higher cognitive potential. This does not mean that cannabis has a beneficial effect on cognition; on the contrary, it worsens cognitive performance, although some of these individuals had better premorbid capacities. Accordingly, Winkel, van Beveren, and Simons (2011) found that the deleterious effect of cannabis use on cognition in patients with psychosis was moderated by the *AKT1* gene. They showed that cannabis-using patients who carry the CC variant in the *AKT1* gene performed worse on tests of attention than patients with this genotype who did not use cannabis, whereas cannabis users with the TT variant in *AKT1* performed as well as, or better, than cannabis nonusers (Winkel et al., 2011).

Other methodological limitations are that some studies included patients with a history of previous cannabis

use, and did not examine current cannabis use (de la Serna et al., 2010; DeRosse, Kaplan, Burdick, Lencz, & Malhotra, 2010). Stopping cannabis use has beneficial effects on outcome, as already discussed; this may include cognition, although this has not been well studied.

TREATMENT FOR FEP CANNABIS USERS

Research showing the involvement of environmental factors, such as cannabis use, in the development of psychosis (Rutten & Mill, 2009) will drive the search for new targets for prevention, early diagnosis, and intervention to reduce functional impairment of patients with psychotic disorders. People presenting with a first psychotic episode show reduced cognitive performance and functional impairment, compared with matched control subjects, and these deficits can lead to reduced social integration (Kravariti et al., 2009). Cannabis use has become a target for the prevention and treatment of patients with first psychotic episodes because of its influence on the development and prognosis of the disease. Unlike patients with chronic psychosis, individuals with a first psychotic episode show cannabis use of varying frequency and intensity, as well as greater motivation for change (Lambert et al., 2005). This highlights the need to intervene in the early stages of the disease, while the patient is young, and has a shorter history of substance abuse.

Early prevention, detection and treatment (pharmacological and psychological) of FEP patients is closely linked to better prognosis (Bertelsen et al., 2008). Early intervention may not only allow substance abuse in FEP patients to be detected, but may also enable it to be reduced. In a systematic review of studies examining the effectiveness of psychological intervention in FEP, Vega, González-Pinto, Ruiz de Azua, Barbeito, and Rico (2010) concluded that psychoeducation as an adjunct to medication is effective in improving negative symptoms and patient functionality. Despite the clinical consequences of cannabis use in early psychosis (Baeza et al., 2009), very few clinical trials have evaluated specific interventions aimed at reducing cannabis use in this patient population (Copeland, 2004). However, psychoeducation may be insufficient (Edwards et al., 2006). Furthermore, the effectiveness of the intervention and type of approach used were unclear, as well as the small sample size and the lack of appropriate control groups used in the studies, all this making it difficult to draw conclusions (Edwards et al., 2006).

There is an urgent need to develop specific interventions that effectively reduce cannabis consumption, as part of a comprehensive treatment program for patients with psychosis. An intervention focused on the management of cannabis use is needed to prevent the relapse and progressive impairment that often arises after the first psychotic episode (Lewis, Tarrier, & Drake, 2005). Some evidence suggests that cognitive behavioral therapy and motivational techniques might be effective in treating psychotic patients who are cannabis users (Edwards et al., 2006). Such psychological interventions are a promising therapeutic approach, not only for treating psychosis, but also for detecting and reducing drug abuse in patients experiencing a first psychotic episode. However, there is currently no evidence that any one specific type of psychosocial treatment is more effective than standard care at reducing substance use, or improving the course of illness in people with serious mental disorders. In a systematic review of 32 randomized controlled trials of the effectiveness of psychosocial interventions in people with both severe mental illness and substance misuse, the authors found that cognitive behavioral therapy, motivational interviewing, or motivational interviewing plus cognitive behavioral therapy had no advantage over usual treatment for reducing substance use, relapse, or global functioning (Hunt, Siegfried, Morley, Sitharthan, & Cleary, 2014).

Hunt et al. (2014) discussed some of the methodological limitations of existing studies, and concluded that there is a need for better quality trials that adhere to proper randomization methods; use clinically valuable, reliable, and validated measurement scales; and clearly report data, including retention in treatment, relapse, and abstinence rates. Finally, there is a need for interventions based on a more accurate understanding of the different patterns of cannabis consumption, and the factors that maintain or inhibit drug abuse in young people with first episode psychosis.

MINI-DICTIONARY

Attention Attention is the cognitive process that inlcudes the ability of selecting and inhibiting some information for further processing. There are different types of attention, such as: selective attention, focused attention, divided attention and/or sustained attention.

Canabidiol Active compound of cannabis that can counteract the effects of THC.

Cannabis abuse Continued use of cannabis despite negative consequences (health, work, school, family, or social relationships).

Cognitive functioning Cognitive functioning is the intellectual activity that includes mental processes, such as, attention, processing speed, learning and memory, executive function, verbal fluency, and working memory.

Executive function Cognitive process that involves reasoning, flexibility, and problem solving ability and cognitive skills to plan, organize, and execute tasks.

First episode psychosis (FEP) A first psychotic episode was defined as the first time a patient displayed positive psychotic symptoms of delusions and/or hallucinations.

Learning and memory Cognitive domain that includes the process of acquiring, processing, and consolidating knowledge.

Outcomes Outcomes of patients are the clinical and/or functional effects measured during follow-up, and associated with the course of disease.

Processing speed Ability to process information automatically and fluently. Processing speed requires visual-motor coordination, as well as motor and mental speed.

Psychosis Psychosis is a mental disorder characterized by loss of contact with reality. The affected organ is the brain, causing changes in thinking, perception, feelings, and behavior of the person. The most common diagnoses associated with psychosis are: schizophrenia, schizophreniform disorder, schizoaffective disorder, brief psychotic disorder, schizotypal disorder, bipolar disorder, and major depressive disorder with psychotic symptoms.

Δ^9-Tetrahydrocannabinol (THC) Main psychoactive substance of cannabis.

Verbal fluency Ability to form and express words that includes phonological and semantic fluency tasks.

Working memory Ability to manipulate and maintain information over short-term.

CHAPTER

28

Cannabis, Associative Memory, fMRI, and the Implicit Association Test

S.L. Ames, A.W. Stacy

School of Community and Global Health, Claremont Graduate University, Claremont, CA, United States

SUMMARY POINTS

- Imaging neurobiological processes of cannabis users with paradigms that tap into associative memory advances the understanding of habit-based processes.
- Associative memory principles provide a neurobiologically plausible explanation for why cannabis use can become self-perpetuating.
- Implicit association test (IAT) is one method used to examine associative memory structures.
- Neural activity generated by IAT compatible and incompatible trials allow for the detection of potential associative/habit-based learning, since they reflect neural response to *more* or *less* effortful processing of concepts.
- Marijuana users showed greater neural activity in striatal brain regions during compatible trials of a marijuana-IAT.
- Nonusers showed greater neural activity in regions requiring more effortful processing during incompatible trials.
- Marijuana IAT imaging findings suggest that different networks mediate (1) implicit associations underlying habit, namely circuitry dependent on the striatum, and (2) effortful/control processes that are more dependent on prefrontal and frontal cortical regions.

KEY FACTS OF A DUAL PROCESS DISTINCTION IN BRAIN FUNCTION RELEVANT TO HABITUAL BEHAVIORS

- A complex interaction between cortical and subcortical neural systems is thought to underlie the growth of habitual behaviors.
- A key subcortical neural system implicated in implicit associative/habit-type processes is the amygdala-striatal system.
- The striatum is further divided into regions; the dorsal region includes the caudate and putamen, and ventral region consists of the nucleus accumbens.
- The amygdala-striatal system is critical for the incentive motivational effects of a variety of nonnatural rewards (Robbins et al., 1989).
- The insula is a subcortical region emerging as a substrate involved in this habit-based circuitry.
- Key cortical circuits supporting executive functions (eg, inhibitory control, attentional processes, working memory capacity, and reflective/deliberative processes) involve several brain structures of the prefrontal and frontal cortex.
- These include (but are not limited to) the dorsolateral prefrontal cortex, lateral regions of the orbitofrontal cortex, and adjacent ventrolateral region (inferior frontal gyrus; eg, Aron, Robbins, & Poldrack, 2004), and anterior cingulate cortex (Botvinick, 2007).

LIST OF ABBREVIATIONS

ACC	Anterior cingulate cortex
A-O	Action outcome
CB1	Cannabinoid 1
CB1-R	Cannabinoid 1 receptors
DLPFC	Dorsolateral prefrontal cortex
fMRI	Functional magnetic resonance imaging
IAT	Implicit association test
RIFG	Right inferior frontal gyrus
S-R	Stimulus-response

INTRODUCTION

Cannabis is one of the most prevalent drugs used around the world. The imaging of neurobiological processes of cannabis users with task-based paradigms that tap into associative memory processes can help us understand habit-based processes that perpetuate its use. Drug use habits, as well as some other appetitive behaviors (ie, rewarding behaviors that are often dopamine dependent), may be conceptualized as a potent form of reinforced associative learning (Yin & Knowlton, 2006a). Several researchers have proposed that associative learning processes and memories that involve reward or positive outcomes mediate, and can explain, appetitive behaviors (DiChiara, 2002; Schultz, 2004). Animal studies have provided evidence that exposure to cues previously associated with a reward can trigger a neurobiological anticipatory response that occurs quite rapidly (within a few milliseconds) at the synaptic level (Phillips, Stuber, Heien, Wightman, & Carelli, 2003). Through repetitive experiences, neutral cues strongly associated with rewarding behaviors can come to represent the behavior, and elicit an "automatic" pattern of activation in memory, which, in turn, promotes the behavior (Stacy, Ames, & Knowlton, 2004; White, 1996). These automatic associative effects have implications for cannabis use and other habits highly sensitive to prior learning experiences and predictive cues.

Although considerable research has focused on neuroadaptive effects of drug use (Bechara, 2005; Everitt, Dickinson, & Robbins, 2001; Robinson & Berridge, 2003; Volkow, Fowler, Wang, & Goldstein, 2002), nuances of neural processes and functional changes underlying drug and other habit formation continue to be revealed. Use of new and emerging imaging methodologies has contributed to increased understanding of the brain mechanisms through which continued drug use influences cognitions, memory, emotional states, and behavior itself. These imaging methodologies in concert with refined cognitive paradigms allow researchers to observe neural populations associated with drug use-related phenomena. This chapter addresses one, such paradigm—IAT—in the study of cannabis use, and elaborates on associative memory processes believed to account for IAT-related neural effects. Associative memory principles provide a neurobiologically plausible explanation for why cannabis and other appetitive behaviors can become self-perpetuating.

OVERVIEW OF ASSOCIATIVE MEMORY

Associations in memory develop through experience, with associative learning processes likely enhanced through the reinforcing effects of a behavior. Associative memories may involve any linked information, and can operate nonreflectively and spontaneously when associations are sufficiently strong. Strong, spontaneously-acting associations can be revealed when an individual applies previously acquired knowledge without recalling a previous event, or without being prompted for deliberation. Paradigms used to study the activation of associated concepts in memory have been around for decades, and have contributed to many theories from basic research that are diverse in structural and computational architectures but, nonetheless, converge on the fundamental importance of associations or connections in memory (for examples of applicable theories, see Stacy & Wiers, 2006).

Consistent with theories of memory that propose parallel processes, automatic associative or relational memory effects operate well beyond the traditional associations studied in conditioning literatures, extending to perceptual, affective, and more general multimodal/conceptual distributed forms of memory that can jointly affect the prevailing pattern of activation in memory. Central associations may involve key habit associations [stimulus–response (S-R) associations], action outcome associations (A–O associations), as well as conceptual, perceptual, or affective associations in which an event or situation triggers a chain of activations across distributed memory systems, triangulating on a strongly associated behavior, rather than less-strongly associated behavioral options. A biasing effect of automatic memory processes on behavior is consistent with a history of work in social psychology revealing, such effects (for summary, see Payne & Gawronski, 2010), and with our application of these processes to appetitive health behaviors (Stacy, Ames, Wiers, & Krank, 2010). In research at the neural level, some researchers have pointed out that, at some point, A–O associations may not be relevant because habit has become so strong that S-R associations prevail (Yin & Knowlton, 2006a). Thus, habits may prevail paradoxically, despite negative outcomes. Further, in the present analysis, the "S" in S-R can be usefully defined as not only a single instigating stimulus or setting linked to behavior, but also as a constellation of cues that together can automatically promote a

distributed pattern of activation in memory that reflexively triggers, or at least biases a behavioral response, more than alternatives.

NEUROSCIENCE OF DUAL SYSTEMS AND ASSOCIATIVE MEMORY PROCESSES IN HABIT FORMATION

Research on impaired memory function and imaging of brain activation has helped define the influence of associative processes on behavior, and provided evidence for the neural basis of distinct memory/cognitive systems (Gabrieli, 1998; Knowlton, Mangels, & Squire, 1996; Rolls, 2000; White, 1996). A distinction between spontaneous associative memory and controlled process systems has been reinforced through several independent lines of research in neuroscience (Bechara, Noel, & Crone, 2006; Chein & Schneider, 2005; Levy, Stark, & Squire, 2004; Yin & Knowlton, 2006b).

With respect to drug use, a dual process distinction proposed by several researchers describes appetitive behaviors as a dynamic interplay between (1) a relatively implicit or automatic associative system (or set of systems), and (2) an executive control/inhibitory system (Bechara, 2005; Stacy et al., 2004; Strack & Deutsch, 2004; Wiers et al., 2007). As habit-type appetitive behaviors develop, an imbalance can occur between executive control and automatic associative systems. The general idea is that associative processes that are reinforced and likely enhanced by appetitive behaviors (such as drug use) result in neurobiological consequences that include the strengthening of motivationally relevant associations that affect subsequent behavior. As associative processes become stronger, the involvement of neural regions implicated in control processes is weakened in effects on behavior. That is, behavior can come to be increasingly under cue control, and less under voluntary control (Bechara et al., 2006; Stacy et al., 2004; White, 1996; Wiers et al., 2007). Cues can then trigger an essentially "automatic" pattern of activation in memory that can be described in a variety of neural network models (Botvinick & Plaut, 2004; Bowers, 2009). Across neural systems, this evolution may be represented by the "transition from prefrontal cortical control systems to subcortical striatal control and within the striatum from ventral to dorsal domains of the striatum" (p. 1741; Vollstädt-Klein et al., 2010) as habitual behaviors develop (Everitt & Robbins, 2005; Robbins, Ersche, & Everitt, 2008; Schneider & Chein, 2003). In the compatible decision theory of Kahneman (2003), the associative system (labeled System 1 in his taxonomy) governs the majority of human decision-making, and is more or less the "default" system that guides behavior, unless modified by control processes (System 2).

LINKING ASSOCIATIVE EFFECTS TO CANNABIS-RELATED NEURAL SUBSTRATES

Although drugs have specific receptor sites in the brain, most act directly or indirectly on brain reward (ie, dopamine) systems. Cannabis indirectly activates dopamine systems by stimulating neurons that modulate the release of dopamine through direct effects on cannabinoid receptors (Baler & Volkow, 2006). Animal models have shown endocannabinoid signaling through cannabinoid 1 receptors (CB1-R) to play a key role in reward and habit development, with the striatum implicated as a critical neural substrate for CB1 signaling (Hilario, Clouse, Yin, & Costa, 2007). Dopaminergic activity in the striatum reinforces the repetition of certain behaviors, and the encoding and processing of proximal stimuli associated with rewarding events (eg, Everitt & Robbins, 2005; Cardinal & Everitt, 2004). As learned associations in memory are strengthened, they may come to represent and subsequently cue behavior spontaneously, with little involvement of deliberative or control processes. Yin and Knowlton (2006a) reviewed multiple lines of evidence mapping cue-habit associations to the dorsolateral striatum (putamen), action–outcome associations to the dorsomedial striatum (caudate), and cue and affective outcome associations with the basolateral amygdala. These types of associations and implicated brain regions involve complex neural circuitry with clear implications for cannabis use.

ASSOCIATIVE MEMORY ASSESSMENTS, THE IMPLICIT ASSOCIATION TEST, AND CANNABIS USE

Consistent findings in behavioral research document the value of associative process effects in the prediction of drug use across a range of populations (for reviews, Rooke, Hine, & Thorsteinsson, 2008; Wiers & Stacy, 2006). Prospective studies have confirmed these predictive effects with the use of varied indirect tests of association (Grenard, Dent, & Stacy, 2013; Kelly, Haynes, & Marlatt, 2008; Kelly, Masterman, & Marlatt, 2005; Thush et al., 2007). Associative memory assessments of drug use tap into and activate preexisting associations in memory (Wiers & Stacy, 2006), with some aspects of memory expressed by facilitated performance (reaction time) on indirect tests of association. In general, these tests of association do not require conscious or intentional recognition of past experiences, and are relatively free from demand characteristics (Roediger, 1990).

The IAT (Greenwald, McGhee, & Schwartz, 1998) is one of the most common methods used to examine attitude and behavior-related associative memory structures.

Hundreds of studies have been published using the IAT to evaluate a variety of associations, for example, toward gender, age, race, alcohol, and other drugs, among others (for review, Greenwald, Poehlman, Uhlmann, & Banaji, 2009). With respect to cannabis, in a behavioral study comparing marijuana users to nonusers, Field, Mogg, and Bradley (2004) found significantly more negative implicit associations toward marijuana-related words in the group of nonusers. In another behavioral study, Ames et al. (2007) used an adapted unipolar marijuana-IAT in a population of at-risk youth and found positive reinforcement associations (ie, excitement) to be predictive of marijuana use, controlling for gender, ethnicity, explicit cognitions, sensation seeking, and working memory capacity.

The IAT is a categorization task that provides a relative measure of associative strength between concepts. On the task, participants categorize stimuli rapidly (making as few mistakes as possible) into categories, by pressing a left or right response key. Reaction time to the task is faster when the categories are highly associated in memory, and when associated categories require the same key press. Mapping of key to category is switched in different within-subject conditions to assess relative association strength. The basic assumption is that past experiences can be represented by the ease of information processing of associated concepts, and this is assessed by reaction time, or rate of processing of information (see Greenwald et al., 1998). The behavioral IAT effect (D600) can be calculated as the mean reaction time in incompatible task blocks (concepts unlikely to be associated), minus the mean reaction time in compatible task blocks (concepts likely to be associated), divided by the pooled standard deviation for the blocks (Greenwald, Nosek, & Banaji, 2003).

IMAGING THE IMPLICIT ASSOCIATION TEST

Human functional imaging techniques provide a way to correlate cognitive processes engaged during a task with patterns of activation in neural populations. For example, the processing of drug-relevant associations on a task can be correlated with neural activity in specific brain regions. Although functional magnetic resonance imaging (fMRI) provides insight into neural activation of cognitive processes associated with tasks, findings are correlational, and other variables (ie, confounders) may affect findings attributed to information processing. Nevertheless, measuring task-related neural responses can, at times, be a more sensitive measure than some behavioral measures, providing key information about relevant neural processes.

Several studies have observed the neural correlates of IAT performance in the scanner. It is important to note that, although the IAT is a test of the relative strength of associations of specific concepts, when evaluating brain function, the task involves dual cognitive processes. That is, IAT performance recruits both effortful/control and automatic associative processes. The neural activity comparisons generated by the task conditions (ie, compatible and incompatible trials) allow for the detection of potential associative/habit-based learning, since they reflect neural response to *more* or *less effortful/controlled processing* of concepts.

The neural correlates of nonsubstance-related IATs have been observed in several imaging studies (eg, racial preference, Beer et al., 2008; flowers/insect pleasantness, Chee, Sriram, Soon, & Lee, 2000; politics, Knutson, Wood, Spampinato, & Grafman, 2006; gender and race-related, Knutson, Mah, Manly, & Grafman, 2007; morality, Luo et al., 2006). The task elicits neural populations involved in automatic associative processing during the task's compatible trials and effortful/controlled processing on incompatible trials. In general, performance on incompatible trials has been found to elicit greater frontal activity, relative to the compatible trials [eg, increased activity in the ventrolateral, dorsolateral prefrontal cortex (DLPFC), and anterior cingulate (ACC): Chee et al., 2000; Luo et al., 2006; left inferior frontal gyrus: Knutson et al., 2006; middle frontal gyrus: Knutson et al., 2007]. In a study by Beer et al. (2008) on a racial preference IAT, activity in the caudate, insular cortex, and lateral orbital frontal cortex were observed during compatible association trials. Both the caudate and the insula have been implicated in habit-based circuitry (Noël, Brevers, & Bechara, 2013).

In a substance-related imaging study, Ames et al. (2014) assessed activity in neural substrates of an alcohol-IAT focused on positive outcomes of alcohol use, in heavy and light drinkers. Behaviorally, heavy drinkers showed significantly stronger positive implicit associations toward alcohol use than light drinkers. In terms of neural response, heavy drinkers showed greater activity during compatible trials (relative to incompatible trials) in habit-based regions, namely the left putamen, insula, and amygdala. Alternatively, no significant difference in activity between conditions was observed in light drinkers. During both compatible and incompatible trials, light drinkers showed more activity in the left orbital frontal cortex (relative to heavy drinkers), and both groups showed significantly greater activity in the DLPFC during incompatible trials (relative to compatible trials). Findings from this imaging study suggest that different networks mediate associative and effortful/control processes, and activation of these networks vary by level of experience with alcohol.

IMAGING THE MARIJUANA-IAT

In another substance-related IAT imaging study, Ames and colleagues (2013) evaluated differences in neural correlates of 13 marijuana-users and 15 nonusing

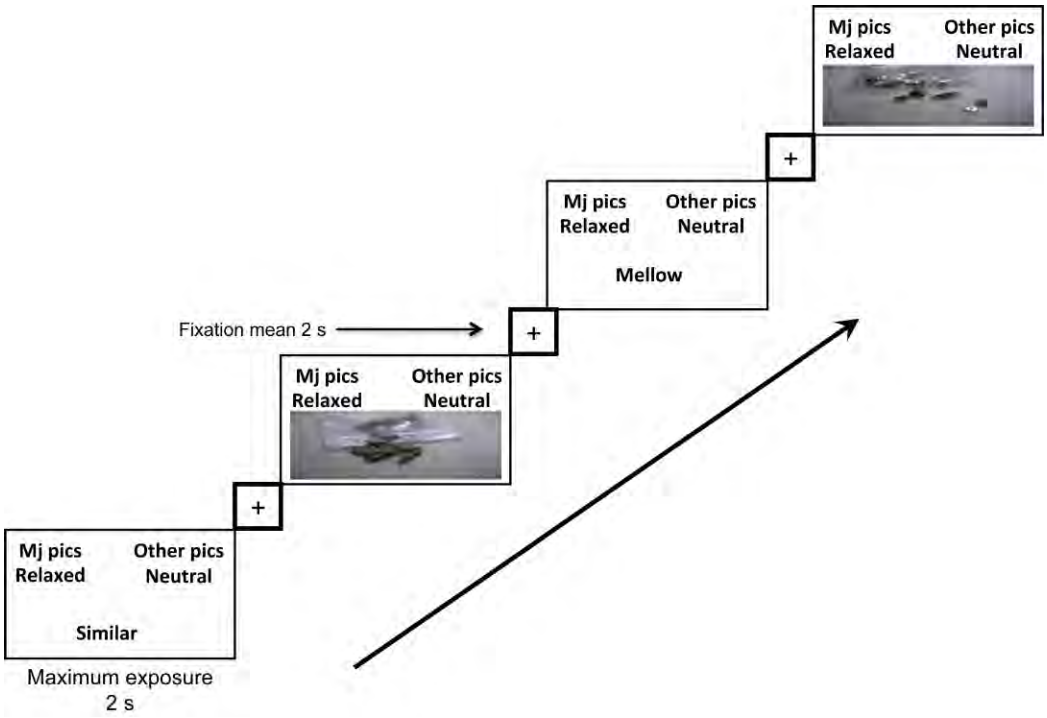

FIGURE 28.1 Temporal layout of 40 compatible trials or implicit associations toward marijuana use. Individuals react faster when categorizing *strongly associated* concepts that share a response key. This should be fairly easy to do for someone with past experience of marijuana use. Temporal jitter was used in the presentation of the fixation with onset timing ranging from 1 to 4.5 s, with a mean exposure of 2 s, followed by stimuli presentation. Maximum exposure of test stimuli was for 2 s. After a participant pressed a response key, the screen would go blank for the remainder of the 2 s. Total trial time ranged from 3 to 6.5 s. *Source: Reprinted from Ames et al. (2013), with permission from Elsevier; see http://dx.doi.org/10.1016/j.bbr.2013.09.013.*

controls, while performing a marijuana-IAT in the scanner. The majority of the nonusing controls had never used marijuana, with only two having used only a few times in their lifetimes. The marijuana users reported using marijuana more than 500 times in the past 3 years, and current daily use.

There were no significant differences in mean age between groups [marijuana users, mean age 21.15 (1.9); controls mean age 20.27 (2.3)]. However, 18% of the marijuana users were female, and 67% of the nonusers were female ($p < .01$). All participants were right-handed, native English speakers, and void of a history of psychiatric or neurological disorders. Further, participants were matched on ethnicity, and past 3-year alcohol, tobacco, and other drug use, with minimal lifetime use of drugs other than marijuana. There were no significant differences between groups in working memory capacity (a proxy measure for general fluid intelligence; see Kane & Engle, 2002).

Imaging Paradigm

The marijuana-IAT consisted of five different words and five different images that were randomly presented (Ames et al., 2007). The target categories were "Marijuana Pictures" and "Other Pictures." Images were closely matched in size and shape, and consisted of a joint, rolling papers, pipe, dried marijuana buds, and dried marijuana in a plastic baggie. The matched "Other Pictures" were images of a ballpoint pen, small memo pad, small flashlight, loose thumbtacks, and thumbtacks in a clear plastic box. The affective categories paired with the images consisted of a "Relaxed" category for positive reinforcement, and a "Neutral" category. Relaxed category words were chill, calm, cool, mellow, and comfortable. The matched Neutral category words were count, square, common, similar, and historical. The task was a standard IAT (Nosek, Greenwald, & Banaji, 2005), and included seven blocks of trials inclusive of both practice and test trials. The order of IAT incompatible and compatible blocks of trials was counterbalanced across participants. The headers for compatible association trials were "marijuana pictures + relaxed words," and "other pictures + neutral words." The headers for incompatible trials were "marijuana pictures + neutral words," and "other pictures + relaxed words" (Figs. 28.1, 28.2).

In the scanner, participants were instructed: "*Press the #1 key for items that fit into a category on the top left. Press the #4 key for items that fit into a category on the top right. The categories change from time to time. You will not receive any instructions during the task. Go as fast as you*

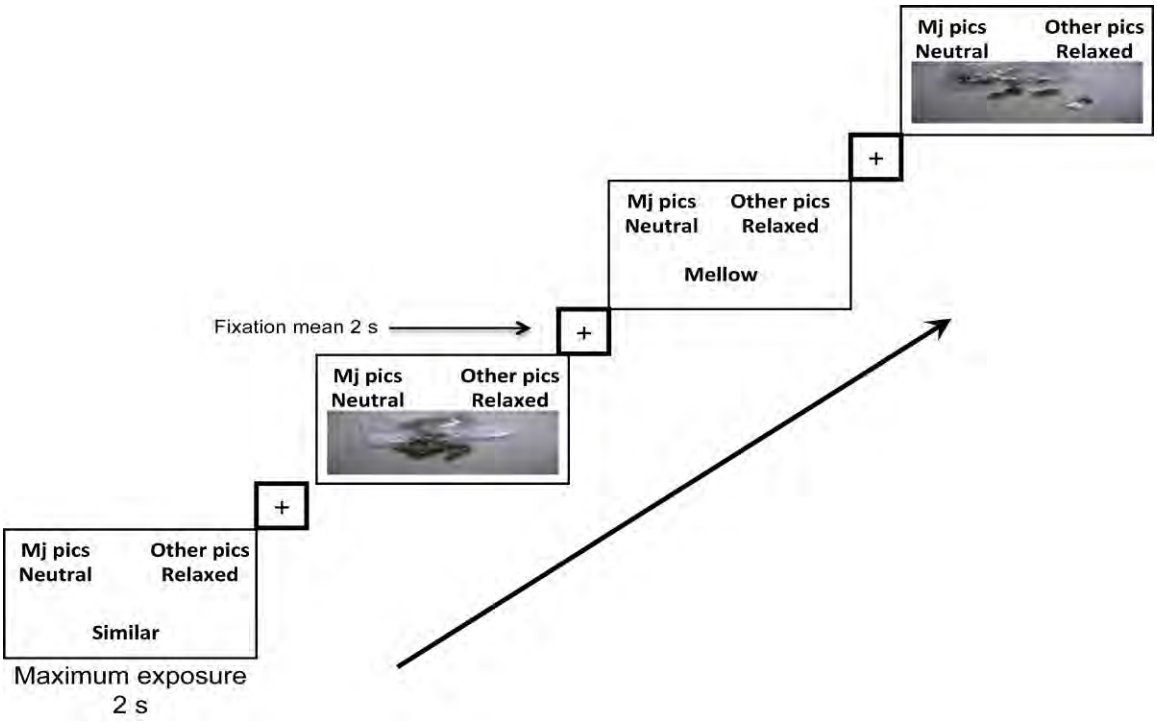

FIGURE 28.2 **Temporal layout of 40 incompatible trials.** In this figure, the attribute categories are switched. Individuals react slower when categorizing concepts *not typically associated* that share a response key. These trials require more effortful processing across all subjects. *Source: Reprinted from Ames et al. (2013), with permission from Elsevier; see http://dx.doi.org/10.1016/j.bbr.2013.09.013.*

can without making mistakes. Please wait for the task to start automatically."

Based on previous imaging studies, it was expected that the marijuana users (compared to nonusing controls) would show greater neural activity in regions critical for associative memory processes underlying habit, during the compatible trials. Individuals with positive past experiences with marijuana should be able to perform these trials with little effort, and faster than individuals with little to no experience with the drug. The neural regions expected to be more active among the marijuana users on the compatible trials were the dorsal striatum (caudate/putamen), and ventral striatum (nucleus accumbens).

The incompatible trials were expected to elicit more activity among all participants in regions requiring more controlled processing of information, when compared to the compatible trials. The idea was that, during incompatible trials, participants are categorizing concepts that require more deliberative/effortful processing, since the concepts are not generally associated with each other. Further, it was predicted that the degree of increased activity in these regions would be less in the marijuana-using group, perhaps reflecting poorer controlled processing due to chronic effects from use. The regions implicated were lateral regions of the orbitofrontal cortex, dorsolateral and adjacent ventrolateral, and inferior frontal gyrus, all regions associated with control processing (Aron, Robbins, & Poldrack, 2004).

For imaging, the study used a 3 Tesla magnetic resonance scanner, fitted with head coil arrays for parallel imaging to minimize signal loss and image distortion. An MRI-compatible response box with a fiber-optics response pad and four buttons that accepts a trigger from the scanner was used to collect participants' responses. Participants lay supine on the scanner bed while visual stimuli were back-projected onto a screen and viewed through a mirror attached onto the head coil. Functional images were acquired using a z-shim gradient, single-shot T2*-weighted echo-planar imaging sequence with prospective acquisition correction. The scanning parameters were as follows: TR = 2000 ms (whole brain); TE = 25 ms; flip angle = 90 degree; 64 × 64 matrix size with resolution 3 × 3 mm^2; bandwidth: 1906 Hz/pixel. The image data underwent the standard preprocessing to improve signal detection and sensitivity of statistical analyses. The fMRI whole brain analyses used a standard two-level general linear modeling approach (Friston et al., 1995). F tests were used to detect the main effects of condition and group and their interaction. The significance threshold was set at an exploratory uncorrected $p < .005$, with clusters larger than 30 voxels.

Behaviorally, no significant difference between the marijuana users and nonusing comparison group was found on the D600 measure of the IAT. However, the mean response latencies on the compatible trials were less than the mean for the incompatible trials across all

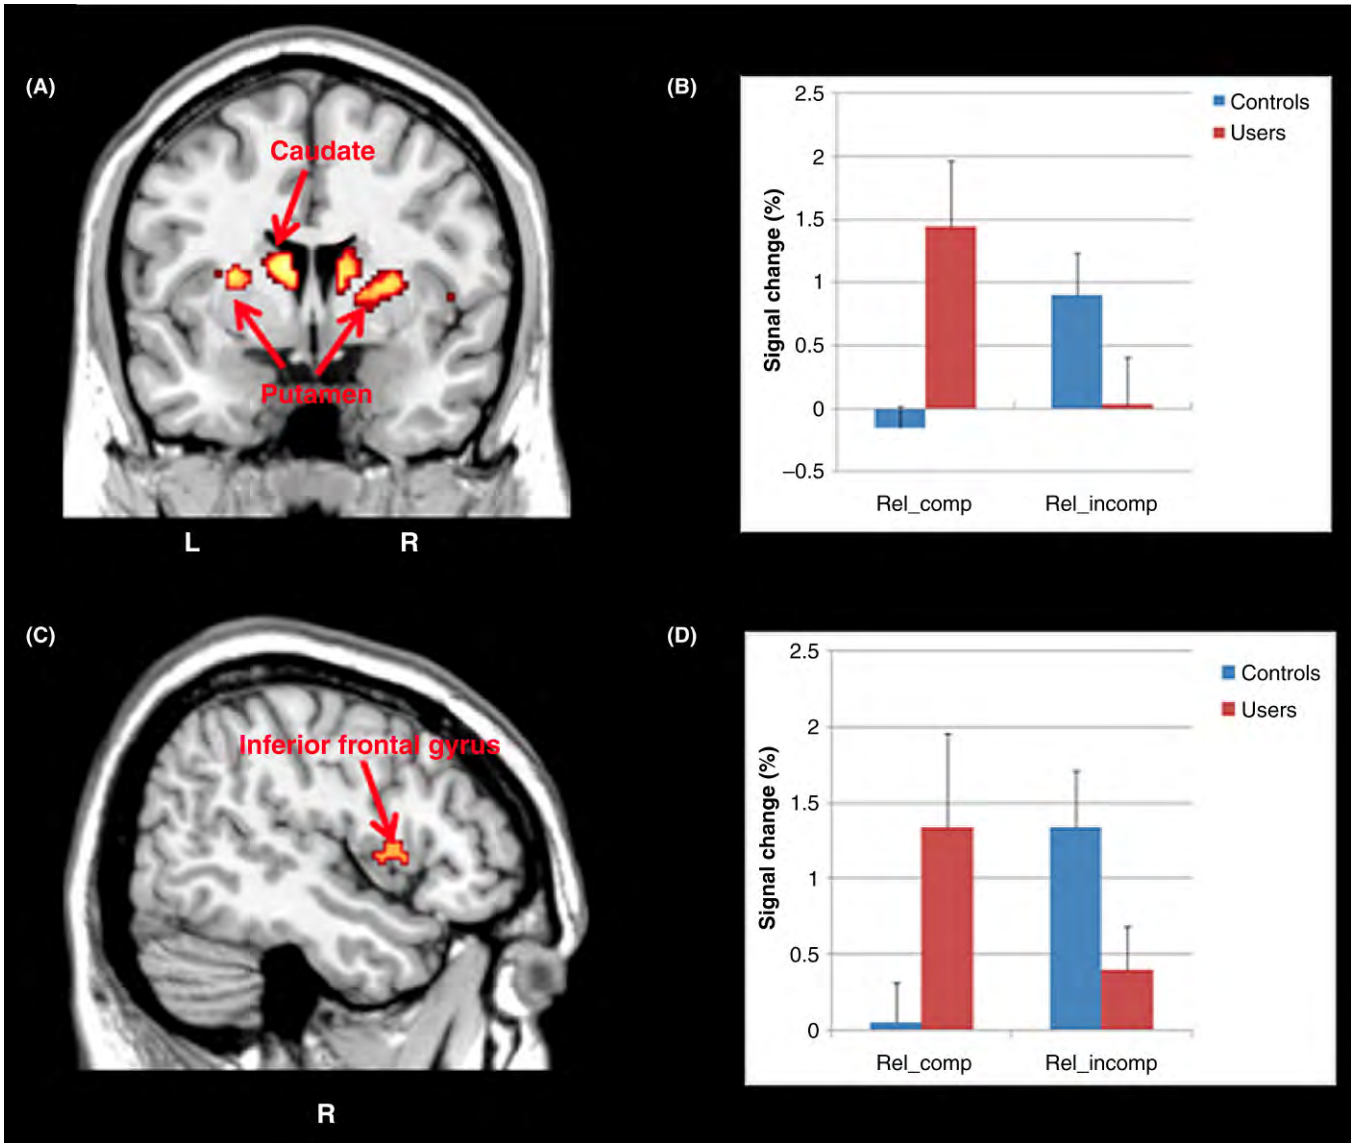

FIGURE 28.3 **Interaction effect during compatible and incompatible trials by user and control groups in subcortical and cortical regions.** (A) Coronal view of activity in the caudate and putamen; (B) signal change (%) for both caudate and putamen. Error bars denote within-subject error; (C) sagittal view of the activity in the right inferior frontal gyrus; (D) signal change (%) for the right inferior frontal gyrus. Error bars denote within-subject error. Significance set at $p < .005$, uncorrected, voxels > 30. *Source: Reprinted from Ames et al. (2013), with permission from Elsevier; see http://dx.doi.org/10.1016/j.bbr.2013.09.013.*

participants, and fewer errors were made during compatible trials than incompatible trials. It is possible that no group effect was found because the stimuli presented were too culturally common and a limited set to behaviorally differentiate users from nonusers. The categories and stimuli used are important determinants of behavioral IAT effects (Nosek, Greenwald, & Banaji, 2007).

Although the behavioral measure did not detect group differences, the data clearly showed differences in neural response, confirming a distinctive advantage of using fMRI in detecting differences in functioning that otherwise might not be detected with conventional behavioral assessments. Imaging data showed a clear interaction between the two groups and task conditions. Findings revealed a difference between marijuana users and nonusers in regions of the brain implicated in habit-based (associative) learning (Robbins et al., 2008). Increased bilateral activity in the caudate and putamen (striatal regions) were observed in the marijuana users during the compatible trials. These are the trials in which the strength of positive implicit associations toward marijuana, among the users, should be detected as a result of repetitive use experiences. This pattern of activity observed in the marijuana users is consistent with animal research regarding CB1 activity in the dorsal striatum, and the role of endocannabinoids in habit formation and habitual responding (Hilario et al., 2007) (Fig. 28.3).

TABLE 28.1 Significant Regions of Activity Within Groups During Compatible and Incompatible Trials

	Hemisphere	Region	*x*	*y*	*z*	Voxels in cluster	T statistic
Compatible association trials							
Marijuana users	Left	Inferior frontal gyrus	−46	28	24	2223	6.16
	Right	Posterior cingulate cortex	6	−40	6	85	4.85
	Left	Inferior frontal gyrus operculum	−54	12	0	85	4.24
	Right	**Putamen**	**30**	**−16**	**0**	**63**	**4.18**
	Right	**Caudate**	**20**	**24**	**8**	**223**	**3.99**
	Left	**Putamen**	**−24**	**6**	**12**	**100**	**3.74**
	Left	**Caudate**	**−18**	**−4**	**20**	**49**	**3.73**
	Right	Hippocampus	22	−28	−6	30	3.65
Incompatible association trials							
Nonusing controls	Left	Frontal inferior gyrus operculum	−58	12	2	165	5.70
	Right	Superior frontal gyrus	30	24	50	2179	5.70
	Left	Hippocampus	−28	−30	−4	95	4.85
	Left	Middle frontal gyrus	−42	54	10	750	4.59
	Left	Inferior frontal gyrus	−48	30	24	261	4.30
	Right	Caudate	18	10	22	252	4.02

Note: All peak activity based on whole brain analyses. Results are for single group/condition results relative to fixation. Significance $p < .005$, uncorrected, voxels > 30. Bolded regions represent predicted regions.
Reprinted from Ames et al. (2013), with permission from Elsevier; see http://dx.doi.org/10.1016/j.bbr.2013.09.013.

Further, among the marijuana users (relative to nonusers), some activity in the right inferior frontal gyrus (RIFG) was observed during compatible trials. This finding may have been the result of a need for inhibitory control over intensified striatal activity. That is, the marijuana users may have been working harder to inhibit habit-based tendencies, or suppressing well-learned associations requiring the engagement of frontal regions. The RIFG has been implicated in a more general role of executive processing, including detection of salient cues during task performance (Hampshire, Chamberlain, Monti, Duncan, & Owen, 2010), as well as inhibitory control (Aron et al., 2004).

Interestingly, little activity was observed during task performance in the ventral striatum (accumbens), a region traditionally implicated in motivation and reward. The lack of significant activity in this region is consistent with theories arguing that what may originate as motivational (supported by the ventral striatum) in essence transfers control to the dorsal striatum, the region supporting more habitual responding, following repetition of rewarding behavior, and without need for involvement of the ventral striatum (Robbins et al., 2008; Yin & Knowlton, 2006b). The marijuana users were quite habitual users, suggesting that transfer of control was plausible. It is also conceivable that merely observing marijuana stimuli was simply not sufficient to activate reward processing.

Finally, on incompatible trials, the nonusing group showed more activity in some frontal regions (although not the predicted regions) relative to fixation. Again, these trials require more effortful processing of information since the concepts to be categorized are not typically associated. Alternatively, marijuana users showed no significant activity on these trials in the study (see Tables 28.1 and 28.2). This finding partially supported the prediction that these trials would elicit more activity in frontal regions among all participants, but less activity in marijuana users perhaps as a result of chronic effects from current daily use. This finding is similar to other research that has shown reduced frontal activity in substance-using populations (Koob & Volkow, 2010).

In sum, the marijuana users showed greater activity in regions of the brain implicated in habit-based associative learning during compatible trials relative to fixation and relative to nonusers, while nonusers showed greater activity in regions of the brain requiring more effortful/controlled processing during incompatible trials relative to fixation. These findings are consistent with habit-related changes that occur in neural systems, and the transition or switch from predominantly effortful or control-related processing to more automatic (or implicit)

TABLE 28.2 Significant Regions of Activity Associated With the Group by Condition Interaction

Hemisphere	Region	*x*	*y*	*z*	Voxels in cluster	F statistic
Left	Caudate	−8	12	12	322	15.34
Right	Caudate	10	8	16	283	14.79
Right	Putamen	30	−14	0	46	14.07
Left	Putamen	−28	0	12	64	12.20
Right	Inferior frontal cortex	44	16	4	48	10.74

Note: All Fs, $p < .005$, uncorrected, voxels > 30.

processing with experience (Chein & Schneider, 2005; Schneider & Chein, 2003). Findings from this work provide support for a framework of appetitive behaviors proposing that (1) implicit associations underlying habit are mediated through neural circuitry dependent on the striatum, and (2) deliberative/controlled behaviors are mediated through circuitry more dependent on the prefrontal and frontal cortex.

CONCLUDING REMARKS

The imaging of neurobiological processes of cannabis users with task-based paradigms that engage associations in memory, such as the IAT, contribute insight into the neural substrates of marijuana-related associative memory processes (habit-based learning). Eliciting activation of associative drug-relevant memories during performance on substance-related IATs advances knowledge about neural mediators of a repeated or habitual behavior. Finally, neuroimaging research extends findings derived through behavioral research, demonstrating convergent, consistent predictive effects of associative memory processes in drug use. Such processes have implications for interventions, as outlined in previous work by the authors, and others working in this intriguing area.

MINI-DICTIONARY

Appetitive behaviors Behaviors that are rewarding and tend to be, in part, dopamine dependent.
Associative memory Memory for any linked information or interrelated concepts; memory revealed on indirect tests of association that tap into preexisting associations generally without awareness.
Dopamine Primary neurotransmitter involved in brain reward pathways; typically associated with arousal, reward, motivation and pleasure.
Functional magnetic resonance imaging (fMRI) Indirect measure of neural activity utilizing different magnetic properties of oxygenated and deoxygenated hemoglobin. Blood oxygenation level-dependent (BOLD) fMRI detects the hemodynamic response associated with neural activation during cognitive tasks and is used to observe relative changes in regional blood flow.
Implicit association test (IAT) An indirect test of association; a categorization task that provides a relative measure of associative strength between concepts assessed through rate of processing.
TE Echo time, or the time between consecutive 90 degree radio frequency pulse.
TR Repetition time or time between pulse sequences.

Stress Response in Cannabis Users and Psychosis

M. Bioque[*], *H.-H. Tseng*[**,†], *R. Mizrahi*[**]

[*]Barcelona Clínic Schizophrenia Unit, Hospital Clínic de Barcelona, Centro de Investigación Biomédica en Red de Salud Mental (CIBERSAM), Barcelona, Spain; [**]Centre for Addiction and Mental Health (CAMH), Research Imaging Centre, Toronto, ON, Canada; [†]Department of Psychosis Studies, Institute of Psychiatry, King's College London, London, United Kingdom

SUMMARY POINTS

- Several neuropsychiatric disorders are related to stress, and stress exposure modifies the onset and evolution of these conditions. Stress activates the hypothalamic–pituitary–adrenal axis (HPA) and the sympathetic nervous system (SNS). This activation results in a compensatory, physiological change or adaptation.
- The dysregulation of the stress response, including dopamine release, is a potential etiological factor in the development and relapse of dopamine-related human disorders, including addictions, drug-induced psychosis, and schizophrenia.
- Dopamine is one of the main actors in stress response, specially related to addictions, drug-induced psychosis, and schizophrenia.
- Exogenous cannabinoids alter the dopaminergic balance, most frequently causing alterations of dopamine release at downstream forebrain territories.
- Putative physiological and psychological effects of cannabis could be potentiated in individuals experiencing adverse environmental stress.
- The exposure to certain environmental factors interacting with genetic factors can alter dopaminergic system function, in response to stress.
- The endocannabinoid system—proposed as a main homeostatic system implicated in the regulation of the complex neuroimmune interactions in diverse neuropathological scenarios, reducing both neurodegenerative and inflammatory damage—may play a role as a possible link between stress, continuous cannabis use, and psychosis.
- Several studies have related endocannabinoid system alterations with psychotic disorders, while frequent cannabis exposure, especially in adolescence, may increase the risk of psychosis.
- Knowing the prominent role that the endocannabinoid system has in stress recovery, future research in this filed will have to clarify its relation to dopamine response to stress, in psychotic disorders, and how it is altered for exogenous cannabis use.

KEY FACTS OF PERIPHERAL BLOOD MONONUCLEAR CELLS (PBMC)

- Peripheral blood mononuclear cells (PBMC) are any blood cell having round nuclei, including lymphocytes, monocytes, and macrophage.
- As a main actor of the immune system, PBMC are critical to fight infection and foreign intruders in the body.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00033-8
Copyright © 2017 Elsevier Inc. All rights reserved.

- PBMCs are widely used in research and clinical applications in the fields of immunology (including autoimmune disorders), infectious disease, hematological malignancies, cancer, vaccine development, and transplants.
- PBMCs are also vital to cellular therapy, a process that introduces new blood cells into damaged tissue to treat a particular disease. This type of therapy often focuses on hereditary diseases, and may include gene therapy, stem cell treatments, and cell replacement therapy.
- There are currently emerging new biomarkers (inflammatory, metabolic, vitamin...) to neuropsychiatric diseases in PBMC.
- These cells can be extracted from whole blood using ficoll, a reagent that separates layers of blood that will separate the blood into a top layer of plasma, followed by a layer of PBMCs, and a bottom fraction of polymorphonuclear cells (such as neutrophils and eosinophils) and erythrocytes.

KEY FACTS OF MONTREAL IMAGING STRESS TASK (MIST)

- The Montreal Imaging Stress Task (MIST) is a computerized task derived from the Trier Mental Challenge Test, and adapted for imaging applications, consisting of a computerized mental arithmetic challenge and social evaluative threat component.
- The social evaluative threat involves built-in visual and auditory cues, as well as pretask priming and external feedback from the investigator.
- The MIST can be used in functional magnetic resonance imaging (fMRI) or positron emission tomography (PET) research, with either a block or an event-related design.
- The MIST has two test conditions (control and experimental). In both conditions, participants are asked to mentally solve arithmetic problems displayed on the computer screen, while positioned in the scanner.
- The feedback (correct/incorrect/time-out) and an assessment of overall performance in comparison to the population average is displayed on the screen.
- The experimental condition provides a time-limit associated with visual and auditory cues for each question, with the available time per question adjusted to keep the individual's performance below the adequate level.
- In the experimental condition, the investigator presents negative performance evaluations to further increase the social evaluative threat.

LIST OF ABBREVIATIONS

2AG	2-Arachidonoylglycerol
AEA	Anandamide
CB1	Cannabinoid receptor 1
CB2	Cannabinoid receptor 2
DA	Dopamine
DAGL	Diacylglycerol lipase
ECS	Endocannabinoid system
FAAH	Fatty acid amide hydrolase (FAAH)
FEP	First episode of psychosis
fMRI	Functional magnetic resonance imaging
HPA	Hypothalamic–pituitary–adrenal axis
MAGL	Monoacylglycerol lipase
MIST	Montreal Imaging Stress Task
mRNA	Messenger ribonucleic acid
NAPE	*N*-Acyl phosphatidylethanolamine phospholipase
PBMC	Peripheral blood mononuclear cells
PET	Positron emission tomography
SNS	Sympathetic nervous system
VTA	Ventral tegmental area
WB	Western blot

STRESS AND MENTAL DISORDERS

The physiologist Hans Selye defined for the first time the physiological responses to stressors (Selye, 1950). He adapted the term to its current use in the medical vocabulary from physics and engineering, and was the first to use the terms "stress" and "stress response" (Selye, 1950). The stress response, consisting of a three-phase process, and defined by Selye as "general adaptation syndrome," results from the adaptation necessary to overcome situations in which an organism has to fight or escape to survive (eg, higher blood pressure, a faster cardiac rhythm, suppression of the digestive processes, redirection of blood to muscles) (Selye, 1950).

Stress begins with a stimulus of external or internal origin to the organism that activates the hypothalamic–pituitary–adrenal axis (HPA) and the sympathetic nervous system (SNS). This activation results in a compensatory, physiological change or adaptation, so that the organism can deal with the threat. In response to those environmental or psychological stressors, the initial stress response comprises the generation of cerebral cortical neuronal activity, extending to the limbic system, where it activates the cascading physiological responses (summarized in Fig. 29.1), such as, the release of catecholamine (including dopamine—DA), glucocorticoids, and excitatory amino acids. Available data has been summarized in reviews of Borges, Gayer-Anderson, and Mondelli (2013) and Garcia-Bueno, Caso, and Leza (2008).

Several neuropsychiatric disorders, including schizophrenia and drugs use disorders, are related to stress, and deregulation of the stress response is a potential etiological factor in the development and relapse of these DA-related mental illnesses (see Table 29.1). For

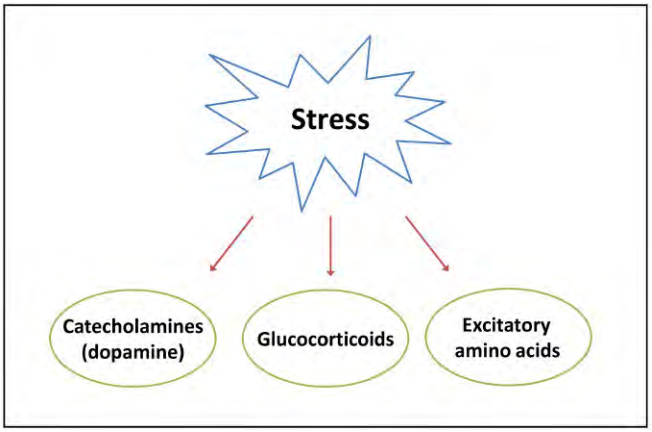

FIGURE 29.1 **Brain response induced by stress.**

example, stress-related HPA activity is often elevated in first-episode and nonmedicated psychosis, and may represent one of the biomarkers of vulnerability to psychosis (Walker et al., 2010).

In this chapter, the discussions will be focused on the dopaminergic response to stress, given the particular relevance of the dopaminergic systems for psychosis illnesses. The research method of dopaminergic response to stress will be briefly introduced, and dopaminergic response to stress in chronic cannabis users and in psychosis will be discussed accordingly, followed by a discussion of the potential link between stress, continuous cannabis use, and the development of psychosis.

STRESS STUDY, INDUCTION, AND EVALUATION

The widespread use of animal models is leading to the progressive unraveling of the basic mechanisms responsible for the consequences of stress on mammalian physiology. In rodents, those tasks or designs characterized by exposure to an unavoidable physical stress are the most extensively used: immobilization, exposure to extreme temperatures, fasting, immersion or electric shocks, etc. Models of physical stress, such as fasting or forced exercise, are more suitable for the study of metabolic responses, whereas models of social or emotional stress, such as crowding or social isolation, have translational value for psychiatric disorders, although precise and robust interpretations are more challenging. Further information can been found in reviews of Garcia-Bueno et al. (2008) and Blanchard, McKittrick, and Blanchard (2001).

In humans, measurement of the cortisol-awakening response (Pruessner, Hellhammer, & Kirschbaum, 1999) and stressful interviewing protocols, including free speech and mental arithmetic tasks (Kirschbaum, Pirke, & Hellhammer, 1993), are the most used stress protocols for accessing basal activity and reactivity of HPA axis. For further discussions, see review of Kudielka and Wust (2010).

Montreal Imaging Stress Task (MIST)

One of these stressful interview tasks based in mental arithmetic task questions is the Montreal Imaging Stress Task (MIST) (Dedovic et al., 2005), which has a special interest for the studies developed in this chapter. Together with neuroimaging techniques, this task has shown to be appropriate to investigate the effects of perceiving and processing psychosocial stress in the human brain.

Briefly, during the MIST subjects perform mental arithmetic tasks on a computer screen that also displays information about the performance level (numbers of errors, and time spent), and performance feedback (correct, incorrect, timeout) for each problem. During the stress condition, subjects complete six 6-min block segments of arithmetic tasks. The time constraint is adjusted to be slightly beyond each individual's abilities. Because of the manipulation of the difficulty level, the average performance was set at 20–30% correct answers. In addition, subjects are given negative verbal feedback by the investigator between each block, telling them that they need to improve their performance to reach minimum performance requirements. Before the stress task, subjects are required to perform a nonstress sensory motor control session, with similar arithmetic tasks, but without time constraints or negative verbal feedback.

TABLE 29.1 Main Dopaminergic Pathways in the Brain

Dopaminergic pathway	Description	Disorders related
Mesolimbic	Transmits dopamine (DA) from the ventral tegmental area (VTA) to the limbic system via the nucleus accumbens	Addictions to drugs of abuse
Mesocortical	Transmits DA from the VTA to the frontal cortex	Schizophrenia
Nigrostriatal	Transmits DA from the substantia nigra to the striatum	Motor control and movement disorders
Tuberoinfundibular	Transmits dopamine from the hypothalamus to the pituitary gland. This pathway influences the secretion of certain hormones, including prolactin	Hyperprolactinemia due to antipsychotics

Different neuroimaging techniques, including functional magnetic resonance imaging (fMRI) and positron emission tomography (PET), have been successfully used with the MIST in order to determine the cortical activation and neurochemical response to stress. These studies have been done especially with cannabis users and subjects with psychotic spectrum disorders in different phases (Lederbogen et al., 2011; Mizrahi et al., 2012, 2013a,b; Lataster et al., 2014). Other physiological measures, such as saliva-derived cortisol immunoassay, have also been used to assess the stress response to induction combined to the MIST (Dedovic et al., 2005; Mizrahi et al., 2013a).

DOPAMINE RESPONSE TO PSYCHOSOCIAL STRESS IN CHRONIC CANNABIS USERS

Numerous animal studies show that exogenous cannabinoids alter the excitatory/inhibitory balance reaching dopamine cells, most frequently causing alterations of dopamine release at downstream forebrain territories. However, the attempts to establish whether the psychomimetic effects of Δ^9-tetrahydrocannabinol (Δ^9-THC, the primary psychoactive compound of cannabis) in humans are mediated via excessive DA release in the striatum have produced mixed results. For further details, see review of Murray, Mehta, & Di Forti (2014).

Although many individuals admit recreational use of cannabis, fewer users become dependent (about 9% of users), compared to most of the use of other illicit drugs (see Table 29.2).

However, the percentage in cannabis users increases among those who started at a younger age (about 17%) and among the daily users (25–50%; NIDA, 2014). Among cannabis users, psychosocial stress is a potent trigger of relapse, and an important risk factor for chronic use. See review of Hyman and Sinha (2009).

Potentially addictive drugs share the ability to produce long-lasting adaptations in neural systems (Gruber & Pope, 2002). Low striatal DA receptor (D2/3) availability, and low amphetamine-induced DA release in the ventral striatum have been observed in several substance-use disorders, including alcoholism, heroin, cocaine, and methamphetamine use (Volkow et al., 1993, 1994, 2001; Martinez et al., 2012), but less is known about the changes in DA transmission in chronic cannabis use.

By using the MIST task, it has been demonstrated that chronic cannabis users, during early abstinence, did not show difference in stress-induced DA release (Mizrahi et al., 2013b). This work supports previous observations by Urban et al. (2012), who found no difference between cannabis users and healthy controls in DA release following an acute amphetamine challenge, and pointing to the fact that chronic cannabis use does not seem to increase DA release. Consistent with these findings, cocaine dependence has been shown to reduce amphetamine-induced DA release (Martinez et al., 2007).

This different dopaminergic response can partially be explained by the fact that cannabinoids produce behavioral, as well as neurochemical, changes dependent on the environmental conditions under which they are administered. For example, classical animal studies showed that cannabinoids administered to rats housed in stressful conditions altered striatal DA uptake and metabolism, in contrast to the absence of effect on rats housed in normal conditions (Littleton, Maclean, & Brownlee, 1976). Furthermore, cross-sensitization between Δ^9-THC and stress reported in animal models (Suplita Ii, Eisenstein, Neely, Moise, & Hohmann, 2008) suggest that cannabis effects could be potentiated in individuals experiencing adverse environmental stress.

STRESS-INDUCED DOPAMINE RELEASE IN PSYCHOSIS

The research in recent decades demonstrates the heterogeneity of the etiology of psychotic disorders, where environmental factors play a key role as genetic factors (van Os & Kapur, 2009) (see Fig. 29.2). These environmental factors can be summarized as biological stress (eg, prenatal stress, high paternal age, malnutrition,

TABLE 29.2 Percentage of Dependence Development Between Drugs of Abuse Users

infections during pregnancy, perinatal hypoxia), psychosocial stress (eg, prenatal stress, presence of traumatic events, membership of a minority ethnic groups), or drug exposure (Matheson, Shepherd, Laurens, & Carr, 2011).

The exposure to certain environmental factors interacting with genetic factors can alter dopaminergic transmission, neuroendocrine and cognitive functioning, patterns of interpersonal interaction, and affective processing, and may lead to a psychopathology worsening (see review of van Os & Kapur, 2009). An exaggerated response with increased DA release under biological stressor (stimulant) has also been observed in schizophrenia (Laruelle & Abi-Dargham, 1999; Yuii, Suzuki, & Kurachi, 2007). These findings are in line with the vulnerability-stress model, suggesting a crucial role of the interaction between vulnerability and environmental stressors in the development of psychotic disorders (Walker & Diforio, 1997).

One of the proposed underlying neurobiological mechanisms that result in the exaggerated response to stress is DA sensitization. Repeated exposure to life stressors or DA drugs sensitizes neurochemical response of the mesolimbic/mesocortical DA system progressively, which in turn increases stress-associated neurochemical activation of HPA axis and stress-associated DA release (Laruelle & Abi-Dargham, 1999; Yuii et al., 2007). Consequently, the dopaminergic system responds to mundane environmental stimuli with excessive DA release, precipitating illness in vulnerable individuals, and relapse in those with schizophrenia.

Converging evidences links dysregulated dopamine function with disrupted salience processing, and the development of psychotic symptoms (Kapur, 2003). Salience processing refers to "…a process whereby events and thoughts come to grab attention, drive action, and influence goal-directed behavior…" (Kapur, 2003). Animal studies show that midbrain dopamine neurons are activated by unexpected salient events. Functional imaging studies have located altered salience response in prefrontal and striatal dopaminergic projection fields in psychotic patients. Together with the evidence that increased subcortical striatal DA synthesis and DA release and transmission in psychosis (Howes & Kapur, 2009), the functional dysregulation of dopamine system in the striatum are a core feature of psychosis (Grimm, Heinz, & Walter, 2014), and may lead to aberrant salience. With repeated exposure to life stressors or DA drugs, the DA system may have been tune into a sensitized, hyperresponsive state, in which daily-life events are responded as unexpected salient events. This may account for the altered sense of meaning and significance that predates the onset of psychosis. For a comprehensive review, see Winton-Brown, Fusar-Poli, Ungless, and Howes (2013).

So far, few studies have examined the association between stress and psychotic-like experiences in vulnerable individuals. Vulnerable persons with genetic high risk for psychosis (ie, first-degree relatives) show increased homovanillic acid (a DA metabolite) following a metabolic stress challenge which correlates with increased psychotic-like experiences (Myin-Germeys, Marcelis, Krabbendam, Delespaul, & van Os, 2005; Holtzman, Shapiro, Trotman, & Walker, 2012; Holtzman et al., 2013). These findings are in line with those in patients with schizophrenia (both antipsychotic-free and treated), who demonstrate a significant homovanillic acid elevation, relative to matched healthy controls, in response to a physiologic stress test (Breier, Davis, Buchanan, Monde, & Munson, 1993), suggesting increased DA release in response to stress, in both subjects at higher risk, and with overt psychosis.

By using the MIST task, Mizrahi et al. (2012) report increased stress-induced DA release in both clinical high-risk group and schizophrenia patients (Mizrahi et al., 2012). This DA sensitization in schizophrenia-related disorders is consistent with previous studies in amphetamine-induced DA release in patients with schizophrenia (Laruelle & Abi-Dargham, 1999; Yuii et al., 2007). These results again highlight the role of DA dysregulation in psychosis, and its possible link to stress.

ENDOCANNABINOID SYSTEM: A POSSIBLE LINK BETWEEN STRESS, CONTINUOUS CANNABIS USE, AND PSYCHOSIS

The endocannabinoid signaling system (ECS) is a widespread neuromodulatory system that modulates neurotransmitter release in brain and in the periphery (Salzet, Breton, Bisogno, & Di Marzo, 2000; Hillard, Weinlander, & Stuhr, 2012). Considerable data support the notion that

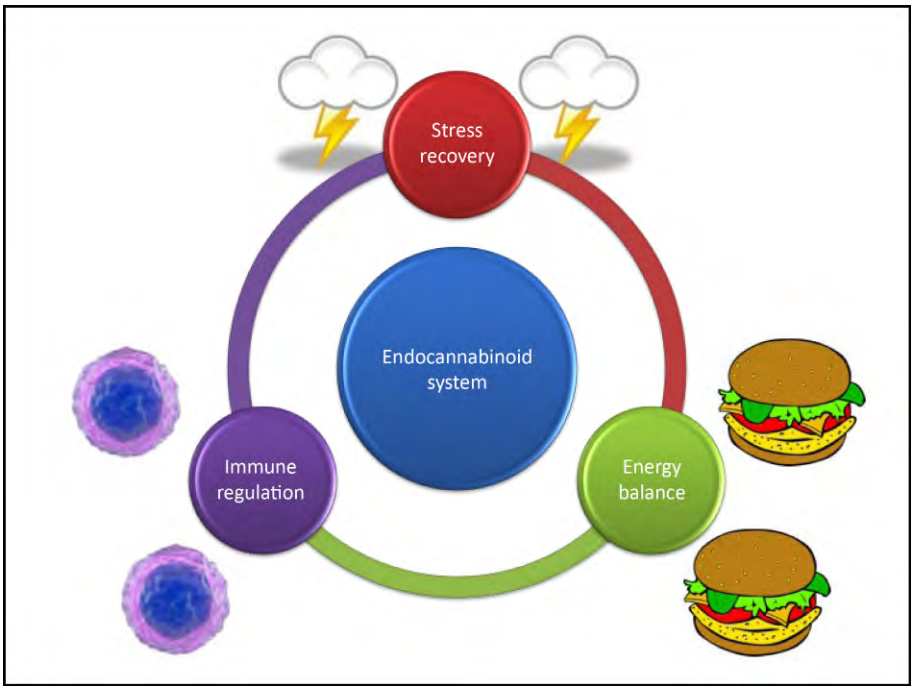

FIGURE 29.3 **Main endocannabinoid system functions in mammals.**

endocannabinoid signaling has three broad and overlapping functions in mammals (summarized in Fig. 29.3) (Klein & Cabral, 2006; Di Marzo, Ligresti, & Cristino, 2009; Hill et al., 2010). In particular, the ECS is present in stress-responsive neural and peripheral circuits, reducing both neurodegenerative and inflammatory damage (see review of Wolf, Tauber, & Ullrich, 2008).

In short, the ECS comprises the arachidonate-based lipids anandamide (AEA) and 2-arachidonoylglycerol (2AG); their cannabinoid G protein-coupled receptors, CB1 and CB2; enzymes involved in cannabinoid synthesis, for example, N-acyl phosphatidylethanolamine phospholipase (NAPE) and Diacylglycerol lipase (DAGL); and the enzymes that are responsible for their degradation or reuptake, fatty acid amide hydrolase (FAAH) and Monoacylglycerol lipase (MAGL) (summarized in Fig. 29.4) (Di Marzo et al., 1994; Stella, Schweitzer, & Piomelli, 1997).

CANNABIS USE, ENDOCANNABINOID SYSTEM, AND PSYCHOSIS

Cannabis use is one of the most important and studied environmental risk factors related to psychosis (van Os & Kapur, 2009). Epidemiological study shows a higher incidence of psychosis with early cannabis use, which has been linked to a significant increased risk of developing psychosis, with an estimated odds ratio of 2.10–2.93 (Moore et al., 2007). Around 25–50% of subjects who suffer a first episode of psychosis use cannabis (see review of Volkow, 2009). The cessation of cannabis use after a first episode, both in adults and adolescents, is associated with clinical and functional improvement (Gonzalez-Pinto et al., 2011).

Several lines of research have related the ECS with psychotic disorders, such as, a dramatic elevations of AEA in cerebrospinal fluid (CSF) in patients with schizophrenia (Leweke et al., 2007); a reduced peripheral expression of endocannabinoid synthesis enzymes, and increased expression of degradative enzymes in first-episode psychosis (Bioque et al., 2013). In terms of central cannabinoid CB1 receptors, there is an association between CB1 receptors polymorphism and schizophrenia (Ujike et al., 2002). An increased CB1 binding is reported in postmortem autoradiography and in vivo PET studies in patients with schizophrenia (Zavitsanou, Garrick, & Huang, 2004; Wong et al., 2010). In terms of peripheral CB2 receptors, the patient subgroup with a history of heavy cannabis use showed a lower CB2 receptor expression (Bioque et al., 2013), and an association has also been reported between a diminished CB2 function and an increased susceptibility to schizophrenia, together with other risk factors (Ishiguro et al., 2010).

ENDOCANNABINOID SYSTEM, STRESS REGULATION, AND PSYCHOSIS RISK

The role of ECS in stress regulation and recovery postulate the potential link between ECS and DA system responding to stress. It has been proposed that ECS

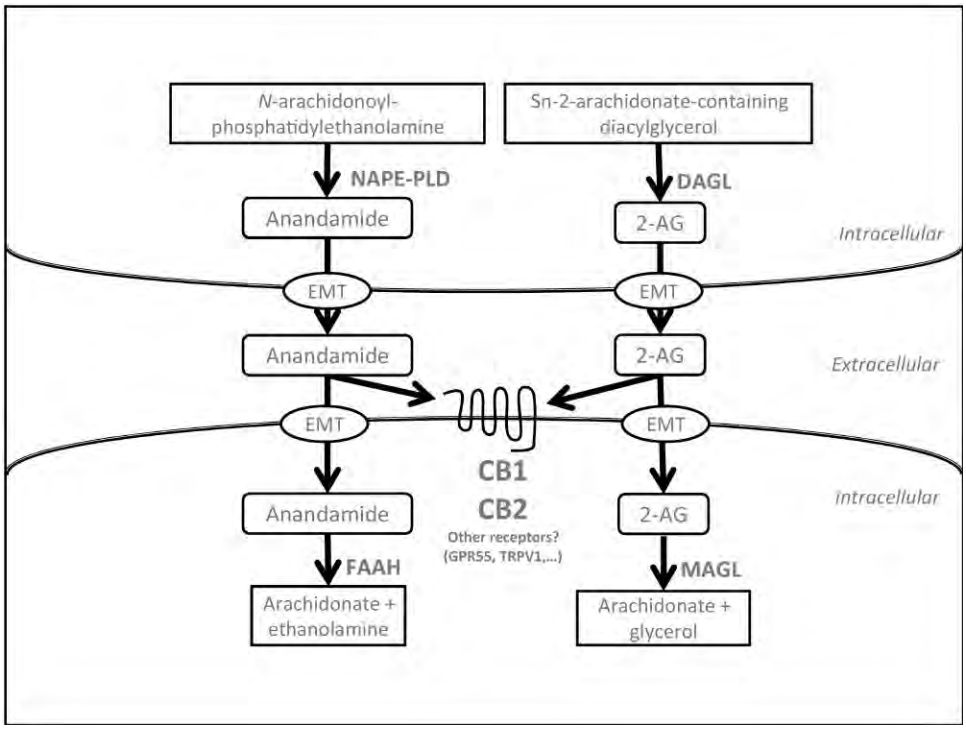

FIGURE 29.4 **Main endocannabinoid system components.** *2-AG*, 2-arachidonoylglycerol diacylglycerol; *CB2*, cannabinoid receptor 2; *DAGL*, diacylglycerol; *EMT*, endocannabinoid membrane transporter; *FAAH*, fatty acid amide hydrolase; *GPR55*, G-protein coupled receptor 55; *MAGL*, monoacylglycerol lipase; *NAPE-PLD*, *N*-acyl-phosphatidylethanolamine-selective phosphodiesterase; *PBMC*, peripheral blood mononuclear cell; *TRPV1*, transient receptor potential vanilloid type 1.

activity mediates HPA function via regulating the intensity and duration of the neurohormonal response to stress. The presence of CB1 receptors within the corticolimbic circuits, and robust evidence from animal studies implicating AEA, plays a regulatory role in HPA (Hill et al., 2005, 2009).

Notably, the human cortical ECS undergoes dramatic changes in early life and adolescence (Cass et al., 2014), with increased metabolism until early adulthood (Long, Lind, Webster, & Weickert, 2012). These early-life changes in the ECS could potentially increase the sensitivity to cannabis use, and potentiate their susceptibility to environmental and social stressors, which may, in turn, increase the risk for psychosis. The observation that cannabis use before the age of 15 leads to increased risk for psychosis (Arseneault et al., 2002), while later use does not have the same effect on brain neurochemistry, supports this speculation. In addition, risk of psychosis has been shown to increase with childhood trauma, and cannabis use through a synergistic interaction (Harley et al., 2010), which would be consistent with the aforementioned data related to the role of the ECS in stress regulation, and supports the notion.

Exogenous cannabinoids stimulate CB1 receptors, and suppress the excessive HPA response to stress. In this sense, cannabis use in psychosis and in at-risk youths could represent an attempt to regulate an existing abnormal stress response. However, frequent cannabis exposure may downregulate AEA signaling in the CNS, and potentially dampen ECS, which has only been seen in patients with schizophrenia (Leweke et al., 2007). Nevertheless, the neurobiological mechanisms underlying this increased psychosis susceptibility in cannabis users remain poorly understood (D'Souza, Sewell, & Ranganathan, 2009).

Although existing evidence cannot explain why cannabis use itself may lead to psychosis in at-risk populations, an intermingled relationship between cannabis use and stress response in DA system in this population has been observed. A recent study shows that in those at risk for psychosis with concomitant cannabis use, despite aggravated psychotic symptoms in response to stress, the DA system does not show significant response (increase in DA release) to the psychosocial stress task (MIST) (Mizrahi et al., 2013a), suggesting that minute increases in DA release may already contribute to the aggravation of psychotic-like experiences.

CONCLUSIONS

Repeated environmental and social stress, and substance use in earlier years, contributes to sensitization of DA systems, and the risk of developing psychosis,

wherein the alteration of ECS may play a modulatory role. Genetic traits, on the other hand, represent a vulnerability that interacts with these environmental factors, may further increase the susceptibility to upcoming social stressors and continuous drug use, and ultimately leads to neurochemical and other functional changes underlying the development of psychosis.

In this regard, early interventions with pharmacological and/or psychosocial approaches in adolescence or early adulthood are extremely important, and establishing reliable biomarkers which may capture the change during the "critical window" represent the stepping stone for initiating these early interventions in time. The sophisticated interplay between dopamine system and ECS implicates that novel biomarkers should aim to depict changes in both systems. Future research should focus on the modulation of stress-induced DA release, clarifying the interaction between DA stress response and ECS, and potential alterations of ECS modulatory effects on stress recovery, particularly in those individuals who have higher risk to develop psychosis. This may, in turn, shed light on novel ways to detect, intervene and, perhaps, even prevent the impact of developing psychosis.

MINI-DICTIONARY

Dopamine Hormone and neurotransmitter of the catecholamine and phenethylamine families that plays a number of important roles in the human brain and body, including a major role in reward-motivated behavior, motor control, and in controlling the release of other hormones.

Drug dependence Compulsive use of a substance, despite its negative or dangerous effects, that leads to a state in which the person needs a drug to function normally.

Endocannabinoid system Group of neuromodulatory lipids and their receptors in the brain that are involved in a variety of physiological processes, including appetite, pain sensation, mood, and memory; it mediates the psychoactive effects of cannabis.

Functional magnetic resonance imaging (fMRI) A functional neuroimaging procedure that measures brain activity by detecting associated changes in blood flow, relying on the fact that cerebral blood flow and neuronal activation are coupled.

Hypothalamic–pituitary–adrenal (HPA) axis The common mechanism for interactions among glands, hormones, and parts of the midbrain, a major part of the neuroendocrine system that controls reactions to stress and regulates many body processes, including digestion, the immune system, mood and emotions, sexuality, and energy storage and expenditure.

Montreal Imaging Stress Task (MIST) A series of computerized mental arithmetic challenges, along with social evaluative threat components that are built into the program, or presented by the investigator, developed to induce moderate psychologic stress in a functional imaging setting, and evaluate the effects of stress on physiology and brain activation.

Physiological or biological stress An organism's response to an agent, such as an environmental condition or a stimulus.

Positron emission tomography (PET) A nuclear medicine, functional imaging technique that produces a three-dimensional image of functional processes in the body, based on the detection of pairs of gamma rays emitted indirectly by a positron-emitting radionuclide (tracer), which is introduced into the body on a biologically active molecule.

Psychosis Refers to an abnormal condition of the mind, generally described as a mental health state involving a loss of contact with reality.

Sensitization Nonassociative learning process in which repeated administrations of a stimulus results in the progressive amplification of a response. It is often characterized by an enhancement of response to a whole class of stimuli, in addition to the one that is repeated.

CHAPTER

30

Motivation in Chronic Cannabis Use

R. Hirst, L. Sodos, S. Gade, L. Rathke

Palo Alto University, Palo Alto, CA, United States

SUMMARY POINTS

- Empirical evidence for the "amotivational syndrome" in cannabis users is contradictory, with many studies finding no support.
- It is likely that other confounding factors, such as, socioeconomic status, family conflict, and anticonventional behaviors contribute to the negative correlation between cannabis use and motivation for educational and occupational achievement.
- Laboratory measures of motivation yield mixed results, though most evidence suggests that chronic cannabis users interpret monetary reinforcers differently than nonusers.
- A distinction must be made between research examining the acute effects of cannabis use (which is not well supported), and the long-term effects on those who use regularly but are not currently intoxicated.
- It is critical to measure motivation in cannabis users within the research design to ensure validity in the assessment of cognitive performance and other characteristics.
- The authors suggest a unique method for enhancing the motivation of chronic cannabis users during research participation, referencing the contribution that will be made to research that could contribute to legislation on marijuana policy.

KEY FACTS OF CHRONIC CANNABIS USE

- The motivational effects of cannabis are difficult to isolate, as many users also use other legal and illicit substances.
- "Motivation" is difficult to define, and cannabis may affect various aspects of motivation differently.
- Research suggests that the "amotivational syndrome" only exists in a small proportion of chronic cannabis users.
- 40% of the variance in apathy in chronic cannabis users may be due to the reduction in striatal dopamine synthesis that may underlie reduced reward sensitivity and amotivation.
- Positron Emission Tomography (PET) imaging suggests that cannabis users exhibit differential activation of the ventral medial prefrontal cortex, an important component of the dopaminergic reward pathway, during decision-making and motivational tasks.
- Despite the proposed link between motivation and chronic cannabis use, tests of effort (to ensure participants are putting forth adequate effort for valid results) are rarely used in research on cannabis users.

INTRODUCTION

One of the most commonly associated stereotypes of chronic cannabis users is a lack of motivation, sometimes referred to as the "amotivational syndrome." This notion gained widespread publicity in the 1970s, when marijuana use was increasing, and concern about its effects grew. Suggested symptoms included apathy, lethargy, lack of motivation, and difficulty concentrating (Kolansky & Moore, 1972; Smith, 1968; Soueif, 1976). As many of these variables overlap with aspects of cognitive functioning, it has garnered much debate, with many studies finding little evidence for support (eg, Halikas, Weller, Morse, & Shapiro, 1982). In fact, the original proponent later stated that the syndrome exists "only in a very small and susceptible segment of adolescent marijuana users" (Smith & Seymour, 1982, p. 69). The difficulty in defining and operationalizing motivation has also contributed to the confusion. Some researchers suggested that the syndrome characteristics actually represented symptoms of preexisting mood or anxiety disorders (eg, Musty & Kaback, 1995). Others hypothesized that some cannabis users simply experience a reorientation in attentional style, meaning, and values, which does not follow the norm, and is thus characterized as pathological (eg, Nelson, 1994-5). Neurobiological evidence suggests that many substances of abuse, including cannabis, affect reward mechanisms in the mesolimbic dopamine system of the brain (for review, see Martin-Soelch et al., 2001). Thus, it is possible that cannabis users may process reinforcers differently if changes have occurred within the dopamine system, thereby impacting their motivation to work for that reinforcer. A thorough review of the physiological mechanisms is beyond the scope of this chapter, but several neuroimaging studies examine motivation in cannabis users through the dopamine system, and the results of these studies will be described.

In this chapter, we examine motivation in chronic cannabis users through studies assessing self-report, educational and occupational achievement, and laboratory measures of motivation. Methodological variability likely contributes to the conflicting evidence demonstrated, and we present limitations to the current studies. Further, a distinction is made between research on the acute effects of cannabis intoxication and the long-term effects on regular users. Finally, we describe the importance of measuring motivation in cannabis users within all research designs, and suggest a unique method for enhancing the motivation of chronic cannabis users during research participation.

MOTIVATION: ACHIEVEMENT AND SELF-REPORT

Motivation Self-Report

Initial studies suggesting the "amotivational syndrome" in chronic cannabis users primarily consisted of subjective self-reports from the participants themselves, describing their affective states and employment histories, as well as their behavior while under the acute effects of the drug (for review, see Kolansky & Moore, 1972). However, researchers gathered these patients from psychiatric clinical practice, and the samples are representative of patients suffering from cannabis dependence with other mental health difficulties and problems in functioning, rather than the typical cannabis user.

More recent analyses of nonpsychiatric samples have yielded mixed results when analyzing self-report of motivation in chronic cannabis users, which is likely due, in part, to differences in how motivation is operationalized. Face valid self-report motivational measures demonstrate a low incidence of amotivation (about 5%) in chronic cannabis users (Halikas et al., 1982). On another self-report measure, the apathy evaluation scale, daily cannabis users did not differ from nonusers (Fig. 30.1; Barnwell, Earleywine, & Wilcox, 2006). Further, low motivation may simply be misattributed to cannabis use—one study found that 5% of all undergraduates reported symptoms of amotivation, regardless of cannabis use status (Duncan, 1987).

When defining motivation as personally salient life goals, researchers found a negative relationship with cannabis use. University students who attribute strong meaning toward life goals were less likely to use cannabis (Wright & Palfai, 2012). Further, participants who rated academic achievement as a meaningful goal were less likely to use cannabis, while those who rated socialization as meaningful were more likely to use. However, Simons, Christopher, Oliver, and Stanage (2006) assessed 15–24 year olds and found that cannabis use had no significant relationship to achievement goals in one's life. Thus, evidence for a relationship between cannabis use and life goals appears mixed.

Motivation has also been examined through self-reported life satisfaction and subjective well-being. One study found higher levels of life satisfaction in heavy cannabis users, relative to light users, suggesting that while life goals may differ, heavy users do not have a passive view of achievement (Kouri, Pope, Yurgelun-Todd, & Gruber, 1995). Cannabis users may simply derive life

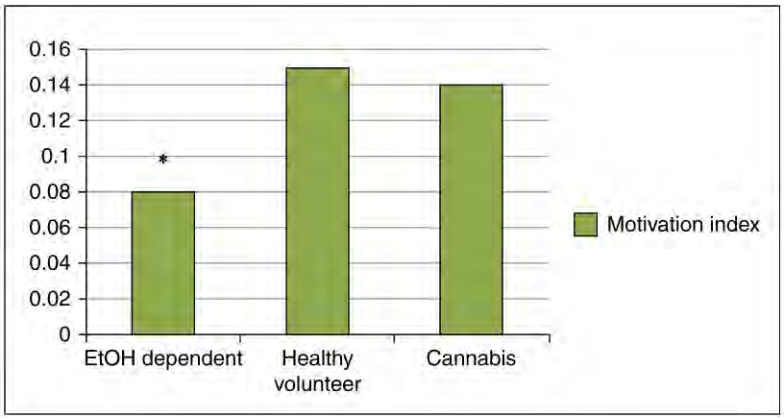

FIGURE 30.1 Motivation scores on the apathy evaluation scale. A comparison of motivation scores among cannabis users and nonusers yielded no significant group differences. *Source: Barnwell et al. (2006): Open Access article distributed under terms of the Creative Commons Attribution License (http://creativecommons.org/licenses/by/2.0), permitting unrestricted use, distribution, and reproduction in any medium, provided the original work is properly cited.*

satisfaction from nontraditional routes, as a subculture with different values than the norm (Earleywine, 2003). Others found that, although users reported lower subjective well-being than nonusers, removing medical cannabis users from the analyses eliminated this difference (Barnwell et al., 2006). This suggests that medical illness may be responsible for lower subjective well-being in users, as opposed to cannabis use itself.

Another recent study examined self-reported motivation in cannabis users through an examination of dopamine and found that perceived apathy negatively correlated with dopamine synthesis capacity (Bloomfield, Morgan, Kapur, Curran, & Howes, 2014). Thus, subjective apathy reported by cannabis users could be due to decreased capacity for dopamine production, though a longitudinal study would be necessary to determine if cannabis use directly led to decreased dopamine production.

The limitations of these correlational analyses should be kept in mind, as none of these studies evaluated cannabis users prior to initiation, thus reducing the possibility of causal inferences. Further, in early research, researchers rarely controlled for other confounding factors (eg, low socioeconomic status, mood disorder diagnoses, or preexisting personality traits), which may explain the conflicting findings.

Motivation for Achievement: High School

Another definition of motivation toward life goals is achievement in academics. As cannabis use is most often initiated during high school, the impact of use on educational attainment is of particular interest. Some cross-sectional studies have identified a negative impact of chronic marijuana use on grade point average and academic performance (Resnick et al., 1997), but not on negative attitudes toward school (Jones & Heaven, 1998). Cannabis use has also been associated with lower school satisfaction, poor school performance, absenteeism, and higher rates of suspension or expulsion from school (for review, see Fergusson, Horwood, & Beautrais, 2003). The link with high school dropout has been mixed, with some studies finding an association (eg, Ensminger, Lamkin, & Jacobson, 1996), and others finding none (eg, Ellickson, Bui, Bell, & McGuigan, 1998). Based upon retrospective report, college graduates reported significantly lower use of cannabis during adolescence, relative to high school-only graduates, even after controlling for socioeconomic status, academic ability, self-esteem, and delinquency (Mensch & Kandel, 1988). Another study linked low academic motivation and substance use (including cannabis use specifically) in high school students, as well as a relationship between perceived negative school attitudes of friends, and increased cannabis use (Fig. 30.2; Bryant & Zimmerman, 2002). Thus, most evidence does support a link between lower academic achievement and cannabis use.

It is important to note that these conclusions are limited by cross-sectional and correlational research designs, which make it impossible to draw causal inferences related to cannabis. One study employed a longitudinal design to examine motivation for educational achievement in high school students. Researchers followed 1182 New York students over a 5-year period (Brook, Balka, & Whiteman, 1999). Those who used cannabis once per month or more were more likely to leave school before completing 12th grade, despite controlling for a range of factors at age 14. They were also more likely to report delinquency, drug-related problems, and sexual risk-taking. Other longitudinal studies linked low academic motivation to youth cannabis use (Brown, Schulenberg, Bachman, O'Malley, & Johnston, 2001; Ellickson, Martino, & Collins, 2004); however, neither of these studies found that increased cannabis use over time was associated with decreased motivation. Therefore, it remains unclear

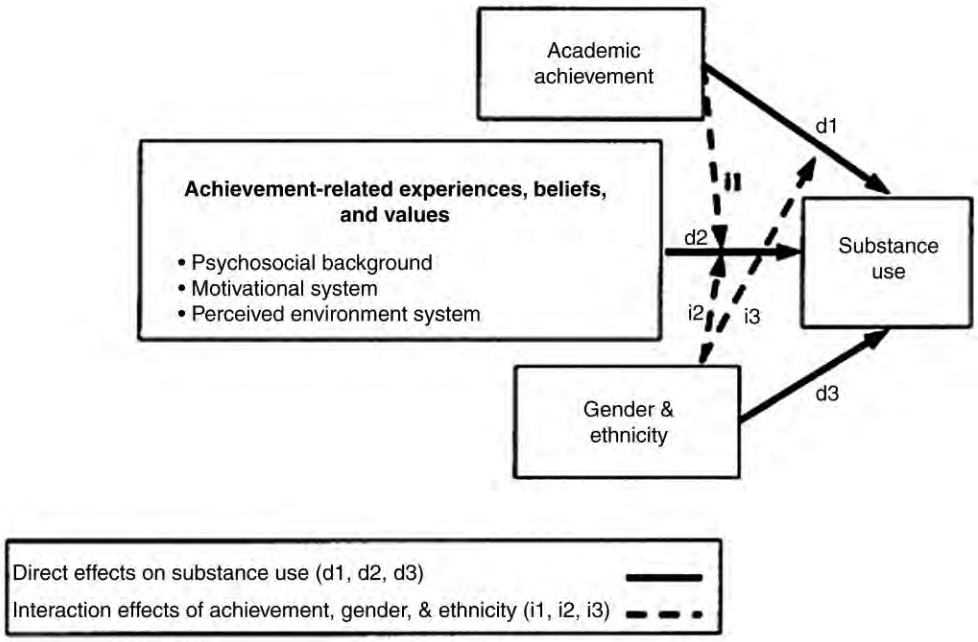

FIGURE 30.2 **Conceptual model of achievement and achievement-related effects on substance use during adolescence.** Many factors influence cannabis use in adolescents, including low academic motivation and perceived negative school attitudes of friends. *Source: Bryant and Zimmerman (2002): APA article; permission is not required for figures from a journal article.*

whether cannabis truly demonstrated a causal influence on academic achievement, or whether students who exhibited a vulnerability to substance use also exhibit a tendency toward low school achievement.

Motivation for Achievement: University and Employment

Longitudinal studies have also examined motivation through university and employment status. A 25-year longitudinal study in New Zealand revealed that increased marijuana use was associated with school dropout, failure to enter college, and failure to obtain a university degree (Fergusson et al., 2003). While some studies show that young cannabis users are at greater risk for unemployment (eg, Brook, Adams, Balka, & Johnson, 2002), others demonstrate that many frequent cannabis users earn more than non-users (eg, Kaestner, 1994). Further, one study showed that university cannabis users were more likely to pursue graduate study (Hochman & Brill, 1973). Thus, there is some evidence that cannabis use is distinct from motivation toward higher education and employment achievement. It is possible that there are subsets of cannabis users who are driven to achieve success, both academically and occupationally, regardless of cannabis use.

The relationship between cannabis use and educational and occupational achievements remains unclear, with conflicting findings. It is likely that variability in research methodology contributes to this confusion. Researchers have proposed several hypotheses for the link between motivation for achievement and chronic cannabis use.

Theories of Motivation for Achievement

Cannabis Use Leads to Educational Underachievement

One theory is that cannabis use leads to educational underachievement, either through cognitive or motivational deficits (Solowij, 1998), or through the encouragement of anticonventional behaviors (eg, Kandel, Davies, Karus, & Yamaguchi, 1986). Support for this theory is weak, because those who use cannabis also often experience other disadvantages, such as, low socioeconomic status (SES), childhood adversity, early-onset behavioral difficulties, and negative peer influences. Many studies suggest that, with increasing age and cannabis use, the effects on achievement actually decrease, rather than increase (eg, Fergusson et al., 2003). Although controlling for these factors reduced the relationship between cannabis use and early school leaving, a significant association remained for those who initiated use early in life (Fergusson et al., 2003). Therefore, while experimentation with cannabis use may be normative during high school, earlier initiation may be suggestive of other behavioral problems (Wills, McNamara, Vaccaro, & Hirky, 1996).

Furthermore, metaanalyses of the effect of chronic cannabis use on cognition found only a small effect on two cognitive domains: learning, and forgetting/retrieval (Grant, Gonzalez, Carey, Natarajan, & Wolfson, 2003).

Other cognitive domains (eg, attention, reaction time, executive functioning) demonstrated effect sizes with confidence intervals overlapping zero, suggesting little, if any, effect of cannabis use (Grant et al., 2003). In addition, these studies included participants who used more frequently (at least 4 days per week) and for longer periods of time (about 5 years) than most adolescents included in the studies on educational achievement. Thus, there is no strong evidence to suggest that cannabis use leads to such significant impairments that adolescents are no longer capable of completing school.

Educational Underachievement Leads to Cannabis Use

A second theory explaining the link between motivation for achievement and cannabis suggests that the experience of educational underachievement encourages cannabis use, similar to the social development model of Hawkins and Weis (1985) where school failure leads to education demotivation and, subsequently, association with deviant peers and substance use. Evidence for this theory is weak; when allowances are made for confounding factors, educational failure was not associated with increased risk of later cannabis use (eg, Schulenberg, Bachman, O'Malley, & Johnston, 1994). Later cannabis use was not associated with earlier academic deficits, but rather with socially disadvantaged backgrounds, childhood adversity, parents with prior criminality or substance use, early conduct problems, novelty-seeking behavior, and affiliations with delinquent or substance-abusing peers—suggesting later cannabis use was associated with a pattern of many factors related to the development of externalizing behaviors, including substance use. Cannabis use had the greatest impact on young users, with impacts declining with increasing age (Schulenberg et al., 1994). In fact, illicit drug use in young adulthood was unrelated to academic motivation. Therefore, most evidence does not support the theory that school failure leads to cannabis use.

Propensity for Problem Behaviors Leads to Both Cannabis Use and Educational Underachievement

The third and final theory explaining the link between low motivation for academic achievement and chronic cannabis use is that a tendency toward anticonventional behaviors, and association with peer groups engaging in these behaviors, leads to lower prioritization of education and occupation and the selection of an alternative lifestyle. Jessor and Jessor (1977) first proposed this problem behavior theory, stating that adolescents exhibit one common syndrome representing a penchant for a range of problem behaviors, including relationships with deviant peers. Donovan and Jessor (1985) suggested that this represents general unconventionality, assumed to stem from both personal and environmental influences that increase problem behavior in general. In other words, individuals with this syndrome exhibit many problematic behaviors that may or may not include cannabis use.

Although this theory is vulnerable to the risk of circular logic, it is generally supported, and suggests that the effects of early cannabis use are more strongly related to the social context of cannabis use, rather than true physiological effects of the drug (eg, Fergusson & Horwood, 1997; for review, see Lynskey & Hall, 2000).

Limitations of Research on Motivation

As mentioned previously, cross-sectional methodologies make causality nearly impossible to determine and are vulnerable to overinterpretation. For example, Brown et al. (2001) analyzed cross-sectional data over a 20-year period and found variability in the relationship between low academic motivation and cannabis use, as this link was identified during some time periods but not during others. Thus, cross-sectional studies reporting this relationship (eg, Wright & Palfai, 2012) may not reveal the full complexity of the interaction of factors, as it is unclear which variable presented first in the individual. Further, many longitudinal studies first assess subjects in their teens; in many cases, cannabis initiation may have already occurred.

Another difficulty in drawing conclusions from the research to date is the variability in defining "chronic" users: definitions vary from any "current" users of cannabis, to those who use 4 or more days per week, to those who use daily. Many cannabis users also use other substances (such as alcohol or other illicit drugs), making it difficult to determine the effects of cannabis alone (Hall, Solowij, & Lemon, 1994). Researchers may also group multiple forms of substance use into one variable (eg, Duncan, Duncan, Biglan, & Ary, 1998), despite evidence that substances differ in their impact on educational or occupational attainment, such as, by gender (Mensch & Kandel, 1988) and by race (Ellickson et al., 1998). Cultural differences also exist; in regions where cannabis use is widespread, such as Jamaica and Costa Rica, those with steady jobs smoked more cannabis than those who were unemployed or had an unstable work history (Carter, Coggins, & Doughty, 1980). Thus, results of broad, longitudinal studies with diverse populations do not necessarily generalize to all cannabis users.

Finally, and perhaps most significantly, numerous confounds impact the relationship between cannabis use and motivation for achievement. These include factors, such as, parental age and education, socioeconomic status, changes in family environment, childhood verbal, physical, or sexual abuse, parental attachment, parental drug use, childhood cognitive and educational ability, behavioral problems, and other illicit substance use.

Early studies made little attempt to take these into account, and while more recent studies do control for some of these confounding factors, there is variability in the precision of measurement. In addition, other confounds may be present and, as yet, unidentified by researchers.

MOTIVATION: LABORATORY MEASURES

Despite the many studies examining chronic cannabis users' motivation through self-report and educational and occupational achievement, comparatively few attempted to measure motivation in a controlled, laboratory setting. The results of these studies are generally mixed, again, perhaps due to the difficulty in operationalizing such a construct. Motivation is often operationalized as the quality or completeness of task performance in order to gain some reinforcer, usually money. Yet there is variability in the extent to which monetary rewards are motivating for participants, due to differences in socioeconomic status or in the value of, or desire for, money. This variability makes it quite difficult to design a study where the reinforcer motivates all participants to the same degree. Furthermore, a distinction should be made between assessing cannabis users' motivation while under the acute effects of the drug and assessing whether a more persistent impact on motivation exists in long-term chronic cannabis users.

Laboratory Measures of Motivation: Acute Effects

To examine the hypothesis that cannabis intoxication impacts motivation, Cherek, Lane, and Dougherty (2002) designed a two-option experimental task. The "work" option required participants to systematically increase output to earn a monetary reward, while the "nonwork" alternative did not require any output to earn money. Participants under the influence of cannabis switched out of the "work" option and into the "nonwork" option earlier than in a placebo condition, despite being told that the nonwork option would result in less money earned. While the implications of the results are limited by a small sample size ($N = 5$), this may be interpreted as revealing lower motivation in the user group, particularly given that increasing the monetary reinforcement resulted in staying in the "work" option longer.

Many other studies, however, find no evidence for decreased motivation in users under the influence of cannabis. For example, although researchers found that both monetary compensation and verbal encouragement were insufficient to improve performance on cognitive tasks (Creason & Goldman, 1981; Pihl & Sigal, 1978), users performed as well as nonusers on the tasks, suggesting that they were already putting forth full effort. Kagel et al. (1980) analyzed the effect of cannabis intoxication on work output in a residential environment, and found no difference in total output between cannabis and placebo conditions. Although work output decreased immediately after cannabis administration, participants increased productivity after the acute effects of the drug had subsided. Cohen (1976) found no differences between users and nonusers in motivation, productivity, or clarity in work tasks during a 64-day intoxication period of smoking at least one joint per day. Another study demonstrated that, in a residential environment, administration of cannabis actually resulted in an increase in work activities (a nonsense-word alphabetizing task; Foltin et al., 1990). All six participants showed increases in work activities while under the effects of cannabis, relative to a placebo condition. Overall, there is little laboratory evidence for decreased motivation when under the acute effects of cannabis.

Laboratory Measures of Motivation: Effects of Chronic Use

Recently, laboratory studies of motivation in cannabis users have focused on the effects of chronic cannabis use, rather than intoxication. Lane, Cherek, Pietras, and Steinberg (2005) assessed the performance of adolescent daily cannabis users who were not currently under the influence of cannabis, using the two-option experimental motivational measure by Cherek et al. (2002) described previously. Relative to nonusers, cannabis users switched to the "nonwork" option earlier in the experiment and earned more total money from that option than from the "work" option, which the authors interpreted as suggestive of lower motivation (Lane et al., 2005). However, total money earned was not reported, so it was unclear whether the switch was actually detrimental for the cannabis users in amount earned (Fig. 30.3).

Researchers have also examined motivational inhibitory control by assessing risk-taking during gambling-type tasks. Most studies identify poorer performance on gambling tasks in chronic cannabis users, relative to nonusers (eg, Fridberg et al., 2010). One study found that users took greater risks on a gambling task measuring motivational inhibitory control, despite no group differences in cognitive inhibitory control (inhibiting a response in reaction to a stimulus; Griffith-Lendering, Huijbregts, Vollebergh, & Swaab, 2012). However, it is interesting that users and nonusers did not differ in the amount of "points" won or lost on the task, suggesting that greater risk-taking did not have negative consequences for the participants.

Positron Emission Tomography (PET) imaging also suggests differences in brain activity between chronic cannabis users and nonusers while completing

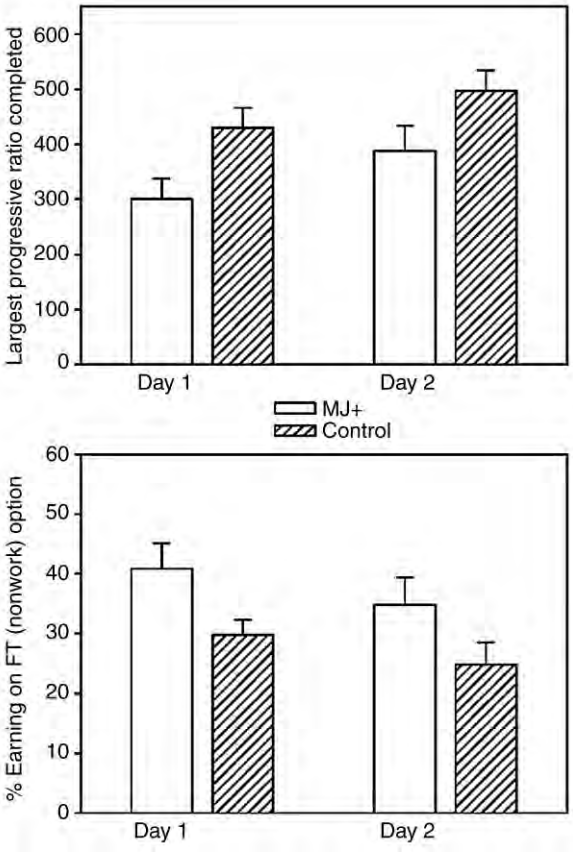

FIGURE 30.3 Performance on a motivational task in marijuana users and controls. Marijuana users completed a smaller ratio on the "work" option of the task relative to controls on both days. Marijuana users also obtained a greater percent of their total earnings from the "nonwork" option of the task on both days. *Source: Lane, Cherek, Pietras, & Steinberg (2005). FIGURE 30.4 Differences in PET activation between chronic marijuana users and controls during the Iowa Gambling Task (IGT). Results shown indicate that chronic marijuana users showed greater activity in the vmPFC and in the cerebellum, compared with control subjects. *Source: Vaidya et al. (2012). Open Access article; permission not required.*

gambling tasks. On the Iowa Gambling Task (IGT; Bechara, Damasio, Damasio, & Anderson, 1994), duration of cannabis use correlated with greater activity in the ventromedial prefrontal cortex, an area involved in the mesolimbic dopamine reward system described earlier (Fig. 30.4), despite cannabis users performing equally well as nonusers on the standard version of the task (Fig. 30.5; Vaidya et al., 2012). This suggests that prolonged exposure to cannabis could affect neural reward circuitry, though not necessarily in a way that impacts performance on a motivation task. However, participants also reported other drug use, both legal and illicit, making it difficult to determine whether the effects were due to cannabis or other substances. Ultimately, this evidence suggests that cannabis users demonstrate increased sensitivity for immediate rewards, which could weaken motivational inhibitory control and increase the propensity toward future risk-taking or reward-seeking behavior (Nestor, Hester, & Garavan, 2010). This may explain why users sometimes exhibit greater risk-taking performance. However, longitudinal studies are necessary to determine whether this is a preexisting vulnerability or a deficit that develops subsequent to cannabis use.

Nevertheless, not all laboratory evidence supports the presence of motivational deficits in chronic cannabis users. Using a spatial recognition task with monetary reinforcement, researchers demonstrated that cannabis users performed equally well relative to nonusers and tobacco smokers, with performance improving similarly when monetary reinforcers were provided to enhance motivation (Martin-Soelch et al., 2009). Further, there were no group differences in the amount of money earned performing the task. In addition, a comparison of cannabis users and nonusers during performance on a reaction time task assessing motivation for monetary reward revealed no group differences (Voon et al., 2014), although,

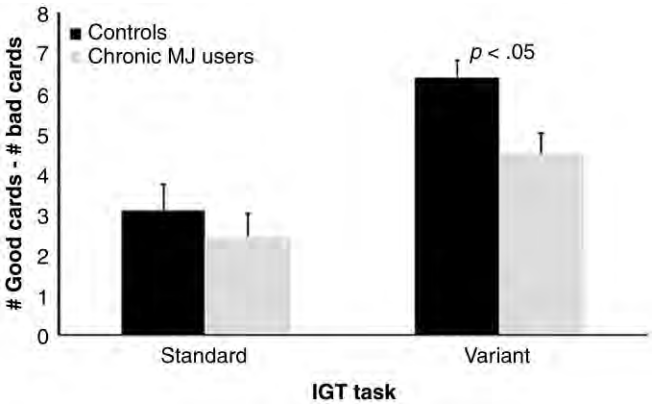

FIGURE 30.5 Performance differences between chronic marijuana users and controls on the Iowa Gambling Task (IGT). There were no group differences in performance on the standard version of the IGT; however, chronic marijuana users performed worse than controls on the more challenging variant version. *Source: Vaidya et al. (2012). Open Access article; permission is not required.*

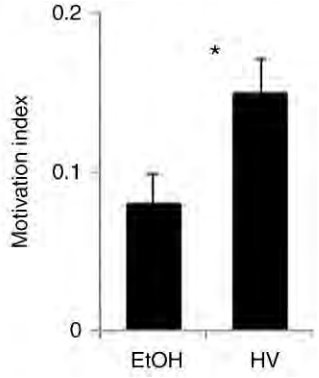

FIGURE 30.6 Motivational index scores in chronic alcohol users (EtOH) relative to healthy volunteers (HV). Alcohol-dependent participants demonstrated decreased motivation to reward feedback than both cannabis-dependent participants and healthy volunteers. There were no significant differences in motivation between cannabis-dependent participants and healthy volunteers. *Source: Voon et al. (2014). Open Access article; permission is not required.*

interestingly, alcohol-dependent participants did exhibit decreased motivation (Fig. 30.6).

Given the variability in cannabis users' response to monetary rewards, Macher and Earleywine (2012) selected a unique method for enhancing motivation. Prior to administering a battery of cognitive tests, the researchers informed one group of chronic users "it is important that you try your very best on these tasks, because this research will be used to support legislation on marijuana policy." Interestingly, those users did significantly better (by nearly one standard deviation) on the California Verbal Learning Test-II, a neuropsychological test of learning and memory, relative to users who were not given that statement (Fig. 30.7). Further, their cognitive abilities were comparable to nonusers, suggesting that frequent cannabis users may not demonstrate learning and memory deficits provided they are inherently motivated to perform well on the assessment.

Despite the widespread notion of a link between motivation and cannabis use, few research studies on cognition in cannabis users include performance validity tests, or effort tests (tests which ensure that participants are motivated, and putting forth sufficient effort on assessments to obtain valid results). In fact, the authors were able to find only one study examining cognitive functioning in chronic cannabis users that used a measure of effort. Rabin, Zakzanis, Daskalakis, and George (2013) used the Test of Memory Malingering (TOMM; Tombaugh, 1997) "as a proxy for motivation and adequacy of effort."

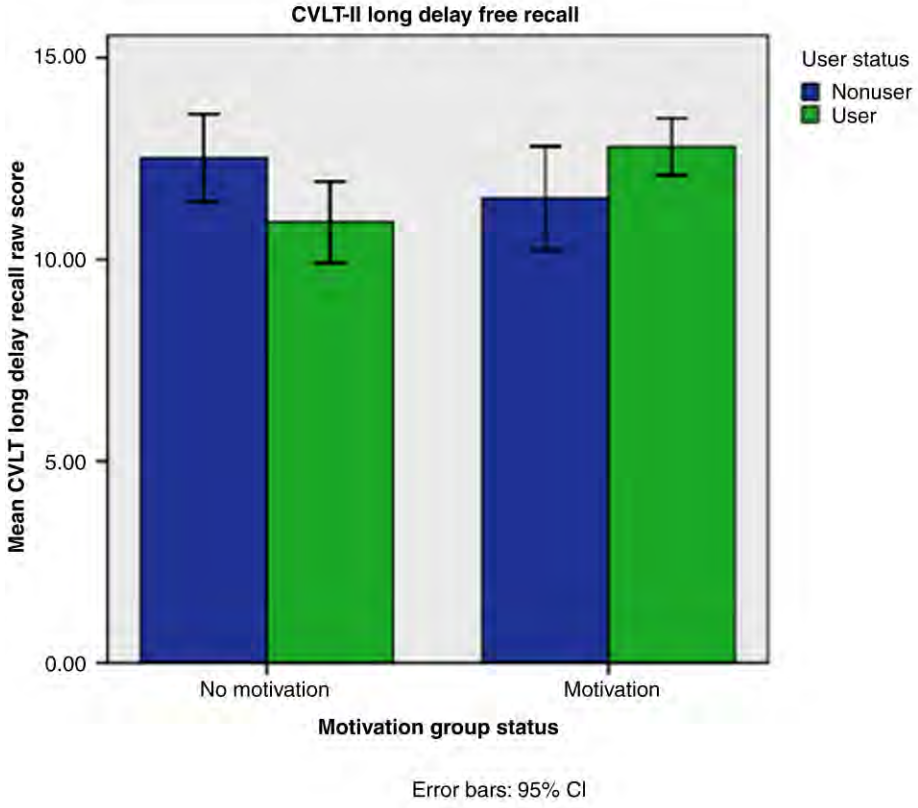

FIGURE 30.7 Learning and memory performance on the California Verbal Learning Test-II (CVLT-II) in chronic cannabis users and nonusers, in motivated and nonmotivated conditions. Cannabis users given a motivational statement demonstrated better learning and memory performance than those not given the statement, and their performance was consistent with nonusers. *Source: Macher and Earleywine (2012). Permission obtained from Routledge Taylor & Francis.*

However, the authors did not clarify whether any participants failed this measure of effort, and if they did, whether their results were excluded from the study. All participants in the study by Macher and Earleywine (2012) passed the three effort tests administered; however, the lower performance of those who were not given the motivational statement suggests that they may not have put forth their absolute best effort. Further research examining the effect of this motivational statement is necessary, and effort tests to ensure adequate motivation should be included in all studies, before drawing conclusions about the effects of chronic cannabis use on cognition.

CONCLUDING REMARKS

The relationship between chronic cannabis use and motivation remains unclear, but research has revealed some patterns. Most evidence suggests that chronic cannabis use does not lead to an "amotivational syndrome," resulting in school dropout or poor occupational success. Many contributing factors exist, and it is most likely that individuals with multiple risk factors are drawn to various problem behaviors, of which cannabis use is often only one. However, laboratory motivational measures provide mixed evidence, some in support and some in opposition. Results indicate that cannabis users do exhibit enhanced motivation when rewards are inherently motivating for them. However, most evidence suggests that users are often differentially motivated to work toward monetary reinforcers, relative to nonusers. Further research utilizing laboratory tasks with the supplement of neuroimaging will be critical in understanding the dopamine reward system in chronic cannabis users and its impact on motivation.

MINI-DICTIONARY

"Amotivational syndrome" A proposed syndrome of chronic cannabis users, including symptoms, such as, apathy, lethargy, lack of motivation, and difficulty concentrating. Most research findings do not support this syndrome.
Cognitive inhibitory control The ability to inhibit a response in reaction to a stimulus.
Effort tests Measures used during neuropsychological assessment to ensure that examinees are giving adequate effort for valid test results.
Hawkins and Weis's social development model (1985) A hypothesis that school failure leads to education demotivation, and, subsequently, association with deviant peers and substance use (including cannabis use)
Iowa Gambling Task (IGT) An empirically-validated measure of complex monetary decision-making.
Jessor and Jessor's problem behavior theory (1977) A theory that adolescents exhibit one common syndrome representing a penchant for a range of problem behaviors that may or may not include cannabis use.
Mesolimbic dopamine system A system of the brain involved in motivation, reinforcement, and reward circuitry.
Motivational inhibitory control The control over one's feeling of inherent motivation.
Positron emission tomography (PET) A functional imaging technique producing a three-dimensional image of metabolic activity in the brain.
Test of memory malingering (TOMM) An empirically-validated measure of effort used in neuropsychological assessment.

Cannabis Use and Its Association to Mental Illness: A Focus on Mood and Anxiety Disorders

S. Lev-Ran[*,**], *D. Feingold*[*,†]

*Department of Psychiatry, Sheba Medical Center, Tel Hashomer, Israel
**Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel
†Ariel University, Ariel, Israel

SUMMARY POINTS

- This chapter reviews the association between cannabis use and mental illness, focusing on mood and anxiety disorders.
- There is strong evidence suggesting that cannabis use and mental illness highly cooccur; that is, that mental illness is common among cannabis users (compared to nonusers), and that cannabis use is common among individuals with mental illness (compared to those without mental illness).
- Notwithstanding, evidence indicates that the majority of cannabis users do not suffer from concurrent mental illness and vice versa.
- Longitudinal studies reveal conflicting results regarding the association between cannabis use and future incidence of mood and anxiety disorders, and suffer from methodological challenges.
- The inverse notion that mood and anxiety disorders are associated with future initiation of mood and anxiety disorders does not receive sufficient support in longitudinal studies.
- Causal association between cannabis use and mood and anxiety disorders is yet well established. Cross-sectional association between the two may be attributed to cooccurring sociodemographic and clinical variables.
- Cannabis use may have a negative effect on the course of mood and anxiety disorders, and on treatment efficacy for these disorders.

KEY FACTS ON MENTAL ILLNESS

- Mental illness is generally associated with disturbances in mood, thought, and/or behavior.
- Mental illness affects about 46% of the population in the Western world over their lifetime course, and about 30% of the population over a 1-year course.
- Each year, mental illness accounts for about 25% of all health loss due to disability worldwide, and approximately 7% of the life-years lost.
- People with mental illness are more prone than people without mental illness to use addictive substances like alcohol, cannabis, and other drugs.
- There are various means for treating metal illness, including psychiatric medication, psychotherapy, and vocational interventions.

OR	Odds ratio
THC	Tetrahydrocannabinol

INTRODUCTION

Cannabis is the most commonly used illicit drug, with estimated worldwide 12-month prevalence of 2.8–4.5% of the population (Degenhardt et al., 2011; UNODC, 2012), or roughly between 125 to 203 million individuals (Degenhardt & Hall, 2012). Mental illness steadily affects about 30% of the population in high-income countries each year (Kessler et al., 2005), accounting for about one quarter of all health loss due to disability (World Health Organization, 2002) and approximately 7% of the global loss of life-years worldwide (Whiteford et al., 2013). There is strong scientific evidence indicating an association between cannabis use and mental illness. This chapter will review this association, addressing both cross-sectional data on the prevalence of mental illness among cannabis users and vice versa, as well as longitudinal data exploring potential causal association between cannabis use and mental illness. As the association between cannabis use and psychotic disorders is covered elsewhere in this book, we will focus on longitudinal data exploring the association between cannabis use and two major groups of psychiatric disorders: mood disorders, and anxiety disorders.

Several methodological challenges should be recognized a priori when addressing the association between cannabis use and mental illness. One of the most evident is the lack of consistency with regard to the measures used for both cannabis use and mental illness. For example, while some studies define exposure to cannabis as the mere use of cannabis, or in some cases according to the frequency of cannabis use (monthly/weekly/daily), other studies refer exclusively to disorders associated with pathological cannabis use, that is, cannabis abuse or cannabis dependence, collectively termed "cannabis use disorder" (CUD). Moreover, there is no standard measure for cannabis—not only are there multiple methods of ingestion, cannabis strains differ substantially in their potency (as measured by tetrahydrocannabinol (THC) concentrations), and cannabis "joints" may include substantially different amounts of cannabis (Mariani, Brooks, Haney, & Levin, 2011). Similar discrepancies can be found in the definition of mental illness used. Though mental illness is usually defined using criteria-based diagnosis, as defined by the Diagnostic and Statistical Manual of Mental Disorders (DSM) (American Psychiatric Association, 2013) or the International Classification of Diseases (ICD) (World Health Organization, 1992), many studies exploring the association between cannabis use and mental illness define mental illness as presence of symptoms associated with the illness, rather than a full diagnosis. Furthermore, studies vary in terms of disorders included in the general term "any mental illness," and the particular disorders included when dealing with "mood" or "anxiety disorders." Accordingly, presenting standardized and comparable data regarding the association between cannabis use and mental illness is challenging. Nevertheless, it seems like many of the limitations mentioned above will be part of any report exploring the association between cannabis use and mental illness, and the aim of this chapter is to represent the current state of knowledge on this association.

COOCCURRENCE OF CANNABIS USE AND MENTAL ILLNESS

Cannabis Use Among Individuals With Mental Illness

Substantial data regarding the cooccurrence of cannabis use and mental illness is derived from large-scale population-based samples focusing on substance use and mental illness in the general population. In the United States, three major cohorts have sought to investigate the cooccurrence of substance use, including cannabis use, and mental illness: the Epidemiological Catchment Area (ECA) conducted in the early 1980s (Regier et al., 1984), the National Comorbidity Survey (NCS) conducted in the early 1990s (Kessler et al., 1994), and the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC), conducted in the early 2000s (Grant & Kaplan, 2005). Similar large-scale projects were carried out elsewhere worldwide, including Australia, (Degenhardt, Hall, & Lynskey, 2000) and Europe (Hibell et al., 2012).

The NESARC data presents detailed information on cannabis use and mental illness (Fig. 31.1), reporting that among individuals with any mental illness prevalence of past-year cannabis use was 9.8%, compared to 1.7% among individuals without mental illness. Though rates of cannabis use in this sample are reported to be lower than those in other population-based samples (Grucza, Abbacchi, Przybeck, & Gfroerer, 2007), these data nevertheless emphasize the increased rates of cannabis use among individuals with mental illness. Individuals with mental illness were almost 10 times as likely to use cannabis weekly and more than 5 times as likely to use cannabis less than weekly, compared to individuals without mental illness. Furthermore, it is suggested that 83% of

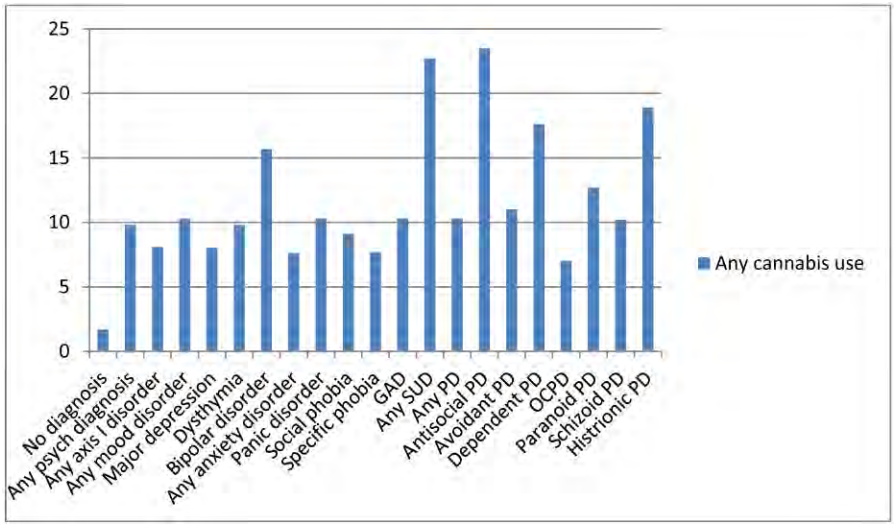

FIGURE 31.1 **Prevalence of cannabis use according to specific mental illness.** This graph describes the prevalence of past-year cannabis use among individuals suffering from various mental illnesses. For comparison, the bar on the left indicates the prevalence of cannabis use among individuals with no mental illness (Lev-Ran et al., 2013b).

all cannabis use in the United States is attributed to individuals who had a diagnosis of past-year mental illness (Lev-Ran, Le Foll, McKenzie, George, & Rehm, 2013b). Among individuals with mental illness, prevalence of cannabis use increases with the increase in the number of psychiatric diagnoses (Fig. 31.2). This data is important in light of finding indicating that the majority of individuals diagnosed with mental illness have an additional comorbid disorder (Gadermann, Alonso, Vilagut, Zaslavsky, & Kessler, 2012; Regier et al., 1990).

The growing body of cross-sectional evidence on the association of cannabis use and mood disorders led Degenhardt et al. (2003) to conclude that "there is increasing evidence that regular cannabis use and depression occur together more often than we might expect by chance" (Degenhardt et al. 2003, p. 1497). Lifetime prevalence of cannabis use among individuals with major depressive disorder (MDD) was 60% (Chen, Wagner, & Anthony, 2002), and results from the National Survey on Drug Use and Health show that 25% of the teenagers with past-year depression also reported they used cannabis in the past year, compared to 12% who did not have depression (SAMHSA, 2007). A 10-year longitudinal study conducted in Europe revealed that prevalence of lifetime cannabis use was significantly higher among teenagers with lifetime depression [OR = 2.7 (1.6–4.4)], dysthymia [OR = 6.0 (2.6–13.8)] and hypomania/mania [OR = 4.7 (2.2–10.0)], compared to those without a specific diagnosis (Wittchen et al., 2007).

Prevalence of cannabis use was found to be significantly higher among individuals with bipolar disorder (BPD) compared to the general population (Etain et al., 2012). Prevalence of lifetime CUDs among individuals with bipolar I disorder was reported to be as high

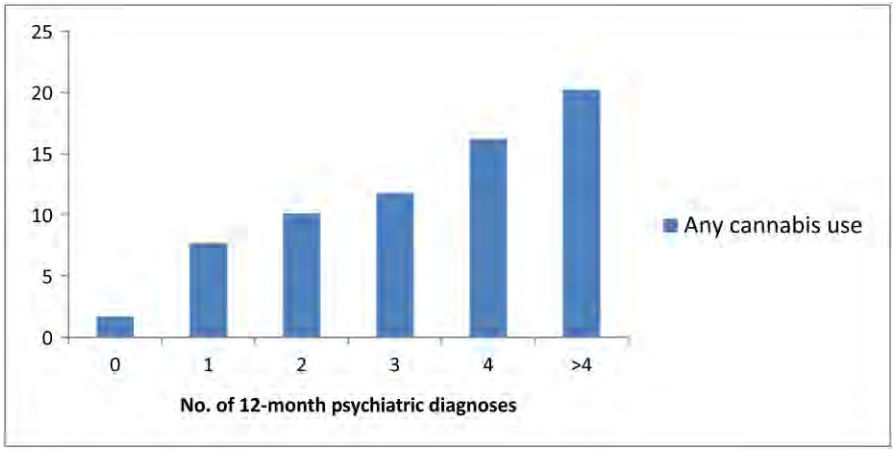

FIGURE 31.2 **Prevalence of cannabis use according to the number of 12-month mental illnesses.** This graph describes the prevalence of cannabis use according to the number of psychiatric diagnoses individuals had in the last 12 months (Lev-Ran et al., 2013b).

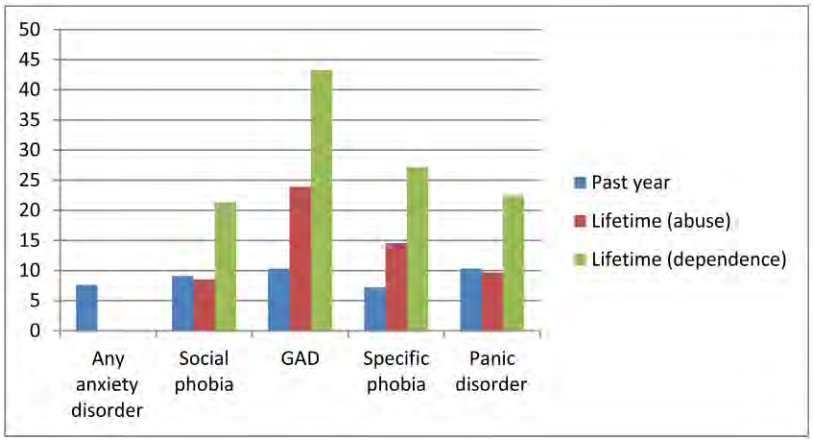

FIGURE 31.3 **Prevalence of past-year cannabis use, and lifetime abuse and dependence according to specific anxiety disorders.** This graph describes the prevalence of cannabis use in the past year, as well as lifetime cannabis abuse and dependence, among individuals with various anxiety disorders (Buckner et al., 2012b; Lev-Ran et al., 2013b).

as 46% (Cerullo & Strakowski, 2007), and prevalence of 12-month CUDs among individuals with bipolar I and II disorder was reported to be 7.2%, 6 times higher than that the general population in the same sample (Lev-Ran, Le Foll, McKenzie, George, & Rehm, 2013a). Reports based on the NESARC sample show that individuals with anxiety disorders are more prone to use cannabis and suffer from a CUD, compared to individuals without mental illness (Fig. 31.3).

Mental Illness Among Cannabis Users

Evidence suggest that rates of mental illness among cannabis users are related to the pattern of cannabis use, as this cooccurrence is more common among individuals diagnosed with a CUD, compared to occasional users (Troisi, Pasini, Saracco, & Spalletta, 1998). Data from the Epidemiologic Catchment Area study suggests that more than 50% of the individuals with a lifetime CUD had a concurrent diagnosis of mental illness (Regier et al., 1990), and that individuals with a CUD were 2 times more prone to receive such diagnoses, compared to those without a CUD. Anxiety disorders were the most common class of disorders among individuals with a CUD; 26.4% of individuals with a CUD had an anxiety disorder, compared to 7.3% in the general population. Troisi et al. (1998) reported that 29% of the individuals who used cannabis in the past year also received a concurrent psychiatric diagnosis.

The National Survey on Mental Health and Wellbeing (NSMHWB) revealed that past-year prevalence of mood and anxiety disorders among cannabis users without a history of a CUD was 12.1% and 8%, respectively, more than twice as high as nonusers (Degenhardt, Hall, & Lynskey, 2001). In Canada, Cheung et al. (2010) reported that prevalence of mood or anxiety disorders among heavy cannabis users (defined as almost-daily or daily users) was 18.1%, more than twice the rate of these disorders among abstainers (8.4%).

Results from several epidemiological surveys conducted in Australia and in the United States suggest that the past-year prevalence of any anxiety disorder is 17–29% among individuals with past-year cannabis dependence (Degenhardt et al., 2001; Stinson, Ruan, Pickering, & Grant, 2006), compared to 5–7% among individuals who did not use cannabis (Degenhardt et al., 2001; Regier et al., 1990). Analysis revealed that cannabis users [OR = 1.78 (1.31–2.41)] and individuals with cannabis dependence [OR = 4.3 (2.88–6.4)] were significantly more likely to receive a past-year diagnosis of an anxiety disorder, compared to nonusers (Degenhardt et al., 2001).

Possible Mechanisms Underlying Concurrent Cannabis Use and Mental Illness

As presented above, there is strong evidence suggesting that cannabis use and mental illness cooccur more than one would expect by chance. Several explanations were given to the underlying mechanisms that account for this strong association. Notably, it was argued that the association between cannabis use and mental illness is attributed to various common factors that may elevate the risk for developing mental illness and initiating cannabis use. For example, it was suggested that stressful life events (de Graaf, Bijl, Ten Have, Beekman, & Vollebergh, 2004), use and misuse of other substances rather than cannabis (van Laar, van Dorsselaer, Monshouwer, & de Graaf, 2007), and a neurological predisposition related to the influence of the human endocannabinoid system on mental health (Hill & Patel, 2013) may crucially attribute to the association between cannabis use and mental illness. Conversely, some writers argue for a direct causal association between the two

phenomena, suggesting that cannabis use may lead individuals to develop mental illness, or that mental illness may lead individuals to initiate cannabis use, or to use it more frequently. This notion will be discussed in the following sections of this chapter.

Significance and Limitations of Cross-Sectional Data

Cross-sectional data on the cooccurrence of cannabis use and mental illness is of high importance, as it holds valuable clinical implications for both general psychiatric services and substance-related treatment services. Evidence regarding the high prevalence of cooccurring cannabis use and mental illness in the population imply that a complete clinical evaluation of both mental illness and patterns of substance use is required in both settings, in order to allow for more accurate diagnosis and efficient treatment, as Johns (2001) concludes: "for any psychiatric patient, risk-management and care-planning is incomplete without a thorough assessment of substance misuse" (Johns, 2001, p. 121). However, cross-sectional data is limited in terms of exploring the causal association between cannabis use and mental illness (Degenhardt, Hall, & Lynskey, 2003). We will now review available longitudinal research pertaining to the association between cannabis use and mood and anxiety disorders.

CANNABIS AND MOOD DISORDERS

The term "mood disorders" relates to a group of mental illnesses associated with dysregulation in affective states, accompanied by changes in levels of activity and motivation, with disturbed patterns of sleep and appetite (Hammen, 2003). MDD and BPD are considered the most severe mood disorders, accounting for 60% of the general burden of disease of mental illness, and nearly 4% of the burden of disease of any medical condition worldwide (Whiteford et al., 2013). With high mortality rate and substantial functional disability caused directly by these two conditions, extensive research has focused on identifying clinical correlates associated with MDD and BPD, including substantial work on the association with substance use and misuse (Moore et al., 2007; Whiteford et al., 2013). Fig. 31.4 presents the 3-year incidence of mood and anxiety disorders, by category, among lifetime cannabis users, compared to nonusers (van Laar et al., 2007).

Longitudinal studies have enabled further investigation of the cross-sectional association between cannabis use and mood disorders by exploring two alternative temporal hypotheses. The majority of the studies focused on the association between cannabis use at baseline and the incidence of mood disorder at follow-up, revealing conflicting findings. Several studies showed that cannabis use at baseline was significantly associated with future occurrence of MDD (Bovasso, 2001; Fergusson & Horwood, 1997) and BPD (Tijssen et al., 2010), while other studies reported that cannabis users, even heavy users, were not significantly more prone than nonusers to develop MDD or BPD at follow-up (Degenhardt et al., 2013; Georgiades & Boyle, 2007). A metaanalysis exploring the longitudinal association between cannabis use and depression conducted by Lev-Ran et al. (2014) concluded that cannabis use, and particularly heavy cannabis use, may be associated with an increased risk for developing depression [OR = 1.17 (1.05–1.30)] for any cannabis

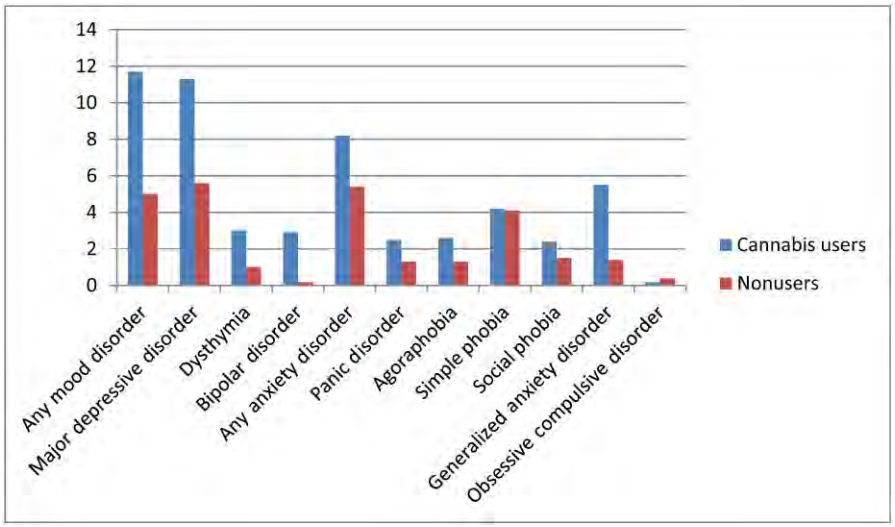

FIGURE 31.4 Three-year incidence of mood and anxiety disorders, by category, among lifetime cannabis users compared to nonusers. This graph shows the percentage of cannabis users and nonusers that developed various mood and anxiety disorders over the course of 3 years (van Laar et al., 2007).

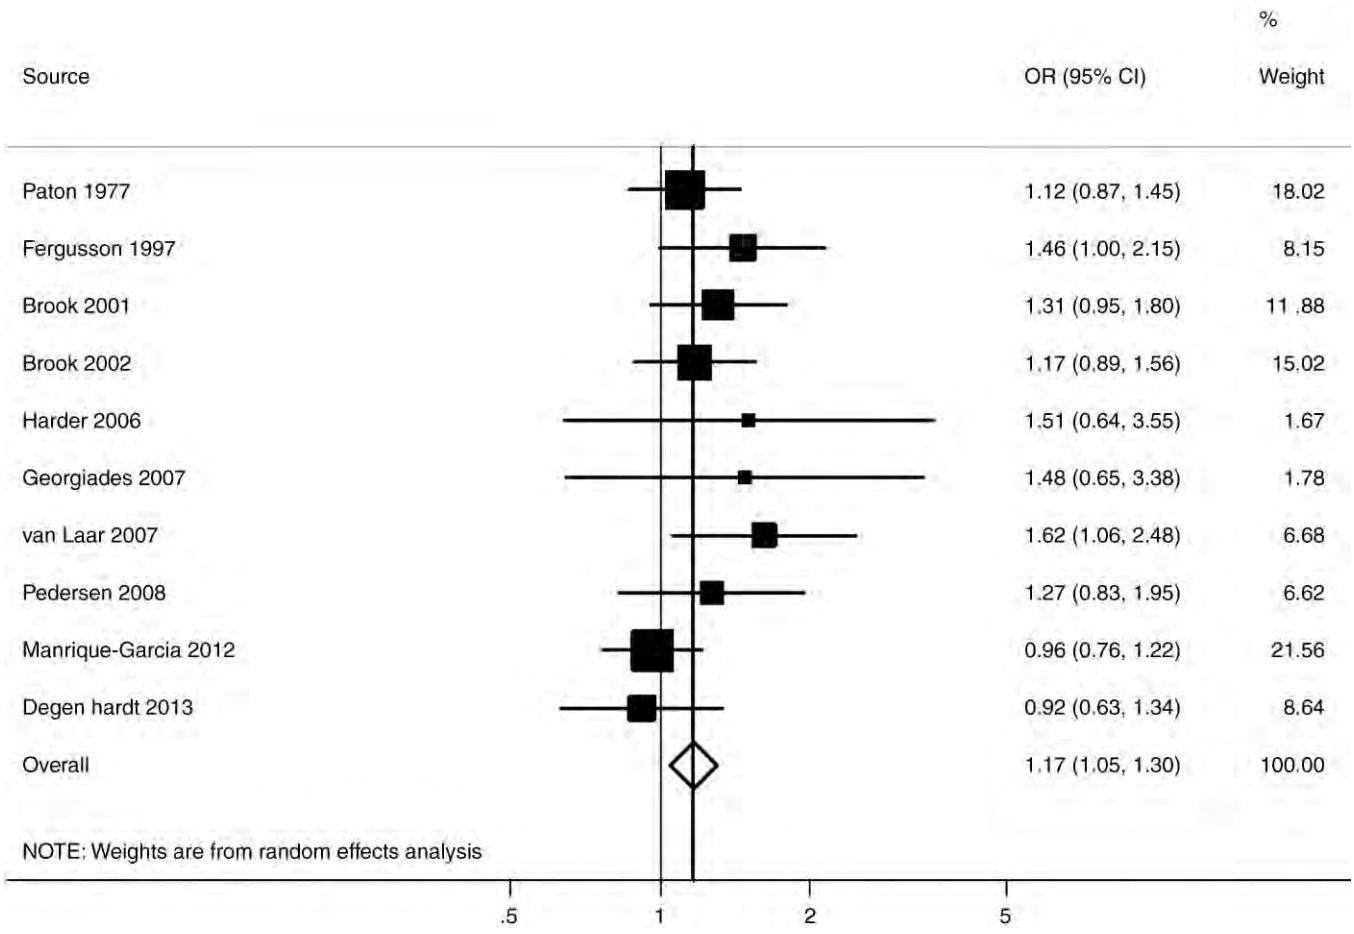

FIGURE 31.5 Forest plot showing adjusted odds ratios (AORs) and 95% confidence intervals (CIs) for any depressive outcome, according to cannabis use in individual studies (random effects). This graph describes the odds ratio (adjusted) for developing a depressive disorder among cannabis users, compared to nonusers (Lev-Ran et al., 2014).

use, and OR = 1.62 (1.21–2.16) for heavy cannabis use (Figs. 31.5 and 31.6). Though results of this metaanalysis were in line with an integrative data analysis published by Horwood et al. (2012), based on four Australian cohorts, the authors concluded that results pertaining to increased risk for depression among cannabis users should be regarded with caution, given modest pooled results and heterogeneity between studies, in terms of adjustment for confounders. Data regarding causal association between cannabis use and BPD is sparse. Though individual studies point to a possible longitudinal association between the two, some of these do not control for baseline manic and hypomanic symptoms, confounding conclusions (van Rossum, Boomsma, Tenback, Reed, & van Os, 2009). Hence, available data do not suffice to clearly indicate a longitudinal association between cannabis use and BPD.

An inverse notion, claiming that mood disorders at baseline may be associated with an increased risk for future cannabis use, has been reported in several clinical observations (Khantzian & Albanese, 2008), exploratory studies (Ogborne, Smart, Weber, & Birchmore-Timney, 2000), and retrospective studies (Gruber, Pope, & Oliva, 1997). Furthermore, a longitudinal association between MDD and initiation of cannabis use has been reported (Feingold, Weiser, Rehm & Lev-Ran, 2015). The term "self-medication" was elaborated by Khantzian (1985), suggesting that substance use is primarily a means of subduing psychological distress. According to Bolton, Robinson, and Sareen (2009) up to 24% of individuals with mood disorders who use alcohol, drugs, or misused prescription medication report they did so in order to relieve depressive or manic symptoms. Yet, based on large-scale longitudinal studies, there is yet no sufficient data based on multiple studies suggesting a causal relationship between MDD or BPD and the initiation of cannabis use, or increased frequency of use (Bolton et al., 2009; Degenhardt et al., 2003).

Effects of Cannabis Use on the Course of Mood Disorders

There is some evidence linking cannabis use with changes in the course of illness among individuals with mood disorders. Cannabis use was significantly associated with elevated sense of dysphoria among individuals

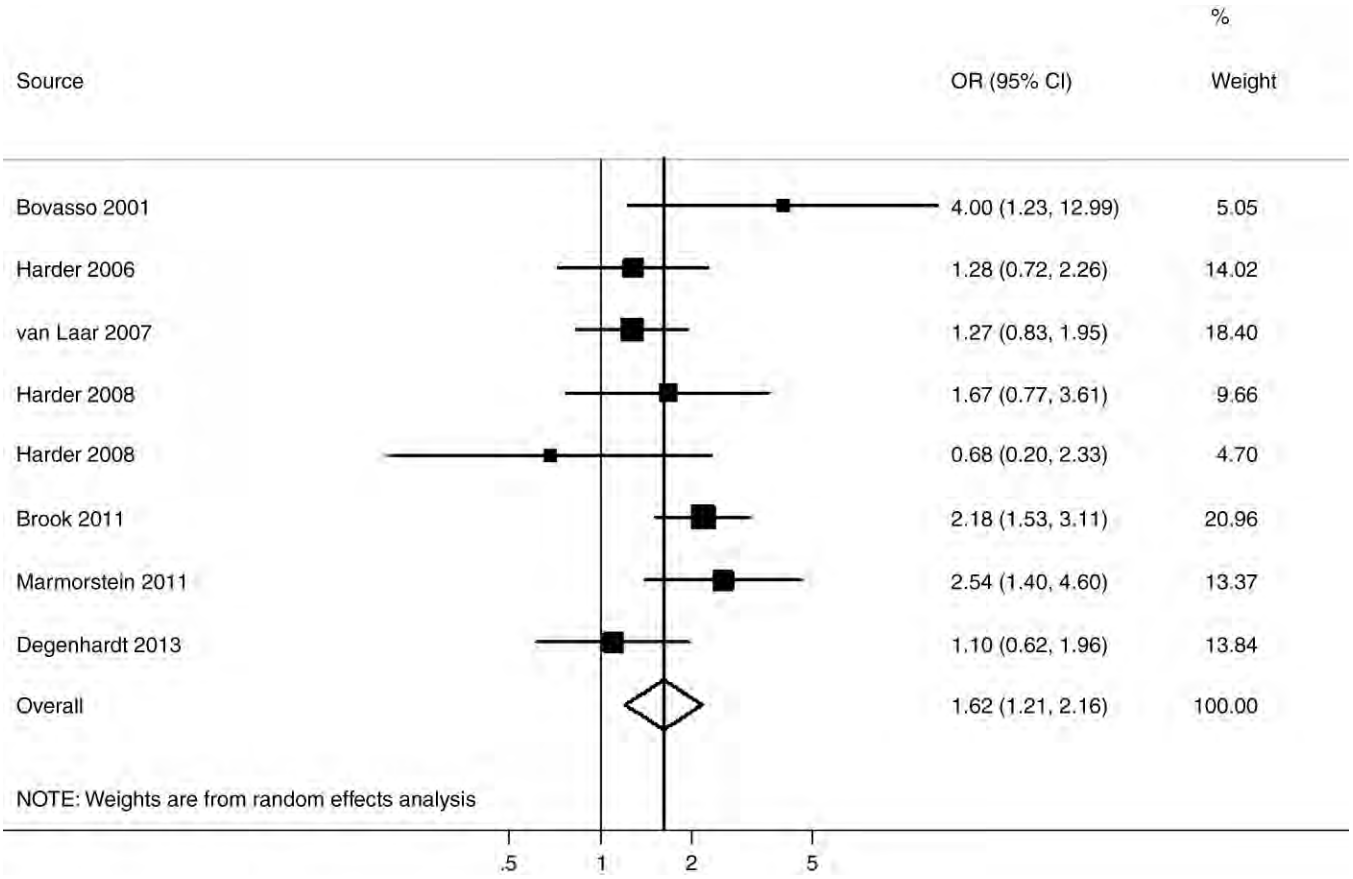

FIGURE 31.6 Forest plot showing adjusted odds ratios (AORs) and 95% confidence intervals (CIs) for any depressive outcome, according to heavy cannabis use (defined as a cannabis use disorder or at least weekly use) in individual studies (random effects). This graph describes the odds ratio (adjusted) for developing a depressive disorder, among heavy cannabis users, defined as individuals using cannabis at least weekly, or suffering from a cannabis use disorder (Lev-Ran et al., 2014).

with MDD (Ablon & Goodwin, 1974), and an incline in depressive symptoms among adolescents, over a 4-year course (Otten & Engels, 2013). There is some evidence that cannabis use, and frequent cannabis in particular, may moderate the efficiency of pharmacological treatment for depressive symptoms in clinical population (Bricker et al., 2007). Individuals with BPD and cooccurring cannabis problem were more prone to have earlier onset of the disorder (Etain et al., 2012; Lev-Ran, Le Foll, McKenzie, George, & Rehm, 2013a), more depressive and manic/hypomanic episodes per year (Lev-Ran et al., 2013a), longer duration of mixed and manic episodes (Strakowski et al., 2007), and poorer life functioning (Agrawal, Nurnberger, & Lynskey, 2011).

CANNABIS AND ANXIETY DISORDERS

There is evidence that cannabis use, particularly consumption of cannabis with high-concentration THC, can induce anxiety-like symptoms that are usually residue as the effect of THC subsides (D'Souza et al., 2004; Fusar-Poli et al., 2009). Evidence regarding longitudinal association between cannabis use and anxiety disorders is conflicting, and suffers from scarcity of substantial research on the subject. Several retrospective studies suggested that cannabis use may precede the development of panic attacks (Zvolensky et al., 2006) and generalized anxiety disorder (GAD) (Kessler et al., 2002). Furthermore, evidence from a longitudinal cohort study conducted in New Zealand revealed that past-year cannabis use at the age of 16 predicted significantly higher prevalence of any anxiety disorder in a 2-year follow-up (Fergusson & Horwood, 1997). However, these associations were not maintained after controlling for sociodemographic and various clinical variables. A prospective study conducted in the Netherlands (van Laar et al., 2007) revealed similar results; after controlling possible sociodemographic and clinical confounding variables, no significant association was found between cannabis use at baseline and occurrence of anxiety disorders in general [AOR = 1.18 (0.71–1.97)], as well as for individual anxiety disorders: panic disorder [AOR = 1.29 (0.61–2.71)], agoraphobia

[AOR = 1.14 (0.53–2.46)], specific phobias [AOR = 0.91 (0.52–1.58)], social phobia [AOR = 0.80 (0.36–1.79)], GAD [AOR = 1.83 (0.97–3.44)], and obsessive compulsive disorder [AOR = 0.12 (0.01–1.28)].

An inverse notion states that specific anxiety disorders may serve as risk factors for future initiation of cannabis use and incidence of CUD, possibly as means of self-medicating anxiety symptoms (Buckner, Crosby, Wonderlich, & Schmidt, 2012a). This notion is supported by evidence suggesting that one of the most common reasons for using cannabis in the general population is relief from stress (Hathaway, 2003). Accordingly, several prospective and longitudinal studies controlling for confounding psychiatric and substance use disorders at baseline suggested that preliminary social anxiety and GAD were associated with increased risk for future incidence of cannabis use and CUD (Buckner et al., 2008; Marmorstein, White, Loeber, & Stouthamer-Loeber, 2010).

Effects of Cannabis Use on the Course of Anxiety Disorders

Individuals who used cannabis were more prone to have earlier onset of panic attacks (Zvolensky et al., 2006), elevated intensity of anxiety symptoms during panic attacks (Szuster, Pontius, & Campos, 1988), and increased sensitivity to anxiety symptoms (Buckner, Leen-Feldner, Zvolensky, & Schmidt, 2009). Whether cannabis use reduces the efficacy of treatment for anxiety disorders is yet unclear. Bricker et al. (2007) reported that use of cannabis at least monthly did not affect the efficiency of a combined medical and psychological treatment for panic disorder and social phobia, compared to less than monthly use, yet additional research is needed to understand the impact of cannabis use, especially frequent use, on treatment of anxiety disorders.

SUMMARY

Repeated studies show substantial bilateral cross-sectional associations between cannabis use and mental illness: individuals with mental illness consume more cannabis, and individuals who use cannabis have increased prevalence of mental illness. Nevertheless, available research indicates that the majority of cannabis users, particularly occasional users, do not suffer from concurrent mental illness. Moreover, the available cross-sectional data does not suffice to point to a causal relationship between cannabis and mental illness. Longitudinal research indicates that cannabis use, particularly heavy use, may be associated with increased incidence of mood disorders (MDD and BPD), though individual studies suffer from various methodological drawbacks that confound clear conclusions. There is no clear evidence for a longitudinal association between cannabis use and incidence of anxiety disorders, and though cannabis users may be more prone to develop anxiety disorders, this is probably attributed to additional sociodemographic and clinical factors, and not to a direct causal relationship. In both cases of mood and anxiety disorders, it seems that concurrent cannabis use has a negative effect on the course of illness, and possibly on treatment.

Additional research pertaining to the association between cannabis use and mental illness is required. This includes longitudinal research controlling for baseline mental illness, as well as multiple potential covariates, focusing both on incidence as well as course of mental illness among cannabis users. In addition, improving methods for quantifying cannabis consumption is important for determining possible dose-dependent effects on mental illness. As rates of cannabis use continue to be high worldwide, further elucidating possible associations between cannabis use and mental health holds great implication for public health.

MINI-DICTIONARY

Adjusted odds ratio (AOR) A statistical quantification of the strength of association between an exposure variable and an outcome variable, after controlling for possible contributions of other factors in the model.

Anxiety disorders A group of psychiatric disorders associated with excessive feelings of anxiety (about the future) and fear (from present events), usually manifesting in physical, cognitive, and emotional symptoms.

Bipolar disorder (BPD) A psychiatric disorder characterized by episodes of mania or hypomania (excessively elated or irritable mood causing functional difficulties), usually alternating with episodes of depression.

Cannabis use disorders A collective term indicating cannabis abuse or dependence. In the updated DSM-5, previous cannabis abuse and dependence are combined into one diagnosis called "cannabis use disorder."

Major depressive disorder (MDD) A psychiatric disorder characterized by a pervasive low mood or loss of interest or pleasure in normally enjoyable activities. Additional symptoms may include sleep and appetite disturbances, difficulties in concentration, excessive guilt or worthlessness and suicidal thoughts and intent.

Mental illness A collective term indicating psychiatric disorders, generally characterized by dysregulation of mood, thought, and/or behavior, as recognized by the Diagnostic and Statistical Manual (DSM) or International Classification of Diseases (ICD).

Mood disorders A group of psychiatric disorders associated with dysregulation in affective states, levels of activity, motivation and patterns of sleep and appetite.

Odds ratio (OR) A statistical quantification of the strength of association between an exposure variable and an outcome variable. When the odds ratio is larger than 1, the exposure variable is considered to significantly increase the risk of the outcome variable.

Cannabis Use and Well-Being

J. Allen, M.D. Holder, Z. Walsh

Psychology Department, IKBSAS, University of British Columbia, Kelowna, BC, Canada

SUMMARY POINTS

- The majority of research on the relationship between cannabis and well-being is concentrated on depression, anxiety, and psychopathology.
- The primary ways of studying the relationship between cannabis and well-being are causation, reverse causation, and the third factor model.
- Early onset (before the age of 17) initiation of cannabis use and gender have been identified as risk factors in the development of depressive and anxious symptoms.
- Some studies find cannabis to be associated with increased well-being.
- Although many studies fail to do so, after controlling for confounding factors, such as personality, demographics, and polydrug use, the relationship between cannabis and well-being often becomes nonexistent.
- Some individuals may benefit from cannabis use, through reduction of depressive and anxious symptoms, and facilitation of social relationships.
- Individuals who use cannabis for therapeutic purposes (CTP) may benefit psychologically through increased confidence in their ability to self-manage their illness, reduction in pain-related anxiety, increased positive, and decreased negative experiences.

KEY FACTS OF WELL-BEING

- Well-being includes the balance of the combination of positive and negative components (ie, depression, anxiety, happiness, life satisfaction, etc.).
- The positive component of well-being includes a combination of affective (happiness) and subjective (life satisfaction) dimensions.
- The negative component of well-being includes low, but appropriate, levels of depressive and anxious symptoms.
- Well-being and its components can be assessed with self-report measures (eg, Positive and Negative Affect Schedule and the Satisfaction with Life Scale).

KEY FACTS OF POSITIVE PSYCHOLOGY

- In contrast to traditional psychology, positive psychology is the scientific study of variables that allow individuals and communities to thrive, and how these can be promoted.
- Although referred to earlier, positive psychology formally originated in 1998, when Martin Seligman became president of the American Psychological Association, and proposed it as his theme.
- Positive psychology is intended to supplement traditional psychology, and provide a more complete version of the human condition.
- Goals of positive psychology include: families and schools that allow children to flourish, workplaces that foster satisfaction and high productivity, communities that encourage civic engagement, therapists who identify and nurture their patients' strengths, the teaching of Positive Psychology, and the dissemination of Positive Psychology interventions in schools, corporations, government, hospitals, and communities.

KEY FACTS OF CANNABIS FOR THERAPEUTIC PURPOSES

- The use of CTP can be traced to antiquity, and cannabis-based medicines played a prominent role in the western pharmacopeia from the late 19th century until the 1920s.
- Cannabis-based medicines were marginalized beginning in the 1930s due to technological changes and social stigma.
- Cannabis-based medicines have experienced a renaissance in the 21st century due to patient advocacy, and increased understanding of the endocannabinoid system.
- Human research with cannabis has been impeded by barriers related to the war on drugs.
- There is empirical support for the effectiveness of cannabis for the treatment of symptoms related to HIV, cancer, multiple sclerosis, and chronic pain conditions.
- Anecdotal and preclinical evidence suggests that cannabis-based medicines may have broad applications for physical and mental health.

AIDS Acquired immunodeficiency syndrome
CTP Cannabis for therapeutic purposes
HIV Human immunodeficiency disease

INTRODUCTION

Cannabis is the most commonly used illicit substance worldwide, with 147 million people using it annually (WHO, 2013). The effective use of cannabis for medicinal, spiritual, and recreational purposes can be traced to antiquity (Russo, 2007). However, diverse sociocultural factors led to the modern stigmatization and marginalization of cannabis (Boyd, 2004), and by the 1940s, mainstream characterizations focused almost exclusively on the putative negative impacts of cannabis use on human health. The 21st century has witnessed a more balanced and nuanced evaluation of the impact of cannabis use on well-being, with public discourse characterized by increased consideration of both potential positive and negative influences.

Traditionally, mental health fields, including psychology and medicine, have primarily focused on dysfunctions, deficits, disorders, and diseases (Holder, 2012). Consistent with this tradition, recent research on cannabis and well-being focuses on negative associations, such as those involving depression, anxiety, and psychopathology (Moore et al., 2007). However, historical descriptions of cannabis use often focused on the euphoric and salutary effects. Most notably, Moreau, in the 1840s, introduced Europeans to the potential of cannabis as an antidepressant, with the potential for "effectively combatting the fixed ideas of depressives, disrupting the chain of their ideas, of unfocusing their attention on such and such a subject." (Moreau, 1973, p. 211). Despite the focus of mental health fields on the negative associations between cannabis and well-being, some research does address the possible role cannabis may play in positive well-being.

CANNABIS AND POSITIVE WELL-BEING

In contrast with the traditional focus of mental healthcare on the identification and treatment of maladaptive behaviors and emotional states, positive psychology focuses on strengths and factors that enhance well-being. Positive psychology aims to identify variables that promote positive well-being, and to understand how these variables can be used to encourage well-being, rather than exclusively focusing on dysfunctions, deficits, disorders, and diseases (Holder, 2012). Although it is important to consider ill-being, the relevance of positive well-being should not be underestimated. For instance, happier individuals have been shown to be healthier, more productive members of society, experience more satisfaction and success in their careers, and have more successful relationships (Holder, 2012). Additionally, an absence of positive mental health predicts a 62% increased likelihood of mortality, after controlling for other variables, including depression and anxiety (Keyes & Simoes, 2012).

Studies of cannabis are often limited as they only consider ill-being, and studies that examine the effects of cannabis on positive well-being are generally limited to examining only one dimension of well-being, such as happiness or life satisfaction. Although happiness and life satisfaction are both related and components of well-being, they are separable. Happiness refers to an individual's subjective evaluation of the positive affective components of their life, and includes both hedonic and eudaimonic components. Predictors of happiness include marriage, job satisfaction, involvement in leisure activities, and social relationships (Argyle, 2001). Life satisfaction refers to an individual's cognitive evaluation of their quality of life as a whole. Together, happiness and life satisfaction contribute to one's overall well-being. Well-being refers to an individual's evaluation of various aspects of their lives, including satisfaction with their health, relationships, recreation, work, meaning, and purpose, as well as their affective reactions to life events and level of interest and engagement. These evaluations can be positive or negative, and, taken together, are encompassed under the label of subjective well-being.

Research on cannabis use and positive well-being has yielded inconsistent results. Although mood often improves while under the influence of cannabis (Green, Kavanagh, & Young, 2003), it is unclear whether this endures once the person is no longer experiencing cannabis intoxication. A longitudinal study showed that adolescent cannabis use precedes lower life satisfaction, and an increased incidence of major depressive disorder (Georgiades & Boyle, 2007), and both current and former heavy cannabis use is associated with reduced life satisfaction and happiness (Gruber, Pope, Hudson, & Yurgelun-Todd, 2003). Additionally, those who use cannabis less than 100 times do not differ from abstainers in their level of life satisfaction, although increased use is associated with decreased life satisfaction (Fergusson & Boden, 2008). There is also evidence linking cannabis use and increased well-being. For instance, cannabis users have higher levels of subjective well-being than nonusers (Barnwell, Earleywine, & Wilcox, 2006), and heavy users have higher life satisfaction in comparison to occasional users (Kouri, Pope, Yurgelun-Todd, Gruber, & 1995). One of the few studies to explore the relationship between cannabis use and well-being assessed frequency of use (past year, past month, and amount of cannabis consumed per session). No direct relationship was found between frequency of cannabis use and well-being, although there was a relationship between the negative consequences of drug use and well-being (Allen & Holder, 2013). Users who experienced negative consequences, such as getting into a fight or missing a test, reported more depression symptoms and negative affect. These results suggest it may not be simply that cannabis use affects well-being, but whether people experience negative consequences resulting from drug use. Additionally, participants low in the personality traits of Agreeableness and Conscientiousness were more likely to use cannabis, as well as experience negative consequences. Personality traits account for a large percentage of the variance in happiness, and they are strong predictors of happiness; individuals who exhibit stable levels of happiness also typically display high levels of Extraversion, and low levels of Neuroticism (Steel, Schmidt, & Shultz, 2008). Therefore, personality likely plays a large role in mediating the relationship between cannabis use and well-being (Table 32.1).

TABLE 32.1 Medical Cannabis and Well-Being: Direct and Indirect Effects

Direct	Indirect
Analgesia	Reduced symptom-related anxiety
Sedation	Increased social support from other users
Appetite	Increased positive affect
Other symptom reduction	Improved self-efficacy (via self-cultivation)

MOTIVATIONS FOR CANNABIS USE

Cannabis users have identified the importance of both hedonistic and therapeutic motives for use (Nail, Gunderson, & Kolb, 1974). Among the hedonistic motives, the sole desire to "feel happy" was identified by 17% of light users and 36% of heavy users. Among the therapeutic motives, the desires to be in a social group, increase understanding of others, and having closer relationships were significant to both occasional and heavy users. Social motives, such as bonding with people and hanging out with friends, are identified by 25% of adolescent cannabis users, with 9% citing it as their primary motive (Lee, Neighbors, & Woods, 2007). Social motives for cannabis use, such as enjoying a party or fitting in with a group, have also been identified in adults (Buckner, Zvolensky, & Schmidt, 2012). Social relations are critical to well-being; indeed, social affiliation is the primary strategy used by undergraduates to promote happiness (Tkach & Lyubomirsky, 2006). Additionally, an investigation of the friendship components which are the strongest predictors of happiness found "companionship" and "self-validation" to be significant (Demir & Weitekamp, 2007). Companionship is an important contributor in both initiation and continuation of cannabis use (Shrier, Walls, Kendall, & Blood, 2012). The combination of social inclusion, companionship, and self-validation provided by social cannabis use is likely a contributor to the continuation of use, particularly among groups where social motivation is important, such as adolescents and postsecondary students (Table 32.2).

TABLE 32.2 Primary Motives for Cannabis Use: Recreational and CTP

Recreational	CTP
Social motivation (eg, fit into a group, fun, companionship, self-validation)	Symptom reduction (eg, appetite stimulation, antiemetic effects, and analgesia for chronic pain)
General anxiety reduction (can be counter-effective)	Anxiety reduction associated with mental health issues, chronic pain, and illness
	Aid in sleep
	Escape from reality and relax
	Coping with mental health disorders (clinical and personality)

Note: CTP, cannabis use for therapeutic purposes.

CANNABIS AND ILL-BEING

Recent research has focused primarily on negative associations between cannabis and well-being, and has been conceptualized in three primary ways. The first way is causal, suggesting that cannabis use leads to an increase in negative affect (Bovasso, 2001; Johns, 2001). The second way suggests that individuals with preexisting mood and psychotic disturbances self-medicate using cannabis (Hooshmand, Willoughby, & Good, 2012). The third way is the third factor model, in which both cannabis use and its negative associations are caused by independent factors, such as personality, environment, neurobiology, or social influence (Crippa et al., 2009).

CANNABIS AND DEPRESSION

Research on cannabis use and depression is equivocal, and much research on this topic has been unable to control for diverse factors, including physical and emotional development. Adolescence is a period of heightened risk for both the initiation of substance use and the development of psychological and behavioral dysfunction. Interest in the identification of potential interactions between cannabis and the developing brain has led to substantial research on the effects of cannabis use on adolescents (Hayatbakhsh et al., 2007). Cross-sectional studies of adolescents have identified associations between cannabis use, depression, and suicide (Fergusson, Horwood, & Swain-Campbell, 2002; Rey, Sawyer, Raphael, Patton, & Lynskey, 2002). Longitudinal studies have shown that cannabis use during adolescence is associated with depression and depressive symptoms in adulthood, with some studies reporting stronger associations among those whose use began in early adolescence (Hayatbakhsh et al., 2007; de Graaf et al., 2010). However, results of recent studies regarding the associations between cannabis use and adolescent depression are equivocal; a study assessing early onset and adult onset cannabis users found both groups equally at risk for experiencing a depressive episode (Fairman & Anthony, 2012). Additionally, cannabis use during adolescence may be unrelated to depression 10 years later (Degenhardt et al., 2010), and although cannabis worsens depressive symptoms in young women predisposed to depression and anxiety, it does not directly cause depression (Marmorstein et al., 2010). The effects of cannabis use on depression may be attenuated when cannabis use begins in adulthood, after a critical period of brain development (van Laar, van Dorsselaer, Monshouwer, & de Graaf, 2007). Cannabis use and dependence are only weakly associated with increased risk of depression in adults (Chen, Wagner, & Anthony, 2002), and heavy and infrequent cannabis users demonstrate a similar prevalence of mood disorders (Cheung et al., 2010).

Gender may moderate the association between cannabis use and the development of depression, with female cannabis users more likely to exhibit depressive symptoms than males. For example, adult marijuana abuse and dependence were associated with lifetime incidence of major depressive disorder in females, but not in males (Durdle, Lundahl, Johanson, & Tancer, 2008). Similarly, studies of adolescents report stronger associations between cannabis use and depression among females than males (Poulin, Hand, Boudreau, & Santor, 2005; Patton et al., 2002). These findings indicate the need for further examination of sex and gender-related variations in the functioning of the cannabinoid system, and add to broader calls for the routine incorporation of sex and gender analyses in studies of mental health and addictions (Johnson, Greaves, & Repta, 2007). Though some research has reported a positive association between cannabis use and depression, other cross-sectional and longitudinal studies have failed to find these associations (Pedersen, 2008; Ranney, 2013), and a large online survey found that frequent cannabis users reported less depressed mood, and more positive affect than abstainers (Denson & Earleywine, 2006).

CANNABIS AND ANXIETY

Cannabis has also been associated with anxiety, and, as is the case with depression, the empirical literature remains equivocal, with reports of both anxiolytic and anxiogenic effects. Positive associations have been reported between cannabis use and anxiety (Bonn-Miller, Zvolenksy, Leen-Feldner, Feldner, & Yartz, 2005), and higher prevalence of anxiety disorders have been identified among heavier cannabis users (Cheung et al., 2010). Consistent with these findings of anxiogenic effects are common reports of panic-like responses to cannabis intoxication (Crippa et al., 2009), and longitudinal studies indicating that cannabis use by adolescents predicts young adult anxiety disorders (Degenhardt et al., 2013; Hayatbakhsh et al., 2007). In contrast, anxiolytic effects are among the primary motives for recreational cannabis use (Simons, Correia, Carey, & Borsari, 1998), and a diagnosis of mood or anxiety disorders in adolescence predicted cannabis use 10 years later (Wittchen et al., 2007). A literature review (Crippa et al., 2009) concluded that, although cannabis use and anxiety disorders are positively correlated, the directionality of the relationship remains unclear.

CONFOUNDING FACTORS

In sum, research remains equivocal regarding the association between cannabis and depression and anxiety. Variability in findings across studies may be

attributable to diverse factors, including sample selection (ie, treatment vs community), and assessment of cannabis use (ie, diagnosis vs frequency of use). Additionally, many studies lack controls for potential confounds, such as personality or polydrug use. Some studies fail to observe a relationship between cannabis use and depression, after controlling for confounding factors, such as personality, demographics, and polydrug use (Degenhardt, Hall, & Lynskey, 2001), and adjusting for between-group differences and risk factors (Harder, Morral, & Arkes, 2006). Cannabis use is unrelated to anxiety, after controlling for variables including personality, demographics, polydrug use, and baseline mental health (Degenhardt et al., 2001; van Laar et al., 2007), and covariation among rates of cannabis use, depression, and anxiety may be attributed to personality characteristics underlying all three variables. Therefore, interpretation of studies that did not assess important mediators of the relationship between cannabis and well-being should be cautious.

DOSE–RESPONSE THEORY

Quantity and frequency of use may play an important role in moderating the association between cannabis use and mental health. A review examined the extent to which increased consumption of cannabis leads to greater incidence of psychiatric symptoms (Moore et al., 2007). This review found some support for a dose–response relationship for depression, but not for psychosis or anxiety. Other studies found more consistent support for a dose–response relationship between cannabis and well-being, such that risk of mood disorders appears to be elevated in weekly and daily cannabis users, but not for less frequent cannabis users (van Laar et al., 2007; Poulin et al., 2005). Heavy cannabis use may increase the risk for anxiety (Cheung et al., 2010), with frequent users showing more severe levels of anxiety (Bonn-Miller, Zvolensky, Bernstein, & Timothy, 2008). Additionally, weekly adolescent users were twice as likely to develop anxiety in adulthood, and daily users 5 times more likely (Patton et al., 2002).

SELF-MEDICATION THEORY

The directionality of the associations between cannabis use and ill-being is difficult to infer from extant studies. Some studies suggest that their findings can be explained through the "self-medication hypothesis" (Poulin et al., 2005), and it has been hypothesized that mentally ill individuals self-medicate, using drugs and alcohol, to gain relief from psychiatric issues and negative emotional states (Khantzian, 1985). Studies on the self-medication hypothesis in relation to cannabis use, depression, and anxiety have produced mixed results (Hooshmand et al., 2012; Martins, 2011). Consistent with the self-medication perspective, some adolescents reported that they did not use cannabis for recreational purposes, but rather to alleviate feelings of anxiety, stress, and depression (Bottorff, Johnson, Moffat, & Mulvogue, 2009). In addition, cannabis self-medication may vary according to gender (Poulin et al., 2005). Furthermore, other studies failed to identify a predictive association of anxiety for subsequent cannabis use (Chabrol, Ducangé, Casas, Roura, & Carey, 2005), or have reported that cannabis produced neither anxiolytic or anxiogenic effects in participants (Tournier, Sorbara, Gindre, Swendsen, & Verdoux, 2003). Indeed, a study of frequent cannabis users found only moderate elevations in anxiety preceding use, and no decrease in anxiety subsequent to use (Buckner, Crosby, Silgado, Wonderlich, & Schmidt, 2012). Furthermore, depressed individuals provided rationale similar to nondepressed participants (eg, "to get high," "to increase pleasure," "to become more outgoing") for using cannabis (Arendt et al., 2007).

CANNABIS USE FOR THERAPEUTIC PURPOSES

The relationship between cannabis and well-being is complicated among those who use CTP. Interest in the therapeutic potential of cannabis has enjoyed a renaissance associated with the identification of the endocannabinoid system in the 1990s. Over the past two decades, some governments have instituted policies and laws, which enable their citizens to access CTP. Although motives for recreational and therapeutic use sometimes overlap, there are unique considerations when it comes to CTP. Currently, cannabis and its preparations are utilized for diverse physiological effects, including their appetite-stimulating and antiemetic properties in the treatment of HIV/AIDS, and cancer-related chemotherapy, symptom relief treatment in neurodegenerative diseases, such as Parkinson's and multiple sclerosis, as well as their analgesic effect on chronic pain.

In addition to reducing physical symptoms associated with illness, there may be psychological benefits to CTP. Although not well researched, there are situations in which cannabis may be a unique and effective contributor to psychological well-being. For instance, many people applying for medical cannabis licenses have exhausted other treatment options, including prescription drugs, therapy, and surgery (Reinarman, Nunberg, Lanthier, & Heddleston, 2011), and some are doubtful of traditional medicines' utility in managing their condition, and their ability to self-manage their medications.

A summary of the research on the biopsychosocial model in chronic pain concluded people's appraisals of their symptoms and their ability to self-manage pain and related problems were associated with more positive treatment outcomes (Turk & Okifuji, 2002). Although some medical conditions are intractable, the option to access CTP may increase people's confidence in their ability to take a proactive approach to symptom management through alternative treatment options.

Chronic illness is associated with anxiety related to current and anticipated pain (Turk & Okifuji, 2002). Cannabis users with chronic pain may expect cannabis to alleviate their negative mood and somatosensory states (Zvolensky et al., 2011). Furthermore, across medical conditions, those who use high levels of CTP report that they use cannabis to address anxiety and depression (Walsh et al., 2013). Chronic physical conditions are associated with mood and anxiety disorders (Scott et al., 2007), and health-related quality of life is often diminished by this relationship (Sherbourne et al., 2000). Medical cannabis users report feelings of relaxation and happiness while under the influence (Harris et al., 2000), and motives for cannabis use include enjoyment of the effects and feelings, forgetting problems and worries, and helpfulness in sleeping (Zvolensky et al., 2007). In this context, cannabis removes negative emotions through symptom reduction, and also facilitates positive emotions by allowing users a period of escape from illness, and the opportunity to relax and enjoy themselves. The Broaden and Build Theory of Positive Emotions states that positive emotions allow people to build on their physical and psychological resources by broadening their thought-action repertoires (Fredrickson, 2004). These resources fuel resiliency in times of struggle, and can be drawn on later for coping and survival (Fredrickson, 2004). Although positive emotions are momentary, they may have enduring consequences for positive well-being by removing lingering negative emotions, and providing people with resources to deal with stress. People may become more successful at dealing with stress by utilizing the resources they acquired through positive emotions experienced while using cannabis. Medicinal cannabis users tend to be more depressed than the general population (Korthuis et al., 2008), and chronic illness is strongly related to depression (Moussavi et al., 2007). Users of CTP report more depressed mood and increased somatic complaints, in comparison to recreational users, suggesting that factors related to illness contribute to well-being, independent of cannabis use (Denson & Earleywine, 2006). In sum, cannabis use may increase well-being among CTP users by increasing confidence in their ability to self-manage their illness, reducing pain-related anxiety, increasing positive and decreasing negative experiences while under the influence, and facilitating the use of coping resources acquired during those experiences.

LIMITATIONS AND FUTURE DIRECTIONS

The extant research on cannabis and well-being is limited. For instance, although some studies attempt to determine causality through the use of longitudinal methodology (Hayatbakhsh et al., 2007), the majority of studies are cross-sectional (Rey et al., 2002). Drug use and well-being may vary greatly over time, and although experimental research is not plausible, longitudinal design should be utilized in an attempt to determine causality. Also, many studies do not employ multiple measures, or base their results on a few questions. Measuring a variety of psychological dimensions (eg, happiness, life satisfaction, and depression) is beneficial in ensuring a more complete assessment of well-being, and ensuring that the findings are not dependent on any single measure. Future research on the impact of cannabis use on well-being would benefit from the incorporation of a positive psychology perspective, particularly with regard to CTP. The majority of research on the relationship between cannabis and well-being is concentrated on ill-being (Moore et al., 2007). The purpose of positive psychology is not to replace the common research focus on dysfunction and disorder, but rather to supplement it with a more complete version of the human condition. Positive psychology emphasizes goals, well-being, satisfaction, happiness, and interpersonal skills (Holder, 2012). If there is a possible role for cannabis to play in promoting positive well-being, it would be important to identify what it is, and the best way to encourage it. Additionally, there are gaps in the current research on the role of cannabis in medicinal users. For instance, the relationship between cannabis and well-being appears to be distinct when the primary motive is medicinal, rather than recreational. Although recreational and medicinal users identify some of the same motives (eg, relaxation), medicinal cannabis users may experience additional benefit through increased confidence in their ability to self-manage their illness, reduction of pain-related anxiety, increased positive and decreased negative experiences while under the influence, and facilitation of coping resources acquired during those experiences. Future research should concentrate on the unique differences in motivation between recreational and medicinal users, and determine the extent of cannabis' efficacy in satisfying these motives. By examining the relationship between cannabis and well-being through the lens of positive psychology, insight may be gained into the potential unique benefits of cannabis for both recreational and medicinal users (Table 32.3).

TABLE 32.3 Future Research Directions: Recreational and CTP Users

- Identification of unique and shared motivations for cannabis use among recreational and CTP users
- Further incorporation of the positive psychology perspective to understand the relationship between cannabis use and well-being, particularly concentrated on social inclusion, companionship, and self-validation
- Elucidating the possible roles of positive psychology in CTP: increased confidence in ability to self-manage illness, reduced pain-related anxiety, increased positive and decreased negative experiences while under the influence, and enhanced coping during those experiences
- The extent to which recreational and CTP users' motivations are satisfied

Note: CTP, cannabis for therapeutic purposes.

MINI-DICTIONARY

Anxiogenic Producing anxiety.
Anxiolytic Reducing anxiety.
Biopsychosocial model The view of illness as a dynamic and reciprocal interaction between biological, psychological, and sociocultural variables that shapes a person's response to pain.
Broaden and Build Theory of Positive Emotions The theory that positive emotions allow people to build on their physical and psychological resources by broadening their thought-action repertoires, that these resources fuel resiliency in times of struggle, and can be drawn on later for coping and survival.
CTP (cannabis for therapeutic purposes) The use of cannabis to treat medical or psychological ailments.
Dose–response hypothesis The hypothesis that increased cannabis use is associated with an increased development of psychological dysfunction.
Happiness An affective component of well-being, conceptualized as an individual's subjective state of mind, which is subject to changes in mood in a similar way as emotions.
Life satisfaction An individual's cognitive evaluation of their quality of life as a whole.
Positive psychology The scientific study of positive human functioning, and flourishing on multiple levels that include the biological, personal, relational, institutional, cultural, and global dimensions of life.
Self-medication hypothesis The hypothesis that substances of abuse relieve human psychological suffering in susceptible individuals, and there is a considerable degree of psychopharmacologic specificity in an individual's preferred drug.
Well-being An individual's evaluation of aspects of their lives, including satisfaction with their health, relationships, recreation, work, meaning, and purpose, and also their affective reactions to life events, and level of interest and engagement.

CHAPTER

33

Craving and Cannabis: A Potential Paradox

M.J. Loflin, M. Earleywine

Department of Psychology, School of Arts and Sciences, University at Albany, State University of New York, Albany, NY, United States

SUMMARY POINTS

- Cannabis is the second most common reason for entering treatment for substance abuse and dependency in the United States, and the most commonly used illicit drug.
- Current models of cannabis use include craving as a potential indicator of problematic use, and a major reason for relapse following abstinence.
- While a substantial literature exists, supporting craving's role in substance abuse generally, less basic science exists for cannabis craving.
- Given cannabis' pharmacological properties, craving for the plant might not develop the same as other drugs of abuse.
- Despite inconsistencies with theoretical etiology, a significant proportion of cannabis users in treatment report craving for the plant.

KEY FACTS

- The Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) is most the commonly used classification manual of mental disorders in the United States. ICD-10 more commonly used outside the United States.
- Majority of research on substance abuse conducted using DSM criterion schema.
- Changes to classification of substance use disorders in Fifth edition of manual controversial in the research community.
- DSM-5 added criterion of craving for diagnosis of cannabis use disorder and lowered overall criterion threshold.

LIST OF ABBREVIATIONS

ANS	Autonomic nervous system
CBI	Cannabinoid receptor
DSM	Diagnostic and Statistical Manual of Mental Disorders
IRT	Item response theory
THC	Tetrahydrocannabinol
VTA	Ventral tegmental area

INTRODUCTION

Marijuana (cannabis) is the second most commonly cited reason for seeking drug treatment. Marijuana users represent 17.5% of all those who are in treatment for substance-related problems in the United States (SAMHSA, 2012). Identifying what differentiates problematic from nonproblematic use of the plant has been a major focus of cannabis research to date, and is vital as cannabis regulations loosen across the United States and globally. Research on drug abuse more generally suggests that craving might be an important factor of interest. However, it is unclear whether craving can result as a natural development of ingestion of the cannabis

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00037-5

plant, and whether or not it is a distinguishing indicator of problematic use. Evidence exists that both supports and refutes the assumption that problematic cannabis users crave. While basic science would suggest that cannabinoid intoxication should not result in craving, many problematic cannabis users do report "craving." These users cite craving as a major reason for relapse, following abstinence and an obstacle in treatment (Budney, Vandrey, Hughes, Thostenson, & Bursac, 2008; McRae, Hedden, Malcolm, Carter, & Brady, 2007; Coffey et al., 2002). In addition, applied research on cannabis craving uses similar cue-based craving paradigms to manipulate craving as those used for other drugs (Singleton, Trotman, Zavahir, Taylor, & Heishman, 2002; Wolfling, Flor, & Grusser, 2008). This assumes that cannabis craving functions the same as other substances of abuse. There is an apparent paradox in the literature between the known etiology of craving and problematic cannabis users' experience.

FUNCTION OF CRAVING IN DRUG ABUSE

The role of craving in drug abuse has received increased attention in the research literature due to the new inclusion of craving as a diagnostic criterion for substance-related disorders in the DSM 5 (American Psychiatric Association, 2014). From the bench to the bedside, experimental and applied research suggests that drug users' experience of craving is associated with maintenance of use, an increased risk of dependency, and an increased risk of relapse following abstinence from use of the drug (Flannery et al., 2006; Robinson & Berridge, 2003; Everitt, 1997; Pickens & Johanson, 1992; Ludwig, Wikler, & Stark, 1974). Though no universally accepted definition of drug craving exists, the experience of craving is broadly defined by its motivational state, where the individual experiences strong desire to use a drug (Tiffany & Wray, 2012). Craving differs from thoughts of enjoyment, or liking, of the effects of a drug in both degree and kind (West, 1987). Craving is certainly a more severe form of liking or wanting (Kozlowski, Mann, Wilkinson, & Poulos, 1989); however, dependency and other problems related to use do not predict differences across users in how well one likes or enjoys the effects of a drug (Volkow et al., 1993). Craving represents a shift away from mere enjoyment of the rewarding aspects of use of the drug (pleasurable effects) toward a motivational drive to obtain the drug (Robinson & Berridge, 1993; Wise, 2004).

Despite a substantial body of literature supporting cravings role in drug seeking behavior (for review see Tiffany & Wray, 2012), researchers and clinicians disagree on how best to conceptualize and measure craving (Drobes & Thomas, 1999). Moreover, theoretical inconsistency across measures and assumptions of drug similarity can lead to problems, when attempting to cross-apply work on craving from one substance to another. The rationale provided by the American Psychiatric Association's work group responsible for the addition of craving in the newest DSM cited extensive literature on the role of craving in problematic alcohol and cocaine users (Casteel & Valora, 2010). No work was cited that investigated the role of craving for other drug classes. Clinicians are meant to assume that what is good for the goose is good for the gander when diagnosing drug-related problems. Studies that rely on an assumption of similar nomothetic principles of drug abuse across substances tend to cite early work demonstrating that, across drug users, we see similar reports of problems (Koston, Rounsaville, Babor, Spitzer, & Williams, 1987; Feingold & Rounsaville, 1995). This assumption, however, also assumes that those individual symptoms and problems are also similar in both degree and kind across substances, and equally indicate problematic use. This assumption is not supported by the literature; individual symptom criteria perform differently across substances in item response theory (IRT) analysis (Gillespie, Neale, Prescott, Aggen, & Kendler, 2007). If craving is understood as a more severe form of liking, or enjoyment of a drug's effects, and drug's effects differ across classes, then endorsement of "craving" cannot be assumed to be analogous when cross-comparing drug users. To explore whether we have grounds to cross-apply this literature to cannabis we will first turn to the literature on craving, more generally.

THEORETICAL ETIOLOGY

Craving is generally thought to develop through a process of behavioral learning and neurobiological stimulation from ingestion of the psychoactive substance (Skinner & Aubin, 2010). When a behavior is followed by reward, it is more likely that the behavior will be repeated in the future (Skinner, 1938). Using a substance with pleasurable effects results in reward via the subjective effect of the drug (Berridge & Robinson, 2003). Through a process of instrumental conditioning, regular use of the rewarding substance will increase motivation for future use of the drug. Moreover, tenants of learning theory can also explain how environmental cues can take on incentive value, increasing one's motivational state to use through a process of Pavlovian conditioning. When environmental variables related to drug use are repeatedly paired with the pleasurable/rewarding effects of use of that drug, those variables (drug cues) will begin to act as conditioned stimuli that can invoke expectation of the anticipated response (Fig. 33.1). When the pleasurable response (eg, intoxication, euphoria) that would typically follow presentation of drug cues is denied (as one

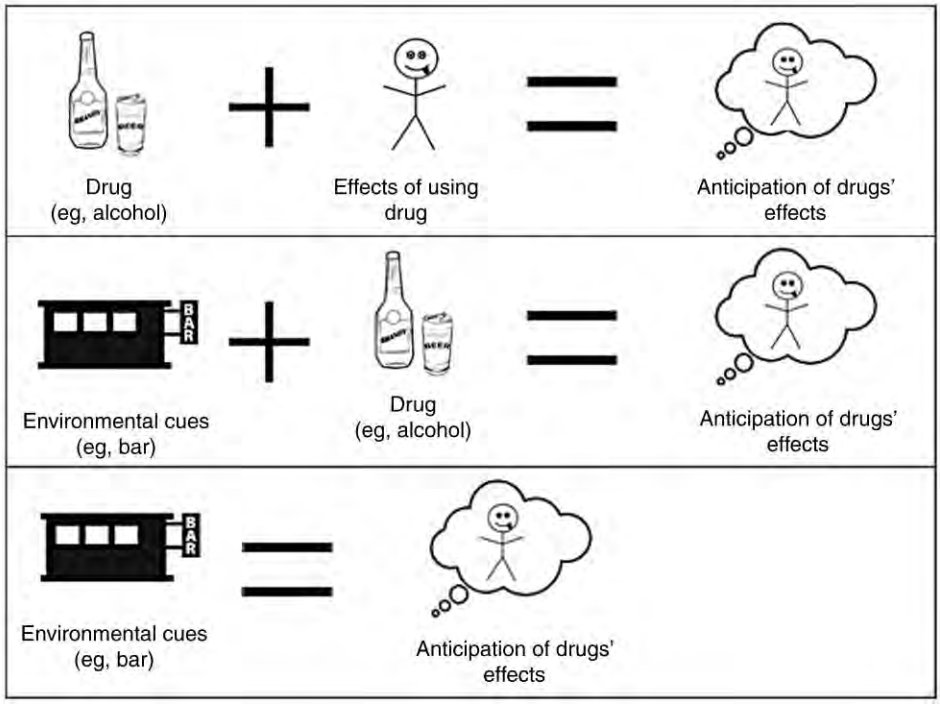

FIGURE 33.1 **How stimuli in the environment can cue craving.** Drug related stimuli in the environment can eventually take on incentive value through repeated pairings with the drug, and start to act as conditioned stimuli to elicit craving.

would see if cues are presented and use is restrained), the body goes into an anticipatory appetitive response. The anticipatory response is functionally analogous to an acute state of withdrawal (Verheul, van den Brink, & Geerlings, 1999). Environmental cues associated with use of the drug then motivate future use of the drug through both positive and negative forms of reinforcement.

While enjoyment of the effects of the drug can certainly act as a reinforcer, pleasure and reward are distinct phenomena (Smith, Berridge, & Aldridge, 2011). Not all behaviors that are subjectively pleasurable are craveable in a pathological sense. Early research in addiction attributed the craveable nature of drugs to activation of dopamine pathways in the ventral tegmental area (VTA), colloquially referred to as the "pleasure pathway" (Fig. 33.2). Studies suggested that the subjective pleasurable experience of drug use was due to activation of the dopaminergic system (Wise, 1980; Volkow et al., 1999). Dopamine, however, likely plays a more complicated role in development of motivation to use a drug than simply being the neurotransmitter associated with pleasurable experience. Craving is more than mere liking. More recent work in addiction suggests that mesolimbic dopamine release is associated with increases in attention (Berridge, 2007; Schultz, 2013). This new role of dopamine would explain why pathological craving is present in substance abuse, gambling, and binge eating (Potenza, 2008; Blumenthal & Gold, 2010), but to a lesser degree with other naturally enjoyable, but less abused, activities. Activation of

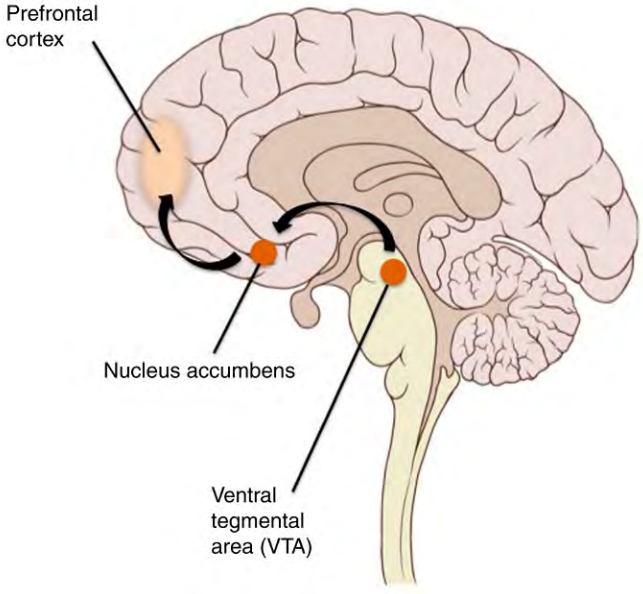

FIGURE 33.2 **The "pleasure pathway."** The pleasurable effects of drugs are largely attributable to neural communication between the ventral tegmental area *(VTA)*, nucleus accumbens, and the prefrontal cortex. *Source: Modification from open content image created by Patrick J. Lynch, medical illustrator; C. Carl Jaffe, MD, cardiologist. http://creativecommons.org/licenses/by/2.5/. dopaminergic pathways in the VTA increase attention, thereby increasing attention to environmental stimuli being presented at the time of drug use. By increasing the salience of stimuli, dopamine acts to reduce the proximal distance between cues, use of the drug, and the pleasurable effects. Learning, therefore, occurs more rapidly. Dopaminergic activation, by means of increasing attention to cues, facilitates more effective reinforcement.

CRAVING AND CUE-REACTIVITY

When stimuli in the environment become associated with drug reward through Pavlovian conditioning, the stimuli can then elicit the conditioned response. Expectation of the drug's effects can be induced even in the absence of use of the drug itself. This state of expectation that motivates interest in use of the drug is referred to as cue-elicited craving (Drummond, 2000). Presenting environmentally relevant cues and examining whether or not they induce drug-incentive expectation can determine whether or not craving for a drug is present. If cues associated with the use of a drug lead to an increase in interest for taking the drug, there is support that classical conditioning has occurred. Studies using cue-based paradigms to test for craving appear frequently in the literature. Support for the use of these paradigms comes from neuroimaging studies (a visual of neuroimaging technology appears in Fig. 33.3), which find that drug-related stimuli are able to induce dopamine release in the mesolimbic VTA, even before the experience of pleasure (Duvauchelle, Ikegami, & Castaneda, 2000). The conditioned stimulus can invoke a conditioned response.

Testing for the presentation of craving using cue-eliciting stimuli rests on the assumption that all forms of drug craving are functionally and etiologically similar. The paradigm assumes that craving develops through a process of classical and instrumental conditioning, and that the readiness of the user to learn these associations is increased through the pharmacological effects of the drug on VTA dopamine release. If we assume this general etiological framework for craving, then the paradigm makes specific predictions about what will occur following the presentation of drug-related cues.

In addition to overt thoughts about wanting to use the drug, we would also expect to see changes in attention, cognitive functioning, and autonomic arousal as the user enters into an anticipatory state where the user is awaiting pleasure, and experiencing acute withdrawal. The body is expecting the pharmacological and subjective effects of drug use when shown cues of the drug. As the body prepares for the drug's anticipated effects, dopamine is being released and increasing selective attention to reward-sensitive stimuli (Duvauchelle et al., 2000). We would expect users who have been cued to overly attend to drug-relevant stimuli. Moreover, this state of increased selective attention to drug cues should also make it more difficult to attend to stimuli that are not relevant to use of the drug, and interfere in completion of cognitive tasks that rely on switching of attention. Indeed, studies on alcohol and cocaine abuse find that attention to drug-related stimuli tends to increase, and cognitive flexibility that requires attentional switching tends to decrease (increased perseverance) following the presentation of drug cues (Dunning et al., 2011; Cox, Fadardi, & Pothos, 2006; Ehrman et al., 2002; Franken, Kroon, & Hendriks, 2000).

Finally, cues should also increase physiological arousal. Autonomic nervous system (ANS) activity is a major component of emotion (for review see Kreibig, 2010). Craving is an affective state driven by an appetitive response (Orford, 2001). When primed to anticipate the effects of a drug, which is rewarding, the user is thinking

about experiencing pleasure. Imagining exposure leads to the affective (emotional) experience of anticipatory pleasure (Marlatt, 1987). Engaging with emotionally evocative materials that signal anticipatory pleasure activates ANS activity. The experience of anticipatory pleasure is associated with increases in overall galvanic skin-conductance response (Bernat, Patrick, Benning, & Tellegan, 2006; Codispoti, Surcinelli, & Baldaro, 2008) and decreases in heart rate (Bernat et al., 2006; Codispoti et al., 2008; Ritz, Thons, Fahrenkrug, & Dahme, 2005). Some studies suggest, however, that when anticipatory pleasure is cued through cognitive processes (eg, imaginally invoked), heart rate instead decreases (Van Diest et al., 2001).

In addition, neuroadaptation to the effects of the drug establish a threshold of pleasure/homeostasis that the brain anticipates when in a given state (in the presence of drug cues; DiFranza & Wellman, 2005). When anticipated effects are not reached, the body experiences mild withdrawal symptoms, such as irritability/anxiety (Jasova, Bob, & Fedor-Freybergh, 2007; Table 33.1). The body invokes a mild stress response. Therefore, autonomic arousal would also be expected following the presentation of drug-cues as a product of frustration from anticipating, but not receiving reward. Autonomic activation during states of anxiety is primarily a sympathetic response. Anxiety increases heart rate (Adsett, Schottsteadt, & Wolf, 1962) and increases galvanic skin response (Chan & Lovibond, 1996). Drug cues that can invoke an emotional experience of anticipatory pleasure and/or acute withdrawal-related stress, therefore, should modify heart rate and overall galvanic skin response.

CUE-REACTIVITY PARADIGM

Specific predictions that stem from theories of craving have been tested using the cue-reactivity paradigm. Cue-elicited craving manipulations with alcohol, nicotine, cocaine, and heroin all consistently find that when presented with drug-relevant cues users demonstrate increases in self-reported craving (Hone-Blanchet, Wensign, & Fecteau, 2014; Carter & Tiffany, 1999; Cepeda-Benito & Tiffany, 1996; Cortese et al., 2014). These studies also find postcue changes in attention and increases in autonomic arousal (Carter & Tiffany, 1999; Cepeda-Benito & Tiffany, 1996).

THEORETICAL ISSUES WITH CANNABIS CRAVING

Craving of cannabis is assumed to develop and function the same as other drugs of abuse. Interventions focused on reducing craving to all drugs, including cannabis, rely on this assumption of similarity in etiology and function. Nevertheless, the dependency risk associated with cannabis is less understood than with other substances of abuse. The assumption that cannabis craving develops and functions similar to other drugs of abuse might not be supported.

The addictive potential of most drugs of abuse is thought to result from properties of the substance acting on the brain's mesolimbic dopamine system (Wise, 2004; Hyman, Malenka, & Nestler, 2006). This system projects from the VTA to the ventral striatum, which is composed of the nucleus accumbens. The generally accepted theory of the rewarding, and thereby addictive, nature of drugs of abuse is that these substances enhance synaptic dopamine levels in the ventral striatum. As discussed previously, the enhancement of dopamine in the VTA is functionally related to both reward/reinforcement, and increased selective attention. Increased synaptic dopamine levels in the VTA have been found following administration of many drugs of abuse, including amphetamine (Breier et al., 1997), cocaine (Schlaepfer, Pearlson, Wong, Marenco, & Dannals, 1997), alcohol (Boileau et al., 2003), and nicotine (Brody et al., 2006).

Some work does suggest that cannabis can stimulate striatal dopamine neurotransmission (Martin-Santos et al., 2010; Bossong et al., 2009). However, the amount of increased dopaminergic availability following administration of psychoactive components of cannabis differs markedly from other drugs of abuse. Whereas amphetamine, cocaine, alcohol, and nicotine cause 10–30% reductions in dopamine D2/D3 receptor availability, human administration of tetrahydrocannabinol (THC) is only related to decreases of 3.4–3.9% (Bossong et al., 2009). Reductions in receptor availability lead to increases in striatal dopamine levels, suggesting that the amount of increase in striatal dopamine after ingestion of THC is less than the increases seen for amphetamine, cocaine, alcohol, and nicotine. Moreover, while high doses of THC can induce small increases in dopamine release in the VTA, the effect likely occurs indirectly

through CBI receptors on glutamate and GABA neurons (Schlicker & Kathmann, 2001; Lupica, Riegel, & Hoffman, 2004). Drugs with higher dependency indices tend to have stronger and more direct effects on the VTA dopamine pathway (Hyman et al., 2006). Whether or not the increase in dopamine following use of cannabis is sufficient to lead to craving in its classic sense has not been determined.

Even if use of cannabis does work on the dopaminergic pleasure pathway, the effects of cannabis intoxication undermine a purely biobehavioral etiology for craving of cannabis. Dopamine's role in craving development is in increasing attention to cues and reward for the purposes of increasing reinforcement of drug use. Reinforcement leads to craving by means of classical and instrumental conditioning. Two important effects of cannabis' psychoactive compound Δ^9-THC are decreased sustained and transient attention (Crean, Crane, & Mason, 2011; Ilan, Smith, & Gevins, 2004) and acute impairment of several forms of memory (for review see Ranganathan & D'Souza, 2006). Right dorsolateral prefrontal cortex, (para)hippocampal, and regions of the cerebellum show evidence of decreased activation during acute intoxication of cannabis, major pathways for associative learning. Basic and applied studies demonstrate that intoxication leads to deficits in associative learning (Nestor, Roberts, Garavan, & Hester, 2007; Skosnik et al., 2008). Contextual encoding is also disrupted during cannabis intoxication (Ranganathan & D'Souza, 2006). If craving develops in part through behavioral reinforcement, then associative learning is critical for being able to learn the pairing of stimulus and response. If associative learning is disrupted, then reinforcement value can't be learned, and cues should not lead to an appetitive response (Fig. 33.4).

Known neurological intoxication effects of cannabis use are inconsistent with current theory of the etiology of drug craving. Cannabis users might not "crave" in the same way that other drug users experience craving. Nevertheless, many of those in treatment for cannabis use do report experiencing craving.

CUE-REACTIVITY STUDIES WITH CANNABIS

Cannabis craving is typically studied using the same cue-reactivity paradigms as other drugs of abuse. Nickerson et al. (2011) looked at cue-reactance of cannabis by showing pictures of flower marijuana to cannabis-dependent adolescents. They found that those who were presented with the cue reported higher craving for marijuana than those who were not. Comparable results of increased self-reported craving appear in other studies that employ primarily visual cues (Lundahl & Johanson, 2011; Wolfling et al., 2008). The study by Wolfling et al. (2008) examined physiological responses to visual material associated with cannabis (ie, pictures of marijuana) among heavy long-term cannabis users. Again, the results showed that visual cues increased self-reported craving, but also found that the cues increased arousal, specifically skin-conductance, among the cannabis users. This result relating cues to arousal did not replicate, however, in another experiment that found increased craving in response to cues (Lundahl & Johanson, 2011). While marijuana-associated pictures consistently increase reports of interest in use, they apparently do not always lead to heightened physiological reactions.

The experience of craving reported by marijuana users is not always consistent with theories of craving development. File-drawer problems and publication bias for significant results (Rosenthal, 1979) also raise questions about the few studies that do suggest that cannabis cues can induce craving in functionally similar ways to other substances of abuse. Nevertheless, limitations in previous cannabis craving studies also might account for modest effect sizes and failures to find effects. Most

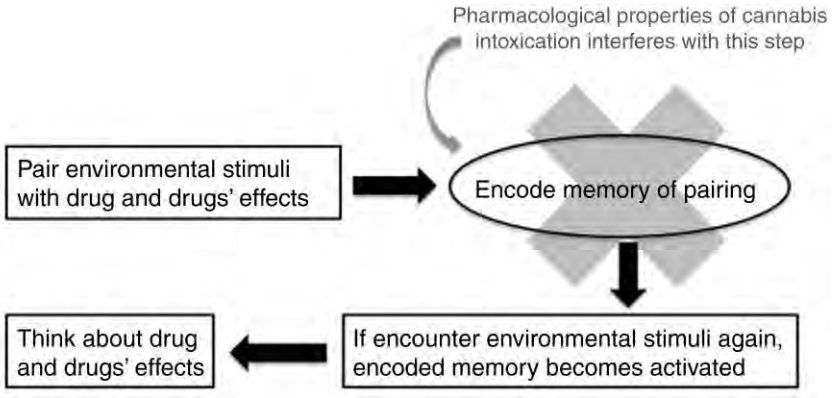

FIGURE 33.4 Craving unlikely to develop if memory encoding is disrupted. Cannabis intoxication impacts associative learning; a necessary step in the development of craving.

FIGURE 33.5 Cue-reactivity experiment using virtual reality. Cue-reactivity experiments have started incorporating the use of virtual reality to try to sidestep research design problems of relying on cues with poor generalizability. *Source: From NASA, and appears in public domain. No permissions are needed to replicate. NASA image use policy: http://www.jpl.nasa.gov/imagepolicy/*

studies use pictures and generic paraphernalia as cues (for additional, see Fig. 33.5). Participants might not use the type of ingestion mechanism presented (eg, glass pipes), and photographs might not generalize well to real world environmental stimuli. Moreover, the very fact that no accepted definition of craving exists in the scientific community suggests that definitions of what craving is likely differ across drug users. Cannabis users' definition of craving might not look the same as that of other substance users.

Findings remain inconsistent as to whether cannabis craving is a real phenomenon, and not just an issue of self-report. If craving really does develop as a response to regular cannabis use, then understanding its etiology will be a necessary task for future cannabis researchers.

MINI-DICTIONARY

Cue-reactivity Measurable reactions to environmental contexts or drug paraphernalia that reliably accompany use of the drug.
Diagnostic and Statistics Manual of Mental Disorders 5 (DSM 5) The most recent classification and diagnostic manual of the American Psychiatric Association (APA).
Instrumental conditioning (also known as Skinnerian conditioning) Process of behavior modification where a subject comes to emit a given response due to manipulation of the antecedents, and consequences of the given behavior.
Item response theory (IRT) analysis (also known as latent trait theory) Examines the response of examinees of a similar theoretical ability or attribute of interest to test whether they respond in similar ways on each item on the test or measure.
Learning theory Related to tenants of behaviorism; where learning is viewed as an observable change in behavior.
Pavlovian conditioning (also known as classical conditioning) Process of behavior modification where a subject comes to emit a given response in the presence of a previously neutral stimulus, because the neutral stimulus was associated with an unconditioned stimulus that elicits the desired response.

CHAPTER

34

Delta-9-Tetrahydrocannabinol and Catalepsy-Like Immobilization

N. Egashira

Department of Pharmacy, Kyushu University Hospital; Department of Neuropharmacology, Faculty of Pharmaceutical Sciences, Fukuoka University, Fukuoka, Japan

SUMMARY POINTS

- This chapter focuses on catalepsy-like immobilization induced by THC, the major psychoactive component of marijuana.
- THC induces catalepsy-like immobilization, and this behavior is antagonized by the CB1 receptor antagonist rimonabant.
- Also, the microinjection of THC induces catalepsy-like immobilization when injected into the nucleus accumbens.
- THC-induced catalepsy-like immobilization is prevented by lesions in the nucleus accumbens.
- 5-HT receptor agonists inhibit the THC-induced catalepsy-like immobilization.
- In contrast, 5-HT receptor antagonists enhance the THC-induced catalepsy-like immobilization.
- THC-induced catalepsy-like immobilization is also prevented by NMDA receptor antagonists MK-801 and amantadine.
- THC decreases extracellular 5-HT levels in rat nucleus accumbens, and this effect is antagonized by rimonabant.
- Moreover, MK-801 abolishes this THC-induced decrease in 5-HT release.
- Taken together, these results demonstrate that CB1-mediated, THC-induced catalepsy-like immobilization is mediated by decreased 5-HT neurotransmission in the nucleus accumbens, due to the action of glutamate-containing neurons.

KEY FACTS OF CATALEPSY

- Microinjection of THC induces catalepsy-like immobilization when injected into the nucleus accumbens, central amygdala, lateral hypothalamus, or ventromedial hypothalamus.
- THC-induced catalepsy-like immobilization is prevented by lesion in nucleus accumbens, central amygdala, lateral hypothalamus, or ventromedial hypothalamus.
- Haloperidol-induced catalepsy is abolished by lesion in the caudate putamen, substantia nigra, globus pallidus, central amygdala, or lateral hypothalamus.
- Haloperidol-induced catalepsy is not abolished by lesion in the nucleus accumbens.

KEY FACTS OF RECEPTOR

- THC-induced catalepsy-like immobilization is antagonized by the CB1 receptor antagonist rimonabant, but not by the CB2 receptor antagonist AM630.

KEY FACTS OF SEROTONIN

- The 5-HT precursor 5-HTP, and the 5-HT receptor agonist 5-MeODMT inhibit THC-induced catalepsy-like immobilization.
- The 5-HT_{1A}/5-HT_{7} receptor agonist 8-OH-DPAT inhibits THC-induced catalepsy-like immobilization, and this inhibition is reversed by WAY100635, the selective 5-HT_{1A} receptor antagonist, but not by SB269970, the selective 5-HT_{7} receptor antagonist.
- The 5-HT_{1A} receptor partial agonist buspirone inhibits THC-induced catalepsy-like immobilization.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00038-7
Copyright © 2017 Elsevier Inc. All rights reserved.

- The 5-$HT_{2A/2C}$ receptor agonist DOI inhibits THC-induced catalepsy-like immobilization, and this inhibition is reversed by the 5-HT_{2A} receptor antagonist ketanserin, but not by the 5-HT_{2C} receptor antagonist SB242084.
- The selective 5-HT_{2C} receptor agonist WAY161503 had no effect on THC-induced catalepsy-like immobilization.

KEY FACTS OF GLUTAMATE

- THC-induced catalepsy-like immobilization is prevented by NMDA receptor antagonists, such as MK-801 and amantadine, but not the AMPA receptor antagonist YM-90K.

LIST OF ABBREVIATIONS

AMPA	α-Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid
CB	Cannabinoid
EPS	Extrapyramidal side effects
GABA	γ-Aminobutyric acid
HPLC-ECD	High-performance liquid chromatography-electrochemical detector
5-HT	5-Hydroxytryptamine, serotonin
5-HTP	5-Hydroxy-L-tryptophan
5-MeODMT	5-Methoxy-*N*,*N*-dimethyltryptamine
NMDA	*N*-methyl-D-aspartic acid
8-OH-DPAT	8-Hydroxy-2-(di-*n*-propylamino) tetralin
SSRIs	Selective 5-HT reuptake inhibitors
THC	Delta-9-tetrahydrocannabinol
WAY100635	*N*-[2-[4-(2-methoxyphenyl)-1-piperazinyl] ethyl]-*N*-(2-pyridinyl) cyclohexane carboxamide dihydrochloride

INTRODUCTION

Delta-9-tetrahydrocannabinol (THC), the principal psychoactive component of marijuana, is known to cause catalepsy in mice and rats (Egashira et al., 2006a; Fujiwara & Egashira, 2004; Tseng & Craft, 2004; Varvel et al., 2005). This effect is attenuated by the cannabinoid (CB)1 receptor antagonist rimonabant (Egashira et al., 2006a; Lichtman & Martin, 1997; Nagai et al., 2006; Sano et al., 2008; Tseng & Craft, 2004; Varvel et al., 2005), indicating that the effect is mediated by CB1 receptors. In contrast, rimonabant is not able to affect catalepsy induced by haloperidol or raclopride (Anderson, Kask, & Chase, 1996; Marchese et al., 2003), indicating that catalepsy induced by dopamine D_2 blockade does not involve stimulation of CB1 receptors. In fact, haloperidol fails to bind to CB1 receptors, and THC and rimonabant do not show appreciable affinity for D_2 receptors (Marchese et al., 2003). Consequently, the mechanism mediating THC-induced catalepsy-like immobilization is different from that mediating D_2 receptor antagonist-induced catalepsy. Moreover, THC-induced catalepsy was inhibited by air blowing and sound stimuli, whereas haloperidol-induced catalepsy was not inhibited by those stimuli (Sano et al., 2008). Additionally, THC did not impair motor coordination in the rota-rod test in mice and rats (Egashira et al., 2006a; Nagai et al., 2006). Thus, THC-induced catalepsy is clearly distinct from that induced by large doses of major tranquilizers, which cause extrapyramidal side effects (EPS), such as akinesia. This cataleptic immobilized state may be thought to represent a decreased motivation toward movement. Therefore, we have called this cataleptic immobilized state catalepsy-like immobilization (Fig. 34.1; Fujiwara & Egashira, 2004).

FIGURE 34.1 Photograph of THC-induced catalepsy-like immobilization. THC-induced catalepsy was inhibited by air blowing and sound stimuli, whereas haloperidol-induced catalepsy was not inhibited by those stimuli. Additionally, THC did not impair motor coordination in the rota-rod test. THC-induced catalepsy is clearly distinct from that induced by large doses of major tranquilizers, which cause extrapyramidal side effects (EPS), such as akinesia. We have called this cataleptic immobilized state catalepsy-like immobilization.

The present article introduces studies related to the THC-induced catalepsy-like immobilization.

INVOLVEMENT OF THE CB1 RECEPTOR IN THC-INDUCED CATALEPSY-LIKE IMMOBILIZATION

Two CB receptors have been cloned: the CB1 receptor in the central nervous system (Matsuda, Lolait, Brownstein, Young, & Bonner, 1990), and the CB2

receptor in immune cells and peripheral tissues (Munro, Thomas, & Abu-Shaar, 1993). THC binds both CB1 and CB2 receptors. We previously reported THC-induced catalepsy-like immobilization in mice and rats, and that this behavior was antagonized by a CB1 receptor antagonist rimonabant (Egashira et al., 2006a; Nagai et al., 2006; Sano et al., 2008). These results are consistent with previous findings (Lichtman & Martin, 1997; Tseng & Craft, 2004; Varvel et al., 2005). However, THC-induced catalepsy-like immobilization was not reversed by the CB2 receptor antagonist AM630 (1 and 10 mg/kg, i.p.) (unpublished data). Moreover, the CB1 receptor agonists HU210 (0.06 mg/kg, i.p.) and WIN55,212-2 (15 mg/kg, i.p.) induced catalepsy-like immobilization in rats (unpublished data). These results suggest that the action of THC is CB1 receptor-mediated. In contrast, cannabidiol did not induce catalepsy-like immobilization (Hayakawa et al., 2008). Cannabidiol is a nonpsychoactive component of cannabis, and is generally known to have a very low affinity for the CB1 and CB2 receptors. Additionally, endocannabinoids anandamide (6, 10, and 20 mg/kg, i.p.; 100, 160, and 240 µg/brain, i.c.v.) and 2-AG (1 and 10 mg/kg, i.p.; 50, 100, and 250 µg/brain, i.c.v.) did not induce catalepsy-like immobilization (unpublished data). These findings suggest that THC induces catalepsy-like immobilization through direct action at CB1 receptors.

INVOLVEMENT OF THE NUCLEUS ACCUMBENS IN THC-INDUCED CATALEPSY-LIKE IMMOBILIZATION

Microinjection of THC into the nucleus accumbens has been reported to induce catalepsy in mice (Onaivi, Chakrabarti, Gwebu, & Chaudhuri, 1995). We reported that the microinjection of THC induced catalepsy-like immobilization when injected into the nucleus accumbens, central amygdala, lateral hypothalamus, or ventromedial hypothalamus that contains CB1 receptors (Table 34.1; Sano et al., 2008). Furthermore, THC-induced catalepsy-like immobilization was prevented by lesion in the nucleus accumbens, central amygdala, lateral hypothalamus, or ventromedial hypothalamus (Sano et al., 2008). However, haloperidol-induced catalepsy was abolished by lesion in the caudate putamen, substantia nigra, globus pallidus, central amygdala, or lateral hypothalamus, whereas it was not abolished by lesion in the nucleus accumbens (Sano et al., 2008). These findings suggest that the brain regions involved in THC-induced catalepsy-like immobilization are different from those involved in haloperidol-induced catalepsy. Also, microinjection of THC into the nucleus accumbens strongly induces catalepsy-like immobilization (Sano et al., 2008), indicating that the nucleus

Microinjection of delta-9-tetrahydrocannabinol (THC) induced catalepsy-like immobilization when injected into the nucleus accumbens, central amygdala, lateral hypothalamus, or ventromedial hypothalamus regions. Furthermore, THC-induced catalepsy-like immobilization was prevented by lesions in the nucleus accumbens, central amygdala, lateral hypothalamus, or ventromedial hypothalamus regions. However, haloperidol-induced catalepsy was abolished by lesions in the caudate putamen, substantia nigra, globus pallidus, central amygdala, or lateral hypothalamus, whereas it was not abolished by lesions in the nucleus accumbens.

accumbens plays an important role in THC-induced catalepsy-like immobilization. In fact, this region contains a moderately high density of CB1 receptors (Herkenham et al., 1991; Tsou, Brown, Sanudo-Pena, Mackie, & Walker, 1998). It has been suggested that the nucleus accumbens is a site that directly mediates the rewarding or primary motivational characteristics of natural stimuli, such as food, water, and sex, and it is an interface for the integration of emotional information. Therefore, THC-induced catalepsy-like immobilization may be due to impairment of emotional behavior.

INVOLVEMENT OF THE SEROTONERGIC NEURONAL SYSTEM IN THC-INDUCED CATALEPSY-LIKE IMMOBILIZATION

There is evidence that the serotonergic system is involved in THC-induced behavioral effects. The 5-hydroxytryptamine (5-HT, serotonin) precursor 5-hydroxy-L-tryptophan (5-HTP), clomipramine, citalopram, the 5-HT receptor agonist 5-methoxy-*N*,*N*-dimethyltryptamine (5-MeODMT), the 5-HT_{1A}/5-HT_7 receptor agonist 8-hydroxy-2-(di-*n*-propylamino) tetralin (8-OH-DPAT), and the 5-$HT_{2A/2C}$ receptor agonist 2,5-dimethoxy-4-iodoamphetamine (DOI) attenuate THC-induced impairment of spatial memory in the eight-arm radial maze, in rats (Egashira et al., 2002b, 2006b; Inui et al., 2004). THC decreases 5-HT release in the ventral hippocampus, which is an important area of the brain for THC-induced impairment of spatial memory (Egashira, Mishima, Iwasaki, & Fujiwara, 2002; Egashira et al., 2002b). Moreover, citalopram and 8-OH-DPAT reduce the enhancement of immobility by THC in the mouse forced swim test (Egashira et al., 2008). Additionally, THC, CB1 receptor agonists, anandamide, and endocannabinoid modulators inhibit DOI-induced 5-HT_{2A} receptor-mediated behaviors in mice (Darmani, 2001; Egashira et al., 2004, 2011). These findings suggest that there is an interaction between the CB and serotonergic systems.

5-HT has been implicated in the control of motor behavior, including catalepsy. Selective 5-HT reuptake inhibitors (SSRIs), such as paroxetine and sertraline, have been shown to attenuate haloperidol-induced catalepsy in mice (Pires et al., 2005). Moreover, 5-HT_{1A} (Invernizzi, Cervo, & Samanin, 1988; Lucas, Bonhomme, De Deurwaerdere, Le Moal, & Spampinato, 1997; McMillen, Scott, & Davanzo, 1988; Prinssen, Kleven, & Koek, 1999) and 5-HT_{2A} receptor agonists (Elliott, Walsh, Close, Higgins, & Hayes, 1990; Hicks, 1990; Neal-Beliveau, Joyce, & Lucki, 1993; Wadenberg & Ahlenius, 1995) attenuate D_2-receptor-mediated catalepsy. Also, these anticataleptic effects of 5-HT_{1A} and 5-HT_{2A} receptor agonists were antagonized by a selective 5-HT_{1A} receptor antagonist (Bartoszyk, Roos, & Ziegler, 1996) and a 5-HT_2 receptor antagonist (Neal-Beliveau et al., 1993), respectively, indicating that the serotonergic system is involved in the onset of catalepsy. In contrast, *N*-[2-[4-(2-methoxyphenyl)-1-piperazinyl]ethyl]-*N*-(2-pyridinyl) cyclohexane carboxamide dihydrochloride (WAY100635), a selective 5-HT_{1A} receptor antagonist, enhances haloperidol-induced catalepsy (Prinssen, Colpaert, & Koek, 2002). Thus, 5-HT_{1A} and 5-HT_{2A} receptors play an important role in the regulation of catalepsy.

Serotonergic drugs, such as 5-HTP and 5-MeODMT inhibited THC-induced catalepsy-like immobilization in rats (Sano et al., 2008). This evidence indicates the involvement of 5-HT receptors in THC-induced catalepsy-like immobilization. The 5-HT_{1A}/5-HT_7 receptor agonist 8-OH-DPAT and 5-HT_{1A} receptor partial agonist buspirone inhibited THC-induced catalepsy-like immobilization, and that this inhibition was reversed by WAY100635 (Egashira et al., 2006a). In contrast, the selective 5-HT_7 receptor antagonist SB269970 did not affect this inhibitory effect of 8-OH-DPAT (Egashira et al., 2006a). These findings therefore indicate that 8-OH-DPAT and buspirone inhibit THC-induced catalepsy-like immobilization through a direct action on 5-HT_{1A} receptors. The 5-$HT_{2A/2C}$ receptor agonist DOI inhibited THC-induced catalepsy-like immobilization (Egashira et al., 2007). By contrast, the selective 5-HT_{2C} receptor agonist WAY161503 had no effect on THC-induced catalepsy-like immobilization (Egashira et al., 2007). Additionally, the 5-HT_{2A} receptor antagonist ketanserin completely reversed the inhibitory effect of DOI on THC-induced catalepsy-like immobilization, whereas the selective 5-HT_{2C} receptor antagonist SB242084 did not affect this inhibitory effect of DOI (Egashira et al., 2007). Thus, these findings indicate that DOI inhibits THC-induced catalepsy-like immobilization through a direct action on 5-HT_{2A} receptors. Furthermore, WAY100635 and ketanserin enhanced the catalepsy-like immobilization induced by THC (Egashira et al., 2006a, 2007). Hence, these findings suggest that 5-HT_{1A} and 5-HT_{2A} receptors are involved in THC-induced catalepsy-like immobilization.

Microinjection of THC into the nucleus accumbens induces catalepsy-like immobilization in rats (Sano et al., 2008). The nucleus accumbens is densely innervated by serotonergic projections from the dorsal raphe nucleus (Van Bockstaele, Biswas, & Pickel, 1993). Also, THC decreased extracellular 5-HT levels in rat nucleus accumbens, and this effect was antagonized by rimonabant (Figs. 34.2 and 34.3; Sano et al., 2008), indicating that the effect is mediated by CB1 receptors. These findings suggest that THC-induced inhibition of 5-HT neurotransmission in the nucleus accumbens is involved in THC-induced catalepsy-like immobilization.

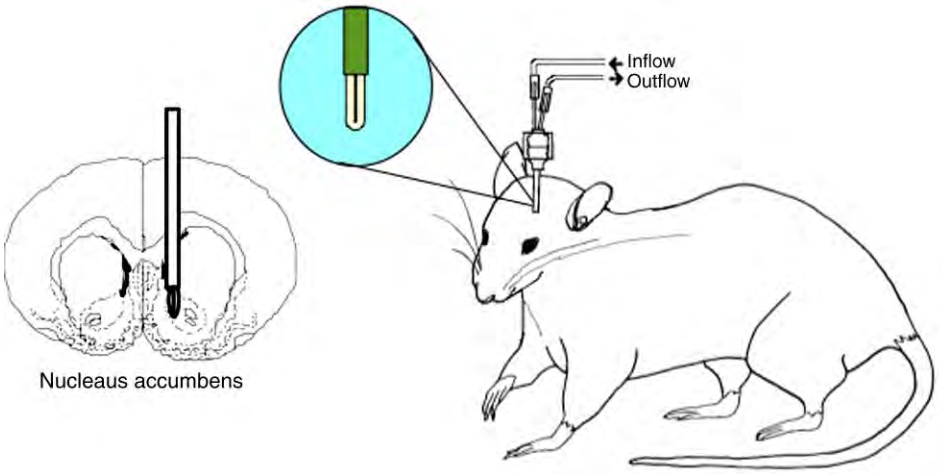

FIGURE 34.2 Diagram of the nucleus accumbens and in vivo microdialysis. Animals are stereotaxically implanted with a guide cannula in the nucleus accumbens, and a microdialysis probe is inserted into the guide cannula, which is perfused with a solution, such as Ringer's solution. The sample is collected, and the sampled concentrations are measured by a high-performance liquid chromatography-electrochemical detector (HPLC-ECD) system.

INVOLVEMENT OF THE GLUTAMATERGIC NEURONAL SYSTEM IN THC-INDUCED CATALEPSY-LIKE IMMOBILIZATION

We previously reported that the glutamatergic neuronal system may be involved in the THC-induced impairment of spatial memory (Fujiwara & Egashira, 2004). We found that THC inhibited the release of glutamate in the dorsal hippocampus, and this inhibition was antagonized by rimonabant in an in vivo microdialysis study, indicating that the release of glutamate is mediated by the CB1 receptor (unpublished data). Moreover, we found that D-cycloserine, a partial agonist at the glycine modulatory site on the *N*-methyl-D-aspartic acid (NMDA) receptor, and aniracetam, a positive modulator of the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor, improved the THC-induced impairment of spatial memory (unpublished data). These findings suggest that THC impairs spatial memory, at least in part, by inhibiting the release of glutamate through CB1 receptors in the dorsal hippocampus. Thus, the glutamatergic system is also involved in THC-induced behavioral effects.

Administration of NMDA receptor antagonists has been reported to prevent haloperidol-induced catalepsy (Kaur, Ozer, & Starr, 1997; Mehta & Ticku, 1990; Moore, Blackman, Awere, & Leander, 1993; Schmidt & Bubser, 1989; Verma & Kulkarni, 1992; Yanahashi et al., 2004). Moreover, NMDA has been reported to potentiate catalepsy induced by haloperidol (Mehta & Ticku, 1990). These findings indicate that the glutamatergic system is also involved in the induction of catalepsy.

THC-induced catalepsy-like immobilization was also prevented by NMDA receptor antagonists, such as MK-801 and amantadine, but not YM-90K, an AMPA receptor antagonist (Sano et al., 2008). Similarly, MK-801 and selective γ-aminobutyric acid (GABA) reuptake inhibitor tiagabine have been reported to modify THC-induced catalepsy in mice (Kinoshita et al., 1994; Pertwee, Greentree, & Swift, 1988). Furthermore, THC decreased extracellular glutamate levels in rat nucleus accumbens, and this effect was antagonized by rimonabant (Fig. 34.3; Sano et al., 2008), indicating that this effect is also mediated by CB1 receptors. This evidence is consistent with reports of in vitro electrophysiological studies showing that cannabinoids inhibit glutamatergic neurons projecting to the nucleus accumbens (Hoffman & Lupica, 2001; Pistis, Muntoni, Pillolla, & Gessa, 2002; Robbe, Alonso, Duchamp, Bockaert, & Manzoni, 2001). As described earlier, it is suggested that serotonergic and glutamatergic neurons are associated with the induction of catalepsy. It has also been reported that NMDA receptor antagonists MK-801 and phencyclidine increase the release and/or metabolism of 5-HT in the nucleus accumbens (Hernandez, Auerbach, & Hoebel, 1988; Loscher, Annies, & Honack, 1991; Martin, Carlsson, & Hjorth, 1998; Yan, Reith, Jobe, & Dailey, 1997). Moreover, the serotonergic system seems to be significantly involved in the behavioral syndrome induced by NMDA antagonists (Loscher & Honack, 1992; Nabeshima et al., 1984). These studies indicate that serotonergic and glutamatergic neurons interact with each other. Immunocytochemical and electrophysiological studies have demonstrated the presence of CB1 receptors at both GABAergic and glutamatergic synapses in the nucleus accumbens (Manzoni & Bockaert, 2001; Robbe et al., 2001). Also, presynaptic CB1 receptor-mediated inhibition of glutamate and GABA release from neurons in the nucleus accumbens has been demonstrated

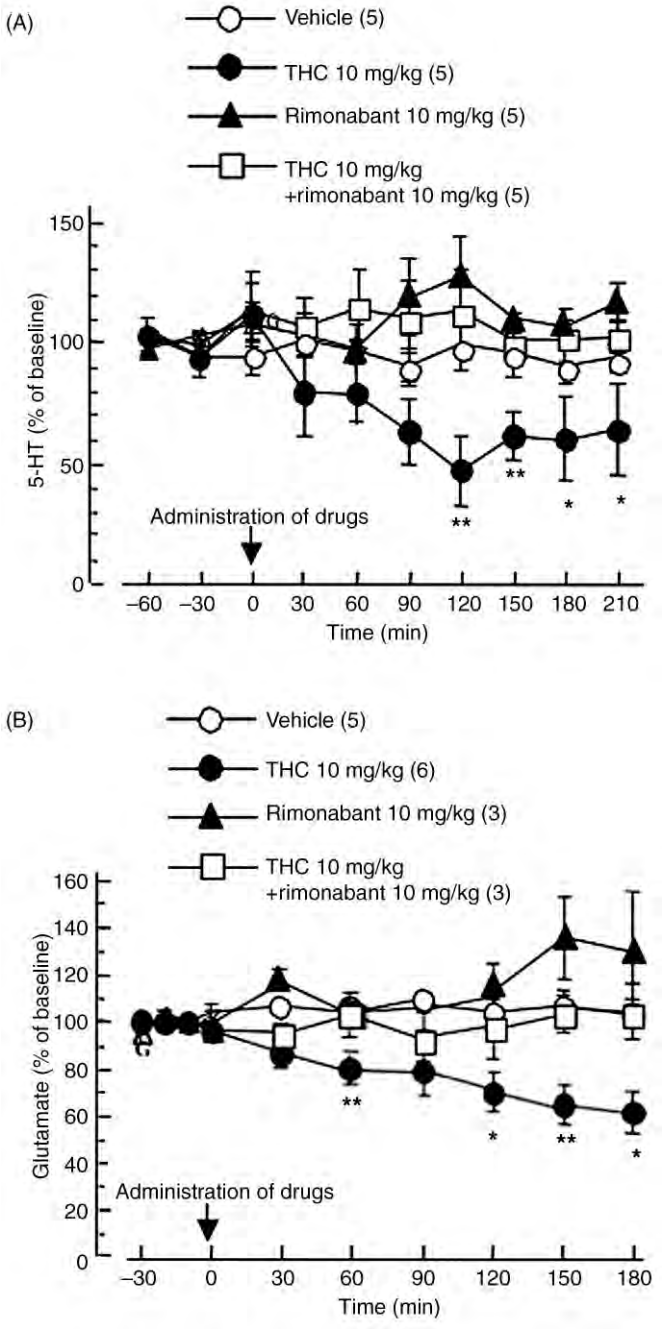

FIGURE 34.3 **Effects of THC on 5-HT and glutamate release in the nucleus accumbens.** THC and rimonabant were administered i.p. 60 min prior to the test. THC significantly decreased (A) 5-HT and (B) glutamate release in the nucleus accumbens. Rimonabant reversed the decrease in 5-HT and glutamate release. $^{*}P < 0.05$, $^{**}P < 0.01$ compared with vehicle. *Source: Reproduced from Sano et al. (2008), with permission.*

(Hoffman & Lupica, 2001; Manzoni & Bockaert, 2001; Robbe et al., 2001). Moreover, we found that MK-801 abolished the THC-induced decrease in 5-HT release in the nucleus accumbens (Fig. 34.4; Sano et al., 2008). Hence, THC inhibits 5-HT release in the nucleus accumbens, at least in part, through glutamatergic mechanisms.

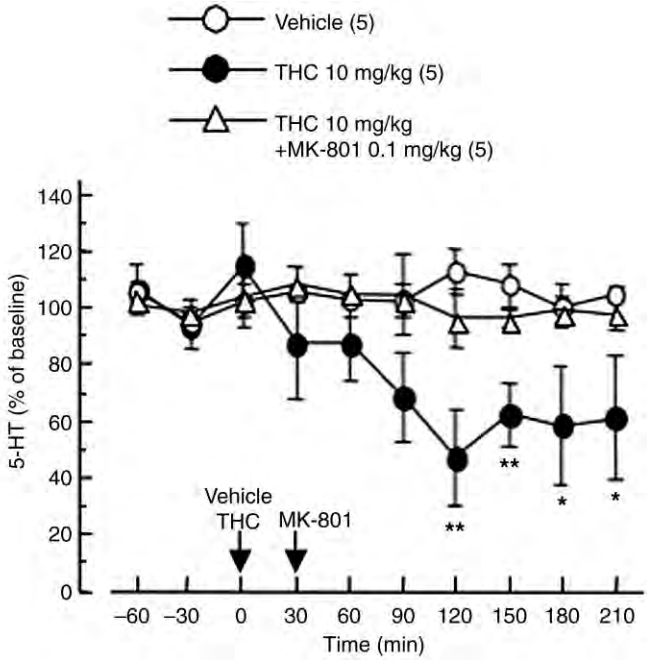

FIGURE 34.4 **Effects of MK-801 on the THC-induced reduction in 5-HT release in the nucleus accumbens.** THC and MK-801 were administered i.p. 60 and 30 min prior to the test, respectively. MK-801 inhibited the reduction in 5-HT release induced by THC. $^{*}P < 0.05$, $^{**}P < 0.01$ compared with vehicle. *Source: Reproduced from Sano et al. (2008), with permission.*

CONCLUSIONS

In conclusion, these studies implicate that THC-induced catalepsy-like immobilization is distinct from that induced by large doses of major tranquilizers, such as haloperidol, and is mediated by decreased 5-HT neurotransmission in the nucleus accumbens, due to the action of glutamate-containing neurons through the CB1 receptors (Fig. 34.5). Moreover, we concluded that 5-HT_{1A} and 5-HT_{2A} receptors are involved in THC-induced catalepsy-like immobilization.

MINI-DICTIONARY

Cannabinoid (CB)1 receptor Two cannabinoid receptors have been cloned, and the CB1 receptor is located in the central nervous system.
Catalepsy-like immobilization THC induces catalepsy. However, THC-induced catalepsy is clearly distinct from that induced by large doses of major tranquilizers. This cataleptic immobilized state is thought to represent a decreased motivation toward movement. Therefore, we have called this cataleptic immobilized state catalepsy-like immobilization.
Delta-9-tetrahydrocannabinol (THC) THC is a major psychoactive component of marijuana. THC induces abnormal behaviors, such as impairment of spatial memory, catalepsy-like immobilization, and aggressive behavior in rats and mice.
Impairment of spatial memory THC impairs performance in the radial maze in rats. We have called this impairment state impairment of spatial memory.

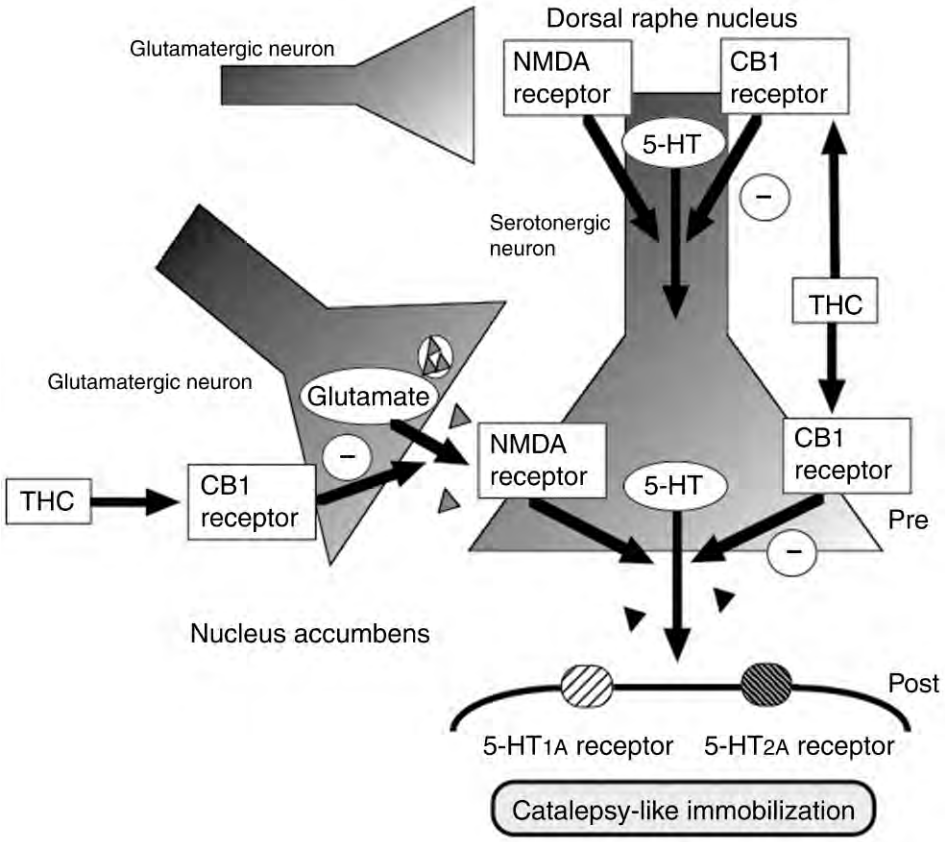

FIGURE 34.5 **A hypothetical overview of the mechanisms underlying THC-induced catalepsy-like immobilization.** THC-induced catalepsy-like immobilization is mediated by decreased 5-HT neurotransmission in the nucleus accumbens, due to the action of glutamate-containing neurons through CB1 receptors. 5-HT_{1A} and 5-HT_{2A} receptors are involved in THC-induced catalepsy-like immobilization.

Microdialysis Microdialysis is a method used for the measurement of the release of brain neurotransmitters. Animals are stereotaxically implanted with a guide cannula, and a microdialysis probe is inserted into the guide cannula, which is perfused with a solution, such as Ringer's solution. The sample is collected, and the sampled concentrations are measured by a high-performance liquid chromatography-electrochemical detector (HPLC-ECD) system.

Microinjection Microinjection is a method for injection into each brain. A stainless steel injection cannula is used to infuse the drug.

SUMMARY POINTS

- Schizophrenia is a multifactorial disease characterized by high heritability, and pronounced sensitivity to environmental factors.
- The neurodevelopmental theory of schizophrenia predicts that genes and environment together affect brain development negatively during critical periods of neuronal development.
- Heavy cannabis abuse, in particular during adolescence, increases the risk of psychosis at least twofold, and enhances the severity of positive symptoms, and the risk of psychotic relapse.
- A recent genetic study revealed an association between an individual's burden of schizophrenia risk alleles and the frequency and quantity of cannabis abuse.
- A functional polymorphism in the catechol-O-methyltransferase (*COMT*) gene confers vulnerability to cannabis-induced psychosis, and magnifies the negative consequences of adolescent cannabis abuse on the development of schizophrenia.
- Extensive mouse model research has provided evidence that the *neuregulin 1* (*NRG1*) gene mediates increased susceptibility to the neurobehavioral effects of cannabis.
- A *COMT* Val158Met polymorphism has recently been associated with the susceptibility to abuse cannabis, and develop cannabis dependence and a single nucleotide polymorphism (SNP) in *NRG1* was associated with the development of cannabis dependence in African Americans.

KEY FACTS OF SCHIZOPHRENIA

- Schizophrenia is a neurodevelopmental disorder where a variety of genetic and environmental risk factors modify brain maturation.
- Schizophrenia has a prevalence of around 1% worldwide
- Patients suffering from the disorder exhibit positive, negative, and cognitive symptoms.
- Current treatment options are limited, as antipsychotic drugs have severe side effects (eg, extrapyramidal symptoms, obesity, and impotence), and do not treat all symptoms.
- Heavy cannabis abuse is a component/cumulative cause for the development of schizophrenia.

KEY FACTS OF CANNABIS

- *Cannabis sativa* has more than 100 different plant constituents called phytocannabinoids.
- The main plant constituent is Δ^9-tetrahydrocannabinol (THC), which has psychotic-like properties, whereas

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00039-9

another cannabinoid, cannabidiol (CBD), might actually possess antipsychotic-like potential.
- Cannabis abuse can increase positive symptoms, and the severity of psychotic relapse in patients with schizophrenia.
- Heavy cannabis abuse during adolescence increases the risk to develop psychosis by around twofold.

LIST OF ABBREVIATIONS

2-AG	2-Arachidonoylglycerol
CB_1	Cannabinoid receptor 1
CB_2	Cannabinoid receptor 2
CBD	Cannabidiol
COMT	Catechol-O-methyltransferase
CP	CP 55,940
FLOT1	Flotillin-1
$GABA_A$	γ-Aminobutyric acid receptor (GABA) A
GxE	Gene-environment interaction
$5\text{-}HT_{2A}$	Serotonin 5-HT 2A receptor
LSV	Ventrolateral septum
MAGL	Monoacylglycerol lipase
NAPE-PLD	*N*-Acyl phosphatidylethanolamine phospholipase D
NMDA	*N*-Methyl-D-aspartic acid receptor
NRG1	Neuregulin 1
OF	Open field test
PPI	Prepulse inhibition of the startle response
THC	Δ^9-Tetrahydrocannabinol
WIN	WIN 55,212-2

Cannabis increases the risk of developing schizophrenia in genetically vulnerable individuals. Genetically modified mice offer a means to improve our understanding of the genes that confer vulnerability to the effects of cannabis in humans. Such models have been useful in forward (mouse to human) and reverse (human to mouse) translational research. On one hand, mouse research guides human studies on which genes to focus on; on the other hand, human studies that identify genetic variants can then be modeled in mice in an effort to delineate mechanisms involved in gene–cannabis interactions. This chapter will focus on two genes that are associated with schizophrenia, and appear to confer vulnerability to the effects of cannabis on psychosis—that is, the genes for catechol-O-methyltransferase (*COMT*) and neuregulin 1 (*NRG1*). Importantly, both genes have been investigated in mouse and human studies. *COMT*–cannabis interactions were first identified in human schizophrenia studies that were then reverse translated to mice, in order to appraise basic mechanisms. *NRG1*–cannabis interactions were first identified in mouse studies, as mice hypomorphic for transmembrane domain Nrg1 displayed altered neurobehavioral responses to cannabinoids in schizophrenia-relevant domains. The *Nrg1*-cannabis interaction was then confirmed in human studies. This chapter will focus on mouse preclinical research, which has improved our understanding how *COMT* and *Nrg1* modulate the schizophrenia-relevant effects of cannabinoids.

SCHIZOPHRENIA

Schizophrenia is a complex mental disorder with a prevalence of around 1%, although a number of related diagnoses, such as schizophreniform disorder, schizoaffective disorder, delusional disorder, and drug-induced psychosis could be added to the lifetime prevalence of psychosis. The disease is characterized by positive (eg, hallucinations, delusions), negative (eg, social withdrawal, anhedonia, impairment of sensorimotor gating), and cognitive symptoms. Current treatment options are limited, as typical and atypical antipsychotics are variably effective in ameliorating positive symptoms, and have limited success in treating cognitive symptoms. Furthermore, up to 30% of patients remain treatment resistant, and negative side effects of treatments available (eg, obesity, impotence, extrapyramidal symptoms) result in poor compliance.

GENE-ENVIRONMENT INTERACTIONS IN SCHIZOPHRENIA

Schizophrenia is a multifactorial disease characterized by high heritability (up to 80%), and pronounced sensitivity to environmental factors. The "two-hit hypothesis" of schizophrenia states that genetic and environmental risk factors interactively cause the development of the disorder (Bayer, Falkai, & Maier, 1999; Caspi & Moffitt, 2006). Interactions of genetic and environmental risk factors (GxE) occur when an individual's genetic predispositions are expressed dependent on their environment, or when environmental influences on a trait differ according to the individual's genome (Tsuang, Bar, Stone, & Faraone, 2004). Twin studies have shown that nature and nurture both play a role in the development of schizophrenia, as the concordance rate of monozygotic twins is around 50%. Furthermore, genome-wide association studies have failed to confirm common single nucleotide polymorphisms of so-called "schizophrenia candidate genes" as being accountable for a substantial proportion of the risk to develop the mental disorder (Sanders et al., 2008). Rather, the combined actions of a number of genes with small effect sizes (Owen, Craddock, & O'Donovan, 2005) and a variety of environmental risk factors (van Os, Kenis, & Rutten, 2010; van Os, Rutten, & Poulton, 2008) on brain development appear to cause

schizophrenia. Indeed, there might be subgroups in the population that are more vulnerable to particular environmental risk factors of schizophrenia (eg, cannabis abuse, developmental trauma). Thus, it is important to consider an interplay of genetic and environmental risk factors in order to understand the etiology of the disorder in depth. This is in line with the neurodevelopmental theory of schizophrenia, which predicts that genes and environment together affect brain development negatively during critical periods of neuronal development, thereby causing schizophrenia.

CANNABIS AND SCHIZOPHRENIA

The exact causes of schizophrenia are still unknown. However, cannabis has been suggested as a major environmental risk factor for the disease. Indeed, there is substantial evidence that cannabis use is much higher among schizophrenia patients than in the general population (Green, Young, & Kavanagh, 2005), and cannabis intoxication can trigger an acute transient psychotic episode (Thornicroft, 1990). Furthermore, there is substantial epidemiological evidence showing that heavy cannabis abuse, in particular during adolescence, increases the risk of psychosis by at least twofold, and enhances the severity of positive symptoms, and the risk of psychotic relapse (Arseneault et al., 2002; Henquet, Murray, Linszen, & van Os, 2005). Anecdotal evidence suggests that some schizophrenia patients may self-medicate with cannabis to reduce schizophrenia symptoms, or to alleviate some of the side effects of antipsychotic medication (Compton, Furman, & Kaslow, 2004; Dixon, Haas, Weiden, Sweeney, & Frances, 1990, 1991). However, more recent studies could not confirm a major therapeutic-like effect of cannabis on schizophrenia symptoms (Loberg & Hugdahl, 2009). In conclusion, an ever increasing number of researchers believe that cannabis users with a family history of schizophrenia (ie, genetic vulnerability to the disease) have a higher risk to develop psychotic disorder than the general population, thus classifying heavy cannabis abuse as a component/cumulative cause for schizophrenia (Caspi & Moffitt, 2006).

Recently, Power et al. (2014) investigated whether cannabis is a component cause of schizophrenia because it raises the risk of psychosis directly, or whether the same genes that increase the risk to develop psychosis also increase the likelihood of cannabis abuse (Power et al., 2014). This study was important, as the possibility of reverse causation had not been ruled out, and a few studies suggested that psychosis may be a risk factor for cannabis use (Addington & Duchak, 1997; Spencer, Castle, & Michie, 2002). Furthermore, cannabis use appears to be heritable (Agrawal & Lynskey, 2006; Verweij et al., 2012), and this heritability could result from a shared heritability with schizophrenia. Power's genetic association study revealed an association between an individual's burden of schizophrenia risk alleles and the frequency and quantity of cannabis abuse. Thus, at least part of the association between schizophrenia and cannabis abuse might be due to a shared genetic etiology and, therefore, not simply one of an environmental risk factor, but rather involving gene-environment correlations. It should be noted here that the authors did not rule out the possibility of cannabis being a risk factor for schizophrenia on its own right.

STUDIES EXAMINING GENETIC VULNERABILITY TO CANNABIS-INDUCED PSYCHOSIS

Early rodent work recognized that the rewarding properties of the main psychoactive component of the cannabis plant, Δ^9-tetrahydrocannabinol (THC), or its synthetic analogues, was dependent on genetic background (Arnold, Hunt, & McGregor, 2001; Chen, Paredes, Lowinson, & Gardner, 1991; Lepore, Liu, Savage, Matalon, & Gardner, 1996). Importantly, Lyons and coworkers confirmed in humans that the response to cannabis differed across individuals (Lyons et al., 1997). These studies suggest that the genetic background (or particular genes) influences the actions of cannabinoids. Considering the findings by Power and his colleagues (Power et al., 2014), it appears likely that at least some of these potential genetic candidates are also of relevance to schizophrenia research. Two major gene candidates with relevance to schizophrenia, *COMT* and *NRG1*, will be outlined in the following sections, as both mouse and human research support their role in conferring vulnerability to the propsychotic effects of cannabis.

MAJOR CANDIDATES FOR GENE–CANNABIS INTERACTIONS IN SCHIZOPHRENIA

Catechol-O-Methyltransferase

COMT is an enzyme which inactivates dopamine. A functional polymorphism in this gene conferred vulnerability to cannabis-induced psychosis, and magnified the negative consequences of adolescent cannabis abuse on the development of schizophrenia (Caspi & Moffitt, 2006; Henquet et al., 2006). Subsequently, a genetic mouse model for *COMT* (ie, adolescent homozygous and heterozygous *Comt* mutant mice; for a summary of *Comt* mouse model phenotypes see Table 35.1) was treated chronically with two doses of THC. Adolescent

TABLE 35.1 Overview of Knockout Mouse Model Phenotypes for COMT and NRG1

	Mouse model phenotypes
COMT	Improved spatial working memory Increased aggression Unaltered social behaviors and social recognition memory (reviewed in O'Tuathaigh et al., 2010a; O'Tuathaigh, Kirby, Moran, & Waddington, 2010b)
NRG1	Hyper-locomotive (Karl, Burne, Van den Buuse, & Chesworth, 2011; Stefansson et al., 2002) Moderate prepulse inhibition deficit (Karl et al., 2011; Stefansson et al., 2002) Impaired learning and memory (Chesworth, Downey, Logge, Killcross, & Karl, 2012; Duffy, Cappas, Lai, Boucher, & Karl, 2010; O'Tuathaigh et al., 2007) Deficient social behaviors (O'Tuathaigh et al., 2007) Increased expression of 5-HT_{2A} and NMDA receptors in cortical areas (Dean et al., 2008; Newell, Karl, & Huang, 2013) Altered NMDA receptor expression in the nucleus accumbens and thalamus (Newell et al., 2013) Increased CB_1 expression in the substantia nigra (Newell et al., 2013)

Abbreviations: *CB_1*, cannabinoid receptor 1; *NMDA*, *N*-methyl-D-aspartic acid receptor; *5-HT_{2A}*, serotonin 5-HT 2A receptor; *COMT*, Catechol-O-methyltransferase; *NRG1*, *Neuregulin 1*.

mice were chosen to model the findings from the Caspi study as closely as possible. *Comt* mice were more sensitive to THC-induced working memory impairments and anxiolysis, compared to wild type-like control mice (O'Tuathaigh et al., 2010a). In another study, adolescent *Comt* knockout mice were also more vulnerable to the disruptive effects of long-term treatment with the synthetic cannabinoid receptor 1 (CB_1) agonist WIN 55,212-2 (WIN) on sensorimotor gating (a behavioral hallmark of schizophrenia). On the other hand, knockout mice were less susceptible to the inhibiting effects of WIN on sociability (O'Tuathaigh et al., 2012). These behavioral responses were related to changes in dopamine metabolism in the prefrontal cortex of the mutant mice (O'Tuathaigh et al., 2012; Yavich, Forsberg, Karayiorgou, Gogos, & Mannisto, 2007). Mice also showed a genotype-specific response in components of dopaminergic and γ-aminobutyric acid (GABA)ergic pathways, as well as in the expression of CB_1 receptors. In particular, *Comt*–cannabis treatment interactions were found to influence dopaminergic cell sizes in the ventral tegmental area, expression of hippocampal CB_1 protein, and for parvalbumin-positive GABA interneuron cell size in the prefrontal cortex (Behan et al., 2012). Importantly, the mouse model research also suggested a developmental component of *Comt* genetic vulnerability to the actions of cannabis, as all effects were detected after adolescent but not adult cannabinoid exposure. This might be due to the slow maturation of cannabinoid receptors, which peak in expression around adolescence, and are reduced later in life due to postadolescent pruning events (Belue, Howlett, Westlake, & Hutchings, 1995). Finally, gene-dose effects were observed as the effects described were less prominent in heterozygous than in homozygous *Comt* mice. Interestingly, a recent human study showed that a *COMT* Val158Met polymorphism was associated with the susceptibility to develop cannabis dependence (Baransel Isir et al., 2008).

Neuregulin 1

The protein NRG1 influences key developmental processes, including cardiac development and neuronal migration, myelination, and synaptogenesis in the brain. It is also involved in the expression and activation of $GABA_A$ and *N*-methyl-D-aspartic acid (NMDA) receptors (Harrison & Law, 2006; Mei & Xiong, 2008). Alternative promoter usage and splicing has resulted in more than 30 different NRG1 isoforms, classified into at least six different isoform types (Mei & Xiong, 2008). This has led to the development of an increasing number of germline and conditional genetic mouse models for *NRG1*. The mouse model which has been evaluated in greatest detail and shows face, construct, and predictive validity for schizophrenia research is the heterozygous transmembrane domain *Nrg1* mutant mouse model (TM *Nrg1* HET mice) (Stefansson et al., 2002). The transmembrane domain of *NRG1* has been associated with schizophrenia (Walss-Bass et al., 2006) and TM *Nrg1* HET mice show behavioral characteristics relevant to schizophrenia endophenotypes (Powell & Miyakawa, 2006), including hyperactivity, sensorimotor gating deficits, cognitive and social impairments, some of which are reversible with antipsychotic treatment (Chesworth et al., 2012; Duffy et al., 2010; Karl, Duffy, Scimone, Harvey, & Schofield, 2007; Karl et al., 2011; Stefansson et al., 2002) (for a summary of *Nrg1* mouse model phenotypes see Table 35.1). Furthermore, adult *Nrg1* mutant male mice have increased expression of 5-HT_{2A} and NMDA receptors in cortical areas (Dean et al., 2008; Newell et al., 2013), altered NMDA receptor expression in the nucleus accumbens and thalamus, and increased CB_1 expression in the substantia nigra (Newell et al., 2013). Finally, *Nrg1* mutant mice are more susceptible to environmental factors such as housing and stress (as reviewed in Karl, 2013). Importantly, our team has studied the effects of cannabis constituents in this mouse model extensively.

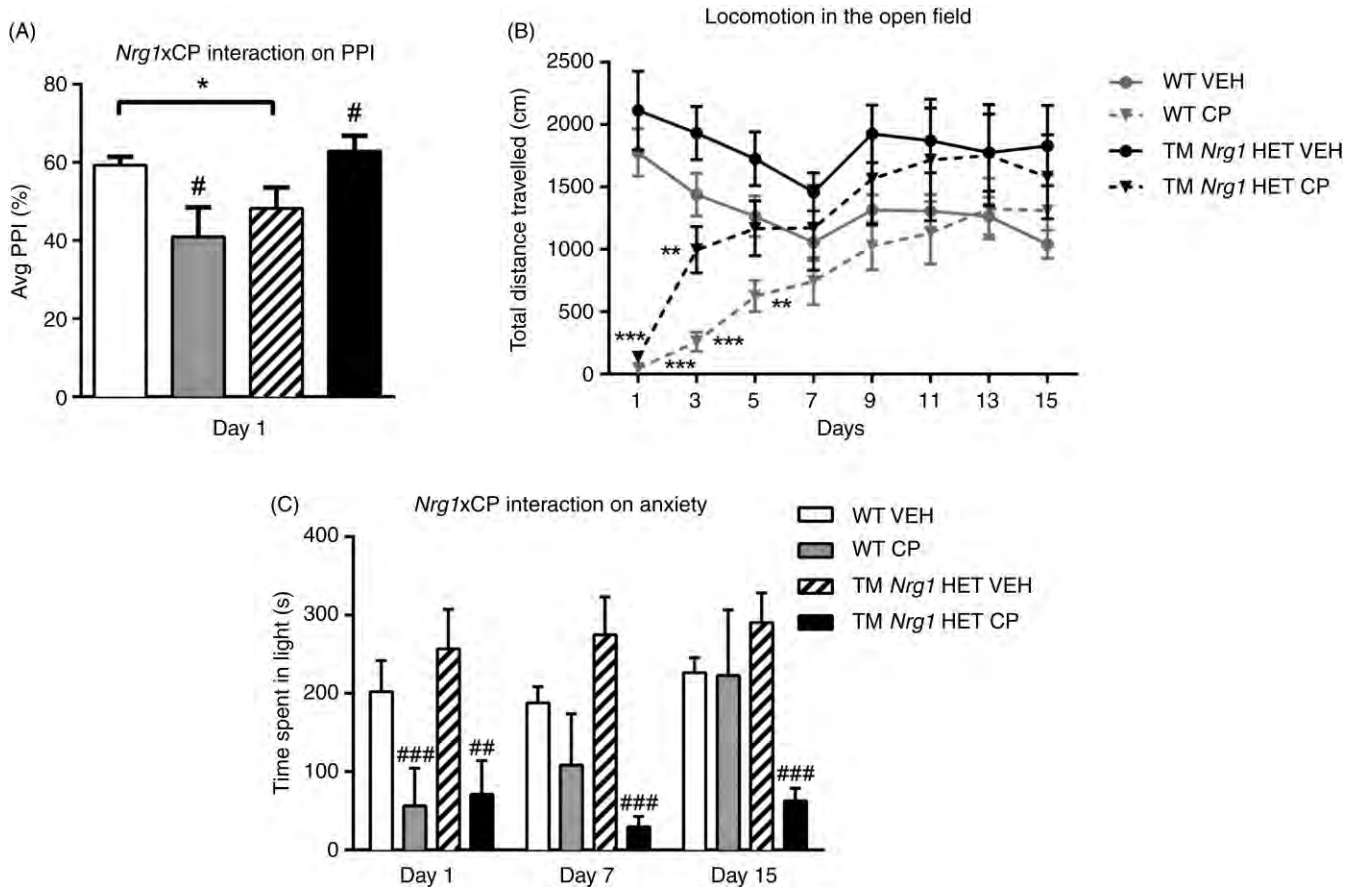

FIGURE 35.1 Mutant Nrg1 interacted with acute and repeated CP 55,940 *(CP)* exposure on (A) sensorimotor gating [as measured by prepulse inhibition *(PPI)*] and (B) behavioral tolerance development in the open field; but not (C) anxiety-relevant light-dark testing. Means ±SEM are shown. Significant effects for "genotype" are indicated by $^{*}p < 0.05$, $^{**}p < 0.01$, and $^{***}p < 0.001$ and for "drug treatment" by $^{\#}p < 0.05$, $^{\#\#}p < 0.01$, or $^{\#\#\#}p < 0.001$. Abbreviations: *PPI*, prepulse inhibition; *WT*, control littermates; *TM Nrg1 HET*, transmembrane domain *neuregulin 1* mutant mice; *VEH*, vehicle treatment; *CP*, CP 55,940 treatment. *Source: Modified from Boucher et al. (2011).*

Nrg1 mutant male mice challenged with an acute dose of THC showed an increased susceptibility to the sedative and anxiogenic effects of this cannabinoid, compared to wild type-like control mice (Boucher et al., 2007a). Importantly, acute cannabinoid challenge with THC or the synthetic CB_1 agonist CP 55,940 (CP) ameliorated deficits in sensorimotor gating (Boucher et al., 2007b, 2011), one of the hallmarks of schizophrenia (Geyer, Krebs-Thomson, Braff, & Swerdlow, 2001) (Fig. 35.1A). This beneficial impact of THC on prepulse inhibition of the startle response (PPI) in *Nrg1* mutant mice was unexpected, and could support the idea that initial exposure to cannabis might be beneficial in alleviating schizophrenia endophenotypes, similar to antipsychotic drugs normalizing sensorimotor gating deficits in schizophrenia patients (Geyer et al., 2001). The neural substrates of acute THC–*Nrg1* interaction were examined using c-Fos immunohistochemistry. THC increased c-Fos expression in the ventral part of the lateral septum (LSV) of mutant *Nrg1* mice only (Boucher et al., 2007b). This is significant, as drugs which modulate PPI, including both propsychotic drugs and antipsychotic drugs, elevate c-Fos expression in the lateral septum (Sumner et al., 2004). *Nrg1* HET mice also exhibited a more pronounced enhancement of c-Fos levels in stress-related brain regions (ie, paraventricular nucleus of hypothalamus and central nucleus of amygdala) than control littermates. The finding of increased behavioral sensitivity of *Nrg1* mutant males to THC was sex-specific, as female TM *Nrg1* HET mice exhibited no such sensitivity, and developed resistance to aspects of THC-induced social withdrawal (Long, Chesworth, Arnold, & Karl, 2010). The mechanisms responsible for the sexually dimorphic effects of cannabinoids on *Nrg1* mice require further investigation, as they may offer insight into the observed gender dimorphism in human *NRG1*–cannabis interactions (Han et al., 2012), and gender differences observed in the clinical course of schizophrenia (Fattore et al., 2007; Lacroix-Fralish, Tawfik, Nutile-McMenemy, Harris, & Deleo, 2006; McGregor & Arnold, 2007). In summary, these mouse studies were the first to show convincingly that cannabis might interact with the schizophrenia risk gene *NRG1*, and that genes

and gender may interact in a complex manner to modulate sensitivity to cannabinoids.

To model chronic cannabis abuse in schizophrenia, we also determined the neuroadaptive response of male TM *Nrg1* HET mice to repeated exposure (ie, 15 days) to the synthetic CB_1 agonist CP 55,940 (CP). *Nrg1* mutant mice more rapidly developed tolerance to the locomotor-inhibiting and hypothermic effects of the synthetic cannabinoid than control mice (Boucher et al., 2011) (Fig. 35.1B). On the other hand, *Nrg1* mutant mice failed to develop tolerance to the anxiogenic effects of CP (Fig. 35.1C). All mice developed tolerance to the genotype-specific effects of acute CP on PPI (ie, impairment in WT and facilitation in *Nrg1* HET mice) (Fig. 35.1A). FosB/ΔFosB expression was measured in brain tissue to detect for long-term neuroadaptive changes: CP induced a selective increase in FosB/ΔFosB in the LSV of mutant mice only. Thus, *Nrg1* not only affected the acute effects of cannabinoids, but also the neuroadaptive response to long-term cannabinoid exposure in a brain region implicated in the regulation of stress and anxiety responses. The data also reinforced the notion that the LSV is a critical brain region for *Nrg1*-cannabinoid interactions. The LSV is interconnected to various brain regions, including the hypothalamus, amygdala, hippocampus, and the prefrontal cortex, all implicated in the pathogenesis of schizophrenia, and expressing both Nrg1 and CB_1 receptors (reviewed in Arnold, Boucher, & Karl, 2012). Female TM *Nrg1* HET mice exhibited THC-induced facilitation of sensorimotor gating (measured by PPI), which was not evident in THC-treated control animals, following repeated dosing with THC for 21 days. (Spencer, Chohan, Karl, & Arnold, 2013). However, those effects were only significant for one particular interstimulus interval (ie, 32 ms) of the PPI protocol. Testing female mice again 21 days post THC treatment period revealed no residual effects of THC in either genotype. Thus, the lack of genotype-specific response of female *Nrg1* mice to acute THC discussed earlier (Long et al., 2010a) might be overcome following chronic THC treatment.

As earlier research on COMT–cannabis interactions had identified adolescence as a time of increased vulnerability to the psychotic and detrimental effects of heavy cannabis abuse (Caspi et al., 2005), we carried out an additional experiment where adolescent male TM *Nrg1* HET mice and control littermates where treated chronically with THC. Different to what had been observed in adulthood, *Nrg1* mice were less sensitive to the inhibiting effects of THC on investigative social behavior (Long et al., 2013). *Nrg1* also modulated the effects of adolescent THC on neurotransmitter receptor systems relevant to the pathophysiology of schizophrenia. Vehicle-treated *Nrg1* mutant mice displayed reduced CB_1 levels in the substantia nigra (Fig. 35.2A) and THC treatment increased CB_1 binding in TM *Nrg1* HET mice in this brain region. *Nrg1* also conferred opposing effects of THC on $5\text{-}HT_{2A}$ receptor expression in the insular cortex (ie, increased in *Nrg1* mice, decreased in control mice; Fig. 35.2B), and THC increased NMDA receptor binding in the hippocampus and cingulate cortex in *Nrg1* HET mice but not in WT control mice (Long et al., 2013) (Fig. 35.2C).

To gain insights into the molecular pathways involved in *Nrg1*–cannabis interactions during adolescence proteomic analyses were conducted for the hippocampus (Spencer et al., 2013b). THC treatment increased NMDA receptor binding in the hippocampus of *Nrg1* mice (Long et al., 2013), and our proteomic analysis revealed altered hippocampal expression of proteins involved in intracellular trafficking, and stabilization of NMDA receptors at the synapse in mutant mice, such as G protein signaling modulator 2 (GPSM2) and flotillin 1. This study also revealed that *Nrg1* and cannabinoid systems might interact through modulation of the endocannabinoid system. *Nrg1* mice repeatedly exposed to THC in adolescence showed a selective increase in the anandamide synthesizing enzyme *N*-acyl phosphatidylethanolamine phospholipase D (*NAPE-PLD*), implying a corresponding increase in hippocampal anandamide levels. A recent study reinforces the notion that interplay exists between Nrg1 and endocannabinoid systems, as exposure of cultured hippocampal neurons to recombinant Nrg1 increased the expression of the 2-arachidonoylglycerol (2-AG) degrading enzyme monoacylglycerol lipase (MAGL), lowering levels of 2-AG and disrupting long-term depression, a form of synaptic plasticity (Du, Kwon, & Kim, 2013). Taken together, these studies suggest *Nrg1*–cannabinoid interactions might be subserved through alteration of endocannabinoid levels and disruption of normal synaptic plasticity.

The importance of the *Nrg1* mouse model for research into the neurobehavioral effects of cannabis has recently been confirmed by a genome-wide linkage and single nucleotide polymorphism (SNP) association analysis, which discovered *NRG1* as a major candidate for the development of cannabis dependence in an African American test cohort (Han et al., 2012). Furthermore, *NRG1* may also confer increased sensitivity to the effects of THC on auditory evoked mismatch negativity in humans, as *NRG1* polymorphisms worsened THC-induced information processing dysfunction (Stadelmann et al., 2010).

DO GENES ALSO MODULATE THE EFFECTS OF OTHER PHYTOCANNABINOIDS LIKE CBD?

Some of the contrary reports regarding the role of cannabis in the development of schizophrenia might be due to the phenomenon that the *Cannabis sativa* plant is a mix

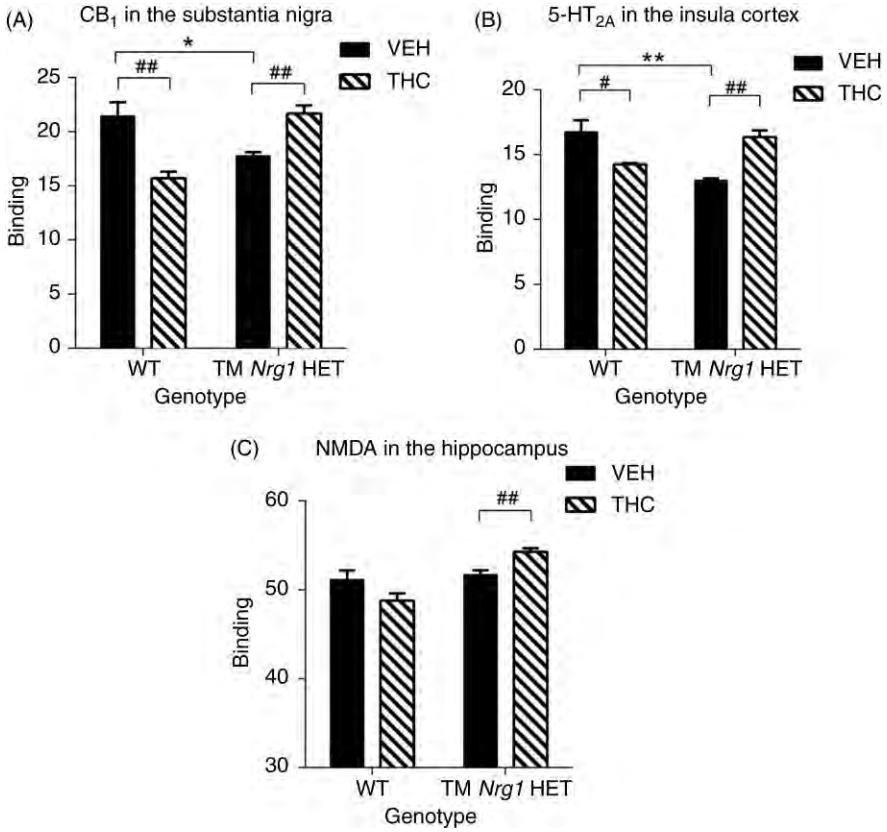

FIGURE 35.2 (A–C) Mutant Nrg1 interacted with repeated THC exposure during adolescence to alter schizophrenia-relevant receptors in the brain. Means ± SEM are shown. Significant effects for "genotype" are indicated by $^{*}p < 0.05$ and $^{**}p < 0.01$ and for "drug treatment" by $^{\#}p < 0.05$ and $^{\#\#}p < 0.01$. Abbreviations: *CB_1*, cannabinoid receptor 1; *NMDA*, *N*-methyl-D-aspartic acid receptor; *5-HT_{2A}*, serotonin 5-HT 2A receptor; *WT*, control littermates; *TM Nrg1 HET*, transmembrane domain *neuregulin 1* mutant mice; *VEH*, vehicle treatment; *THC*, Δ^9-Tetrahydrocannabinol treatment. *Source: Modified from Long et al., (2013).*

of over 100 different cannabinoids, including other cannabinoids that might antagonize the effects of THC, or have antipsychotic properties in their own right, like cannabidiol (CBD). CBD has been shown to block or reverse the effects of THC and other psychotropic drugs, including ketamine and dexamphetamine (Long et al., 2010b; Zuardi, Crippa, Hallak, Moreira, & Guimaraes, 2006). Thus, it is possible that varying levels of THC and CBD in different cannabis strains could influence the consequences of long-term cannabis consumption, and the nature of gene–cannabis interactions. We examined the effects of acute and repeated CBD on adult TM *Nrg1* HET mice, and hypothesized that CBD might offset schizophrenia-relevant behavioral phenotypes in these mice (Long et al., 2012). CBD did not alter the schizophrenia-relevant hyperlocomotive or impaired PPI phenotypes of *Nrg1* mice, although acute high-dose CBD improved PPI in *Nrg1* mutant mice, at a specific prepulse intensity of 86 dB. *Nrg1* mice developed tolerance to this effect, following repeated dosing. Furthermore, chronic high-dose CBD increased investigative social behavior (ie, *anogenital sniffing*) selectively in mutant *Nrg1* mice, but not control littermates. CBD enhanced 5-HT_{2A} receptor binding in the substantia nigra in control mice, but failed to reverse the reduced 5-HT_{2A} receptor binding that was observed in TM *Nrg1* HET mice. Further, CBD selectively increased $GABA_A$ density in mutant mice. Thus, *Nrg1* may not only modulate neurobehavioral actions of THC, but also of CBD in a task- and brain region-specific manner.

In conclusion, both mouse and human translational research has been effective in isolating two genes, *COMT* and *NRG1*, that both moderate the effects of cannabis or particular cannabinoids (summarized in Table 35.2). Mouse research on these vulnerability genes have progressed our understanding of the cellular, molecular, and neurobiological mechanisms of cannabis-induced psychosis. Future large-scale genetic screenings could enable clinicians to identify high risk patient groups (ie, particular SNPs in *COMT* or *NRG1*), who are at heightened risk to develop psychosis when abusing cannabis. In addition, it will be important to carry out novel mouse and human translational research to isolate additional genes that might confer vulnerability to cannabis-induced psychosis.

TABLE 35.2 Overview of Major Research Findings for Gene-Cannabis Interactions in Schizophrenia

COMT, Catechol-O-methyltransferase; *NRG1*, *Neuregulin 1*.

MINI-DICTIONARY

Cannabis Taxa of three plants, namely *Cannabis sativa*, *Cannabis indica*, and *Cannabis ruderalis*, containing more than 100 different plant constituents (ie, phytocannabinoids).
Cannabidiol (CBD) CBD can account for up to 40% of the plant's extract (although most cannabis available illegally contains only minimal levels of CBD, (Swift, Wong, Li, Arnold, & McGregor, 2013; Arnold et al., 2012). CBD has been shown to block some of the effects of Δ^9-tetrahydrocannabinol (THC), and is currently evaluated for its therapeutic potential in Alzheimer's disease and schizophrenia.
Catechol-O-methyltransferase (COMT) An enzyme which degrades catecholamines, including dopamine, and has a role in the metabolism of dopamine released into synapses (encoded by the *COMT* gene).
Endophenotype Attempt to separate a complex variety of behavioral disease symptoms into more stable phenotypes with a clear genetic component and mechanistic basis.
Mouse model of schizophrenia A model for genetic or environmental risk factors of schizophrenia, showing one or a limited number of schizophrenia-relevant endophenotypes. These models aim to possess face, construct, and predictive validity for the disease.
Neuregulin 1 (NRG1) A protein that is essential for brain and heart development. It is encoded by the *NRG1* gene in humans, and has been found to be involved in myelination, neuronal migration, and the activity of neurotransmitter receptors.
Prepulse inhibition (ie, model for sensorimotor gating) The inhibition of the startle response to an acoustic or tactile stimulus because of a weaker preceding stimulus. Prepulse inhibition is disrupted in schizophrenia, and deficits can be reversed by antipsychotic treatment.
Schizophrenia A mental disorder characterized by positive (eg, hallucinations and delusions), negative (eg, social withdrawal and anhedonia), and cognitive symptoms (eg, working memory deficits). Genetic and early environmental factors, including psychological and social processes, trigger the onset of the disease.
Schizophrenia candidate gene (also risk gene or susceptibility gene) A gene that has been found in human linkage or association studies to modify an individual's risk to develop schizophrenia. Importantly, a number of recent genome-wide association studies failed to validate any of those candidate genes identified over the last two decades for schizophrenia.
Δ^9-Tetrahydrocannabinol (THC) The main psychoactive component of the cannabis plant. It is a partial agonist for the cannabinoid receptor 1 and 2 (CB_1 and CB_2). THC has a number of behavioral effects, including hypomotility, catalepsy, analgesia, and hypothermia (called the tetrad effect of THC).
Two-hit hypothesis of schizophrenia The two-hit hypothesis of schizophrenia states that a combination of (multiple) genetic and environmental risk factors causes the development of schizophrenia. Interactions of genetic and environmental risk factors (GxE) occur when an individual's genetic predispositions are expressed dependent on their environment, or when environmental influences on a trait differ according to the individual's genome.

CHAPTER

36

Neuroimaging Findings in Adolescent Cannabis Use and Early Phase Psychosis

C.E. Crocker[*,**], *J. Cookey*[*], *P.G. Tibbo*[*]

*Department of Psychiatry, Dalhousie University, Halifax, NS, Canada
**Division of Neurology, Department of Medicine, Dalhousie University, Halifax, NS, Canada

SUMMARY POINTS

- A theory of the development of schizophrenia is the two-hit hypothesis. The first hit may be subtle abnormal brain development that leaves the brain susceptible to a second hit in damage from cannabis use.
- There is damage to oligodendrocytes by cannabis use, demonstrated by reduced integrity of white matter tracts.
- Cannabis use makes the white matter damage in FEP patients (observed as decreased FA values) more pronounced.
- NAA is reduced with cannabis use, suggesting reduced neuronal integrity.
- Glutamate is also reduced with adolescent cannabis use, particularly in female users. This may be indicative of reduced metabolism, and potentially alters the remodeling of the brain in adolescence.
- Unfortunately, we know of no studies examining adolescent cannabis users, FEP patients, and cannabis-using FEP patients to observe directly what the interplay between drug and disease might be on neurometabolism in these groups.

KEY FACTS IN DIFFUSION TENSOR IMAGING

- Diffusion tensor imaging was developed in 1990.
- The complex equations that allow a numerical quantitation of this measurement were developed in 1994.
- Diffusion tensor imaging measures the movement of water inside a tissue, in three dimensions, and generates a value that represents an ellipse pointed in a particular direction.
- Freely moving water is said to be anisotropic; fluid inside axons is said to be constrained and isotropic.
- The direction of water movement can be evaluated in individual blocks of brain images (called voxels) to determine the neuronal pathways.

LIST OF ABBREVIATIONS

Cho	Cytosolic choline
DISC1	Disrupted in schizophrenia 1
DTI	Diffusion tensor imaging
FA	Fractional anisotropy
FEP	First-episode psychosis
GABA	Gamma-aminobutyric acid
Gln	Glutamine
Glu	Glutamate

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00041-7

^{1}H-MRS	Magnetic resonance spectroscopy
ILF	Inferior longitudinal fasciculus
MD	Mean diffusivity
mI	Myo-inositol
NRG	Neuregulin
NAA	*N*-acetyl-aspartate
NAA-G	*N*-Acetylaspartylglutamic acid
SLF	Superior longitudinal fasciculus
tCr	Total creatine
TE	Echo time
THC	Delta-9-Tetrahydrocannabinol
TR	Relaxation time

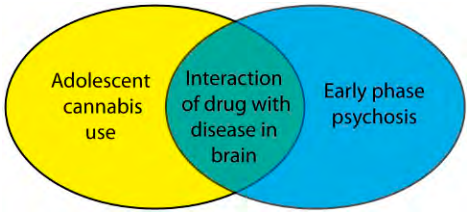

FIGURE 36.1 Venn diagram of chapter aim. Our focus is on two areas of study: cannabis use and first episode psychosis, and how these two areas overlap. This chapter examines our current knowledge in these areas with particular focus on the fields of MRS and DTI.

The human brain undergoes a critical phase of development during adolescence (Dahl, 2004; Spear, 2000). Neuronal maturation and rearrangement takes place with processes, such as myelination, synaptic pruning, and synaptic plasticity occurring. As a result of these adolescent processes, cortical structures (eg, prefrontal cortex) become fully integrated, allowing for better executive functioning, and other higher order functions (Arain et al., 2013). Interestingly, the brain develops in a "posterior to anterior" manner, with the prefrontal cortex the last to mature; this delay is particularly easy to observe when white matter is examined. Adolescents thus have less mature, and physically less, white matter in their frontal lobes than adults (Giedd et al., 1999).

Importantly, from a developmental perspective, as well, white matter tracts can be altered by environmental influences, for example, in humans who have been raised in institutions under conditions of neglect (Hanson et al., 2013). Preclinical studies with mice have shown that oligodendrocyte maturation and myelination are both dependent upon social experience in a critical period after weaning, and that the neuregulin (*NRG1*)/ErbB3 pathway is required for these processes (Makinodan, Rosen, Ito, & Corfas, 2012), in addition to the *disrupted-in-schizophrenia-1* (*DISC1*) gene (Hattori et al., 2014). Both *DISC1* and the *NRG1* signaling pathway have also been implicated as candidate genes for the underlying cause of schizophrenia (Roussos & Haroutunian, 2014). As oligodendrocytes play a key role in ensuring normal brain maturation takes place, it is thus not unreasonable to consider that until myelinogenesis is complete, the brain may be vulnerable to deleterious changes, as a result of environmental insults, which may include cannabis use.

The endocannabinoid system is itself important for cortical development, neural migration, connectivity, and synaptogenesis; interestingly, with cannabinoid receptors being located on human oligodendrocytes (Molina-Holgado et al., 2002). The majority of the work examining what role endocannabinoid receptors may play in oligodendrocyte development, and thus brain development, has occurred in vitro or in animal models. The effects of cannabis exposure on juvenile animals have demonstrated significant changes in the morphology, as well as functioning, of the maturing frontal cortex (Zamberletti et al., 2014). Additionally, the density of cannabinoid receptors in these regions diminishes with progress through adolescence, as well as their distribution, suggesting refinement of the system (Glass, Dragunow, & Faull, 1997).

Schizophrenia affects 1% of the population, has an average age of onset in late adolescence or early adulthood, and often causes significant chronic cognitive and psychosocial impairment. The neurodevelopmental hypothesis for schizophrenia suggests, in part, the prefrontal cortex of the brain does not develop properly; however, this is not apparent until an individual reaches late adolescence, when this region of the brain begins to be more fully integrated into the circuitry of the whole brain (Murray & Lewis, 1987). A variant of this hypothesis is the "two-hit hypothesis" that posits that while the neurodevelopment is disrupted, malfunction does not reach a critical level unless a second environmental insult occurs, further damaging the brain circuitry (Bayer, Falkai, & Maier, 1999). One of the postulated second "hits" is cannabis use (Fig 36.1).

There is clear evidence that use of cannabis increases an individual's risk of developing psychosis. Early work by Andreasson, Allebeck, Engstrom, & Rydberg (1987) conducted a 15-year follow-up study of 50,465 Swedish male conscripts, and found that those who had tried cannabis by age 18 were 2.4 times more likely to be diagnosed with schizophrenia than those who had not. This is a modest increase in risk, as other work has suggested that the risk of developing a psychosis roughly doubles from around 7 in 1000 in nonusers to 14 in 1000, for regular cannabis users (Saha, Chant, Welham, & McGrath, 2005). The effect of cannabis use is more profound for persons with an affected first degree relative (van Os et al., 2002). There is very little disagreement that marijuana use can contribute to the development of psychosis, the link potentially being THC effects on the developing brain (eg, on white matter) at a critical time point.

Human in vivo neuroimaging techniques will play an important role in shedding further light in this area, aiding us in moving the preclinical animal work to adolescent humans. We have chosen to review neuroimaging

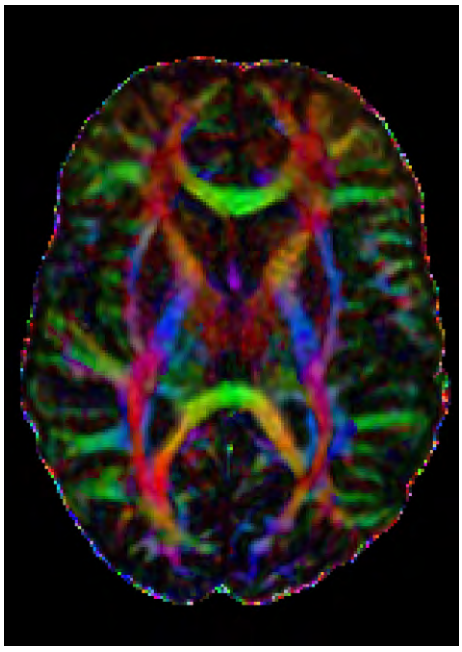

FIGURE 36.2 Example of FA map from diffusion tensor imaging. MRI image showing combined FA map with directional information. The colors indicate the direction of the diffusion. The map is RGB-based, so *red* indicates a left–right direction; *green*, antero-posterior; and *blue*, superior–inferior. *Source: This image was generated in FSL (Analysis Group, FMRIB, Oxford, UK) from a healthy control subject enrolled in one of our studies. The individual gave informed consent for use of their images (unpublished).*

studies in early adolescent cannabis use and early phase psychosis, with a focus on two techniques: diffusion tensor imaging (DTI), and magnetic resonance spectroscopy (MRS) to report the current state of work on this area (Fig. 36.2).

WHAT DOES DIFFUSION TENSOR IMAGING TELL US?

DTI is a magnetic resonance imaging modality that can measure macroscopic axonal organization in the human brain noninvasively, and is important for investigating brain white matter. The technique relies upon measuring the rate of tissue water diffusion in multiple directions at once, in order to estimate the overall direction of the diffusion (anisotropy) in each measured unit (voxel). As the diffusion of water inside the white matter tracts is limited in the fiber bundles, the overall direction of the fiber tracts can be discerned by comparing the dominant direction of diffusion in each adjoining voxel. DTI is usually reported as measures of fractional anisotropy (FA); 0 where there is free diffusion, to 1 where diffusion is highly restricted (anisotropic). FA is highly sensitive to microstructural changes, with higher FA considered representative of thicker myelinated fibers. Further analysis can be done to map the tracts of white matter using diffusion information. This tractography information, when compared between subject groups, gives information on the integrity of the pathways linking various brain regions (Mori & Zhang, 2006).

One particularly interesting DTI tractography study investigated 78 healthy adolescent controls, and compared their results to a metaanalysis of other DTI analyses done in healthy children. Their conclusion was that, bilaterally, the superior longitudinal fasciculus (SLF) was the most important tract in terms of adolescent development. Proper myelination of this tract was an absolute requirement for development of a normal healthy brain (Peters et al., 2012), as the SLF connects parts of the frontal lobe with the parietal, occipital, and temporal lobes. This is particularly interesting, as impaired structure/function of the SLF has also been implicated in schizophrenia, with the impaired working memory often found in schizophrenia being hypothesized to be due, in part, to SLF dysfunction (Peters et al., 2012).

DTI has been employed to explore the hypothesis that, in schizophrenia, abnormal communication between different regions of the brain may be due to disconnected or abnormal axonal tracts, and is well suited to examine cannabis effects on white matter structures, in early phase psychosis. Early studies in schizophrenia focused on medicated patients and, in hindsight, we know that antipsychotic medication can alter oligodendrocytes, resulting in reduced white matter volume and cell density (Konopaske et al., 2008). Thus, this chapter includes only DTI studies reporting on unmedicated early phase psychosis patients. We will explore the literature in early phase psychosis first (illness effects), followed by cannabis in adolescence (drug effects), then overlapping studies (illness and drug effects).

DTI Studies in Early Phase Psychosis

The body of literature examining unmedicated early psychosis patients is not large, and we excluded cohorts with heavy alcohol or illicit drug use, and studies with a sample size of less than 20 in the clinical group. Excluding multidrug and alcohol use removes this as a potential confounding factor, while excluding studies that used a small patient cohort avoids reporting noise discoveries (Ioannidis, 2005a, 2005b). There were 18 studies reported that meet these criteria. In the majority of studies (12 out of 18), the patients have decreased FA relative to healthy controls (Cheung et al., 2008; Gasparotti et al., 2009; Guo et al., 2012; Hao et al., 2006; Kumra et al., 2005; Kyriakopoulos, Vyas, Barker, Chitnis, & Frangou, 2008; Luck et al., 2011; Perez-Iglesias et al., 2010; Szeszko et al., 2008; Tang et al., 2010; Wang et al., 2011; White, Schmidt, & Karatekin, 2009). A recent metaanalysis that did not use our sample size criteria also confirmed the consistent finding of decreased FA in FEP patients, and identified the main tracts involved

as the cingulum bundle, the left inferior longitudinal fasciculus, the left inferior fronto-occipital fasciculus and, interestingly, the intrahemispheric connections of the corpus callosum (Yao et al., 2013). This change in water anisotropy points to changes in cell packing, or less robust myelination, both of which could be the result of decreased number or function of oligodendrocytes. One other interesting paper by Guo et al. (2012) is worth mentioning. This study showed FA reductions in several tracts, but only in the right hemisphere. This work only recruited drug naïve paranoid schizophrenic patients, and raises an interesting point about the consistency of results in psychosis research when broad or narrow classification systems are used (Guo et al., 2012). Similarly, the results of DTI studies may also be impacted by the genetic profile of the participants; both *neuregulin 1* and schizophrenia risk gene *ZNF804A* have both been shown to alter white matter microstructure in healthy individuals (Ikuta et al., 2014; Nickl-Jockschat et al., 2014). Thus, for future DTI research, it will be important to examine rigorously white matter structure in healthy controls and in unmedicated early phase psychosis, with clarity around methodology, samples sizes, diagnosis, and genetic influences, in addition to environmental influences.

DTI Studies in Adolescent Cannabis Use

Examination of DTI measures with cannabis use in adolescence also shows measurable brain changes. There is a small group of three studies to consider that strictly examined cannabis use without polydrug use in adolescents. These studies examined cannabis use in adolescent age subjects, or chronic cannabis use that began in adolescence. The studies have found decreases in FA between adolescent cannabis users and controls, regardless of region (Table 36.1) (Epstein et al., 2014; Gruber, Dahlgren, Sagar, Gonenc, & Lukas, 2014; Zalesky et al., 2012). This finding is not surprising, as the overriding hypothesis posits a reduction in connectivity with cannabis use that is greater, if use is begun in adolescence.

To further examine the possibility of reduced connectivity, tractography and DTI measures of axial and radial connectivity are additional measures that can be employed. Radial diffusivity is the measure of diffusion perpendicular to a fiber, whereas axial diffusivity is diffusion parallel to the fiber tract. Zalesky et al. (2012) examined radial and axial diffusivity in 59 chronic cannabis users, and found that both these measures positively correlated with the age at which regular cannabis use commenced in both fimbria and commissural fiber tracks. All the users commenced use in adolescence or early adulthood. Further work on cannabis using adolescents has been reported that examined alcohol use, as well. A group of 31 adolescents with cannabis use disorder and 20 healthy controls were also found to have decreased FA in prefrontal and parietal cortices. The 31 users were part of a larger group that also had alcohol users, yet statistical analysis showed that the decreased FA was associated with cannabis-related symptoms only, not alcohol (Clark, Chung, Thatcher, Pajtek, & Long, 2012). Neuroanatomical analysis methods showed white matter disorganization in the SLF (Clark et al., 2012). There is one further study of interest to note, although this study violates our 20 subject inclusion criteria. Kim et al. (2011) used deterministic tractography in concert with graph theory analysis to examine carefully the integration of 44 different brain regions, in 12 cannabis users (average age 19 years), and 13 similarly aged healthy controls. The application of this method allowed consideration of brain networks, rather than single paths, and could potentially be a method that would yield a better understanding of changes in global connectivity. This study demonstrated that cannabis-using participants had altered patterns of local network organization in the cingulate region, as well as having reduced global network efficiency (Kim et al., 2011).

TABLE 36.1 DTI studies in Early Psychosis and Cannabis

First author (year)	Group (*n*)	Age (years): mean (SD)	Substance use	Results
1. FIRST-EPISODE PSYCHOSIS PATIENTS

2. CANNABIS USE IN ADOLESCENTS OR BEGUN IN ADOLESCENCE				
Clark et al. (2012)	CAN+ (31) HC (20)	17 (1) 16 (1)	Group of 31 a subset of other substance use disorders	CAN+ < HC in FA in SLF. Significant gender effect
Kim et al. (2011)	CAN+ (12) HC (13)	19 (1) 22 (4)	No other illicit drugs previous 3 months	Decreased regional connectivity in CAN+
Gruber et al. (2014)	CAN+ (25) HC (18)	23 (6) 23 (4)	Exclusion of other illicit drugs	CAN+ < HC in FA. Subanalysis with earlier start (14-year-olds vs 17-year-olds) showed greater FA decrease
Zalesky et al. (2012)	CAN+ (59) HC (33)	33 (11) 32 (12)	Exclusion of other illicit drugs	CAN+ < HC in FA, in callosal and limbic fiber tract families. Use begun in adolescence
3. ADOLESCENT CANNABIS USE IN FEP				
Epstein et al. (2014)	FEP (53) UHR (19) CAN+ (28) HC (53)	17 (2) 16 (3) 18 (2) 17 (3)	Exclusion of other illicit drugs	Corticospinal and left ILF and left inferior fronto-occipital fas were all sig differed between FEP and control. Left ILF sig diff from HC for CAN+
James et al. (2011)	FEP (32) −16 CAN+ −16 CAN− HC (28)	16 (1) 16 (1)	Exclusion of other illicit drugs	FEP < controls in FA, in association, brainstem, callosal and projection fibers. CAN+ FEP < CAN− FEP in FA, in brainstem, projection and association fiber tracts

The minimal threshold for significance in this table is $p < .05$ (uncorrected for comparisons. FEP, first-episode psychosis; HC, healthy control; UHR, high risk for psychosis; CAN+, cannabis using; CAN−, do not use cannabis; FA, fractional anisotropy.

Overlapping DTI Findings

There are only two DTI studies reporting on cannabis use in early phase psychosis. The first considered 32 adolescents with FEP and 28 healthy adolescents. The FEP group was further divided into 16 cannabis users and 16 nonusers. The FEP group overall had significantly reduced FA values, compared to the healthy controls; patients with the cannabis use had the lowest FA values in a subgroup analysis. Changes in the SLF and ILF were seen, as well as the corona radiate, brain stem, and internal capsule (James et al., 2011). The second study compared FEP subjects with people at high risk of developing schizophrenia, adolescents with cannabis use disorder, and healthy controls. Patients had lower FA in four areas, including bilateral corticospinal tracts, left ILF, and left interior fronto-occipital fasciculus. The patients had significantly lower FA values, compared to cannabis users, in the corticospinal tracts and the left ILF. Cannabis-using subjects had FA values that were significantly lower than controls in the left ILF (Epstein et al., 2014). Interestingly, there was overlap in the ILF region, again, between the FEP and the cannabis users.

WHAT DOES MAGNETIC RESONANCE SPECTROSCOPY TELL US?

Proton magnetic resonance spectroscopy (^{1}H-MRS) uses proton information to examine tissue for the presence and concentration of various metabolites (Fig. 36.3). ^{1}H-MRS uses a spectrophotometer inside the MRI

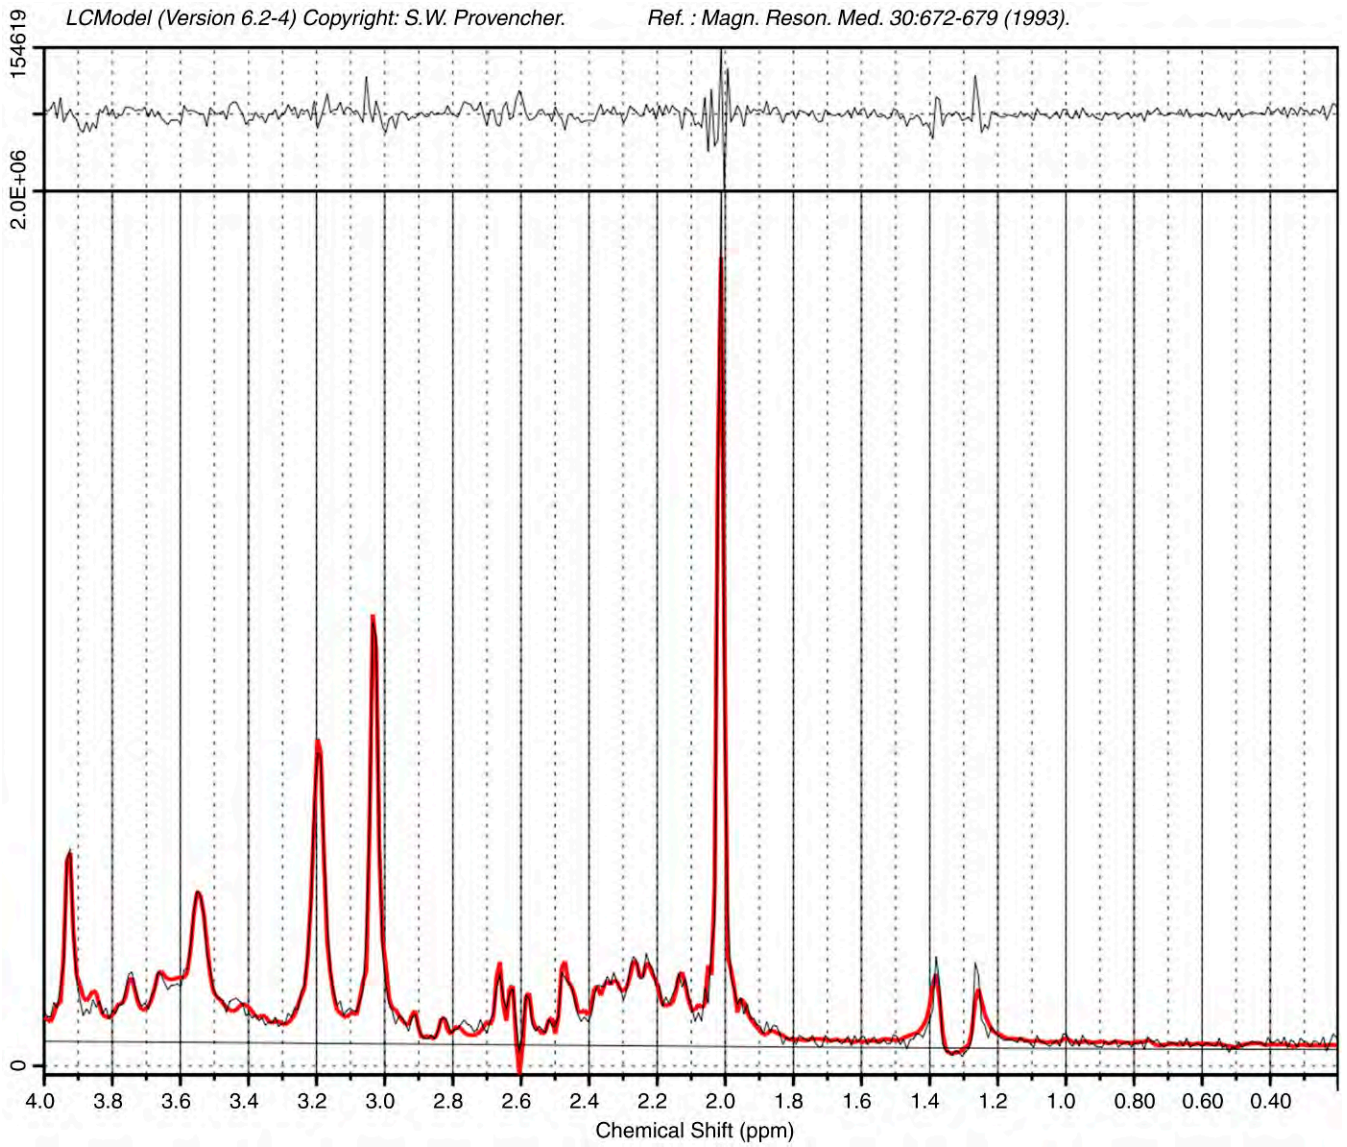

FIGURE 36.3 Example of a ^{1}H-MRS spectroscopy trace. ^{1}H-MRS trace generated at a short echo time (TE35) on a spectroscopy phantom at 1.5 T. *Source: The output is from a LCmodel analysis (Stephen Provencher Incorporated) (unpublished).*

machine to make measurements in vivo noninvasively. This allows quantification of cerebral metabolites, including *N*-acetyl-aspartate (NAA), myo-inositol (mI), total creatine (tCr), cytosolic choline (Cho), gamma-aminobutyric acid (GABA), glutamine (Gln) and glutamate (Glu). NAA is generally considered to be a marker of neuronal health. The tCr signal includes creatine and phosphocreatine, and is a product of the energy metabolism in the brain. MI is a marker of astroglial function, and also plays a role in neuronal energy production. The choline measure is a pooled measurement of free choline, glycerolphosphocholine, and phosphocholine, so Cho is considered a marker of membrane turnover. Gln and Glu can be difficult to differentiate, as Gln is a metabolic product of Glu and, consequently, are sometimes collectively referred to as Glx. Glu is the predominant excitatory neurotransmitter in the brain, and found in greatest concentrations in gray matter (Rothman, Behar, Hyder, & Shulman, 2003).

MRS Studies in Early Psychosis

There are a number of studies examining ^{1}H-MRS in FEP patients. However, again after limiting to papers that had more than 20 subjects, used minimal antipsychotic treatment, and allowed no concurrent recreational drug use, nine studies remained. Seven of the nine papers showed no differences between healthy control subjects and FEP patients, regardless of region examined (Table 36.2) (Bustillo et al., 2008; Crocker et al., 2014; Stanley et al., 1996; Tibbo et al., 2013; Tunc-Skarka et al., 2009; Uhl et al., 2011; Wood et al., 2003). The remaining two papers were from the same group, with one study reporting significant increases in Gln levels, between healthy controls and never treated FEP, in the anterior cingulate and thalamus (Theberge et al., 2002), with another study examining patients at the start of treatment and 30 months later (Theberge et al., 2007). The second study only had 16 subjects in each group, but longitudinal methodology added rigor to the design. The naïve FEP group had elevated Gln; however, after 30 months of treatment, Gln was reduced in the thalamus, but still elevated in the anterior cingulate (Theberge et al., 2007).

The absolute metabolite levels of each cohort may not tell the whole story, though. Work by our group suggests that, within the FEP group, bioenergetics may be affected. In one study, we noted a significant decline in tCr levels with age, not present in the healthy control group (Tibbo et al., 2013). In the other study from our group, we noted the absence of a normal relationship between NAA and Glu in the anterior cingulate of FEP patients (Crocker et al., 2014). Both of these studies suggest that alterations in brain metabolism are present at a young age, and that, by strictly examining group differences between healthy controls and FEP patients, we may be missing brain abnormalities, as measured by MRS within FEP cohorts. Another methodological consideration is that, while the focus of spectroscopy has been in gray matter, with increasing field strength, white matter spectroscopy may be a useful modality to examine changes in oligodendrocyte metabolism.

MRS Studies in Cannabis Use

There are very few studies examining the metabolic effects of chronic cannabis use in adolescents and, thus, the authors had to relax our inclusion criteria of subjects per group. In two studies, adolescent chronic cannabis users demonstrated significantly lower Glu, NAA, tCr and mI, as well as GABA, in the anterior cingulate cortex, compared to healthy age-matched nonusers (Prescot,

Silveri et al. (2011)	CAN+ (13) HC (10)	Between-group TE = 30-330 ms PRESS ^{1}H-MRS at 3T		Anterior cingulate cortex, basal ganglia, thalamus, temporal, parietal, and occipital lobe	• HC > CAN+ for global mI • HC = CAN+ for NAA, Cr, Cho, Glu

The minimal threshold for significance in this table is $p < .05$ (uncorrected for comparisons of multiple neurochemicals), two-tailed. FEP, first episode psychosis; HC, healthy controls; UHR, ultrahigh risk; SCZ, established schizophrenia; NAA, *N*-acetyl-aspartate and *N*-acetyl-aspartyl-glutamate; Cho, choline-containing compounds (trimethylamines), the two main constituents of the Cho signal are phosphorylcholine (PC) and glycerophosphorylcholine (GPC); Glu: glutamate; Gln, glutamine; GABA, gamma-amino butyric acid; Glx, GABA, glutamate and glutamine quantified together; Cr, creatine and phosphocreatine; mI, myoInositol; Tau, taurine.

Locatelli, Renshaw, & Yurgelun-Todd, 2011; Prescot, Renshaw, & Yurgelun-Todd, 2013). Covarying for gender increased the significance of the Glu levels in cannabis-using subjects (Prescot et al., 2011). A more recent study looking at combined Glu plus Gln in the dorsal striatum did not see an overall group effect but, again, when adjusted for gender, there was a significant decrease in Glu + Gln for female users. Similarly for mI, when covaried for gender, mI was increased in female users (Muetzel et al., 2013). These results could have been the result of differing voxel locations; however, they raise interesting thoughts on gender effects that need to be more fully explored. A recent study comparing cannabis-using adolescents to bipolar cannabis-using adolescents and healthy controls found no differences in NAA between cannabis users and healthy controls (Bitter et al., 2014). There is one further ^{1}H-MRS study in adult chronic users of cannabis, with use begun in adolescence, which is useful to report. Thirteen cannabis-using males and 13 male controls were examined by ^{1}H-MRS with a voxel in the dorsolateral prefrontal cortex, a region known to have abnormalities in schizophrenia. There was again a significant decrease in NAA/Cr ratio in users, compared to nonusers (Hermann et al., 2007). If chronic cannabis use in FEP compounds effects on the DLPFC remains to be examined.

The lowering of Glu is a particularly troubling finding in the adolescent brain. There are a number of maturational changes that take place due to the glutamatergic system during adolescence, including subtype switching and synaptic pruning (Egerton, Fusar-Poli, & Stone, 2012). There is also evidence from preclinical studies that application of glutamatergic antagonists results in neuronal apoptosis and schizophrenia-like symptoms (Egerton et al., 2012). It can thus be inferred that decreasing Glu through the intake of cannabis could adversely affect cortical structure. Glu is also the precursor for GABA and NAA-G, both of which would be adversely affected by the decreased Glu levels. Altering both the major excitatory (Glu) and inhibitory (GABA) neurotransmitters in the brain is likely to alter synaptic plasticity. It is not clear how long such changes will last. However, a PET imaging study has shown that there is anterior cingulate cortex hypoactivity after 25 days of cannabis abstinence (Eldreth, Matochik, Cadet, & Bolla, 2004).

There are no reports, to our knowledge, of MRS studies that examine both early psychosis and cannabis use combined. We are currently conducting a multimodal study combining DTI and ^{1}H-MRS in cannabis-using FEP patients (Bernier et al., 2013). The complete absence of direct MRS measurement of brain metabolism in FEP patients who have used/are using cannabis needs to be addressed, as this is especially important, given the strong evidence of a link between cannabis use and onset of psychosis.

CONCLUSIONS

DTI can tell us that there are changes occurring in the structure of the white matter tracts with FEP and cannabis use, and that these changes are different in location and extent from illness effects and cannabis effects alone (Fig. 36.4). These changes are reflected in decreased FA values, indicating greater anisotropy of tissue water and, thus, less restricted diffusion. DTI tractography suggests that the ILF and the SLF are both candidates for consideration of where the white matter tract dysfunction (connectedness) may occur. DTI's limitation is that it cannot tell us anything specific about the nature of the changes we are measuring, for example, if oligodendrocytes may be dying, or if myelination is simply less robust. DTI can confirm that white matter structures can be affected; however, further research into the process of how this occurs needs to be developed. Even with the limitations of DTI, valuable information can be obtained on outcomes of illness combined with cannabis effects on white matter structures. A focus on refined methodology with larger sample sizes will help inform us better, and drive research in the future.

MRS tells us that there are changes in NAA levels with cannabis use, in various brain regions; however, little work has been completed on combined illness and cannabis effects. A limitation of MRS is that we are unsure, at this stage, of what cell types are contributing to this change, and if the decreased levels of NAA may reflect changes in the bioenergetics of the neuronal cells, or changes in cell

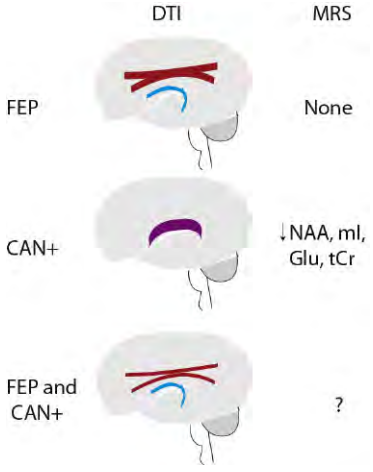

FIGURE 36.4 Summary of the presented findings. For DTI: the best evidence suggests ILF and SLF are affected in FEP, whereas fimbria and commisures are affected in cannabis, and when combined in FEP patients that use cannabis, the ILF and SLF are more dramatically affected. For MRS: there are no global group differences in FEP patients, but in cannabis users there are decreases in NAA, mI, Glu, and tCr. There is currently no information on MRS in Cannabis using FEP (unpublished).

numbers. As with DTI, continued work is needed to improve our understanding of the effects of cannabis in the developing brain at risk for schizophrenia.

What we hope to have illustrated in this chapter is the need for better research into the mechanisms of the action of cannabis on the living human brain. There is a paucity of research using neuroimaging techniques to look into cannabis use. Given what we now know from epidemiological studies about the link between psychosis and cannabis use, and increasing legal access to cannabis, there is an urgent need for well-designed, suitably powered studies into neuroimaging and cannabis use.

MINI-DICTIONARY

Adolescence Phase of human development generally from 12 to 17 years of age, but sometimes up to 24 years. A second surge of neurodevelopment takes place at this time.
Diffusion Tensor Imaging A magnetic resonance imaging technique that allows the measurement of water movement (diffusion) within a tissue of interest, in vivo.
First episode psychosis First psychotic episode, but also the first 5 years of schizophrenia, a time when early intervention can substantially improve overall disease outcome.
Fractional anisotropy (FA) A measure of the diffusion of water inside a specified area of the brain.
Glutamate Major excitatory neurotransmitter in the human brain involved in neuronal energy metabolism.
Longitudinal fasciculi The inferior (ILF) and superior longitudinal fasculi (SLF) are white matter tracts. The SLF connects the frontal lobe to the occipital lobe. The ILF connects the occipital lobe to the temporal lobe.
Magnetic Resonance Spectroscopy A technique used in conjunction with magnetic resonance imaging that allows measurement of biochemical compounds within a tissue, noninvasively.
NAA Amino acid present in the brain at high concentrations. Thought to play a role in neuronal energy metabolism.
Oligodendrocyte A type of neuroglia with myelination as their major function.
Tractography A three-dimensional representation of the white matter connections within the brain, usually between two specified regions.

†Department of Psychiatry, Faculty of Medicine, University of Montreal, Montreal, QC, Canada

SUMMARY POINTS

- Cognitive deficits are a hallmark of schizophrenia present in close to 80% of individuals.
- Cognitive deficits are present at an early stage of the disorder.
- In the general population, cannabis smoking is associated with a two- to threefold increase in psychosis outcomes.
- Cannabis smoking can trigger first episodes of psychosis in vulnerable individuals.
- Cannabis use in healthy individuals causes small-to-moderate deficits in working memory, executive functions, attention, and episodic memory.
- In schizophrenia, cannabis smoking seems to be paradoxically associated with better cognition.
- fMRI studies using cognitive and emotional stimuli have shown that schizophrenia patients using cannabis have increased prefrontal activity, relative to nonusing schizophrenia patients.
- Factors that may explain these paradoxical findings include the neuroprotective properties of cannabis, social factors related to the lifestyle of cannabis smoking, and uncontrolled premorbid differences.
- Limitations: most studies did not assess all the cognitive domains known to be impaired in schizophrenia, did not confirm self-reports of cannabis smoking with urine drug analyses, did not take into account the potential confounding influence of socio-demographic variables, and did not use longitudinal designs.

KEY FACTS OF SCHIZOPHRENIA

- Schizophrenia is a severe psychiatric disorder characterized by positive and negative symptoms, as well as disorganized thinking/behavior.
- Schizophrenia is associated with high rates of hospitalizations, homelessness, and unemployment.
- The lifetime prevalence of substance use disorder is close to 50% in schizophrenia.
- The life expectancy of schizophrenia patients is 20% shorter than that of the general population.
- 7–8% of schizophrenia patients will end their life by committing suicide.

KEY FACTS OF THE ENDOCANNABINOID SYSTEM

- The endogenous cannabinoid system is composed of (at least) two ligands (anandamide and 2-arachidonylglycerol).

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00042-9
Copyright © 2017 Elsevier Inc. All rights reserved.

- Endocannabinoids bind to (at least) two cannabinoid receptors (CB_1 and CB_2).
- CB_1 receptors are mostly found in the prefrontal cortex, basal ganglia, hippocampus, anterior cingulate cortex, and cerebellum.
- These brain regions are known to be dysfunctional in schizophrenia.
- Delta-9-Tetrahydrocannabinol (Δ^9-THC), the main psychoactive ingredient in cannabis, binds to CB_1 receptors.

LIST OF ABBREVIATIONS

Δ^9-THC	Delta-9-tetrahydrocannabinol
CUD	Cannabis use disorder
dlPFC	Dorso-lateral prefrontal cortex
DD	Schizophrenia group with cannabis abuse
fMRI	Functional magnetic resonance imaging
MATRICS	Measurement and Treatment Research to Improve Cognition in Schizophrenia
mPFC	Medial prefrontal cortex
PCC	Posterior cingulate cortex
Sz + Can	Schizophrenia patients smoking cannabis
Sz	Schizophrenia patients not smoking cannabis
SUD	Substance use disorders

COGNITION IN SCHIZOPHRENIA

The lifetime prevalence of schizophrenia is lower than 1% worldwide. Schizophrenia is a severe psychiatric disorder, characterized by positive (delusions and hallucinations) and negative (flat affect, anhedonia) symptoms, as well as disorganized thinking/behavior. A source of considerable social and economic burden, schizophrenia has been ranked by the World Health Organization as one of the top 10 causes of disability in developed countries (Tandon, Keshavan, & Nasrallah, 2008a). Over the years, cognitive dysfunctions have emerged as being of critical importance in schizophrenia. Given that cannabis smoking is highly prevalent in schizophrenia, and that it has deleterious effects on cognition in nonpsychosis individuals, the potential cognitive effects of cannabis on cognition in schizophrenia have recently attracted growing interest.

It is widely known that individuals with schizophrenia have to cope with a variety of cognitive deficits (Goldberg, David, & Gold, 2011), with close to 80% of them struggling with either socio- or neurocognitive deficits or both. Factor analyses have revealed that six neurocognitive domains are significantly impaired in schizophrenia, namely speed of processing, attention/vigilance, working memory, verbal and visual learning, as well as reasoning, and problem solving. The socio-cognitive domains known to be impaired in schizophrenia include deficits in social knowledge, emotion recognition, Theory of Mind, attribution style, as well as emotion regulation. When compared to the general population, the cognitive deficits of schizophrenia range from 1 to 1.5 standard deviations below the normal scores. Mild deficits are also present, even in the prodromal phase of the disorder, indicating that they could partly be independent of duration of illness and medication intake. Furthermore, nonaffected family members of individuals with schizophrenia tend to show similar though attenuated cognitive deficits, suggesting that the cognitive impairments of schizophrenia are partially heritable. Finally, research has shown that cognitive impairments in schizophrenia are relatively stable over time, even when psychotic symptoms are in remission. Cognitive dysfunctions are, therefore core features of schizophrenia, known to severely impede upon recovery and rehabilitation. Indeed, numerous studies have shown that cognition (especially social cognition) is a better predictor of social and occupational functioning, and overall recovery, than the negative or positive symptoms of schizophrenia. As a result, interest in investigating cognition in schizophrenia has rapidly grown over the past years, in the hopes of pinpointing where the deficits specifically lie, in order to identify better treatments. As such, the National Institute of Mental Health created a standardized battery of tests to assess cognition in clinical settings: the MATRICS Consensus Cognitive Battery, which measures seven domains of cognition (six neuro-cognitive, one socio-cognitive; Table 37.1) (Nuechterlein et al., 2008).

On neurobiological grounds, considerable efforts have been made in order to identify the neurobiological bases of the cognitive impairments of schizophrenia, considered as putative endophenotypes of the disorder. Thus far, functional imaging studies have mostly paid attention to deficits in working memory, executive functions, emotion processing, Theory of Mind, and episodic memory in schizophrenia. This vast functional imaging literature has shown that schizophrenia is a complex psychiatric disorder characterized by impaired fronto-parietal, fronto-striatal, fronto-limbic, and frontal-temporal networks (Delvecchio, Sugranyes, & Frangou, 2013; Minzenberg, Laird, Thelen, Carter, & Glahn, 2009; Ragland et al., 2009; Sugranyes, Kyriakopoulos, Corrigall, Taylor, & Frangou, 2011; Van Snellenberg, Torres, & Thornton, 2006) (Table 37.2).

CANNABIS AND PSYCHOSIS OUTCOMES

The administration of delta-9-tetrahydrocannabinol (Δ^9-THC, the main psychoactive agent of cannabis) to healthy subjects has been shown to consistently produce

TABLE 37.1 MATRICS Cognitive Domains and Associated Tests

Cognitive domain	MATRICS test beta-battery	Most frequently used tests from 20 studies reported in the table
Speed of processing	Category fluency, animal naming	Groove pegboard
	Trail making test (TMT)	CogState
	Wechsler Adult Intelligence Scale, 3rd ed. (WAIS-III), digit symbol-coding subtest	Rapid visual information processing from Cambridge neuropsychological test automated battery
	Brief assessment of cognition in schizophrenia (BACS), symbol coding subtest	Forced-choice span of apprehension test
Attention/vigilance	3–7 Continuous performance test, shortened version	Digit span test (forward version), from the WAIS-III
	Continuous performance test—identical pairs version	Spatial span forward items of the Wechsler Memory Scale-III (WMS-III)
Working memory	BACS, digit sequencing subtest	Bergen N-back paradigm
	WAIS-III, letter-number sequencing subtest	Working memory–mental arithmetic test
	Letter-number span test	CPT identical pairs test
	Wechsler Memory Scale, 3rd ed., spatial span subtest	
	Spatial delayed response task	
Verbal learning/memory	Neuropsychological assessment battery, daily living memory subtest	Rey auditory verbal learning test
	Hopkins verbal learning test—revised, immediate recall	California verbal learning task
		Controlled oral word association test
Visual learning/memory	Neuropsychological assessment battery, shape learning subtest	Spatial-delayed response test (SDR)
	Brief visuospatial memory test—revised	Pattern recognition memory from the Cambridge neuropsychological test automated battery
Reasoning and problem solving	WAIS-III, block design subtest	Wisconsin card sorting test
	BACS, Tower of London subtest	Delis Kaplan executive functioning system
	Neuropsychological assessment battery, mazes subtest	Stroop color word test
Social cognition	Mayer-Salovey-Caruso emotional intelligence test, perceiving emotions branch	Hinting task for theory of mind
	Mayer-Salovey-Caruso emotional intelligence test, managing emotions branch	Degraded facial affect recognition task for emotional recognition

This table includes all the cognitive domains of the MATRICS battery and the associated tests used to measure them.

positive-like and negative-like symptoms, as well as disorganized thinking (D'Souza et al., 2004)—therefore reproducing the complex phenomenology of schizophrenia. Similarly, in some individuals, it has also been observed that cannabis can induce a transient psychotic disorder mimicking the positive symptoms of schizophrenia. The psychomimetic effects of cannabis has led some authors to propose that cannabis may be a risk factor for psychosis, an idea that was first substantiated by the classic study from Andreasson, Engström, Allebeck, and Rydberg (1987) among 45,570 conscripts from the Swedish army. Since then, better controlled studies have been performed, which have provided substantial evidence that cannabis smoking is associated with a two- to three-fold increase in psychotic symptoms or schizophrenia-spectrum diagnoses (Moore et al., 2007). The magnitude of the relationship between cannabis smoking and psychosis outcomes seems to be dose-dependent, and to be influenced by age of cannabis smoking initiation, traumatic experiences, premorbid psychosis vulnerability, and genetic factors (Gage, Zammit, & Hickman, 2013).

In individuals diagnosed with schizophrenia, the risk of compulsive cannabis smoking is increased by 3–6, compared to the general population. A recent metaanalysis

TABLE 37.2 Neurofunctional Alterations in Schizophrenia

Cognitive function	Example(s) of task	Hypoactivations	Hyperactivations	References
Working memory	N-Back	*High working memory load* • dlPFC • Parietal cortex	*Low working memory load* • dlPFC • Parietal cortex	Van Snellenberg et al. (2006)
Executive functions	Stroop; Go-No-Go	• dl and vlPFC • ACC • Striatum	—	Minzenberg et al. (2009)

Abbreviations: *dlPFC*, dorsolateral prefrontal cortex; *vlPFC*, ventrolateral prefrontal cortex; *ACC*, anterior cingulated cortex; *mPFC*, medial prefrontal cortex.

of 35 studies reported that the current rate of cannabis use disorder is 16%, and the lifetime rate is 27.1% in this population (Koskinen, Löhönen, Koponen, Isohanni, & Miettunen, 2009). Cannabis smoking negatively interferes with the course and treatment of schizophrenia, as it is associated with higher rates of hospitalizations, more severe positive symptoms, noncompliance, and more suicide attempts (Bourque et al., 2013). Finally, based on 80 studies, it has been shown that cannabis smoking is associated with an earlier age of psychosis onset (~2 years), after controlling for the influence of sex, smoking chronicity, and other psycho-active substances (Myles, Newall, Nielssen, & Large, 2012). Though no firm inference can be made on causality, based on cross-sectional studies, these results raise the possibility that, in vulnerable people, cannabis smoking is a powerful trigger of psychosis.

THE COGNITIVE EFFECTS OF CANNABIS IN NONPSYCHOSIS INDIVIDUALS

In nonpsychiatric smokers, intoxication with cannabis or Δ^9-THC has been consistently shown to impair working memory, executive functions, attention, and episodic memory (Crean, Crane, & Mason, 2011). The residual cognitive effects of cannabis use have also been studied. While the short-term abstinence from cannabis is associated with small-to-moderate deficits in episodic memory, executive functions, and attention, the magnitude of the long-term residual cognitive effects of cannabis smoking remains unclear (Crean et al., 2011). Study results seem influenced by the quantities of cannabis smoked by participants, as well as the length of abstinence. While some studies have shown that it usually takes about 28 days of abstinence from cannabis smoking to recover one's cognitive abilities, others have reported that certain cognitive deficits may last longer. The magnitude of the cognitive effects of cannabis may also be influenced by earlier age of smoking initiation, as shown in a 25-year cohort study involving 1037 subjects (Meier et al., 2012).

Neuroimaging studies performed on individuals without psychiatric disorders have shown that acute Δ^9-THC intoxication and chronic cannabis smoking both produce neuro-functional alterations echoing the neurophysiologic disturbances seen in schizophrenia (Bossong, Jansma, Bhattacharyya, & Ramsey, 2014). Indeed, cannabinoids have been shown to disrupt working memory-related activity in dorso-lateral prefrontal and parietal cortices, to impair amygdala reactivity during

the viewing of fearful or angry faces, to alter the functioning of frontal and striatal regions during response inhibition tasks, and, finally, to disrupt prefrontal and medial temporal regions during episodic memory tasks. Regardless of heterogeneity of results, cannabinoids seem to reproduce (at least, partially) the fronto-parietal, fronto-striatal, fronto-limbic, and frontal-temporal alterations observed in schizophrenia (Table 37.2).

COGNITIVE PERFORMANCE IN CANNABIS-USING PATIENTS WITH SCHIZOPHRENIA

Considering the (mild) cognitive impairments associated with cannabis smoking, the logical expectation would be that schizophrenia patients who smoke cannabis (Sz + Can) would have more prominent cognitive deficits, compared to schizophrenia patients who do not smoke cannabis (Sz). More than 20 studies have been performed on the topic, and surprisingly, most of them have shown the opposite, namely that Sz + Can patients have *fewer* cognitive deficits than Sz patients (Table 37.3). It must be mentioned, however, that results have been inconsistent across studies, with a minority of studies showing that Sz + Can patients have *more* cognitive deficits than Sz patients, while others failed to show between-group differences (Table 37.3). Theoretically, this heterogeneity of results may reflect the heterogeneity of the recruited samples (schizophrenia, schizo-affective disorder and/or psychotic disorders), as well as the heterogeneous definitions of cannabis smoking status (use, heavy use, abuse, dependence; lifetime, current) (Table 37.3). However, the paradoxical cognitive performance of Sz + Can patients has been observed in various studies, regardless of diagnosis type, and of cannabis use frequency (Table 37.3).

In view of the diversity of results, systematic quantitative reviews have been performed (Table 37.4). Two of them focused solely on cannabis (Rabin, Zakzanis, George, 2011; Yücel et al., 2010), and both showed that cannabis smoking is associated with better cognitive functioning (eg, attention, planning, speed of processing, visual memory, and visuo-spatial abilities) in schizophrenia. Both reviews revealed between-group differences in the small-to-moderate range.

Interestingly, two metaanalyses examined the effects of other psychoactive substances on cognition in schizophrenia, which showed that the better cognitive performance of substance-using schizophrenia patients is mostly related to cannabis. In a metaanalysis of 23 studies, Potvin, Joyal, Pelletier, and Stip (2008) showed that substance-using patients had faster speed of processing, regardless of the substance used. Secondary analyses revealed that alcohol was associated with increased deficits in working memory; cocaine, with contradictory findings; and cannabis, with better global cognition. A subsequent metaanalysis from Donoghue and Doody (2012) showed that cannabis smoking is associated with better cognition in schizophrenia, and that cocaine use/abuse is associated with small-to-moderate impairments in verbal memory. Overall, the evidence suggests that alcohol and cocaine compromise cognition in schizophrenia, whereas cannabis is associated with better cognition. Noteworthy, a metaregression analysis performed by Potvin et al. (2008) showed that there is a negative relationship between age and cognition in substance-using schizophrenia patients. That is, older substance-using schizophrenia patients (>30 years) have worse cognitive functioning than schizophrenia-only patients, whereas younger substance-using schizophrenia patients have better cognition than schizophrenia-only patients. In these studies, older schizophrenia patients tended to prefer alcohol, whereas younger ones preferred cannabis. These results suggest that age × substance type interactions may explain heterogeneity in findings across studies.

SCHIZOPHRENIA, CANNABIS, AND COGNITION: THE FUNCTIONAL IMAGING STUDIES

Despite the wide interest in the psychosis-cannabis link, only six functional imaging studies have been performed in Sz + Can patients (Table 37.5). In the first two functional magnetic resonance imaging (fMRI) studies performed in schizophrenia patients with SUD, negative emotional stimuli were shown to patients while in the scanner (Mancini-Marië et al., 2006; Potvin, Mancini-Marië, Fahim, Mensour, & Stip, 2007). In both studies, schizophrenia patients with SUD had stronger emotional reactions than Sz patients, which translated into increased activations in the medial prefrontal cortex—which plays a critical role in self-relevancy processes. Unfortunately, both studies involved schizophrenia patients who abused both cannabis *and* alcohol. Moreover, the study lacked a control group, making it difficult to determine the exact meaning of the increased activations of the medial prefrontal cortex found in the substance-abusing group. Subsequently, Løberg et al. (2012) performed an fMRI study examining the neural correlates of attention in schizophrenia patients with and without lifetime cannabis smoking. The study showed that Sz + Can patients had increased activations in the posterior cingulate gyrus, the inferior parietal gyrus, and the precentral gyrus, compared to Sz patients. Again, the lack of a control group made it difficult to determine if Sz patients had hypoactivations, or if Sz + Can patients actually had hyperactivations during the task. Recently, our group performed

TABLE 37.3 Studies Showing Intact, Better, or Worse Cognition in Schizophrenia Patients Who Smoke Sannabis

Authors	N (cannabis only)	Mean age	Drugs assessed	Use profile	Illness profile	MATRICS domains	Main results	Confounding factors
Bahorik et al. (2013)	974 (128)	39.21 (drug users)	Cannabis, cocaine, and methamphetamine	Positive radioimmunoassay of hair for drug use	Sz diagnosis according to DSM-IV criteria	Reasoning/problem solving; speed of processing; verbal learning/memory; vigilance	No between group differences (cannabis use versus no drug use)	High male-to-female ratio in Sz + Can group
Coulston et al. (2007)	52 (18)	26.4 (Sz)	Cannabis	DSM-IV criteria for lifetime cannabis abuse/dependence. "High" frequency: at least weekly or more frequent basis "Medium" frequency: between two to four times per month	Diagnosis of Sz or schizoaffective disorder according to DSM-IV criteria	Attention; speed of processing; reasoning/problem solving; verbal learning/memory; visual learning/memory	Better attention, reasoning and problem solving and speed of processing in DD patients	
DeRosse et al. (2010)	455 (175)	37.3	Cannabis	Cannabis use disorder (abuse/dependence)	Sz or schizoaffective disorder	Verbal learning/memory; speed of processing	Better speed of processing/verbal fluency and verbal memory in DD patients	High male-to-female ratio in Sz + Can group
Ferraro et al. (2013)	119 (86)	29.6	Cannabis	Lifetime cannabis use (used at least once)	Affective psychosis and nonaffective psychosis diagnosis according to ICD-10 criteria for psychosis	Other: IQ	Higher current and premorbid IQ in psychotic patients who had smoked cannabis at least once	High male-to-female ratio in Sz + Can group
Jockers-Scherübl et al. (2007)	39 (19)	27.7	Cannabis	Cannabis abuse defined as having consumed an average of $\geq$ 0.5 g/day of cannabis for a minimum of 2 years before the onset of the disorder. Substance use disorders, other than cannabis, were excluded	Sz diagnosis according to DSM-IV criteria	Verbal learning/memory; attention; visual learning/memory; speed of processing; reasoning/problem solving; other: language abilities	Better language abilities and speed of processing in DD patients	High male-to-female ratio in Sz + Can group Younger in Sz + Can group
Leeson et al. (2012)	99 (65)	23.4	Cannabis	High-frequency cannabis users (daily or almost daily use), and low-frequency cannabis users (1–2 days/week to less than monthly). Substance misuse, other than cannabis, was excluded	First psychotic episode	Verbal learning/memory; working memory; reasoning/problem solving	Better on all measure for DD patients except on working memory	Younger in Sz + Can group

Lev-Ran et al. (2012)	28 (12)	18–45 n/a	Cannabis	Cannabis dependence diagnosis according to DSM-IV criteria. Substance use, other than cannabis, was excluded	Sz diagnosis according to DSM-IV criteria	Attention; visual learning/memory; working memory; reasoning/ problem solving	Worse sustained attention and speed of processing (shorter initial thinking time) in DD patients	
Løberg and Hugdahl (2009)	29 (13)	n/a	Cannabis	Current substance use and former substance use	Acute psychosis and Sz	Attention; reasoning/ problem solving; speed of processing; verbal learning/memory; working memory	Better attention, reasoning, and problem solving, speed of processing, verbal memory, and working memory in DD patients	
Mata et al. (2007)	132 (61)	23.4	Cannabis	Cannabis abuse: at least weekly use of cannabis during the previous year. Drug dependence was excluded	First episode of a schizophrenia-spectrum psychosis	Verbal learning/ memory; speed of processing; working, memory; reasoning/ problem solving; other: decision-making and IQ	Worse decision-making in DD patients	High male-to-female ratio in Sz + Can group Younger in Sz + Can group
Meijer et al. (2012)	956 (632)	27.3	Cannabis	Lifetime cannabis use and current use were included	Nonaffective psychosis	Verbal learning/ memory; attention/ vigilance; speed of processing; working memory; reasoning/ problem solving; social cognition	Poorer performance on verbal learning, processing speed and working memory in patients with current cannabis use. Better performance on acquired knowledge, facial affect recognition and social cognition in patients with lifetime cannabis use	High male-to-female ratio in Sz + Can group Younger in Sz + Can group
Rabin et al. (2011)	58 (18)	31.6	Cannabis	Current or former cannabis dependence diagnosis according to DSM-IV criteria	Sz or schizoaffective disorder diagnosis according to DSM-IV criteria	Attention; speed of processing; visual learning/ memory; verbal learning/memory; working memory; reasoning/ problem solving	Better psychomotor speed in patients with lifetime cannabis dependence	Younger in Sz + Can group
Ringen et al. (2010)	140 (23)	33.3	Cannabis	Cannabis abuse/dependency diagnosis according to DSM-IV criteria. Substance use other than cannabis in the previous 6 months was excluded	Sz, schizophreni-form disorder, or schizo-affective disorder diagnosis according to DSM-IV criteria	Speed of processing; attention; working memory; verbal learning/memory; reasoning/ problem solving	Worse reasoning and problem solving, verbal memory, and working memory in DD patients

TABLE 37.3 Studies Showing Intact, Better, or Worse Cognition in Schizophrenia Patients Who Smoke Sannabis (*cont.*)

Authors	N (cannabis only)	Mean age	Drugs assessed	Use profile	Illness profile	MATRICS domains	Main results	Confounding factors
Ringen et al. (2013)	364 (57)	31.2	Cannabis	Lifetime DSM-IV diagnosis of cannabis abuse/addiction. Cannabis-positive urine group (n = 21) was compared to cannabis-negative urine group (n = 343)	Sz, schizophreniform disorder, and schizoaffective disorder diagnosis according to DSM-IV criteria	Speed of processing; attention; working memory; verbal learning/memory; reasoning/problem solving; other: IQ	No between-group differences after adjusting for premorbid functioning	
Rodríguez-Sánchez et al. (2010)	104 (47)	23.6	Cannabis	Cannabis use: at least weekly use of cannabis during the previous year. Drug dependence was excluded	First episode of nonaffective psychosis	Verbal learning/memory; visual learning/memory; speed of processing; working memory; attention; reasoning/problem solving	Better speed of processing in DD patients	High male-to-female ratio in Sz + Can group Younger in Sz + Can group
Sánchez-Torres et al. (2013)	42 (n/a)	37.02	Cannabis, alcohol, stimulants, other drugs (eg, opioids) and tobacco use	Lifetime cannabis use, excluding patients with a diagnosis of cannabis dependence	Sz, schizoaffective disorder, psychotic mood disorder and brief psychotic disorder	Speed of processing; attention/vigilance; working memory; social cognition; reasoning/problem solving	Lifetime cannabis consumption was not associated with negative cognitive outcomes Lifetime cannabis consumption was associated to a negative effect on performance in a social cognition task	
Schnell et al. (2009)	69 (35)	27.1	Cannabis	Cannabis abuse/dependence diagnosis according to DSM-IV criteria. No additional substance use disorders, except for nicotine, were included	Sz or schizoaffective disorder diagnosis according to DSM-IV criteria	Verbal learning/memory; working memory; visual learning/memory; attention; speed of processing; reasoning/problem solving; other: IQ	Better speed of processing, verbal memory and working memory in DD patients.	
Scholes and Martin-Iverson (2010)	71 (22)	35.8	Cannabis	Current use of cannabis	Sz or schizo-affective disorder diagnosis	Attention; working memory; reasoning/problem solving	No between-group differences	

Sevy et al. (2007)	27 (14)	29.0	Cannabis	Current DSM-IV diagnosis for cannabis abuse/dependence, and having cannabis as the main drug of choice	Sz or schizoaffective disorder diagnosis according to DSM-IV criteria. Substance induced psychotic disorder was excluded	Visual learning/ memory; working memory; attention; verbal learning/ memory; speed of processing	Better working memory in DD patients	
Wobrock et al. (2013)	498 (115)	23.9 (drug users)	Cannabis, cocaine, amphetamine or other stimulants, heroin, XTC, LSD or other hallucinogens	Current or former substance use disorder (abuse/dependence) diagnosis according to DSM-IV criteria	First episode of Sz, schizophreniform disorder, and schizoaffective disorder diagnosis according to DSM-IV criteria	Verbal learning/ memory; speed of processing; attention; visual learning/memory; other: complex visual scanning	Better complex visual scanning and psychomotor speed and reasoning/ problem solving (cognitive flexibility) with longer duration of cannabis use	High male-to-female ratio in Sz + Can group Younger in Sz + Can group
Yücel et al. (2010)	85 (59)	20.7	Cannabis	Regular cannabis use (defined as >2 years of use and >2 g/week)	First-episode psychosis	Speed of processing; attention; working memory; verbal learning/memory; reasoning/ problem solving	Better reasoning/ problem solving and working memory in DD patients	

This table summarizes the studies reporting that patients with both schizophrenia and cannabis smoking have intact, better or worse cognition. The relevant cognitive domains are cited.

TABLE 37.4 Systematic Quantitative Reviews on the Cognitive Effects of Psychoactive Substances in Schizophrenia Patients

Authors	Number of studies	Substances	MATRICS?	Main results
Donoghue and Doody (2012)	21	11 on polysubstance, seven studies on cocaine, three on cannabis	No	For polysubstance: • Substance users performed better on verbal learning and memory, executive function, and attention and psychomotor speed, and worse on spatial working memory task than nonusers For cocaine: • Cocaine users performed better on attention and psychomotor speed, and worse on verbal learning and memory than nonusers For cannabis: • Cannabis users performed better on executive function, attention and psychomotor speed, and verbal learning and memory than nonusers
Potvin et al. (2008)	28	Mixed psychoactive substances	Yes	Individuals with comorbid substance use had faster speed of processing Secondary analyses revealed significant associations with age and substance type
Rabin et al. (2011)	8	Cannabis	No	Patients smoking cannabis were better in all domains assessed: general cognitive ability and intelligence, sustained and divided attention, executive abilities, working memory, learning, retrieval and recognition, receptive and expressive language abilities, and visuo-spatial and constructional abilities
Yücel et al. (2010)	10	Cannabis	Yes	Patients smoking cannabis had better processing speed, visual memory, working memory, executive functioning, and sustained attention

This table summarizes the systematic reviews that investigated the effects of psychoactive-substances on the cognitive domains known to be impaired in schizophrenia.

two fMRI experiments in 14 Sz + Can patients, 14 Sz patients, and 21 healthy volunteers. Patients with schizoaffective or schizophreniform disorders were excluded, as well as those receiving antidepressants, and those who abused other psychoactive substances than cannabis. In a first experiment, participants performed an emotional memory task. At the cognitive level, Sz + Can patients had a better mnesic performance than Sz patients, but a poorer performance than healthy controls. Neurally, both patient groups had hypoactivations, compared to controls—again, with Sz + Can patients showing more activation than Sz patients, for both negative and positive stimuli (Figs. 37.1 and 37.2). However, Sz + Can patients had increased activations in the dorso-lateral prefrontal cortex, compared to Sz patients (Bourque et al., 2013). In a second experiment, participants performed a mental rotation task that measures visuo-spatial abilities. Although both patient groups performed worse than controls on the mental rotation task, Sz patients had decreased activations in the superior parietal gyrus, whereas the functioning of this region was normal in Sz + Can patients (Potvin et al., 2013). Taken together, these preliminary fMRI results *tentatively* suggest that the brain functioning of Sz + Can patients is less impaired than that of Sz patients.

EXPLANATORY MODELS

To explain these seemingly paradoxical results, three main models have been proposed: the neuro-protection hypothesis, the social hypothesis, and the hypothesis of a lower vulnerability to psychosis in Sz + Can patients. Whereas the first hypothesis postulates that the better cognition of Sz + Can patients is caused by cannabis smoking, the latter two hypotheses propose, on the contrary, that the better cognitive performance of some Sz patients is primary, not secondary, to cannabis smoking.

The Neuro-Protection Hypothesis

The first model trying to explain these seemingly paradoxical findings is a neurobiological one. In preclinical studies, it has been shown that cannabinoids have anti-inflammatory, antioxidant, and neuroprotective effects, and that the endocannabinoid system (Pertwee, 2005), which mediates the effects of cannabis in the brain, is critically involved in various neurodevelopmental processes (neuronal specification, axonal elongation, and synaptogenesis) (Sarne & Mechoulam, 2005). Thus, it

TABLE 37.5 Neurofunctional Alterations in Cannabis-Using Schizophrenia Patients

Authors	Population	Task	Main results	Confounds/limitations
Bourque et al. (2013)	21 healthy controls; 14 Sz patients; 14 Sz patients with CUD	Emotion recognition (positive and negative images)	• Better emotion recognition in cannabis-abusing Sz patients • Increased dlPFC activations in the cannabis-abusing Sz patients, compared to nonusing Sz patients	Lack of a group of nonpsychosis cannabis abusers
Løberg et al. (2009)	26 Sz patients; 13 cannabis users; 13 nonusers	Auditory dichotic listening task	• Increased activations of the PCC, the inferior parietal gyrus and the precentral gyrus in the cannabis-using group	Lack of a control group of healthy volunteers; lack of a group of nonpsychosis cannabis users
Mancini-Marië et al. (2006)	11 Sz patients; 12 Sz patients with SUD (cannabis and alcohol)	Aversive emotional pictures	• Higher emotional ratings in substance abusing Sz patients • Increased activations in the mPFC in Sz patients with SUD	Sz patients were also abusing from alcohol; lack of a control group of healthy volunteers; lack of a group of nonpsychosis cannabis users
Potvin et al. (2013)	21 healthy controls; 14 Sz patients; 14 Sz patients with CUD	Mental rotation task	• Decreased activations of the superior parietal gyrus in Sc patients without CUD, compared to controls	Lack of a group of nonpsychosis cannabis abusers
Potvin et al. (2007)	11 Sz patients; 12 Sz patients with SUD (cannabis and alcohol)	Social emotions (sad movie clips)	• Higher emotional ratings in substance abusing Sz patients; • Increased activations in the mPFC	Sz patients were also abusing from alcohol; lack of a control group of healthy volunteers; lack of a group of nonpsychosis cannabis users

This table summarizes the results of the functional brain imaging studies performed in schizophrenia patients using cannabis
Abbreviations: *Sz*, schizophrenia; *CUD*, cannabis use disorder; *dlPFC*, dorsolateral prefrontal cortex; *PCC*, posterior cingulate cortex; *SUD*, substance-use disorder; *mPFC*, medial prefrontal cortex.

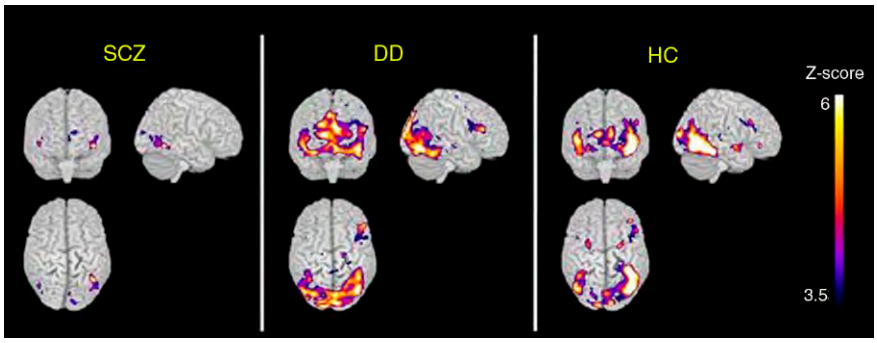

FIGURE 37.1 **Brain activation corresponding to recognition of negatively valenced images.** *SCZ*, schizophrenia group without cannabis abuse; *DD*, schizophrenia group with cannabis abuse; *HC*, healthy controls. *Source: Adapted from Bourque et al. (2013) with permission from the publishers.*

can be hypothesized that cannabis may improve cognition in schizophrenia due to its neuroprotective properties. Although intriguing, this hypothesis seems unlikely, for three main reasons. First of all, cannabinoids produce cognitive impairments, not cognitive enhancement effects, in individuals who do not suffer from psychiatric disorders. Moreover, functional imaging studies have shown that cannabinoids produce brain alterations similar to those seen in schizophrenia patients performing executive or memory tasks. Finally, D'Souza et al. (2004, 2005) administered Δ^9-THC to healthy participants and to schizophrenia patients, and found that Δ^9-THC impaired verbal memory, attention, verbal fluency, and working memory in healthy participants, and that

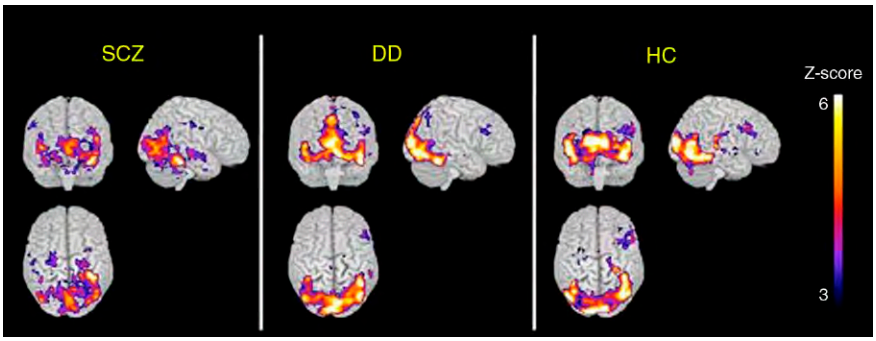

FIGURE 37.2 **Brain activation corresponding to recognition of positively valenced images.** *SCZ*, schizophrenia group without cannabis abuse; *DD*, schizophrenia group with cannabis abuse; *HC*, healthy controls. *Source: Adapted from Bourque et al. (2013) with permission from the publishers.*

it impaired verbal memory and attention in schizophrenia patients. More importantly, the trial showed that the amnesic effects of Δ^9-THC were more pronounced in schizophrenia patients than in controls. These results suggest that acute Δ^9-THC intoxication has more deleterious cognitive effects in schizophrenia than it does in nonpsychiatric individuals. Such results are inconsistent with the notion that cannabinoids may improve cognitive performance in schizophrenia.

The Social Hypothesis

An alternative hypothesis proposes that the better cognitive performance of Sz + Can patients has to do with the set of skills required to sustain the lifestyle of substance use. In order to get substances, the user needs to be able to manage money, to make contacts with dealers, and to strike deals—which means that minimally, intact relational, emotional, and cognitive abilities are required. According to this alterative hypothesis, first proposed by Mueser et al. (2000), the better cognitive performance of Sz + Can patients would not be the result from the pharmacological effects of cannabis, but would rather reflect a difference *primary* to cannabis use/abuse. One of the main implications of this hypothesis is that cognitive results should vary, based on the difficulty to access the substance. According to this hypothesis, Sz + Can patients should perform cognitively better than Sz patients in countries where cannabis is illegal or less common, but not in countries where cannabis smoking has been prevalent for many years. However, two main criticisms can be raised against this hypothesis. First, cannabis is now a substance easily accessible in many Western countries, regardless of its legal status (Schnell, Koethe, Daumann, & Gouzoulis-Mayfrank, 2009). Second, although cocaine is a psychoactive substance harder to access than cannabis, it is cannabis smoking that is associated with better cognition in schizophrenia, not cocaine use.

The Lower Vulnerability Hypothesis

A final hypothesis proposes that the relatively better cognition of Sz + Can patients reflects a lower vulnerability to psychosis (Schnell et al., 2009). According to this hypothesis, the paradoxical performance of Sz + Can patients has to be interpreted in light of the studies showing that cannabis smoking is a risk factor for psychosis outcomes (Moore et al., 2007). As explained by Schnell et al. (2009), one of the plausible implications of the literature showing that cannabis increases the risk for psychosis is that Sz + Can patients might have not developed schizophrenia had they not regularly smoked cannabis. From a developmental perspective, the vulnerability to psychosis, during the prodromal phase, may be lower in Sz + Can patients than it is in Sz patients, who go on to develop schizophrenia in the absence of the effects of cannabis. If so, we would expect Sz + Can patients to have milder deficits on core features of schizophrenia, such as cognitive impairments, especially during the early phase of the disorder.

As in the case of the social hypothesis, the lower vulnerability hypothesis assumes that the paradoxical cognitive performance of Sz + Can patients reflects a difference primary, not secondary, to cannabis use/abuse in schizophrenia. Obviously, only longitudinal studies performed in adolescents, before the onset of the disorder, could resolve this critical issue. Meanwhile, Ferraro et al. (2013) have shown that Sz + Can patients have higher premorbid IQ than Sz patients, a fact that raises the possibility that the better cognitive performance of Sz + Can patients is explained by this premorbid difference.

STUDY LIMITATIONS

Although the current state of the literature suggests that Sz + Can patients have better cognitive functioning than Sz patients, it is important to keep in mind that group differences are not of a large magnitude.

Additionally, the literature is plagued with limitations that will need to be addressed before concluding that it is a proven fact that cannabis smoking is associated with better cognition in schizophrenia. Thus far, most studies in the field have measured a limited number of cognitive functions that do not cover the whole range of cognitive dysfunctions associated with schizophrenia. Importantly, only a few studies have measured sociocognitive variables in Sz + Can patients, although social cognition deficits significantly impede upon recovery and rehabilitation in schizophrenia. Similarly, only a few studies have measured inferior executive functions in Sz + Can patients, although deficits in emotional decision-making, risk-taking, response inhibition, and delay discounting are core features of SUD (Potvin, Stavro, Rizkallah, & Pelletier, 2014; Stavro, Pelletier, & Potvin, 2013). A notable exception is the study from Mata et al. (2008) that measured emotional decision-making, and found that cannabis smoking in schizophrenia was associated with poorer performance.

Another limitation of the literature is that the grouping of Sz patients into cannabis smokers and nonsmokers has relied, most of the time, on self-report, and that smoking status has not been confirmed by urine drug analyses. Moreover, the quantities of cannabis smoked by patients have not been measured in most studies, and insufficient attention has been paid to the potential influence of other psychoactive substances. Deficits in attention, episodic memory, executive functions,, and speed of processing have been consistently observed in nonpsychiatric individuals with alcohol use and cocaine use disorders (Potvin et al., 2014; Stavro et al., 2013). In addition, alcohol use disorders have been shown to exacerbate the cognitive deficits of schizophrenia, while cocaine intake has been associated with mixed findings. As a result, the unreliable measurement of those substances, in either Sz + Can or Sz patients, may significantly confound results.

Socio-demographic variables may also have influenced study outcomes. For instance, in close to 50% of studies, the Sz + Can group had an elevated male-to-female ratio, compared to the Sz group (see Table 37.3). Theoretically, this between-group difference may explain some of the discrepancies in results, since there are subtle effects of sex-differences on cognition in schizophrenia (Mendrek & Stip, 2011). Similarly, in close to 50% of studies, Sz + Can patients were younger than Sz patients (see Table 37.3). Theoretically, it may be hypothesized that Sz + Can patients outperform Sz patients simply because they are younger. Although very plausible, both explanations do not necessarily rule out the presence of a real difference between Sz patients with and without cannabis smoking. Indeed, a better performance of Sz + Can patients, compared to Sz patients, has been found in studies in which the sex ratio did not differ between groups, as well as in studies in which Sz + Can patients were not younger than Sz patients (see Table 37.3).

Arguably, one of the main limitations of the literature on the cognitive effects of cannabis smoking in schizophrenia is that all studies have employed cross-sectional design thus far. While attempts at controlling for premorbid functioning have improved the methodological quality of studies, these attempts are not sufficient to paint a clear picture of the effect of cannabis on cognition in schizophrenia. Ideally, longitudinal studies initiated in adolescence until early adulthood in individuals with and without psychotic vulnerability, with and without cannabis smoking, would be required. However, given the low prevalence of schizophrenia, such studies would require very large sample sizes that could possibly compromise feasibility. In the meantime, it would be highly needed to perform longitudinal studies in first-episode schizophrenia patients, with and without cannabis smoking, and to measure their cognitive performance both when they are smoking cannabis, and after they stop. If the better cognitive performance of Sz + Can patients is not secondary to cannabis use, then, Sz + Can patients should have better cognition then Sz patients not only when they are actively smoking, but also after they cease.

CONCLUSIONS

Cognitive dysfunctions are core features of schizophrenia, significantly impeding upon social and occupational functioning in these patients. A significant risk factor for psychosis, cannabis smoking is highly prevalent in schizophrenia. In nonpsychosis individuals, cannabis smoking has been shown to impair cognition, and to alter the functioning of brain networks known to be impaired in schizophrenia. Paradoxically however, most studies performed in Sz + Can patients have shown that cannabis smoking is associated with better, not worse, cognition in schizophrenia. Due to the cross-sectional nature of studies, it remains to be determined if the better cognitive functioning of Sz + Can patients is primary or secondary to cannabis smoking. In the future, large-scale longitudinal studies will need to be performed in psychosis-prone and schizophrenia patients who smoke cannabis.

MINI-DICTIONARY

Comorbid A disorder that co-occurs with another one is said to be comorbid.
Endo-phenotype Traits that are purported as having a genetic component.
Mnesic Pertaining to memory.
Negative symptoms Deficient emotional and behavioral responses that are normally present in individuals from the general population. Example: amotivation.

Neurocognition Includes speed of processing, attention/vigilance, working memory, verbal and visual learning, as well as reasoning and problem solving.
Neuroprotection Refers to the preservation of functions and/or structures of the central nervous system.
Positive symptoms Ideas and perceptions that are not usually present in individuals from the general population, such as delusions and hallucinations (eg, hearing voices).
Prodromal Early symptoms preceding the onset of the disease.
Self-relevancy Something that has strong implications for an individual.
Socio-cognition Refers to how people process, store, and apply social information. Includes social knowledge, emotion recognition, Theory of Mind, attribution style, as well as emotion regulation.

CHAPTER

38

The Long-Lasting Effects of Cannabis Use on Movement and Brain Regions that Control Movement

G. Todd, J.M. White

School of Pharmacy and Medical Sciences, University of South Australia, Adelaide, SA, Australia

SUMMARY POINTS

- This chapter focuses on the long-lasting effects of cannabis use on movement and movement-related brain regions.
- Very few studies have investigated movement in individuals with a history of cannabis use.
- History of cannabis use is associated with abnormal performance of rhythmical movement, but tremor is unaffected.
- Subtle changes in the integration of sensory and motor information also appear to be evident in abstinent cannabis users.
- Not all types of movement have been investigated in individuals with a history of cannabis use.
- Long-lasting abnormalities in movement-related brain regions in former cannabis users suggest that other movement abnormalities are likely to be present.
- Further research is needed to fully understand the long-lasting consequences of cannabis use on movement, and the clinical implications of movement dysfunction.

KEY FACTS OF MOVEMENT

- The control of movement involves much of the central and peripheral nervous system.
- Several steps are involved.
- The conscious "will" to move is followed by formation of a movement plan.
- The movement plan involves coordinated activation of muscles involved in the task, and those involved in stabilizing the limbs and maintaining posture and balance.
- The movement plan is stored and then implemented at the appropriate time.
- Ongoing adjustment of movement in response to internal and external factors (via afferent feedback) takes place during each phase of the movement.
- We are generally unaware of these steps, and they occur over many milliseconds.
- Damage or disease to an area of the nervous system involved in movement usually results in movement dysfunction.

INTRODUCTION

In recent years, there has been considerable advancement in the understanding of the effect of cannabis use on cognition, mental health, and a range of behaviors. However, very little is known about a behavior that plays a key role in activities of daily living: movement. Many of the movements that we perform each day happen without the need to engage a large amount of conscious thought. For example, once we decide to make ourselves a cup of coffee, we perform the required sequence of movements without consciously assessing our grip on the spoon or the trajectory of the cup to our mouth. This would seem to imply that movement may be a simple brain function, but the planning, initiation, and ongoing adjustment of movement are complex, and involve much of the central and peripheral nervous system. Changes in any one of the regions involved in movement can lead to movement dysfunction.

In this chapter, the long-lasting effects of cannabis use on movement and movement-related brain regions will be discussed. The discussion on movement will focus on knowledge gained from studies involving (1) objective assessment of movement in humans, and (2) participants with a history of cannabis use, but no history of illicit stimulant use. Use of illicit stimulant drugs, such as methamphetamine, ecstasy, and cocaine, is associated with acute and long-lasting changes in monoamine neurotransmission in movement-related brain regions (Benowitz, 1993; Green, Mechan, Elliott, O'Shea, & Colado, 2003; Yamamoto, Moszczynska, & Gudelsky, 2010). The existing literature on the long-lasting effects of other drugs is less clear. The literature on animal movement will not be discussed in detail because it is not readily transferable to humans, due to large differences in movement between species, particularly in gait (bipedal versus quadrupedal) and hand dexterity.

Before considering the long-lasting effects of cannabis use on movement, it is important to have an understanding of the acute effects of cannabis on movement in healthy adults.

ACUTE EFFECTS OF CANNABIS ON MOVEMENT

Not all types of movement are affected by acute cannabis use. However, use of the hand appears to be particularly vulnerable to cannabis intoxication. The ability to track a moving target on a computer screen with movements of the hand (ie, visuomotor tracking) is impaired for up to 7 h after cannabis use (eg, Barnett, Licko, & Thompson, 1985; Kiplinger, Manno, Rodda, & Forney, 1971; Manno, Kiplinger, Scholz, & Forney, 1971; Weil, Zinberg, & Nelsen, 1968; cf Zuurman et al., 2008).

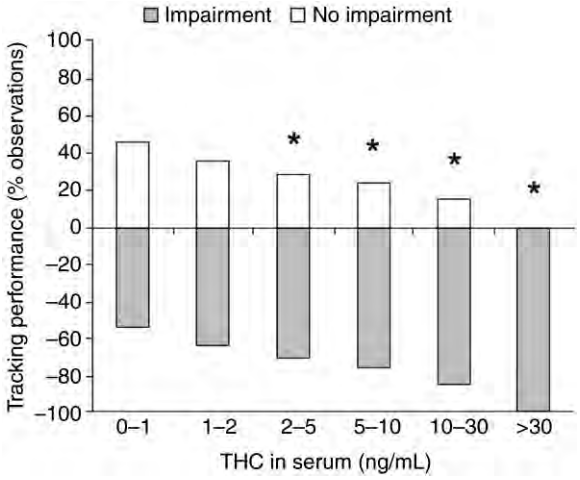

FIGURE 38.1 Acute changes in performance of a visuomotor tracking task after cannabis administration. Performance at varying levels of plasma Δ^9-THC are shown. Data are distribution of observations showing performance "impairment" (negative change score from placebo) and "no impairment" (change score equal to or greater than zero).*, $P < 0.05$. *Reprinted from Ramaekers et al. (2006) with permission from Elsevier.*

Fig. 38.1 shows that significant impairment in visuomotor tracking is evident at low levels (eg, 2–5 ng/mL) of plasma Δ-9-Tetrahydrocannabinol (Δ^9-THC), and the magnitude of impairment increases with increasing level of plasma Δ^9-THC (Ramaekers et al., 2006). Acute decreases in the frequency of maximal finger tapping (plasma Δ^9-THC level: 1–2 ng/mL) (Roser et al., 2009) and accuracy of hand movement (Milstein, MacCannell, Karr, & Clark, 1975), and a dose-related increase in reaction time and motor response time have also been observed after cannabis administration (Borg, Gershon, & Alpert, 1975).

Cannabis use is also associated with acute disturbances in balance (Evans et al., 1973; Kiplinger et al., 1971). Balance is commonly assessed by measurement of body sway during quiet standing with the eyes closed. Zuurman et al. (2008) measured balance up to 90 min after incremental doses of cannabis that resulted in plasma Δ^9-THC levels of approximately 10, 30, 45, and 65 ng/mL, respectively. Fig. 38.2 shows that body sway increases when plasma Δ^9-THC levels exceed 30 ng/mL (Zuurman et al., 2008), suggesting that cannabis use disturbs balance in a concentration-dependent manner.

Acute changes in the control of eye movement (Fant, Heishman, Bunker, & Pickworth, 1998; Ploner et al., 2002; Zuurman et al., 2008), speech production (prolonged pause and syllable length) (Zeidenberg et al., 1973), and level of physical activity (Babor, Mendelson, & Kuehnle, 1976) have also been reported after cannabis use (plasma Δ^9-THC: >3 ng/mL and cannabis cigarette, respectively). It is important to note that the acute effects of cannabis on movement are influenced by the dose and population investigated (naïve or experienced cannabis

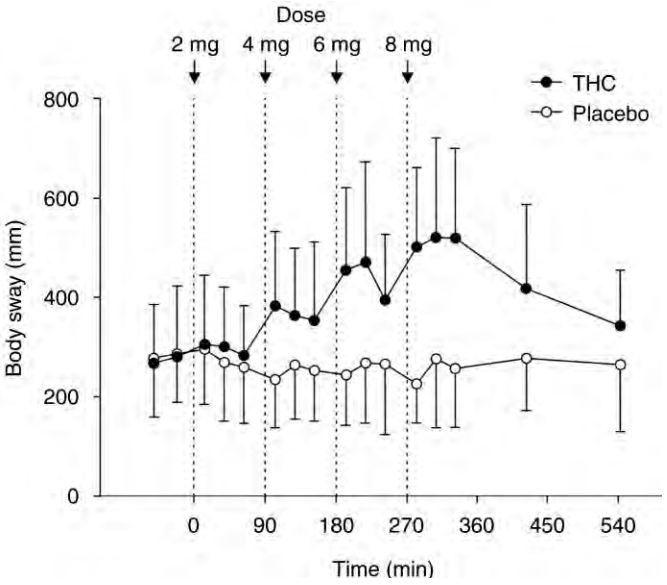

FIGURE 38.2 The acute effect of inhaled THC extract on balance (body sway). Group data are mean + SD. Four incremental doses (2, 4, 6, 8 mg THC) were administered at 0, 90, 180, and 270 min, resulting in plasma Δ^9-THC levels of approximately 10, 30, 45, and 65 ng/mL, respectively. *Adapted from Zuurman et al. (2008) with permission from Elsevier.*

users) (for review see Moskowitz, 1985). Objective investigation of gait immediately after cannabis use has not been conducted, and grip strength (Steadward & Singh, 1975), skin sensation (Milstein, Maccannell, Karr, & Clark, 1974), maximum number of finger or foot taps performed in 10 s (Milstein et al., 1975), and subjective assessment of tremor appear to be unchanged up to 24 h after cannabis use (Kurzthaler et al., 1999).

The underlying mechanism responsible for the change in movement is difficult to differentiate from the acute effect of cannabis on attention (eg, Hunault et al., 2009). Attention is known to affect performance on visuomotor tracking tasks, independent of cannabis use (Kam et al., 2012). However, several pieces of evidence suggest that cannabis has a direct effect on movement. First, the density of CB_1 receptors is high in brain regions that are involved in movement, particularly in the basal ganglia, cerebral cortex, and cerebellum (Howlett et al., 2002), and CB_1 receptors are present in the dorsal and ventral horn of the spinal cord in primates (Ong & Mackie, 1999). Second, activation of presynaptic CB_1 receptors in the central and peripheral nervous system can inhibit neurotransmitter release. For example, reduced GABAergic transmission is evident in several rat brain structures after administration of Δ^9-THC (Maneuf, Nash, Crossman, & Brotchie, 1996), including brain regions involved in movement (Chan, Chan, & Yung, 1998). Reduced $GABA_A$-mediated intracortical inhibition is evident in human motor cortex when plasma Δ^9-THC levels exceed 2 ng/mL in heavy cannabis users (Fitzgerald, Williams, & Daskalakis, 2009). Third, cannabis use is associated with acute changes in baseline regional cerebral blood flow in the frontal, insular, and anterior cingulate cortex (Mathew et al., 2002), and in the motor cortex and cerebellum during an auditory reaction time task (O'Leary et al., 2002).

CHANGES IN MOVEMENT FOLLOWING LONG-TERM CANNABIS USE

Repeated cannabis use over a long period of time is also associated with long-lasting changes in the neurophysiology of movement-related brain regions. Studies involving transcranial magnetic brain stimulation suggest that history of cannabis use is associated with changes in the excitability of circuitry in the motor cortex and corticomotoneuronal pathway in conscious humans. Fig. 38.3 shows that $GABA_A$-mediated short-interval intracortical inhibition in motor cortex is reduced for up to 7 days after cannabis use, in individuals with a history of moderate to heavy use (1–4 times per week) (Fitzgerald et al., 2009), but not in individuals with a longer duration of abstinence (average 0.7 ± 1.6 years) (Flavel, White, & Todd, 2012b). Conversely, there does not appear to be

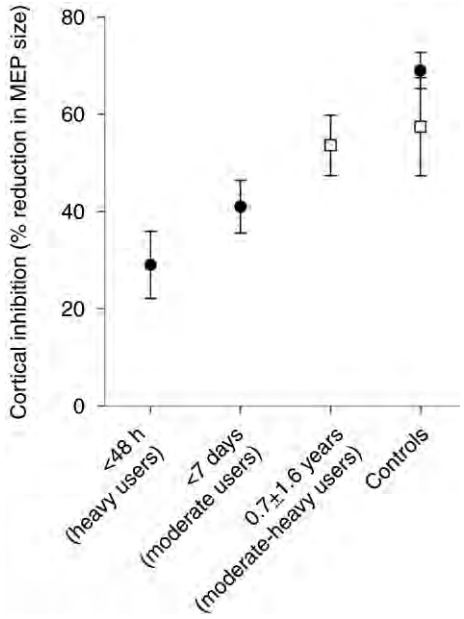

FIGURE 38.3 Short-interval intracortical inhibition in the motor cortex of cannabis users and nondrug using control subjects. Short-interval intracortical inhibition was measured in the hand region of the motor cortex with paired-pulse transcranial magnetic brain stimulation (2 ms interstimulus interval). The intensity of the conditioning pulse was set at approximately 70% of resting motor threshold, and the intensity of the test pulse was set to evoke a motor-evoked potential of approximately 1 mV in amplitude. Group data are mean ± SEM and are derived from Fitzgerald et al. (2009; *circles*) and Flavel et al. (2012b; *squares*). The *x*-axis labels indicate lifetime use and duration of abstinence from cannabis use.

an acute or long-lasting change in resting corticomotoneuronal excitability and $GABA_B$-mediated intracortical inhibition within motor cortex (ie, cortical silent period). However, there is a trend for increased corticomotoneuronal excitability during movement in individuals who have been abstinent from cannabis for 0.7 ± 1.6 years (Flavel et al., 2012b). Prolongation of the latency of the response evoked by transcranial magnetic stimulation in abstinent cannabis users also suggests altered conduction of descending cortical volleys (Flavel et al., 2012b).

Neuroimaging suggests that cannabis use is associated with long-lasting changes in brain activation, metabolism, and regional cerebral blood flow. Studies involving positron emission tomography and magnetic resonance spectroscopy suggest that chronic cannabis users exhibit decreased glutamate in the basal ganglia (Chang, Cloak, Yakupov, & Ernst, 2006), and changes in regional blood flow, metabolism, and activation in movement-related brain regions, particularly the cerebellum (for review see Batalla et al., 2013).

It is unclear if the long-lasting changes in neurophysiology of movement-related brain regions are accompanied by changes in brain morphology. Morphometric magnetic resonance imaging studies show no change in gray and white matter volume (Block et al., 2000; Tzilos et al., 2005), but studies involving voxel-based morphometry suggest that gray matter density is decreased in the right parahippocampal gyrus, and increased in the precentral gyrus and thalamus of abstinent (20 days) heavy cannabis users (Matochik, Eldreth, Cadet, & Bolla, 2005). The morphology of the substantia nigra, viewed with transcranial ultrasound, is unaltered in abstinent cannabis users (Todd et al., 2013). However, decreased white matter density has been observed in chronic cannabis users (Matochik et al., 2005). The morphological findings have not been uniform across studies, and factors such as current age, age of first cannabis use, history of cannabis use, and duration of abstinence from cannabis may have contributed to variability in the findings.

There is evidence that long-lasting changes in the neurophysiology of movement-related brain regions in abstinent cannabis users have functional consequences for certain types of movement. Movement speed and rhythmicity is abnormal in abstinent cannabis users during maximal finger tapping, a task that is used widely in clinical and experimental settings to assess motor changes associated with a range of neurological disorders. Individuals that had abstained from heavy cannabis use for 28 days exhibited reduced performance on a 10 s finger tapping task. Heavy cannabis users (78–117 joints per week; $n = 7$) performed 45–47 taps in 10 s, less than individuals with a history of light (2–14 joints per week; 49–51 taps, $n = 7$) to moderate (18–70 joints per week; 49–50 taps, $n = 8$) cannabis use. However, the effect only reached statistical significance on the left side, possibly due to the small sample size ($n = 7$–8 per group) (Bolla, Brown, Eldreth, Tate, & Cadet, 2002). The finding needs to be interpreted with care because the study lacked a nondrug using control group, and history of other illicit drug use was not reported.

Our group explored long-lasting changes in movement speed and rhythmicity, further, by investigating finger tapping in abstinent cannabis users with no history of illicit stimulant or opioid use, and nondrug using controls. Fig. 38.4 shows that abstinent cannabis users exhibit a slow onset frequency of tapping, and increased variability of tapping over a 5 s period, but the overall number of taps performed did not differ between groups (Flavel, White, & Todd, 2013). The abnormality appeared to be long-lasting (it was observed in individuals that had been abstinent from cannabis for 0.6 ± 1.6 years), and was observed in individuals with normal neuropsychological performance (Flavel et al., 2013). Slow initial speed of finger movement is likely to contribute to the prolonged reaction time observed on simple tasks in abstinent heavy cannabis users (Bolla et al., 2002).

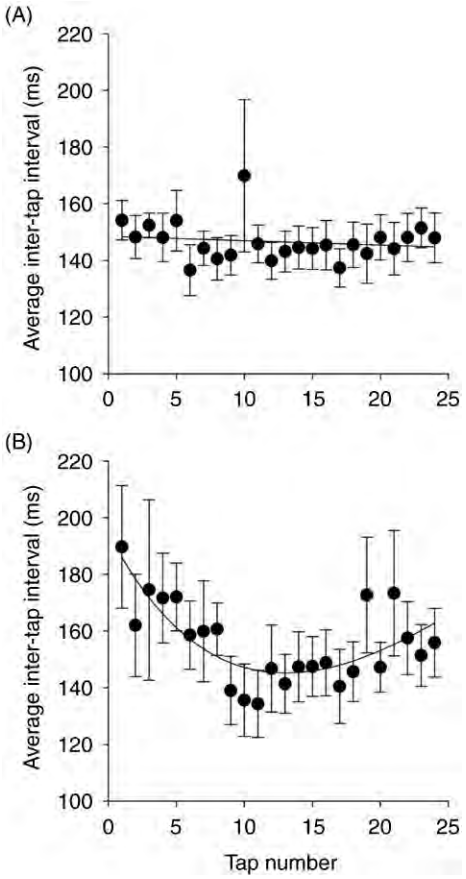

FIGURE 38.4 **Relationship between performance (intertap interval) and time (tap number) during a maximal finger tapping task (duration 5 s).** (A) Nondrug control group with linear regression. (B) Abstinent cannabis users with exponential regression. Group data are mean + SEM. *Reprinted from Flavel et al. (2013) with permission from John Wiley and Sons.*

Cannabis use may also be associated with long-lasting changes in sensorimotor integration, and hand dexterity. A study on a small group of abstinent (28 days) cannabis users found a correlation between lifetime cannabis use and performance on the grooved pegboard test. The grooved pegboard test involves placing 25 key-shaped pegs into corresponding holes, as fast as possible. Performance declined with increasing lifetime cannabis use (joints per week) but the effect only reached statistical significance on the nondominant hand (Bolla et al., 2002). The effect is unlikely to be related to peripheral changes in skin sensation, because acute cannabis use does not affect tactile acuity (two-point discrimination) or sensitivity to touch (Milstein et al., 1974). Another study involving subjects with a longer period of abstinence from cannabis use (52 ± 17 months) reported unaltered performance on the grooved pegboard test (Chang et al., 2006).

Cannabis use does not have a long-lasting effect on all types of movement. The amplitude and frequency of tremor during relaxation and movement of the hand appears to be normal in abstinent individuals with a history of cannabis use (Flavel, Koch, White, & Todd, 2012a). The level of daily physical activity also does not differ between adults with a history of moderate to heavy cannabis use and nondrug using controls (Babor et al., 1976). Further research is needed to fully understand the long-lasting consequences of cannabis use on movement, and the clinical implications of movement dysfunction.

CONCLUSIONS

Investigation of the long-lasting effect of cannabis use on movement is challenging. The studies undertaken so far have been cross sectional in design and, thus, interpretation of the data has been limited to an association between history of cannabis use and movement dysfunction. Studies with a longitudinal design are needed to eliminate the possibility that movement dysfunction predated onset of cannabis use. It is also important to study movement in cannabis users that have *no* history of illicit stimulant use. Illicit stimulant drugs, such as methamphetamine, ecstasy, and cocaine, are associated with acute and long-lasting changes in monoamine neurotransmission (for review, see Boghdadi & Henning, 1997; Green et al., 2003; Yamamoto et al., 2010). Methamphetamine in particular is associated with damage to dopaminergic neurons, and the importance of dopaminergic neurons in movement is evidenced by the symptoms associated with Parkinson's disease, a disease that is characterized by loss of dopaminergic neurons in the substantia nigra (Fearnley & Lees, 1991). Even minimal use of illicit stimulant drugs has the potential to cause long-lasting changes in movement-related brain regions, if the dose is sufficiently high. Thus, the results of studies performed on subjects that were "not dependent" on other illicit drugs, or lack information on use of other illicit drugs, need to be interpreted with care. Other factors that need to be considered include possible tolerance to the impairing effects of cannabis in daily cannabis users (for review see Gonzalez, Cebeira, & Fernandez-Ruiz, 2005), age of first cannabis use, and higher rates of symptoms of depression (eg, Lev-Ran et al., 2014; Roebke, Vadhan, Brooks, & Levin, 2014; Todd et al., 2013), and lifetime use of alcohol and tobacco (eg, Fletcher et al., 1996; Todd et al., 2013) in cannabis users, compared to controls.

The long-lasting effects of cannabis use on movement and movement-related brain regions also need to be considered in the proposed therapeutic use of cannabis in patients with certain neurological disorders. Although the effects of cannabis use on movement tend to be negative in otherwise healthy subjects, studies suggest that cannabis use may reduce the severity of movement symptoms in some patient populations. In patients with multiple sclerosis, cannabis extract appears to be beneficial for reducing the severity of muscle spasticity and stiffness (eg, Zajicek, Hobart, Slade, Barnes, & Mattison, 2012), but not tremor, although disturbed balance is a noted movement related side-effect (for review see Koppel et al., 2014; Syed, McKeage, & Scott, 2014). A small number of studies have investigated the therapeutic efficacy of cannabis extract in patients with Huntington's disease (eg, Consroe et al., 1991; Curtis, Mitchell, Patel, Ives, & Rickards, 2009), Tourette syndrome (Muller-Vahl et al., 2002), dystonia (Consroe, Sandyk, & Snider, 1986), and levodopa-induced dyskinesia in Parkinson's disease (Sieradzan et al., 2001), but the sample sizes were too small to draw meaningful conclusions.

MINI-DICTIONARY

Body sway A parameter used to investigate balance. Movement of the body in the posterior–anterior and medial–lateral direction is measured, usually during quiet standing.
Grooved pegboard A test used to assess sensorimotor integration and hand dexterity. It involves recording the time taken to place 25 key-shaped pegs into corresponding holes.
Maximal tapping A test used to assess movement speed and rhythmicity. It involves tapping, usually the index finger, on a keyboard, or strain gauge as fast as possible for 5–10 s.
Transcranial magnetic brain stimulation A noninvasive and painless technique used to investigate excitability of the motor cortex and corticomotoneuronal pathway, in conscious humans.
Tremor An involuntary, rapid, and rhythmic oscillation of a body part.
Visuomotor tracking The ability to track a moving target with movement of a limb (most commonly the arm).

SUMMARY POINTS

- Traffic legislation-related knowledge shows growing concerns about acute effects of cannabis on psychomotor performance involved in safe driving.
- Laboratory studies assessing the acute effects of cannabis on cognitive functions involved in normal driving tasks found that working memory, motor inhibition, and divided-attention or tracking tasks were mostly impaired.
- In simulator and on-road experiments, cannabis-induced effects mostly altered mean headway and road tracking by increasing lane position variability.
- The correlation between blood levels and psychoactive effects of THC is challenged by a nonlinear time relationship, making the detection of DUIC difficult.

KEY FACTS IN TRAFFIC MEDICINE

- Cannabinoids were present in 5.3–35.7% of the blood samples collected from European impaired drivers suspected of drug use, and were the most frequently encountered illicit drugs on the roads.
- Many laboratory, simulator, and on-road experimental studies have shown an alteration in several cognitive functions.
- Brain imagery has shown changes in activations of brain areas and networks potentially involved in drivers' impairment after cannabis smoking.
- According to the duration of the majority of psychomotor impairments, it is recommended that patients using marijuana as a self-treatment abstain from driving for 8 h after a subjective "high."
- A driver's whole blood THCCOOH concentration higher than 40 µg/L is proposed as the indication of heavy use, requiring medical assessment of the fitness to drive.

LIST OF ABBREVIATIONS

11-OH-THC	11-Hydroxy-THC
BAC	Blood alcohol concentration
BART	Balloon analog risk task
CTT	Critical tracking task
DAT	Divided attention task
DSST	Digit-symbol substitution test
DUIC	Driving under the influence of cannabis
DUID	Driving under the influence of drug
EDT	Experiential discounting task
fMRI	Functional magnetic resonance imaging
RT	Reaction time
SDLP	Standard deviation of lateral position
SST	Stop signal task
THC	Δ^9-Tetrahydrocannabinol
THCCOOH	11-Nor-9-carboxy-THC
WCST	Wisconsin card sorting test

INTRODUCTION

The prevalence of drivers under the influence of cannabis in the entire driving population or in the population of drivers involved in traffic accidents is poorly estimated. One main reason is the inability to collect reliable and comprehensive statistical information from abstinent, sober, or stoned drivers. Collection of data about these drivers depends on political decisions, police strategies, and also on the drivers' and the public's consent. Methodological choices and differences in statistical processing may also influence the results. In Europe, the project "Driving Under the Influence of Drugs, Alcohol and Medicines (DRUID)," cofunded by the European Commission, estimated that the proportions of positive cannabis drivers involved in accidents vary from 4% to 14%, while 1% to 7% drive undetected under the influence of cannabis (DUIC cases), and without being involved in traffic accidents. In Switzerland, a nationwide study, conducted on 4794 blood samples gathered from suspected impaired drivers, showed that cannabinoids were present in 48% of the total number of cases and, thus, were the most frequently encountered drugs (Senna et al., 2010). A systematic review of observational studies with metaanalysis performed by Asbridge, Hayden, and Cartwright (2012), including nine studies (49,411 participants), concluded that the risk of a motor vehicle collision under the effects of acute cannabis consumption was almost twice the risk observed for sober drivers. According to a case-control study conducted by Blows et al. (2005), car crash injuries appear strongly associated with frequent use of marijuana.

DRIVING ABILITY AFTER ACUTE CANNABIS EXPOSURE

Many European and American studies show that the involvement of cannabis users is frequent in car accidents, and raises the question of the influence of cannabis effects on driving ability. Experimental studies have assessed the acute effects of cannabis on neurocognitive functions required in normal driving tasks. Cannabis-induced impairment of various aspects of a driver's performance, such as driving coordination, reaction time (RT), decision-making, critical tracking, and attention, has been evaluated (Table 39.1). Working memory and reasoning were also tested.

To reach these goals, researchers used laboratory and simulator testing, as well as on-road studies, in real situations or on closed courses and, more recently, brain imaging. Findings made in past experimental studies were often equivocal or focused on very specific psychomotor and cognitive functions (Moskowitz, 1985; Rafaelsen et al., 1973; Smiley, 1998; Ward & Dye, 1999). Subsequent studies (Kurzthaler et al., 1999; Robbe, 1998; Sexton et al., 2000) have shown that acute cannabis inhalation impairs psychomotor skills in a dose-related manner (Liguori, Gatto, & Robinson, 1998; Ramaekers et al., 2006). The tests that show the biggest effects of cannabis are those involving reaction time measurement (Lenné et al., 2010; Liguori et al., 1998; MacDonald, Schleifer, Richards, & de Wit, 2003; Rafaelsen et al., 1973; Ramaekers et al., 2006; Ronen et al., 2008), a divided attention task (DAT), a critical tracking task (CTT) (Chait & Perry, 1994; Lenné et al., 2010), or an urgent task (Moskowitz, 1985). In contrast to drunk

drivers, cannabis-intoxicated drivers seem to be aware of their impairment, and try to compensate by driving more cautiously, or by forgoing driving (Anderson, Rizzo, Block, Pearlson, & O'Leary, 2010; Lenné et al., 2010; Lamers & Ramaekers, 2001; Ménétrey et al., 2005; Robbe & O'Hanlon, 1999; Ronen et al., 2008). In on-road and driving simulator studies, cannabis-induced effects on psychomotor function alter braking latency, headway, speed, and mostly road tracking, by increasing lane position variability, and steering wheel variability (Lenné et al., 2010; Ménétrey et al., 2005; Robbe, 1998; Ronen et al., 2008).

Results of relevant experimental studies of cannabis-induced acute effects on neurocognitive functions that may affect the performance of driving are detailed later in the chapter and summarized in Tables 39.2A,B, 39.3, and 39.4. Subjects were considered occasional smokers when cannabis use occurred less than once a week.

Laboratory Studies

Working Memory

Several studies demonstrated that cannabis consumption impairs working memory (as reviewed by Crean, Crane, & Mason, 2011). Kurzthaler et al. (1999) tested the verbal memory of subjects having consumed a 290 µg/kg dose of cannabis, and observed a moderate defect of learning immediately after consumption, reflecting a difficulty in quickly processing new information after cannabis use. Impairment in working memory was also found in frequent and occasional smokers, after 3.9% Δ^9-tetrahydrocannabinol (THC) smoking, or after intravenous (IV) administration of 2.5 mg dronabinol (synthetic THC) (Hart, van Gorp, Haney, Foltin, & Fischman, 2001; Morrison et al., 2009).

Time Perception

Different studies resulted in conflicting findings about cannabis effects on time perception: on one hand, Chait and Perry (1994) found an underestimation of time intervals after smoking two 3.6% THC cigarettes, while MacDonald et al. (2003) only observed an increased estimation of the duration of short time intervals. These latter results were not replicated with chronic daily cannabis smokers using THC doses of 13 and 17 mg (Weinstein et al., 2008b). One study involving IV administration showed that an acute THC dose, ranging from 0.015 to 0.05 mg/kg, induced a time overestimation in infrequent cannabis users, while no differences was found in chronic smokers (Sewell et al., 2013).

Motor Inhibition and Impulsivity

Among the few studies that have assessed cannabis-induced acute effects on impulsivity and inhibition of inappropriate behavior, two found an increased measure of impulsivity in a group of recreational users (MacDonald et al., 2003; Ramaekers et al., 2006). Moreover, it has been shown that a 13 or 17 mg THC inhalation resulted in a dose-related significant impairing effect in a Wisconsin card sorting test (WCST) (Weinstein et al., 2008b). These results were replicated using a stop signal task (SST) used to investigate neurocognitive performance during acute THC intoxication (500 µg/kg) in occasional and heavy users (Ramaekers, Kauert, Theunissen, Toennes, & Moeller, 2009). Interestingly, Metrik et al. (2012) found that, for some regular marijuana users, the assumption of having smoked THC induced a compensation for expected intoxication effects, and resulted in less impulsive and risky decisions, while direct pharmacological effects are not compensated.

Decision Making

Some discrepancies among studies appear concerning the effects of cannabis use on decision making or planning, as well as on reaction time (RT). Ramaekers et al. (2006) found that, compared to the placebo group, recreational smokers receiving 500 µg/kg THC (≈35 mg) were significantly less likely to make correct decisions in the Tower of London test. Additionally, those in the THC-treated groups had an increased response latency. Subsequently, it has been shown that frequent smokers were not significantly affected. However, RT was not significantly increased either in occasional or frequent smokers (Ramaekers et al., 2009, 2011). Several investigators studied the acute effects of cannabis on risk-taking tasks. High doses (3.6% THC) resulted in significantly increased risk-taking behavior, compared to lower doses, in one study (Lane, Cherek, Tcheremissine, Lieving, & Pietras, 2005). MacDonald et al. (2003) and Ramaekers et al. (2006) found no significant differences in performance between groups. In another study, 36 chronic, daily cannabis users were tested after smoking placebo, low (1.8%), or high (3.9%) THC cigarettes (Vadhan et al., 2007), and their performance was not altered. However, more time was necessary to perform the task in THC groups. Conversely, Weinstein et al. (2008b) reported that neither 13 mg nor 17 mg THC significantly affected speed in a gambling task, although regular users of marijuana chose least-likely outcomes after the higher dose.

Attention

Both divided and sustained attention are required for safe driving, and are known to be mediated by the frontal lobes. The CTT is a simple test of psychomotor functioning that measures eye-hand coordination and delays in visual motor response, shown to be particularly sensitive to the impairing acute effects of cannabis for a wide range of doses (Moskowitz, 1985). However, Ward and Dye (1999) reported that, while both divided and sustained attention were affected, it was not in a dose-related manner. Then, Sexton et al. (2000) confirmed a significant performance decrease in a DAT after a high dose of

THC (2.67%), both in the CTT and in the proportion of correct answers concerning the additional task. These results were replicated in occasional smokers (with 250 or 500 µg/kg or with 2.5% THC), but regular smokers were only affected in the DAT (Morrison et al., 2009; Ramaekers et al., 2006, 2009, 2011), suggesting that an increased mental load may impair the information processing and, thus, the performance on a central task. Weinstein et al. (2008b) found a significant impairment during a virtual maze task, in a regular smokers group, after a 17 mg THC cigarette inhalation, and this effect was not detected with a 13 mg THC dose. Then, Schwope et al. (2012) showed that no significant differences were observed for CTT or DAT performance in a cohort of 10 heavy, chronic cannabis smokers after smoking a 6.8% THC cannabis cigarette. Interestingly, other studies found that after acute THC intoxication, daily cannabis users significantly improved their performance in sustained attention tasks and DAT tests (Haney et al., 1999; Hart et al., 2001), raising the question of the existence of a tolerance, or of a functional adaptation to long-term cannabis exposure. An alleviation of withdrawal symptoms or the feeling of expected and rewarding effects of cannabis can be also put forward to explain these positive effects.

Brain Imaging

In a study by Theunissen et al. (2012), using neuropsychological tests such as DAT and SST on occasional or heavy cannabis smokers after a 500 µg/kg THC, event-related potentials recordings confirm that heavy cannabis smokers develop tolerance to some of the impairing behavioral effects of cannabis that cannot be attributed to behavioral compensation alone.

Weinstein et al. (2008a) have shown that regular marijuana smokers undergoing PET scan under the effects of 17 mg THC were impaired in a virtual maze task, and that during task performance their brain metabolism was increased in the middle and medial frontal cortices and anterior cingulate, in areas related to motor coordination and attention, while it was reduced in the occipital lobes in areas associated with visual integration of motion. These observations suggest an immediate effect of marijuana on cognitive–motor skills and brain mechanisms that modulate coordinated movement and driving. Battistella et al. (2013), using a brain fMRI paradigm based on a visuomotor tracking task, found that, even at low THC blood concentrations, psychomotor skills were impaired. This effect was correlated with an alteration of the activity of the brain networks involved in cognition. Brain areas that were concerned were the anterior insula, the dorsomedial thalamus, and the striatum, as well as regions of the right superior parietal cortex, and the dorsolateral prefrontal cortex. These brain areas involve the Control Executive network known to operate once the most relevant stimuli (ie, the saliencies) are identified. Moreover, it increases activity in the rostral anterior cingulate cortex, and ventromedial prefrontal cortices, suggesting an increase in self-oriented mental activity leading to insufficient attention to task performance. In addition, these effects were not significantly correlated with the blood levels of THC, but with subjective felt side-effects.

Simulator Studies

Driving simulator studies have been useful for better describing the effects of cannabis on specific driving performances, such as variability of lateral position, decision making in case of emergency, and speed control. Since the 1980s, several former experiments cited by Smiley (1998) have shown that the behavior of subjects under the influence of cannabis is altered when they have to face an unexpected situation, indicating decreased risk taking (speed decrease, mean headway increase), and confirming an impairment during DATs. Then, Liguori et al. (1998) proposed a rapid judgment task consisting in asking the subject to maintain a speed and to choose the correct lane in a crossing, or to avoid hitting a fence that suddenly appears. The scores did not differ across those conditions after a 1.77 or 3.95% THC dose, although brake latency was marginally increased after the higher dose, similarly to prior results in subjects with breath alcohol concentration near 0.5 g/L. According to Sexton et al. (2000), who observed an increased variability in the lateral position, in participants under the influence of a 2.67% (≈ 20 mg) THC dose (not significant with a lower dose: 1.70% ≈ 10 mg), standard deviation of lateral position (SDLP) appeared to be one of the most sensitive road-tracking measures associated with THC impairment. However, variability in the cannabis history of subjects, the THC dose ranges and the time lapse between the end of the consumption and the beginning of the task can explain several discrepancies observed in the results. Other studies confirmed an SDLP increase after 13 and 17 mg THC smoked by occasional smokers (Ronen et al., 2008), or after 19 and 38 mg doses (Lenné et al., 2010). Conversely, no significant increases in SDLP were found after a 13 mg dose in occasional smokers (Ronen et al., 2010), or after a 22.9 mg dose in a heterogeneous group of smokers (1–10 times/month) (Anderson et al., 2010). In addition, other authors used various road-tracking outcomes to demonstrate a THC-induced impairment. In occasional smokers, Ménétrey et al. (2005) revealed obvious and statistically significant differences in a road-tracking task, as well as in a visual search and processing testing, after ingestion of 16.5 or 45.7 mg THC decoction, or 20 mg synthetic THC (dronabinol), compared to placebo, especially when the strongest decoction was used. Papafotiou et al. (2005) observed altered performances 80 min after 14 or 52 mg THC was

smoked, while not present at 30 min. A decrease in mean speed was also observed in several studies, after THC doses from ≈ 10 to 38 mg (Anderson et al., 2010; Lenné et al., 2010; Ronen et al., 2008, 2010; Sexton et al., 2000), confirming previous results that suggest subjects' awareness of their impairment leads to more careful driving. In a group of regular smokers (at least weekly but not daily) no significant cannabis-induced effect was noticed (Liguori et al., 1998). Some studies found a dose-related increase in RT (Lenné et al., 2010; Rafaelsen et al., 1973; Ronen et al., 2008), while others produced nonsignificant results (Anderson et al., 2010; Liguori et al., 1998; Liguori, Gatto, & Jarrett, 2002). Experiments using DATs have shown a dose-related increase in mean headway and SD, after smoking 13 and 17 mg, or 19 and 38 mg THC doses (Lenné et al., 2010; Ronen et al., 2008). One study failed to detect any effect after smoking a 22.9 mg THC dose (Anderson et al., 2010).

On-Road Studies

On-road studies strengthened the previous experimental results, excepting those of Smiley (1986), who found no significant effect on RT in situations when anticipation was possible. In the Netherlands, Robbe (1998) conducted a series of studies most relevant to the effect of cannabis on driving skills. Recreational cannabis users were exposed to three different THC doses (100, 200, and 300 µg/kg), according to a pilot study that defined the maximal administered dose necessary to achieve the desired psychological effect (called "high") corresponding to 20.8 mg THC (308 µg/kg). Several experimental designs were then based on similar doses. In a restricted highway study, a significant increase in the lateral position variability, measured as the SDLP, was observed, whether the 100, 200, or 300 µg/kg dose of cannabis was used, resulting in an effect similar to a blood alcohol concentration (BAC) from 0.3 to 0.7 g/L, whereas blood plasma concentrations of THC were not related to the degree of impairment. In a second study including a road-tracking task and a car-following task on a normal highway, the lateral position variability appeared to be the variable most sensitive to the effects of THC. The SDLP increased in a dose-related manner, although the slight effect produced by the lowest dose was not significant. The mean headway was increased, corresponding to distance variability during deceleration maneuvers of 8, 6, and 2 m, respectively, after a 100, 200, or 300 µg/kg THC dose, suggesting an effect of practice. RTs increased, compared to placebo, but not in a significant way. Robbe (1998) concluded that a different type of information processing is required in each test. Road-tracking is basically controlled by an automatic information processing system which is relatively impervious to environmental changes, but highly vulnerable to internal factors such as THC or other drugs. On the other hand, the car-following task depends more on controlled information processing and, thus, compensatory mechanisms can work to restore the situation. Other studies replicated these results. Ramaekers et al. (2000) found that the driving tasks previously described were impaired 30 and 75 min after a 100 or 200 µg/kg THC dose inhalation. Moreover, higher SDLP values were reported in the second drive. In a subsequent experiment, similar THC doses showed the same SDLP impairment 40 and 100 min after smoking (Lamers & Ramaekers, 2001).

DETECTION OF DRIVERS UNDER THE INFLUENCE OF CANNABIS (DUIC)

Two broad approaches can be used to determine whether the driver was driving under the influence of cannabis or not. First, we can evaluate the blood levels of psychoactive cannabinoids. Indeed, several authors tried to associate specific THC blood levels with increased risk of driving accidents. However, this correlation is challenged by the nonlinear time relationship between blood levels and effects, and the complex metabolism of THC, making the detection of DUIC uneasy. Furthermore, large variations exist between individuals, with respect to the subjective and objective effects of cannabis, even at similar concentrations. THC is rapidly metabolized into psychoactive 11-hydroxy-THC (11-OH-THC), and a broad range of other metabolites. 11-OH-THC is then oxidized in the liver into 11-nor-9-carboxy-THC (THC-COOH). This nonpsychoactive metabolite is glucuronidated and excreted into bile and urine. The urinary metabolite THCCOOH can be easily detected by a large panel of immunoassays and chromatographic methods. Its detection demonstrates cannabis exposure, but provides no indication with regard to the level of impairment, and the time of use. However, some minor cannabinoids (THC-glucuronide, cannabidiol, cannabinol) have been advocated as possible markers of recent cannabis use (Desrosiers et al., 2014; Mareck et al., 2009). The second strategy is based on determining the time of exposure, and relating it to the duration of impairment found in most pharmacodynamic studies. If the time-lapse between cannabis use and the relevant event (eg, a car crash) is short (less than 6–8 h), we can assume than the relevant event happened under the influence of cannabis. This is in agreement with a recent review by Neavyn, Blohm, Babu, and Bird (2014), which notes that the majority of psychomotor impairments occur in the first 2 h and disappear within 3–6 h after smoking, and recommends that patients using marijuana as self-treatment for medical purposes abstain from driving for 8 h after a subjective "high." Calculation of the time of exposure relies mainly on the different pharmacokinetic

(PK) models suggested by Huestis, Barnes, and Smith (2005). Their predictive PK models provide an estimation of the time between cannabis smoking and blood sampling, based on THC concentration alone or on the THCCOOH/THC concentration ratio in a single blood or plasma specimen.

Assessment of Cannabis Effects From Blood Levels

Although the blood concentrations of psychoactive THC are not directly correlated with those in the brain, where they exert their adverse behavioral, cognitive, and motor side-effects (Mura, Kintz, Dumestre, Raul, & Hauet, 2005), blood sampling remains the most effective way to confirm or refute recent consumption of cannabis, and to evaluate the extent of its effects. THC blood level rises rapidly, reaches peak concentrations within 10 min, and then drops rapidly, though remaining detectable for about 4–8 h. However, whether single THC blood concentration values are suitable to estimate the level of driver impairment or not needs to be discussed, considering the nonlinear relationship and counterclockwise hysteresis between THC blood levels and cannabis effects: just after smoking, the concentration rapidly reaches high levels, while the effects are still low. During the elimination phase, the effects still persist, while the concentrations have already sharply declined. On the other hand, THCCOOH can be detected in the blood up to several hours or even days after smoking. Bergamaschi et al. (2013) observed that cannabinoids are still detectable in the blood of chronic daily cannabis smokers after a month of sustained abstinence.

Other Biological Matrices for Cannabis Screening (Urine, Oral Fluid, Hair)

THCCOOH can be detected in the urine from 30 min after ingestion to several weeks, and cannot be used to determine when cannabis use occurred. Thus, urine specimens can be "cannabis" positive while driving skills are completely unaffected. Conversely, a urine specimen taken just after smoking can test "negative" while the smoker's performances are impaired. Currently, the evaluation of oral fluid for cannabis detection is an active area of research. THC contamination of the oral cavity during cannabis smoking could result in very high THC levels in saliva. On the other hand, THCCOOH, an indicator of actual exposure to cannabis, is found only in trace levels in this matrix. The European Rosita projects examined several drug testing devices between 2003 and 2005, and established criteria for accurate and reliable tests, but none of the devices met the criteria. A comprehensive review by Lee and Huestis (2014) supported oral fluid as an interesting matrix for clinical and forensic cannabinoid screening, although a better understanding is still needed of the mechanisms underlying cannabinoid disposition in oral fluid, as well as of the relationship between the selection of oral fluid THC concentration cutoffs and impairment. For example, a significant correlation with performance on the Tower of London but not on the CTT was mentioned. Furthermore, a strong correlation with blood concentrations was also noted. Conversely, the integrated project DRUID concluded that there is no reliable correlation between oral fluid and blood THC concentrations (Verstraete et al., 2011).

Hair analysis is not appropriate to detect recent use, but may provide information concerning the extent of chronic use, in the context of abstinence control. However, as discussed by Fabritius et al. (2014), this matrix could be contaminated by passive cannabis smoke exposure, or by a urine-contaminated environment, or hand contact. In this regard, experimental studies failed to establish significant correlations between hair and urine THCCOOH concentration or self-reported frequency of use.

Assessing Heavy Versus Occasional Use

The long-term fitness to drive can be influenced by many parameters, such as the frequency of cannabis use, suggesting the need for a specific criterion to distinguish between regular and occasional cannabis use. Considering that cannabis history is of limited utility with respect to performing relevant driving ability evaluations, objective data are preferable. Fabritius et al. (2014) investigated differences in THCCOOH levels of 797 whole blood specimens collected in these two populations of smokers, and proposed a THCCOOH threshold concentration to help determine to which group they belong. In agreement with previously published experimental data, a concentration higher than 40 µg/L of whole blood was found to strongly suggest heavy use. Thus, the threshold of 40 µg/L could be used as a cutoff to detect drivers who require further investigation of their long-term fitness to drive. Moreover, it is proposed that a THCCOOH level below 3 µg/L strongly suggests occasional use, and that no medical assessment of the fitness to drive is required.

MINI-DICTIONARY

Divided attention task Neuropsychological tests related to the ability of a subject to perform two different tasks simultaneously.
Executive functions Neuropsychological term referring to a group of integrated cognitive processes, including working memory, reasoning, attention and planning, that regulate adaptive behavior.
Fitness to drive Long-term ability to drive safely, considering the driver's physical and mental health.

functional Magnetic Resonance Imaging Noninvasive technique to map brain activity by evaluating changes in blood oxygenation level.

Standard deviation of lateral position Measure of dispersion of the distances from the car position to a virtual central line on the lane.

SUMMARY POINTS

- Evidence that long-term cannabis use may be hazardous to white matter in the developing brain has been accumulating.
- Early onset cannabis use in particular is thought to decrease white matter structural integrity during the critical neurodevelopment occurring in adolescence.
- We report specific localized axonal connectivity disturbances in adult long-term heavy cannabis users, rather than any widespread dysconnectivity throughout the brain, with 84–88% reductions in streamlines in the fimbria of the hippocampus, and commissural fibers extending to the precuneus. We found associations between the white matter integrity within these fiber bundles and the age of onset of cannabis use. Our findings require replication.
- The endocannabinoid system is critically involved in axonal growth in the developing brain; mechanisms underlying axonal morphological alterations following exposure to cannabis in utero have been identified.
- Mechanisms that may be specifically perturbed by cannabis use impacting the neurodevelopment and brain maturational processes that occur during adolescence require further research.
- Dysfunctional connectivity may underlie a wide range of cognitive disturbances and psychological symptoms, including vulnerability to psychosis, depression, and anxiety disorders, all of which are significant public health concerns.

KEY FACTS OF CONNECTIVITY DISTURBANCES

- The brain is an amazingly complex network. Mounting evidence suggests that disorders of the brain and mind are associated with disturbances to the axonal fibers interconnecting different cortical and subcortical regions.
- Advances in brain imaging have enabled comprehensive mapping of the human brain's axonal connectivity architecture, giving rise to the human connectome, while novel statistical techniques have been developed to pinpoint specific circuit-level, topological, and connectome-wide disturbances.
- The human connectome provides a powerful framework to formulate hypotheses about how the brain responds, either adaptively or maladaptively, to pathological insult. For example, the brain is particularly vulnerable to disturbances at highly connected hub regions concentrated in cortical association areas.
- Connectivity disturbances are disease specific, and may provide novel targets for targeted interventions and drug therapies.

KEY FACTS OF CANNABIS USE

- Cannabis use is highly prevalent throughout the world, with adolescence being the prime time for experimentation and progression to regular use.
- Long-term or heavy cannabis use is associated with cognitive dysfunction, functional and structural brain alterations, and elevated psychological symptoms.
- The hippocampus is a key brain region thought to be impacted by long-term and heavy cannabis use, and verbal learning and memory are frequently impaired in cannabis users.
- There is rapidly growing evidence to suggest that early onset cannabis use during adolescence may be detrimental to the developing brain, and lead to a range of adverse consequences.
- There is a paucity of studies aimed at assessing the extent to which the adverse cognitive, brain, and psychological effects of cannabis may recover following prolonged abstinence.

LIST OF ABBREVIATIONS

AD	Axial diffusivity
CB1R	Cannabinoid receptor type 1
DW-MRI	Diffusion-weighted magnetic resonance imaging
eCB	Endogenous cannabinoid or endocannabinoid
FA	Fractional anisotropy
MD	Mean diffusivity
NAA	*N*-acetylaspartate
RD	Radial diffusivity

INTRODUCTION

Chronic exposure to cannabis has been associated with cognitive impairment, elevated psychological symptoms (eg, anxious, depressive and psychotic), and alterations of brain function and structure (Solowij, Yücel, Lorenzetti, & Lubman, 2009). Neurofunctional alterations are increasingly being demonstrated across diverse cognitive tasks (Batalla et al., 2013), while the most consistent morphological alterations include reduced hippocampal volume, and changes in the gray matter density of medial temporal brain regions (Batalla et al., 2013; Lorenzetti, Solowij, Fornito, Lubman, & Yücel, 2014; Yücel et al., 2008). While examination of the activity and structure of individual brain regions informs understanding of the adverse neurobiological effects of cannabis, this corpus of research does not provide information about the detrimental effect of cannabis on the human connectome: the brain's complex network of interconnecting structures and nexus of communication (Sporns, Tononi, & Kötter, 2005). Advances in brain imaging technology have enabled comprehensive mapping of the human connectome in vivo, and statistical comparison of its structure between different groups.

Interrogating the connectome may ultimately lead to a better understanding of the mechanisms by which exposure to cannabis leads to gross morphological changes in the brain, and the functional significance and behavioral consequences of such alterations. Connectivity disturbances have risen to prominence as the neural substrates of complex phenotypes that characterize a range of other clinical and psychiatric disorders (eg, schizophrenia; Fornito, Zalesky, Pantelis, & Bullmore, 2012), with increasing interest in the field of addictions (Filbey, 2013; Gulley & Juraska, 2013). A further reason to focus on brain connectivity is because its establishment forms the major part of the normal maturational processes in brain development during adolescence. It is precisely during this period of brain maturation that the vast majority of cannabis users are first exposed to the drug, and progress to regular use. During adolescence, substantial restructuring of neural connections occurs, involving apoptosis, dendritic pruning, and ongoing myelination. Gradual reduction of gray matter and increasing white matter reflect the strengthening of important and elimination of redundant connections and synapses to promote efficiency of neural conductivity (Dennis et al., 2013; Lebel & Beaulieu, 2011), with concomitant changes in associated neurotransmitter receptor density, gene expression, and signaling. Notably, the endocannabinoid (eCB) system, which mediates the effect of cannabinoids on the brain, is thought to be critically involved in shaping neurodevelopment (Harkany, Keimpema, Barabas, & Mulder, 2008; Schneider, 2008).

Cannabinoid type 1 receptors (CB1R) are located on white matter structures that comprise the physical foundations of connectivity in the brain: terminal boutons, axons, myelin sheaths, and associated oligodendrocytes and astrocytes (Molina-Holgado et al., 2002). Their presence is associated with guiding white matter development during brain maturation (Malone, Hill, & Rubino, 2010), and their concentrations are high in white matter tracts during development, progressively diminishing during adulthood (Glass, Dragunow, & Faull, 1998; Romero et al., 1997). As such, developing white matter may be at greater risk of damage during this neurodevelopmental period due to its higher concentration of cannabinoid receptors, relative to the mature brain, and downregulation of the eCB system with repeated exposure to cannabis. Indirect support for this claim comes from many studies finding an association between an earlier age of onset of cannabis use and a range of greater adverse outcomes, including cognitive

impairment (Solowij & Pesa, 2012). Further to this, an association between cannabis use and the development of schizophrenia (Malone et al., 2010) speaks to the potential impact of cannabis on the brain developmental processes thought to go awry in this disorder during adolescence and young adulthood, the peak period for the development of the disorder.

MOUNTING EVIDENCE FOR DYSCONNECTIVITY IN CANNABIS USERS

White matter abnormalities such as altered volume, density, and hyperintensities have been observed in cannabis users using standard magnetic resonance imaging (Batalla et al., 2013; Solowij et al., 2011). More advanced imaging methods such as diffusion weighted MRI (DW-MRI, of which diffusion tensor imaging (DTI) is one particular model fitted to DW-MRI data) provide a means to map the trajectories followed by white matter axonal tracts, and assess the integrity of white matter microstructure with fractional anisotropy (FA), radial (RD), axial (AD), and mean diffusivity (MD) indices (see Mini-dictionary for definitions).

White matter microstructural alterations in adult and adolescent cannabis users—most often reduced FA—have been reported in the corpus callosum, the largest fiber bundle interconnecting the two hemispheres (Arnone et al., 2008; Bava et al., 2009; Gruber, Silveri, Dahlgren, & Yurgelun-Todd, 2011), frontotemporal regions including the arcuate or superior longitudinal fasciculus (Ashtari et al., 2009; Bava et al., 2009; Bava, Jacobus, Mahmood, Yang, & Tapert, 2010; Clark, Chung, Thatcher, Pajtek, & Long, 2012; Jacobus et al., 2009; Yücel et al., 2010), and in white matter surrounding the hippocampus (Yücel et al., 2010). Bava et al. (2009, 2010) also reported increased MD in the corpus callosum, in adolescent cannabis users. Associations between reduced frontal FA or increased MD and a younger age of onset of cannabis use have been reported (Gruber et al., 2011, 2014). Some studies included extensive other substance use in addition to cannabis, especially alcohol use, and reported widespread white matter alterations (Bava et al., 2009, 2010; Clark et al., 2012; Jacobus et al., 2009). The findings from these studies are summarized in Table 40.1. Abnormalities in FA have also been observed in cannabis-using patients with early psychosis, in these same brain regions (Dekker et al., 2010; James et al., 2011; Peters et al., 2009). While most often FA was found to be reduced, some studies reported increased FA which might reflect increased oligodendrocyte transcription factor and expression of myelin basic protein due to CB1R stimulation (Arevalo-Martin et al., 2007), or premature myelination (DeBellis et al., 2008). Taken together, these studies suggest cannabis use may be particularly detrimental to the white matter structures of the developing brain, both in healthy volunteers and patients with recent onset schizophrenia.

The functional significance of the observed white matter abnormalities in cannabis users remains underinvestigated. Bava et al. (2010) showed that lower FA in temporal regions in heavy cannabis and alcohol-using adolescents was associated with poorer cognitive performance, on tasks of attention, working memory, and processing speed, but higher FA in the anterior internal capsule was associated with poor verbal memory performance. Traditional structure–function relationships may be altered by exposure to cannabis in the context of brain maturation. A further means of interrogating structure–function relationships in cannabis users is to probe functional connectivity in the brain, assessed by examining the temporal correlation of neural signals across brain regions, using indices such as independent component analysis applied to functional magnetic resonance imaging data during the performance of a cognitive task or at rest. There is a growing literature reporting mostly increased functional connectivity in cannabis users (for a review see Batalla et al., 2013), particularly in association with early onset use. These methods can be informative regarding the communication nexus of the connectome; increased functional connectivity may reflect decreased white matter integrity, requiring greater signal between network elements to compensate for white matter loss (Filbey, 2013).

Few DW-MRI studies of cannabis users have moved beyond a focus on measures of microstructural integrity (mostly FA). One study assessed structural brain connectivity measures derived from DW-MRI and white matter tractography, by means of a graph theoretic analysis of both global and local brain network properties in adult cannabis users. Kim et al. (2012) found reduced global network efficiency, and increased localized clustering, particularly altered in the cingulate region, reflecting less efficiently integrated networks, and altered regional connectivity. Higher resolution imaging coupled with advances in DW-MRI methods have enabled tractography, through more reliable measurement of directional diffusion information, to reconstruct the neural fiber tracts throughout the brain.

AN INVESTIGATION OF AXONAL FIBER CONNECTIVITY IN LONG-TERM HEAVY CANNABIS USERS

In a study aimed at improving upon previous research in this area, DW-MRI and tractography were used to interrogate axonal fiber pathways in long-term heavy cannabis users (see Zalesky et al., 2012 for details). We recruited from the general community a sample of cannabis users substantially larger than that of previous studies, carefully screened for neurological conditions,

TABLE 40.1 White Matter Integrity Perturbations in Cannabis Users

Authors	Nature of sample	Extent of cannabis use	Regions where alterations were observed	Findings
Arnone et al. (2008)	Young adult males, *n* = 11, 19–21 y, no other illicit substance use	Daily use ≥ 2 y, mean 9 y	Corpus callosum	↑MD in prefrontal subregion of corpus callosum, trend association duration of use
Ashtari et al. (2009)	Adolescent and young adult males in treatment for CUD, *n* = 14, 18–21 y, no other illicit substance use, some past alcohol abuse	Mean 5.3 y, mean 5.8 j/day, abstinent mean 6.7 m	Arcuate fasciculus, internal capsule/thalamic radiation, corpus callosum, prefrontal cortex	↓FA, ↓AD, ↑RD in most regions, ↓FA in the right arcuate, ↓AD in motor fibers
Bava et al. (2009, 2010, 2013)	Adolescent, *n* = 36, 16–19 y, with 18 m follow-up of *n* = 41, 16–21 y, significant alcohol use, some extensive other substance use in follow-up sample	Lifetime occasions of use mean 552, 453 at baseline in follow-up sample with 652 uses during the follow-up period	Superior longitudinal fasciculus, thalamic radiations, corpus callosum, temporal regions and other widespread alterations	↓FA in 10 clusters, ↑MD in other clusters; some associations with NP/↓FA in 3 clusters and ↑MD, ↑RD, ↑AD in multiple clusters at follow-up, related more to alcohol than cannabis use during that period
Clark et al. (2012)	Adolescents in treatment for substance use disorders (most with CUD), *n* = 35, 14–19 y, other substance use and psychological disorders	Onset age substance use disorder 11–18 y, mean 14.7 y, use in month prior to testing mean 6.6 days (SD 11.1)	Prefrontal, temporal, and parietal regions	↓FA, correlated with CUD symptoms and psychological dysregulation
Gruber et al. (2011, 2014)	Adult, predominantly male, *n* = 15/*n* = 25, mean 25 y (SD 8.4)/mean 23 y (SD 5.9), no other illicit substance use	Mean 10 y, 25 j/week ≥2500 occasions of use	Left frontal, right genu/left and right genu of corpus callosum	↓FA, ↑MD, correlate with age of onset and impulsivity
Jacobus et al. (2009); Jacobus, Squeglia, Bava, and Tapert (2013)	Adolescent, *n* = 14 binge drinkers with cannabis use, 16–19 y/*n* = 21 for 36 m follow-up, 19–22 y; no other illicit substance use	180–1800 occasions of use, mean 550, abstinent 23–61 days	Superior longitudinal fasciculus; corona radiate/widespread white matter alterations at 36 m follow-up	↓FA, inversely correlated with lifetime use/↓FA in 14/15 regions at follow-up but no difference between binge drinkers with or without cannabis use
Yücel et al. (2010)	Adolescent/young adult, *n* = 11	≥1 y, 0.8 g/day (SD 0.5)	Superior longitudinal fasciculus, white matter surrounding hippocampus	↓FA
Zalesky et al. (2012)	Adult, *n* = 59, mean 33.4 y (SD 10.9); no other illicit substance use	Mean 15.6 y (SD 9.5), near daily, ≈26,000 lifetime j	Right fimbria to splenium of corpus callosum, commissural fiber from splenium to right precuneus	↓Streamline count,↓FA; RD and MD correlated with age of onset

AD, Axial diffusivity; CUD, cannabis use disorder; FA, fractional anisotropy; j, joints; m, months; MD, mean diffusivity; NP, neuropsychological performance; RD, radial diffusivity; y, years.

psychiatric diagnoses, and other substance use confounds, including heavy alcohol use. Fifty nine cannabis users with 15.6 years of near daily cannabis use, consuming 147 joints per month on average, were compared with 33 age-, IQ-, education-, and gender-matched non-user controls. The mean age at which regular cannabis use commenced was 16.7 years (SD 3.3).

The DW-MRI data were processed using a validated fiber-tracking algorithm to create high-resolution white matter connectivity maps indicating the extent of axonal connectivity between thousands of distinct voxel pairs. Specifically, millions of streamlines (3D curves following the trajectory of a particular fiber bundle) were generated to reconstruct the brain's entire network of axonal fibers. The reconstructed trajectories followed the direction of maximum water diffusion, aligned with the path of underlying axonal fiber bundles (Fig. 40.1). A connectivity matrix was mapped for each participant, to provide a

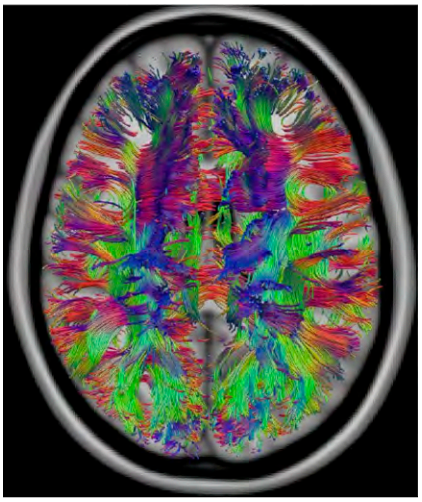

FIGURE 40.1 **Whole-brain tractography results registered to standard space, shown here for a representative nonuser control.** *Source: Adapted with permission from Zalesky, A., Solowij, N., Yücel, M., Lubman, D. I., Takagi, M., Harding, I. H., Lorenzetti, V., Wang, R., Searle, K., Pantelis, C., Seal, M. (2012). Effect of long-term cannabis use on axonal fibre connectivity.* Brain, 135, 2245–2255.

measure of the extent to which each voxel pair from spatially distinct brain regions was anatomically (axonally) connected. Using a data-driven whole brain analysis (as opposed to predefined regions of interest as in previous studies), a novel network-based statistic (Zalesky, Fornito, & Bullmore, 2010) was applied to control the family wise error rate in comparing the 169,863 voxel pairs that were interconnected by at least one streamline and, hence, identify between-group connectivity differences. Two indices of white matter microstructure, axonal and radial diffusivity (AD and RD), were averaged over all voxels intersected by at least one streamline, yielding a network-wide measure of AD and RD for each significant network. AD and RD were regressed against the age at which regular cannabis use commenced, cumulative lifetime dose of exposure to cannabis, and duration of regular use, with biological age included as a nuisance regressor to control for maturation effects.

Whole brain volume did not differ between groups (p = 0.9), and we found no evidence of brain-wide connectivity disturbances. Approximately 1.19 ± 0.1 million streamlines were found in cannabis users which did not differ in number from nonuser controls (p = 0.9), and there was no evidence of any brain-wide shortening of axonal fibers. However, two specific localized networks were found to be interconnected with significantly fewer streamlines in users, compared to nonusers, indicating tract-specific disturbances in axonal integrity. The first network (Fig. 40.2) implicated the right fimbria (crus of the fornix), a prominent band of fibers running alongside the medial periphery of the hippocampus and extending to the hippocampal commissure, as well as

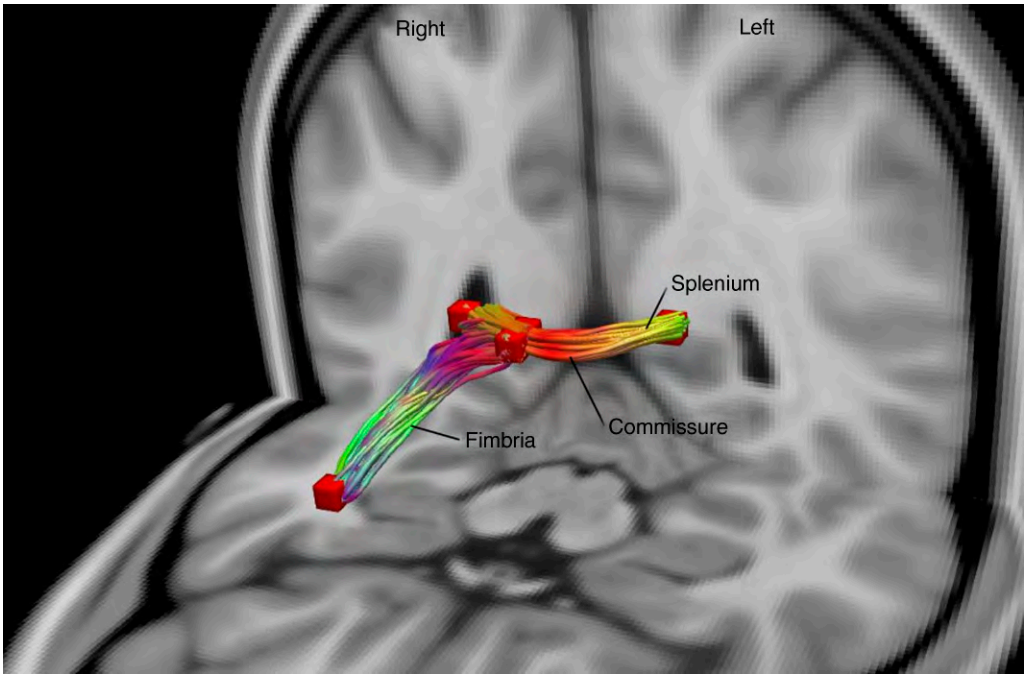

FIGURE 40.2 **The right fimbria of the hippocampus, hippocampal commissure, and splenium, comprising 84% fewer streamlines in cannabis users compared to nonusers.** Voxels interconnected by fewer streamlines are colored *red*, and the corresponding streamlines via which they are interconnected are colored such that: left–right is *red*, superior–inferior is *blue*, and anterior–posterior is *green*. *Source: Adapted with permission from Zalesky, A., Solowij, N., Yücel, M., Lubman, D. I., Takagi, M., Harding, I. H., Lorenzetti, V., Wang, R., Searle, K., Pantelis, C., Seal, M. (2012). Effect of long-term cannabis use on axonal fibre connectivity.* Brain, 135, 2245–2255.

the splenium of the corpus callosum bilaterally. This network comprised 7.0 ± 1.6 streamlines in users, and 44.0 ± 6.4 in nonusers, representing an 84% reduction ($p < 0.05$, corrected). The second network (Fig. 40.3) exclusively implicated a commissural fiber bundle beginning at the splenium of the corpus callosum, and extending to the right precuneus, which comprised 9.0 ± 1.7 streamlines in users, and 78.0 ± 15.1 in nonusers—an 88% reduction ($p < 0.05$, corrected). No significant gender effects were found, other than a trend level greater reduction in male users in the commissural fiber. FA was significantly lower in the corpus callosum in the cannabis users ($p = 0.01$) and FA, RD, and AD indices in the fimbria correlated with those in the corpus callosum ($p < .001$).

Group membership (user/nonuser) was the only significant regressor for streamline counts in both networks (fimbria: $p < 0.001$; commissural: $p < 0.001$), with alcohol, tobacco, trait anxiety, and depressive symptoms nonsignificant in the models. RD and AD were positively correlated with the age at which regular cannabis use commenced in both the fimbria (RD: $p = 0.02$, AD: $p = 0.06$) and commissural fiber (RD and AD: $p < 0.001$), remaining significant after controlling for age and duration of regular cannabis use. No associations with duration of regular cannabis use and cumulative lifetime dose were found for RD or AD, indicating a specific effect of age of onset of use during adolescence, and not simple brain maturation or dose-dependent effects.

Our findings are particularly compelling, given that our whole-brain investigation of white matter exclusively localized some of the very few fiber pathways that are particularly abundant with cannabinoid receptors during brain development (Romero et al., 1997; Molina-Holgado et al., 2002), and all of the cannabis users in our study commenced regular use during adolescence. The significant associations observed with age of onset of regular cannabis use provide evidence for white matter reacting differently to cannabis exposure commencing during adolescence, compared with adulthood, most likely due to the high concentration of cannabinoid receptors in the corpus callosum and fornix during adolescence.

Although users had greater trait anxiety and depressive symptoms, and lower Global Assessment of Functioning scores, these were not found to be significantly associated with measures of axonal integrity or connectivity, and nor were measures of impaired verbal learning and memory, or scores from a range of other cognitive tests. Future research should aim to replicate these findings, and determine the functional significance of such dramatic reductions in connectivity in cannabis users. Further, it is important to determine the extent to which these white matter abnormalities may recover following a substantial period of abstinence.

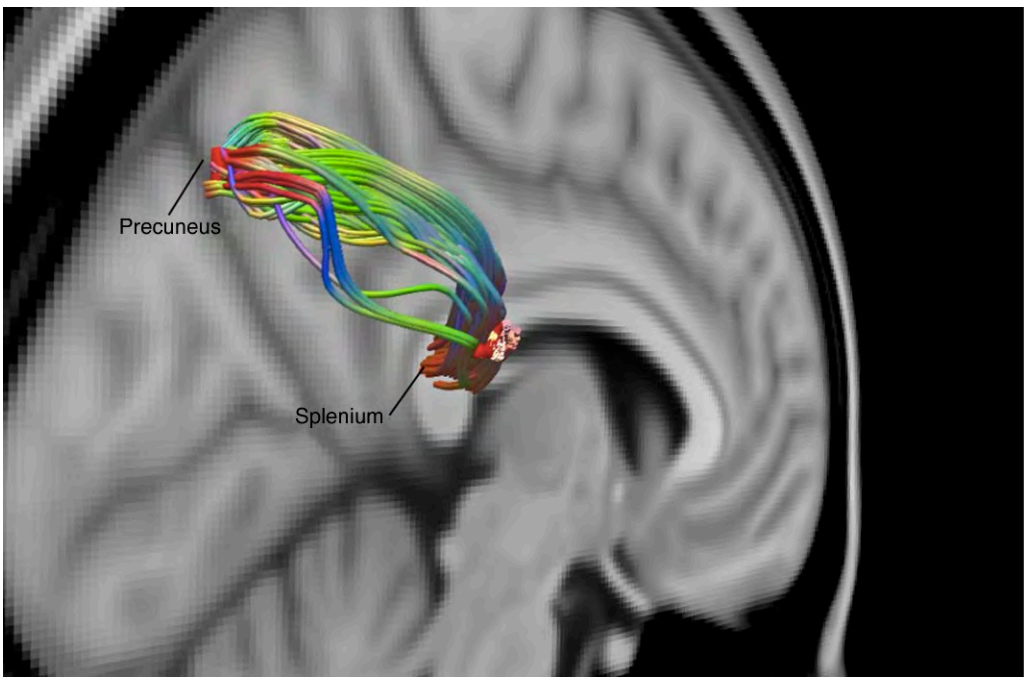

FIGURE 40.3 Streamlines interconnecting the right precuneus with the splenium, comprising an 88% reduction in cannabis users compared to nonusers. Voxels interconnected by fewer streamlines are colored *red*, and the corresponding streamlines via which they are interconnected are colored such that: left–right is *red*, superior–inferior is *blue*, and anterior–posterior is *green*. *Source: Adapted with permission from Zalesky, A., Solowij, N., Yücel, M., Lubman, D. I., Takagi, M., Harding, I. H., Lorenzetti, V., Wang, R., Searle, K., Pantelis, C., Seal, M. (2012). Effect of long-term cannabis use on axonal fibre connectivity.* Brain, 135, *2245–2255.*

FURTHER EVIDENCE

Additional studies continue to extend on prior findings. Bava et al. (2013) and Jacobus et al. (2013) recently reported on the longitudinal follow-up of their adolescent sample with substantial cannabis and alcohol use. Bava et al. (2013) report that greater alcohol consumption over an 18-month period predicted higher diffusivity in the superior longitudinal fasciculus and posterior corona radiate (thalamic fiber tracts), but there were no cannabis-related effects on diffusivity or FA. By the 3-year follow-up, Jacobus et al. (2013) report that 15 white matter clusters within projection, association, and interhemispheric fiber tracts differed between adolescent controls, alcohol, and heavy alcohol and cannabis users. In 14 of those clusters, the heavy alcohol and cannabis group showed significantly lower FA than controls, but no difference from those with heavy alcohol use alone and, in the remaining cluster (right uncinate fasciculus), the cannabis-exposed group showed higher FA than the group exposed to alcohol alone. Significant declines in white matter integrity from baseline to 3-year follow-up were not associated with poorer cognitive performance. Gruber et al. (2014) report reduced FA in a number of brain regions of cannabis users, particularly in early onset users, and an association between these changes and greater impulsivity. Yücel et al. (2010) report reduced FA in the corpus callosum of cannabis and inhalant users. White matter disturbances may be implicated from several further functional connectivity studies that have been reported (Filbey & Yezhuvath, 2013; Harding et al., 2012; Houck, Bryan, & Feldstein Ewing, 2013; Orr et al., 2013; Pujol et al., 2014). Direct investigations of the relatedness of functional and structural dysconnectivity are required in cannabis users, and are now possible by means of novel multimodal network imaging and analysis methods (Nixon et al., 2014; Preti et al., 2014; Sporns, 2014).

MECHANISMS OF AXONAL DISTURBANCE

CB1R are critically involved in the axonal growth process, and cannabinoid exposure during brain development is thought to disrupt neuronal specification, structural organization and, hence, synaptic wiring of neuronal networks (Berghuis et al., 2007; Cristino & Di Marzo, 2014). Pharmacological manipulation of CB1R had previously been shown to introduce corticofugal axon fasciculation errors, in particular enlargement of axons with reduced myelination (Mulder et al., 2008). Prenatal exposure to cannabinoids is now known to alter CB1R-mediated specification, and distance migration of neurons, axonal growth, and synapse formation in fetuses (Cristino & Di Marzo, 2014). In a series of elegant studies in mice and in human fetal postmortem brain tissue, Tortoriello et al. (2014) identify the molecular signaling cascade mechanisms directly involved in this disruption, thought to permanently impair wiring during corticogenesis. Superior Cervical Ganglion 10 (SCG10)/stathmin-2 was identified as a substrate of altered neuronal connectivity and axonal morphology, particularly in the hippocampus. This is a microtubule-binding protein in axons that contributes to the maintenance of cytoskeletal instability required for axonal growth and synaptic plasticity at Schaffer collaterals. Tortoriello et al. (2014) showed that repeated cannabinoid exposure in pregnant dams disrupted eCB signaling in offspring, particularly CB1R temporal dynamics and molecular cascades, to induce cytoskeletal modification in neuronal specification, disrupting the wiring of fetal cortical circuitry, particularly involving hippocampus, and ultimately altering axon morphology. The axonal specificity of CB1R-dependent SCG10 degradation was established, specifically implicating this mechanism in the modulation of axonal growth and guidance. The authors suggest that the mode of action of exogenous cannabinoids involves the disrupted development and maintenance of synapses critical for highly ordered executive and cognitive functions, and that altered neuronal integrity and connectivity may result in a range of adverse phenotypes, including cognitive deficits, psychological symptomatology, and risk-taking behaviors.

Gilbert and Soderstrom (2014) showed that repeated cannabinoid exposure in zebra finch during brain development (coinciding with song learning that these researchers have repeatedly demonstrated to be impaired) but not during adulthood, produces persistent changes in cytoskeletal proteins critical to both dendritic (MAP2) and axonal (Nf-200) morphology in CB1R-expressing brain regions, demonstrating that exogenous cannabinoids can alter normal brain development through these mechanisms. These same markers were previously shown to be altered in pubertal rats following chronic cannabinoid treatment (Tagliaferro et al., 2006).

FUTURE DIRECTIONS

Multimodal imaging approaches are particularly useful for furthering the field. Bernier et al. (2013) report a study protocol for examining the impact of early adolescent onset of cannabis use on white matter tissue integrity in young adults with schizophrenia (diagnosed within the past 5 years). They propose to assess indices of diffusion tensor imaging, proton magnetic resonance spectroscopy, transverse relaxation time constants of regional tissue water and of *N*-acetylaspartate (NAA) in a large frontal white matter fiber bundle – the left superior

longitudinal fasciculus, connecting the dorsal prefrontal and caudal-inferior parietal regions of the brain. Abnormalities in this fiber bundle have been reported in cannabis users as described earlier, as well as in people with schizophrenia. The combined approach will provide information on underlying cellular abnormalities of white matter in schizophrenia, and how this is perturbed by exposure to cannabis use during adolescence. Previous research has used magnetic resonance spectroscopy to assess neuronal integrity in cannabis users, finding reduced NAA levels in the dorsolateral prefrontal cortex (Hermann et al., 2007) and anterior cingulate cortex (Prescot, Locatelli, Renshaw, & Yurgelun-Todd, 2011; Prescot, Renshaw, & Yurgelun-Todd, 2013). NAA is the most concentrated molecule in the brain, after glutamate. We found an association between reduced NAA in hippocampus and smaller hippocampal volumes in adult cannabis users (Yücel et al., 2013), likely reflecting neuronal loss or damage, mitochondrial anomalies, or reduced synaptic connections. There is preliminary evidence also for an altered metabolic profile in white matter (Silveri, Jensen, Rosso, Sneider, & Yurgelun-Todd, 2011), and Bernier et al. (2013) propose to specifically interrogate white matter tissue where reduced NAA would indicate insufficient availability of acetate, one of the main building blocks necessary for myelin repair and maintenance. Examining the interplay between NAA, FA, and T2 relaxation time constant outcomes will enable greater attribution of specificity of disturbances to myelin sheaths, axons themselves, or involvement of oligodendrocytes. Other means by which the specificity of axons or myelin could be interrogated from MRI measures include the magnetization transfer ratio (MTR) contrast (eg, Chen et al., 2008) or *g*-ratio—the ratio of inner axon to total outer, including myelin, and circumference (eg, Chomiak & Hu, 2009).

Replication of our findings of 84–88% reduction in the streamline count of two specific localized fiber bundles in long-term very heavy cannabis users are required. Given these dramatic reductions, further research needs to identify their functional significance. Application of advanced DW-MRI methods will overcome inherent technical problems, particularly regarding crossing fibers that could potentially lead to spurious measures of reduced FA (Baker, Yücel, Fornito, Allen, & Lubman, 2013). Additional research might aim to address the extent to which abnormal white matter microstructure might precede the onset of substance use, and increase the risk for the development of substance use disorders. Prospective and longitudinal studies would be informative for understanding vulnerability to, and biological underpinnings of addiction, exposure consequences differentiated from those of other substance use, and potential recovery of white matter microstructure following abstinence (Baker et al., 2013). The mechanisms described earlier for specific eCB involvement in axonal structural development, and exogenous cannabinoid perturbation of these processes during gestation, provide solid evidence for persistent consequences of cannabinoid exposure at neurodevelopmentally critical times—whether similar mechanisms and their perturbation by cannabis use during adolescent neural maturation may underlie structural connectivity disturbances in cannabis users is an important question for future research.

MINI-DICTIONARY

AD Axial diffusivity refers to the magnitude of diffusion parallel to fiber tracts. Lower AD might reflect axonal injury, reduced axonal caliber, or less coherent orientation of axons. There is evidence that AD is not influenced by myelin.

DW-MRI Diffusion weighted magnetic resonance imaging is a neuroimaging technique that enables mapping of the diffusion of water molecules in brain tissue, which is highly directional in proximity to white matter tracts. The hydrophobic phospholipid bilayer of the myelin sheath restricts the flow of water perpendicular to axonal processes, resulting in anisotropic diffusion (see FA later). Analysis of DW-MRI measures involves tractography using tract-based spatial statistics of whole brain white matter, a whole brain voxelwise approach, or interrogation of hypothesis-driven regions of interest (ROI).

FA Fractional anisotropy refers to the fraction of diffusion that is directionally dependent (anisotropic). Lower FA might reflect damage to the myelin sheath surrounding axons, enlarged axonal diameter, reduced axonal packing density, or increased membrane permeability, but FA is not myelin specific.

MD Mean diffusivity is the overall directionally averaged magnitude of diffusion, and its increase reflects reduced white matter integrity due to either axonal or myelin degradation.

RD Radial diffusivity refers to the magnitude of diffusion perpendicular to fiber tracts. RD may be relatively more sensitive to myelin, but higher RD might reflect myelin loss, or loss of axons and/or reduced axonal packing density.

CHAPTER

41

Microglial Activation and Cannabis Exposure

L. Cutando, R. Maldonado, A. Ozaita

Department of Experimental and Health Sciences, Laboratory of Neuropharmacology, School of Health and Life Sciences, Pompeu Fabra University, Barcelona, Spain

SUMMARY POINTS

- Microglia is a surveillance cell population sensitive to changes in the brain parenchyma composition, and to cytokines and other cell mediators.
- Microglial cells may change their phenotype from a resting/surveillance state to an activated state, characterized by morphological but also altered genes expression that results in neuroinflammation.
- Components of the endocannabinoid system, such as cannabinoid receptors, are differentially expressed in the diverse stages on microglia reactivity.
- Cannabis components may produce an antineuroinflammatory response through the interaction with cannabinoid receptors in activated microglia.
- Chronic Δ^9-tetrahydrocannabinol (THC) administration affects cerebellar microglia due to the downregulation of cannabinoid receptor type I (CB1 receptors) in parallel fiber terminals.
- After THC withdrawal, cerebellar microglia reactivity increases due to the deregulation of CB1 receptors, affecting cerebellar function. Under these conditions, inhibitors of microglial reactivity normalize cerebellar function even when CB1 receptors remain downregulated.

KEY FACTS OF CYTOKINES

- Term applied to small protein and polypeptide mediators synthesized and released by immune cells, such as microglia, during inflammation.
- Cytokines include interleukins, chemokines, interferons, colony-stimulating factors, growth factors, and tumor necrosis factors.
- They affect cell function through autocrine and paracrine mechanisms, by the activation of specific, high-affinity receptors usually coupled to kinase activity or to G-proteins.
- They have a role in the induction of the immune response, but also as pro- and antiinflammatory agents.
- Interleukin-1 (IL-1) and tumor necrosis factor alpha (TNF-α) are the primary proinflammatory cytokines.

LIST OF ABBREVIATIONS

Abn-CBD	Abnormal-cannabidiol receptors
2-AG	2-Arachidonoylglycerol
AEA	*N*-arachidonoylethanolamine or anandamide
AMPA	α-Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor
ATP	Adenosine-5′-triphosphate
CB1 receptor	Type I cannabinoid receptor
CB2 receptor	Type II cannabinoid receptor
CBD	Cannabidiol

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00047-8

CNS	Central nervous system
DAMP	Danger-associated molecular pattern molecules
eCB	Endocannabinoids
ECS	Endogenous cannabinoid system
GPR 18	G protein-coupled receptor 18
GPR 55	G protein-coupled receptor 55
IFN-gamma	Interferon gamma
IL	Interleukin
LPS	Lipopolysaccharide
NAGly	*N*-arachidonoyl glycine
NF-κβ	Nuclear factor kappa-light-chain-enhancer of activated B cells
NMDA	*N*-methyl-D-aspartic acid or *N*-methyl-D-aspartate receptor
NO	Nitric oxide
PAMP	Pathogen-associated molecular pattern molecules
PEA	Palmitoylethanolamide
PPAR	Peroxisome proliferator-activated receptor
SIRPα	Signal regulatory protein alpha receptor
TGF-beta	Transforming growth factor beta
THC	Δ^9-Tetrahydrocannabinol
TLR	Toll-like receptors
TNF-α	Tumor necrosis alpha
TREM2	Triggering receptor expressed on myeloid cells 2
TRPV	Transient receptor potential cation channel subfamily vanilloid
UTP	Uridine-5′-triphosphate

OVERVIEW OF MICROGLIA

Microglial cells are the immune effector cells in the central nervous system (CNS), where they comprise approximately 10% of the total cell brain population (Lawson, Perry, Dri, & Gordon, 1990; Mittelbronn, Dietz, Schluesener, & Meyermann, 2001). They are considered the macrophages of the brain. Microglial cells are differently distributed along the brain parenchyma, where their density varies depending on the brain region, going from 5% in corpus callosum to 12% in substantia nigra (Lawson et al., 1990), and are more abundant in gray matter compared to white matter (Kofler & Wiley, 2011). Microglial cells have a hematopoietic origin and, in mammals, they derive from the invasion of peripheral mesodermal primitive macrophages arising from the yolk sac (Alliot, Godin, & Pessac, 1999). During early embryogenesis, they migrate into the CNS and, under the influence of different molecules and transcription microglial precursors, differentiate and proliferate from an amoeboid to a more mature ramified phenotype. By the time of birth, an important amount of microglial cells are present in the brain, forming a dense network along the parenchyma contributing to brain homeostasis (Saijo & Glass, 2011). Microglial cells have been implicated in cellular and synaptic maintenance, myelin homeostasis, and responses to brain damage. These cells act as local sentinels of the CNS, playing also a key role in the innate immune response of the brain. Once microglial cells are activated by the so-called "On" signals (Fig. 41.1), they express different surface markers and release diverse substances such as cytokines, reactive oxygen species, and nitric oxide (NO), which may exacerbate the surrounding neuronal damage, and complicate the synaptic homeostasis (Kofler & Wiley, 2011; Benarroch, 2013). Upon infection or brain injury, activated microglial cells efficiently phagocyte pathogens and damage dying cells. It is well known that excessive microglial cell activation may produce pathological situations contributing to the pathogenesis of neurodegenerative diseases (Hanisch & Kettenmann, 2007). However, under certain conditions, microglial cells have an alleviating role, promoting neuroprotective and neurotrophic functions (Saijo & Glass, 2011). In addition, microglial cells have an important role removing synapses from injured neurons, a process called *synaptic stripping* (Kettenmann, Kirchhoff, & Verkhratsky, 2013). Thus, microglial cells may play a key role exerting proinflammatory, cytotoxic, immunoregulatory, and repairing functions. Because of this wide variety of processes and functions, this cell type has been the focus of much research in recent years. The accumulated information shows that microglia plays a crucial role in the control of neuronal activity, becoming an extremely important player in brain function.

MICROGLIAL ACTIVATION PROCESS

Microglial cells may be found in the brain in two different states, depending on their morphology and the expression of activation markers: "resting state" and "activated state". Under basal conditions (absence of brain injury or alteration), microglial cells present a "resting" phenotype characterized by small soma and highly ramified and elongated branches (Cuadros & Navascués, 1998). In these quiescent conditions, microglial cells form an organized net of cells along the brain parenchyma, where each microglial cell scavengers its own immediate area without overlapping their processes with those of the neighboring microglial cell. In the ramified form, microglial cells actively move their processes without translocation of the soma. Indeed, in vivo two-photon laser-scanning microscopy experiments revealed that microglial cells present highly dynamic processes in intact healthy brains, and can elongate or retract more than 1–3 μm/min, voiding the idea that microglia from healthy brain is a resting component (Nimmerjahn,

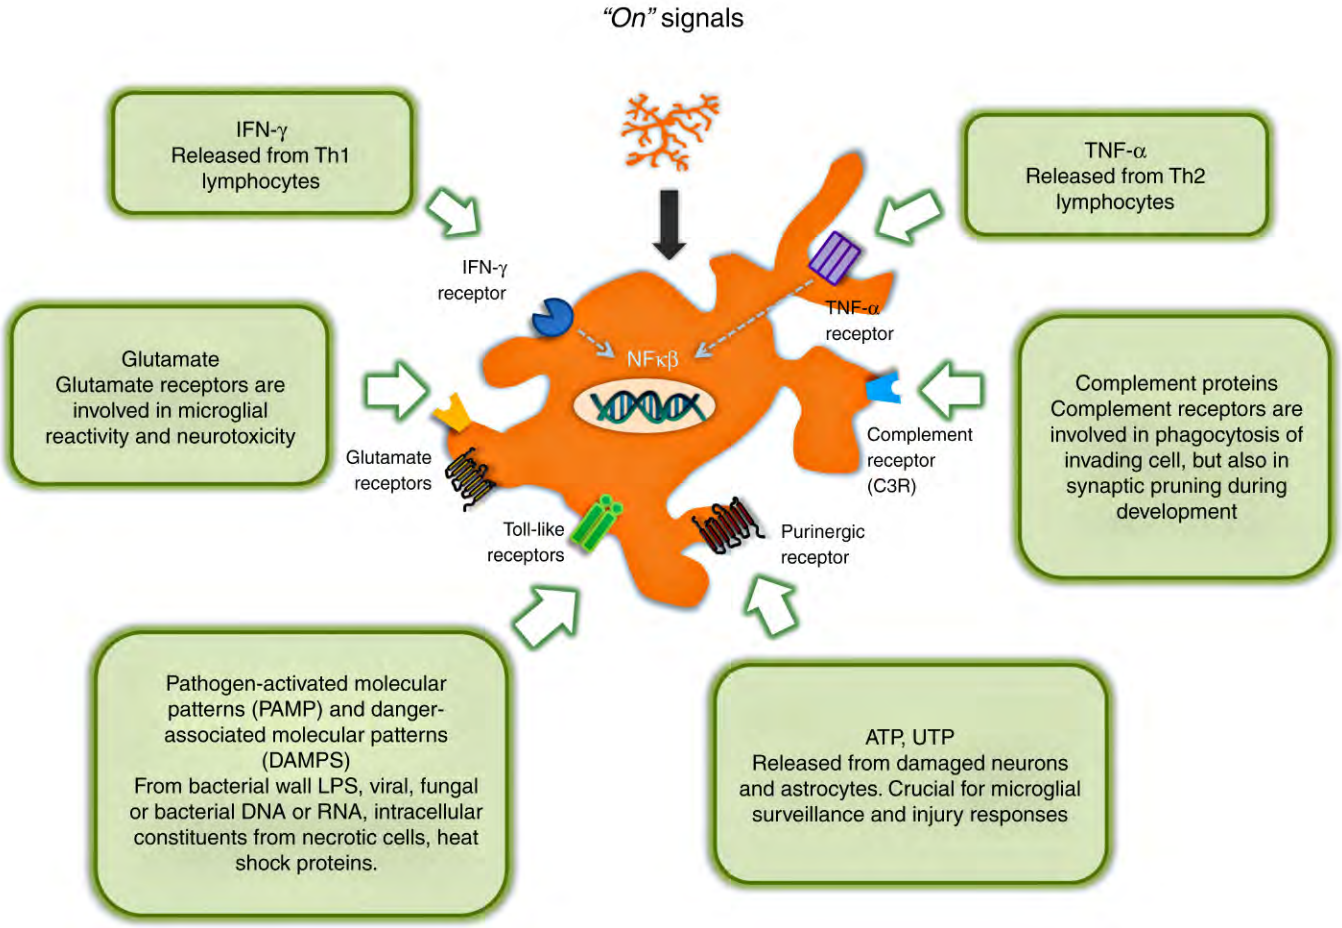

FIGURE 41.1 **Schematic drawing of "On" signals that trigger the microglial activation.** Resting/surveillance microglia turns activated in response to the presence in the brain parenchyma of IFN-gamma, glutamate, PAMPs or DAMPs, ATP or UTP, complement proteins or TNF-α.

Kirchhoff, & Helmchen, 2005). In this regard, microglial cells act as "active sensors" of their environment, in order to survey their own parcel of parenchyma. Microglial motility control depends on extracellular adenosine-5′-triphosphate (ATP) concentration level, thus a reduction in ATP concentration by ATP-hydrolyzing enzyme apyrase decreases microglial motility, whereas artificial ATP gradients enhance their motility (Davalos et al., 2005). Purinergic P2Y12 metabotropic receptors seem to be involved in these responses (Haynes et al., 2006). Therefore, microglial resting state is an active surveillance state of the surrounding extracellular milieu.

After brain injury or upon recognition of a pathogen, microglial cells become activated, retracting their processes and enhancing the perimeter of their soma, and move following chemotactic gradients to the site of lesion, or to contact the aggressor pathogen. Activated microglial cells are really heterogeneous and plastic cells, and they could present different phenotypes, depending on the type of stimulus, or the environmental factors that produced their activation. Thus, activated microglial cells executing a number of adaptive responses to a given challenge are also known as "effector cells," and they may present really different phenotypes, such as amoeboid, rod, or multinucleated morphologies (Hanisch & Kettenmann, 2007).

Microglial activation is tightly controlled, and sensitive to different signals that can turn on or inhibit this process in order to orchestrate the wide range of microglial functions. As mentioned above, microglial activation may occur due to "On" signals that appear in the brain, and mediate the microglial activation, or from the reduced expression of "Off" signals (those that maintain microglial cells in resting state) (Biber, Neumann, Inoue, & Boddeke, 2007). Multiple "On" signals have been described to activate microglia through microglial toll-like receptors (TLR), such as infection signals like bacterial wall lipopolysaccharides, bacterial and viral RNA or DNA, viral structural envelopes, intracellular elements released from necrotic cells, heat shock proteins, among others (PAMPs and DAMPs). Other molecules, such as complement proteins, interferon-γ cytokine (IFN) released from Th1 lymphocytes or TNF-α released from Th2 lymphocytes, activate innate immune responses

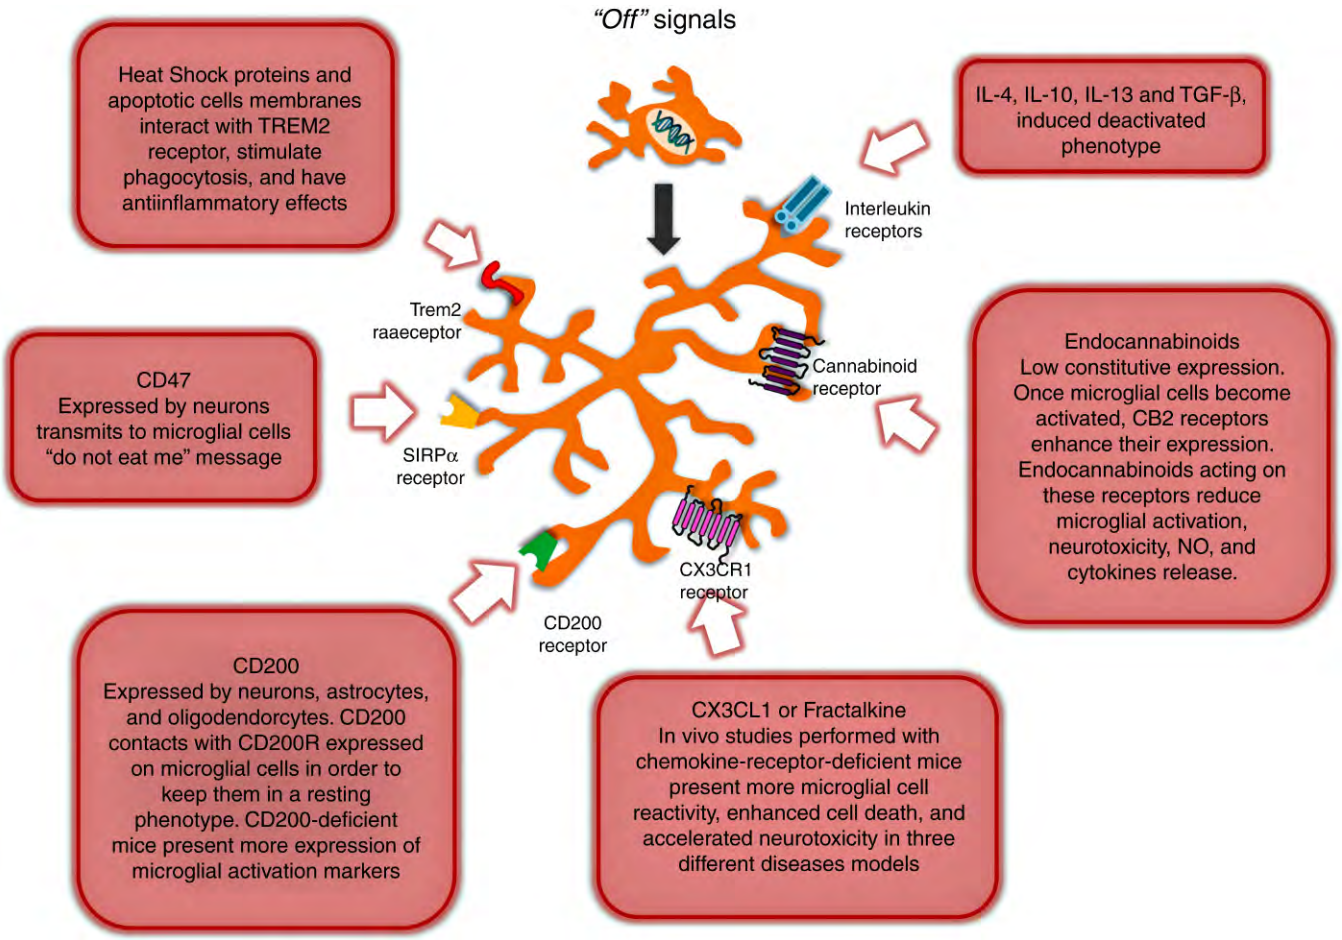

FIGURE 41.2 **Schematic drawing of "Off" signals that reduce microglial activation.** Activated microglia is sensitive to Heat Shock proteins and apoptotic cell membranes, CD47, CD200, CX3CL1, cannabinoid receptor agonists, antiinflammatory cytokines (IL-4, IL-10, IL-13, TGF-beta).

triggering the transcriptional activation of proinflammatory genes through the nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κβ) (Benarroch, 2013; Hanisch & Kettenmann, 2007; Kierdorf & Prinz, 2013; Kettenmann, Hanisch, Noda, & Verkhratsky, 2011). In addition, microglial cells also present purinergic P2X ionotropic receptors (mainly P2X4 and P2X7) and/or P2Y metabotropic receptors (P2Y2, P2Y6, and P2Y12) for UTP and ATP, which are crucial for the role of microglial cells in surveillance and injury responses. ATP released from damaged neurons and astrocytes may induce microglial activation and processes motility (Inoue & Tsuda, 2012; Suzuki et al., 2004, Ohsawa et al., 2007). Furthermore, microglial cells also express AMPA-type glutamate receptors, kainate receptors, and metabotropic glutamate receptors. Activation of AMPA receptors is linked to TNF-α release, and glutamate-induced chemotaxis, while group II metabotropic glutamate receptors trigger neurotoxicity and microglial reactivity (Kettenmann et al., 2011).

Finally, microglial cells also present adenosine, cholinergic, adrenergic, dopamine, and cytokine receptors. The stimulation of these receptors may modulate microglial proliferation, cytokines release, gene expression, and NO production (Kettenmann et al., 2011).

On the other hand, "Off" signals produced by cells surrounding microglia have the purpose to keep microglial cells in a "resting" phenotype imposing a "calming" influence on microglial cells (Fig. 41.2). One of these molecules is CD200, expressed by neurons, astrocytes, and oligodendrocytes that interacts with CD200 receptor (CD200R) expressed by microglial cells. In vivo studies using CD200R-deficient mice demonstrated that CD200R expressed by microglia is important to maintain these cells in a resting phenotype. The lack of this receptor produces an enhancement in CD45 and CD11b expression (markers of microglial activation), together with a less ramified morphology in the microglial cells (Cardona et al., 2006). Other studies clearly demonstrated the crucial role of CX3CL1 chemokine (also known as fractalkine or neurotactin) in the regulation of the microglial cell reactivity, when bound to CX3CR1 receptors expressed in microglial cells. CX3CL1 is highly expressed in CNS parenchyma under healthy conditions.

In vivo studies demonstrated that chemokine-receptor-deficient mice present microglial cells with an overactivated phenotype, enhanced cell death, and accelerated neurotoxicity in different disease models (Cardona et al., 2006; Sheridan & Murphy, 2013). In addition, other inhibitory surface receptors or molecules expressed by microglial cells interact with ligands secreted or expressed by neurons. One of these molecules is the signal regulatory protein α (SIRPα) receptor which interacts with CD47 expressed by neurons to prevent phagocytosis (Biber et al., 2007). Furthermore, another molecule expressed by microglial cells is the triggering receptor expressed on myeloid cells 2 (TREM2), associated with the adapter protein DAP12. This molecule is essential for phagocytosis of membranes from apoptotic cells and microglial clearance function, and its activation has antiinflammatory effects (Takahashi, Prinz, Stagi, Chechneva, & Neumann, 2007). Moreover, it is known that the interactions between IL-4, IL-10, IL-13, and the transforming growth factor-β (TGF-β) with their receptors expressed on microglial cells reduces the microglial activated phenotype (Kettenmann et al., 2011). Finally, microglial cells also express type I (CB1) and type II (CB2) cannabinoid receptors, as well as other cannabinoid-like receptors (Fig. 41.2). The constitutive expression of these receptors is very low in resting microglial cells, and a rapid enhancement of CB2 receptor expression appeared once microglial cells become activated (Stella, 2009, 2010). The stimulation of cannabinoid receptors has been reported to reduce microglial activation and neurotoxicity (Stella, 2009, 2010).

ENDOGENOUS CANNABINOID SYSTEM IN MICROGLIA

The possibility to reduce the microglial proinflammatory responses in some neurodegenerative diseases or after brain injury, maintaining their antiinflammatory properties, has been extensively studied. A number of evidences underline the interest to target the endogenous cannabinoid system (ECS) for these purposes. In this regard, microglial cells express different types of cannabinoid receptors that regulate microglial cell migration and activation, as well as proinflammatory responses. Moreover, microglial cells can produce several neurotransmitters, including endocannabinoids (eCBs) that can directly affect neuronal functions. As explained in the next paragraphs, the impact of cannabis exposure on microglia will depend on the activation state of this cell population, but also on the adaptive changes that cannabis compounds produce on the ECS that may modulate microglial reactivity. In this chapter we will explain the effects of cannabis on microglia, focusing our attention on its main psychoactive component, Δ^9-tetrahydrocannabinol (THC). This interaction has an impact on cerebellar functions, and the mechanisms involved have been recently addressed (Cutando et al., 2013).

Direct Effect of Cannabinoid Agonists on Cannabinoid-Like Receptors

As previously reported, CB1 and CB2 receptors are expressed in microglial cells, although their expression depends on the microglial activation profile. Thus, microglial cells become activated from resting/surveillance phenotype in response to "On" signals. A very low expression of CB1 and CB2 receptors is present in resting microglia, which can only be found in intact healthy brain tissue. Microglial activation rapidly upregulates CB2 receptors "on demand," being highly expressed in activated states (Carlisle, Marciano-Cabral, Staab, Ludwick, & Cabral, 2002; Walter et al., 2003; Stella, 2010). Moreover, it has been demonstrated that microglial primary cultures are intrinsically activated because of the transferring procedure to the culture plate (Becher & Antel, 1996). Indeed, both microglial primary cultures, and microglial cell lines such as BV-2, frequently used in research, express high levels of CB2 receptors (Carlisle et al., 2002; Stella, 2009; Carrier et al., 2004). Furthermore, it has been described that CB2 receptor expression is upregulated in pathological conditions such as Alzheimer disease, Huntington disease, or AIDS-associated dementia (Benito et al., 2003; Palazuelos et al., 2009; Kim, Shin, & Thayer, 2011). Yiangou et al. (2006) also found enhanced levels of CB2 receptor during amyotrophic lateral sclerosis and multiple sclerosis development in spinal cord samples. Therefore, cannabinoids may have therapeutic potential in some of these disorders, acting on the CB2 receptor. In this sense, cannabinoids may improve motor symptoms in a model of Huntington disease targeting CB2 receptors (Palazuelos et al., 2009), and prevent microglial reactivity and the neurotoxicity induced by β-amyloid in models of Alzheimer disease (Ramírez, Blázquez, Gómez del Pulgar, Guzmán, & de Ceballos, 2005). Furthermore, an upregulation of CB2 mRNA expression related with an enhancement in the microglial reactivity process in the spinal cord has been reported in a model of neuropathic pain (but not in a model of chronic inflammatory pain) (Zhang et al., 2003). In summary, experimental evidences show that the stimulation of CB2 receptors by agonists (Fig. 41.3) modulates microglial reactivity, but also chemotaxis, proliferation, phagocytosis, migration, and infiltration into brain areas with neuroinflammation. As a consequence, CB2 receptor agonists have been postulated for the treatment of different neurodegenerative diseases.

On the other hand, it has been described that microglial cells from different species also express CB1 receptors.

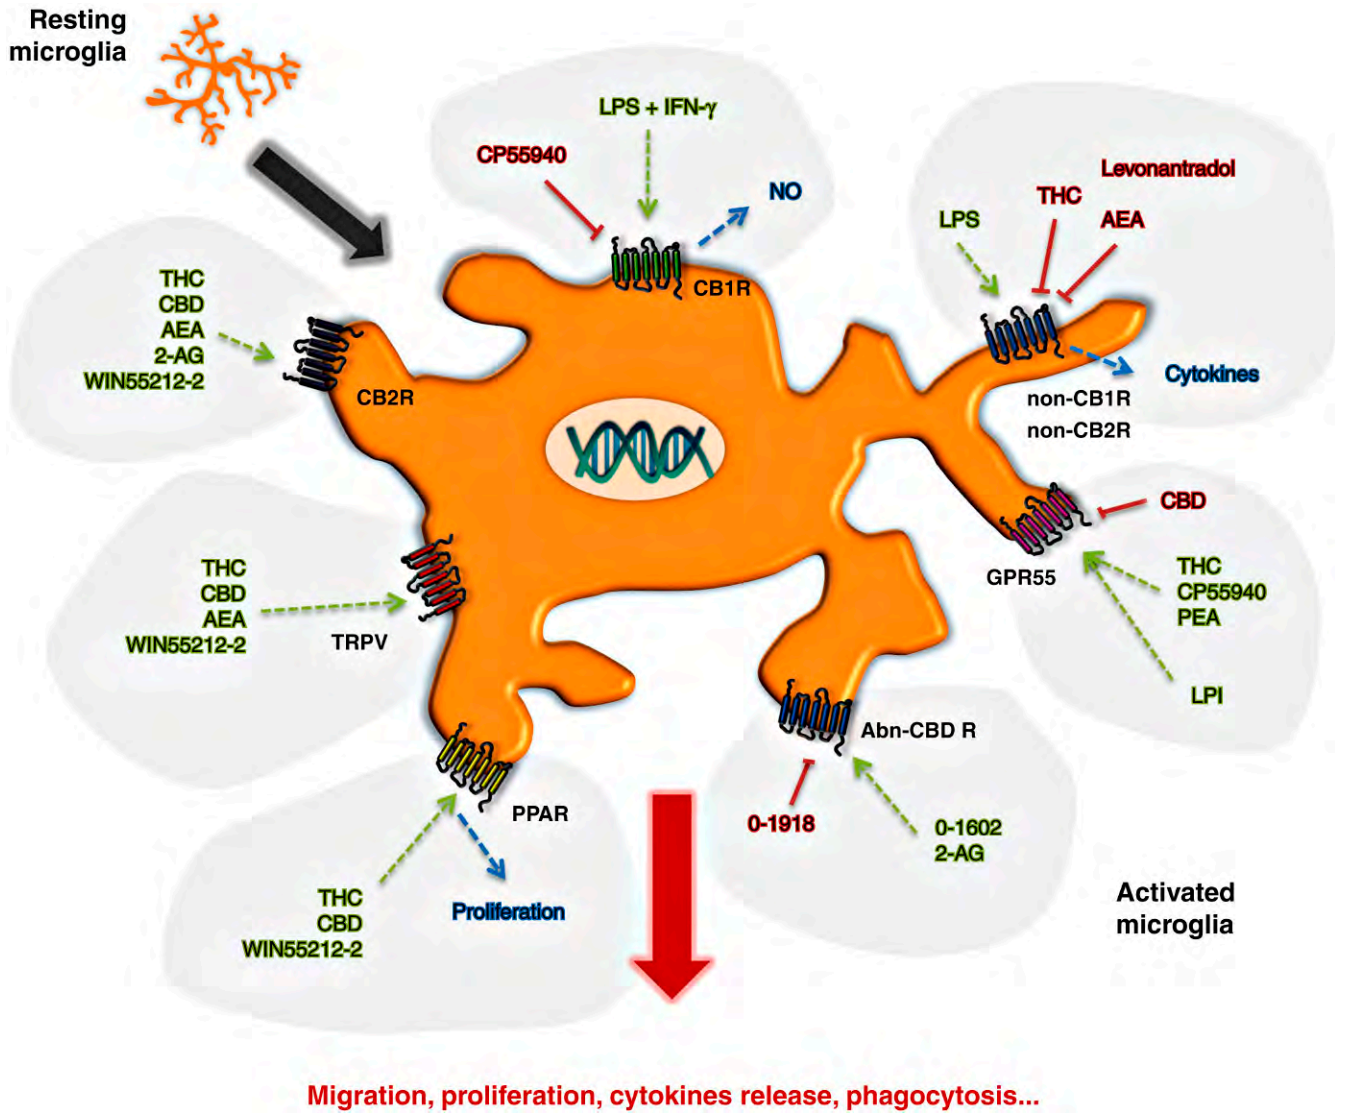

FIGURE 41.3 **Schematic drawing of potential sites in activated microglia sensitive to cannabinoid compounds.** Activated microglia is sensitive to cannabinoid drugs through different receptors described in microglial cells: CB1, CB2, GPR55, abn-CBD, PPAR, TRPV. *Green arrows* denote a decrease in microglial activation, while *red bars* denote an increase in microglial reactivity. *Blue arrows* indicate a cellular response significant for microglia state change.

This cannabinoid receptor has been related with NO production, an inflammatory mediator released from activated microglial cells (Waksman, Olson, Carlisle, & Cabral, 1999). Indeed, NO production induced by lipopolysaccharide (LPS) and interferon-γ was partially inhibited by the cannabinoid agonist CP55940. Moreover, functional studies performed previously also demonstrated that the CB1-selective antagonist SR141716A could prevent the inhibition of NO production mediated by CP55940 (Rinaldi-Carmona et al., 1994). Altogether, these results clearly demonstrate the role of CB1 receptors regulating NO production by activated microglial cells (Fig. 41.3).

In addition, other studies demonstrated that cannabinoids, such as THC, and anandamide, inhibit LPS-inducible cytokine mRNA expression for IL-6, IL-1β, IL-1α, and TNF-α in cortical rat neonatal microglial cells. The same inhibitory outcome was observed with the synthetic cannabinoid analogs of dronabinol, the enantiomers levonantradol and dextronantradol. Neither the CB1-selective antagonist SR141716A, nor the CB2-selective antagonist SR144528 were able to reverse the inhibition of cytokine mRNA expression by levonantradol, suggesting that the blockade of cytokine mRNA expression by cannabinoids is apparently mediated through cannabinoid receptors, unlike CB1 and CB2 receptor. Indeed, other cannabinoid-like receptors different from CB1 and CB2 may be involved in the microglial immune-related response, when high concentrations of cannabinoid agonists are used (Puffenbarger, Boothe, &

Cabral, 2000). Candidates are G protein-coupled receptor 55 (GPR55), abnormal-cannabidiol receptors (abn-CBD), peroxisome proliferator-activated receptor (PPAR), transient receptor potential cation channel (TRP), and WIN 55,212-2-like receptors (Fig. 41.3). All these receptors are expressed in microglial cells, and respond to endogenous or synthetic cannabinoids in different ways in order to modulate microglial activation processes.

GPR55 is expressed in healthy brain and exhibits 13.5 and 14.1% sequence homology to CB1 and CB2 receptors, respectively (Baker, Pryce, Davies, & Hiley, 2006). GPR55 mRNA is expressed and functional in BV-2 cells and in mouse microglia, and its activation mediates similar changes to those determined in CB2 receptor (Pietr et al., 2009). These results suggest that GPR55 and CB2 are involved in neuroinflammation processes, and that their expression depends on the activation state of the microglial cells. A role for GPR55 has been recently reported in neuroprotection using an excitotoxicity model on rat organotypic hippocampal slice cultures (Kallendrusch et al., 2013). Indeed, the GPR55 selective agonist l-α-lysophosphatidylinositol (LPI) prevents dentate gyrus granule cells excitotoxic damaged and reduces the number of activated microglia after NMDA induced lesions, suggesting a clear role of GPR55 receptor in neuroprotection (Fig. 41.3).

Moreover, it has been also demonstrated that the synthetic atypical cannabinoid closely related to cannabidiol O-1602 can activate cannabinoid-like receptors, such the abn-CBD receptor GPR18 and GPR55. It has been shown that the effect of O-1602 was antagonized by the synthetic compound O-1918, also related to cannabidiol (Ashton, 2012). In addition, McHugh, Wager-Miller, Page, and Bradshaw, (2012) determined that GPR18 was the abn-CBD receptor involved in the BV-2 microglial cell migration and chemotaxis. These researchers demonstrated that NAGly (an enzymatically oxygenated metabolite of the endocannabinoid *N*-arachidonoyl ethanolamide, anandamide AEA) initiates directed microglial migration in the CNS through activation of GPR18 (McHugh et al., 2012). Similarly, it was previously shown that 2-arachidonoylglycerol (2-AG) can stimulate BV-2 cell chemotaxis and migration (Franklin & Stella, 2003). In addition, 2-AG acting on abn-CBD receptors expressed on microglial cells reduces microglial reactivity and toxicity on excitotoxically lesioned dentate gyrus granule cells (Kreutz et al., 2009) (Fig. 41.3).

PPAR are also expressed in microglial cells. Different cannabinoids like 2-AG, AEA, palmitoylethanolamide (PEA), WIN 55,212-2, CBD, and THC interact with PPAR to modulate their activity. Some studies demonstrated the role of these receptors in the regulation of microglial activation process, after brain injury. Indeed, PPAR-γ from microglial cells control ischemia-induced microglial activation and neuronal damage/death in the dentate gyrus of the hippocampus, after transient global cerebral ischemia (Lee & Won, 2014). In addition, an inflammatory and neuroprotective action of PPAR-γ agonists through the modulation of CD200, mainly expressed in neurons but also in astrocytes, and CD200R, mainly present in microglia, has been recently demonstrated (Dentesano et al., 2014). CD200R receptors are involved in maintenance of the microglial proinflammatory activated phenotype, and alterations in this mechanism are related to neurodegenerative diseases. Considering the therapeutic value of these targets, more intensive research will be necessary to increase our understanding of the possible consequences of the modulation of PPAR receptors.

Microglial cells are also TRPV receptors. It has been demonstrated that TRPV1 and TRPV4 stimulation from BV-2 and microglial cells may modulate the abnormal microglial activation process in an acute model of inflammation (Raboune et al., 2014), and are induced by LPS (Konno et al., 2012). Cannabinoid agonists including THC, CBD, WIN 55,212-2, AEA, and the antagonist SR141716 have been described to operate on this ion channel at micromolar concentrations, and modify its action. In this sense, CBD enhances microglial phagocytosis via TRPV channel activation, evidencing the pharmacological potential of TRPV channel for treating neuroinflammatory disorders involving changes in microglial function (Hassan et al., 2014).

As mentioned above, endocannabinoids act on microglial cells to modulate their functions and activation. Several studies demonstrated the effect of 2-AG on the regulation of microglial reactivity. 2-AG, acting on CB2 receptors, triggers microglial migration, decreases proinflammatory molecule release, and enhances BDNF release and microglial proliferation (Carrier et al., 2004). These results evidence that, after brain damage, the ECS responds by enhancing local 2-AG production in order to recruit new microglial cells to face and solve the brain damage.

Similar results were found for PEA which interacts with an orphan receptor expressed by microglial cells, and regulates microglial activation and recruitment after focal cerebral ischemia (FCI) damage induction (Franklin & Stella, 2003; Stella, 2010). The neuroinflammation process in the injured brain area after FCI damage enhanced microglial cell motility, as well as the PEA levels. PEA acts through an orphan Gi/o-coupled receptor, and this receptor would be distinct from CB1, CB2, and abn-CBD receptors (Franklin & Stella, 2003). PEA interacts with PPAR-α in the micromolar range, and reduces the number of microglial cells, protecting dentate gyrus granule cells in excitotoxically damaged organotypic hippocampal slice cultures (Koch et al., 2011). These results suggest PPAR-α receptors as a possible target for therapeutic interventions to mitigate symptoms of secondary neuronal damage.

Taken together, these studies evidence the importance of the ECS in microglial physiology. Cannabinoid

agonists acting through microglial cannabinoid-like receptors modulate several processes in microglial cells, such as activation, proliferation, cytokines, and NO release, migration and/or phagocytosis postulating the microglial ECS as a key element in the treatment of neuroinflammation

Microglia as a Downstream Effector of ECS Deregulation: Cerebellar Motor Impairment

Chronic cannabis exposure may affect brain microglial reactivity through an indirect mechanism recently described that results in motor coordination deficits beyond the cannabis consumption (Cutando et al., 2013). The repeated administration of THC in healthy naïve mice enhances microglial reactivity in the cerebellum (Fig. 41.4). This effect was related to the impact that repeated cannabis administration has on CB1 receptor expression. In rodents receiving THC, but also in heavy cannabis smokers, repeated cannabis exposure results in strong downregulation and desensitization of CB1 receptors. In the cerebellum, a brain region crucial for motor learning and fine motor coordination, the downregulation of CB1 receptor by chronic THC was

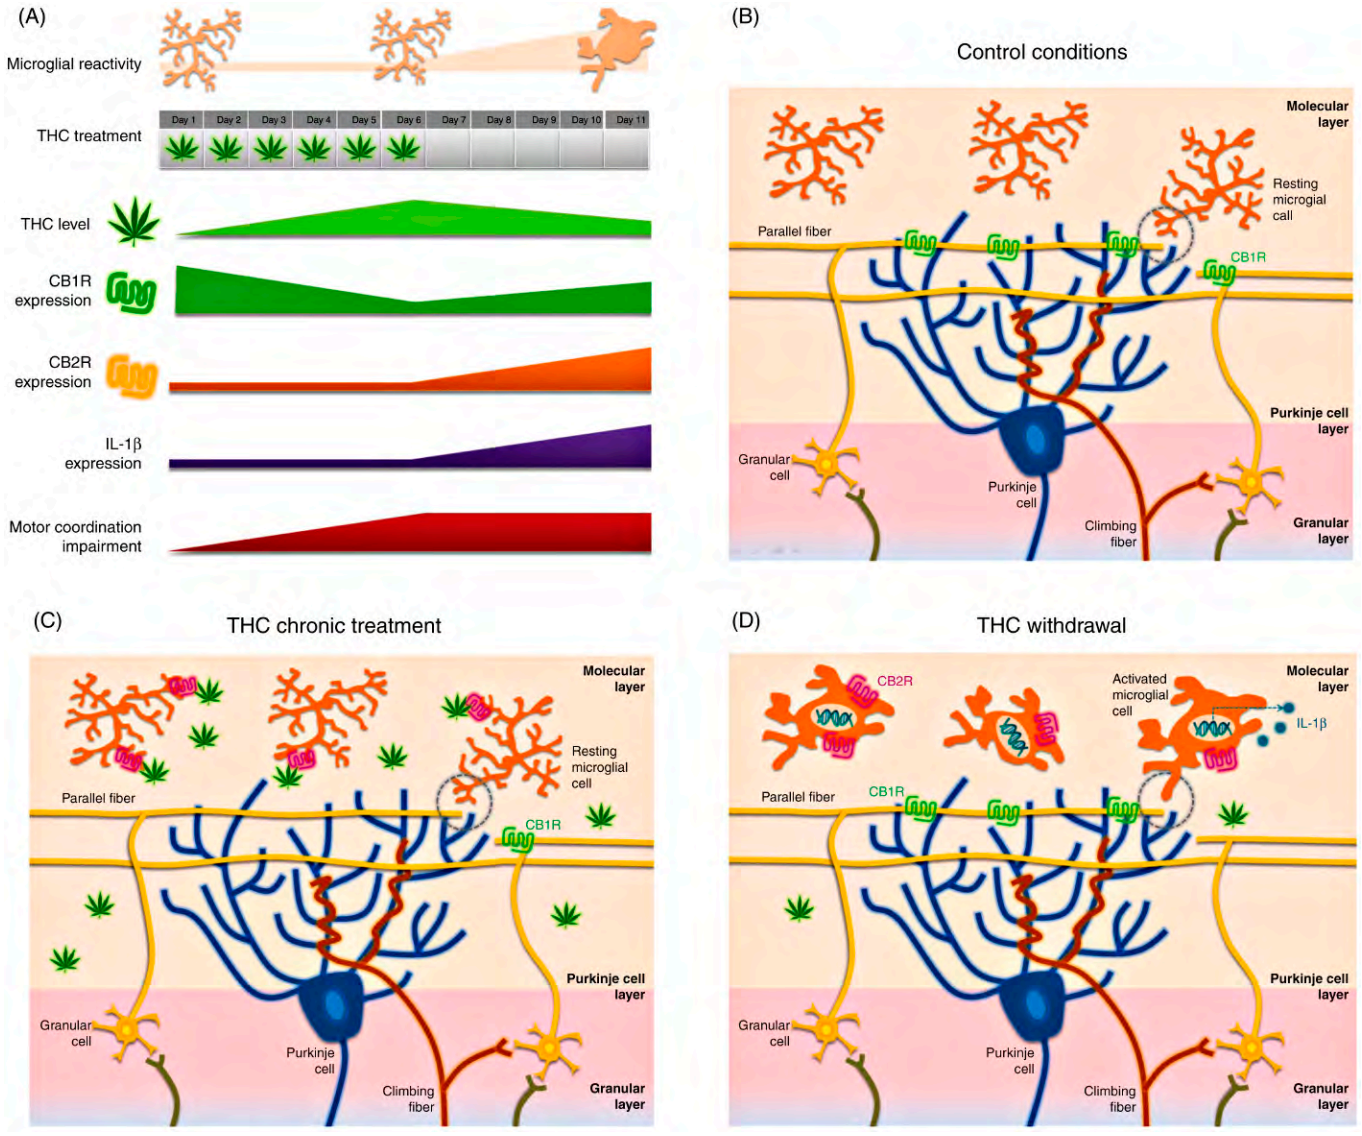

FIGURE 41.4 Effect of THC exposure in the neuronal circuit of the cerebellar cortex. (A) Schematic time-course for repeated THC exposure over the days of cannabinoid administration and subsequent withdrawal, representing the microglial reactivity, the measured levels of CB1 and CB2 receptors, the expression of IL-1β, and the cerebellar functional assessment in behavioral paradigms in mice; (B) neuronal circuit in the cerebellar cortex under control conditions, with the main cell populations (Purkinje cells, granular cells, and resting microglia), and the main fibers contacting Purkinje neurons (climbing fibers and parallel fibers); (C) chronic THC exposure downregulates CB1 receptor expression in the cerebellar parallel fibers, and may have antineuroinflammatory effects on microglial reactivity; (D) after THC withdrawal, microglial cells in the cerebellar cortex become activated, produce IL-1β, and affect cerebellar function.

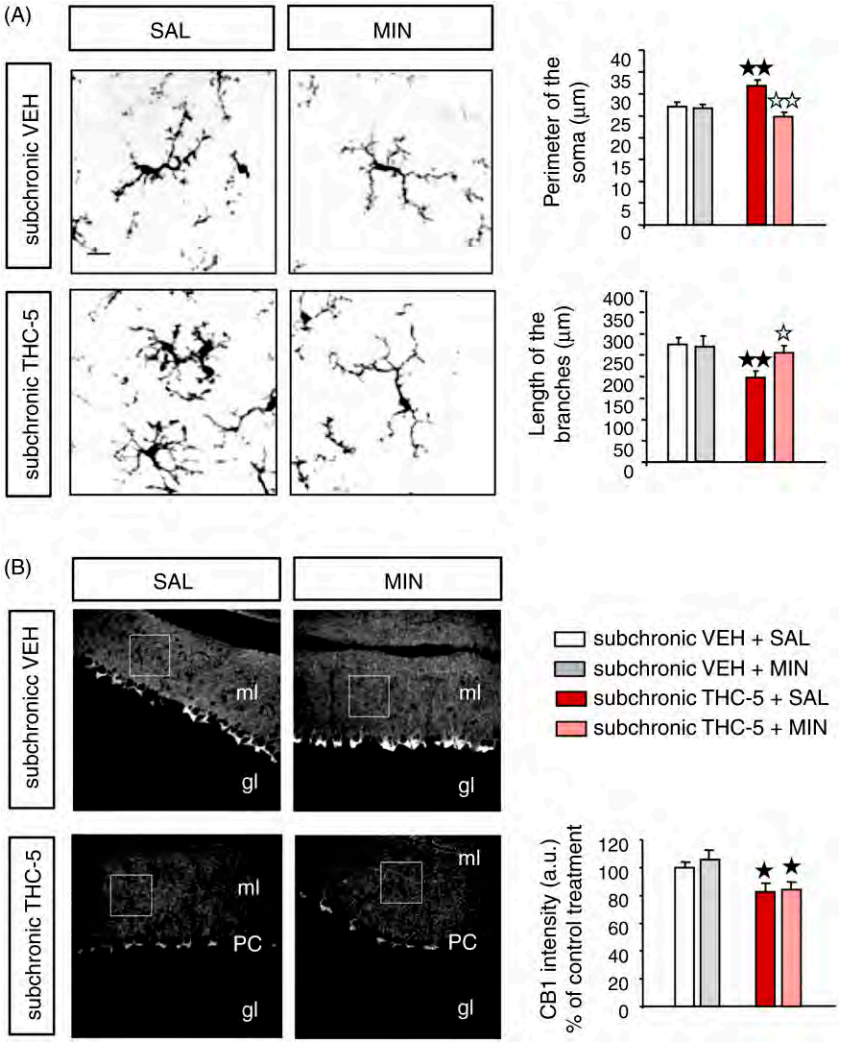

FIGURE 41.5 Experimental data supporting Fig. 41.4, on the activation of cerebellar microglia and CB1 receptor expression after THC withdrawal. (A) Immunofluorescence detection of Iba1 to reveal microglial morphology in the cerebellum of mice after subchronic THC exposure. The administration of minocycline, a tetracycline antibiotic that reduces microglial activation, normalizes microglial cell morphology in this brain area. Note the increase in the perimeter of the soma and the reduced branch length after subchronic THC administration, a microglial phenotype that is reversed by minocycline treatment; (B) immunofluorescence detection of CB1 receptor and signal density quantification in the molecular layer of the cerebellum, after chronic THC administration on mice that received subsequent minocycline. Note that minocycline treatment does not affect CB1 receptor downregulation in this cerebellar layer (modified from Cutando et al., 2013). Data are expressed as mean ± SEM. *$p < 0.05$, **$p < 0.01$ (compared to vehicle-treated group); *$p < 0.05$, **$p < 0.01$ (compared to THC-treated group) *Source: From Cutando et al. (2013), reproduced with permission of the* Journal of Clinical Investigation.

responsible for the appearance of reactive microglial cells at the cerebellar cortex molecular layer, as well as the enhanced excitability at Purkinje cells, the main output cell of the cerebellar cortex. This microglial activation process produced by chronic cannabis exposure is accompanied by changes in CB2 and IL-1β expression, as well as alterations in the microglial morphology toward an activated phenotype (Fig. 41.4). Moreover, constitutive genetic removal of CB1 receptor, or conditional removal of CB1 receptor from the parallel fibers of the cerebellum in mice, also resulted in reactive microglia in the cerebellar molecular layer. This result points to the necessary deregulation of CB1 receptor expression for the appearance of microglial reactivity, accompanied by an overactivation of Purkinje cell excitability. The pharmacological inhibition of microglial reactivity was sufficient to prevent the deficits in cerebellar function produced by repeated cannabis exposure. Indeed, the coat-hanger test for fine motor coordination, and the eye-blink conditioning test for conditioned motor learning (Fig. 41.6) were normalized with the microglial inhibition, even while CB1 regulating expression was below control levels (Fig. 41.5). In addition, the inhibition of microglial reactivity reduced Purkinje cell excitability. This recent study provides new insights into the role of the ECS on the microglial reactivity, and highlights the

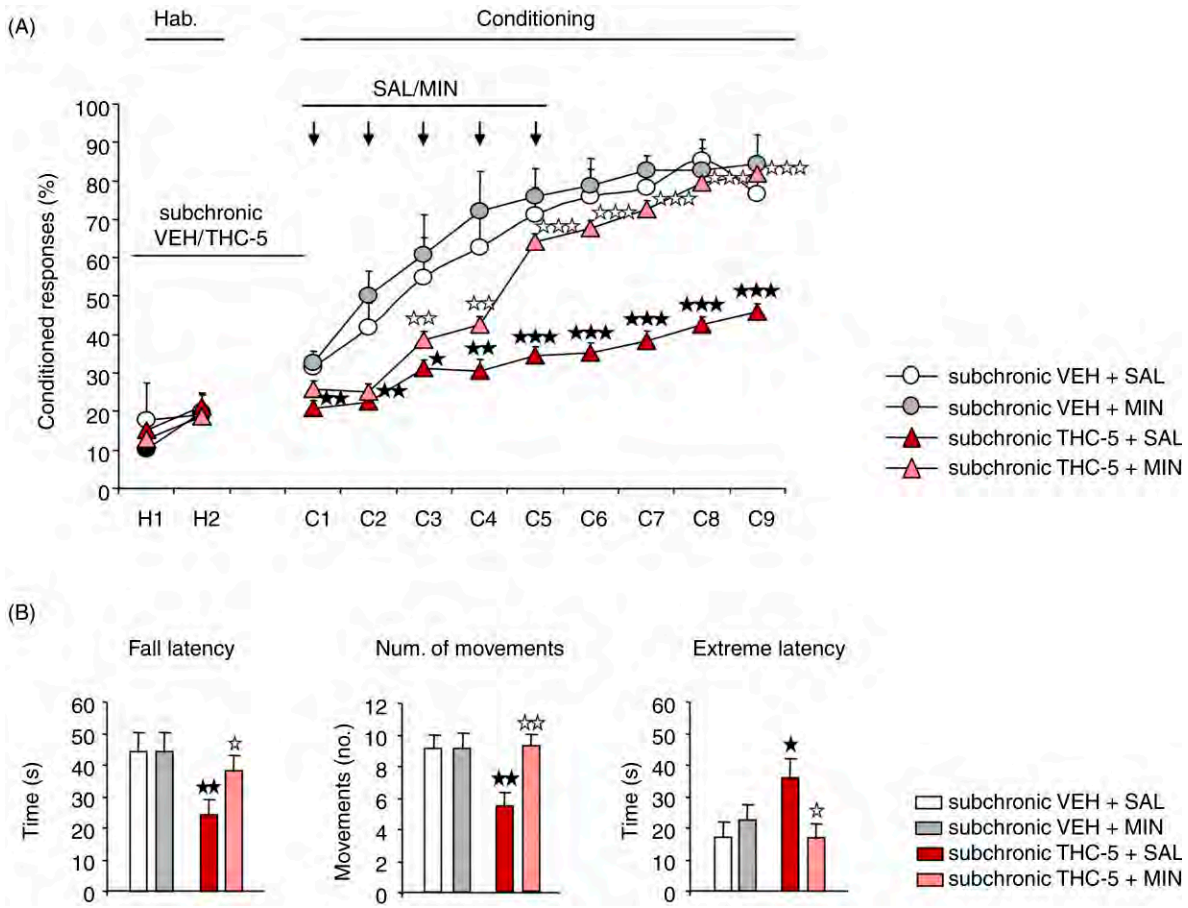

FIGURE 41.6 **Experimental data on the impact of subchronic exposure to THC and its withdrawal on conditioned cerebellar learning and motor coordination.** (A) Conditioned cerebellar learning in the eye-blink conditioning in mice that received THC followed by the administration of minocycline *(arrows)*. The number of conditioned responses in the eye-blink conditioning is a measure of cerebellar function. After two days of habituation to the procedure (H1, H2), mice were trained during nine consecutive days (C1–C9) where the number of conditioned responses to a conditioned stimulus (sound) was measured. THC-treated mice showed a clear deficit *(red triangles)* that was fully prevented by minocycline treatment *(arrows)* during THC withdrawal *(pink triangles)*; (B) motor coordination measured in the coat-hanger test was impaired after THC withdrawal *(red bars)*. Preventing microglial activation with minocycline normalized motor coordination. Data are expressed as mean ± SEM. $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$ (compared to vehicle-treated group), $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$ (compared to THC-treated group) *Source: From Cutando et al. important role of microglial cells in brain function and pathological states.

MINI-DICTIONARY

Chemokines Type of chemoattractant cytokines that regulate the migration of immune cells, and help to coordinate immune and inflammatory reactions.

Coat-hanger test Behavioral test to evaluate fine motor coordination. The experimental animal is located on a coat-hanger above a cushioned surface. Then the animal movements and time on the coat-hanger while it moves to reach the hanging bar are analyzed to reveal cerebellar deficits.

Danger-associated molecular pattern molecules (DAMPs) Intracellular constituents (DNA or intracellular proteins) from necrotic cells that can initiate the noninfectious innate immune response in macrophages.

Eye-blink conditioning Neurophysiological test of cerebellar function where the eyelid movement of the experimental subject is analyzed. The subject must learn the association of a conditioned stimulus (sound) with an unconditioned stimulus (electric stimulus or air puff to the eye). Proper cerebellar function will produce an increasing number of conditioned responses over the days of training sessions. Cannabis smokers show a marked deficit in this cerebellar test, which is mimicked by mice after THC administration.

Interferon gamma Cytokine produced by T lymphocytes as part of the immunological response to viral and nonviral antigens, as well as to other cytokines.

Interleukins Type of cytokines with relevant functions in immune cell modulation. This is the most diverse family of cytokines, with more than 30 types. There are proinflammatory (IL-1β) but also antiinflammatory interleukins (IL-4, IL-10, or IL-13).

Microglial activation Change in microglial state from a surveillance/resting state to a reactive or activated state. The microglial activation process involves changes in gene expression and cell surface marker, such as CD11b, but also changes in cell morphology from a ramified cell with small soma to a cell with amoeboid phenotype, characterized by short or no branches, and an enlarged soma.

Neuroinflammation Refers to a central nervous system status in which reactive microglial cells and astrocytes, but not

peripheral immune cells, are usually implicated in the secretion of proinflammatory factors.

Pathogen-associated molecular pattern molecules (PAMPs) Conserved components that are widely common to pathogens (viruses, bacteria, or fungi) that initiate the innate immune response through Toll (pattern recognition) receptors on macrophages.

Th1 and Th2 lymphocytes Types of T helper lymphocytes derived from a common clone of T cells. The presence of specific interleukins promotes the development of one or the other type of Th cell. Usually, Th1 lymphocytes promote macrophage/cell-mediated response, while Th2 lymphocytes intervene in the antibody-mediated response.

Cannabis and Psychosis: Correlation, Causality, and Consequences

D. Basu, P. Parakh***

***Drug De-addiction and Treatment Centre, Department of Psychiatry, Postgraduate Institute of Medical Education and Research, Chandigarh, India**

****Department of Psychiatry, Ruby General Hospital, Kolkata, India**

SUMMARY POINTS

- Epidemiological studies have shown that cannabis use is associated with a higher risk of developing psychosis.
- The association is dose-dependent, with heavy users having a higher risk.
- Exposure to cannabis in early adolescence is associated with a higher risk of developing psychosis.
- Since only a small proportion of cannabis users go on to develop psychosis, gene–environment interactions are likely to be responsible.
- People with stronger genetic liability for schizophrenia are more susceptible to the psychosis-inducing effects of cannabis.
- Exposure to environmental factors like childhood sexual trauma and urban upbringing has also been implicated in the link between cannabis and psychosis.
- Cannabis acts as a component cause of psychosis. That is, cannabis is neither a necessary nor a sufficient cause of psychosis. Presence of some other factor or factors is required for cannabis to have a causal influence on the risk for psychosis.

KEY FACTS OF GENE–ENVIRONMENT INTERACTION

- It is a type of interplay between genetic and environmental factors.
- When people with different genotypes show different responses to the same environmental factor, it is said to be a gene–environment interaction.
- For example, people with different genotypes may differ in their response to a medicine.
- In gene–environment interaction, either the genotype can affect the response to the environmental factor, or the environmental factor can modulate the expression of the genotype.
- Gene–environment interaction is different from gene–environment correlation where the genotype moderates the exposure to an environmental factor.
- Gene–environment interactions have been implicated in many common diseases like diabetes, obesity, cancer, etc., as well as mental illnesses like schizophrenia, and affective disorders.

LIST OF ABBREVIATIONS

CB1	Cannabinoid-1 receptor
CB2	Cannabinoid-2 receptor
CBD	Cannabidiol
COMT	Catechol-O-methyltransferase
DAT1	Dopamine transporter-1 gene
THC	Tetrahydrocannabinol

INTRODUCTION

Cannabis has been used by man since time immemorial for its psychotropic effects. However, its widespread use has often made people wonder if it has any detrimental effects on the human body. This was a matter of debate even as early as in the 19th century, when the British government established the Indian Hemp Drugs Commission to investigate the effects of cannabis. The Commission submitted its seven-volume report in 1893, and concluded that there was no evidence of any weight regarding mental and moral injuries from moderate use of cannabis (Kaplan, 1969). Over the next century, in spite of reports of acute psychotic symptoms following heavy cannabis use (Chopra & Smith, 1974; Talbott & Teague, 1969), cannabis gradually came to be perceived as a harmless recreational drug and, being widely available and inexpensive, became very popular amongst the youth.

CORRELATION

There is ample research to show that regular cannabis use and psychotic disorders such as schizophrenia are associated in the general population (Degenhardt & Hall, 2001; Tien & Anthony, 1990). It is also well known that heavy cannabis users are overrepresented among new cases of schizophrenia (Barbee, Clark, Crapanzo, Heintz, & Kehoe, 1989). However, because of the large number of confounding factors that could have had a bearing on these results, these findings have to be interpreted with caution. Stronger evidence in favor of an association between cannabis and psychosis comes from longitudinal studies of large representative samples of the population who have been followed-up over time to see if cannabis users are at a higher risk of developing psychosis.

The earliest such evidence was from a 15-year prospective study of the Swedish conscript cohort (Andreasson, Allebeck, Engstrom, & Rydberg, 1987). Around 50,000 Swedish conscripts were followed-up, and it was found that those who had tried cannabis by age 18 were 2.4 times more likely to be diagnosed with schizophrenia 15 years later than those who had not. The risk increased to around six times with higher frequency of cannabis use. The risk was substantially reduced but still significant after statistical adjustment for variables that were related to the risk of developing schizophrenia. The same cohort was followed-up over 27 years (Zammit, Allebeck, Andreasson, Lundberg, & Lewis, 2002), and this study also found a dose–response relationship between frequency of cannabis use at baseline and risk of schizophrenia during the follow-up. Again, the relationship between cannabis use and schizophrenia persisted, even after statistically controlling for the effects of other substance use, and other potential confounding factors, including a history of psychiatric symptoms at baseline. Assuming a causal relationship, and given current patterns of use, the authors estimated that 13% of cases of schizophrenia could be averted if all cannabis use was prevented. The recently published 35-year follow-up of the same cohort also supported these results (Manrique-Garcia et al., 2012).

In another study, a birth cohort of 1034 children born in Dunedin, New Zealand, were asked about their drug consumption at the ages of 15 and 18 (Arseneault et al., 2002). At 26 years of age, the sample was interviewed using a standardized psychiatric assessment. It was found that those who had used cannabis by the age of 15 or 18 reported significantly more psychotic symptoms at 26 years of age, as compared with nonusers. In addition, 10% of those who used cannabis by the age of 15 were diagnosed with schizophreniform psychosis when they were 26 years old, as compared with 3% of those who had not used cannabis. Similar results, as summarized in Table 42.1, have been reported by other prospective cohort studies from the Netherlands, New

TABLE 42.1 General Population Studies of the Effect of Cannabis Use on the Risk of Psychosis

Authors	Sample	Follow-up	Odds ratio (95% confidence interval)
Andreasson et al. (1987)	45,570 Swedish male conscripts	15 years	6.0 (4.0–8.9)
Zammit et al. (2002)	50,087 Swedish male conscripts	27 years	3.1 (1.7–5.5)
Arseneault et al. (2002)	1037 New Zealander males and females from Dunedin birth cohort	15 years	3.1 (0.7–13.3)
van Os et al. (2002)	4104 Dutch males and females from population sample, aged 18–64 (NEMESIS)	3 years	2.8 (1.2–6.5)
Fergusson et al. (2003)	1265 New Zealander males and females from Christchurch birth cohort (CHDS)	3 years	1.8 (1.2–2.6)
Henquet et al. (2005a)	2437 German males and females from population sample, aged 14–24 (EDSP)	4 years	1.7 (1.1–2.5)
Manrique-Garcia et al. (2012)	50,087 Swedish male conscripts	35 years	3.7 (2.3–5.8)

This table shows some of the large-scale epidemiological follow-up studies, which have found that cannabis users have a higher risk of developing psychosis later in life.
From Parakh, P., & Basu, D. (2013). Cannabis and psychosis: have we found the missing links? Asian Journal of Psychiatry, *6, 281–287.*

Zealand, Germany, and elsewhere (Fergusson, Horwood, & Swain-Campbell, 2003; Henquet et al., 2005a; van Os et al., 2002).

Cannabis is known to improve negative and depressive symptoms, and may be used to self-medicate symptoms of schizophrenia (Schneier & Siris, 1987). Therefore, a possible explanation of the association between cannabis and psychosis is that cannabis use is a consequence, rather than a cause, of psychosis. In order to control for this, some longitudinal studies excluded patients with psychotic symptoms at baseline, or made statistical adjustments for the same, and yet found an increased risk of psychosis in cannabis users (Arseneault et al., 2002; van Os et al., 2002).

In a study on another birth cohort from New Zealand, data on both cannabis use and psychotic symptoms were collected from the cohort at the ages of 18, 21, and 25 years (Fergusson et al., 2003). The investigators were therefore able to study both the effects of cannabis use on later psychotic symptoms, and also the effect of psychotic symptoms on later cannabis use. Like the other studies discussed earlier, this study also found that cannabis use at the age of 18 was associated with more psychotic symptoms 3 and 7 years later. Moreover, in contradiction of the self-medication hypothesis, the presence of psychotic symptoms at the age of 18 appeared to inhibit, rather than encourage, subsequent cannabis use. However, conflicting results were reported by a 10 year follow-up study (Foti, Kotov, Guey, & Bromet, 2010). The authors concluded that the relationship of cannabis use with psychotic symptoms was bidirectional; cannabis exposure predicted severity of psychosis, and individuals with more severe psychotic symptoms were more likely to use cannabis in the future. In view of the mixed results, it is perhaps too early to discard the self-medication hypothesis altogether.

It has been argued that the association between cannabis and psychosis that many epidemiological studies have found can be due to confounding factors like other substance use. A systematic review of seven longitudinal studies on the relationship between cannabis and psychosis, which adjusted for about 60 confounding factors, including other substance use, personality traits, sociodemographic markers, intellectual ability, other mental health problems, etc., reported an increased risk (odds ratio = 1.4) of any psychotic outcome in individuals who had ever used cannabis (Moore et al., 2007). Findings were consistent with a dose-response effect, with greater risk in people who used cannabis more frequently. Another study attempted to exclude the possibility of unmeasured confounding variables by conducting a sibling pair analysis, nested within a prospective birth cohort, and still found that early cannabis use is associated with psychosis-related outcomes in young adults (McGrath et al., 2010).

Indirect evidence in favor of an association between cannabis and psychosis came from a metaanalysis which found that the age at onset of psychosis for cannabis users was 2.70 years younger than for nonusers, while alcohol use was not associated with a significantly earlier age at onset of psychosis (Large, Sharma, Compton, Slade, & Nielssen, 2011). Another study of heavy cannabis users who went on to develop psychosis found that age at onset of cannabis use was directly associated with age at onset of psychosis, and age at first hospitalization (Galvez-Buccollini et al., 2012). That the association remained significant even after adjusting for potential confounding factors is, according to the authors, consistent with the hypothesis that cannabis can cause or precipitate the onset of psychosis after a prolonged period of time. Similar results were reported by another study, which found that age at initiation of cannabis use predicts the age at onset of psychosis, with the gap being approximately 7–8 years (Stefanis et al., 2013). A study of 410 first-episode psychosis patients designed to investigate the association between gender, patterns of cannabis use, and age at onset of psychosis reported that a younger age at first cannabis use (≤15 years) is associated with a younger age at onset of psychosis, but only in those who had used cannabis daily (Di Forti et al., 2014b). The authors concluded that daily use, especially of high-potency cannabis, drives the earlier onset of psychosis in cannabis users, irrespective of gender.

The epidemiological evidence in favor of an association between cannabis and psychosis is buttressed by studies showing that the association is biologically plausible. The endocannabinoid system (briefly described in Table 42.2) has been implicated in the causation of schizophrenia. Anandamide levels are significantly elevated in schizophrenia patients, both in the cerebrospinal fluid and in the blood (De Marchi et al., 2003; Giuffrida et al., 2004; Koethe et al., 2009; Leweke, Giuffrida, Wurster, Emrich, & Piomelli, 1999). Studies on schizophrenic patients have shown upregulation of cannabinoid-1 (CB1) receptors in cortical brain regions such as the dorsolateral prefrontal cortex (Dalton, Long, Weickert, & Zavitsanou, 2011; Dean, Sundram, Bradbury, Scarr, & Copolov, 2001) and in cingulate cortex (Newell, Deng, & Huang, 2006; Wong et al., 2010; Zavitsanou, Garrick, & Huang, 2004). Cannabinoid-2 (CB2) receptors have also been implicated in schizophrenia. Clinical remission of schizophrenia has been shown to be accompanied by a significant decrease in CB2 receptor mRNA levels in the blood (De Marchi et al., 2003). An increased risk of schizophrenia has been reported for people with low CB2 receptor function (Ishiguro et al., 2010).

There is also direct evidence of cannabis leading to structural, neurophysiological, and neurochemical changes in the brain, which are similar to those seen in schizophrenia. A systematic review combining in vivo

TABLE 42.2 The Endocannabinoid System

Major constituents	Role
Cannabinoid receptors	
• Cannabinoid-1 (CB1) receptors	Found mainly in the central nervous system, in areas such as globus pallidus, hippocampus, cerebral cortex, hypothalamus, cerebellum, and striatum Mostly located in the presynaptic neurons, and control release of other neurotransmitters like dopamine, GABA, acetylcholine, and glutamate Involved in brain functions such as pain, emotion, cognition, and motivation Also found in the periphery in reproductive, metabolic, cardio-vascular, and gastrointestinal systems
• Cannabinoid-2 (CB2) receptors	Mostly located in the periphery, mainly in immune cells Also found in the brain on glial cells, and neurons in brainstem and cerebellum Modulate immune cell migration and cytokine release, in periphery and in brain
Endocannabinoid ligands	
• Anandamide	Binds to both CB1 and CB2 receptors Also activates some noncannabinoid receptors
• 2-arachidonoyglycerol	Selectively binds to CB1 receptors

This table briefly describes the major constituents of the endocannabinoid system, which modulate many central and peripheral cellular processes involved in neuronal development, neurotransmission, inflammation, energy metabolism, pain relief, and efficient functioning of cardiovascular, respiratory, reproductive, and hormonal systems (Galve-Roperh, Aguado, Palazuelos, & Guzman, 2007).

structural neuroimaging and post mortem studies on cannabis-using patients with psychosis, as well as individuals at high risk for psychosis, found evidence for consistent brain structural abnormalities in CB1 receptor-enhanced brain areas such as the cingulate and prefrontal cortices and the cerebellum, which have not been seen in healthy samples (Rapp, Bugra, Riecher-Rössler, Tamagni, & Borgwardt, 2012). Tetrahydrocannabinol (THC) has been shown to decrease theta coherence between the right and left frontal lobes and, since the reduction in coherence was strongly associated with positive psychotic symptoms, this has been proposed as one of the mechanisms for the psychotogenic property of cannabis (Morrison et al., 2011). Long-term cannabis use has been shown to be associated with deficits in working memory and abnormalities in basalganglio-thalamic morphology, similar to that seen in schizophrenia (Smith et al., 2014).

It has been hypothesized that cannabis increases the risk of psychotic disorders by inducing the same dopaminergic alterations seen in schizophrenia. Dopamine neuronal firing in the ventral tegmental area of midbrain is modulated by retrograde endocannabinoid signaling, which is disrupted by exogenous cannabinoids, resulting in excess dopaminergic transmission in mesolimbic tract (Cheer, Wassum, Heien, Phillips, & Wightman, 2004; French, Dillon, & Wu, 1997; Riegel & Lupica, 2004). However, conflicting results were reported by a recent study, which found that chronic cannabis use is associated with reduced dopamine synthesis capacity (Bloomfield et al., 2014). Some researchers have hypothesized that psychosis results from aberrant reward prediction, and abnormal attribution of salience caused by disordered dopamine transmission (Kapur, Mizrahi, & Li, 2005). This may be one of the ways by which cannabis can lead to psychosis as THC has been shown to increase the aberrant attribution of salience (Bhattacharyya et al., 2012b).

Endocannabinoid signaling is an important determinant of maturation of the adult brain, and plays a critical role in neuronal proliferation, migration, axonal guidance, positioning of cortical interneurons, and synaptogenesis (Galve-Roperh et al., 2007). Therefore, disruption of normative endocannabinoid signaling during adolescence may have longstanding consequences on adult brain function (Malone, Hill, & Rubino, 2010). Exposure to exogenous cannabinoids in adolescence can lead to a disturbance of the endocannabinoid system in the brain, and interfere with neurodevelopmental processes. Epidemiological studies have also found that exposure to cannabis in early adolescence is associated with a higher risk of psychosis (Arseneault et al., 2002; Konings, Henquet, Maharajh, Hutchinson, & van Os, 2008; Stefanis et al., 2004).

CAUSALITY

Although the evidence, largely from prospective epidemiological studies, strongly suggests that heavy cannabis use is associated with an increased risk of developing psychosis, the fact remains that a vast majority of cannabis users never go on to develop psychosis. At the same time, it also cannot be denied that not all patients with psychosis have been exposed to cannabis. Thus, cannabis is neither a necessary nor a sufficient cause; rather it must be a component cause of psychosis (Henquet, Murray, Linszen, & van Os, 2005b; Murray, Morrison, Henquet, & Di Forti, 2007; Parakh & Basu, 2013). In other

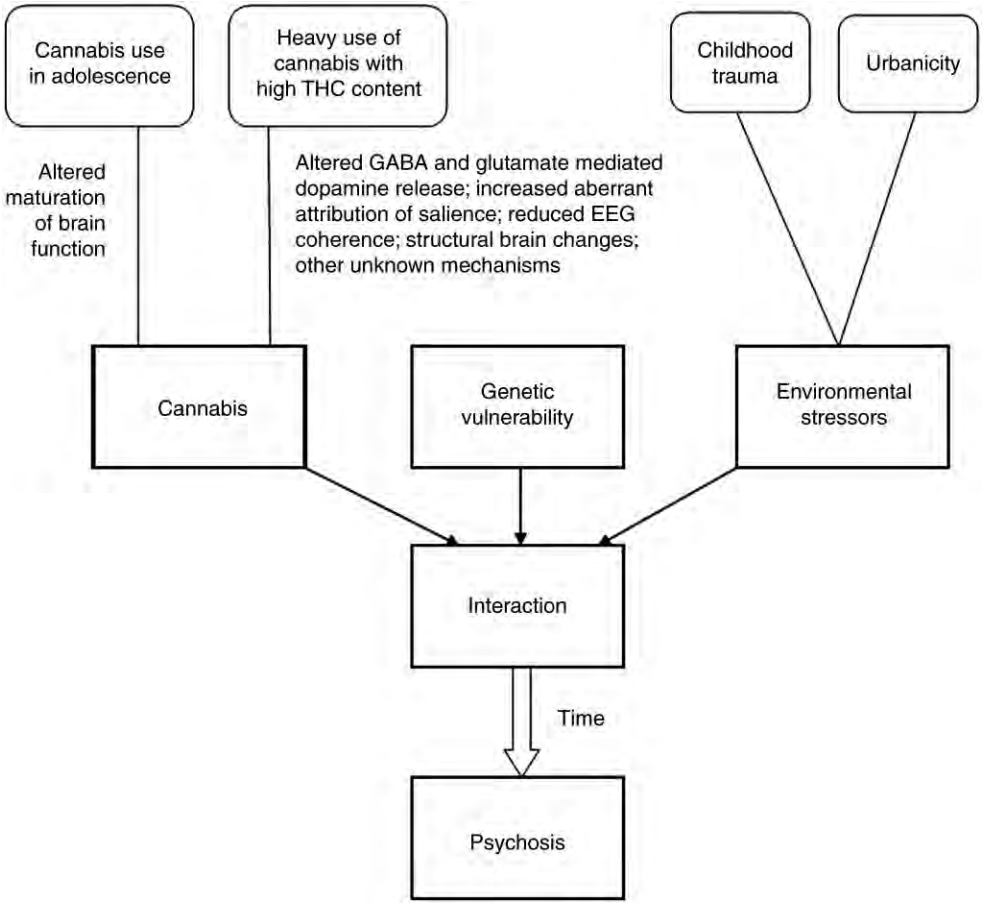

FIGURE 42.1 **Cannabis is a component cause of psychosis.** Cannabis can cause psychosis only in the presence of other susceptibility factors, which may be genetic or environmental, thus acting as a component cause. *THC*, Tetrahydrocannabinol; *GABA*, gamma-amino butyric acid; *EEG*, electroencephalography. *Source: From Parakh, P. & Basu, D. (2013). Cannabis and psychosis: Have we found the missing links?* Asian Journal of Psychiatry, 6, 281–287.

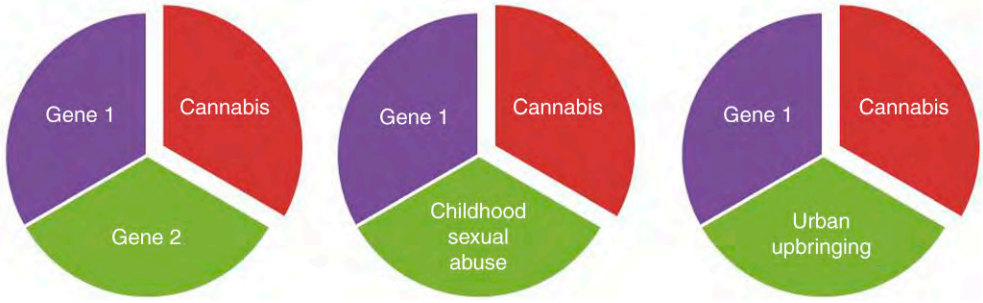

FIGURE 42.2 **Cannabis, by itself, is not a sufficient cause of psychosis.** These are some possible examples of how the presence of other factors is needed for cannabis to cause psychosis.

words, presence of some other factor or factors is required for cannabis to have a causal influence on the risk for psychosis (Figs. 42.1 and 42.2).

Genetic vulnerability to psychosis is one of the factors that make one susceptible to the psychosis inducing potential of cannabis. That is, gene–environment interactions (Fig. 42.3) that explain how one's genotype moderates one's response to cannabis form the basis of the link between cannabis and psychosis. A case-control study of patients with cannabis-associated psychosis found that the risk of schizophrenia was ten times higher for relatives of patients who developed psychosis using cannabis than for the relatives of patients who had not used cannabis and suggested that individuals who have a stronger genetic liability for schizophrenia, indicated by the higher prevalence of schizophrenia in their family, are more vulnerable for the psychotogenic effect of cannabis (McGuire et al., 1995).

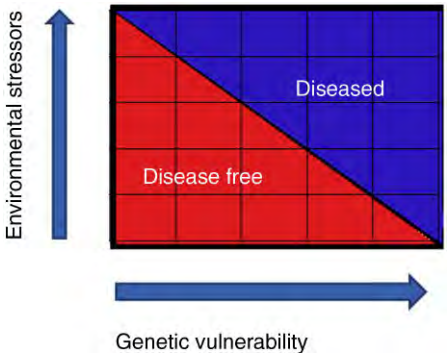

FIGURE 42.3 Genes and environment interact to cause diseases. The figure shows how the interaction between a person's genes and the environment influences the chance of developing a disease. Environmental insults are more likely to cause a disease in people who are inherently susceptible because of their genetic makeup.

Direct evidence for the role of gene–environment interactions comes from studies on genes and their patterns of expression. The first such evidence came from a study on the functional polymorphism in the catechol-O-methyltransferase (*COMT*) gene (Caspi et al., 2005). COMT is the enzyme that degrades dopamine, epinephrine, and norepinephrine. A functional polymorphism of the *COMT* gene results in two common allelic variants, the valine (Val), and the methionine (Met) allele, associated with high versus low enzyme activity, respectively. The authors reported that for individuals homozygous for the Val allele, the relative risk of developing psychotic illness after adolescent cannabis exposure was 10.9, while in individuals homozygous for the methionine allele, the risk was only 1.1. This effect was observed only in those with adolescent-onset cannabis use, and not in those with adult onset cannabis use. However, these findings could not be replicated in a later study (Zammit et al., 2007), while a more recent study reported that cannabis use increased the likelihood to report positive psychotic experiences in Val carriers only, when they were exposed to childhood abuse (Alemany et al., 2014). Another study examined interactions between cannabis use and 152 single-nucleotide polymorphisms in 42 candidate genes, and found that variation in the AKT1 rs2494732 single nucleotide polymorphism may mediate both short-term as well as longer-term effects on psychosis expression associated with use of cannabis (van Winkel & Genetic Risk and Outcome of Psychosis (GROUP) Investigators, 2011). The role of genetic variation at rs2494732 of *AKT1* gene in influencing the risk of developing a psychotic disorder in cannabis users was confirmed in a subsequent case-control study (Di Forti et al., 2012). Another study reported that people using high potency cannabis daily, and having susceptible genetic variants in three candidate genes that affect dopamine signaling (*AKT1*, *DAT1*, and *COMT*) are far more likely to develop psychosis than others (Di Forti, Iyegbe, Falcone, Powell, & Murray, 2014a).

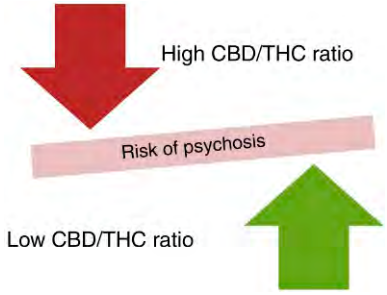

FIGURE 42.4 CBD/THC ratio and the risk of developing psychosis. Use of cannabis strains with low CBD/THC ratio is associated with a higher risk of psychosis. *CBD*, Cannabidiol; *THC*, tetrahydrocannabinol.

Given the complexity of the relationship between cannabis and psychosis, it seems unreasonable to expect that variation in a single gene can explain the differential effects of cannabis. It is more likely that two or more genes are interacting to cause psychosis in cannabis users, or perhaps other environmental factors interact with cannabis to cause psychosis in genetically vulnerable persons (Henquet, Di Forti, Morrison, Kuepper, & Murray, 2008). For example, people with specific genotypes of both *DAT1* and *AKT1* genes have been found to be more sensitive to the psychotogenic effects of cannabis than people with only one of those, and this effect involves an alteration in the neural response to Δ^9-THC in the dopamine-rich regions of striatum and midbrain, consistent with evidence that the psychotic effects of cannabis are mediated by dopamine (Bhattacharyya et al., 2012a).

Environmental factors like childhood sexual trauma (Houston, Murphy, Adamson, Stringer, & Shevlin, 2008) and urban upbringing (Kuepper, van Os, Lieb, Wittchen, & Henquet, 2011) have also been implicated in the link between cannabis and psychosis. While the exact biological basis of this is not known, it has been proposed that repeated exposure to environmental stressors, especially in young age, sensitizes one to the psychotogenic effects of Δ^9-THC (Henquet et al., 2008), and this cross-sensitization process is likely to be mediated by dopamine (Kuepper et al., 2010).

Another factor that has a bearing not only on the relationship between cannabis and psychosis, but also creates methodological hurdles in scientific research on the subject, is the high variability of Δ^9-THC content in the cannabis available on the street. Δ^9-THC is the main psychoactive ingredient in cannabis, and is thought to be the ingredient responsible for the increased risk of developing psychosis following regular cannabis use. Cannabidiol (CBD) is the other major constituent found in cannabis. It has been shown to have opposite effects to Δ^9-THC, and may even have antipsychotic properties (Bhattacharyya et al., 2010). The relative content of Δ^9-THC and CBD, which varies widely between different places and different products, has a bearing on the risk of progression to psychosis (Fig. 42.4). But it is of concern that use

of sinsemilla or skunk, which contains high levels of THC and almost no CBD, is gradually increasing, and may lead to a spate in the incidence of psychosis (Henquet & Kuepper, 2010; Potter, Clark, & Brown, 2008).

CONSEQUENCES

With support for decriminalization of cannabis growing all over the world, the consequences of an association between cannabis and psychosis cannot be overemphasized. Both the public and the policy makers need to be made aware of the scientific evidence available, and the implications. A metaanalysis estimated that about 14% of psychotic outcomes in young adults currently in the United Kingdom would not occur if cannabis were not consumed, considering that around 40% of adolescents and young adults in the United Kingdom have ever used cannabis (Moore et al., 2007). Although individual lifetime risk of chronic psychotic disorders such as schizophrenia, even in people who use cannabis regularly, is likely to be less than 3%, cannabis use is so common that it can be expected to have a substantial effect on psychotic disorders at a population level (Moore et al., 2007). Even if the actual figures turn out to be less, and reducing exposure to cannabis can avert psychotic outcome in only a few people, it should still be of utmost priority, considering how debilitating a psychotic illness can be. This is especially applicable for young adults, for whom a psychotic breakdown can have lifelong consequences, both in the personal and professional spheres.

With interest in prevention of schizophrenia rising all over the world amongst both researchers and policy makers, elucidation of the link between cannabis and psychosis is highly relevant. Unlike genetic vulnerability and other similar factors, which cannot be modified, cannabis use can be regulated. Public health interventions like education campaigns to alert people to the possible risks associated with cannabis, and to warn young people that using cannabis could increase their risk of developing a psychotic illness later in life, can be expected to yield positive results. This becomes even more pertinent in the current scenario as, when governments legalize cannabis, the public is indirectly conveyed the impression that cannabis is quite harmless and people can safely consume it. Since there is no doubt of the link between cannabis and psychosis, as well as a broad understanding of the biological basis of the association, there is no reason why this information should not be disseminated among the masses. While policy makers dither and dally, young lives are being lost to psychosis. The other thing that must be encouraged is further research to unravel the exact biological mechanism of how cannabis leads to psychosis. Once we have a precise knowledge of how cannabis leads to psychosis, it can be expected that newer and more efficacious antipsychotic agents, especially those that can reverse the detrimental effects of cannabis, can be developed.

MINI-DICTIONARY

Cannabidiol It is one of the chemical constituents of the cannabis plant. It is believed to have opposite effects to tetrahydrocannabinol (THC). While THC can cause anxiety and psychotic symptoms, CBD has anxiolytic and possibly antipsychotic activity.

Endocannabinoids Endocannabinoids are the endogenous ligands that bind to the cannabinoid receptors present in the body. Anandamide is the most well-known endocannabinoid. The endocannabinoid system modulates neurotransmission at both inhibitory and excitatory synapses in brain regions, which have a role in the regulation of pain, emotion, motivation, and cognition.
