Genetic polymorphism It refers to natural variations in genes that occur with fairly high frequency in the general population. Single nucleotide polymorphisms are the most common type of genetic polymorphism among people, and are produced due to a variation in a single nucleotide. A polymorphism is said to be functional if it can alter the function of a gene.

Sinsemilla It refers to a technique of growing cannabis where only the female plant is allowed to blossom. Without pollen from the male plant, the female blossoms produce no seeds, and have a high content of tetrahydrocannabinol (THC).

Skunk A cannabis strain produced by cross-breeding *Cannabis sativa* and *Cannabis indica* plants. It is very potent and has a high THC content.

Tetrahydrocannabinol (THC) THC or, more precisely, Δ^9-THC, is one of the principal chemical constituents of the cannabis plant. The psychoactive and addictive properties of cannabis are believed to be due to its THC content.

CHAPTER

43

Cannabis Use in Bipolar Disorder

T.V. Lagerberg

NORMENT KG Jebsen Centre for Psychosis Research, Institute of Clinical Medicine, University of Oslo, Oslo, Norway; Division of Mental Health and Addiction, Oslo University Hospital, Oslo, Norway

SUMMARY POINTS

- Cannabis use and use disorders are common in bipolar disorder.
- There are three main hypotheses regarding the association between cannabis use and bipolar disorder: cannabis use triggers bipolar disorder, patients with bipolar disorder self-medicate with cannabis, and common third factors, such as genes and traumas, confound the relationship.
- Evidence that cannabis use may trigger bipolar disorder in vulnerable individuals is growing.
- Cannabis use disorders are associated with a more severe course of the bipolar disorder, including increased symptom levels, and frequency of episodes.
- Cannabis use disorders in bipolar disorder are associated with additional substance use disorders, as well as additional psychiatric comorbidity.
- There are some indications that cognitive functioning is better in subjects with bipolar disorder and cannabis use, compared to subjects with bipolar disorder only.

KEY FACTS OF BIPOLAR DISORDER

Bipolar disorder, previously referred to as manic-depressive disorder, is a severe mental disorder. Descriptions of the disorder date back to the 1st century AD. Bipolar disorder comprises periods with elevated and depressed mood, in between periods of normal mood. The pathophysiology of the disorder is not fully known, but the disorder is highly heritable, and involves disturbances in several brain functions. Bipolar disorder also appears to be linked to creativity. The main treatment for the disorder consists of medication with mood stabilizing or antipsychotic properties, with psychosocial treatments as an important supplement. The propensity for substance abuse in bipolar disorder was observed more than 200 years ago, and has been a focus of research in the last decades.

LIST OF ABBREVIATIONS

BD	Bipolar disorder
CBD	Cannabidiol
CUD	Cannabis use disorder
THC	Tetrahydrocannabinol

INTRODUCTION

Bipolar Disorder

Bipolar disorder (BD) is a severe mental illness characterized by periods of depressive and elevated mood, with normal mood in between. There are two main types of disorder, distinguished by a greater severity of the manic episodes in bipolar I disorder, compared to the less severe hypomanic episodes in bipolar II disorder. Hypomania and mania share features such as heightened mood, irritability, increased self-esteem, energy, and activity levels, in addition to reduced inhibition, concentration, and need for sleep. Mania, as opposed to hypomania, is also characterized by a marked reduction in daily functioning, and often accompanied by psychotic symptoms such as delusions and hallucinations, and with a need for hospitalization. The vast majority of patients with BD suffer from longer periods of depression than of elevated mood (Judd et al., 2003), and the

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00049-1

disorder is associated with a substantially increased risk for suicide (Tondo, Isacsson, & Baldessarini, 2003). The lifetime prevalence is approximately 1% for bipolar I and 1% for bipolar II disorder, although rates vary somewhat across studies. Due to its profound impact on ability to work and function, and its association with premature mortality, BD, together with other mental disorders and substance use disorders, is highly ranked in the WHO's global burden of disease list (Whiteford et al., 2013).

Cannabis Use Disorders

Cannabis use disorders (CUD) refer to the abuse of or dependence on cannabis, according to diagnostic criteria. Most often in clinical studies, the criteria of the *Diagnostic and Statistical Manual* are used (APA, 1994), but a range of different use levels and criteria have been used, creating challenges when comparing results in different studies.

Prevalence of Cannabis Use and Use Disorders in BD

In BD, as in other severe mental disorders, the rates of substance use and use disorders are high, that is, 3–11 times that of the general population (Hartz et al., 2014; Regier et al., 1990). As in the general population, cannabis is the most commonly used illegal drug (Cerullo & Strakowski, 2007). It is estimated that individuals with mental illnesses consume approximately 83% of all cannabis consumed in the United States (Lev-Ran, Le Foll, McKenzie, George, & Rehm, 2013b). Individuals with BD have been reported to be approximately 7 times more likely to use cannabis than healthy subjects (Agrawal, Nurnberger, Jr., & Lynskey, 2011), and have lifetime rates of CUDs (abuse and dependence) in the range of 10–50% (Agrawal et al., 2011; Lagerberg et al., 2014) (Fig. 43.1). The prevalence is higher in the United States, compared to Europe and other parts of the world, which also reflects the level of use in the general populations (Degenhardt et al., 2013). Rates also seem to be higher in bipolar I compared to bipolar II disorder (Lev-Ran, Le Foll, McKenzie, George, & Rehm, 2013a), in first episode compared to multiepisode samples (Tohen, Vieta, Gonzalez-Pinto, Reed, & Lin, 2010) in younger compared to older subjects (Dell'Osso et al., 2011), and in males compared to females (Cotton et al., 2013). Interestingly, cannabis use peaks at the age when BD usually develops, around 20–24 years (Degenhardt et al., 2013).

There are also indications that cannabis is more commonly used in BD than in schizophrenia and other mood disorders (Lev-Ran et al., 2013b; Hartz et al., 2014). In line with this, patients with BD seem to be at greater risk for continuing their cannabis use after hospitalization, compared to patients with schizophrenia and depression (Bahorik, Newhill, & Eack, 2013).

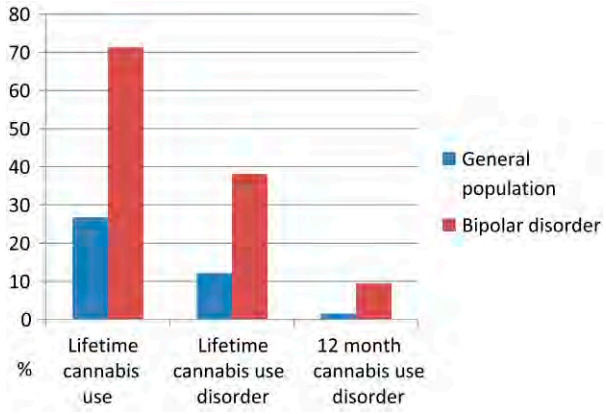

FIGURE 43.1 Prevalence of cannabis use and use disorders in bipolar disorder and the general population in the United States. Lifetime and 12 month prevalence of cannabis use, and use disorders, in bipolar disorder and the general population, according to epidemiological and clinical studies from the United States, published recently. *Source: Agrawal et al. (2011),* Psychiatry Research*; Etain et al. (2012),* Journal of Clinical Psychiatry*; Lev-Ran et al. (2013),* Comprehensive Psychiatry*; Haberstick et al. (2014),* Drug and Alcohol Dependence.

WHY DO BIPOLAR DISORDER AND CANNABIS USE DISORDERS OFTEN COOCCUR?

Hypotheses for the Strong Association

There are several models that may explain the relationship between psychotic disorders and cannabis use. These models are also the most relevant ones for the relationship between BD and CUDs, and can be described as follows (van Winkel & Kuepper, 2014; Mueser, Drake, & Wallach, 1998) (Fig. 43.2):

1. BD causes cannabis use;
2. Cannabis use causes BD;
3. Genetic vulnerability models: gene-environment interaction, genetic confounding, and environmental mediation of genetic influences;
4. Other common factor models.

Does Bipolar Disorder Cause Cannabis Use Disorders?

The first hypothesis implies that BD leads to an increased risk for using cannabis. This can happen in a "direct" way: that is, in an elevated mood state, one of the symptoms is lack of inhibition, or an increased tendency to involve oneself in pleasurable activities. In this state, the barriers to using drugs may be reduced. While this may be the case for the *use* of cannabis, it is unlikely to be true for *use disorders*, which usually need a longer period of time to develop than the duration of a manic episode. To the author's knowledge, there are no empirical studies directly addressing this hypothesis; that is, in

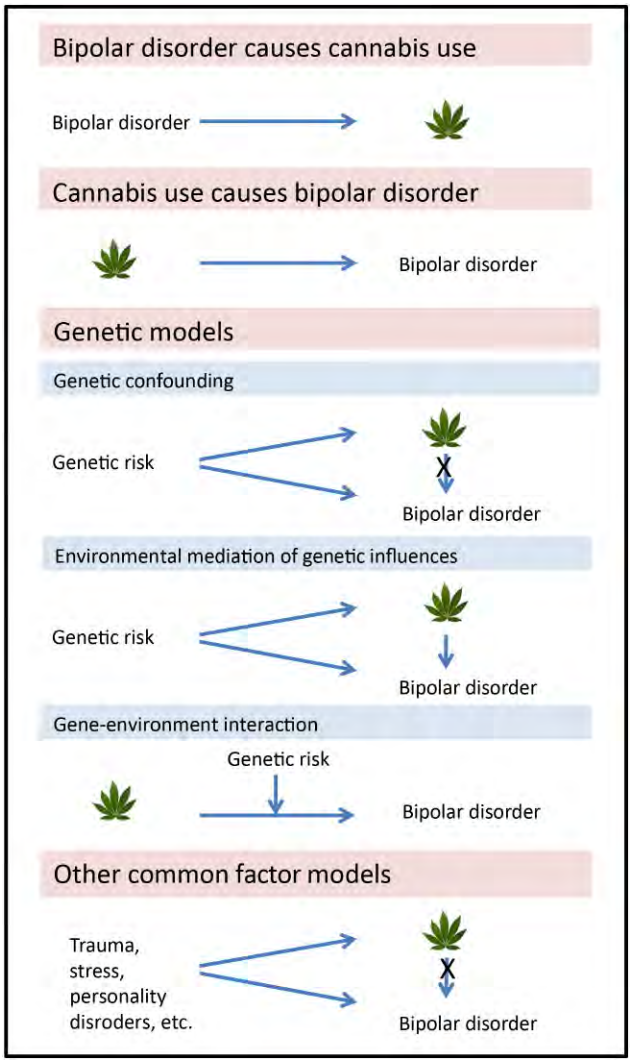

FIGURE 43.2 Representations of the relationship between cannabis use disorders and bipolar disorder. Fig. 43.2 shows a representation of the possible relationships between cannabis use and bipolar disorder.

which phase of BD is cannabis use usually initiated, and whether it is associated with inhibition.

BD could also lead to cannabis use, if the drug is used as an attempt to deal with the symptoms of the disorder, usually referred to as the "self-medication hypothesis" (Khantzian, 1997). This hypothesis does not aim at explaining the specific link between cannabis use and BD, but rather the link between dysphoria and other negative psychological experiences, and substance use in general. To date, there is mixed evidence regarding the self-medication hypothesis from two prospective epidemiological studies investigating BD and cannabis use. Manic/hypomanic symptoms predicted subsequent onset of cannabis use, and use disorders in one study (Wittchen et al., 2007), but not in another (Henquet, Krabbendam, de Graaf, Ten Have, & van Os, 2006). Research is also limited regarding clinical observations of cannabis use as an attempt to self-medicate symptoms of BD. Only a few studies specifically address reasons for cannabis use in BD. One qualitative study on 15 patients with BD and different substance use disorders reported that the subjects used cannabis to curb elevated mood, and manage anxiety and depressive symptoms (Healey, Peters, Kinderman, McCracken, & Morriss, 2009). Furthermore, a few anecdotal reports indicate that patients with BDs use cannabis to stabilize their mood (Grinspoon & Bakalar, 1998; Ashton, Moore, Gallagher, & Young, 2005). While smoking marijuana was found to reduce depressive symptoms and tension, and increase vigor in subjects with BD, in a pilot study investigating whether attempts to self-medicate may be successful, it increased depressive symptoms, confusion, and fatigue in cannabis smokers without psychiatric morbidity (Gruber et al., 2012). Based on these and other findings, some have argued that the cannabis compound cannabidiol (CBD) may have therapeutic potential in psychiatric disorders, including BD (Campos, Moreira, Gomes, Del Bel, & Guimaraes, 2012; Ashton et al., 2005). There is, however, no evidence suggesting relief of the whole *syndrome* of BD from cannabis. On the contrary, cannabis use appears to have a negative impact on the symptoms and course of BD. This will be addressed later in this chapter. However, since a substantial proportion of patients start using cannabis after the onset of their BD, and patients report using substances to alleviate affective symptoms, and seem to experience instant relief after cannabis use, further exploration of the self-medication hypothesis is warranted.

Does Cannabis Use Cause Bipolar Disorder?

When investigating the causal relationship between BD and cannabis use, a focus has been put on sequencing, that is, which of the phenomena most commonly occurs first. Results have been somewhat mixed, with the sequence of the onsets proving difficult to determine. In two studies, the first hypomanic/manic episode more often occurred before the onset of the CUD than the opposite (Agrawal et al., 2011; Heffner et al., 2012). In another study, the proportions with cannabis use or BD onset first was approximately the same (Strakowski et al., 2007), and in a study on the prodromal phase of BD, 68% of the subjects had substance use disorders (of which 82% had a CUD) prior to the onset (Conus et al., 2010). In a prospective study on established BD, it was found that cannabis use tended to precede or coincide with, rather than follow, manic symptoms (Baethge et al., 2008). From these findings, we can conclude that CUDs appear to both precede and follow the development of BD. In established BD, however, cannabis use does not seem to follow manic episodes.

This leads us to the second main hypothesis of the relationship between cannabis use and BD, namely that cannabis use can lead to or trigger BD. The onset

TABLE 43.1 Age at Onset, Medication Use, and Suicide Attempts in BD Patients With and Without Recent Cannabis Use

	No cannabis use last 6 months			Cannabis use last 6 months

One or more suicide attempts, lifetime	16	28.1		12	63.2		0.012

[a] *Lower N because not all patients experienced this episode.*
[b] *Psychotic, manic, depressive or mixed onset.*
Patients early in the course of bipolar disorder with recent cannabis use showed an earlier onset, and a higher prevalence of lifetime suicide attempt, compared to patients without recent cannabis use. The results remained significant after controlling for possible confounders, such as use of medication. Abbreviations: *BD I*, bipolar I disorder; *SD*, standard deviation.
Source: Reprinted from Kvitland, L. R., Melle, I., Aminoff, S. R., Lagerberg, T. V., Andreassen, O. A., and Ringen, P. A. (2014). Cannabis use in first-treatment bipolar I disorder: relations to clinical characteristics. Early Intervention in Psychiatry, 8*(2); with permission from Elsevier.*

of mania following excessive cannabis use has been noted by clinicians, and described in case reports (Iskandar, Griffeth, & Sharma, 2011). There are strong indications that cannabis use increases the risk for developing schizophrenia and other psychotic disorders (van Winkel & Kuepper, 2014). As BD and schizophrenia are closely related disorders, with shared pathophysiology and genetic risk, there is a possibility that cannabis may be a risk factor in BD, as well. Growing evidence from both clinical and epidemiological studies supports this. Prospective population studies have shown that cannabis use is associated with increased rates of manic symptoms (Henquet et al., 2006; Tijssen et al., 2010), and also with BD (van Laar, van Dorsselaer, Monshouwer, & de Graaf, 2007; Wittchen et al., 2007), following the use, with odds ratios in the range of 2.5–5 after controlling for possible confounders such as psychotic symptoms, and previous manic symptoms.

Furthermore, clinical studies have identified a relationship between cannabis use and earlier onsets of BD (Etain et al., 2012; Lagerberg et al., 2011; de Hert et al., 2011), also pointing toward cannabis use as a possible trigger of the disorder. This association has also been found in early phases of BD (Kvitland et al., 2014) (Table 43.1), reducing the possibility that the association is confounded by a recall-bias regarding the sequencing of the disorders. Furthermore, there are indications of a dose-response relationship, that is, the higher levels of cannabis use, the higher the risk of developing the disorder (van Laar et al., 2007), and the earlier the onset of the BD. Earlier age at onset has also been found in relation to cannabis use, regardless of whether the onset episode was depression or (hypo)mania, suggesting that cannabis may trigger the whole syndrome of BD, and not only manic *or* depressive episodes (Fig. 43.3) (Lagerberg et al., 2014). However, there are contradictory findings. One study found a later onset in patients with cannabis use preceding the BD, compared to patients with the opposite sequencing and patients with no cannabis use (Strakowski et al., 2007). In this study, the patients with BD first also had a faster recovery. As the authors point out, these findings may point toward cannabis as a possible trigger, since cannabis could have precipitated the BD at a later age in individuals with a lower constitutional vulnerability for the disorder.

IN SEARCH OF MECHANISMS: THE NEUROBIOLOGY OF CANNABIS IN BIPOLAR DISORDER

What could be the neurobiological mechanisms by which cannabis may trigger manic episodes and BD? The causes of BD are not fully identified, and the pathophysiology is still largely unknown. We do know, however, that the levels and actions of several neurotransmitters, such as dopamine and glutamate, are disturbed in the brain of subjects with BD, that is, hyperactivity in mesolimbic dopaminergic pathways has been implicated in mania. Cannabinoids affect such transmitter systems involved in affect regulation (Moreira & Lutz, 2008). For instance, THC, one of the psychoactive compounds of cannabis, is known to enhance activity in dopaminergic

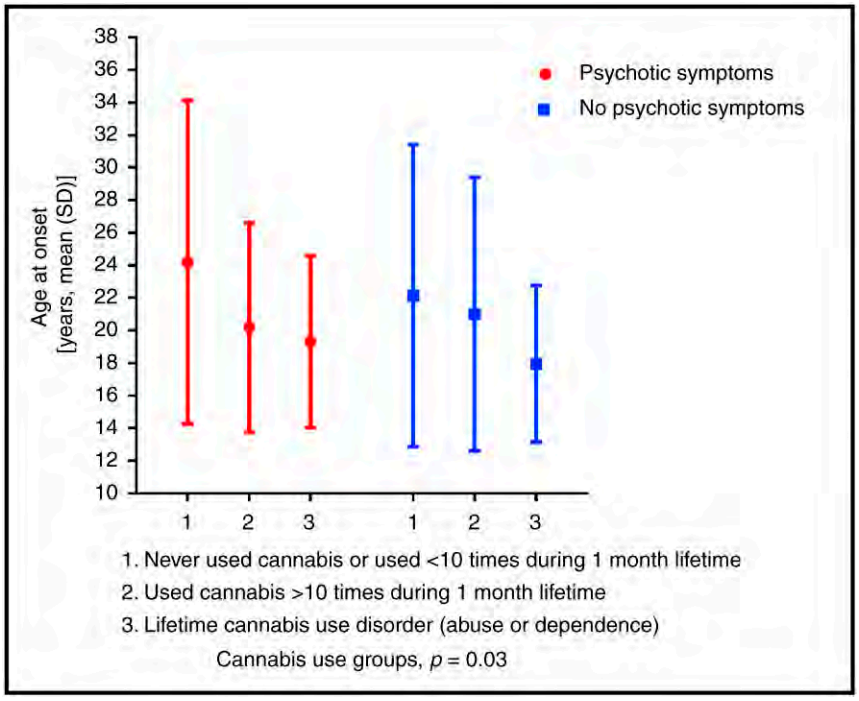

FIGURE 43.3 **Indications of a dose-response relationship between cannabis use and age at onset in bipolar disorder.** **Fig. 43.3** shows a decreasing age at onset of bipolar disorder with increasing levels of cannabis use. It also shows that the pattern is the same, regardless of presenting polarity: age at onset decreases as levels of cannabis use increase for patients presenting with both depressive and (hypo)manic episodes. *Source: Reprinted from Lagerberg, T. V., Kvitland, L. R., Aminoff, S. R., Aas, M., Ringen, P. A., Andreassen, O. A., and Melle, I. (2014). Indications of a dose-response relationship between cannabis use and age at onset in bipolar disorder.* Psychiatry Research, 215*(1), 101–104; with permission from Elsevier.*

pathways (D'Souza et al., 2005). Furthermore, cortical glutamate levels seem to play a significant role in acute mania (Öngur et al., 2008), and have also been found to be increased by THC, in rats (Tomasini et al., 2002). Also, the potential negative impact of cannabis on mental health is most likely related to the concentration ratio of THC/CBD (Englund et al., 2013), which has been increasing the last decade. Furthermore, there are indications of certain critical periods of brain development that are vulnerable for the use of cannabis, and it has been argued that cannabis may shift the brain's development trajectory toward a disease-vulnerable state (Chadwick, Miller, & Hurd, 2013).

Genetic Vulnerability Models

Since the majority of subjects using cannabis do not develop BD or other psychotic illnesses, a genetic vulnerability for the disorder is likely to be a prerequisite. This would imply a *gene-environment interaction*, in which cannabis use elicits BD only in individuals with a genetic predisposition. So far, genetic vulnerability has been difficult to measure directly, but it has been measured indirectly through the subject's family history of relevant disorder(s). In a prospective study investigating individuals with familial risk (offspring of individuals with BD), those who developed a substance use disorder (in most cases a CUD) were at greater risk for developing BD, suggesting a gene-environment interaction (Duffy et al., 2012). There is also the possibility of an interaction between several environmental factors, increasing the risk for BD only when occurring in combination. This has, to the author's knowledge, not been investigated specifically. Relevant to this, however, are findings from a study investigating cannabis use and childhood trauma in BD. Here, both factors were independently associated with earlier onsets and other BD severity indicators (Aas et al., 2013).

A matter of debate is whether the comorbidity of CUDs and psychotic disorders (including BD) could be due to *genetic confounding*, meaning that the relationship is explained by a common genetic diathesis between the two disorders, and not by a causal relationship between them. The finding that CUDs increase the risk of developing BD in high risk individuals would, however, not be expected if a common genetic diathesis was the only basis for the association (Duffy et al., 2012). A third possibility, *environmental mediation of genetic influences*, implies that, in addition to a common genetic diathesis, cannabis use additionally increases the risk for BD. This has not yet been investigated empirically. As modern genetic studies (genome-wide association studies) are starting to identify the genetic basis for severe mental disorders such as BD, the possibility to investigate these genetic models will increase substantially.

Other Common Factor Models

Other common factors, such as sociodemographic factors, trauma, stress, or personality traits, could also contribute to explaining the high prevalence of CUDs in BD. For instance, childhood trauma appears to be highly prevalent in both BD and substance use disorders (Larsson et al., 2013; Enoch, 2011). Childhood trauma is also associated with CUD comorbidity in BD (Aas et al., 2013). Furthermore, stressful life events have been suggested as risk factors for BD (Post, 1992), as well as for CUDs (Hyman & Sinha, 2009). Temperament or personality traits have also been suggested as common factors. Impulsivity appears to be associated with both BD and substance use disorders (Swann, 2010), and is found to be additionally increased in the comorbid subjects (Etain et al., 2013). Personality disorders are also more prevalent in comorbid subjects (Lev-Ran et al., 2013a).

In conclusion, research on the different hypotheses is sparse, so far, and it is premature to draw any firm conclusions regarding their validity. There are several indications that cannabis may trigger BD in genetically vulnerable individuals. However, competing explanations such as a common genetic diathesis and the self-medication hypothesis have not been ruled out. Also, the relationship may be bidirectional; cannabis use may elicit BD in vulnerable individuals, who also may use cannabis as an attempt to self-medicate the symptoms of the disorder, once it is established. Indications for a bidirectional relationship between the two disorders was found in a prospective study on subjects with familial risk (Duffy et al., 2012), but not in a prospective epidemiological study (Henquet et al., 2006). Most likely, no single model can explain all cases of comorbidity, thus several models may be needed in order to fully account for the relationship.

THE CONSEQUENCES OF CANNABIS USE IN BIPOLAR DISORDER

Cannabis Use Disorders and the Symptoms and Course of BD

CUDs have been associated with more severe clinical characteristics in BD. From cross-sectional studies, we know that comorbid patients have a higher number of illness episodes (Lev-Ran et al., 2013a), an increased prevalence of mixed episodes (Agrawal et al., 2011), and psychotic symptoms (Braga, Burdick, Derosse, & Malhotra, 2012), as well as higher rates of suicide attempts (Aas et al., 2013; Bellivier et al., 2011), compared to patients without a CUD. The duration of cannabis use has also been found to be associated with the duration of manic episodes (Cerullo & Strakowski, 2007). However, since these studies are cross-sectional, one cannot conclude whether subjects with a greater illness severity use cannabis because of the increased symptoms (eg, self-medication), or whether the increased severity is a consequence of cannabis use.

Findings from a few longitudinal studies, in which causal relationships can be explored, indicate that there is a negative effect from CUDs on the response to treatment and the course of the BD. In these studies, CUDs were associated with reduced compliance with medication, higher levels of manic and psychotic symptoms, and higher overall illness severity (Van Rossum, Boomsma, Tenback, Reed, & van Os, 2009; Bahorik et al., 2013). Also, there appears to be an increased risk for rapid cycling and prolonged duration of manic episodes (Strakowski et al., 2007), and for switching into mania in depressed individuals (Ostacher et al., 2010), in the presence of a CUD. In a study on subjects with a first psychotic episode, manic symptoms improved more in subjects that stopped their cannabis use during follow-up, compared to subjects that continued their use (Stone et al., 2014).

Cannabis Use, and Brain Structure and Functioning

To date, this area has only been studied in one research group focusing on adolescent subjects after a first manic episode with psychosis. The comorbid adolescents showed greater structural abnormalities in frontal and temporal cortical regions, as well as in subcortical areas linked with emotion and motivational regulation, compared to adolescents with BD alone (Jarvis et al., 2008). In a functional brain imaging study from the same research group, the comorbid adolescents did not show the same overactivation of regions involved in emotional processing seen in adolescents with BD alone, when compared to healthy controls (Bitter et al., 2014). These findings could imply either a different neuropathology in the cannabis using group, or that cannabis use influences brain structure, and reduces the overactivation in the brain regions found in subjects with BD only.

Cannabis Use and Cognition

Although research so far is sparse, in a few studies, cognitive functioning was somewhat surprisingly found to be better in comorbid subjects, compared to subjects with BD alone (Braga et al., 2012; Ringen et al., 2010). This has been interpreted in several ways: as supporting the notion that cannabis may trigger the disorder in less vulnerable individuals, that cannabis may improve cognitive functions related to dopamine, or that these subjects constitute a selected group, since regular cannabis consumption requires certain cognitive skills. Further replications and investigations are needed to clarify this issue.

Cannabis Use, Daily Functioning, and Quality of Life

The results are somewhat mixed regarding CUD and daily functioning, and quality of life. CUD was associated with reduced social functioning in a cross-sectional study (Hellvin, Sundet, Aminoff, Andreassen, & Melle, 2013). In a longitudinal study, cannabis was associated with not being in a relationship (Van Rossum et al., 2009). General life functioning appears to be reduced (Agrawal et al., 2011), also confirmed by a longitudinal study (Bahorik et al., 2013). Work functioning, however, has not been found to be associated with CUDs (Goetz, Tohen, Reed, Lorenzo, & Vieta, 2007; Van Rossum et al., 2009). Furthermore, results are mixed regarding whether or not life satisfaction is reduced in comorbid subjects, compared to subjects with BD only (Van Rossum et al., 2009; Lev-Ran et al., 2013a). The lack of additional reductions in measures of functioning and quality of life in comorbid subjects, found in some studies, could be due to the already low levels associated with BD itself.

The Challenge of Additional Comorbidities

CUDs are often accompanied by excessive use of other substances such as nicotine, alcohol, and other drugs (Lev-Ran et al., 2013a; Wittchen et al., 2007; Heffner et al., 2012). Furthermore, individuals with BD and CUD often also suffer from additional psychiatric disorders, such as personality disorders (Lev-Ran et al., 2013a). Many of these comorbidities contribute independently to more severe outcomes. In addition to causing major challenges in the lives of the patients, and in the treatment of the disorders, it causes difficulties in disentangling the effect of cannabis from effects of other disorders on the BD course. Many studies have failed to control for the presence of other substance use disorders. Thus, further research is warranted to establish independent effects from cannabis use on the symptoms and course of BD. However, knowledge is sufficient to conclude that cannabis use should be prevented in individuals at risk, and treated when present in established BD.

MINI-DICTIONARY

Bipolar disorder A severe affective disorder comprising elevated and depressed mood episodes in between periods of normal mood.
Cannabis use disorders A maladaptive pattern of cannabis use which leads to substantial clinical discomfort or functional loss.
Comorbidity When two or more diseases cooccur.
Depression (severe) A period of severe sadness and loss of pleasure or interest, in addition to symptoms such as loss of energy, appetite, sleep, and suicidal thoughts.
Hypomania A less severe form of mania in which symptoms are similar, but does not include psychotic symptoms, and does not cause marked functional loss.
Mania Periods of elevated or irritable mood, and additional symptoms such as increased self-esteem, activity levels and, in some cases, psychotic symptoms, causing marked functional loss.
Mixed episode A period of cooccurring manic and depressive symptoms.
Neurotransmitters Endogenous chemicals transmitting signals between neurons across a synapse.
Pathophysiology The mechanisms whereby a disease or condition develops and progresses.
Psychotic symptoms Delusions, hallucinations, and disorganized thought or behavior.
Rapid cycling Having four or more bipolar episodes within 1 year.
Schizophrenia Severe psychotic disorder comprising delusions, hallucinations, disorganized behavior, apathy, and social withdrawal.

Cannabis Use in Epilepsy—Risks and Benefits

*M. Holtkamp**, M. Hamerle***

***Epilepsy-Center Berlin-Brandenburg, Department of Neurology, Charité – Universitätsmedizin Berlin, Berlin, Germany**

****Department of Psychiatry and Psychotherapy, Ludwig-Maximilian-University Hospital, Munich, Germany**

SUMMARY POINTS

- This chapter focuses on cannabis and some of its well characterized compounds in the treatment of epilepsy.
- In one-third of patients with epilepsy, seizures cannot be adequately controlled with antiepileptic drugs.
- Therefore, novel treatment options are needed.
- Animal data suggest that cannabinoids have anticonvulsant properties.
- Available human data give hints for some seizure-preventing properties of cannabinoids, but the quality of those studies is poor.
- Clinically significant side effects of cannabinoids, beyond the psychoactive properties of Δ^9-tetrahydrocannabinol, have not been described.
- A high-quality, placebo-controlled, randomized controlled trial on efficacy and safety of cannabidiol in patients with intractable epilepsy is warranted.

KEY FACTS OF SEIZURES AND EPILEPSY

- An epileptic seizure is a clinical symptom, the pathophysiological correlate are excessive synchronized neuronal discharges in the brain.
- Depending on the brain region in which the neuronal discharges occur, clinical symptoms and signs vary.
- Subjective epileptic symptoms comprise visual, auditory, somatosensory, mnestic, and psychic perceptions, and speech arrest; motor signs include circumscribed or generalized tonic, clonic, or tonic clonic features.
- An epileptic seizure may occur due to some acute brain disorders, such as stroke or trauma; conceptually, this seizure is provoked, or of acute-sympomatic origin.
- Unprovoked epileptic seizures define epilepsy if more than two seizures have occurred, or if an MRI or EEG reveal an enduring condition of the brain that indicates an increased risk for further seizures, after one has occurred.

KEY FACTS ON TREATMENT OF EPILEPSY

- The hallmarks of treatment of epilepsy are pharmacological substances that aim to prevent the occurrence of further unprovoked epileptic seizures.
- Thus, conceptually, epilepsy treatment is secondary prophylaxis; the underlying condition "epilepsy" is not affected by antiepileptic drugs.
- Antiepileptic monotherapy results in seizure freedom, that is, no seizures in the last 12 months, in 50–60% of patients.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00050-8
Copyright © 2017 Elsevier Inc. All rights reserved.

- Antiepileptic polytherapy is initiated after failure of two trials of monotherapy; polytherapy adds another 10% of seizure-free patients.
- If two antiepileptic drugs have failed, epilepsy is pharmacoresistant by definition; this applies to one-third of all patients with epilepsy.
- Patients with pharmacoresistant epilepsy should be assessed whether they are eligible for epilepsy surgery, that is, the operative removal of the seizure focus; less than 10% of all patients undergoing presurgical assessment are eventually resected.
- Thus, a large number of epilepsy patients urgently need novel—pharmacological or nonpharmacological—treatment approaches.

KEY FACTS ON CANNABIDIOL USE IN EPILEPSY

- The two most studied active compounds of the plant *Cannabis sativa* are cannabidiol (CBD) and Δ^9-tetrahydrocannabinol (THC); the latter is psychoactive, the former is not.
- In animal models, both compounds have anticonvulsant properties; in some species, THC turned out to be proconvulsant.
- Human data on efficacy of CBD in epilepsy are scarce, but they give some first hints for an anticonvulsant potential.
- High-level evidence for efficacy and safety of CBD in epilepsy is so far lacking, accordant randomized controlled trials are urgently needed and currently planned.
- Until reliable data on CBD in epilepsy are available, treatment trials in individual patients with various burdens of difficult-to-treat epilepsy are explicitly warranted.

LIST OF ABBREVIATIONS

AED Antiepileptic drug
CBD Cannabidiol
EEG Electroencephalogram
OR Odds ratio
THC Δ^9-Tetrahydrocannabinol

INTRODUCTION

Cannabis has been used for millennia, and across various cultures, to treat a plethora of chronic medical conditions, including epilepsy. In modern medical research, physicians have been discussing for decades whether cannabis or its compounds cannabidiol (CBD) and Δ^9-tetrahydrocannabinol (THC) facilitate or prevent epileptic seizures, in people with and without epilepsy. Recently, interest in this topic has intensified (Mathern, Nehlig, & Sperling, 2014).

One in three patients with epilepsy continues to have epileptic seizures, despite polypharmacological treatment regimen. Some of these patients have dozens of convulsive seizures per day. They or their proxies are looking desperately for novel adjunctive treatment options, one of which may be cannabis or its compounds.

The plant *Cannabis sativa* produces more than 80 different cannabinoid compounds (Devinsky et al., 2014) that are highly lipophilic and, therefore, capable to easily cross the blood–brain barrier. The two most studied compounds are THC, which has prominent psychoactive properties, and CBD, which lacks psychoactive effects. In experimental models, THC has been shown to be pro- (Martin & Consroe, 1976) and anticonvulsant (Hill et al., 2010), while CBD had only anticonvulsant properties (Izquierdo & Tannhauser, 1973; Jones et al., 2010, 2012).

The aim of this review is to discuss seizure facilitating or preventing characteristics of cannabis, and its two clinically relevant compounds, CBD and THC. We assess currently available data on people with and without prior seizures or established epilepsy. We further discuss the safety of cannabis use for medical purposes. A short overview on allocation, classification, and treatment of epileptic seizures and epilepsy will be introduced into the field.

SOME FACTS ON SEIZURES AND EPILEPSY

The pathophysiological basis of an epileptic seizure is constituted by paroxysmal synchronized depolarization of neuronal networks. Clinical signs and symptoms of an epileptic seizure depend on the functional properties of the brain region involved in the onset and propagation of epileptic activity. Following the seizure classification of the International League against Epilepsy, seizures are dichotomized into partial onset and generalized forms (Commission on Classification and Terminology of the International League Against Epilepsy, 1981). The former comprises seizures that commence in a circumscribed area of the brain, and comprehends simple partial (consciousness maintained), complex partial (consciousness impaired), and secondary generalized tonic clonic (consciousness lost) seizures. Common generalized seizure types are absences, myoclonus, and "primary" generalized tonic clonic seizures. These seizure types are characterised by simultaneous onset in widespread bilateral neuronal networks.

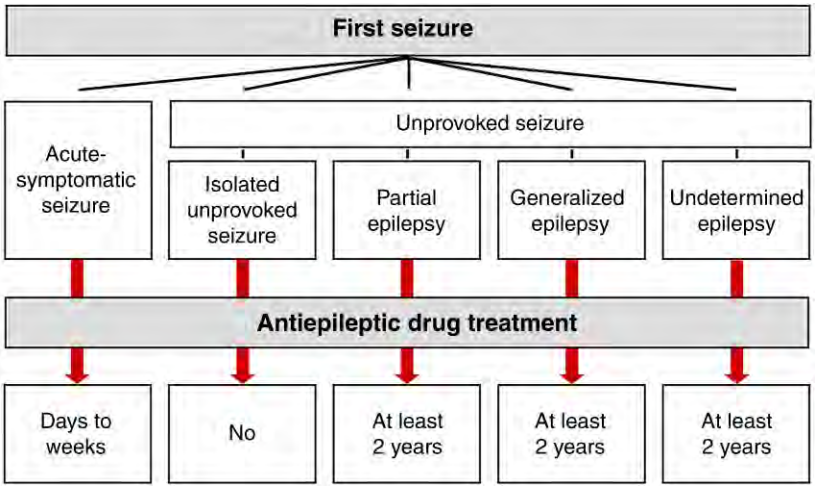

FIGURE 44.1 **Stratification of first seizures.** The first epileptic seizure has to be stratified dichotomously into either an acute symptomatic seizure or an unprovoked seizure. The former occurs in close temporal relation to acute systemic disturbances or acute brain disorders; acute symptomatic seizures are provoked by these transient conditions. A first unprovoked seizure may be associated with no clinically relevant recurrence risk; conceptually, this condition is accordant to an isolated unprovoked seizure. If pathological findings in cranial MRI and/or EEG suggest an enduring increased risk for further unprovoked seizures, the patient suffers by definition from epilepsy, that syndromatically may be partial (60% of cases), generalized (20%), or undetermined (20%). Indication for and initially presumed duration of antiepileptic drug treatment depends on seizure recurrence risk. This is why correct stratification to one of the groups as given in this figure is paramount.

The proper etiological allocation of an epileptic seizure is the basis for further antiepileptic drug (AED) treatment. On the one hand, epileptic seizures can be the consequence of an acute systemic medical disturbance, or of an acute brain disorder. In this case, epileptic seizures are of acute symptomatic origin. On the other hand, epileptic seizures can be unprovoked when they are not timely related to such acute conditions.

Even in otherwise healthy subjects, acute medical disturbances may facilitate occurrence of epileptic seizures. These comprise intoxications (eg, with lithium or theophylline), abrupt detoxications (eg, from alcohol or benzodiazepines), metabolic disturbances (eg, hyponatremia or hypoglycemia), and systemic infections with elevated body temperature. Within the first week, brain disorders, such as stroke, trauma, or infection can cause acute symptomatic epileptic seizures. Risk of seizure recurrence is elevated as long as the predisposing condition is prevalent; a couple of days in systemic disturbances, and a couple of weeks in acute brain disorders. These are the specific time frames patients with acute symptomatic seizure should be treated for, either with oral benzodiazepines (seizures caused by systemic disturbances), or with AEDs that can be titrated rapidly and, ideally, can be administered intravenously, for example, levetiracetam or valproic acid (seizures caused by acute brain disorders).

A first unprovoked seizure is either isolated, that is, brain magnetic resonance imaging and electroencephalogram (EEG) are normal; or can already be defined as epilepsy if neuroimaging or EEG are pathologic, and indicate an enduring increased risk for further seizures (Fisher et al., 2014). Epilepsy is also defined by two or more unprovoked epileptic seizures. If seizure recurrence risk is increased, patients should be recommended to take AEDs regularly to prevent occurrence of further seizures, at least for the next 2 years, and in most cases even longer (Fig. 44.1). At epilepsy onset, the overall aim of AED treatment is seizure freedom, and occurrence of no, or at most minimal, side effects. Two-thirds of patients with new-onset epilepsy remain seizure-free upon the first or second AED administered in monotherapy. The other patients require AED polytherapy, and most of these patients are pharmacoresistant, that is, they continue to suffer from epileptic seizures despite treatment with AEDs. Patients with pharmacoresistant epilepsy should be thoroughly assessed if they are eligible for epilepsy surgery, that is, for resection of the epileptogenic focus. If not, other nonpharmacological and, up to now, "experimental" pharmacological treatment options are urgently needed. A treatment algorithm for treatment of epilepsy is shown in Fig. 44.2.

The main burden and danger of epileptic seizures is the unexpected occurrence that implies the risk of falls, drowning, and other injuries. Half of the patients report rather severe headache following an epileptic seizure (Duchaczek, Ghaeni, Matzen, & Holtkamp, 2013), and generalized strong muscle soreness is common following generalized tonic clonic seizures.

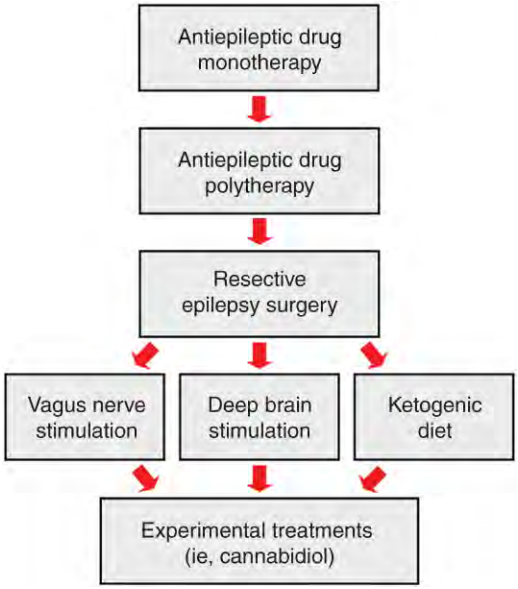

FIGURE 44.2 Treatment algorithm in epilepsy. The mainstay of treatment in epilepsy is pharmacotherapy. This is not a real "antiepileptic" treatment, but the drugs aim to prevent the occurrence of the next seizure. Conceptually, this is a secondary prophylaxis, or an "antiseizure" treatment. Usually, treatment starts with a substance in monotherapy. When seizures persist even in high doses of this drug, this is either changed to another substance, or a second drug is added to the first one. If two drugs in sufficiently high dose—either administered subsequently or in combination—fail, epilepsy is by definition pharmacoresistant. In this constellation, it is highly unlikely that the patient becomes seizure-free with further antiepileptic drugs. There is common sense among experts that patients with pharmacoresistant epilepsy should be assessed by continuous video-EEG-recording and further tests, if they are eligible for epilepsy surgery. If the seizure focus can clearly be identified, and eventually resected, epilepsy has a high chance of 50–70% to become resolved. However, only a minority of patients qualify for resective surgery and, in this group of patients, further treatment options may be tried. At this stage, the realistic aim is not seizure-freedom, but some kind of control of seizures in regard of frequency and severity of events. Randomized controlled trials have demonstrated efficacy of vagus nerve and deep brain stimulation, as well as ketogenic diet. If these treatments do not have a sustained effect, experimental treatment approaches, which so far have not been assessed in controlled trials, may be applied. One of these is cannabidiol.

DOES CANNABIS USE AFFECT SEIZURES AND EPILEPSY?

Pro- and anticonvulsant effects of cannabis have to be assessed in two entirely different clinical constellations. On the one hand, cannabis or its major medically used compound, CBD, may provoke epileptic seizures in people without history of epilepsy; on the other hand, the substance may prevent or facilitate seizures in patients with prior seizures, or established epilepsy.

Cannabis in People Without Epilepsy

Proconvulsant effects of cannabis in people without epilepsy may be seen following habitual recreational use, or in patients treated with CBD for conditions other than epilepsy.

The former situation, so far, has not been assessed in epidemiological studies of regular cannabis users, so no conclusions on proconvulsant properties in otherwise healthy individuals can be drawn. However, one retrospective study gives some indirect hints on preventive properties of cannabis consumption regarding occurrence of new-onset seizures (Brust, Ng, Hauser, & Susser, 1992). In 308 subjects who were admitted to the emergency department of the Harlem Hospital, New York, with new-onset seizures, male patients had consumed cannabis significantly less often in their life time (adjusted OR 0.42) or in the last 3 months (adjusted OR 0.36), compared to a control group that had presented with other clinical conditions. In addition, male subjects with acute symptomatic seizures had also used cannabis less often in the last 3 months (OR 0.8). Neither of these effects was observed in women. These data may suggest possible protective effects of cannabis use regarding manifestation of acute symptomatic and new-onset unprovoked seizures.

Proconvulsant effects of medically administered CBD or THC, in people without epilepsy, were assessed in randomized controlled trials, as performed in patients with social phobia (Bergamaschi et al., 2011), Huntington Disease (Curtis, Mitchell, Patel, Ives, & Rickards, 2009), and other movement disorders (Carroll et al., 2004; Muller-Vahl et al., 2003). In all these trials, occurrence of new-onset seizures has either not been described, or no differences between the study and the control group (treated with placebo or another active comparator) were reported. However, most studies were underpowered and, therefore, available data do not suggest that the use of cannabis, or administration of CBD or THC, facilitates the occurrence of epileptic seizures in people without prior seizures, or established epilepsy.

Cannabis and its Compounds in Established Epilepsy

In patients with difficult-to-treat epilepsy, no high-quality, adequately powered randomized controlled trial has been performed so far comparing add-on CBD or THC with placebo, or an active compound. Most available data is based on case reports, surveys, and four small prospective controlled trials.

Though case reports on efficacy of therapeutic interventions are always biased by possible placebo effects, they may be helpful to highlight clinical problems, and may give first hints for novel treatment approaches. A 5-year-old girl, suffering from Dravet syndrome, a condition based on an *SCN1A* gene mutation, and characterized by frequent daily tonic, tonic clonic, and myoclonic seizures not responding to AEDs, was treated

with adjunctive CDB/THC (Maa & Figi, 2014). Starting with more than 300 generalized tonic clonic seizures per week, after 3 months of treatment with CBD extract, seizure frequency was reduced by more than 90%. CBD was tapered at three different time points, and seizure frequency returned to baseline each time. This gives at least some proof for efficacy; however, the results may be limited to the particular case, and may not be generalized to other patients with severe forms of epilepsy. Other individual case reports on cannabis in epilepsy provide conflicting results. In some cases, cannabis use helped to control epileptic seizures as add-on therapy to conventional AEDs (Consroe, Wood, & Buchsbaum, 1975). In other epilepsy patients, occurrence of tonic clonic generalized seizures associated with acute cannabis use has also been reported (Keeler, 1967).

Porter and Jacobson (2013) surveyed 19 parents whose children were suffering from intractable severe childhood epilepsies, and who had used CBD as additional therapy. Most of the children suffered from Dravet syndrome, and the average number of antiepileptic drugs tried before was 12. Of the 19 parents, 16 (84%) reported reduced seizure frequency in their child, after beginning treatment with CBD, 8 even stated a reduction of seizure frequency of more than 80%. Other beneficial effects of CBD treatment as reported by parents were stabilized mood (79%), increased alertness (74%), and improved sleep (68%). As the authors have mentioned, it is important to notice that the interviewed parents strongly supported medical use of cannabis, and that the reports on beneficial effects on the children's condition may therefore be biased. Also, no experienced clinicians were involved in validating seizure improvement professionally. However, the results of this survey at least support the conclusion that some forms of pharmacoresistant childhood epilepsy may benefit from CBD treatment.

In a Canadian phone survey of 136 adult patients with epilepsy, 48% had consumed cannabis at least once in their lifetime. Moreover, 21% had used cannabis in the last 12 months (= active use), and 68/54% of these reported decreased seizure severity/frequency (Fig. 44.3). 43% of the interviewed subjects stated medical reasons for regular cannabis consumption (Gross, Hamm, Ashworth, & Quigley, 2004).

In an epidemiologic study of 310 adult epilepsy patients, performed by the authors of this chapter, only 28.1% patients had ever consumed cannabis in their lifetime (20.3% after onset of epilepsy), and 4.2% (n = 13) had been active users (Hamerle, Ghaeni, Kowski, Weissinger, & Holtkamp, 2014). In 84.1% of subjects who had used cannabis after the diagnosis of epilepsy had been made (including 11 of 13 active users), cannabis was not reported to affect seizure frequency or severity in either direction. Seven patients stated worsening of seizure frequency associated with cannabis use (repeated seizure manifestation within 24 h after cannabis use). Two active cannabis users stated beneficial effects of cannabis on epilepsy. However, these more likely tended to be secondary beneficial effects, for example, reduction of postictal headache, and did not seem to affect seizure frequency or severity directly (Fig. 44.4).

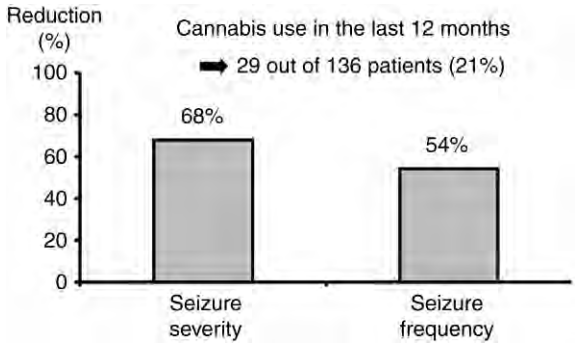

FIGURE 44.3 **Patient-reported effects of cannabis consumption.** In a Canadian telephone survey on 136 patients with epilepsy, 29 (= 21%) reported to have used cannabis in the previous 12 months. Of those, 68% reported decreased seizure severity, and, in 54%, frequency of seizures was reduced.

These results are in line with another survey of 215 adult epilepsy patients, the majority of which (90.2%) did not identify any effect of cannabis use on either seizure frequency or severity (Gordon & Devinsky, 2001). In a further study of 42 patients with epilepsy, 12 subjects reported cannabis use in the past. Only two patients reported effects on epilepsy: one subject stated beneficial effects, the other reported seizure worsening (Feeney, 1976).

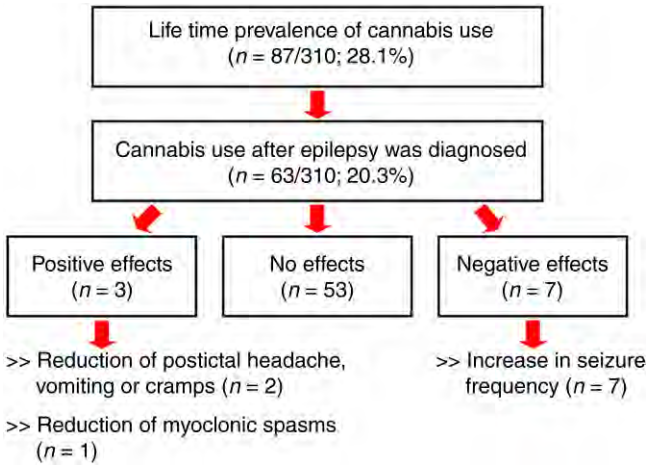

FIGURE 44.4 **Cannabis use and effects in epilepsy.** Findings of a survey study on use and effect of cannabis in 310 adult people with diverse forms of epilepsy, performed by the authors of this article. One in five patients had used cannabis after the diagnosis of epilepsy has been made. The majority of those patients did not report any positive or negative effect on epilepsy. More than 10% of the patients with cannabis use reported some increase in seizure frequency, while three patients reported some benefit.

TABLE 44.1 Clinical Trial on Cannabidiol in Patients With Dravet Syndrome

Primary outcome measures
- Genetic differences between patients with Dravet syndrome (*SCN1A* gene mutation) who appear to respond to high concentration cannabidiol oil therapy versus those who do not
- Patients completing 3 months of therapy with a seizure reduction of >50% will be designated a "responder," and patients who discontinue therapy for any reason prior to 3 months or have a ≤50% seizure reduction will be designated "nonresponder;" between-groups genetic analysis will be performed

Inclusion criteria
- Age 1–50 years with gene-confirmed Dravet syndrome
- Uncontrolled epilepsy, having failed at least two prior treatments (including appropriate antiepileptic drugs, ketogenic diet, vagus nerve stimulation therapy)
- Seizure frequency should be more than two visually countable motor seizures per week (tonic clonic, tonic, clonic, myoclonic, or astatic)
- Care providers able to identify convulsive seizures, drop attacks, or tonic seizures, or any combination of countable seizure types
- Self-seeking therapy with Charlotte Web strain of medical marijuana with the assistance of a medical marijuana doctor, but are still naive to therapy
- Care provider able to complete seizure count diary
- Able to obtain oral swab sample from subject with Dravet syndrome
- Agree to forfeit any right to results of genetic analysis

Exclusion criteria
- Subjects having nonepileptic seizures that are not distinguishable from epileptic seizures by the care provider
- Prisoners
- Pregnant women
- Failure to forfeit right to results of genetic analysis

www.clinicaltrial.gov; identifier: NCT02229032.

A randomized controlled trial of 15 subjects suffering from uncontrolled partial epilepsy with secondary generalized tonic clonic seizures has investigated the anticonvulsant efficacy of CBD versus placebo in addition to conventional AEDs that were kept stable (Cunha et al., 1980). Eight patients received oral CBD (200–300 mg/day), and seven patients were randomized to placebo; all were treated for 3–18 weeks. Seven of eight subjects treated with CBD reported considerable clinical improvement, whereas the condition of six out of seven patients of the placebo group remained unchanged. This study is limited, as one subject changed groups (not clearly blinded), and CBD dose adjustment was possible. Moreover, average treatment time of CBD subjects was longer than in the placebo group.

In another trial by Mechoulam and Carlini (1978), nine patients with refractory epilepsy were randomized to either CBD (200 mg) or placebo, for a period of 3 months, while conventional AED treatment was continued. Two out of four subjects of the CBD group achieved seizure freedom, while improvement of seizures was not observed in any of the five patients of the placebo group.

In these two and two further randomized controlled trials, a total of 48 patients were included (Ames & Cridland, 1986; Trembly & Sherman, 1990). A recent Cochrane Review on cannabinoids for epilepsy criticizes that details of randomization were not included in any of the study reports, and that it was unclear whether baseline parameters of treatment and control groups were same or different (Gloss & Vickrey, 2014). Thus, there is an urgent need for better randomized controlled trials on efficacy and safety of CBD in epilepsy.

In the last years, several Western countries have changed their attitude toward the use of cannabis for medical purposes, and have liberalized their laws accordingly. Therefore, funding for and development of clinical trials have become less complicated. In the United States, randomized, placebo-controlled, double-blind trials on patients with two very severe epilepsy syndromes, Dravet syndrome and Lennox–Gastaut syndrome, are currently planned (Devinsky et al., 2014). Patients with these syndromes are eligible for such trials in particular, as they have an extraordinary high frequency of seizures and, thus, an urgent need for new treatment options, and they have relatively homogeneous epilepsy syndromes making comparison more favorable. For reasons of data accuracy, long-term video-EEG is planned for correct seizure count. In a first step, a currently ongoing study on patients with Dravet syndrome genetically compares CBD responders (>50% reduction in seizure frequency in 3 months of treatment) to nonresponders (www.clinicaltrials.gov; identifier: NCT02229032); for details see Table 44.1.

In summary, efficacy of cannabis in epilepsy patients, regarding reduction of seizure frequency and severity, so far has not been investigated comprehensively. Therefore, the previously mentioned randomized controlled trial planned in the United States is a step in the right direction. So far, only limited data exists on subjective effects of cannabis use on ancillary symptoms associated with epileptic seizures, such as postictal headache and muscle soreness.

IS CANNABIS SAFE AND WELL TOLERATED IN EPILEPSY PATIENTS?

Neither controlled trials nor case reports on cannabis use in epilepsy patients indicate clinically relevant medical or neurological side effects (Ames & Cridland, 1986; Cunha et al., 1980; Mechoulam & Carlini, 1978; Trembly & Sherman, 1990). A 2014 Cochrane Review on cannabinoids for epilepsy summarizes the available data as follows: "The dose of 200 to 300 mg daily of cannabidiol was safely administered to small numbers of patients generally for short periods of time, and so the safety of long term cannabidiol treatment cannot be reliably assessed." (Gloss & Vickrey, 2014).

Safety data on adult subjects using CBD for other indications than epilepsy, or for recreational purposes, also demonstrate favorable tolerability within a dose up to 1500 mg cannabinoid per day (Bergamaschi et al., 2011; Devinsky et al., 2014). As is the case with efficacy, side effects as a marker for tolerability that are specific to CBD can only be demonstrated or excluded by a double-blind randomized controlled trial. Opposite to CBD, THC is well-known to produce psychoactive adverse effects (Cilio, Thiele, & Devinsky, 2014). In children younger than 15 years of age, risk of psychosis (Griffith-Lendering et al., 2013) and long-term impairment of executive functions (Fontes et al., 2011) have been described.

In a recent review on cannabidiol in epilepsy, Devinsky et al. (2014) discuss the potential risk of immunosuppression, as interleukin 8 and 10 production may be suppressed (Srivastava, Srivastava, & Brouhard, 1998; Wu et al., 2008). The clinical relevance of these finding so far is undetermined.

In patients with epilepsy, drug interactions between cannabidiol and AED have not been assessed thoroughly. Cannabidiol is an inhibitor of hepatic CYP isozymes, and is metabolized itself by CYP3A4. Therefore, metabolism of AED may be affected, and enzyme inducers, such as the standard AED carbamazepine may reduce serum concentrations of cannabidiol (Devinsky et al., 2014).

In summary, CBD for medical use presumably is well tolerated and safe; whether immunosuppression or interaction with specific AED are of clinical significance requires further research.

PRACTICAL ISSUES OF CANNABIS USE FOR MEDICAL PURPOSES

Practical issues of CBD/cannabis use for medical purpose in patients with epilepsy

- CBD has been administered in several smaller studies as augmentation therapy in a dosage of 200–300 mg/day with favorable tolerability
- CBD augmentation has been shown to be usually well tolerated in dosages up to 1500 mg/day, even with chronic administration (Bergamaschi et al., 2011)
- In children, cannabis use may impair cognitive development or may increase the risk for psychosis (Fontes et al., 2011; Griffith-Lendering et al., 2013)
- CBD may theoretically induce immunosuppression by suppressing interleukin-8 and interleukin-10. However, clinical relevance has not been clearly demonstrated (Srivastava et al., 1998; Wu et al., 2008)

MINI-DICTIONARY

Anti- and proconvulsant effects Any therapeutic intervention in patients with epilepsy may suppress or prevent seizures (anticonvulsant effect), or facilitate their occurrence (proconvulsant effect).
Antiepileptic drugs (AED) Pharmacological substances that have the propensity to prevent the occurrence of further epileptic seizures but do not interfere with the underlying chronic condition of epilepsy; therefore a more precise term would be antiseizure or anti-ictal drug.
Dravet syndrome Genetically determined epilepsy syndrome described by Charlotte Dravet; it is based on an SCN1A gene mutation, characterized clinically by frequent and often daily tonic, tonic clonic, and myoclonic seizures. It is commonly pharmacoresistant.
Electroencephalogram (EEG) A method to record physiological and pathological brain activity by electrodes commonly placed on the scalp; intracranial recording with special electrodes is also possible.
Epileptic seizure Clinical correlate of excessive synchronized neuronal discharges in the brain.
Epilepsy Chronic condition of the brain which facilitates the occurrence of further unprovoked seizures after at least one seizure had already occurred.
Lennox–Gastaut syndrome Etiologically heterogeneous epilepsy syndrome described by William Lennox and Henri Gastaut; commonly childhood-onset, frequent and various seizures. It is often associated with developmental delay.
Long-term video-electroencephalography Simultaneous video recording of patient's behavior and scalp, EEG recording of brain activity for the purpose of detecting and analyzing epileptic seizures; duration of recording is commonly at least 24 h, and may last several days.
Magnetic resonance imaging (MRI) Noninvasive technique to visualize morphology and on occasion functional properties of the brain; essential to help clarify the etiology of epilepsy.
Randomized controlled trial Clinical study design that is characterized by treatment with intervention A, or a control intervention B (that in pharmacological studies may be an inactive placebo) by chance; generally, the patient (single blind), or the patient and the treating physician (double blind) are unaware of which treatment is given to the patient.

CHAPTER

45

Cannabis, Cannabinoids, and Visceral Pain

R. Abalo, M. Isabel Martín-Fontelles

Area of Pharmacology and Nutrition, Faculty of Health Sciences, University Rey Juan Carlos, Alcorcón, Madrid, Spain; Associated Unit I+D+i of the Institute of Medicinal Chemistry (IQM) and of the Institute of Research in Food Sciences (CIAL), Spanish National Research Council (CSIC), Madrid, Spain

SUMMARY POINTS

- This chapter focuses on pain originating in internal organs (visceral pain).
- Visceral pain is characterized by distinct anatomical and functional features.
- The endocannabinoid system (ECS) is found throughout the different viscera and their innervation.
- In some organs, expression of the ECS components is low in nonpathological conditions, but increases under inflammation and/or cancer, with effective reduction of visceral pain by cannabinoid agonists (particularly CB2R agonists), and inhibitors of endocannabinoids degradation.
- The involvement of the ECS, and possible usefulness of cannabinoids, has not been tested yet in some painful visceral syndromes such as biliary or renal colic pain, orchialgia, or polycystic ovary.
- The major limitations of cannabinoids for treatment of visceral pain are their central side effects.
- Acute heavy cannabinoid use may induce visceral pain associated to visceral toxicity.

KEY FACTS OF VISCERAL PAIN

- It is poorly localized with referral to somatic structures.
- It produces nonspecific regional or whole-body motor responses, strong autonomic responses, and strong affective responses.
- It leads to sensitization of somatic tissues and visceral organs.
- Visceral afferents travel together with autonomic efferents.
- The components of the endocannabinoid system (ECS) have been demonstrated in visceral tissues, and also along the afferent pathways up to the brain.

LIST OF ABBREVIATIONS

Δ^9-THC	Δ^9-Tetrahydrocannabinol
CB1R	Cannabinoid receptor type 1
CB2R	Cannabinoid receptor type 2
ECS	Endogenous cannabinoid (or endocannabinoid) system
FAAH	Fatty acid amide hydrolase
GPR55	G-protein coupled receptor 55
IBD	Inflammatory bowel disease
IBS	Irritable bowel syndrome
LUTS	Lower urinary tract symptoms
MAGL	Monoacyl glycerol lipase

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00051-X

mRNA Messenger ribonucleic acid
NSAID Nonsteroidal antiinflammatory drugs
PPAR Peroxisome proliferator-activated receptor
TRPA1 Ion channel transient receptor potential A1
TRPV1 Transient receptor potential vanilloid-1 channels

INTRODUCTION

Marijuana, obtained from the plant *Cannabis sativa*, is the most widely used recreational drug in the Western world for its psychotropic properties, mainly exerted by its main component, Δ^9-tetrahydrocannabinol (Δ^9-THC). Cannabis and cannabinoids (both natural and synthetic) exert their effects mainly through cannabinoid receptors type 1 and 2 (CB1R and CB2R). In addition to these receptors, the endogenous cannabinoid system (ECS) include endogenous ligands (anandamide, 2-arachidonoylglycerol, …), their biosynthetic and degradative enzymes (fatty acid amide hydrolase, FAAH; monoacyl glycerol lipase, MAGL), and other cannabinoid-related receptors (G-protein coupled receptor 55, GPR55; peroxisome proliferator-activated receptors, PPAR α and γ; transient receptor potential vanilloid-1 channels, TRPV1), as well as a hypothetical membrane transporter not yet cloned (Di Marzo, 2009).

The ECS is one of the most ubiquitous neural systems in the body. All the components of the ECS have been found in the viscera, including their sensory innervation (Fig. 45.1), and may participate in the generation/relief of visceral pain. In this chapter, we will first briefly describe the basics of visceral pain, and then we will focus on the role cannabinoids may play in this context.

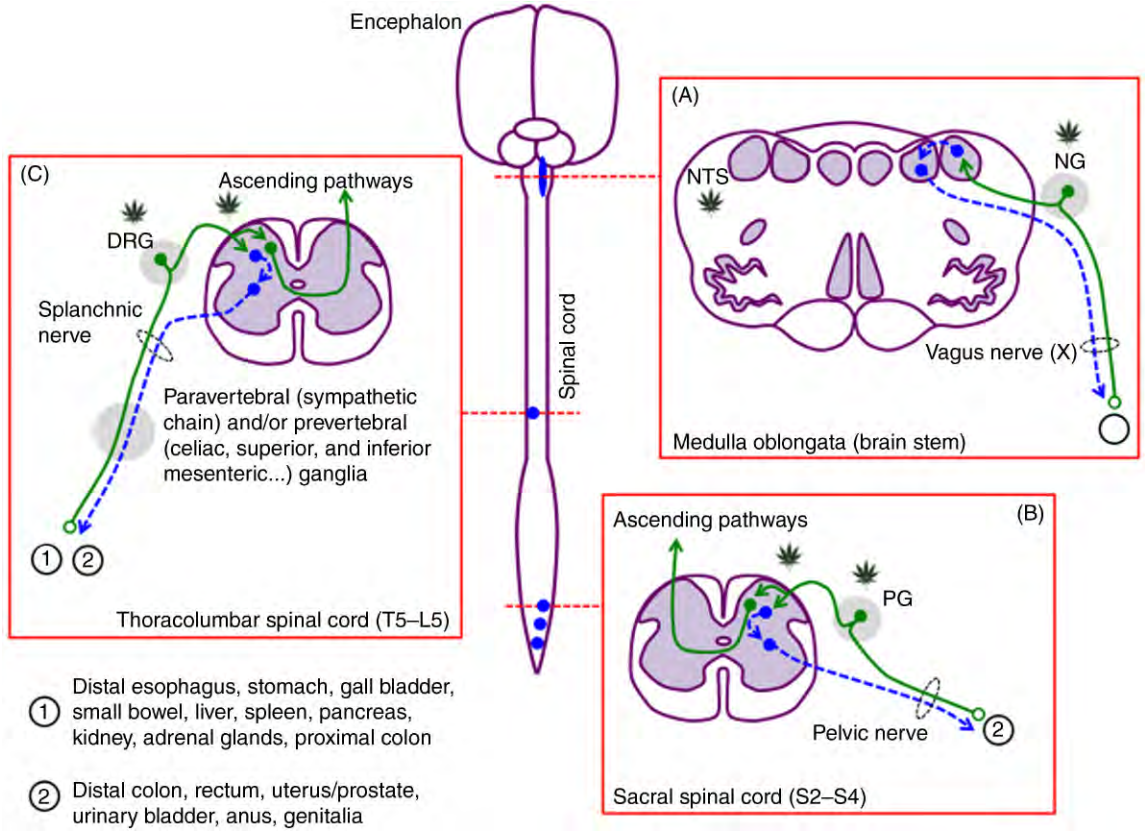

FIGURE 45.1 Sensory innervation of abdominal and pelvic viscera and the endocannabinoid system. Abdominal and pelvic viscera can be classified into two main categories according to their sensory innervation: distal esophagus, stomach… (1); distal colon, rectum… (2). Afferents from the vagus nerve (X) have their somata in the nodose ganglion (NG), and innervate the first category; afferents from the pelvic nerve have their somata in the pelvic ganglia (PG) and innervate the second category. Both have a role in transmitting mainly physiological signals to the central nervous system: the vagus nerve to the nucleus of the solitary tract (NTS) (A: cross-section of medulla oblongata in the brain stem at this level); the pelvic nerve to the dorsal horn of the sacral spinal cord (B: cross-section of the spinal cord, level S2–S4). Additionally, both categories of viscera are innervated by splanchnic afferents with their somata in the dorsal root ganglia (DRG), and connections with neurons lying in the paravertebral and/or prevertebral ganglia. The splanchnic nerves transmit signals generated by painful stimuli to the thoracolumbar spinal cord (C: cross-section of the spinal cord, level T5–L5). All these signals (vagal, pelvic, and splanchnic) travel to higher brain nuclei within different ascending pathways and are modulated by central information traveling downward within descending pathways (not shown). CB1R (marijuana leaf symbol) have been demonstrated immunohistochemically in NTS, NG, PG, DRG, and the dorsal horn of the spinal cord. *Green lines*: afferents from the abdominal and pelvic viscera. *Blue dotted lines*: parasympathetic (A,B) and sympathetic (C) efferents to the gut.

VISCERAL PAIN

Visceral pain can be defined as the pain originating from internal organs within the thoracic, abdominal, or pelvic cavities. It is a common cause for seeking medical attention. Thus, a recent review and metaanalysis (Viniol et al., 2014) showed that mean consultation prevalence for abdominal pain is 2.8%, with an unknown underlying cause in about one-third of patients. The most common declared etiologies were: gastroenteritis (7.2–18.7%), inflammatory bowel disease (IBD) (2.6–13.2%), urological cause (5.3%), and gastritis (5.2%). About 1 in 10 abdominal pain patients suffers from an acute disease like appendicitis (1.9%), diverticulitis (3%), biliary/pancreatic (4%) or neoplastic (1%) diseases needing immediate therapy.

In the case of visceral cancer pain, the growth of a tumor may lead to many activating noxious stimuli, ranging from chemicals released by cancer cells, immune cells, distension or obstruction of luminal organs, and/or neuropathic events such as denervation and/or nerve sprouting, and other changes in neuronal function (Sikandar & Dickenson, 2012). Furthermore, as demonstrated in experimental animals, use of antineoplastic drugs may also alter visceral innervation and function (Vera et al., 2011; Cabezos, Vera, Martín-Fontelles, Fernández-Pujol, & Abalo, 2010; Wafai, Taher, Jovanovska, Bornstein, Dass, & Nurgali, 2013), probably contributing also to altered pain responses.

Importantly, common painkillers such as nonsteroidal antiinflammatory drugs (NSAID) or opioids often adversely affect visceral (gastrointestinal) function or even integrity, thus limiting their clinical utility, and prompting a search for alternatives (Christianson et al., 2009). Thus, "visceral-specific" analgesics would be most useful; among them, some molecules targeting the ECS have shown potential therapeutic profiles (see next section: "Cannabinoids and visceral pain").

Different recent reviews describe how visceral pain is generated, its features, differences with somatic pain, etiology, management, etc. (Sengupta, 2009; Sikandar & Dickenson, 2012; de Carvalho Rocha, Dantas, Rolim, Costa, & de Medeiros, 2014; Vermeulen, De Man, Pelckmans, & De Winter, 2014; González, Merrill, & Vizzard, 2014; Larauche, Mulak, & Taché, 2012; Davis, 2012). As shown in Fig. 45.2, visceral pain is poorly localized with referral to somatic structures, produces nonspecific regional or whole-body motor responses, as well as strong autonomic responses, and strong affective responses. Therefore, visceral pain can be reinforced by anxiety and depression (Sikandar & Dickenson, 2012). It also leads to sensitization of somatic tissues and visceral organs. Visceral hypersensitivity can occur due to: sensitization of primary sensory afferents innervating the viscera; hyperexcitability of spinal ascending neurons (central sensitization) receiving synaptic input from the viscera; and dysregulation of descending pathways that modulate spinal nociceptive transmission (Sengupta, 2009). Interestingly, some of the general features of visceral pain (namely referral to somatic structures and autonomic changes) can also be observed in animal models upon which new drugs may be tested (Sengupta, 2009).

Frequently, several pathologic processes and targets are involved in visceral diseases. One example might be the lower urinary tract symptoms (LUTS). In male LUTS, many factors are involved: androgen signaling, inflammation and metabolic factors, the urothelium, prostate, interstitial cells, detrusor, neurotransmitters, neuromodulators… Therefore, the potential therapeutic approaches are complex, and must take into account both the functional and sensory disorders.

CANNABINOIDS AND VISCERAL PAIN

The palliative effects of *Cannabis sativa* (marijuana) and its main active ingredient (Δ^9-THC), include inhibition of nausea and emesis associated with chemo- or radiotherapy, appetite stimulation, pain relief, mood elevation, and relief from insomnia in cancer patients (Pacher, Batkai, & Kunos, 2006). Synthetic Δ^9-THC (dronabinol, in Marinol) and its derivative nabilone (Cesamet), as well as plant-derived extracts containing controlled amounts of Δ^9-THC and other plant-derived cannabinoids (ie, nabiximols = Δ^9-THC + cannabidiol, in Sativex), have been approved in several countries to control nausea in cancer patients undergoing chemotherapy, to stimulate appetite and/or to attenuate cancer-related pain (Pacher et al., 2006; Velasco, Sánchez, & Guzmán, 2012).

In animal models of nonspecific, noncancerous visceral pain, such as intraperitoneal administration of acetic acid, Δ^9-THC reduced abdominal pain behavior. Cannabinol also reduced pain behavior, whereas tetrahydrocannabivarin antagonized Δ^9-THC (Booker, Naidu, Razdan, Mahadevan, & Lichtman, 2009). In addition, inhibitors of FAAH alone, or in combination with NSAID, also reduced acetic acid-induced abdominal stretching in mice (Naidu, Booker, Cravatt, & Lichtman, 2009).

Recent literature demonstrating the presence of the ECS and their hypothetical use in different viscera will be discussed below (Table 45.1).

Heart

In the last few years, some cases of acute chest pain associated to myocardial infarction have been reported in young consumers of designer drugs like K2/Spice, which contain cannabinoid agonists with higher affinity

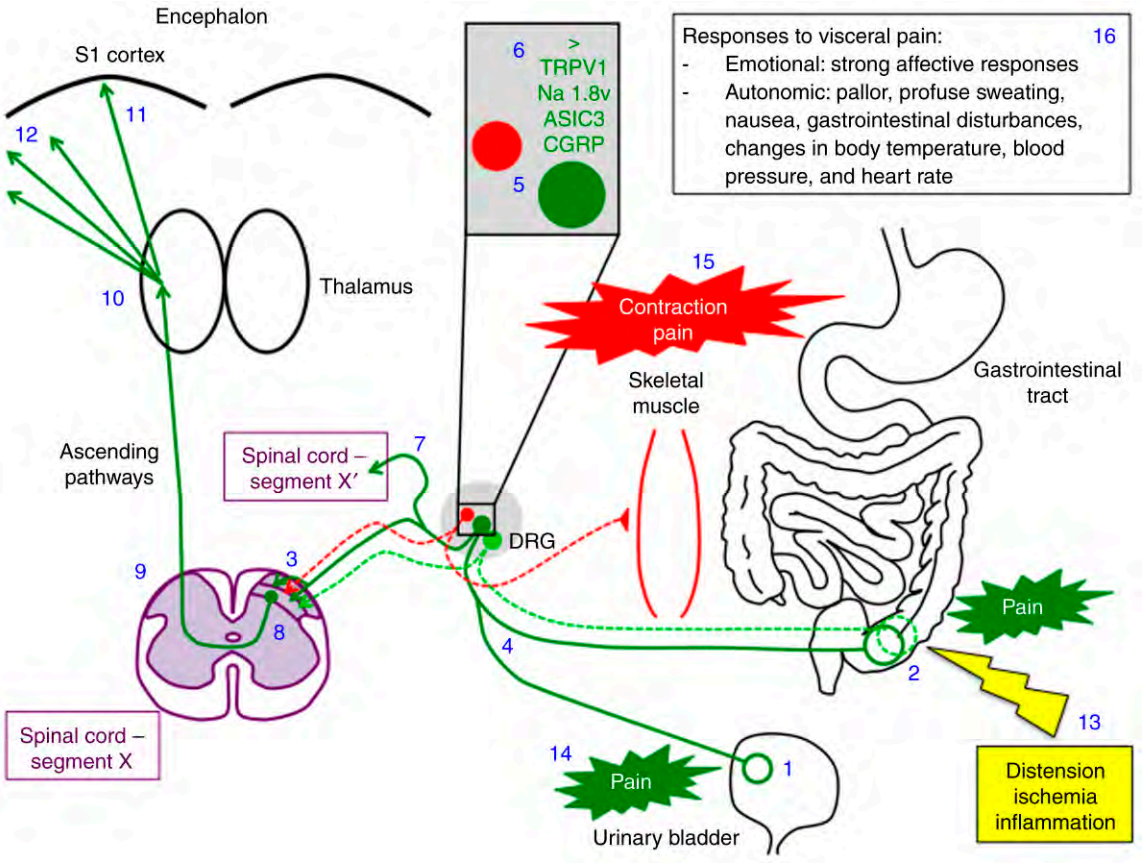

FIGURE 45.2 **Anatomic and functional features of visceral pain.** In this figure, viscera are represented by the gastrointestinal tract and the urinary bladder. Cell bodies of primary visceral *(green)* and somatic *(red)* afferents reside within the dorsal root ganglia (DRG). Ascending pathways include second order sensory neurons (projecting from the dorsal horn of the spinal cord to the thalamus), and third order sensory neurons (projecting from the thalamus to the brain cortex). Anatomic features of visceral pain are: lack of specialized nerve terminals (1); widely overlapping receptive fields (2); dual extrinsic afferent system—afferents ascend with parasympathetic and sympathetic neuronal projections (see Fig. 45.1); convergence of afferents on somatic and other visceral afferents within the spinal cord (3); dichotomization of fibers where a single neuron innervates two viscera (4); cell bodies within DRG *(green circle)* are larger than somatic ones *(red circle)* (5), and with greater expression of TRPV1, Na 1.8 and ASIC3 ion channels, as well as CGRP (6); first-order afferents arborize over several spinal segments (X and X′) (7); discrete location of first-order terminals within the spinal cord (superficial dorsal horn, lamina V, and central) (8); second-order afferents ascend in the dorsal column (9); nonsomatotopically arranged input in dorsal column and central lateral thalamus (unlike the lateral spinothalamics) (10); poor representation in S1 cortex (11); extensive divergence within the central nervous system (12). Functional features of visceral pain are: limited number of stimulus responses (distension, ischemia, and inflammation) (13); viscerovisceral hyperalgesia and hypersensitivity *(green stars)* (14); visceromotor responses and referred pain to somatic sites within the same metameric field *(red star)* (15); greater emotional and autonomic responses to noxious stimuli than somatic pain (16). *TRPV1*, Transient receptor potential vanilloid 1; *Na 1.8v*, sodium channel 1.8; *ASIC3*, acid-sensing ion channel 3; *CGRP*, calcitonin gene-related peptide.

and selectivity to CB1R than Δ^9-THC. These synthetic cannabinoids are 2–100 times more potent than Δ^9-THC (Castaneto et al., 2014). In long-term marijuana users, adverse cardiovascular events, including tachyarrhythmias, acute coronary syndrome, vascular complications, and even congenital heart defects may also occur (Aryana & Williams, 2007), and smoking marijuana increased myocardial oxygen demand in anginal patients (Gottschalk, Aronow, & Prakash, 1977). In more recent research, patients with coronary artery disease had elevated blood levels of endocannabinoids, and increased expression of CB1R in coronary atheroma. CB1R blockade reduced the production of proinflammatory mediators by macrophages, which might provide beneficial effects on atherogenesis (Sugamura et al., 2009).

Gastrointestinal Tract

In the gastrointestinal tract, cannabinoids reduce motility and pain sensitivity (Izzo & Camilleri, 2008). The cannabinoid inhibitory effects on gastrointestinal motility are generally mediated via the CB1R, while actions via the CB2R have been associated to resolution of inflammation (Wright et al., 2008). The role of cannabis and cannabinoids on gastrointestinal motility has been described in detail in another Chapter 98 of this book

TABLE 45.1 Cannabinoid Involvement in Visceral Pain of Nongastrointestinal and Gastrointestinal Origin

Nongastrointestinal organ	Species	Drug	Effect	References
Heart	Human	Synthetic cannabinoids (smoked)	Acute chest pain associated to myocardial infarction	Castaneto et al. (2014)
	Human	CB1R antagonists	Reduced production of proinflammatory mediators	Sugamura et al. (2009)
Kidney	Human	Synthetic cannabinoids (smoked)	Acute kidney injury with flank/abdominal pain	Buser et al. (2014)
	Mice	CB2R agonists, cannabidiol	Protection against cisplatin-induced nephrotoxicity	Pan et al. (2009)
Urinary bladder	Rats, mice	CB1R agonists, FAAH inhibitors. TRPV1 agonists	Reduced sensory activity of isolated tissues, antihyperalgesia in animal models of bladder inflammation	Hedlund (2014); Walczak and Cerveró (2011)
Urethra	Human (isolated tissues)	CB1R agonists	Reduced the relaxing effect of TRPA1 agonists	Weinhold et al. (2010)
		TRFV1 agonists	Enhanced the relaxing effect of TRPA1 agonists	Weinhold et al (2010)
Ovary	Human		CB1R gene polymorphisms are involved in the polycystic ovary syndrome	Kuliczkowska Plaksej et al. (2014)
Endometrium	Human	Cannabis	Relieve endometriosis-related pelvic pain, back pain, dysuria, dyschezia, dyspareunia	Dmitrieva et al. (2010)
	Rat	WIN55, 212-2 (through CB1R activation)	Decreased endometriosis-associated hyperalgesia	Dmitrieva et al. (2010)
Testes and scrotum		Cannabinoid agonists	They might alleviate neuropathic pain symptoms associated to orchialgias	NR
Prostate		Cannabinoid agonists	They might relieve chronic prostatitis/chronic pain syndrome	NR
		Cannabinoid agonists	They might relieve pain associated to bone metastatic prostate cancer	NR but suggested by Ramos and Bianco (2012)
Gastrointestinal organ	**Species**	**Drug**	**Effect**	**References**
General	Human, animals	CB1R agonists	Inhibit motility	Izzo and Camilleri (2008); Wright, Duncan, and Sharkey (2008)
		CB2R agonists	Resolve inflammation	
		TRPV1 agonists	Favor visceral hypersensitivity	
Stomach	Rat	Cannabis extract (through CB2R activation)	Reduced gastric-induced pain	Wallace et al. (2013)
	Rat, mice	CB1R agonists, MAGL inhibitors	Were gastroprotective in models of gastric damage induced by NSAID or cold-restraint stress	Wallace et al. (2013); Rutkowska and Fereniec-Goltbiewska (2006); Germanò et al. (2001)
Small and large intestine	Rodents	CB1R agonists, CB2R agonists, FAAH inhibitors, EMT inhibitors	Protect mucosa and reduce visceral sensation and abdominal pain induced by various stimuli modeling IBS or IBD (mustard oil, DNBS, TNBS, DSS, LPS…)	For references, see Chapter 49 by Salaga et al.: "Cannabinoids and the effects on gastroinstestinal functions"
	Human	Dronabinol	Increased pain during colorectal distension

TABLE 45.1 Cannabinoid Involvement in Visceral Pain of Nongastrointestinal and Gastrointestinal Origin (*cont.*)

Gastrointestinal organ	Species	Drug	Effect	References
Pancreas	Human	CB1R agonists	In pancreatic cancer, high CB1R levels in nerves are associated with less pain but shorter survival	Michalski et al. (2008)
		Cannabinoid agonists	In acute pancreatitis, they might reduce pain and inflammation (endocannabinoid ligands and receptors are upregulated)	Michalski et al. (2007)
	Human	Heavy cannabis use	Case of acute pancreatitis with transfixiant epigastric abdominal pain, nausea, and vomiting	Fatma, Mouna, Leila, Radhouane, and Taoufik (2013)
	Rat	CB2R agonists	Tissue protection and analgesia in a model of chronic pancreatitis	Zhang, Kline, McNearney, Johnson, and Westlund (2014)
Liver	Mammals	CB2R agonists	Endocannabinoids are protective in hepatic inflammatory conditions and other diseases	Pacher and Mechoulam (2011)
Biliary tract and gall bladder	Rat	WIN55-212-2, FAAH inhibitors (through CB1R activation)	Reduced cholestasis-induced pruritus	Gingold and Bergasa (2003); Hasanein, Shahidi, Komaki, and Mirazi (2008)

NR, Not reported.

(*Cannabinoids and the effects on gastrointestinal tract: a focus on motility*). Here we will focus on cannabinoid effects on pain of gastrointestinal origin.

Stomach

In anesthetized rats, a cannabis extract was able to reduce gastric distension-induced pain, measured as bradychardia, via CB2R activation (Wallace et al., 2013).

In models of gastric damage induced by naproxen (Wallace et al., 2013), aspirin (Rutkowska & Fereniec-Goltbiewska, 2006), or cold-restraint stress (Germanò et al., 2001), CB1R stimulation was protective. Interestingly, the gastroprotective effect of the MAGL inhibitor JZL184, used at low doses in a mouse model of NSAID-induced gastric hemorrhages, did not decrease with chronic administration (Kinsey et al., 2013). The brain-impermeant FAAH inhibitor, URB937, which per se exerted peripheral antinociceptive effects in different experimental models of pain, reduced the number and severity of gastric lesions produced by indomethacin, while exerting no ulcerogenic effect when administered alone, suggesting that this kind of drug may be beneficial when NSAID are to be used as painkillers (Sasso et al., 2012).

Small and Large Intestine

The role of the ECS and the potential therapeutic usefulness of cannabinoids in IBS, IBD, and colorectal cancer have been discussed more deeply in another Chapter 49 within this book (*Cannabis, cannabinoids and the effects on gastrointestinal function: an overview*).

Pancreas

Immunohistochemical analyses of normal human pancreas revealed weak immunoreactivity for CB1R and CB2R in pancreatic acini, nerves, blood vessels, and ductal cells, but this profile changes in malignant tissue. Furthermore, high levels of CB1R were associated with less pain, whereas low CB1R levels in nerves were associated with strong pain symptoms, demonstrating the involvement of the ECS in pancreatic pain perception. However, high CB1R levels were associated with shorter survival, a fact that has been attributed to the role of pain as a warning symptom leading to earlier diagnosis (Michalski et al., 2008), although this hypothesis is not fully confirmed.

Acute pancreatitis is also associated with upregulation of endocannabinoid ligands and receptors and, therefore, cannabinoids might be therapeutically useful to reduce pain associated with acute pancreatitis and, perhaps, also inflammation (Michalski et al., 2007). Nevertheless, a case of acute pancreatitis with transfixiant epigastric abdominal pain, nausea, and vomiting induced by heavy cannabis use was recently reported, pointing at the complexity of ECS involvement in this condition (Fatma et al., 2013).

Finally, in a rat model of chronic pancreatitis induced by an alcohol/high fat diet, stimulation of CB2R showed tissue-protective and analgesic properties (Zhang et al., 2014).

Liver

CB1R and CB2R expression is very low in the normal liver. However, the ECS may play a major role in

several liver pathological conditions. As recently reviewed, the ECS seems to be protective in hepatic inflammatory conditions, and other diseases affecting the liver, including fibrogenesis, cirrhosis, hepatic ischemia-reperfusion injury, autoimmune hepatitis, and even hepatic encephalopathy (Lotersztajn et al., 2008; Miller & Devi, 2011; Pacher & Mechoulam, 2011). Although CB1R may as well participate, the role of CB2R upregulation seems to be prominent in all these conditions (Pacher & Mechoulam, 2011). In addition, CB1R, CB2R, and TRPV-1 overexpression was associated to improved prognosis in patients with hepatocellular carcinoma (Xu et al., 2006)

Specific studies addressed at evaluating the role of ECS in pain of liver origin have not been reported. However, in view of its role in hepatic inflammation, and in pain in other sites, it is conceivable that they would also be useful in these conditions.

Regarding disorders of the biliary tract and gall bladder, in rats subjected to bile duct resection, cholestasis-induced nociception (measured by the tail-flick assay) was reduced by previous administration of the nonselective cannabinoid agonist WIN55,212-2, suggesting that cannabinoids could be useful in reducing cholestasis-induced pruritus (Gingold & Bergasa, 2003). More recently, the FAAH inhibitor URB597 was also shown to increase the threshold in the tail-flick test in a CB1R-sensitive manner (Hasanein et al., 2008). No study has been performed on the possible role of cannabinoids in biliary colic pain.

Genitourinary Tract

Kidney and Ureter

The presence of CB1R and CB2R and their physiological role in the kidney has been described in animal models (Barutta et al., 2014). Both inflammatory cells and podocytes express CB2R, and their activation had beneficial effects in experimental diabetic nephropathy.

In human adult and fetal kidney, polymerase chain reaction confirmed the presence of CB1R mRNA, and the absence of CB2R mRNA; the presence of the CB1R protein was confirmed by western-blot and immunohistochemical assays, whereas assays for the CB2R protein were consistently negative (Larrinaga et al., 2010).

Smoking synthetic cannabinoids may induce acute kidney injury with intense nausea, and flank or abdominal pain (Buser et al., 2014). In contrast, cannabidiol (a nonpsychotropic constituent of cannabis, with antioxidant properties) and CB2R agonists (also devoid of psychotropic effects) protected against cisplatin-induced nephrotoxicity in mice, through attenuation of oxidative/nitrosative stress, inflammation, and cell death in the kidney, and improved renal function (Pan et al., 2009; Mukhopadhyay et al., 2010).

No study has been performed on the possible role of cannabinoids in renal colic pain.

Urinary Bladder and Urethra

As recently reviewed (Hedlund, 2014), the ECS is involved in regulation of bladder function, possibly at several levels of the micturition pathway. Components of the ECS (CB1R, CB2R, FAAH, TRPV1) have been located to lower urinary tract tissues of mice, rats, monkeys, and humans. CB receptors are found in urothelium and sensory nerves, and FAAH in the urothelium. CB receptor- and FAAH-related activities have also been reported in the lumbosacral spinal cord. Cannabinoids reduce sensory activity of isolated tissues, cause antihyperalgesia in animal studies of bladder inflammation, affect urodynamics parameters reflecting sensory functions in animal models, and appear to have effects on storage symptoms in humans. FAAH inhibitors affected sensory bladder functions, and reduced bladder overactivity in rat models. Cannabinoids may modify nerve-mediated functions of isolated lower urinary tract tissues. Modulation by the cannabinoid system of bladder hypersensitivity during inflammation may be exerted peripherally, via CB1R and TRPV1 (Walczak & Cerveró, 2011).

Ion channel transient receptor potential A1 (TRPA1), as well as cannabinoid receptors, are involved in mechanoafferent signaling from bladder and urethra. CB1R and CB2R were immunohistochemically detected in nerve fibers of the human urethra. CB1R activation reduced – whereas TRPV1 stimulation enhanced – the relaxing effect of TRPA1 agonists on human urethra preparations in vitro (Weinhold et al., 2010).

Ovary

The effects of cannabinoids on animal reproductive system have been known for decades (Adashi, Jones, & Hsueh, 1983; Bagavandoss & Grimshaw, 2010), and their effects on folliculogenesis have also been studied. The presence of the ECS in the human ovary has recently been analyzed (El-Talatini et al., 2009). Immunostaining studies showed the expression of CB1R and CB2R in the ovarian medulla and cortex, in the corpus luteum, and in the corpus albicans. Regarding the oocytes, only those of tertiary follicles (at the last stage of their development) expressed CB2R. In addition, anandamide was produced in the human ovary probably under hormonal control. Thus, the ECS seems to play an important role in ovarian follicle and oocyte maturity (Di Blasio, Vignali, & Gentilini, 2013).

Concerning ovarian pathologies, CB1R gene polymorphisms are involved in the polycystic ovary syndrome (Kuliczkowska Plaksej et al., 2014). However, no information is available on ECS involvement in sensory or painful neurotransmission in the ovary.

Endometrium

The main components of the ECS (receptors and enzymes) coexist in many cells in the human endometrium and in sensory and sympathetic neurons, and suffer modifications throughout the menstrual cycle (Taylor, Abbas, Habiba, & Konje, 2010). It has also been demonstrated that the ECS affects critical mechanisms (inflammation, cell proliferation and cell survival), underlying the establishment and maintenance of endometriosis (Pertwee, 2009).

Endometriosis is usually associated with pelvic pain such as chronic dysmenorrhea, intermenstrual abdominal and pelvic pain, back pain, dysuria, dyschezia, and dyspareunia that have been traditionally treated with cannabis to provide pain relief. Recently, cannabinoids have been evaluated in basic and clinical trials (Dmitrieva et al., 2010). In an animal model of endometriosis WIN55,212-2 decreased endometriosis-associated hyperalgesia, whereas the CB1R antagonist AM251, but not the CB2R antagonist AM630, increased the symptoms, suggesting that the antihyperalgesic effect is mediated by CB1R (Dmitrieva et al., 2010).

Thus, although the potential of cannabinoids must still be clarified, they seem to be a promising alternative for the development of new therapeutic strategies for endometriosis, and especially for endometriosis-related pain.

Testes and Scrotum

As recently reviewed (Bovolin et al., 2014), endocannabinoids are involved in male vertebrate reproduction, and this function involves regulatory mechanisms at both central and gonadal level. The appropriate endocannabinoid tone in the testis is critical for spermatogenesis progression, for sperm quality, and the acquisition of sperm functions related to fertilization. A specific and significant association between the use of marijuana and the occurrence of nonseminomatous and mixed testicular germ cell tumors has been recently reported in humans (Lacson et al., 2012), suggesting that the recreational and therapeutic use of cannabinoids may represent a risk factor for these cancerous processes. In addition, increased levels of anandamide are associated to reduced sperm motility and fertility. Cannabis reduces testosterone production by Leydig cells, and anandamide induces apoptosis of Sertoli cells.

Acute scrotal pain is related mainly to testicular torsion, epididymitis, or torsion of the appendix testis. Whereas testicular torsion requires urgent surgery, epididymitis and torsion of the appendix testis, which may actually present as chronic conditions, may be managed conservatively (once testicular torsion has been ruled out), including treatment with NSAID (Srinath, 2013).

Chronic orchialgia interferes significantly with work and social life, and has important psychological and financial implications. Management is established according to the underlying cause. Whereas surgery is not always useful to improve orchialgia, due to intrascrotal lesion, pharmacological treatment of different orchialgias may vary from simple analgesics to opioids, and adjuvants are added in case of neuropathic pain symptoms (Kumar, Mehta, & Nargund, 2010).

Although cannabinoids have not been tested in either acute or chronic testicular pain, they might be useful, because they alleviate peripheral neuropathy associated to diabetes, or administration of antineoplastic drugs in experimental animals (Vera, López-Miranda, Herradón, Martín, & Abalo, 2012; Vera, Cabezos, Martín, & Abalo, 2013).

Prostate

The distribution of CB receptors in prostatic tissue suggest a role for these receptors in mechanoafferent signals, epithelial homeostasis, emission, or inflammation of the human prostate (Gratzke et al., 2010).

Chronic prostatitis/chronic pelvic pain syndrome is a heterogeneous condition, and many treatments are largely ineffective. Limited success of clinical trials of this condition is related to placebo and treatment duration (Cohen et al., 2012). To our knowledge, cannabinoids have not been tested in this painful condition.

Interestingly, the association between prostatitis and prostate cancer, a global public health problem, has been found to be significant (Jiang et al., 2013). Experimental evidence shows that prostate tissue possesses increased expression of both CB1R and CB2R, and their stimulation results in decreased cell viability, increased apoptosis, and decreased androgen receptor expression, as well as prostate-specific antigen excretion. The ECS can act as a local regulatory mechanism to keep prostate cancer cells in check. Both activation of CB1R by anandamide, and inhibition of MAGL, the primary metabolizing enzyme of 2-arachydonoylglycerol, have shown efficacy to achieve this. In addition, it has been suggested that cannabinoid agonists might be particularly interesting in men with bone metastatic prostate cancer, who would not only benefit from the possible antiandrogenic effects of cannabinoids, but also from analgesia of bone pain, improving quality of life, while reducing narcotic consumption, and preventing opioid dependence (Ramos & Bianco, 2012).

CONCLUDING REMARKS

Visceral pain is difficult to treat, but may benefit from the use of cannabinoid agonists (particularly CB2R agonists for chronic inflammatory conditions) or inhibitors of endocannabinoid degradation. However, excessive use of natural or synthetic cannabinoids by abusers or patients may lead to chest or abdominal pain related to visceral toxicity. In addition, psychotropic undesirable

effects may occur upon systemic administration of fat-soluble drugs, increasing CB1R activity. Local routes of administration or cannabinoid-related drugs devoid of such effects will have to prove their usefulness in clinical settings. Time will tell which cannabinoid approaches are finally adopted in therapy.

MINI-DICTIONARY

Dorsal root ganglion (spinal ganglion) Ganglion located along the dorsal root of a spinal nerve, containing the cell bodies of afferents innervating the viscera (sympathetic afferents), as well as the skin and skeletal muscle (somatic afferents).
Dyschezia Difficulty in defecating (usually as a consequence of long continued voluntary suppression of the urge to defecate).
Dyspareunia Painful sexual intercourse due to medical or psychological causes.
Dysuria Painful urination.
Endometriosis Hormonal and immune system disease in which cells similar to those lining the uterus (endometrium) grow outside the uterine cavity, most commonly on the peritoneum, leading to pain and infertility. Pain is often worse with the menstrual cycle, and is the most common cause of secondary dysmenorrhea.
Lower urinary tract symptoms Group of medical symptoms affecting the lower urinary tract (storage, voiding, and postmicturition symptoms), affecting approximately 40% of older men.
Nodose ganglion (inferior ganglion of the vagus nerve) Ganglion located along the vagus nerve (X), containing the cell bodies of vagal (cranial parasympathetic) afferents innervating distal esophagus, stomach, gall bladder, small bowel, liver, spleen, pancreas, kidney, adrenal glands, and proximal colon.
Nucleus of the solitary tract Major sensory nucleus in the dorsal medulla that receives cardiovascular, gastrointestinal, respiratory, gustatory, and orotactile information from vagal afferents.
Orchialgia Long-term pain of the testes.
Pelvic ganglion Ganglion located along the pelvic splanchnic nerve, containing the cell bodies of the pelvic (sacral parasympathetic) afferents innervating the distal colon, rectum, uterus/prostate, urinary bladder, anus, and genitalia.
Referred pain Pain induced on somatic structures by the presence of pain in a viscus belonging to the same metameric field.

Cannabis and Postoperative Analgesia

S.O Cawich, U. Deonarine*, H.E. Harding**, D. Dan*, V. Naraynsingh**

***Department of Clinical Surgical Sciences, University of the West Indies, St. Augustine Campus, St Augustine, Trinidad and Tobago**

****Department of Surgery, University of the West Indies, Mona Campus, Kingston, Jamaica**

SUMMARY POINTS

- The mechanisms of postoperative pain include peripheral sensitization, central sensitization, inflammation, ischemia, and affective components.
- Multimodal therapy is advocated to target the multidimensional nature of postoperative pain.
- There are two G-protein coupled cannabinoid receptors (CB1 and CB2) that can be stimulated by organic cannabinoids, endocannabinoids, or synthetic cannabinoids.
- Endocannabinoids are released as a natural anesthetic, postoperatively. High concentrations of the endocannabinoids anandamide (AEA) and 2-arachidonoylglycerol (2-AG) have been associated with faster resolution of postoperative pain.
- Endocannabinoids may also decrease postoperative inflammation by inhibition of the cyclooxygenase pathway.
- There is substantial theoretical evidence suggesting cannabinols may be useful medicines in the treatment of postoperative pain, but this has not translated uniformly into the clinical research.
- Clinical human studies have not clearly demonstrated cannabinols as effective postoperative analgesia. At doses high enough to produce adequate analgesia, there is also higher incidence of adverse events.
- Experimental research has shown a clear synergistic effect when cannabinoids are used in combination with opioids. This has not translated into human clinical trials.
- Anecdotal reports are emerging concerning the phenomenon of extreme refractory hyperalgesia, and increased postoperative analgesic requirements in the chronic cannabis user.
- Chronic use of cannabis leads to CB1 receptor downregulation that may, in part, account for this extreme hyperalgesia.
- Based on the current research, the authors do not recommend the use of cannabis or cannabinoids to treat postoperative pain.
- It is not ill advised to express heightened vigilance to the analgesic requirements of the cannabis user.

KEY FACTS

- The endogenous opioid system is comprised of several neurons scattered throughout the body that produce endogenous opioids such as endorphins, enkephalins, and dynorphins.
- These naturally produced endogenous opioids are neuromodulators at various synapses along the pain pathways.
- Cannabinoids play a role in decreasing postoperative pain by interacting with the endogenous opioid system.
- Experimental evidence supports a synergistic interaction between opioid and cannabinoid receptors that leads to enhanced analgesia for chronic pain.
- The possibility exists of increased analgesic requirements in the chronic cannabis user.

LIST OF ABBREVIATIONS

Δ^9-THC	Delta-9-tetrahydrocannabinol
2-AG	2-Arachidonoylglycerol
AEA	Anandamide
cAMP	Cyclic adenosine monophosphate
CB1	Cannabinoid receptor type 1
CB2	Cannabinoid receptor type 2
MAPK	Mitogen-activated protein kinases
mRNA	Messenger ribosomal nucleic acid

INTRODUCTION

Medicinal properties of the cannabis plant were described as early as 2700 BC, in the ancient Chinese pharmacopeia. In ancient India, the plant was also prescribed to treat a multitude of ailments, including infections, pain disorders, inflammation, seizures, and anorexia. There are even early reports of the use of cannabis in an anesthetic setting, dating back to the second century, and the work of Hua Tuo (AD 110–207). Hua Tuo was a renowned ancient Chinese surgeon who used a herbal mixture called "mafeisan"—roughly translated as "cannabis boiling powder"—to anesthetize his patients prior to surgery (Zuardi, 2006).

Since this era, our knowledge of the mechanisms of action of cannabis extracts has improved. As it relates specifically to pain, cannabis has been shown to attenuate the perception of chronic pain through effects on the endogenous opioid system (Mackie, 2008). Based on these properties, it was licensed for medicinal use in chronic pain syndromes, and for terminally-ill cancer patients in the Netherlands, Switzerland, Spain (Martínez-Rodríguez et al., 2008), Canada (Spurgeon, 2001), and in 20 states of the United States of America (Morris, TenEyck, Barnes, & Kovandzic, 2014; Sevigny, Pacula, & Heaton, 2014).

Naturally, the question arose whether it may also be of value to alleviate acute postoperative pain. This is important because, even in the 21st century, there are still reports that acute pain continues to be poorly treated after surgery (Wu & Raja, 2011) in up to 39% of patients (Apfelbaum, Chen, Mehta, & Gan, 2003). These poor outcomes are echoed in statistics across the globe (Myles & Power, 2007; Taylor & Stanbury, 2009). This is disappointing, since there are clear benefits to adequate postoperative analgesia, including early ambulation, quicker recovery, reduced morbidity, shorter hospitalization, and better patient satisfaction.

The potential for cannabis to be used in the treatment of acute postoperative pain has sparked much debate, with opponents pointing out that the mechanism of acute pain differs significantly from chronic pain models. Therefore, it is prudent to review the mechanisms of acute and chronic pain.

MECHANISM OF CHRONIC PAIN

In the chronic pain model, there is downregulation of opioid receptors in the dorsal horn of the spinal cord (Mackie, 2008), explaining the reduced efficacy of opioids in chronic pain. However, there is compensatory upregulation of cannabinoid receptors type 1 (CB1) in the thalamus (Mackie, 2008). When stimulated, CB1 sends inhibitory impulses along descending tracts that synapse on the dorsal horn of the spinal cord at the level of origin of pain impulses (Jefferson, Harding, Cawich, & Jackson-Gibson, 2013) to modulate the upward transmission of chronic pain signals. This is the primary mechanism by which cannabis provides analgesia in chronic pain models.

MECHANISM OF ACUTE POSTOPERATIVE PAIN

On the other hand, several different pathophysiologic mechanisms are active to produce postoperative pain. Firstly, acute pain is transmitted mainly by small-diameter Aδ fibers, in contrast to the large-diameter C-fibers that predominate in chronic pain models (Pogatzki, Gebhart, & Brennan, 2002). As early as the first postoperative day, there is primary sensitization at these peripheral myelinated Aδ fibers, as well as the unmyelinated C fibers (Pogatzki et al., 2002). Several mechanisms are involved in primary sensitization, including reduction of receptor threshold potentials, spontaneous depolarization, enlargement of the receptive fields, and greater recruitment of pain receptors to respond to noxious stimuli (Brennan, 2011). Similar mechanisms lead to central sensitization in the dorsal horn of the spinal cord (Dirks, Møiniche, Hilsted, & Dahl, 2002). An inflammatory component also exists, and is due to prostaglandin-induced neuropeptide release (Schug & Manopas, 2007) that, in turn, leads to prolonged stimulatory input to large diameter C-fibers (Grape & Tramèr, 2007). Tissue ischemia contributes as well, as evidenced by increased lactate levels and decreased pH in tissues, after operation (Wu & Raja, 2011). Finally, there is a significant affective excitatory component that contributes to hyperalgesia (Roykulcharoen & Good, 2004). This explains how relaxation techniques alleviate postoperative anxiety, and reduce analgesic requirements (Roykulcharoen & Good, 2004).

A better understanding of the multifaceted nature of acute postsurgical pain has led to the concept of the multimodal approach to postoperative analgesia, as demonstrated in Fig. 46.1 (Myles & Power, 2007). The choice of analgesia, then, is affected by the pain intensity, the surgical procedure, and integrity of the gastrointestinal tract.

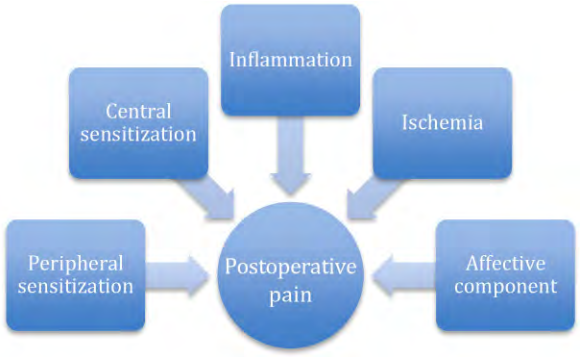

FIGURE 46.1 Multidimensional model for pathophysiology of postoperative pain. The multidimensional nature of postoperative pain. This chart describes the different factors that contribute to the intensity of postoperative pain.

Opioids are still the most commonly utilized drugs to treat moderate-to-severe pain in the acute postoperative setting, but there has been growing interest in multimodal drug therapy which has the potential to reduce opioid dosages, and prevent complications such as respiratory depression (Hamilton & Baskett, 2000).

Many have suggested that cannabis may have a role in the multimodal drug therapy regimens, since CB1 can be located in critical locations, such as the presynaptic cell membranes in the dorsal horn of the spinal cord, the hypothalamus, and periaqueductal gray matter (Mackie, 2008). A detailed understanding of the endocannabinoid system is required to explore the role of cannabis in the treatment of postoperative pain.

THE ENDOCANNABINOID SYSTEM

The crude form of the *Cannabis sativa* plant contains over 100 phytocannabinoids (Hill, Williams, Whalley, & Stephens, 2012). The widely varying chemical composition has made the cannabis plant difficult to work with, from a research perspective. The most active extract that has been isolated is delta-9-tetrahydrocannabinol (Δ^9-THC), which has significant psychotropic effects. The Δ^9-THC extract is the prototype cannabinoid, but there is ongoing research using botanical cannabinoids that have less psychotropic effects, such as cannabidiol and cannabinol (Hill et al., 2012).

Some synthetic cannabinoids have been clinically tested with success. These include synthetic cannabinoids such as nabilone and dronabinol that have been licensed for use since 1985 to treat refractory chemotherapy-induced nausea and vomiting (Borgelt, Franson, Nussbaum & Wang, 2013).

The human body produces several forms of endogenous cannabinoids that are released in response to acute pain (Guindon & Hohmann, 2009). The endocannabinoids, such as anandamide (AEA) and 2-arachidonoylglycerol (2-AG), mediate their effects through the cannabinoid receptors, as outlined in Table 46.1 (Karst, Wippermann, & Ahrens, 2010; Mackie, 2008).

TABLE 46.1 The Distribution of Cannabinoid Receptors

Receptor	Location of the cannabinoid receptors
CB1 (high density)	Basal ganglia (lateral part of the striatum, globus pallidus, entopeduncular nucleus, substantia nigra pars reticulata) Cerebellum Hippocampus Neocortex Hypothalamus Limbic cortex
CB1 (moderate density)	Periaqueductal gray matter Dorsal horn of the spinal cord
CB1 (low density)	Thalamus Brainstem
CB2	Immune cells (peripheral macrophages such as microglia Keratinocytes

This table lists the locations and relative densities of the cannabinoid receptors.

The cannabinoid receptors are transmembrane G-protein coupled receptors (Elikkottil, Gupta, & Gupta, 2009). When activated by cannabinoid binding, there is inhibition of adenylyl cyclase, reduction in cAMP, and closure of voltage-activated calcium channels, leading to reduced calcium conductance across the cell membrane. Simultaneously, there is activation of mitogen-activated protein kinases (MAPK), and opening of potassium channels that lead to increased potassium conductance (Elikkottil et al., 2009). Through these downstream effects, the endocannabinoids attenuate neural transmission of pain impulses, thereby hastening the resolution of postoperative pain in animal models (Alkaitis et al., 2010). These studies have also demonstrated that the levels of AEA and 2-AG are low on the first postoperative day, when pain is most severe, but progressively increase, coinciding with progressive resolution of hyperalgesia (Alkaitis et al., 2010).

Other mechanisms of action are also believed to be active, including inhibition of the cyclooxygenase pathway leading to attenuation of the inflammatory component to acute pain (Costa et al., 2004). Finally, they are also believed to attenuate secondary central sensitization because they are found in moderate concentrations in the dorsal horn of the spinal cord (Alkaitis et al., 2010). In summary, there is theoretical evidence to suggest that cannabinols may be useful in the treatment of postoperative pain, but there are mixed results when tested in clinical trials.

CLINICAL TRIALS USING CANNABINOIDS TO TREAT ACUTE POSTOPERATIVE PAIN

Although animal studies have suggested that cannabinoids have a beneficial effect in treating postoperative pain, the results of clinical trials have not been as clear. To date, 5 randomized blinded clinical trials have been performed in 314 human subjects, in an attempt to determine the effect of cannabinoids.

Two studies actually suggested that cannabinoids *worsened* pain scores in patients with acute pain. Beaulieu (2006) designed a double-blinded trial in which they randomized 44 patients to receive nabilone (a synthetic Δ^9-THC analog), ketoprofen, or placebo at 8-h dosing intervals, after undergoing a range of operative procedures. The patients receiving nabilone reported significantly greater pain scores at rest and during movement, when compared to ketoprofen or placebo. There was also no difference in rescue morphine consumption, quality of sleep, or side effects. Naef et al. (2003) exposed 12 healthy volunteers to thermal, pressure, and electrical stimuli to produce acute pain. The volunteers were randomized either to a placebo, 20 mg THC, 30 mg morphine, or a combination of 30 mg morphine + 20 mg THC. There were worsened pain scores reported in response to thermal stimuli, and no significant analgesic effect with pressure and electrical stimuli.

Two studies suggested that the cannabinoids provided no useful analgesic effect in humans, in the postoperative period. Buggy et al. (2003) investigated a cohort of 40 patients who were scheduled to undergo elective hysterectomies. They were routinely placed on patient-controlled analgesia, in the immediate postoperative phase. Once the PCA was discontinued on the second postoperative day, the patients were prospectively randomized to identical tablets containing 5 mg of Δ^9-THC or placebo. Buggy et al. (2003) found no difference in visual pain scores, summed pain intensity difference, time to rescue analgesia, or adverse events between Δ^9-THC and placebo. Seeling et al. (2006) then studied a cohort of 100 patients scheduled for radical prostatectomy. The patients were randomized to receive either placebo or 5 mg drobanibol (Δ^9-THC analog), starting from the evening before operation. They found no analgesic effect, and no difference in the amount of morphine used as rescue analgesia by patients who received drobanibol.

One prospective blinded randomized trial suggested that cannabinoids were beneficial in controlling postoperative pain. Jain, Ryan, McMahon, and Smith (1981) studied a group of 56 patients who had acute pain after trauma or operation. They prospectively randomized the patients to receive intramuscular injections of levonantradol (Δ^9-THC analog) or placebo. The patients receiving levonantradol reported significant reductions in pain intensity, but significantly more side effects. Approximately 95% of patients taking levonantradol experienced unwanted side effects, most notably CNS sedation and dizziness (Jain et al., 1981).

An interesting study supporting cannabinoid use was reported by Holdcroft, Maze, Dore, Tebbs, and Thompson (2006). They evaluated an extract of cannabis called cannador that contained a mixture of Δ^9-THC and cannabinol in a ratio of 1:0.3 or 1:0.5. A dose of 5 mg of cannador was commenced after discontinuation of patient controlled analgesia, and the dose was escalated to 10 mg, and then to 15 mg—based on the number of patients requesting rescue analgesia. As the doses of cannador escalated, there was a significant reduction in pain intensity at rest, and the requirement for rescue analgesia. They found that cannador at 10 and 15 mg dose was comparable to acetaminophen and ibuprofen to prevent the need for rescue analgesia. However, as the cannador doses rose, there was a significant increase in sedation and adverse events. In fact, the study was terminated due to a serious vasovagal attack in a patient at the 15 mg dose. Nevertheless, these researchers felt the evidence was compelling enough to advocate the use of 10 mg of cannador to treat postoperative pain (Holdcroft et al., 2006).

There is still much heterogeneity in study design and outcomes to make a definitive statement on the effect of cannabis in postoperative pain in clinical trials (Table 46.2).

SYNERGISM BETWEEN CANNABINOIDS AND OPIOIDS

Although there are mixed results from clinical studies investigating the analgesic effects of cannabinoids, researchers have suggested that they may be beneficial through synergistic effects, when combined with opioid analgesics. This important concept follows the principles of multimodal therapy, where cannabinoids produce greater-than-additive effect on the antinociceptive effect of opioids. Therefore, the dose of opioids could be reduced, producing less worrisome side effects. This is important, since morphine remains the mainstay of pharmacologic treatment to control severe postoperative pain, and is associated with a significant risk of respiratory depression at high doses (Hamilton & Baskett, 2000).

Animal experiments have revealed some of the mechanisms for the synergistic effects. Firstly, stimulation of cannabinoid receptors may also stimulate the release of endogenous opioids: CB1 stimulation has been shown to lead to the release of dynorphin A (Pugh, Smith, Dombrowski, & Welch, 1996), and selective CB2 stimulation by AM241 has been shown to stimulate the release of β-endorphin from surrounding keratinocytes (Ibrahim

TABLE 46.2 Clinical Trials Assessing the Role of Cannabinoids in the Postoperative Setting

Authors	Study design	Cannabinoid tested/dose	Study population	Outcomes/results	Adverse events
Jain et al. (1981)	Randomized double-blind trial comparing four doses with placebo	Levonantradol at doses of 1.5, 2, 2.5, and 3 mg compared with placebo	56 patients with moderate to severe postoperative or traumatic pain	Levonantradol was found to have significantly superior analgesic effect compared with placebo. 2.5 mg dose provided best analgesia, but no statistically significant difference among treatment groups	57% of 40 patients who received Levonantradol experienced side effects. Most commonly, sedation (47%)
Buggy et al. (2003)	Randomized double-blind placebo controlled single dose trial	Δ^9-THC/5 mg compared with placebo	40 patients after elective abdominal hysterectomy	No difference among groups in visual analog scale pain scores at movement or rest. No difference in mean sum of pain intensity differences at 6 h. No difference among groups in time to request rescue analgesia	Significantly increased awareness of surroundings in patients who received 5 mg THC (40%) compared with patients who received placebo (5%)
Naef et al. (2003)	Randomized, placebo-controlled, double-blinded, crossover study	Placebo compared with 20 mg THC, compared with 30 mg morphine, compared with a combined preparation of 30 mg morphine + 20 mg THC, all given orally and as single doses	12 healthy volunteers subjected to experimental pain tests: heat, cold, pressure, and transcutaneous electrical stimulation	THC did not reduce pain scores for pressure, heat, cold. THC increased pain scores in cold and heat testing. There was a slight additive analgesic effect with THC-morphine, in electrical stimulation tests	Increased psychotropic and somatic side effects: drowsiness, euphoria, anxiety, confusion, nausea, dizziness
Seeling et al. (2006)	Randomized double blind, placebo controlled trial	5 mg THC given three times a day starting on the evening preoperatively to day 2 post-op compared with placebo	100 patients who underwent radical prostatectomy	No significant difference in opioid (piritramide consumption) or analgesia	Increase in vasovagal reactions in THC group, and a decrease in postoperative nausea and vomiting
Beaulieu (2006)	Randomized double-blind, placebo controlled, parallel group trail	Nabilone at doses of 1 and 2 mg, compared with ketoprofen 50 mg or placebo	41 patients undergoing gynecological (46%), orthopedic (Naef et al., 2003) (44%), or other surgery	No statistically significant difference in 24 h morphine consumption with administration of nabilone. Intensity of pain at rest and on movement (assessed by pain scores) was significantly greater in the group who received 2 mg nabilone	Sedation scores were significantly higher in the group who received 2 mg nabilone. Incidence of nausea and vomiting showed no difference between groups

TABLE 46.2 Clinical Trials Assessing the Role of Cannabinoids in the Postoperative Setting (*cont.*)

Authors	Study design	Cannabinoid tested/dose	Study population	Outcomes/results	Adverse events
Holdcroft et al. (2006)	Multicentre dose-escalation study	Δ^9-THC at doses of 5, 10 or 15 mg	65 patients who underwent breast, general, gynecological, orthopedic, or plastic surgery	There was significant decrease in request for rescue analgesia at increasing dose. 5 mg dose 100% requested rescue analgesia, compared to 50% at 10 mg dose, and 25% at 15 mg dose ($p < 0.001$) There was significant improvement in pain intensity at rest with increasing dose	Significantly increased sedation and nausea with increasing dosage. One serious vasovagal adverse event at the 15 mg dose

This table summarizes the current data assessing the interaction of cannabinoids with mechanisms of acute pain.

et al., 2005). There is also evidence to suggest that Δ^9-THC has some activity at the κ-opioid and δ-opioid receptors (Smith, Cichewicz, Martin, & Welch, 1998).

Experimental animal studies supported the theory of cannabinoid-opioid synergism (Smith et al., 1998; Pugh et al., 1996; Cichewicz & McCarthy, 2003; Ibrahim et al., 2005). Smith et al. (1998) carried out experiments in mice, comparing tail flick responses to painful thermal stimuli, when treated with morphine alone or morphine/Δ^9-THC combinations. They were able to demonstrate a significant potentiation of morphine's analgesic effect, when combined with Δ^9-THC. The synergistic effect was also present when a synthetic selective cannabinoid (CP-55-940) was used in place of Δ^9-THC, and the effects could be reliably reversed when a CB1 agonist (SR141716A) was administered (Smith et al., 1998). Similar synergistic effects between Δ^9-THC and morphine, with a left shift in the morphine dose-response curve, and greater antinociceptive in mice, were demonstrated in mice by Pugh et al. (1996) and Cichewicz and McCarthy (2003). Again, there was reliable attenuation of the morphine/Δ^9-THC synergism, when κ-antagonists (norbinaltorphimine) and δ-antagonists (naltrindole) were administered to interrupt the action of Δ^9-THC (Pugh et al., 1996).

However, human studies did not support the theories of synergism, when evaluated in human trials. Naef et al. (2003) exposed 12 healthy volunteers to a variety of noxious stimuli. The volunteers were then prospectively randomized to analgesia with either placebo, 20 mg of THC, 30 mg of morphine, or combinations of 20 mg THC + 30 mg morphine. Interestingly, in response to thermal stimuli, THC resulted in hyperalgesia. Otherwise, there was a slight additive analgesic effect that did not bear statistical significance (Naef et al., 2003). Similar results were reported by Beaulieu (2006) in a study randomizing 44 patients to nabilone (a synthetic Δ^9-THC analog), ketoprofen, or placebo at 8-h dosing intervals, after undergoing a range of operative procedures. The patients receiving nabilone reported *significantly greater* pain scores at rest and during movement, when compared to ketoprofen or placebo. There was also no difference in rescue morphine consumption, quality of sleep, or side effects (Beaulieu, 2006). Similarly, in a cohort of 100 patients randomized to receive placebo or 5 mg drobanibol (Δ^9-THC analog) after radical prostatectomy, there was no analgesic effect, and no difference in the amount of morphine used as rescue analgesia by patients who received drobanibol (Seeling et al., 2006).

The use of morphine in combination with cannabinols has shown more promising results in the experimental literature but has not translated fully into human trials. Admittedly, this deserves further study to determine the effect of synergism. If there is a role for the use of cannabis as an adjunct to morphine in postoperative pain, this would allow us to reduce the dosage of morphine and the attendant risk of respiratory depression. Additionally, cannabinoid receptors are found in low concentration in the brainstem centers that modulate respiratory drive, hence they do not cause respiratory depression. Furthermore, decreased dosing of cannabinoids will produce decreased undesirable CNS effects associated with high dose cannabinoid use.

ANALGESIC REQUIREMENTS IN THE CHRONIC CANNABIS USER, POSTOPERATIVELY

The National Survey on Drug Use and Health of 2012 reported that there were about 6600 new cannabis users per day. Cumulatively, there were 2.4 million new users of cannabis, in the year of 2012 (US Department of Health and Human Services, 2012). The World Health Organization describes cannabis as the most widely used illicit drug, currently being used by 2.5% of the global population. They estimate that cannabis use is 12 times more prevalent than cocaine and heroin (World Health Organization, 2016). The exceedingly high prevalence of cannabis use has even sparked a significant political debate advocating global legalization of medicinal and recreational usage (Spurgeon, 2001; Morris et al., 2014; Martínez-Rodríguez et al., 2008; Sevigny et al., 2014). With the escalating prevalence of cannabis use, more patients who are chronic cannabis users will be encountered in surgical practice. Therefore, the effects of opioid analgesia on acute pain in the chronic cannabis user must be explored.

Gofeld, Robinson, and Faclier (2006) reported on a case in which a chronic marijuana user experienced intractable postoperative pain despite adequate multimodal therapy. They resorted to the use of nabilone, a synthetic cannabinoid, for supplemental analgesia with good effect. There was a dramatic reduction in visual pain scores, and a decrease in morphine consumption (Gofeld et al., 2006). Jefferson et al. (2013) then carried out a prospective randomized blinded trial in 73 patients undergoing orthopedic operations. They compared postoperative pain control in cannabis users and cannabis naive patients. Cannabis users were found to have a significantly greater mean pain intensity difference in the first postoperative hour, and a significantly greater demand for rescue morphine (Jefferson et al., 2013).

The available data suggest that chronic cannabis users have reduced pain thresholds. Several theories have been proposed to explain this effect, and focus predominantly on three mechanisms: neuroadaptation, cross-tolerance, and withdrawal. Long-term cannabis use in animal studies produces drug tolerance with attenuated cannabinoid-mediated effects (Sulipta, Einstein, Neely, Moise, & Hohmann, 2008; Gonzales, Cebiera, & Fernandez-Ruiz, 2005; Hoffman, Oz, Caulder, & Lupica, 2003). This is believed to be due to a combination of CB1 downregulation (Hirvonen et al., 2010; Villares, 2007), attenuation of G-protein activation (Jefferson et al., 2013), and impaired mRNA second messenger effects (Villares, 2007; Sim-Selley, 2003). The degree of tolerance can be erratic, varying with time (Manning, 1976), individuals (Jefferson et al., 2013), behavior-specific responses (Whitlow et al., 2004), and the degree of tolerance (Ramaekers, Kauert, Theunissen, Toennes, & Moeller, 2009).

In light of the evidence to support interaction between the cannabinoid and opioid receptors, some have hypothesized that cross-tolerance also occurs, leading to neuroadaptation at opioid receptors (Garzón, de la Torre-Madrid, Rodríguez-Muñoz, Vicente-Sánchez, & Sánchez-Blázquez, 2009). This would lead to the observed effect of resistance to opioids, and has also been theorized to produce similar forms of resistance to barbiturates, benzodiazepines, and phenothiazines (Ashton, 1999).

Finally, some have theorized that chronic users develop cannabis dependence. This cannabis withdrawal syndrome may play a role in the observed hyperalgesia that is seen in chronic cannabis users (Jefferson et al., 2013).

CONCLUSIONS

Further research is needed before cannabis can be used as a part of multimodal therapy for postoperative analgesia. There is more experimental evidence for its use as an adjunct to morphine for postoperative analgesia, rather than for use on its own. There are increased analgesic requirements in chronic cannabis users but further work is needed to elucidate the resistance mechanisms.

While experimental research continues to pave the way in knowledge of cannabinoids, animal models have not translated into clinical trials. Without larger, high quality human trials, the use of cannabinoids will continue to be cautious and limited. At this time, based on the current evidence, it would not be harmful to observe the pain requirement of cannabis users more closely during the postoperative period.

MINI-DICTIONARY

Analgesic A medication that attenuates the sensation of pain.
Cannabinoid Chemical compounds with the ability to bind to CB1 or CB2.
Hyperalgesia An exaggerated sensation of pain, out of keeping with that expected in response to the noxious stimulus applied.
Levonotradol A synthetic cannabinoid.
Nabilone A synthetic cannabinoid.
Nociception The processes by which sensory neurons encode and transmit the presence of a harmful stimulus, resulting in the sensation of pain.
Nociceptor Sensory receptor that receives and transmits information indicating the presence of noxious stimuli.
Psychotropic A chemical that acts on the central nervous system to alter mood, sensorium, or level of consciousness.

Aggressive Behavior and Cannabis Use

W. Liu, H. Petras***

***NORC at the University of Chicago, Bethesda, MD, United States**
****American Institutes for Research, Washington, DC, United States**

SUMMARY POINTS

- Substance use (eg, cannabis use) and aggressive and disruptive behavior (ADB) are considered to be major public health problems around the world.
- In middle school, cannabis use and ADB tend to cooccur, but unbiased information about their causal relationship is not available.
- Knowledge about whether ADB causes cannabis use or vice versa is relevant for the design and implementation of interventions targeting such behaviors.
- ADB during the elementary school years has been hypothesized as an antecedent for cannabis use, but a causal relationship has not been established yet.
- During the middle and high school years, both ADB causing cannabis use and vice versa are plausible, and a causal relationship has not been established yet.
- Uncertainty about the relationship between these behaviors is likely due to the large variety in study designs, and this ultimately hinders the identification of typical pathways, as well as documenting the variation across individuals.

KEY FACTS OF AGGRESSION

- Aggressive, disruptive behavior (ADB) is considered to be normal, and highly frequent in young children.
- Approximately 50% of social exchanges between children 12–18 months of age can be considered ADB.
- ADB tends to decrease significantly during late childhood and adolescence.
- For a small number of children, ADB does not decrease, or starts to reemerge in later childhood.
- Persistent ADB is one of the strongest risk factors for negative outcomes later in life, including substance use, juvenile delinquency, school dropout, and adult criminality.

LIST OF ABBREVIATIONS

ADB Aggressive and disruptive behavior
PBT Problem Behavior Theory

INTRODUCTION

The prevention and treatment of both substance use and aggressive, disruptive behavior (ADB) are national priorities in countries around the world. Good epidemiological evidence exists suggesting that both behaviors lead to significant proximal (eg, truancy and suspension), as well as distal (eg, school dropout and criminality), negative social and health outcomes (Petras et al., 2008; Petras, Masyn, & Ialongo, 2011).

Substance use, especially cannabis use, has been often found to have a positive link with aggressive behavior, found in cross-sectional and longitudinal studies (Goodman, 2010; Jester et al., 2008). Liu, Lynne-Landsman, Petras, Masyn, and Ialongo (2013) found that early childhood aggressive behavior (grade 1–3) doubles the odds of high-frequency marijuana use in adolescence (grade 8–12). Petras et al. (2011) found that early childhood aggressive behavior during grade 1–3 increased

the odds of conduct problems during grade 6–12 by eightfold. The common cooccurrence of cannabis and aggressive behavior in adolescence is often explained by the Problem Behavior Theory (PBT; Jessor, 1991). PBT proposes that many problem behaviors, including substance use, conduct problems, and other antisocial behaviors, are interrelated in that the personal and situational factors influencing one behavior may be the same as those influencing another.

Huizinga, Loeber, Thornberry, and Cothern (2000) assessed the level of cooccurrence of multiple problem behaviors in three large longitudinal studies, including the Denver Youth Survey (PI: David Huizinga), the Pittsburgh Youth Study (PI: Rolf Loeber), and the Rochester Youth Development Study (PI: Terence Thornberry). It was found that 34–44% of male delinquents were also drug users, and between 54% and 70% of male drug users were also delinquents. While these relationships are statistically significant, it cannot be assumed that most delinquents are also drug users, and causal inferences are not possible insofar as a causal relationship indicates that changes in one variable cause changes in another (Rosenbaum, 2002).

This raises questions about the causal basis for this association, in particular during adolescence. For example, if the association between early childhood aggression and later cannabis use is noncausal, then harm reduction and substance use prevention/intervention programs in adolescence are expected to be effective. On the other hand, evidence for causality would make cannabis use a hidden, but preventable, public health problem responsible for many psychosocial problems.

This book chapter represents an intermediate step toward the goal of assessing the causality, by conceptually summarizing the current literature focusing on the cooccurrence of these two behaviors during childhood and adolescence. The chapter is structured as follows: building upon the descriptive epidemiology of cannabis use and ADB, we will review theoretical models, as well as the extent of empirical support for the different possible hypothesized associations between the two behaviors.

Descriptive Epidemiology of Cannabis Use

Cannabis is the most widely cultivated, trafficked, and abused illicit drug worldwide. It is estimated that 147 million people, or 2.5% of the world population, consume cannabis. This annual prevalence is over 10 times higher than the prevalence for cocaine or opiates. The most rapid abuse starting in the 1960s has occurred in developed countries, including North America, Western Europe, and Australia.

Initiation and experimentation with cannabis typically begin during late adolescence (Fuller et al., 2005). The hazard of first use follows a typical age-curve characterized by an increase in risk at age 10–11, and peaking around age 18 (Wagner & Anthony, 2002). Recent data from the Monitoring the Future study (Johnston, O'Malley, Bachman, Schulenberg, & Miech, 2014) revealed that, between 2008 and 2013, past-month use increased from 5.8% to 7.0% among 8th graders, from 13.8% to 18.0% among 10th graders, and from 19.4% to 22.9% among 12th graders. The 2011 ESPAD Report (Hibell et al., 2011) reported that the prevalence among 15- and 16-year-old school students was 13% in Europe, with the highest prevalence found in France at 35%.

Descriptive Epidemiology of Aggressive/Disruptive Behavior

ADB (eg, lying and disobeying) is considered to be normal, and highly frequent in young children. Approximately 50% of social exchanges between children 12–18 months of age can be considered ADB (Holmberg, 1980). During this age period, ADB is seen as adaptive, and part of the infants' training ground to develop effective social strategies for assertiveness, ownership of objects, and resolution of social conflict. For the majority of children, ADB tends to decrease during childhood and adolescence, due to increases in self-control, hormonal regulation, and cognitive capacity (Tremblay, 2006).

However, for a small but significant number of children, ADB does not decrease, or starts to reemerge in later childhood, as discussed in two prominent theoretical models. The model by Patterson, DeBaryshe, and Ramsey (1989) features two distinct pathways toward antisocial behavior: *early starters* (ie, involving coercive parenting, school failure, and antisocial behavior starting in childhood), and *late starters* (ie, involving poor parental monitoring, oppositionality, and deviant peer involvement starting in early adolescence). The model by Moffitt (1993) also proposes two mutually exclusive subgroups of antisocial youth: *life-course persistent offenders*, who show high levels of aggressive behavior throughout development, and continue to be violent as adults; and *adolescence-limited offenders*, who engage in nonviolent forms of antisocial behavior only during the teen years.

THEORIES AND EMPIRICAL SUPPORT

Building on the descriptive epidemiology of aggressive behavior and cannabis use, we reviewed theories and empirical support of cannabis use-aggressive behavior relationship. Our review was conceptually motivated by a model depicting three developmental periods: preelementary, elementary, and middle school (Fig. e3.1).

During the preelementary school period, the focus is on delineating etiological factors of ADB, namely family factors and individual vulnerabilities. During the

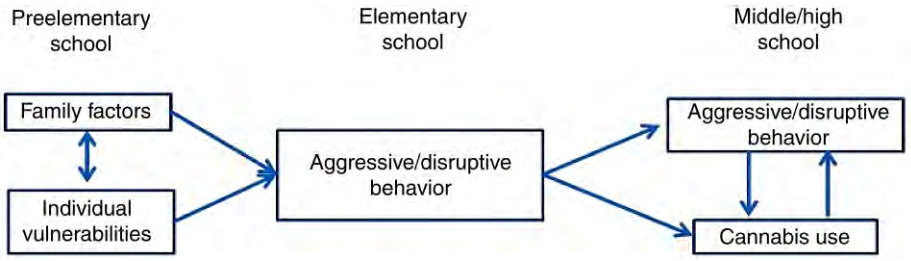

FIGURE e3.1 **Risk factors for cannabis use during three developmental periods.** Risk factors for cannabis use in three developmental periods are depicted in this figure. *Arrows* are not meant to indicate causal pathways. During the preelementary school years, family factors interacting with individual vulnerabilities are hypothesized to influence levels of aggressive behavior during the elementary school years. These levels, in turn, may influence cannabis use directly or indirectly through increasing levels of aggressive and disruptive behavior during the middle and high school years. In addition, it is hypothesized that both cannabis use and levels of aggressive and disruptive behaviors during this period may influence each other.

elementary school period, the focus is on ADB as a risk factor, for both later aggressive behavior, as well as cannabis use. Lastly, during the middle-school period, we focus on the cooccurrence between the two behaviors of interest.

In the following sections, we will discuss three likely pathways of the relationship between cannabis use and aggressive behavior, in elementary school, as well as in middle and high school, respectively: ADB in elementary school leading to later cannabis use (see section "ADB in Elementary School Leading to Later Cannabis Use"); ADB leading to cannabis use in middle and high school (see section "ADB Leading to Cannabis Use in Middle and High school"); cannabis use leading to ADB in middle and high school (see section "Cannabis Use Leading to ADB in Middle and High School").

ADB in Elementary School Leading to Later Cannabis Use

Theory

Life course–social field theory (Kellam, Branch, Agrawal, & Ensminger, 1975) and its integration with the developmental model of antisocial behavior (Patterson et al., 1989) have been used to explain the relationship between early ADB and cannabis use. Life course–social field theory posits that, over the course of development, individuals are evaluated on how they respond to different task demands in various social fields (eg, the family, the classroom, etc.). At the heart of this theory is the tenet that early success in meeting these demands promotes success in later stages of life, as individuals face new challenges (Cicchetti & Schneider-Rosen, 1984).

According to life course–social field theory (Kellam et al., 1975), when first transitioning into formal education, children are confronted with teachers' demands for following classroom rules, and participating in classroom activities. Successfully meeting these demands will promote the successful transition into early adolescence, a period characterized by a different set of demands defined by family, school, and peers. In contrast, engagement in ADB in early elementary school may indicate the failure to meet classroom demands, and eventually lead to negative behavior and consequences in adolescence, such as, engaging in antisocial behavior, and frequent use of illicit drugs.

The origins of early classroom ADB are explained by referring to Patterson's developmental model of antisocial behavior (Patterson et al., 1989). The early starter model by Patterson et al. (1989) posits that aggressive children are more likely to provoke parents' and teachers' punitive discipline, leading to their rejection, which can facilitate children's drift into deviant peer groups, where a range of antisocial behaviors, including drug use and sustained levels of ADB, are reinforced, and further opportunities to engage in these behaviors may be provided.

Peer rejection is another common correlate of chronic aggressive behavior problems (Hektner, August, & Realmuto, 2000) and, in accord with Patterson, Reid, and Dishion (1992), may serve to hasten the aggressive and disruptive child's drift into a deviant peer group in late childhood and early adolescence. In these deviant peer groups, ADB is reinforced, thereby canalizing the pathway to later antisocial behavior, for example, by providing access and opportunities to use illicit drugs, such as, cannabis.

Empirical Support

Large prospective longitudinal studies with sufficiently long follow-ups have been utilized to discover this relationship (Table e3.1). Together, these studies have found a positive relationship between childhood ADB and later cannabis use, that is, increases in aggressive behavior in childhood are longitudinally associated with early onset and/or frequency of cannabis use. Using longitudinal data collected from a community sample consisting predominantly of inner-city African-American youths, a group of scholars have examined the relationship between aggressive behavior, measured as

Galera et al. (2010)	France	A sample of 1107 participants (aged 4–18 years at baseline) recruited from the population-based longitudinal Gazel Youth study with a follow-up assessment 8 years later
Flory, Milich, Lynam, Leukefeld, and Clayton (2003)	Metropolitan area, United States	A sample of 481 young adults with 10–12 years follow-up
Ensminger, Juon, and Fothergill (2002)	Chicago, IL, United States	An inner-city community sample from a Mid-West city followed from age 6 to 32 (N = 1242)
Pedersen, Mastekaasa, and Wichstrom (2001)	Norway	A prospective longitudinal study of a national sample of 2436 adolescents followed up over a year and a half, when the adolescents were in their early teens
Prinstein and La Greca (2004)	Metropolitan area, United States	Participants were 148 girls from diverse ethnic backgrounds, who were initially assessed in Grades 4–6 and again in Grades 10–12

early as in first grade of elementary school, on adolescent substance use. Liu et al. (2013) reported that trajectories of ADB measured at grades 1–3 are significantly associated with frequency of cannabis use in grades 8–12. A similar finding was also documented in Lynne-Landsman et al. (2010), using the same dataset. In addition, Reboussin et al. (2007) also found that aggressive behavior in first grade was associated with an increased risk of cannabis exposure opportunities, as well as cannabis use and problems in middle school.

Using data from the Raising Health Children (RHC) study, Kim et al. (2011) found that self-reported bullying behavior at grade 5 is significantly associated with increased cannabis use at age 21. Analyzing a longitudinal sample of youths followed from kindergarten to high school, Schofield et al. (2008) found that, regardless of gender and race, high rates of ADB at school entry increased risk of substance use, including cannabis use, in middle school.

Using a community sample of children at high risk for conduct disorder, Wu et al. (2010) found that higher levels of childhood conduct problems, including aggressive behavior, in kindergarten predicted higher levels of cannabis use in adolescence.

Korhonen et al. (2010) analyzed data collected from Dutch adolescents as part of the Tracking Adolescents' Individual Survey (TRAILS), and reported that childhood externalizing behavior (including aggressive behavior) measured at age 10–12 predicts the initiation and use of cannabis at age 12–18, both directly and indirectly, through the initiation of cigarettes smoking. Using the same data set, Creemers et al. (2009) found that childhood/early adolescent conduct problems at ages 10–12 predicted early onset of cannabis use in adolescence, at ages 12–14.

Similarly, Jester et al. (2008) found that aggression trajectories in childhood measured between the ages of 7 and 16 predict early onset of cannabis use. Analyzing a 25-year prospective longitudinal study of a New Zealand birth cohort, Fergusson et al. (2008) reported that childhood and early adolescent conduct problems, including aggressive behavior, were significantly associated with illicit drug abuse, including cannabis abuse and dependence, measured at ages 16–25.

Studies also found that, when coupled with other behavioral problems, aggressive behavior is a stronger predictor of cannabis use and abuse/dependence. Using Gazel Youth study, a population-based longitudinal sample, Galera et al. (2010) found that conduct disorder combined with hyperactivity-inattention in childhood predicts early initiation of cannabis use in males.

Using a community sample of youths from multiple schools, Flory et al. (2003) found that disruptive behavior at grade 6 significantly contributed to later cannabis use and dependence in young adulthood, ages 19–22, while this effect on cannabis dependence is stronger, when Hyperactivity–Impulsivity–Inattention is presented, in addition to disruptive behavior. Similarly, using an inner-city community sample from a Mid-West city, followed from age 6 to 32, Ensminger et al. (2002) examined childhood antecedents of cannabis use in adulthood. They found that males who were both shy and aggressive in first grade were more likely to use cannabis in adulthood than those who were neither.

Some studies have specifically examined gender differences in the aggressive behavior–cannabis use relationship. Taken together, these studies suggest that the effect of aggressive behavior on cannabis use may differ by gender, consistent with the general hypothesis that risk factors of cannabis use may be gender-specific (van den Bree & Pickworth, 2005). Using a prospective longitudinal study of a national sample of adolescents in their early teens in Norway, Pedersen et al. (2001) found a strong association between early conduct problems and subsequent early initiation of cannabis use, with strong effect found for girls than for boys. Liu et al. (2013) reported that ADB measured at grades 1–3 is significantly associated with frequency of cannabis use among males in grades 8–12, but not females.

Other studies found that ADB only leads to cannabis use in certain circumstances. For example, Prinstein and La Greca (2004) analyzed a sample of girls assessed in grades 4–6, and then again in grades 10–12. They reported an interaction between aggressive behavior and peer rejection, whereby aggressive behavior was significantly associated with adolescent cannabis use only among those experiencing peer rejection. When girls were accepted by peers, the association between childhood aggression and adolescent cannabis use did not hold.

ADB Leading to Cannabis Use in Middle and High School

Theory

It has been argued that, for adolescents who engage in both conduct disorder and substance use, conduct disorder typically precedes the initiation of substance use (Le Blanc & Loeber, 1998). Khantzian (1985) proposed a "self-medication hypothesis," whereby individuals with mental health problems, including aggression and other externalizing behavioral problems, tend to resort to substance use as a "solution" to their problems. The short-term effects of alcohol and illicit drugs help these individuals to cope with stressful states experienced as a result of their mental health issues. More recently, Khantzian (2003) posits that cannabis has both stimulating (ie, boosting energy and calming hyperactivity) and sedatory (ie, calming intense rage and creating the illusion of relief) effects.

TABLE e3.2 Empirical Studies Supporting ADB Leading to Cannabis Use in Middle and High School

Author (year)	Location	Sample
King, Iacono, and McGue (2004)	Minnesota, United States	A total of 699 twin girls and 665 twin boys from Minnesota Twin Family Study interviewed at age 11 and age 14
Goodman (2010)	United Kingdom	A sample of 3,607 British national cohort (age 11–16 at baseline)
Griffith-Lendering, Huijbregts, Mooijaart, Vollebergh, and Swaab (2011)	The Netherlands	Data were used from the TRAILS study, a longitudinal cohort study of (pre)adolescents (n = 1,449), with measurements at age 11.1 (T1), age 13.6 (T2) and age 16.3 (T3)
van den Bree and Pickworth (2005)	United States	Data were from Add Health study collected over two time points with a sample of middle and high school students (N = 13,718, aged 11–21 years)

Doherty, Green, and Ensminger (2008)	Chicago, IL, United States	A community sample of 1,242 African American youths followed from first grade to age 42
Skara et al. (2008)	Los Angeles and Ventura, CA, United States	Self-reported data were gathered from 2,064 high school students at pretest and 1-year post-test

Empirical Support

A large body or empirical studies have found that adolescent ADB is likely to lead to later substance use (Table e3.2). Using a longitudinal community sample of twins (at age 11 and age 14), King et al. (2004) found that externalizing behavior measured at age 11 (including aggressive behavior) predicts onset and regular use of cannabis use by age 14.

Goodman (2010) examined the longitudinal associations in both directions between externalizing behavior and cannabis use in adolescence, using a British national cohort (age 11–16 at baseline). It was found that externalizing behavior problems (including aggressive behavior) measured at baseline independently predicted cannabis use 3 years later, with a dose–response relationship. No evidence was found that baseline cannabis use predicted externalizing behavior at follow-up.

Using data from the longitudinal TRAILS study, Griffith-Lendering et al. (2011) found that externalizing behavior at age 11 and 13 predicted cannabis use at 13 and 16, respectively. van den Bree and Pickworth (2005) examined the risk factors of five stages of cannabis involvement, including "initiation of experimental use," "initiation of regular use," "progression to regular use," "failure to discontinue experimental use," and "failure to discontinue regular use" among middle and high school students, as part of the Add Health study. They reported that delinquency was one of the strong predictors of all stages, 1 year later.

Using a sample of adolescents (age 13–18) from Seattle Homeless Adolescent Research Project (SHARP), Paradise and Cauce (2003) found that delinquent behavior is associated with changes in frequency of cannabis use, measured 3 and 6 months later. Using data from Mater Hospital and the University of Queensland Study of Pregnancy, a birth cohort study in Australia, Hayatbakhsh et al. (2009) found that adolescent aggressive behavior/delinquency measured at age 14 were strongly associated with cannabis use and disorder in young adulthood. Using a community sample of African-American youths, Doherty et al. (2008) found that serious adolescent delinquency has at least some causal influence on cannabis use initiation through mid-life (age 42).

Some mixed findings were revealed when separate types of aggression were examined. Using self-reported data gathered from high school students, Skara et al. (2008) found that relational aggression at baseline was a strong predictor for cannabis use 1 year later for females, but not for males. However, physical aggression at baseline does not predict cannabis use, either for males or females.

Cannabis Use Leading to ADB in Middle and High School

Theory

Despite the abundant literature supporting the "self-medication" hypothesis, which posits that adolescent

aggressive behavior leads to cannabis use, some studies have pointed out that cannabis use may influence levels of aggressive behavior. It has been proposed that cannabis use can damage the individual's cognitive capacity to process complex stimuli in conflict and, in turn, decreases the ability to constrain oneself from inappropriate responses, and increase premature responses (Moore & Stuart, 2005).

Importantly, different mechanisms were proposed for regular versus novice users. For regular users, it is possible that cannabis intoxication may trigger maladjusted individuals, with previous aggressive behavior and violence history, to behave violently (Levinthal, 2008). It has also been argued that for those who develop cannabis dependence, cannabis withdrawal and abstinence may also increase anger and irritability (Moore & Stuart, 2005; Ostrowsky, 2011). The link between cannabis use and violent behavior for more novice users can be explained by panic reactions and paranoid feelings, in combination with a sense of losing control, which is more commonly experienced by novice users (Moore & Stuart, 2005).

Above and beyond the above short-term effects of cannabis use applicable to both adolescence and adulthood, another mechanism points to the long-term impact of cannabis use in adolescence. High levels of cannabis use in adolescence may interfere with the development of communication and social skills, and increase deviant peer associations, which may together lead to life-long persistent patterns of antisocial behavior manifesting aggressive behavior and violence.

Lastly, it has also been argued that cannabis use may decrease aggressive and violent behavior through mechanisms consistent with the "self-mediation hypothesis," which posits that individuals with mental health problems may seek to relive their problems through using cannabis. First, as cannabis has both stimulant and sedatory effects, under certain circumstances, users may experience calmness rather than increased energy, which typically does not lead to violent behavior (Pujazon-Zazik & Park, 2009). As a related mechanism, cannabis may also create a positive mood, providing the users with a sense of contentment and humor (Goode, 2008). A third reason explaining why cannabis may decrease violent behavior is that users self-reported to be calmer, more open-minded, and tolerant of others' opinions, over time, as a result of long-time leisure consumption cannabis (Hathaway, 1997; Tart, 1970). Fourth, users typically expect cannabis to relax them, and to give them a sense of pleasure and happiness, which increases the chance of them acting according to this expectation, and avoid the use of violence (Moore & Stuart, 2005).

Empirical Support

Empirical studies yield mixed results (see Table e3.3). Using a school-based sample of adolescents, Temple et al. (2013) found cannabis use in grade 10 predicted perpetration of physical dating violence 1 year later, for both males and females. Analyzing longitudinal data on Mexican and European-American adolescents, Brady et al. (2008) found that adolescents who used cannabis at age 15 were more likely to engage in violence perpetration at age 19.

A body of studies examines the relationship between adolescent cannabis use and dating violence, specifically. It was suggested that the association may differ for males and females. For example, using longitudinal data, Foshee et al. (2010) found that cannabis use predicted the onset of dating violence perpetration among girls, but not among boys. Examining a longitudinal sample of youths between grades 8 and 12, Reyes et al. (2014) also found that the effects of cannabis use on dating violence held only for violence perpetrated by girls, not boys.

There are also some mixed results in the literature. Using longitudinal self-reported survey on high school students, Ellickson and McGuigan (2000) reported that frequency of cannabis use in grade 7 was a significant predictor only for the amount of predatory violence in grade 12, not the likelihood of any predatory violence in grade 12. Using data from the Pittsburgh Youth Study, Wei et al. (2004) found the longitudinal relationship between frequent cannabis use and violence (and vice versa) in adolescence and early adulthood to be spurious, after controlling for common risk factors, such as, race, and hard drug use. They concluded that the observed cannabis–violence relationship is due to selection effects, in that both are influenced by shared risk factors.

Using data from the National Longitudinal Study of Adolescence Health, Melander et al. (2010) reported that cannabis use in adolescence was not related to perpetration of interpartner violence. A similar finding was reported by Marie et al. (2008) using a longitudinal study of a New Zealand birth cohort.

The majority of research that supports the claim that cannabis use is associated with decreases in aggressive and violent behavior have been conducted using adult samples, thus, beyond the scope of this study. We identified two studies using adolescent samples. Kaplan et al. (2001) found that cannabis use in early adolescence is inversely related to violent behavior measured 3 years later. The findings were used to support the theoretical explanation that the use of cannabis can assuage distressful feelings that initiate violence. In a four-wave study, White and Hansell (1998) found that heavy cannabis use in early to mid-adolescence predicted decreases in aggressive behavior in late adolescence and young adulthood.

CONCLUSIONS

This chapter examines the current evidence base supporting the cooccurrence hypothesis, and the two directional hypotheses about the relationship between

TABLE e3.3 Empirical Studies Supporting Cannabis Use Leading to ADB in Middle and High School

Author (year)	Location	Sample
Temple, Shorey, Fite, Stuart, and Le (2013)	Houston, TX, United States	A sample of 1042 9th and 10th grade high schools students were recruited and assessed in the spring of 2010, and 93% of the original sample completed the 1-year follow-up in the spring of 2011
Brady, Tschann, Pasch, Flores, and Ozer (2008)	CA, United States	Longitudinal data on a sample of 302 Mexican and European-American adolescents
Foshee, McNaughton Reyes, and Ennett (2010)	NC, United States	A sample of 1666 students in 8th–10th grade who reported ever dated
Reyes, Luz, Foshee, Bauer, and Ennett (2014)	NC, United States	A sample of 2455 students followed up from 6th grade
Ellickson and McGuigan (2000)	CA and OR, United States	A 5-year follow-up of 4300 high school seniors and dropouts
Wei, Loeber, and Whie (2004)	Pittsburg, PA, United States	A sample of 503 youths from the Pittsburgh Youth Study
Melander, Noel, and Tyler (2010)	United States	A sample of National Longitudinal Study of Adolescence Health
Marie, Fergusson, and Boden (2008)	New Zealand	A longitudinal study of over 1000 New Zealand birth cohort sample
Kaplan, Tolle, and Yoshida (2001)	Houston, TX, United States	Using panel data (N = 2222) from subjects tested during early adolescence and 3 years later
White and Hansell (1998)	Rutgers, NJ, United States	1380 subjects followed up at age 12, 15, and 18 from the Rutgers Health and Human Development Project

aggressive behavior and cannabis use. Any support for these hypotheses has the potential to guide public health-based preventive interventions by focusing on the underlying causes of ADB and cannabis use (ie, cooccurrence hypothesis), or by specifically targeting one of the behaviors to prevent the other one (ie, directional hypothesis). To this end, we inspected both the theories underlying these hypotheses, and the existing empirical literature supporting them.

Clear theoretical and empirical support exists to support the claim that early aggressive behavior (ie, during the elementary school years) is an antecedent not only of later ADB, but also of cannabis use. However, the claim for a causal relationship between ADB and cannabis use remains unsupported. In the case of a clear causal relationship, interventions aiming to reduce early aggressive behavior should lead to reductions in cannabis use. In the absence of a causal relationship, factors more proximal to the onset of cannabis use, such as, peer rejection, deviant peer affiliation, and neighborhood disadvantage may be more suitable intervention targets (Liu et al., 2013). A cascading model of accumulating risk during the major socialization phases may be a more appropriate model for capturing the dynamic relationship between ABD and cannabis use.

Similarly, inconsistent results were found for the interrelationship between the two behaviors during adolescence, and no clear support for the directionality could be found. In fact, there exists both theoretical and empirical evidence (albeit not causal) supporting the claim that ABD leads to cannabis use, or vice versa.

Together with Ostrowsky (2011), we can speculate that several study characteristics are plausible culprits for the inconsistent results. Due to a lack of a comprehensive but integrated substance use prevention theory, little guidance exists for researchers how to design their studies appropriately. Consequently, studies differ significantly with respect to measurement (eg, diagnosis vs self-report; minor aggressive behavior vs violence), developmental periods studied (eg, early adolescence and late adolescence), length of time between waves (eg, long-term and short-term relationship); as well as the selection of the population under study (eg, at-risk samples vs population sample).

These inconsistencies hinder the identification of typical pathways, and how they may differ by gender, race/ethnic groups, as well as in different cultures and locations, guided by different substance use policies. It is our hope that the current chapter can help stimulate better coordination of efforts in assessing the etiology and prevention of ADBs and cannabis, as well as other illicit substances.

DISCLAIMER

This study is not meant to be an exhaustive literature review, but it rather aims to describe the quite complex relationship between cannabis-aggressive behavior, and, by identifying important research gaps, this chapter may inspire future empirical research to respond to such challenges.

MINI-DICTIONARY

Aggressive, disruptive behavior A range of rule-breaking behavior during childhood and adolescence, in home and classroom settings.
Causality The relationship between cause and effect.
Conduct disorder Antisocial behavior displayed in childhood or adolescence.
Delinquency Criminal behavior committed by youth.
Prevention The action of stopping something from happening.

COMT Genotypes, Cannabis Use, and Psychosis: Gene-Environment Interaction Evidence from Human Populations, and Its Methodological Concerns

M. Fatjó-Vilas, C. Prats, L. Fañanás

Faculty of Biology, Anthropology Unit, Department of Animal Biology, University of Barcelona, Biomedicine Institute of the University of Barcelona (IBUB), Barcelona, Spain; CIBER of Mental Health (CIBERSAM), Madrid, Spain

SUMMARY POINTS

- This chapter focuses on reviewing the evidences concerning the putative interaction between the Val188Met polymorphism of the *Catecol-O-methyltransferase* gene (*COMT*) and cannabis use on the development of psychosis.
- The Dunedin Multidisciplinary Health and Development Study reported for the first time that the relationship between adolescent cannabis use and the risk of developing psychotic disorders is modulated by *COMT* Val158Met genotype.
- The following cohort, case-control, and case-based studies have offered contradictory results, and have pointed toward the interest of studying the effect of other genetic and environmental factors operating on specific phenotypic subgroups.
- To date, few neuroimaging studies have been conducted in humans, and these have showed that brain changes associated with cannabis use may be influenced by the *COMT* genotype.
- The divergence across *COMT* and cannabis interaction studies has raised several aspects to be considered in the interpretation of these results: the pleiotropic biological and behavioral effects of *COMT* gene, the gene-gene interactions and other gene expression mechanisms, the role of other environmental factors, among others.

KEY FACTS

- Systematic reviews of prospective studies have consistently evidenced the role of cannabis use as a risk factor for the emergence of psychosis.
- Sensitivity to cannabis effects is proposed to be mediated by the genetic variability observed in human populations.
- *COMT* is one of several enzymes that degrade catecholamines such as dopamine, which is central to one of the major neurochemical theories of psychotic disorders.
- *COMT* gene contains a functional single nucleotide polymorphism (Val158Met) which is associated with

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00031-4

changes in enzyme activity in brain (Val allele higher activity than Met allele).
- Diverse strategies and results have led to the conclusion that psychosis liability by itself may explain part of the association between cannabis and psychosis mediated by *COMT*, suggesting that there probably exists a bidirectional relationship between the risk factor and the disorder.

LIST OF ABBREVIATIONS

CB Cannabinoid
CB1 Cannabinoid receptor type 1
COMT Catecol-O-methyltransferase
DA Dopamine
DAT Presynaptic dopamine transporter
GxE Gene–environment interaction
Met Methionine
PFC Prefrontal cortex
SNP Single nucleotide polymorphism
THC Tetrahydrocannabinol
Val Valine

THE ROLE OF CANNABIS USE AS A RISK FACTOR FOR PSYCHOSIS

The endocannabinoid system plays a modulatory role on reward dopamine (DA) neurons, and this is substantiated by the expression of type 1 cannabinoid (CB1) receptors, and the abundance of their endogenous ligands, or endocannabinoids. From a general point of view, endocannabinoids are released on demand by the postsynaptic neurons, and travel retrogradely across the synapse to bind to and activate CB1 receptors located on the presynaptic terminals (Fig. e4.1). The result of such activation is a decreased neurotransmitter release in a short- or long-term manner (Melis, Muntoni, & Pistis, 2012). In this regard, endocannabinoids serve as retrograde signaling molecules at many synapses within the central nervous system. Synapses on midbrain DA neurons (in the ventral tegmental area—VTA) make no exception to this rule. In fact, the effects of cannabinoids on DA transmission, as well as DA-related behaviors, are generally exerted through the modulation of inhibitory and excitatory afferents impinging onto DA neurons (Melis et al., 2012).

Systematic reviews have consistently evidenced the role of cannabis use as a risk factor for the emergence of psychosis, ranging from psychotic symptoms, such hallucinations and delusions, to clinically significant disorders, such as, schizophrenia (2–4). The effects of cannabinoids on increasing DA, reducing GABA, and reducing glutamatergic neurotransmission may contribute to their capacity to induce transient positive, negative, and cognitive symptoms, but the precise mechanism remains unclear (D'Souza, Sewell, & Ranganathan, 2009). However, as expected in multifactorial complex diseases, cannabis use is not sufficient or necessary to cause schizophrenia or related disorders—meaning that only a small proportion of cannabis users develop psychosis, or that not all persons with a psychotic disorder have been exposed to cannabis. Accordingly, the genetic variability observed in human populations is proposed to be the most important factor mediating the sensitivity to cannabis effects on increased risk for mental disorders. In this sense, genetically sensitive studies indicate that the risk of suffering from cannabis-related psychotic experiences is much higher in individuals with evidence of psychosis liability (measured psychometrically, or defined as having an affected first degree relative). These results have led to the view that the differential effect of cannabis may be related to individual predisposition to psychosis, which is strongly accepted to be influenced by genetic factors.

THE *COMT* GENE MOLECULAR VARIABILITY AND THE RISK FOR PSYCHOSIS

Since dopamine is hypothesized to represent a crucial common final pathway between brain biology and experiences of psychosis, the enzyme COMT has been a great focus of attention. COMT is one of several enzymes that degrade catecolamines, such as, dopamine, epinephrine, and norepinephrine. In the brain, COMT-dependent dopamine degradation is of particular importance in brain regions with low expression of the presynaptic dopamine transporter (DAT), such as, the prefrontal cortex (Matsumoto et al., 2003).

In humans, catechol-O-methyltransferase protein is encoded by the *COMT* gene, placed at 22q11.21-q11.23 chromosomal region (Fig. e4.2). The gene has several allelic variants, and the most relevant is the single nucleotide polymorphism (SNP) Val158Met (rs4680) that results in a Valine to Methionine change at protein position 158 (Lotta et al., 1995). The Val variant catabolizes dopamine at up to 4 times the rate of its Met counterpart. The lower activity associated with Met allele results in higher synaptic dopamine levels, following neurotransmitter release, ultimately increasing dopaminergic stimulation of the postsynaptic neuron. Postmortem studies (Akil et al., 2003) have also shown that the number of Val-encoding alleles predicted increased dopamine synthesis in the midbrain, and suggested that this functional polymorphism can modulate prefrontal-midbrain

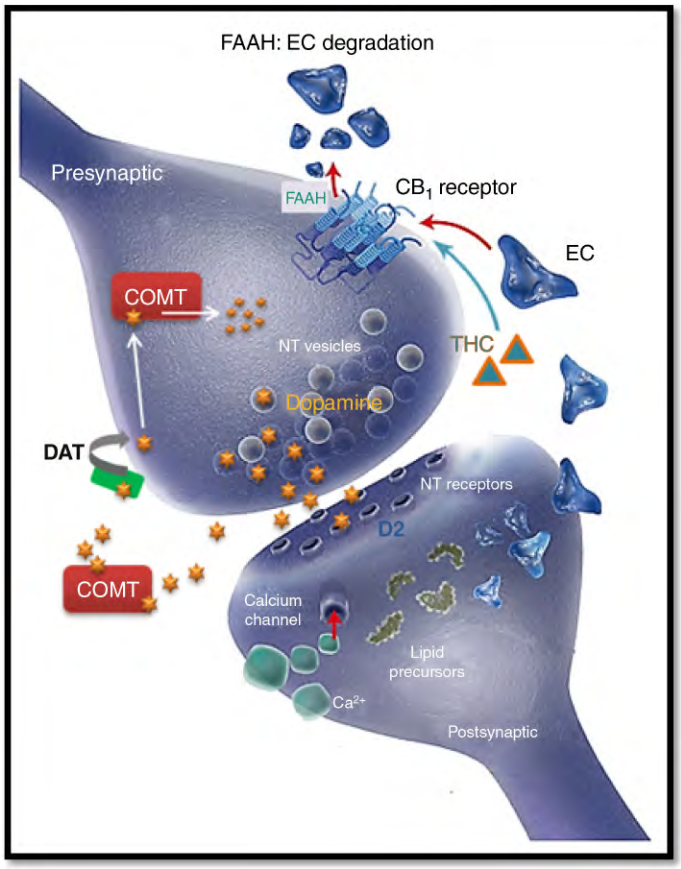

FIGURE e4.1 Schematic representation of the endocannabinoid system in pre- and postsynaptic neurons. The endocannabinoid signaling system (eCBS) is composed of cannabinoid (CB) receptors, their endogenous ligands (the endocannabinoids, EC) and the enzymes that produce and inactivate these ligands. Endogenous cannabinoids and the Δ^9-*tetrahydrocannabinol* (THC) produce effects by binding to and activating the cannabinoid receptor (CB1), the major cannabinoid receptor in the brain. Then, both components compete for access to the CB1 receptor classified as a 1-G-protein, coupled receptors that activate $G_{i/o}$-type G-proteins. The activation of these G-protein subtypes normally produces inhibition of adenylyl cyclase, inhibition of voltage-gated calcium channels, and activation of certain potassium channels. Note that the fatty acid amide hydrolase (FAAH) is distributed in the central nervous system, and degrades fatty acid amide signaling molecules, such as, endocannabinoids. In general, CBs act as a "dimmer switch" for presynaptic neurons, limiting the amount of neurotransmitter (eg, dopamine) that gets released. The *dopamine transporter* (DAT) plays a critical role in terminating the action of *dopamine* by rapid *reuptake* into the presynaptic neuron. Catecol-O-methyltransferase (COMT) is an important degradation enzyme of monoamines, and participates in both the extracellular and intracellular metabolism of dopamine. *Source: Adapted from: http://www.treccani.it/enciclopedia/endocannabinoidi_(Dizionario-di-Medicina)*

interaction. To this respect, using multimodal neuroimaging in healthy subjects, it has been shown that the interaction between prefrontal activity and midbrain dopaminergic synthesis is modulated by *COMT* Val158Met polymorphism (Meyer-Lindenberg et al., 2005).

Although different metaanalyses have not found a clear association between the Val158Met *COMT* polymorphism and vulnerability for schizophrenia (eg, Fan et al., 2005; Munafo, Bowes, Clark, & Flint, 2005), it has been suggested that it might be related to schizophrenia via its effect on cognitive function. In this regard, the study of Egan et al. (2001) reported that *COMT* genotype was associated with variations in executive cognition and with PFC physiological activity during working memory, functions for which DA levels in the PFC are known to be important.

Clinical and epidemiological studies have been interested in understanding the role that *COMT* gene could exert on the differential risk to develop psychoses, between cannabis users and nonusers (Di Forti et al., 2014). Considering that the blockage of CB1 by the THC component of the cannabis can impair dopamine release (Fig. e4.1), weak or subtle changes in COMT activity may contribute to explain individual risk differences in the development of dopaminergic related psychotic symptoms in cannabis consumers. This phenomenon is also called gene–environment interaction (GxE) and represents the genetic control of the sensitivity to the environment. In this scenario (Fig. e4.3), subjects exposed to similar environmental risk factors (eg, cannabis use at the same period of brain development, such as, age), will be at a substantial different risk to develop a particular

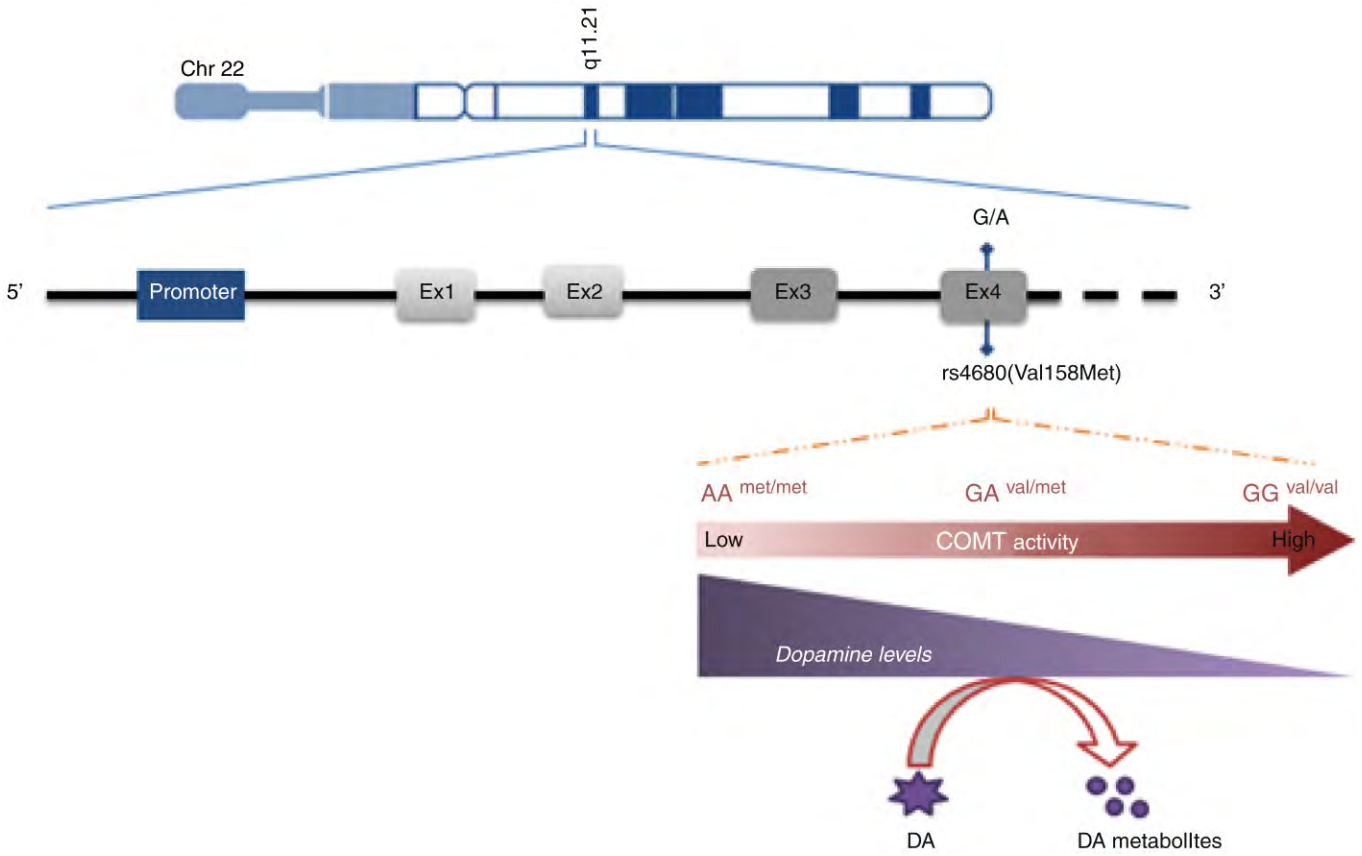

FIGURE e4.2 Diagram showing *COMT* gene and the effect of Val158Met polymorphism on COMT activity. *COMT* gene is located on chromosome 22q11.21, and it contains a functional single nucleotide polymorphism (SNP: Val158Met or rs4680) which entails a nucleotide change from Guanine (G) to Adenine (A) in the sequence of the gene. This polymorphism produces an amino acid change from Valine (Val) to Methionine (Met), at codon 158 of the membrane-bound protein form. The Val allele is associated with higher enzyme activity in the brain than the Met allele (Chen et al., 2004) and, consequently, it is presumed to result in reduced dopamine availability. Coding exons of *COMT* gene are represented in dark gray (wide bars), while noncoding exons are in light gray.

brain dysfunction (eg, psychotic symptoms), depending on their genetic background.

Taking into account evidences from different study designs based on Caucasian subjects (Table e4.1), in the following section we will review the evidences concerning the putative interaction between the Val188Met polymorphism of the *COMT* gene and cannabis use on the development of psychosis and, eventually, cognitive associated conditions.

EVIDENCES OF COMT GENE AND CANNABIS USE INTERACTIONS, AND THE EFFECT ON THE RISK FOR PSYCHOSIS

Evidences From Longitudinal Studies

The first study that provided evidence of interaction between cannabis and the Val158Met polymorphism was conducted by Caspi et al. (2005), using a longitudinal prospective design involving 803 individuals. This showed that adolescent cannabis use, but not adult-onset use, was associated with a 10-fold increase in the risk of developing schizophreniform disorder at the age of 26, among individuals homozygous for the Val allele, whereas cannabis use had no such adverse influence on individuals with two copies of the Met allele. These results, together with studies that have described cannabis effects on the brain, limited to adolescence both in human research and in experimental animal models (Bossong & Niesink, 2010; Schneider & Koch, 2003), have shed light on the relationship between cannabis use, "neurodevelopmental processes", and the emergence of psychiatric disorders, and also on the fact that sensitivity to cannabis effects may depend on the state of brain development and maturity.

Not surprisingly, these results triggered several other studies with diverse designs aiming to replicate and to further understand the interaction between cannabis and *COMT* gene, in relation to the risk for psychosis.

In this respect, another cohort study, based on 2630 individuals aged 16, detected that cumulative use of

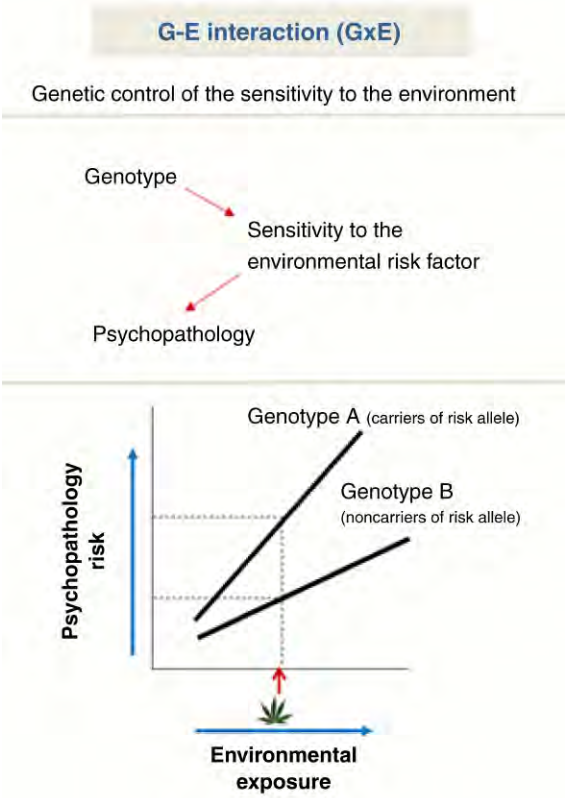

FIGURE e4.3 Example of Gene–environment interaction (GxE) on a hypothetical exposure to cannabis, in a population sample with carriers and noncarriers of a hypothetical risk allele. This theoretical model example assumes similar cannabis quality and age at onset for all the individuals. *Source: Adapted from van Os & Marcelis (1998); van Os et al. (2008).*

cannabis at age 14 increased the risk for self-reported psychotic experiences, irrespective of the underlying *COMT* Val158Met genotype or haplotypes (Zammit, Owen, Evans, Heron, & Lewis, 2011). However, when several sensitivity analyses were conducted, some contradictory interaction effects emerged: the risk for hallucinations after cannabis use was greater in Val allele homozygotes, compared with Met ones; or the risk for psychotic experiences was greater in Met allele homozygotes, but only in subjects that never had definite experiences before the age of 14. Although these findings do not support that the risk for developing psychosis following use of cannabis is dependent upon variation within *COMT*, the observed variation in the interaction in sample subgroups pointed toward the interest of studying the effect of other genetic and environmental factors operating in these specific groups that could account for these variations.

Evidences From Case-Only and Case-Control Studies

Unlike longitudinal data collection, case-only design relies on people recalling the age at first use of cannabis, and relating this in time to the date of the emergence of the first psychotic symptoms. This kind of studies can result in some recall or time sequence bias, but allow having larger genotype and cannabis use sample subgroups, fact that increases the power to detect interaction effects. Despite this, some of these studies have replicated the interaction, while others have failed or have offered controversial results. Firstly, in a sample of 493 patients with schizophrenia, no association was found between three SNPs at *COMT* and cannabis use (Zammit et al., 2007). Secondly, a study based on 169 patients with a first episode of psychosis showed a significant effect of the interaction between Val158Met genotype and cannabis use, on both age of onset and duration of untreated illness (Pelayo-Teran et al., 2010). Due to the fact that this effect was observed only in the group of cannabis nonusers, the authors propose that the use of cannabis modulated the genotype effect by suppressing the delay in the onset of the symptoms, in patients carrying the Met allele. Thirdly, a marginal interaction between Val158Met genotype and lifetime cannabis use on age at emergence of psychotic disorders was reported in a sample of 157 adolescent psychiatric patients, with Val/Val subjects presenting an earlier onset than Met carriers (Estrada et al., 2011). Fourthly, the analysis of five SNPs in *COMT* in two samples of Spanish patients with schizophrenia (n = 383 and n = 365) allowed the definition of three common haplotypes described to have different enzymatic activity (Costas et al., 2011). Association was detected between cannabis use and low activity variants; however, when considering only the Val158Met polymorphism, patients homozygous for the Met allele were observed to double the probability of lifetime prevalence of cannabis use, in comparison to Val homozygotes. Although these data are in contrast with previous studies that identified the Val allele as the one presenting the risk, they add evidence to the cannabis and *COMT* interaction effect on the risk for schizophrenia and, moreover, suggest the interest of studying the haplotype molecular variability over single-nucleotide polymorphisms in order to characterize better the enzymatic activity of each individual. In this respect, a study based on 403 patients with schizophrenia or schizoaffective diagnoses that also analyzed several SNPs in *COMT* reported a sex-specific interaction between cannabis use and age at onset of schizophrenia, but did not detect an interaction between cannabis and *COMT* genotypes (De Sousa et al., 2013).

Finally, few studies have explored the interplay between *COMT* gene and cannabis use on cognitive performance. For example, a study that analyzed the effect of cannabis use on executive functions, by comparing 86 cannabis users with 58 nondrug users controls, described that cannabis users carrying the Val allele exhibited lower performance in attention and monitoring/shifting

TABLE e4.1 Summary of Studies Examining the Effect of the Interaction Between Cannabis Use and *COMT* Gene Val158Met Polymorphism (rs4680) on the Risk for Psychosis in Caucasian Subjects

Study	Study design	Sample size and characteristics	Cannabis use measure	Val158Met *COMT* genotype	Outcome measure	Main results
Longitudinal studies						
Caspi et al. (2005)	General population *(Dunedin Multidisciplinary Health and Development Study)*	*n* = 803 Follow-up from 3 to 26 years 26% classified as adolescent-onset cannabis users	Assessed at ages 13, 15, and 18	Val/Val (25%) Val/Met (50%) Met/Met (25%)	Psychosis outcomes assessed at age 26 (Diagnostic Interview Schedule): • 3.6% met DSM-IV diagnosis criteria for schizophreniform disorder • 13% reported at least one hallucinatory experience • 21% reported at least one delusional belief	Adolescent cannabis use was associated with increased risk of: • schizophreniform disorder in adulthood among Val/Val individuals [OR (95% CI) = 10.9 (2.2–54.1)] • hallucinatory experiences in adulthood among Val/Val individuals [OR (95% CI) = 5.3 (2.2–12.37)] • delusional beliefs in adulthood among Val/Val individuals [OR (95% CI) = 3.5 (1.7–7.0)]
Zammit et al. (2011)	General population *(Avon Longitudinal Study of Parents and Children, ALSPAC)*	*n* = 2630 Annual assessments from 7.5 to 16 years	Assessed at age 14 Cumulative cannabis use: none, <5 times, 5–20, 21–60, >60. 6.5% of individuals ever used cannabis at age 14	Subjects with psychotic symptoms: Val/Val (20.9%) Val/Met (53.1%) Met/Met (26%) Subjects without psychotic symptoms: Val/Val (23%) Val/Met (49%) Met/Met (28%)	Psychosis-like symptoms assessed at age 16 (PLIKS-Q): • 8.6% responded yes to any of the 11 questions	Cannabis use by age 14 increased the risk to present psychotic experiences at age 16: OR (95% CI) = 2.5 (1.62–3.77) No evidence of statistical interaction under a multiplicative model between cannabis use and *COMT* Val15rs4680, or between cannabis use and the other *COMT* SNPs
Cross-sectional studies with retrospective evaluation of cannabis use						
Zammit et al. (2007)	Case-only study: schizophrenia patients	*n* = 493	Binary measure: users/nonusers Age at onset of cannabis use	—	DSM-IV schizophrenia diagnosis assessed with semistructured interview (SCAN)	No evidence of association between *COMT* and cannabis use Results were identical when restricting the analysis to participants who first used cannabis before age 18 and at least 1 year before prior to the illness onset
Pelayo-Teran et al. (2010)	Case-only study: first-episode psychotic patients *(Longitudinal intervention programe of first episode psychosis, PAFIP)*	*n* = 169	Binary measure: users/nonusers 46.15% of cannabis users	Val/Val = 25.4%, Val/Met = 60.4%, Met/Met = 14.2%	DSM-IV psychotic disorders diagnoses assessed with structured interview (SCID-I): • 61.54% schizophrenia Age of onset of psychosis Duration of untreated psychosis (DUP)	Cannabis use had a significant effect on earlier age of onset ($F = 16.89$, $p < 0.001$) but not on DU *COMT* by cannabis use interaction significant effect on both age of onset ($F = 3.82$, $p = 0.024$) and DUP ($F = 3.29$, $p = 0.039$) Age of onset/DUP significantly later/longer in Met homozygote group than in the Val homozygote group ($F = 2.18$, $p = 0.009$), only in cannabis nonusers group

Estrada et al. (2011)	Case-only study: psychiatric patients	n = 157	Binary measure: users/nonusers 45.5% of cannabis users	Schizophrenia-spectrum disorders: Val/Val = 23.75% Val/Met = 52.05% Met/Met = 23.75% Nonpsychotic disorders: Val/Val = 36.30% Val/Met = 45.50% Met/Met = 18.20%	DSM-IV diagnoses : 51% schizophrenia-spectrum disorders 49% nonpsychotic disorders (conduct and affective disorders) Age at disorder onset	Age at first cannabis use correlated with age at onset in both psychotic (β = 1.59, $p < 0.001$) and nonpsychotic disorders (β = 0.4, p = 0.006). *COMT* genotype was associated with age at onset of psychotic disorders only within cannabis users group (β = 01.66, p = 0.04) *COMT* by cannabis use interaction effect on age at onset within schizophrenia-spectrum disorders (β = 2.72, p = 0.04). Val/Val carriers showed an earlier age at onset than Met carriers.
Costas et al. (2011)	Case-only study: schizophrenia patients	Two samples: (1) n = 383 (2) n = 365	Binary measure: users/nonusers 16.9 and 24.6% of cannabis users	(1) Val/Val = 38.7% Val/Met = 42.5% Met/Met = 18.8% (2) Val/Val = 32.9% Val/Met = 46.6% Met/Met = 20.5% Also genotyped four other SNPs (rs4633, rs4818, rs6269, and rs737865) and conducted haplotype analyses	DSM-IV schizophrenia diagnosis	Met/Met subjects doubled the probability of lifetime prevalence of cannabis use, compared to Val homozygous [OR (95% CI) = 2.07 (1.27–3.26), in the combined sample (a + b)]. Association between cannabis use and low activity *COMT* haplotypic variants in patients with schizophrenia [OR (95% CI) = 0.56 (0.38–0.84)]
De Sousa et al. (2013)	Case-only study: schizophrenia or schizoaffective patients	n = 403	Binary measure: low users/high users 60.1% of cannabis high users	Also genotyped 3 other SNPs: rs4633, rs4818, rs6269	Age at onset of schizophrenia	High users of cannabis had an earlier onset relative to low users (p = 0.003) and high cannabis use was more prevalent in males than females [OR (95% CI) = 3.47 (2.0–-6.0)] No interaction between *COMT* genotypes and cannabis use was found

(*Continued*)

TABLE e4.1 Summary of Studies Examining the Effect of the Interaction Between Cannabis Use and *COMT* Gene Val158Met Polymorphism (rs4680) on the Risk for Psychosis in Caucasian Subjects (*cont.*)

Study	Study design	Sample size and characteristics	Cannabis use measure	Val158Met *COMT* genotype	Outcome measure	Main results
Experimental and experience sampling method based studies (ESM)						
Henquet et al. (2006)	Double-blind, placebo-controlled cross-over design Evaluation of psychotic experiences and cognitive performance after exposure to THC/placebo	30 patients 12 relatives 32 healthy subjects	Two test sessions, blinded subjects received in randomized order either 300 µg THC/kg, or 0 µg THC/kg (placebo) in tobacco cigarettes	Total sample Val/Val = 27% Val/Met = 47% Met/Met = 26%	Diagnosis made according to Research Diagnostic Criteria using OPCRIT. PANSS used to measure psychotic symptoms during the previous 2 weeks: patients: 36.7% schizophrenia, 36.7% schizoaffective, 26.6% psychosis not otherwise specified Psychometric psychosis liability determined by using CAPE Cognitive measures: different tasks on verbal and visual memory, attention	A significant three-way condition x genotype x Cape-trait interaction was observed ($X^2 = 9.00$, $df = 1$; $p = 0.003$): carriers of the Val allele were more sensitive to THC induced psychotic experiences, but this was conditional on prior evidence of psychometric psychotic liability Carriers of the Val allele were also more sensitive to THC-induced memory and attention impairments, compared to carriers of the Met allele
van Winkel et al. (2008)	Case-control: psychotic patients with comorbid cannabis misuse and healthy cannabis users	31 cases 25 controls	Dichotomic: users/nonusers	Total sample: Val/Val = 30.4% Val/Met = 55.4% Met/Met = 14.3%	Emotional and psychotic symptoms (ESM)	Significant interaction between *COMT* Val158Met genotype and ESM stress on negative affect in patients ($X^2 = 7.4$, $p = 0.02$), but not in controls ($X^2 = 3.8$, $p = 0.15$) Met/Met patients showed the largest increase in psychotic experiences, in reaction to ESM stress ($X^2 = 10.5$, $p = 0.06$).
Henquet et al. (2009)	Case-control: psychotic patients and controls Case-control: psychotic patients and controls	32 patients 29 controls	Dichotomic: users/nonusers	Total sample: Val/Val = 30% Val/Met = 55% Met/Met = 14%	Psychotic symptoms (ESM) Psychometric psychosis liability determined by using CAPE	Carriers of the Val allele showed an increase in hallucinations after cannabis exposure conditional on prior evidence of psychometric psychosis liability [$\beta = 078$ (95% CI: 0.36−1.19, $p < 0.01$]

tasks than Val carriers who were nonusers (Verdejo-Garcia et al., 2013). From a different approach, these results add to those from an experimental study in which it is described that Val allele carriers are more sensitive to THC-induced memory and attention impairments than Met allele carriers (Henquet et al., 2006). Nonetheless, it must also be taken into account that cognitive performance has also been shown to be modulated by the interaction of Val158Met polymorphisms with other illegal psychostimulants, such as, ecstasy (Cuyas et al., 2011).

Evidences From Experimental and Experience Sampling Method Based Studies

A double-blind placebo-controlled study of THC exposure in 30 patients with psychotic illness and 32 healthy controls (Henquet et al., 2006) was the first to provide understanding of the importance of the role of the genetic vulnerability background in modulation of the *COMT* and cannabis interaction. The authors observed that carriers of the Val allele were most sensitive to THC-induced psychotic experiences, but this was conditional on prior evidence of increased psychosis proneness, as measured by psychometric tests. More recently, the experience sampling method, a structured diary technique assessing current context and emotional and psychotic experiences in daily life (Myin-Germeys, van Os, Schwartz, Stone, & Delespaul, 2001), was used to show that among Val allele carriers the psychometric psychosis liability also mediates the link between cannabis exposure and the hallucinatory phenomena in the flow of daily life (Henquet et al., 2009). This sampling method has also been used to explore the effect of stress on psychotic experiences in 31 patients with a psychotic disorder and comorbid cannabis misuse and 25 healthy cannabis users (van Winkel et al., 2008). In contrast with other studies, Met/Met cannabis users patients showed the largest increase in psychotic experiences in reaction to experience sampling method stress, extending the evidence of the complex mechanisms that underlie gene–environment interactions related to the development of psychotic symptoms by identifying the importance of the daily life stress as another mediating factor of the relationship between cannabis and psychosis proneness.

Evidences From Neuroimaging Studies

Neuroimaging techniques, including functional neuroimaging, provide a powerful means of investigating the central actions of cannabis in human. On the one hand, THC administration has been associated with changes in brain structure and function (Bossong, Jansma, Bhattacharyya, & Ramsey, 2014). On the other hand, stronger evidence for a role of the Val158Met polymorphism in schizophrenia and cognition comes from functional imaging studies (eg, Egan et al., 2001; Pomarol-Clotet et al., 2010). However, to date, few neuroimaging studies have been carried out to measure the combined effects of cannabis, *COMT* genotype, and psychosis in humans. Preliminary data of several genes modulating the adverse effects of cannabis on the brain, including *COMT* polymorphism, were reported in long-term cannabis users (Solowij, Fernandez, Murray, & Yücel, 2012). *COMT* polymorphism has also been described to influence the volume of the bilateral ventral caudate nucleus in both chronic cannabis users and healthy subjects, but in an opposite direction: more copies of Val allele led to lesser volume in chronic cannabis users, and more volume in controls (Batalla et al., 2014). These findings support for the first time that brain changes associated with cannabis use may be influenced by the *COMT* genotype.

CONSIDERATIONS FOR THE INTERPRETATION OF THE STUDIES ON *COMT* AND CANNABIS USE INTERACTION

The divergence across *COMT* and cannabis interaction studies has raised several aspects that need to be considered in the interpretation of these results and in order to design future studies.

The Pleiotropic Biological and Behavioral Effects of *COMT* Gene

The association of the Val allele with diminished executive cognitive functions has been described to be associated with lower incidence of anxiety-related traits, in subjects carrying this allele, while the improved cognitive performance found for Met carriers goes along with impaired emotional processing, such as, increased sensitivity to psychosocial stress (Smolka et al., 2005). It has been proposed that this reciprocal effect on emotion and cognition represents a tradeoff between the cognitive efficiency and emotional resiliency that maintains each allele in the population because each confers an environment-specific selective advantage (Goldman, Oroszi, & Ducci, 2005). Such balance between genotypic variants and mechanisms of cognition and emotion processing may be, therefore, implicated in the gene–environment interaction variability and may be underlying the *COMT* gene and cannabis differential interaction, conditional on other genetic and environmental factors. Accordingly, it is proposed that, by influencing the phenotypic response to environmental exposures, *COMT* gene may thus operate as a plasticity gene, where a genotype can have either a protective or a susceptibility

role, depending on specific genetic background and environmental conditions (Belsky & Pluess, 2009). It is noteworthy that certain periods of brain development are specific vulnerability windows because of both the gene expression patterns associated to brain maturation, but also the sensitivity of the ongoing developmental processes to environmental factors (Sundram, 2006).

Genetic Interactions and Other Biological Mechanisms

Far from being independent units, genes usually interact in complex networks whose expression is tightly regulated and coordinated. Indeed, genetic interactions underlying human complex traits and disease are considered as one possible explanation for their persistence within populations. Then, as already suggested by the description of the interaction of *COMT* Val158Met genotype and psychometric psychosis liability to moderate cannabis effects on psychotic symptoms (Henquet et al., 2009; Henquet et al., 2006), the identification of gene–gene interactions may probably better account for the differential sensitivity to cannabis than a single gene. In this regard, interactions between genes have been described in schizophrenia research before, and genetic and statistical analyses advances are facilitating this approach. For example, consistent with the biological processes related to schizophrenia, a three-way interaction on schizophrenia risk was reported between three functional polymorphisms in *COMT*, brain-derived neurotrophic factor (*BDNF*), and v-akt murine thymoma viral oncogene homolog 1 (*AKT1*) genes (Tan et al., 2012). Interestingly, *AKT1* gene has also been described to interact with cannabis use, with CC homozygous subjects for the rs29494732 SNP having approximately two fold odds of being diagnosed with a psychotic disorder when having used cannabis (van Winkel, 2011). More recently, another study has reported an odds ratio greater than 7 for developing a psychotic disorder for daily cannabis users who are homozygous for the risk allele (CC) of the same polymorphism (Di Forti et al., 2012). In addition, this interaction has also been suggested to mediate long-term changes in cognition measures, such as, sustained attention (van Winkel, van Beveren, & Simons, 2011).

Moreover, biological mechanisms that regulate gene expression and, thus, could indirectly regulate COMT activity, should also be taken into account. As mentioned, only few studies have included not only the Val158Met genotype, but also other polymorphisms along the gene (Costas et al., 2011; De Sousa et al., 2013; Zammit et al., 2007). On the other hand, *COMT* gene promoter differences methylation density has been associated with gene expression levels, and *COMT* gene promoter methylation differences have been reported between schizophrenia patients and healthy subjects (Abdolmaleky et al., 2006). More recently, it has been described that the interaction between *COMT* genotype and *COMT* promoter methylation is associated with cannabis use (van der Knaap et al., 2014), suggesting that combining genetic and epigenetic variation may be helpful in elucidating the gene–environment mechanisms involved in psychosis proneness.

Other Environmental Factors Interaction

In addition to genetic interaction, environmental factors may also interact with each other, as well as on psychosis risk. Some evidence comes from the study of the interaction between cannabis use and childhood trauma. For example, sexual trauma has been associated to an increase of the risk to develop psychosis, but only in those individuals with an early use of cannabis (Houston, Murphy, Adamson, Stringer, & Shevlin, 2008). These results have been extended by three-way interaction studies that have shown, in general population-based samples, that *COMT* genotype may act as a modulator of the interaction between cannabis use and childhood maltreatment on the risk for developing psychotic symptoms (Alemany et al., 2014; Vinkers et al., 2013). Overall, these results suggest that *COMT* gene variability may be involved in the sensitization to several environmental factors.

Methodological Concerns and Challenges

After a decade of gene–environment research on candidate genes in psychiatry, increasing concerns about this kind of approach have appeared, mainly addressing the problem of spurious findings as a result of multiple testing problems, and the large sample sizes required to reliably detect the proposed effects (Duncan & Keller, 2011). However, other authors have indicated that, in the detection of gene–environment interactions, the most appropriate strategy is to weigh the tradeoff between sample size and measurement precision (Wong, Day, Luan, Chan, & Wareham, 2003). Then, while debate is currently open, there is agreement about the need for further well-powered GxE studies based on accurate variables to explain between-subject differences in the risk to develop psychosis, following exposure to cannabis.

Regarding the reliability of cannabis measures, retrospective evaluation can be limited by recall bias and length of time between cannabis use and the assessment of the participant. However, in contrast to other environmental exposures, cannabis use measure is considered to have a fair level of confidence. On the other hand, based on studies that relate intensity/duration of cannabis use, and the cannabis variety used (due to the differences in THC content) (Di Forti et al., 2014), a more detailed

characterization of cannabis use should be considered in future studies.

Moreover, whether the association of cannabis and *COMT* gene with psychosis could be confounded has been a largely discussed issue (Henquet, Murray, Linszen, & van Os, 2005). Studies have included several confounders (such as, age, sex, social class, ethnic group, urbanicity, use of other drugs) in order to ascertain that the cannabis and psychosis association persisted after adjustment for these factors. In parallel, as those on a psychotic spectrum are more likely to experiment with cannabis, studies have also dealt in different ways with reverse causality (or the fact that cannabis use could be a consequence of the individuals' psychosis vulnerability expression). In this respect, a recent GWAS-based study has tested whether the cumulative burden of schizophrenia risk alleles carried by an individual predict cannabis use (Power et al., 2014). Although directly predicting only a small amount of the variance, results from this study have led to the conclusion that psychosis liability by itself may explain part of the association between cannabis and psychosis, suggesting that there probably exists a bidirectional relationship between the risk factor and the disorder. Similarly, studies facing the gene–environment correlation phenomena (the genotype influence on an individual's exposure to cannabis) have shown that the liability to use cannabis is influenced by genetic factors (Kendler, Schmitt, Aggen, & Prescott, 2008). Then, evidence seems to indicate that cannabis use and psychosis share at least part of their genetic roots, and that both GxE and correlation mechanisms should be better explored.

Finally, due to the polygenic architecture of psychotic disorders, it is unlikely that few genes account for cannabis sensitivity. Thus, certainly one of the challenges of genetic epidemiology in the coming years will be the integration of genome-wide association studies (GWAS) and environmental factors. Therefore, the development of gene-environment-wide interaction studies (GEWIS) represents a conceptual and methodological challenge of much interest for their potential and possible applications.

MINI-DICTIONARY

Allele One of two or more alternative forms of a gene or DNA sequence at a specific chromosomal location. In the case of the Val158Met polymorphism at *COMT* gene, there are two possible alleles: the allele G (corresponding to the presence of a Guanine nucleotide), or the allele A (corresponding to the presence of an Adenine nucleotide).

Amino acids Organic compounds containing an amino group (NH_2), a carboxylic acid group (COOH), that combines to form proteins. There are 20 different amino in proteins. The name of the Val158Met polymorphism comes from a single nucleotide substitution that results in an amino acid change from Valine (Val) to Methionine (Met), at codon 158.

Cross-sectional study An observational study that compares different population groups at a single point in time.

Experimental study A type of evaluation in which the participants undergo some kind of intervention (eg, new drug) in order to evaluate its impact. The experimental researcher has control over the intervention, its timing, and dose or intensity.

Genotype Refers to the specific allelic combination for a given locus. In the case of the Val158Met polymorphism at *COMT* gene, the alleles G and A are combined in the following genotypes: homozygote GG, heterozygote GA, or homozygote AA.

Longitudinal study An observational research method in which data is gathered for the same subjects repeatedly, over a period of time. These studies allow researchers to study changes over time, and can be extended over years, or even decades.

Pleiotropic effects Producing or having multiple effects from a single gene. Genes that affect multiple, apparently unrelated, phenotypes are thus called pleiotropic genes.

Polymorphism A DNA sequence variation that is common in the population. To be classed as a polymorphism, the least common allele must have a frequency of 1% or more in the population. The less frequent allele (A) of the Val158Met polymorphism has a frequency of 39% in Caucasian populations.

Single nucleotide polymorphism (SNP) The most common type of polymorphism in the human genome, where a single base (or nucleotide) differs between individuals. The Val158Met polymorphism at *COMT* gene is a single nucleotide substitution of the allele G for the allele, A at the exon 3 of the gene.

SUMMARY POINTS

- This chapter gives an overview of neuroimaging studies of the acute and chronic effects of cannabis on the brain, and also preliminary evidence of the genetic modulation of these effects.
- Cannabinoids showed an acute increase in resting state brain activity in areas rich in CB1R, and altered neural activity during the performance of several cognitive tasks.
- Pharmacological challenge studies involving acute administration of delta-9-THC and CBD showed opposite patterns of brain activation during several cognitive tasks (response inhibition, emotional processing, sensory and salience processing) consistent with their opposite symptomatic effects.
- Chronic cannabinoid use has been associated with gray matter volume reduction in the hippocampus, amygdala, prefrontal and cerebellum, and with the amount of cannabinoid exposure; adolescents showed similar alterations to adults, with preliminary evidence indicating gender differences in sensitivity to these effects.
- Chronic cannabis use has been associated with reduced resting state activation, both globally and in areas rich in CB1R, and altered neural activity during several cognitive tasks, even in the absence of unaltered performance. However, the studies reviewed reveal a great degree of heterogeneity.
- Preliminary data suggest that both the acute and chronic effects of cannabinoids on the brain may be genetically modulated. This may be more important during the neurodevelopment period, and may explain interindividual differences in the effects of cannabis.
- Limitations of current neuroimaging research include the high heterogeneity of studies published, methodological aspects, and the small number of longitudinal studies.

KEY FACTS FOR NEUROIMAGING STUDIES OF ACUTE AND CHRONIC CANNABIS EFFECTS

- Cannabis is the world's most commonly used illicit drug, mainly in young adulthood.
- There is a growing interest in its relationship with mental health.
- Neuroimaging tools offer an opportunity to study in vivo the acute effects of two main compounds of cannabis, delta-9-tetrahydrocannabinol (delta-9-THC) and cannabidiol (CBD), in both healthy volunteers and occasional cannabis users.
- Imaging research into the chronic effects of cannabis show both structural and functional brain impairment.

rCBF	Regional cerebral blood flow
ROI	Region of interest
SNP	Single nucleotide polymorphism
SPECT	Single photon emission tomography
VBM	Voxel-based morphometry

INTRODUCTION

Cannabis is the world's most widely available and most commonly used illicit drug. In Europe, approximately 20 million adults—around 6% of the population aged 15–64 years—are reported to have used the drug in the previous year (EMCDDA, 2013).

Even though many individuals discontinue cannabis use after initial experimentation, the percentage of long-term dependence is around 9% (EMCDDA, 2013). There is a consistent association and a dose-response relationship between the frequency of adolescent cannabis use and adverse health outcomes in young adults (Horwood et al., 2014).

Cannabis use may be associated acutely with effects such as anxiety and panic attacks (especially in first-time users), perception abnormalities, psychotic symptoms at higher doses (or in vulnerable individuals), learning and memory impairment, and road crashes if driving in an intoxicated state (Ramaekers et al., 2004; Hall & Degenhardt, 2009). It has also been associated with neurocognitive alterations, and deficits such as memory impairments, in some (though not all) studies, as well as increased risk of depression and psychotic symptoms and disorders (Bolla et al., 2002; Moore et al., 2007; Schreiner & Dunn, 2012).

However, the neural mechanisms underlying these effects have not been clearly identified. The extract of the *Cannabis sativa* plant has over 60 different cannabinoids (Mechoulam & Gaoni, 1967). Δ^9-Tetrahydrocannabinol (delta-9-THC) is its main psychoactive constituent, and is responsible for most of the drug's psychotropic effects, and cannabidiol (CBD) has been found to induce anxiolytic (Crippa et al., 2004), antipsychotic (Zuardi et al., 2012), and neuroprotective effects (Perez et al., 2013). In the last decade, a tendency for strains with high proportions of delta-9-THC and low proportions of CBD has been noted, a finding that may have clinical and neuroanatomical consequences.

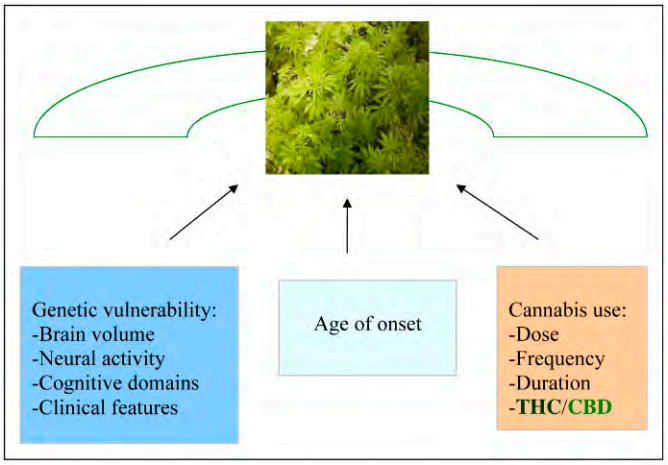

FIGURE e5.1 **Neurodevelopment influences on brain cannabis effects.**

Cannabinoids exert their effects through the endocannabinoid system (eCB), which can modulate the neuronal activity of other neurotransmitter systems such as dopamine, glutamate, or GABA through its action on the most abundant cannabinoid receptor in the brain, CB1. High densities of CB1R are found in the prefrontal cortex, basal ganglia, medial temporal areas and cerebellum (Mechoulam & Parker, 2013). The effect of CB1R activation on neurotransmitter release in these areas is critical for various cognitive processes and for reward, motor function, and psychiatric symptoms. CB2R are found mainly in hematopoietic and immune cells, but are also present in the brain (Onaive, 2006). The eCB system plays an important role in neuromaturation and synaptic pruning, and controls proliferation and neurogenesis in the hippocampus (Fogaça, Galve-Roperh, Guimaraes, & Campos, 2013). During adolescence, the brain may be more vulnerable to disturbances from exogenous cannabinoids which may alter normal brain functioning, as studies with animal models have shown (Maldonado et al., 2011) (Fig. e5.1).

Lastly, cannabis-induced impairment may depend on factors such as gender, age of onset, quantity, frequency and duration of use, comorbidity, as well as genetic aspects (Batalla et al., 2014a).

In this chapter, we review the main results of neuroimaging studies of the effects on the brain of acute and chronic cannabis use, and assess the preliminary evidence of genetic modulation of these effects. We discuss the methodological limitations of the existing evidence, and suggest some directions for future research in the field.

ACUTE EFFECTS OF CANNABINOIDS ON BRAIN FUNCTION

Systematic reviews of the acute effects of cannabinoids on brain functions (Martín-Santos et al., 2010; Batalla et al., 2014b; reviews) in cannabinoid-naïve individuals and infrequent users have provided consistent findings.

During Resting State

After Acute Administration of Delta-9-THC or CBD

Acute administration of cannabinoids has been shown to increase cerebral blood flow in CB1R-rich brain areas during baseline brain perfusion. These areas are involved in the reward pathway, and several other cognitive processes (O'Leary et al., 2003). Measuring baseline perfusion and resting state BOLD signal (fMRI) brain activity in the same group, van Hell et al. (2010) indicated that brain activity was similar in delta-9-THC and placebo in areas with different cerebral blood flows (CBF).

These changes in CBF have been associated with acute symptoms of delta-9-THC use, such as increased anxiety (Mathew & Wilson, 1993), depersonalization and time perception (Mathew et al., 1999), intoxication levels, and feeling "high" effects (van Hell et al., 2010).

The acute effect of CBD on CBF in the resting state has also been investigated in naïve cannabis users. CBD was found to modulate resting brain activity in limbic and paralimbic cortical areas (Crippa et al., 2004), a finding consistent with their anxiolytic clinical effect (Fig. e5.2).

During Cognitive Tasks

In the last decade, researchers have combined pharmacological challenges with cannabinoids and neuroimaging to investigate the neural mechanisms underlying their acute effects on cognition and emotional processing, but also to shed light on psychiatric symptomatology and disorders. Using fMRI or SPECT neuroimaging techniques, the acute experimental administration of cannabis to naïve or occasional cannabis users, during the performance of cognitive tasks such as emotion processing or the inhibitory response, has shown alterations in neural activity (Table e5.1).

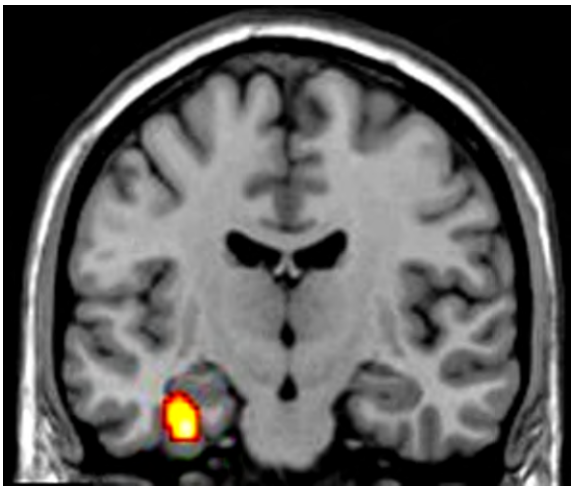

FIGURE e5.2 The brain region where there was significantly increased regional cerebral blood flow (rCBF) located in the left parahippocampal gyrus in healthy volunteers (n = 10) during 400 mg oral cannabidiol (CBD) administration versus placebo has been overlaid on coronal sections (−13, y-axis) *(Crippa et al., 2004)*.

Acute Administration of Delta-9-THC/CBD/Placebo Condition or Delta-9-THC/Placebo Condition

MEMORY

One of the first fMRI studies to apply a learning task involving the repeated presentation of verbal stimuli demonstrated that the impairment in learning and memory induced by cannabis may be mediated by its effects on medial temporal and prefrontal function (Bhattacharyya et al., 2009). In that study, which used a randomized, double-blind, placebo-controlled, crossover design, 10 mg of delta-9-THC was administered in a single oral dose versus 600 mg of CBD. The study also showed that the acute induction of psychotic symptomatology by delta-9-THC was related to its effects on the striatal function.

A second fMRI experimental study (Bossong et al., 2012a), using a randomized, placebo-controlled crossover design but with 9 mg of delta-9-THC administered through the inhalation route, investigated the effects of cannabis on associative memory using a task with pictorial stimuli. These authors reported attenuated activity of the insula, right inferior frontal gyrus, and the left side of the middle occipital gyrus during the encoding condition, and an increase in the activity of the cuneus and precuneus under the effect of delta-9-THC. Task performance was not modified by the administration of delta-9-THC, compared to placebo, in either study. However, using a working memory task, the same authors (Bossong et al., 2012b) found a decline in cognitive performance under the experimental administration of delta-9-THC, with increased activity in brain areas related to working memory, such as the dorsolateral prefrontal, inferior temporal and parietal cortices.

TABLE e5.1 Neuroimaging Studies of Acute Administration of THC and CBD in Naïve Cannabis Users

Author (year)	Type study	Design	Results
RESTING STATE			
Crippa et al. (2004)	90mTC-ECD-SPECT	CBD 400 mg versus placebo	*CBD versus placebo* Decrease rCBF L amygdala, hipoccapus, hypothalamus; posterior cingulate gyrus Increase rCBF L parahypocampus and fusiforms gyrus
fMRI			
Borgwardt et al. (2008)	fMRI 1.5 T Response inhibition task	THC 10 mg versus CBD 600 mg versus placebo	*THC versus placebo* Decrease BOLD R inferior frontal gyrus; L/R anterior cinglated cortex, and precuneus Increase BOLD R hippocampus, transverse temporal and fusiform gyrus, parahippocampus and caudate; L precuneus and prefrontal cortex *CBD versus placebo* Decrease BOLD L insula and superior and transverse temporal gyrus
Fusar-Poli et al. (2009)	fMRI 1.5 T Affective stimuli	THC 10 mg versus CBD 600 mg versus placebo	*THC versus placebo* Neutral face: increase BOLD posterior temporal and L inferior parietal lobule Mildly fearful face: increase BOLD R inferior parietal lobule and decrease BOLD inferior frontal gyrus Intensely fearful face: decrease BOLD L/R frontal gyrus, Pcgyrus; increase BOLD L precuneus, L/R primary sensorimotor cortex *CBD versus placebo* Neutral face: no brain activation differences Mildly fearful face: decrease BOLD L7R posterior lobe cerebellum Intensely fearful face: decrease BOLD amygdala, anterior parahippocampus, anterior and posterior cyngulate gyrus, L occipital gyrus, R posterior lobe cerebellum
Bhattacharyya et al. (2009)	fMRI 1.5 T Verbal paired associated task	THC 10 mg versus CBD 600 mg versus placebo	*THC versus placebo* Encoding block 1: decrease BOLD parahippocampus, 2 & 3: increase BOLD parahippocampus Recall block 1 & 2: no brain activation differences *CBD versus placebo* No brain activation differences
Winton-Brown et al. (2011)	fMRI 1.5 T Auditory and visual stimuli task	THC 10 mg versus CBD 600 mg versus placebo	*THC versus placebo* Auditory: decrease BOLD L/R anterior and posterior superios and middle temporal gyrus, insula, supramarginal gyrus, R inferior frontal gyrus and L cerebellum Visual: decrease BOLD L/R extrastriate visual cortex, increase BOLD R lingual and occipital gyrus, L lingual and fusiform gyrus *CBD versus placebo* Auditory: increase BOLD L/R temporal cortex, insula, parahipocampus and hippocampus, decrease BOLD L superior temporal gyrus, insula, posterior temporal, and supramarginal gyrus Visual: increase BOLD R middle and inferior occipital gyrus, lingual gyrus, and cuneus
Bhattacharyya et al. (2012b)	fMRI 1.5 T Salience stimuli task	THC 10 mg versus CBD 600 mg versus placebo	*THC versus placebo* Increase BOLD R prefrontal cortex, orbitofrontal cortex, and frontal lobe; decrease BOLD R head of caudate, putamen, insula and thalamus *CBD versus placebo* Decrease BOLD R prefrontal cortex; increase BOLD L caudate, parahippocampus, insula, precentral gyrus, and thalamus *THC versus CBD* Increase BOLD R orbitofrontal cortex and decrease BOLD L parahippocampus, caudate, putamen, thalamus, and lingual gyrus
Bhattacharyya et al. (2015)	fMRI 1.5 T Go-No-Go	THC 10 mg versus placebo	*THC versus placebo* During the response inhibition condition (No-Go minus Oddball trials) THC was associated to a decrease in BOLD L inferior frontal gyrus, insula and L precuneus, and increase BOLD hippocampus and caudate nucleus

THC, delta-9-tetrahydrocannabinol; *CBD*, cannabidiol; *BOLD*, blood oxygenation-level dependence; *D*, right hemisphere; *fMRI*, functional magnetic resonance imaging; *L*, left hemisphere; *rCBF*, regional cerebral blood flow; *90mTC-ECD-SPECT*, etyl-cesteinate-dimer labeled with technetium-99m, single-photon emission computed tomography.

These investigations provided evidence that the impairments in learning and memory induced by THC are mediated by its effect on medial temporal and prefrontal functioning.

Emotional Faces Processing Task

Acute use of cannabis has been associated with acute affective symptomatology (Martín-Santos et al., 2012; Crippa et al., 2009).

An initial fMRI study with a randomized, placebo-controlled, crossover design, in which 7.5 mg of delta-9-THC was administered orally to occasional cannabis users, found an attenuation of amygdala activation in response to threatening stimuli, under the effect of delta-9-THC (Phan et al., 2008). The authors suggested that these results were related to the anxiolytic effect of delta-9-THC.

Later, another study using a randomized, placebo-controlled, crossover design and oral route of drug administration investigated the neural effects of 10 mg of delta-9-THC versus 600 mg of CBD, during an emotional processing task (fearful faces) (Fusar-Poli et al., 2009). These authors reported an increase in engagement of the right inferior parietal lobule, and attenuation of engagement of the left medial frontal gyrus while viewing mildly fearful faces. When the naïve cannabis users were exposed to intensely fearful faces, delta-9-THC was found to increase the engagement of the left precuneus and primary sensorimotor cortex bilaterally, and to decrease the engagement of the middle frontal gyrus bilaterally, and in the posterior cingulate gyrus. These results were associated with increases in anxiety symptoms and in skin conductance response. However, no relationship was found with amygdala brain activity (Fusar-Poli et al., 2009).

Taken together, these results suggest the presence of a dose-response relationship between anxiety and delta-9-THC (Crippa et al., 2009). In contrast, CBD showed attenuated activation in the amygdala, and in the anterior and posterior cingulate cortices (Fusar-Poli et al., 2009), as well as in the skin conductance response, thus providing evidence of its anxiolytic role.

These effects of delta-9-THC and CBD while performing emotional processing tasks suggest a role of the eCB system in the modulation of emotion, and corroborate earlier findings in this field (Fogaça et al., 2013).

Response Inhibition Task

Cannabis use has been associated with impulsivity and impaired psychomotor control, resulting in risk behavior such as dangerous driving (Ramaekers et al., 2004). Few studies have examined the brain effects of acute cannabis use, or its main psychoactive component (delta-9-THC) on psychomotor control function under experimental conditions, using different paradigms. Those carried out to date have produced inconsistent results (Ramaekers et al., 2009; Borgwardt et al., 2008). CBD deactivated the left temporal cortex and insula, brain areas which are not involved in this cognitive process (Borgwardt et al., 2008).

Another adverse effect of cannabis use is the acute induction of psychotic symptoms, and the increased risk of schizophrenia following regular use. Impairment of inhibitory control and processing are known to occur under the influence of cannabis and schizophrenia. A recent fMRI investigation studied whether cannabis-induced impairment in inhibitory processing is related to the acute induction of psychotic symptoms (Bhattacharyya et al., 2015). Under experimental conditions, these authors administered delta-9-THC to 36 naïve cannabis users, in a study with a placebo-controlled, double blind, within-subjects design, and tracked their performance on a response inhibition (Go-No-Go) task using fMRI. Interestingly, they observed that, compared to placebo, delta-9-THC caused transient psychotic symptoms, anxiety, intoxication, and sedation, inhibition errors, and impaired inhibition efficiency. The severity of the psychotic symptoms was directly correlated with inhibition error frequency and, inversely, with inhibition efficiency under the influence of delta-9-THC. Moreover, the administration of delta-9-THC attenuated left inferior frontal activation, which was inversely correlated with the frequency of inhibition errors, and the severity of psychotic symptoms, and possibly with inhibition efficiency.

The results suggest that the impairment in the inhibitory control of thoughts, behaviors, and emotions, and the altered inferior frontal function observed under the influence of cannabis may have a role in the transient psychotic symptoms associated with its use.

Sensory Processing Task

As mentioned earlier, acute use of cannabis can lead to sensory–perceptual alterations similar to those experienced during psychotic episodes. This effect of cannabis has also been studied with fMRI (Winton-Brown et al., 2011), using an auditory–visual processing task in naïve cannabis users.

Compared with placebo, delta-9-THC attenuated activation bilaterally in the anterior and posterior superior temporal gyri and middle temporal gyrus, the insulae and in the supramarginal gyri, and in the right inferior frontal gyrus and left cerebellum during auditory processing. Attenuated temporal cortical activation was correlated with psychotic symptomatology. CBD showed the opposite effect to delta-9-THC, for temporal cortical activation. Under the visual processing condition, compared with placebo, delta-9-THC attenuated activation in the extrastriate visual cortex and enhanced activation in lingual and middle occipital gyri (primary visual cortex), on the right side and parts of the lingual and fusiform gyri, extending anteriorly on the left side. Increased

activation in the primary visual cortex was correlated with the severity of psychotic symptomatology.

Attentional Salience Processing

Attentional salience processing has been implicated in schizophrenia, in which aberrant salience attribution has been associated with the presence of psychotic symptoms, such as delusions. Due to this, and to the association between chronic cannabis use and the increased risk of schizophrenia and worse outcome (Moore et al., 2007), the acute effects of 10 mg oral delta-9-THC versus CBD were investigated in a sample of naïve cannabis users using a visual oddball detection task (Bhattacharyya et al., 2012b). Compared with placebo, delta-9-THC attenuated activation in the right caudate, but increased activation in the right prefrontal cortex, including the inferior frontal gyrus during the processing of salient, relative to nonsalient, oddball stimuli. Delta-9-THC also reduced the response latency of salient and nonsalient stimuli, though the effect was greater on the nonsalient stimuli. This may suggest that, under the influence of delta-9-THC, insignificant stimuli became significant. Moreover, the effect of delta-9-THC on striatal activation was inversely correlated to the severity of the psychotic symptomatology it induced. Striatal and lateral prefrontal function are altered during salience processing in psychosis (Juckel et al., 2006), and in drug-induced psychotic states (Roiser, 2010). The study provided evidence that the effect of cannabis use on the risk of psychosis might be mediated by its effect on attentional salience processing.

CBD showed an opposite pattern of activation to placebo. It attenuated activation in the prefrontal cortex on the right side, but increased activation in the left caudate and putamen, and in the left parahippocampal gyrus, lingual gyrus, and thalamus.

Genetic Vulnerability to the Acute Effects of Cannabis

Several studies have shown the genetic modulation of brain activation under cognitive tasks such as response inhibition (Bhattacharyya et al., 2014), and verbal learning (Bhattacharyya et al., 2012a), after a single 10 mg oral dose of delta-9-THC.

Verbal Learning Task

While cannabis use may induce acute psychotic symptoms, increase the long-term risk of schizophrenia, and worsen outcome, as we stated previously, there is marked interindividual variability in the susceptibility to these effects. This variability probably has a genetic basis (Fig. e5.1).

Induction of psychotic symptoms by delta-9-THC is related to its effect on the striatum, a brain region rich in dopaminergic terminals. The marked interindividual variation in the psychotic effects of cannabis may therefore reflect differences in genes that influence the transmission or metabolism of brain dopamine. A preliminary study (Bhattacharyya et al., 2012a) tested the effect of variation in two candidate genes altering central dopaminergic neurotransmission on the symptomatic and neurophysiological response to delta-9-THC: the DAT1 gene, which codes for the dopamine transporter that removes dopamine from central synapses (Dreher et al., 2009), and the protein kinase B AKT1, an integral component of the dopamine signaling cascade (Beaulieu, Gainetdinov, & Caron, 2007).

In an fMRI study with a double-blind, repeated measure, placebo-controlled, within-subject design, the authors examined the ability of the DAT 1 3UTR VNTR and AKI 1 rs1130233 polymorphisms to modulate the acute effects of delta-9-THC on psychotic symptoms and regional brain activation, in 35 healthy volunteers with minimal experience of cannabis use (<25 times/life) (Bhattacharyya et al., 2012a). The authors found that individuals carrying the risk variants of either the DAT1 30 UTR VNTR or the AKI1 rs1130233 polymorphism have an increased sensitivity to the psychotomimetic effects of delta-9-THC, and that the sensitivity was especially high in subjects who carried both these variants. Moreover, the more delta-9-THC attenuated the striatal and midbrain activation, the greater the severity of the psychotic symptoms.

The results showed that the acute psychotogenic effects of cannabis were moderated by two genes that code for proteins which influence dopamine neurotransmission, and modulate the effects of delta-9-THC on midbrain and striatal function.

Response Inhibition Task (Go, No-Go Task) and AKT1 Polymorphism

Another recent fMRI study using a double-blind, repeated-measure design investigated the genetic and neural basis of variable sensitivity to cannabis-induced behavioral dyscontrol in healthy occasional cannabis users during a response inhibition task (Bhattacharyya et al., 2014). Results showed that carriers of the A allele at rs1130233 of AKT1, a protein kinase B (AKT1) which influences central dopaminergic neurotransmission, have a significantly greater risk of impairment in the control of prepotent response under the influence of delta-9-THC. In carriers of the A allele, associated with reduced AKT1 expression (Blasi et al., 2011), and impaired prefrontal executive cognition (Tan et al., 2008), administration of delta-9-THC was associated with a more than twofold increase in the frequency of impaired inhibitory control, and concomitant attenuation of the engagement of the inferior frontal gyrus, the principal neural

substrate for inhibitory control. Furthermore, there was a direct relationship between the effects of delta-9-THC on psychomotor control behavior, and the physiological response of its neural substrate, in that the more delta-9-THC attenuated inferior frontal engagement, the greater the risk of errors of inhibition.

The results of this preliminary study suggest that variation in a gene coding for a protein which influences central dopaminergic neurotransmission may moderate the sensitivity to the acute impairments in psychomotor control induced by use of delta-9-THC.

As we noted previously, cannabis is one of the psychoactive substances most frequently associated with road-traffic accidents (Ramaekers et al., 2004). Although the act of driving involves a complex cognitive process, the results of the study suggest that this effect has a genetic basis related to dopaminergic signaling in the brain. This may help to explain why certain persons are more sensitive to the effects of cannabis on psychomotor control.

Acute Effects on Dopamine Release

Some publications have used functional neurochemical imaging to measure dopamine in cannabis users after acute administration of delta-9-THC with ^{11}C raclopride PET (Bossong et al., 2009; Stokes et al., 2009), and with 123 IBZM SPECT (Barkus et al., 2011). The first study found a decrease in ^{11}C raclopride binding in the ventral striatum and precommisural dorsal putamen, after delta-9-THC inhalation, reflecting an increase in dopamine in these regions. The second study with a large sample of subjects did not find significant differences in ^{11}C raclopride striatal binding with oral delta-9-THC, compared with placebo. Lastly, using ^{123}IBZM SPECT, differences in radioligand binding in caudate or putamen were found under delta-9-THC, compared with placebo. Future studies should explore this area further.

CHRONIC EFFECTS OF CANNABIS USE ON BRAIN STRUCTURE AND FUNCTION

Structural Effects

Specific regional brain analyses demonstrated evidence of structural abnormalities in adult chronic cannabis users, compared with healthy controls. The abstinence period for subjects before undergoing structural MRI was between 12 and 24 h in most studies (Martín-Santos et al., 2010; Batalla et al., 2013 reviews). The most consistently reported brain alteration was reduced hippocampal volume (Lorenzetti et al., 2015). This alteration may persist after several months of abstinence, and may be related to the amount of cannabis used. Morphological alterations were also found in the amygdala (Ashtari et al., 2011), the cerebellum (Cousijn et al., 2012), and the frontal cortex (Matochik et al., 2005). Moreover, some diffusion tensor imaging (DTI) studies have found differences in the mean diffusivity or fractional anisotropy in the corpus callosum and the frontal white matter fiber tract (Arnone et al., 2008; Gruber, Silveri, Dahlgren, & Yurgelun-Todd, 2011). It may be that cannabis also alters white matter structural integrity. More studies are needed in this area (Table e5.2).

On the other hand, the few studies done in adolescents (Ashtari et al., 2011; Medina et al., 2009; Medina, Nagel, & Tapert, 2010; McQueeny et al., 2011) suggest that the effect of chronic cannabis use may appear soon after initiation, may persist after a month of abstinence, and may be moderated by gender. It has been suggested that adolescent females may be at a higher risk of morphological effects than males (McQueeny et al., 2011). These results need to be replicated in further studies.

These effects of chronic cannabis use on brain structure are consistent with those found in studies showing similar alterations in schizophrenia which reported volume reductions of up to 6% in the hippocampus and the amygdala, in schizophrenic patients, particularly during the first years of the illness (Andreasen et al., 2011). Moreover, cannabis misuse in schizophrenia has been associated with a more pronounced loss of gray matter volume than in nonusers (Rais et al., 2010), suggesting that individuals with schizophrenia may be particularly vulnerable to cannabis exposure.

Functional Neuroimaging Studies

Resting State

Using various imaging methods ($H2^{15}O$-PET, ^{133}Xe-SPECT, ^{18}F-FDG-PET, ^{11}C-raclopride PET and ^{18}F FMPEPd2), several studies have evaluated rCBF in resting state in abstinent adult chronic cannabis users (Martín-Santos et al., 2010; Batalla et al., 2013; reviews). The abstinence period before the imaging test was between 12 h and 542 days, depending on the study. These studies showed that, in the global resting state, areas with high concentrations of CB1R (the prefrontal cortex and cerebellar and striatal regions) showed a lower blood flow, compared to healthy controls. These results may indicate a downregulation of CB1R in chronic cannabis users, which are area-specific and reversible in the neocortex and limbic areas (Hirvonen et al., 2012). Furthermore, the resting state findings are consistent with the impairments in attention and working memory (Solowij & Battisti, 2008), decision-making (Bechara et al., 2001), and psychomotor control (Bolla et al., 2002) described in chronic cannabis users. Additional studies are needed to investigate the causes of these results.

TABLE e5.2 Structural Neuroimaging Studies in Chronic Adult Cannabis Users Versus Nonusers Controls[a]

Author (year)	Type study	Results
MRI		
Block et al. (2000)	MRI 1.5 T	*VBM*: no differences between chronic cannabis users and controls
Tzilos et al. (2005)	MRI 1.5 T	*ROI analysis*: negative results
Matochik et al. (2005)	MRI 1.5 T	*VBM*: lower GM density in the R parahippocampus and in the precentral gyrus and R thalamus in cannabis users, compared to controls *ROI analysis*: decreased in hippocampus L/R
Jager et al. (2007)[b]	MRI 1.5 T	*VBM*: no differences between chronic cannabis users and controls
Yücel et al. (2008)	MRI 1.5 T	*ROI analysis*: decrease in hippocampus L/R and amygdala R in chronic cannabis users versus controls
Ashtari et al. (2011)[c]	MRI 1.5 T	*ROI analysis*: decrease in hippocampus L/R in chronic cannabis users, compared to controls
Cousijn et al. (2012)	MRI 3 T	*VBM*: increased cerebellum in chronic cannabis users, compared to controls
Batalla et al. (2014a)	MRI 1.5T	*VBM*: increased in postcentral gyrus L in chronic cannabis users compared to controls
Lorenzetti et al. (2015)	MRI 3T	*ROI analysis*: smaller hippocampus and amygdala volume in chronic heavy cannabis users, compared to controls
DTI		
Gruber et al. (2005)	DTI 3 T	*VBM and ROI analysis*: negative results
DeLisi et al. (2006)	DTI 1.5 T	*VBM and ROI analysis*: negative results
Arnone et al. (2008)	DTI 1.5 T	*ROI analysis*: increased mean diffusivity in the corpus callosum in chronic cannabis users
Gruber et al. (2011)	DTI 3 T	*ROI analysis*: increased mean diffusivity in the R genus, and reduction in L frontal fractional anisotropy in chronic cannabis users

[a] *All chronic cannabis users studies were done after 12–24 h abstinence, except*
[b] *Jager et al. (2007) done after 7 days abstinence, and*
[c] *Study by Ashtari et al. (2011) that was done after 6.7 months abstinence*
D, Right hemisphere; *L*, left hemisphere; *VBM*, voxel-based morphometry; *ROI*, region of interest analysis; *DTI*, diffusion tensor.

Under Cognitive Tasks

Functional neuroimaging studies in chronic cannabis users comparing brain activation with healthy controls under different cognitive tasks (attention memory, inhibition and impulsivity, decision making, motor performance, and affective processing) indicated that chronic cannabis users showed an altered pattern of brain activity in the areas engaged in these cognitive processes (Block et al., 2002; Bolla, Eldreth, Matochik, & Cadet, 2005; Gruber et al., 2011; Jager et al., 2007; Wesley, Hanlon, & Porrino, 2011).

The fact that in most of the studies the level of performance on cognitive tasks was similar in chronic cannabis users and healthy controls indicated that these tasks engage similar brain areas. It has been suggested that, in chronic cannabis users, there is a process of neuroadaptation, possibly activating additional areas as a compensatory mechanism, in order to maintain normal cognitive performance. The few fMRI studies carried out in adolescents did not find differences with respect to adult in studies carried out during the performance of memory (Schweinsburg et al., 2010, 2011), inhibition, and impulsivity tasks (Tapert et al., 2007).

Genetic Vulnerability to Chronic Cannabis Use and its Effect on Brain Structure

In recent years, some studies have shown that genetic variation may play an important role in determining brain morphology. The *catechol-O-methyl-transferase* (*COMT*) gene has a functional polymorphism at codon 156 causing a valine (Val) to methionine (Met) substitution, resulting in three genotypes: Val/Val, Val/Met, and Met/Met. The enzymatic activity of Met/Met is 40% lower, indicating low levels of extrasynaptic dopamine. COMT has an important role in the prefrontal cortex, in subcortical regions such as the basal ganglia and medial temporal lobe, and in the cerebellum and spinal cord. It has been associated with modulation of brain adverse effects in chronic cannabis users (Solowij et al., 2012); the Val allele carrier seems to be more sensitive to the chronic and acute effects of delta-9-THC, especially in subjects at risk of psychosis (Estrada et al., 2011).

Recently, the modulation of the brain structure by the COMT polymorphism has been explored in a sample of early onset chronic cannabis users (Batalla et al., 2014a). The study provided evidence that the COMT genotype influenced the bilateral ventral caudate nucleus in

opposite directions, with more copies of the Val allele being associated with smaller volumes, in chronic cannabis users, and greater volumes in controls. The opposite pattern was found in the left amygdala. The results corroborate previous reports that neuroanatomical changes are associated with chronic cannabis use, and show, for the first time, that these changes may be modulated by the COMT genotype.

METHODOLOGICAL LIMITATIONS OF NEUROIMAGING STUDIES

Several systematic reviews have highlighted the major methodological differences between the studies included (Martín-Santos et al., 2010; Batalla et al., 2013, 2014b; Rochetti et al., 2013), a situation which has often limited the generalization of the results in the area, and hampered comparisons between them. The use of strict definitions (eg, naïve, or recreational/occasional), and predetermined selection criteria, as well as the application of PRISMA guidelines, is essential in order to reduce the heterogeneity. Some of the studies use different designs (for instance within-subject or between-group) and apply different neuroimaging techniques, and few studies apply a multimodal, complementary approach to the same sample; even fewer replicate previous methodologies and objectives, thus making comparisons particularly difficult.

The studies reviewed present several sociodemographic differences, for example, investigating only men in order to obtain a homogeneous sample, but losing information on what happens in the female brain (Crane, Schuster, Fusar-Poli, & Gonzalez, 2013). Patterns of cannabis use (eg, frequency of use, lifetime use) vary widely, as do administration routes (eg, smoking, oral, inhalation, intravenous), which have different pharmacokinetics (Martín-Santos et al., 2012). In nonexperimental studies, the use of diverse units to measure cannabis exposure (eg, joints, grams) may help to explain some discrepancies in the results.

Furthermore, comorbidity with other substance use disorders, and with other axis I/II mental disorders, may be very high in cannabis users. The use of specific structured clinical interviews for screening and diagnosis is also an important issue, and will help to study the cannabis user phenotype (Torrens et al., 2004).

Since the introduction of functional neuroimaging techniques, the question has arisen of whether the drug effect reflects an influence on cerebral blood flow rather than neural activity. In this regard, the results of a group of pharmacological challenges with delta-9-THC and CBD have shown that the same participant in different cognitive and emotional paradigms during fMRI underwent opposite effects of the same drug, in same brain areas, during the same scanning session, both with delta-9-THC and CBD (Bhattacharyya et al., 2012c). Moreover, some of the drug effects observed were similar to the results obtained by electrophysiological methods not related to the CBF (Morrison et al., 2011).

Ethical aspects are also important when studying the acute effects of a psychoactive substance which may induce dependence, and has been linked to psychiatric disorders. Careful participant selection, appropriate choice of screening and settings, adequate counseling, and provision of information and the scheduling of follow-up assessments will minimize the risk.

SOME POINTERS FOR FUTURE STUDIES

Future studies should consider the need to standardize methodology, to replicate known facts with greater methodological rigor, and to combine experimental designs and prospective large samples involving subjects of both genders, from adolescence to adulthood. Collaborative initiatives will allow the joint use of neuroimaging, genetic, psychiatry, and cognitive data from multiple sites around the world.

Finally, the eCB system is a promising target in the treatment of symptoms of psychiatric disorders such as schizophrenia, depression, and anxiety. More experimental studies using different cannabinoid compounds such as CBD should be carried out in the near future.

MINI-DICTIONARY

Functional Magnetic Resonance Imaging (fMRI) A neuroimaging technique for measuring brain activity. It detects changes in blood oxygenation and flow in response to neural activity.

Positron Emission Tomography (PET) A neuroimaging technique that uses trace amounts of short-lived radioactive material to map functional processes in the brain. Areas of high radioactivity are associated with brain activity.

Single Photon Emission Computed Tomography (SPECT) A functional neuroimaging technique that evaluates regional cerebral perfusion through the administration of a gamma-emitting radioisotope injection into the bloodstream. Cerebral blood flow is closely linked to neuronal activity.

Acknowledgments

This chapter has been funded in part by Spanish grants from the Plan Nacional sobre Drogas, Ministerio de Sanidad y Consumo: PNSD/2011/050(R.Martín-Santos); and the support of AGAUR, Catalonia Government SGR2014/1114(R. Martín-Santos), and INCT Translational Medicine (INCT-TM, CNPq), Brazil (J.A. Crippa); S. Bhattacharyya is the recipient of a Clinician Scientist award from the NIHR, United Kingdom; and J.A. Crippa is the recipient of a CNPq-Brazil productivity award. The views expressed are those of the authors and not necessarily those of the NHS, the NIHR or the Department of Health, UK.

SUMMARY POINTS

- Cannabis is a risk factor for psychosis.
- Cannabis users who develop psychosis initially have less brain alterations because they commonly have a better premorbid functioning.
- Executive deficits and brain structural abnormalities are common in patients with first-episode psychosis, after a period of cannabis use.
- Patients only with psychosis present a higher degree of neurodevelopmental involvement, and greater brain abnormalities.
- Individuals with psychosis and cannabis use usually present in their clinical history more "environmental" risk factors in their causal pathway.
- It is important to develop strategies aiming to prevent cannabis use among adolescents, whose brain is still developing, especially those with prodromal psychotic symptoms, and a family history of psychosis.
- Early interventions for patients with FEP could help them prevent relapse on cannabis use for a better prognosis.

KEY FACTS OF NEUROIMAGING

- Neuroimaging has advanced our understanding on the nervous system by investigating both brain structure and functioning.
- Magnetic Resonance Imaging (MRI) is the most used neuroimaging technique in order to study alterations in gray matter (GM) and ventricles' volumes.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00043-0

KEY FACTS OF GRAY MATTER

- Gray matter (GM) is distributed at the surface of the brain, and it is also known as the "cerebral cortex."
- GM is mainly composed by neuron cell bodies, dendrites, capillaries, and glial cells, thus being differentiated of white matter (WM)—composed by myelinated axons—the difference in colors being basically caused by the whiteness of myelin, predominantly composed by lipid tissue.
- GM is predominantly associated with cognitive processing, while WM has been related with communication among different brain cells and regions.

LIST OF ABBREVIATIONS

ACC	Anterior cingulate cortex
ARMS	At-risk mental state
BD	Backward Digits
CBD	Cannabidiol
CB1	Type-1 cannabinoid receptors
CPT	Continuous Performance Test
DARTEL	Diffeomorphic registration algorithm
FD	Forward Digits
FEP	First-episode psychosis
FES	First-episode schizophrenia
GM	Gray matter
LVs	Lateral ventricles
MRI	Magnetic resonance imaging
PCC	Posterior cingulate cortex
PFC	Prefrontal cortex
ROIs	Regions of interest
ROP	Recent-onset psychosis
ROS	Recent-onset schizophrenia
THC	Δ^9-Tetrahydrocannabinol
THs	Temporal horns
VBM	Voxel-based morphometry
VBRs	Ventricle-to-brain ratios
WCST	Wisconsin Card Sorting Test
WMS-III	Wechsler Memory Scale

INTRODUCTION

Cannabis is still one of the most widely used illegal substance worldwide (UNODC, 2014). Community and scientists are still debating the implications of cannabis legalization, and the consequences are unclear, except for an expected tendency toward an increased prevalence of cannabis use among people (UNODC, 2014; Volkow, Baler, Compton, & Weiss, 2014), leading to an increased healthcare utilization related to cannabis use (Monte, Zane, & Heard, 2015). More importantly, considering that cannabis use is associated with a significant increased risk for developing psychosis (Bangalore et al., 2008; Koskinen, Löhönen, Koponen, Isohanni, & Miettunen, 2010; Moore et al., 2007; Murray, Morrison, Henquet, & Di Forti, 2007), it is inevitable to hypothesize that the number of persons who will develop psychosis will increase substantially (Monte et al., 2015). Actually, the prevalence of cannabis use may reach 43% (Bersani, Orlandi, Kotzalidis, & Pancheri, 2002) or even 60% in patients with psychosis (Duke, Pantelis, McPhillips, & Barnes, 2001). The aim of this chapter is to review the brain structural consequences of a chronic exposure to cannabis in the presence of psychosis, more specifically focusing on gray matter (GM) and ventricular alterations.

CANNABIS EFFECTS ON THE BRAIN AND IMPACT ON COGNITION

There is a frequent finding linking cannabis use with a negative impact on brain structure, especially the prefrontal cortex (PFC), amygdala, and hippocampus (Bolla, Brown, Eldreth, Tate, & Cadet, 2002; Batalla et al., 2013; Battistella et al., 2014; Lorenzetti et al., 2015; Rapp, Bugra, Riecher-Rössler, & Borgwardt, 2012; Yücel et al., 2008), but structural abnormalities remain inconclusive due to methodological differences across studies (Filbey et al., 2014; Malchow et al., 2012; Martín-Santos et al., 2010; Weiland et al., 2015). Functional neuroimaging studies have shown more consistent findings. During acute exposure, cannabis users present greater activation in brain areas related to the reward pathway, such as the ventral tegmental area, nucleus accumbens, thalamus, anterior cingulate, orbitofrontal cortex, insula, and amygdala (Filbey, Schacht, Myers, Chavez, & Hutchison, 2009; Martín-Santos et al., 2010). Subjective levels of intoxication and mental confusion have been correlated with such changes (Martín-Santos et al., 2010; Mathew & Wilson, 1993). However, after a long-term period of use, studies suggest that resting global, prefrontal, and anterior cingulate cortex (ACC) blood flow are lower in cannabis users than in controls (Martín-Santos et al., 2010).

Neuropsychological studies have supported such findings, Bolla et al. (2002) have demonstrated that chronic cannabis users have persistent dose-related cognitive deficits on memory, psychomotor speed, manual dexterity, and executive global functioning, even after 28 days of abstinence. Moreover, earlier cannabis use has a greater impact on cognitive functioning than later use. Fontes et al. (2011b) showed that chronic cannabis users who started to use before 15 years old (early-onset) are cognitively more impaired, as compared to late-onset users and controls, suggesting that early exposure to cannabis is associated with more adverse effects on

brain development. Considering that the endocannabinoid system plays an important role in brain development, it is plausible to hypothesize that prolonged use during adolescence results in a disruption in the normative maturational processes that occur during this period (Lubman, Cheetham, & Yücel, 2014). Also, perseverative responding measured by a traditional neuropsychological task named Wisconsin Card Sorting Test (WCST) indicates that early exposure to cannabis is associated with poorer mental flexibility, helping to explain why it is so hard for a cannabis chronic user to stop their compulsive behavior (Fontes et al., 2011a).

CANNABIS, PSYCHOSIS, AND THE BRAIN: COMPLEX MECHANISMS AND PREMORBID FUNCTIONING

Patients with first-episode psychosis (FEP) show significant regional GM alterations in frontal and temporal lobe structures, midline brain abnormalities, and poorer cognitive functioning (Ayres et al., 2007, 2010; Minatogawa-Chang et al., 2009; Rosa et al., 2010; Schaufelberger et al., 2007; Trzesniak et al., 2012). Abnormalities of brain structures have been suggested to underlie cognitive and emotional disturbances commonly seen in schizophrenia (Wobrock, Sittinger, Behrendt, D'Amelio, & Falkai, 2009). Apparently, a patient with FEP who is also cannabis user would presumably have greater alterations on brain structure, and impaired cognitive functioning (Rapp et al., 2012; Wobrock et al., 2009). In fact, Szeszko et al. (2007) used a method in which the frontal regions of interest (ROIs) were outlined manually, and reported that patients with first-episode schizophrenia (FES) who had a history of cannabis use had less anterior cingulate GM, compared with similar patients who did not use cannabis, and with healthy volunteers (see Table e6.1). In the same line, Bangalore et al. (2008) used voxel-based morphometry (VBM) and found decreased GM density in the posterior cingulate cortex (PCC) and in the left hippocampus in FEP cannabis users, when compared with FEP nonusers (see Fig. e6.1), suggesting that cannabis use is associated with altered brain structure, in particular regions rich in type-1 cannabinoid receptors (CB1) (Bangalore et al., 2008).

Also using VBM, Jarvis et al. (2008) found that bipolar adolescents with cannabis use had greater structural abnormalities than adolescents with bipolar disorder alone, in frontotemporal brain regions, as well as in certain subcortical areas associated with emotion, executive functioning, and motivational regulation.

More recently, Rapp et al. (2013) conducted a study with 23 patients with FEP, and 37 subjects in at-risk mental state (ARMS), and they found a significant negative effect of cannabis use on the GM volume of the posterior cingulum, and the left anterior cingulum, which were independent of the diagnostic group. The authors argue that both ARMS and FEP subjects may be particularly sensitive to activation of CB1 receptors that are very concentrated in the cingulate cortex (Rapp et al., 2013).

On the other hand, Cahn et al. (2004) examined brain volumes in cannabis-exposed patients with recent-onset schizophrenia (ROS), but the authors did not find any statistically significant difference between groups (cannabis users × nonusers), except for ventricular volumes (see next section). Wobrock et al. (2009) also found no differences in the brain morphology between the two subgroups of recent-onset psychosis (ROP) with and without substance use, primarily cannabis use. In a prospective study, Haller et al. (2013) did not found any significant differences among 50 patients with FEP, divided in 33 FEP with cannabis use and 17 FEP without cannabis use. However, the authors argue that they cannot exclude subtle morphometric changes associated with cannabis consumption, given the limitations of the study (Haller et al., 2013).

In general, literature involving neuroimaging in FEP with history of cannabis is relatively recent, comprehending different methodologies and distinct results (Malchow et al., 2012). Given the relevance and the high prevalence of cannabis use among patients with FEP, we consider that this issue deserves more attention. Although cannabis use has been associated with cognitive impairments and brain dysfunction in nonpsychotic users (Cunha, Nicastri, de Andrade, & Bolla, 2010; Fontes et al., 2011a,b; Hester, Nestor, & Garavan, 2009; Solowij et al., 2012), there is also evidence that a history of cannabis use could be associated with less abnormalities in brain structure and cognitive functioning, in people with schizophrenia (Rodríguez-Sánchez et al., 2010; Yücel et al., 2012) and bipolar disorder (Braga, Burdick, Derosse, & Malhotra, 2012). Thus, research studies using neuroimaging methods and neuropsychological testing have demonstrated heterogeneous results, due to different neuroimaging methods, cannabis use definitions (ie, lifetime versus recent use, age of onset, and others variables), and distinct cognitive tasks. For example, in two recent studies, individuals who develop psychosis in the context of cannabis use had less GM and lateral ventricles abnormalities than those patients who had no history of substance use (Cunha et al., 2013; Schnell, Kleiman, Gouzoulis-Mayfran, Daumann, & Becker, 2012). Schnell et al. (2012) evaluated 30 FES with cannabis use and 24 FES without cannabis use, using VBM and a diffeomorphic registration algorithm (DARTEL). They investigated specific ROIs such as insula, medial temporal gyrus, and middle frontal gyrus. They found less severe cognitive impairments (verbal and working memory), and less GM deficits in the PFC in patients with schizophrenia and cannabis use, when compared with patients without

TABLE e6.1 Structural Magnetic Resonance Studies in Patients With First Episode Psychosis and Cannabis Use

Authors (year)	Diagnosis	Comparative analysis (N)	Neuroimaging methods	Controlled variables	Cognitive assessment	Structural brain results
Cahn et al. (2004)	ROS	27 patients with ROS and cannabis use, 20 patients with ROS, and no healthy controls (HC)	Quantitative measurements were obtained manually. ROIs: total brain, cerebellum, caudate, lateral and third ventricle volumes	The two groups were matched for sex, height, weight, handedness, and parental education/controlled for age (different among groups)	No cognitive assessment	No differences between ROS with and without cannabis use, except for a decreased asymmetry of the lateral ventricles in the cannabis-exposed group
Szeszko et al. (2007)	FES	20 FES with cannabis use or dependence, 31 FES with no cannabis use and 56 healthy controls	All regions were outlined manually. ROIS: SFG, ACG, and OFC	Patients were volunteers in clinical trials comparing the efficacy of atypical antipsychotic drugs. HC were more educated/controlled by age and gender	No cognitive assessment	Reduced GM in ACG in FES patients with cannabis use compared with both patients with FES and HC
Bangalore et al. (2008)	FES patients	15 FES with cannabis use, 24 FES without cannabis use, and 42 healthy controls	VBM/ROIs consisting of the CB1 receptor rich brain regions that included DLPFC, hippocampus, posterior cingulate, and cerebellum	Age and gender/drug naive	No cognitive assessment	Decreased GM density in the right PCC and left hippocampus in FES patients with cannabis use, when compared with FES patients without cannabis use
Jarvis et al. (2008)	Bipolar disorder (inpatients)	7 patients with bipolar disorder and cannabis use, 7 patients with bipolar disorder without cannabis use, and no healthy controls (HC)	VBM	Adolescents (12–18 years old)	No cognitive assessment	Bipolar patients with cannabis use demonstrated decreased GM in the left fusiform gyrus and increased GM in the right caudate and precentral gyrus, as well as increased GM density in the right middle occipital and fusiform gyri and cerebellar vermis
Rais et al. (2008)	ROS	19 patients with ROS and cannabis use, 32 patients with ROS without cannabis use, and 31 HC	Prospective study examining total brain, GM, and lateral and third ventricle volumes. MRIs were obtained at inclusion (T0) and at 5-year follow-up (T5)	No differences among patients and controls in gender, handedness, age, parental education, and scan interval	No cognitive assessment	No significant differences at baseline/patients with FES and cannabis use demonstrated larger GM loss and larger increase in lateral and third ventricle volumes
Wobrock, Sittinger, Behrendt, D'Amelio, & Falkai (2009)	ROS	20 patients with ROS with comorbid SUD, and 21 patients with ROS without SUD, and no HC	Volumetric measurement of ROIs including STG, amygdala-hippocampus, and cingulum	ROS with SUD were significantly younger, predominantly male, and had a lower socioeconomic status	Premorbid intelligence was estimated/patients with SUD demonstrated elevated anxiety, depression, and less attentional impairments	No differences between ROS with and without substance/cannabis use

Rais et al. (2010)	ROS	19 patients with ROS and cannabis use, 32 patients with ROS without cannabis use, and 31 HC	Prospective study examining differences in cortical thickness/MRIs were obtained at inclusion in the study and at a 5-year follow-up	Patients and HC matched for confounding variables	No cognitive assessment	After 5 years, patients who used cannabis showed additional thinning in the left DLPFC, left ACC, and left occipital lobe, as compared to those patients that did not use cannabis
Schnell, Kleiman, Gouzoulis-Mayfrank, Daumann, & Becker (2012)	FES	30 FES with cannabis use, 24 FES without cannabis use, and no HC	DARTEL and VBM. ROIs investigated: insula, medial temporal gyrus, and middle frontal gyrus	Groups were similar in terms of age, gender, education, psychopathology, medication, alcohol or nicotine use	Patients with FES and cannabis use presenting less severe cognitive impairments	Patients with FES and cannabis use had less severe middle frontal GM deficits/GM density was positively associated with cognitive functioning
Cunha et al. (2013)	FEP	28 FEP with cannabis use, 78 FEP without cannabis use, and 80 HC	VBM/LVs were measured by the manual tracing ROI	Controlled by age and gender/medicated/cognitive results	Patients with FEP and cannabis use had less attentional and executive impairments	Patients with FEP and a history of cannabis use had less brain abnormalities, characterized by GM and ventricle volumes preservation
Rapp et al. (2013)	ARMS subjects with FEP	23 patients with FEP, 37 subjects with ARMS, and no HC	Manually traced cingulum	Corrected by age, gender, alcohol use, brain volume, and psychiatric medication	No cognitive assessment	Decreased GM volume in the posterior and left anterior cingulum associated with cannabis use
Haller et al. (2013)	FEP	33 FEP subjects with cannabis use and 17 FEP patients without cannabis use	Prospective study examining GM by VBM using FSL	Controlled by age and gender	No significant differences in attention and memory performance	No significant differences in GM between user and nonuser FEP groups

cannabis use (Schnell et al., 2012). Also, GM density was positively associated with cognitive performance in the Continuous Performance Test (CPT), which is highly dependent on prefrontal cortex integrity. The authors argue that deficits in these regions might represent preexisting risk factors particularly linked to the biological vulnerability for schizophrenia. In a more recent controlled VBM study, including a healthy control group, investigating GM and cognitive performance in patients with psychosis and a history of cannabis use, compared with psychotic patients without any history of cannabis use, we confirmed that patients with a history of cannabis use had less structural brain abnormalities and less cognitive alterations than patients without a history of cannabis use. Patients were selected from a sample of people with FEP identified for an epidemiological study about the incidence of psychotic disorders in Brazil (Menezes et al., 2007). We included 106 patients aged between 18 and 50 and with the diagnosis of psychosis (affective or nonaffective), who were categorized among those with a lifetime history of cannabis use (with a frequency of at least 3 times/month for at least 1 year, mean duration of cannabis use = 6.5 years, $N = 28$) and those patients who had no history of cannabis use ($N = 78$). Both groups of patients were compared with a control group of 80 nonpsychotic individuals, with no history of cannabis use, living in the same geographical area. As a result, we found GM deficits in medial temporal structures (hippocampus and parahippocampal gyrus), and in the PFC of patients only with FEP, but not in patients with FEP and cannabis use (see Fig. e6.2).

In fact, those abnormalities were found in patients without cannabis use, when directly compared to patients with a history of cannabis use. At first sight, one could precipitately interpret this finding as a "positive" result of cannabis use on brain structure. For example, one of the natural compounds in cannabis is cannabidiol (CBD), known to have opposite effects on the functional connectivity between the dorsal striatum, prefrontal cortex, and hippocampus, when compared with Δ^9-tetrahydrocannabinol (THC), the main psychoactive compound of cannabis, associated with abnormalities in brain functions (Bhattacharyya et al., 2014). Patients submitted to CBD for a period of time show better functional connectivity in brain areas associated with important cognitive functions (idem). For example, Δ^9-THC reduced fronto-striatal connectivity, related to its effect on task performance, whereas this connection was enhanced by CBD (Bhattacharyya et al., 2014). Also, experimental studies confirm that Δ^9-THC may be neurotoxic to the prefrontal cortical dopamine metabolism (Verrico, Jentsch, & Roth, 2003) that, in turn, has an important role in the neurobiology of schizophrenia (Szeszko et al., 2007). Unfortunately, in our study we did not have detailed information about the quality and estimated THC/CBD ratios in the cannabis the patients smoked. Also, patients

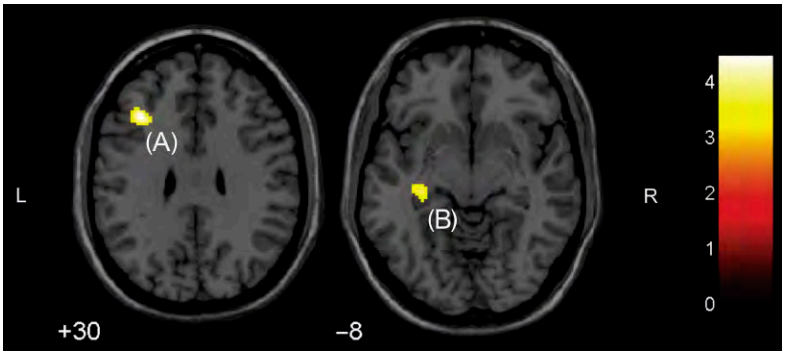

FIGURE e6.2 Brain Structural Analysis Displaying Clusters of Significant Decreased Grey Matter (GM) in Psychotic Patients Without History of Cannabis Use. Note: data indicates GM reduction in the left PFC (A) and in the left hippocampus (B) of patients with FEP, when compared with patients with FEP and a history of cannabis use. *Source: Cunha et al. (2013) (reproduced with permission).*

frequently use cannabis because of its psychoactive effects, so a significant concentration of Δ^9-THC may be part of the cannabis they smoke, so it is expected that at least some degree of impairments would be present after a long period of cannabis use.

In order to investigate this hypothesis, we also divided the cannabis users with FEP into two groups, the first with patients with an abstinence period of at least 6 months (N = 10), and the second comprising patients with less than 6 months of abstinence (N = 18, including "current" users). Results indicated that cannabis users with FEP with a longer period of abstinence had less GM abnormalities than recent users, in the left and right hippocampus/parahippocampal gyrus, thus indicating that some negative effects of cannabis on the brain may depend on the period of abstinence. We conclude that some other factors (other than cannabis use) would explain the lesser GM reduction of psychotic patients with a history of cannabis use. For them, contrary to those who developed psychosis without exposure to such environmental risk factor, previous exposure to cannabis may have had an effect on the development of psychosis in a structurally "preserved" brain, but, after the illness onset, a persistent use of cannabis could lead to GM deficits (Cunha et al., 2013). In other words, cannabis use would affect the late neurodevelopmental processes, involving synaptic plasticity, leading to the development of psychosis, and the continued cannabis use could lead to cognitive deficits.

It is interesting to note that participants in our study also underwent cognitive testing composed by a brief neuropsychological battery, including Forward Digits (FD) and Backward Digits (BD), from the Wechsler Memory Scale (WMS-III) (Wechsler, 1997), measures of attention and working memory (executive functioning), respectively. In this same line, FEP patients with history of cannabis use had a more preserved pattern of executive functioning, when compared with those without history of cannabis use, more specifically with regard to verbal working memory (BD). In other words, patients with history of cannabis use present a more preserved ability to retain and manipulate "*on line*" verbal information while performing a task. Indeed, executive abilities are necessary to find, acquire, and sustain illegal cannabis use (Joyal, Hallé, Lapierre, & Hodgins, 2003). Another finding in this study linked the ability of working memory with GM morphology in the left superior frontal gyrus. Also, it is plausible to hypothesize that patients with more preserved cognitive functioning are precisely those who may be more interactive, less socially withdrawn, and tend to have better social skills, thus having greater propensity to contact with cannabis by peers-influence or not.

Last, but not least, it is very relevant to note that a subsample of our patients with history of cannabis use had significant greater mean IQ scores than those without history of drug use, thus indicating that a supposedly better premorbid IQ could influence the brain structure and neuropsychological measures (Bolla et al., 2002). This is consistent with the recent findings of Ferraro et al. (2013).

Taken together, both studies (Cunha et al., 2013; Schnell et al., 2012) are congruent with the idea that the group of cannabis users with FEP presented less GM reduction in some brain areas, and less cognitive deficits, than the usual patients with FEP, without cannabis use. For these patients, it is plausible to suggest that a psychotic disorder emerged in a more "structurally preserved" brain, probably associated with a better pattern of premorbid functioning, and a higher cognitive potential (Cunha et al., 2013; Meijer et al., 2012; Wobrock et al., 2013).

VENTRICULAR ALTERATIONS IN CANNABIS USERS WITH FIRST-EPISODE PSYCHOSIS

Studies involving volumetric measurements obtained by magnetic resonance imaging (MRI) have demonstrated ventricular enlargement in psychosis (Rosa et al., 2010). In consonance with GM abnormalities, however, studies investigating ventricular alterations in cannabis users with psychosis have shown heterogeneous findings.

Cahn et al. (2004) investigated 27 patients with ROS and cannabis use, and compared them with 20 patients with ROS without cannabis use, and they found a decreased asymmetry of the lateral ventricles in the cannabis-exposed patients.

In our study, we also investigated lateral ventricles (LVs), measured by manual tracing ROI approach (Rosa et al., 2010).

We found significant group differences in VBRs among groups (Table e6.2). Patients with FEP without cannabis use had significant larger left LV and right TH, when compared with the control subjects. At the same time, they present an enlarged left LV, when directly compared with those from cannabis users with psychosis. There were no correlations between VBRs and neuropsychological measures. The absence of alterations in ventricular volumes in patients with FEP and a history of cannabis use would confirm a more preserved pattern of brain structure in these patients, when compared with those with FEP without history of cannabis use, which is compatible with our data on GM described before. In a prospective study, Rais et al. (2008) also observed a more preserved pattern of ventricles in patients with FES at baseline. However, after the period of 5 years, they found a more pronounced lateral ventricle enlargement,

TABLE e6.2 Ventricular Measures in Patients with FEP With History of Cannabis Use, FEP Without Cannabis Use, and Healthy Controls

VBR	FEP with cannabis use (FEP C+)	FEP without cannabis use (FEP C–)	Healthy controls (HC)	*Statistics* (*p* value)	
				FEP C– vs HC	*FEP C– vs FEP C+*
Right LV	0.0041 (0.0015)	0.0047 (0.0021)	0.0041 (0.0026)	0.082	0.727
Left LV	0.0042 (0.0017)	0.0054 (0.0026)	0.0045 (0.0026)	0.016	0.06
Right TH	0.00032 (0.00008)	0.00039 (0.00017)	0.00032 (0.0001)	0.015	0.126
Left TH	0.0003 (0.0001)	0.00036 (0.0002)	0.0003 (0.0001)	0.145	0.549

Note: VBR (ventricle-to-brain ratio) is expressed as a percentage (%) of the brain volume that is occupied by the region of interest; numbers are expressed by means (s.d.); *LV*, lateral ventricle; *TH*, temporal horn.

and third ventricle increase in cannabis-using patients. Also, altered ventricles were associated with more problems in daily life functioning (Rais et al., 2008).

BRAIN CHANGES AND COGNITIVE FUNCTIONING IN PSYCHOTIC CANNABIS USERS OVER TIME

Despite the fact that cannabis users with psychosis present less brain abnormalities and less cognitive deficits, it does not mean that these patients will not develop some degree of deficits. In a prospective study, cannabis-using psychotic patients presented similar cortical thickness, when compared with noncannabis users at baseline, but, after a period of 5 years, they showed progressive alterations in the dorsolateral PFC, and in the ACC (Rais et al., 2010), as well as decreased GM, and larger lateral and third ventricle volumes (Rais et al., 2008). Patients with FEP who continue to use cannabis after illness onset are particularly vulnerable to brain alterations in areas rich in CB1 receptors, related to negative symptoms and to poorer cognitive functioning (Rais et al., 2010). Problems in the ACC could have a role in poor decision-making, and in choosing more risky outcomes in patients with FEP and a history of cannabis use, which could contribute to substance-taking behavior (Szeszko et al., 2007).

It is possible that the development of psychosis should involve genetic factors that are associated with differential cerebral cortical sensitivity to developmental environmental exposures such as cannabis use, and exposure to emotional trauma (Habets, Marcelis, Gronenschild, Drukker, & van Os, 2011). In this line, cannabis may amplify the preexistent brain vulnerability associated with psychosis, but the mechanism by which cannabis may cause neuronal damage in patients with FEP remains unclear (Rais et al., 2008). Future and prospective studies are needed to better characterize the effects of cannabis use on brain structure and cognitive functioning in patients with psychosis.

CONCLUSIONS

While psychosis is often associated with neurodevelopmental deficits, including brain structural and executive abnormalities, cannabis users who develop psychosis are more likely to present a relatively "preserved" brain, and less deficits in executive functioning, at least at the beginning of the disorder, depending on their premorbid functioning. As cannabis use progresses, it is possible that the patient will have more executive deficits and brain structure abnormalities, such as GM reductions and lateral ventricle enlargements. Neuroimaging data presented here suggest that individuals with psychosis would be represented by those patients with a higher degree of neurodevelopmental involvement and greater brain abnormalities, whereas individuals with psychosis and cannabis use would be represented by patients with exposure to other environmental risk factors, such as cannabis, in their causal pathway. In clinical practice, it would be relevant to develop strategies aiming to prevent cannabis use among adolescent individuals and young people, especially those with prodromal symptoms, and a family history of psychosis. Also, early implementation of rehabilitation strategies for patients with FEP could help them prevent relapse on cannabis use for a better prognosis.

MINI-DICTIONARY

Amygdala A subcortical brain region mostly associated with emotional processing.
Cognitive functioning A set of mental functions, including attention, memory, language, executive functioning, and intelligence.
Executive functioning Complex cognitive functions that involve motivation, planning/abstracting, executing, and evaluating the result of a complex task.
First-episode psychosis (FEP) First occurrence of a psychotic episode that usually includes major psychiatric symptoms such as delusion, hallucination and/or motor agitation. Psychosis is basically characterized by the loss of contact with reality.

Frontotemporal brain regions Areas integrating the frontal and temporal cortex of the brain.
Hippocampus Brain area located in the temporal cortex that is predominantly associated with memory and learning new information.
Negative symptoms Common symptoms in patients with psychosis characterized by lack of drive, motivation and energy (ie, apathy), as well as social withdrawal and diminished affective/speech/motor responsiveness.
Prefrontal cortex (PFC) The anterior part of the cortex.
Prodromal symptoms or "at risk mental state" (ARMS) A set of symptoms and clinical signs that might indicate the beginning of a disease such as psychosis. They may include unusual thinking (ie, suspiciousness, thoughts of death, among others), mental confusion, anxiety, less intense perceptual alterations, persistent lack of motivation, and decline in cognitive and social functioning.
Subcortical areas Brain areas under the "cortex;" subcortical areas are basically composed by white matter (WM).
Ventricles They are basically "cavities" inside the brain, filled of cerebrospinal fluid (CSF).

Cannabis Use and Attention-Deficit/Hyperactivity Disorder: Potential Moderators

K.E. Maple, N.E. Wright, K.M. Lisdahl

Department of Psychology, University of Wisconsin-Milwaukee, Milwaukee, WI, United States

SUMMARY POINTS

- The literature remains unclear regarding whether ADHD is a risk factor for, or a consequence of, cannabis use.
- In some samples, childhood ADHD no longer predicts subsequent cannabis use, after controlling for ODD and CD symptoms.
- Some evidence suggests that deviant peer relationships and cigarette use may mediate the relationship between childhood ADHD and later cannabis use.
- Only one known study has investigated neurocognitive functioning in cannabis users with comorbid ADHD. Neuroimaging and longitudinal studies are needed to further investigate this population.
- Greater understanding of the impact of THC and CBD content on neurocognition may provide insight into the relationship between cannabis use and psychiatric problems.

KEY FACTS OF THC:CBD RATIOS IN THE IMPACT OF CANNABIS USE

- CBD has been shown to reduce anxiety in some studies.
- One study suggests that THC increases heart rate, anxiety, and psychosis-like symptoms, compared to either CBD or placebo.
- Decreased preference for cannabis has been associated with higher CBD:THC ratios.
- Using cannabis with increased THC:CBD ratios has been associated with earlier onset of psychosis, while higher CBD content is associated with experiencing fewer psychotic symptoms.
- Cannabis with higher CBD content may be associated with diminished memory impairment, after acute intoxication.
- THC content in many cannabis samples is drastically increasing, while CBD is decreasing.
- More longitudinal studies are needed in adolescent samples to assess the long-term effects of chronic cannabis use, with varying THC:CBD ratios.

INTRODUCTION

Cannabis use is often comorbid with other psychiatric disorders, including attention-deficit/hyperactivity disorder (ADHD), mood disorders, and schizophrenia (Tims et al., 2002; Agosti, Nunes, & Levin, 2002). This chapter will explore the association between cannabis use and ADHD, supplementing other chapters in this volume, which focus on the cooccurrence of cannabis use with mood disorders and psychotic disorders. Secondly, an emerging field of research suggests that cannabis content may influence the relationship between psychiatric disorders and cannabis use. Two cannabis components, Δ^9-tetrahydrocannabinol (THC) and cannabidiol (CBD), may have differential effects on cognition and mood. Thus, we will also review studies of THC and CBD levels, which might partially explain differential findings in the cannabis use comorbidity literature.

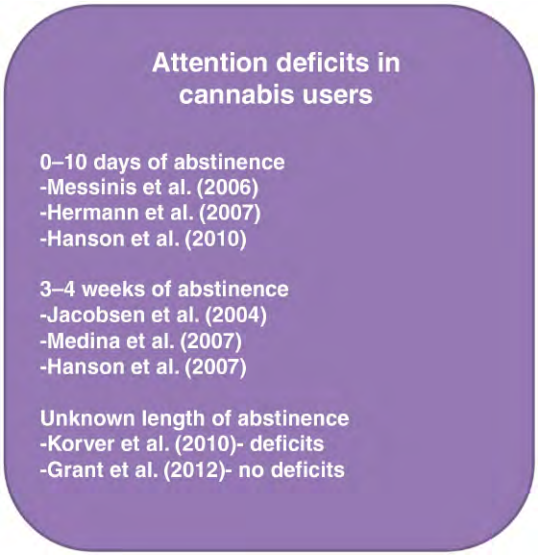

FIGURE e7.1 Attention deficits in cannabis users. Overview of studies examining attention deficits in cannabis users at various levels of abstinence.

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER AND CANNABIS USE COMORBIDITY

Several studies support an association between chronic cannabis use and poor attention and executive functioning, in adolescents and adults without comorbid psychiatric disorders (for reviews, see Crane, Schuster, Fusar-Poli, & Gonzalez, 2013; Lisdahl, Wright, Medina-Kirchner, Maple, & Shollenbarger, 2014). After 3 days or fewer of abstinence, sustained and executive attention deficits have been found in adolescent and adult cannabis users (Hermann et al., 2007; Hanson et al., 2010). Messinis, Kyprianidou, Malefaki, and Papathanasopoulos (2006) found decreased psychomotor speed and sustained attention in adults who were abstinent 1–10 days prior to testing. Deficits in complex and sustained attention persist 3–4 weeks after abstinence, in samples that exclude for childhood ADHD diagnosis (Jacobsen, Mencl, Westerveld, & Pugh, 2004; Medina et al., 2007; Hanson et al., 2010). After an unknown period of abstinence, some studies have found cannabis-related attention differences (Korver et al., 2010), while others have found none (Grant, Chamberlain, Schreiber, & Odlaug, 2012). Age of cannabis use onset may also be related to attention problems. Early onset (before age 16) was associated with impaired reaction times on a visual scanning task, within a group of cannabis using adolescents and young adults, but not other measures of attention, such as alertness, divided attention, and flexibility (Ehrenreich et al., 1999) (Fig. e7.1).

It is also possible that prenatal cannabis exposure or regular cannabis use in youth may predict childhood ADHD symptoms. Increased cannabis use during pregnancy has been associated with sustained attention deficits at the age of 4 (Noland et al., 2005), as well as increased hyperactivity, impulsivity, and inattention problems at the age of 10 (Goldschmidt, Day, & Richardson, 2000). Taken together, the literature indicates that chronic cannabis use is often associated with long-term sustained and divided attention problems, particularly in youth. According to the *Diagnostic and Statistical Manual for Mental Disorders—Fifth Edition* (DSM-V), ADHD is diagnosed in individuals surpassing a threshold level of either inattentive, hyperactive, or combined inattentive/hyperactive problems (American Psychiatric Association, 2013).

Cross-sectional research has indicated that increased ADHD symptoms are associated with greater cannabis use, and cannabis use disorders (CUD), in adolescence and adulthood (De Alwis et al., 2014a; Tims et al., 2002; Walther, Morgenstern, & Hanewinkel, 2012). For example, Loflin, Earleywine, De Leo, and Hobkirk (2014) reported that daily cannabis users are more likely than moderate (5–30 days/month) or casual ($\leq$5 days/month) users to meet ADHD criteria in adults aged 18–74. In addition, more daily users were of the ADHD combined or hyperactive/impulsive subtypes than of the inattentive subtype, suggesting that cannabis use may be more prevalent in ADHD individuals with hyperactive/impulsive symptoms (Loflin et al., 2014). However, as Loflin et al. (2014) note, they did not account for additional substance use or comorbid psychiatric disorders; therefore, confounding factors may be driving the relationship between ADHD and cannabis use. Further, this study did not measure childhood ADHD diagnosis, but rather used a current symptom questionnaire; therefore, it is

not possible to disentangle whether the ADHD symptoms were independent from cannabis use exposure.

Approximately half of those with childhood ADHD will demonstrate persistent ADHD into adulthood (Halperin, Trampush, Miller, Marks, & Newcorn, 2008; Lara et al., 2009), driven primarily by inattention symptoms (Faraone, Biederman, & Mick, 2006). Regular cannabis use in individuals with ADHD may exacerbate symptoms of inattention and executive functioning, placing teens at increased risk for having persistent clinical symptoms into adulthood. Indeed, one longitudinal study found that cannabis use between the ages of 15–25 predicted persistence of ADHD symptoms at the age of 25 (Fergusson & Boden, 2008). Among a sample of adult treatment-seeking primary cocaine abusers, those with adult ADHD had a lower age of cannabis use initiation, compared to those with no history of ADHD (Perez de los Cobos et al., 2011). None of those in the ADHD sample had been previously diagnosed with childhood onset ADHD, suggesting their adult ADHD diagnosis may be dependent upon their adolescent substance use. Thus, preliminary data suggest that early cannabis exposure may be a risk factor for developing ADHD symptoms, or increasing one's risk for having persistent ADHD symptoms into adulthood.

Several studies have attempted to determine the direction of causality between cannabis use and ADHD (for a metaanalytic review, see Charach, Yeung, Climans, & Lillie, 2011). Adolescent boys with high familial risk of substance use score higher on measures of hyperactivity, compared to controls, suggesting a shared genetic factor for hyperactivity and substance use, in general (Aytaclar, Tarter, Kirisci, & Lu, 1999). Elkins et al. (2007) concluded that hyperactivity and inattentive symptoms in early adolescence (M_{age} = 11 years) predicted increased substance use, including cannabis abuse and dependence, at two follow-up points (M_{age} = 14 years, and M_{age} = 18 years). Similarly, Hechtman et al. (1984) conducted a longitudinal study following both children diagnosed with hyperactivity between ages 6–12 and healthy controls. Ten years later, significantly more hyperactive children than controls had tried cannabis or hashish, although there was no difference in past 3 month use levels.

Retrospective studies have also provided evidence for ADHD symptoms predicting later cannabis use (Fig. e7.2). A study of adolescent males determined that those with a history of childhood ADHD had an earlier onset, and more severe history of cannabis use, compared to those without an ADHD history (Kousha et al., 2012). Three studies of young adults determined that both increased hyperactive and inattentive symptoms before the age of 18 predicted lifetime cannabis use, and incidence of CUD (Murphy et al., 2002; Ameringer & Leventhal, 2013; De Alwis et al., 2014b). Alternatively, Lambert and Hartsough (1998) found no differences between adults diagnosed with childhood ADHD and

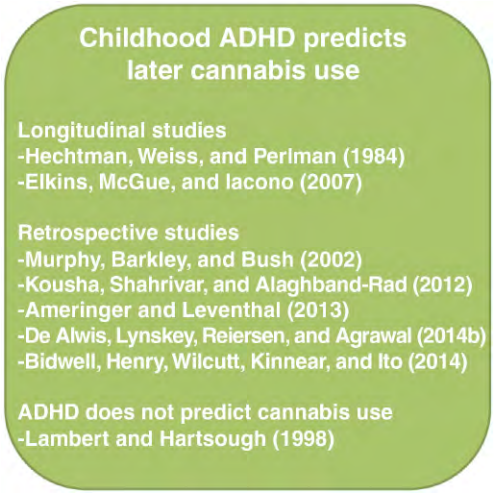

FIGURE e7.2 Associations between ADHD and cannabis use. Overview of studies examining the relationship between ADHD and subsequent cannabis use.

controls on measures of cannabis use. Other evidence indicates that inattention and hyperactivity may differentially predict later cannabis use. Bidwell et al. (2014) found that while inattentive symptoms in childhood were related to more cannabis use and craving in young adulthood, childhood hyperactivity symptoms were related to earlier cannabis use onset. Therefore, it is possible that cannabis use outcomes may depend on specific ADHD symptoms. Therefore, childhood ADHD diagnosis places one at increased risk for cannabis use, earlier age of cannabis use onset, and developing CUD.

Other externalizing disorders, including oppositional defiant disorder (ODD) and conduct disorder (CD), are often comorbid with ADHD, and may also be associated with cannabis use outcomes (Angold, Costello, & Erkanli, 1999) (Fig. e7.3). ADHD, CD, and ODD at the age of 11 have been shown to independently predict cannabis use

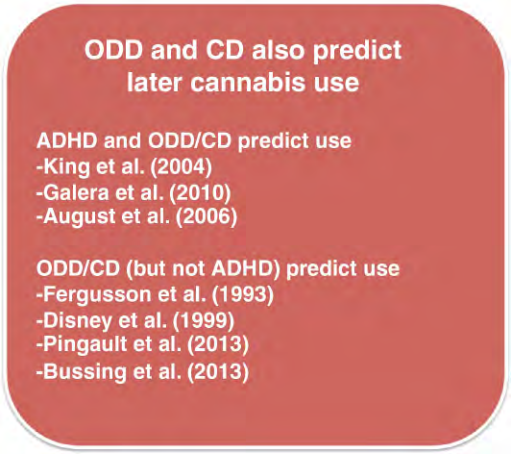

FIGURE e7.3 Associations between ADHD, ODD/CD, and cannabis use. Overview of studies examining the relationship between ADHD and ODD/CD and subsequent cannabis use.

initiation, and monthly use, by the age of 14 (King, Iacono, & McGue, 2004). In males, increased hyperactive-inattentive and CD symptoms in childhood (ages 4–18) have been associated with higher levels of cannabis use onset 8 years later (Galéra et al., 2010). August et al. (2006) found that those diagnosed at aged 11–16 with childhood ADHD, combined with either CD or ODD, reported greater lifetime cannabis use at ages 17–19, compared to both controls and those with only ADHD. In fact, some evidence suggests that the association between ADHD and cannabis use disappears, after controlling for CD and ODD. In one study, conduct problems in middle childhood predicted cannabis use by the age of 15, and early ADHD did not predict cannabis use after controlling for the association between ADHD and CD (Fergusson, Lynskey, & Horwood, 1993). Furthermore, Pingault et al. (2013) assessed behavioral problems in children aged 6–12, and then measured cannabis use at the age of 21. Opposition was the only predictor of adult cannabis use; inattention, hyperactivity/impulsivity, anxiety, and depression were not associated with cannabis outcomes. Similarly, Bussing, Mason, Bell, Porter, and Garvan (2010) observed that ODD, but not ADHD, at the ages of 5–11 increased risk of cannabis use 8 years later. In yet another study, CD, but not ADHD, was associated with cannabis use in 17-year-olds (Disney, Elkins, McGue, & Iacono, 1999). On the other hand, within a sample of first-episode psychosis (FEP) patients, greater childhood inattention problems, but not hyperactivity, ODD, or CD, predicted lifetime cannabis use and difficulty maintaining cannabis use abstinence during FEP treatment (Cassidy, Joober, King, & Malla, 2011). It is possible that comorbidity with psychosis might moderate the relationship between cannabis use and externalizing problems, although more research is needed. Thus, whether ADHD predicts cannabis use independently of CD and ODD in otherwise healthy samples remains unclear. It has been proposed that ADHD, CD, and ODD share underlying socioemotional dispositions, including prosociality, negative emotionality, and daring (Taylor, Allan, Mikolajewski, & Hart, 2013). Therefore, it is possible that individuals with ADHD possessing more aspects of the shared dispositions are at increased risk for cannabis use.

Mediating factors may also help explain the link between ADHD and cannabis use. Affiliation with deviant peers may drive the relationship between childhood ADHD and past 6-month adolescent cannabis use (Marshal, Molina, & Pelham, 2003). Moreover, Korhonen et al. (2010) demonstrated that cigarette use at the ages of 12–15 mediated the relationship between parent reports of externalizing behaviors (conduct, oppositional, and attention-deficit/hyperactivity problems) at the ages of 10–12, and cannabis use at age 15–18. Therefore, further research should investigate the specific mechanisms driving the relationship between externalizing disorders and cannabis use.

Considering that ADHD is twice as prevalent in males as in females (American Psychiatric Association, 2013), gender may moderate the relationship between cannabis use and ADHD symptoms. For example, hyperactivity and inattention symptoms in childhood may be related to increased cannabis use 8 years later in males, but not females (Galéra, Bouvard, Messiah, & Fombonne, 2008). In contrast, in a study of adolescents aged 12–16, childhood ADHD was marginally associated with cannabis use in females, but not in males (Ostojic, Charach, Henderson, McAuley, & Crosbie, 2014). More research is needed to examine the influence of gender on cannabis use outcomes, in those with ADHD.

Only one known study to date has investigated neurocognitive functioning in those with comorbid ADHD and cannabis use. Executive functioning was assessed in regular cannabis users and nonusers, with and without a childhood diagnosis of ADHD (Tamm et al., 2013). Importantly, individuals were excluded for weekly binge drinking, and excessive other substance use. Tamm et al. (2013) found that nonusers without ADHD performed significantly better than those with ADHD on tests of verbal memory, processing speed, cognitive interference, decision-making, working memory, and response inhibition. However, no differences were found between cannabis users and nonusers on any executive functioning tasks. In addition, there were no interactions between ADHD and cannabis use. Although no effects for cannabis use were determined, those who started using cannabis regularly before the age of 16 performed significantly worse on tests of decision-making, working memory, and response inhibition than those who initiated use at a later age. Further, it is notable that only recent (past year) cannabis use was closely measured, so those in the "nonuser" group could have previous years of heavy cannabis exposure. Therefore, this study suggests that recent cannabis use may not worsen executive functioning abilities in emerging adults with childhood ADHD. However, early onset of regular cannabis use was associated with significantly worse executive functioning in those with ADHD. Given the high comorbidity and these initial findings, additional studies are needed to explore the relationship between cannabis use, ADHD, and neurocognition. Neuroimaging studies, in particular, are needed to characterize the independent and interactive effects of cannabis use and ADHD on brain functioning.

IMPACT OF THC AND CBD CONTENT

Cannabis samples differ in levels of THC and CBD, two major psychoactive components of the drug. Due to the unique effects of each, varying levels of THC and CBD may contribute to neurocognitive differences observed in both comorbid and healthy cannabis users.

As THC is the major psychoactive component of cannabis, it has received the largest proportion of attention from the scientific community. However, CBD has emerged as a potentially neuroprotective, antipsychotic, and antianxiety agent (for full review, see Niesink & van Laar, 2013). A single dose of CBD can reduce anxiety in individuals with social anxiety disorder, during a speech (Bergamaschi et al., 2011). In comparison to placebo, THC alone, and THC + CBD, oral inhalation doses of CBD have been shown to increase emotion recognition (Hindocha et al., 2014). CBD administered in an inhaler reduced cigarette smoking in treatment-seeking tobacco smokers (Morgan, Das, Joye, Curran, & Kamboj, 2013). CBD has also been suggested as a possible treatment for cannabis dependence, as using cannabis with a higher CBD:THC ratio has been associated with decreased preference for cannabis (Morgan, Freeman, Schafer, & Curran, 2010). In a study comparing almost pure THC, CBD, and placebo in healthy volunteers, THC was found to increase heart rate, anxiety, and psychosis-like symptoms significantly more than either CBD or placebo (Martin-Santos et al., 2012). Notably, in this study there were very few differences between CBD and placebo, suggesting that, in this sample, CBD did not have as strong an anxiolytic effect as has been previously found (Fig. e7.4).

Other psychological and physical symptoms have been analyzed (Fig. e7.5). Examining psychosis symptoms, using higher THC potency, "skunk-type," cannabis has been associated with earlier onset of psychosis, compared to using cannabis with a higher THC:CBD ratio (Di Forti et al., 2009, 2014). Higher CBD content has also been associated with experiencing fewer psychotic symptoms (Schubart et al., 2011). Therefore, THC:CBD content could provide one explanation for the complicated literature on cannabis use and psychosis. In a naturalistic study, Morgan et al. (2010) found that individuals who smoked cannabis high in CBD content, regardless of THC content, did not have memory impairments, following acute intoxication. Using a similar sample, Morgan et al. (2010) also found high CBD:THC content to predict significantly fewer drug and food attentional biases. In rhesus monkeys, acute effects of THC + CBD reduced some cognitive deficits (Wright, Vandewater, & Taffe, 2013). Yet other studies have found CBD to be less influential, or even found CBD to be harmful. For example, in male adolescent rats, CBD has been shown to potentiate the effects of equal doses of THC, when given repeatedly over a 21 day period, resulting in significantly greater THC levels in their blood content in CBD + THC rats than in THC rats alone, as well as an increase in anxiety levels (Klein et al., 2011). Male rats have also been shown to have either no difference in THC-induced hypothermia or hypolocomotion, when treated or pretreated with CBD and, at times, those who had been exposed to CBD had exaggerated symptoms of hypothermia (Taffe, Creehan, & Vandewater, 2014). More research is needed to clarify the mechanisms and effects of CBD on symptomologies such as psychosis and anxiety.

Magnetic Resonance Imaging (MRI) studies have also indicated differences due to THC:CBD content and exposure. Individuals using cannabis with high THC or low CBD content have been found to have smaller right anterior hippocampal gray matter volume (Demirakca et al., 2011). CBD has also been found to reduce anxiety response in a functional MRI (fMRI) emotion processing task (Fusar-Poli et al., 2009). In an attention task of occasional cannabis users, acute doses of THC or CBD had opposite effects in various attention regions, such that if one resulted in increased connectivity, the other attenuated similar regions (Bhattacharyya et al., 2014). Specifically, THC was associated with reduced frontostriatal connectivity, while CBD increased connectivity in these regions. On the other hand, CBD diminished

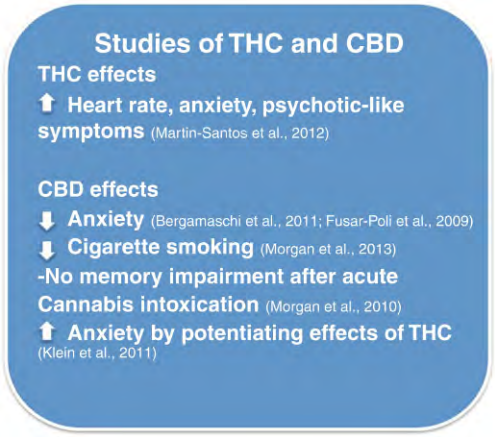

FIGURE e7.4 The effects of THC and CBD. Overview of studies examining the effects of THC and CBD.

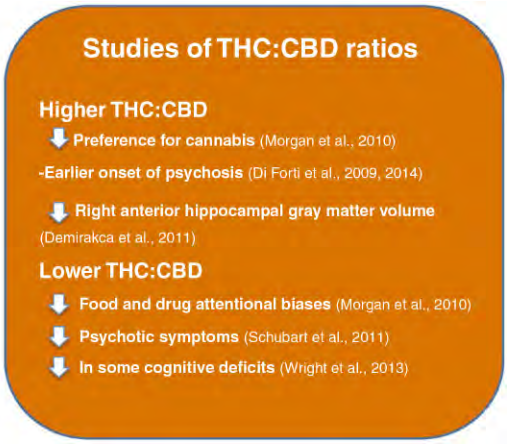

FIGURE e7.5 The effects of differential THC:CBD ratios. Overview of studies examining the effects of THC:CBD ratios.

mediotemporal-prefrontal connectivity, while THC strengthened it (Bhattacharyya et al., 2014). Together, this preliminary evidence suggests there may be neuroanatomical and neuronal functioning differences as a result of THC and CBD concentration.

As THC content is increasing (more than doubling), while CBD content is decreasing and consistently low, in marijuana samples in places like California (Burgdorf, Kilmer, & Pacula, 2011), greater understanding of the neurocognitive influences of CBD is essential for making more informed decisions regarding potential policy implications. Further, as most studies have thus far only looked at the acute effects of THC:CBD when intoxicated (eg, Fusar-Poli et al., 2009; Wright et al., 2013), more longitudinal studies examining chronic exposure are needed.

CONCLUSIONS AND FUTURE DIRECTIONS

Investigation into the effects of cannabis use in comorbid populations, including those with ADHD, is a relatively new field. While many studies report attention problems in cannabis users, the literature is still mixed regarding whether these deficits are premorbid, or if they emerge as a result of cannabis use. Some studies suggest that other factors, such as delinquent peer relationships, comorbid ODD, CD, or cigarette use may be responsible for increased cannabis use in ADHD individuals. Additionally, males and females with ADHD may have different patterns of cannabis use. Therefore, more research is needed in order to determine the specific relationships between cannabis use, ADHD, and other influences as gender and comorbidities. Notably, there is a significant dearth of research on the interactive effects of cannabis use and ADHD on neurocognition, and whether cannabis use during adolescence places individuals with childhood ADHD at increased risk for having persistent adult ADHD symptoms. Longitudinal and neuroimaging studies, in particular, may clarify neurocognitive vulnerabilities specific to ADHD patients who use cannabis. Furthermore, it is possible that inconsistent findings in the cannabis comorbidity literature are due to THC potency in cannabis (Di Forti et al., 2009, 2014). Longitudinal studies may help characterize the effects of chronic exposure to differing THC and CBD levels. Overall, further investigation into the relationships between cannabis use and both ADHD and THC:CBD content is needed.

MINI-DICTIONARY

Attention-deficit/hyperactivity disorder A psychiatric disorder involving either significant inattentive symptoms, significant hyperactive symptoms, or both, that lead to impaired functioning.

Cannabidiol Another psychoactive cannabinoid found in cannabis that is thought to be neuroprotective against the negative effects of THC.

Cannabis use disorder Problematic cannabis use, leading to impairment. Possible symptoms include (but are not limited to) an increase in tolerance and withdrawal symptoms, unintended increase in cannabis use, strong craving or urge to use cannabis, or using cannabis in hazardous situations.

Cognitive interference This measures one's ability to disregard extraneous information in order to suppress an incorrect response to a stimulus.

Conduct disorder A psychiatric disorder involving a pattern of aggression toward people and animals, destruction of property, theft, or serious violation of rules.

Executive functioning A function of the prefrontal cortex, executive functioning is involved in regulating goal-directed behavior. Working memory is a component of executive functioning.

Oppositional defiant disorder A psychiatric disorder characterized by repeated irritability, argumentative behavior, or vindictiveness, lasting at least 6 months.

Processing speed The ability to quickly and accurately react to information in one's environment.

Psychosis A psychiatric condition defined by delusions, hallucinations, disorganized speech, or catatonic behavior that leads to impairment.

Response inhibition The ability to stop oneself from responding inappropriately.

Δ^9-Tetrahydrocannabinol The main psychoactive cannabinoid in the cannabis plant that is thought to be responsible for many of the drug's effects on the brain.

Working memory The ability to briefly retain and manipulate material in one's mind in order to produce a result.

Chronic Cannabis Abuse and Thyroid Function

U. Bonnet

Department of Psychiatry, Psychotherapy and Psychosomatics, Evangelisches Krankenhaus Castrop-Rauxel, Academic Teaching Hospital of the University of Duisburg-Essen, Castrop-Rauxel, Germany

SUMMARY POINTS

- Cannabinoid 1 (CB1) receptors are organized compactly along the central and peripheral thyroid hormone axis.
- Chronic cannabis smoking has only negligible effects on human thyroid function.
- TSH- and free T4-levels remained stable in the serum of regular, even heavier cannabis smokers.
- Thyroid function tests did not correlate significantly with serum THC-levels of chronic cannabis smokers.
- The results of the human studies argue against a relevant influence of regular or chronic cannabis consumption on thyroid function.

KEY FACTS OF THYROID HORMONES

- Trijodthyronine (T3) and thyroxin (T4) are produced by the thyroid gland, and are primarily responsible for regulation of metabolism. Iodine is necessary for the production of T3 and T4. Thyroxin (T4) is the major thyroid hormone in the blood. It has a longer half-life than T3. The ratio of T4 to T3 released into the blood is nearly 20 to 1. T4 is converted to the active T3 within thyroid follicular cells, via deiodinase. T3 is 3–4 times more potent than T4.
- Thyroxin-binding globulin (TBG) is one of three proteins (together with transthyretin and albumin) that bind T3 and T4 in blood. Of these three proteins, TBG has the highest affinity for thyroid hormones, and carries the majority of T4 in circulation.
- TRH is produced in the paraventricular nucleus of the hypothalamus, and spreads via blood stream to the anterior pituitary gland to stimulate TSH-synthesis, and release there. TSH can be also stimulated by cold temperature and hypoglycemia.
- TSH binds to a G-protein coupled TSH-receptor on the thyroid follicular cell, which stimulates the synthesis and release of thyroid hormones.
- Small changes in serum T4 are amplified by changes in serum TSH.
- Thyroid hormones increase basal metabolic rate, stimulate lipolysis/lipogenesis, increase in adaptive thermogenesis and stimulate β-oxidation of fatty acids (Mullur, Liu, & Brent, 2014).
- A deficiency of iodine leads to decreased production of T3 and T4, which enlarges the thyroid tissue via an increase of TSH, and will cause goiter.

KEY FACTS OF CANNABINOID RECEPTORS

- CB1-receptor is expressed in the hypothalamus and the pituitary gland, and CB1-receptor stimulation is known to modulate all the endocrine hypothalamic-peripheral endocrine axes (Pagotto, Marsicano, Cota, Lutz, & Pasquali, 2006).

LIST OF ABBREVIATIONS

CB1-receptor	Cannabinoid 1-receptor
HPT-axis	Hypothalamic-pituitary-thyroid axis
T3	Triiodthyronine
T4	Thyroxin

TGB	Thyroxin-binding-globulin
THC	Δ^9-Tetrahydrocannabinol
THC-COOH	11-nor-delta-9-tetrahydrocannabinol-9-carboxylic acid
THC-OH	11-hydroxy-delta-9-tetrahydrocannabinol
TRH	Thyrotropin releasing hormone
TSH	Thyroid stimulating hormone (thyrotropin)

INTRODUCTION

Cannabinoid 1 (CB1) receptors are organized compactly along the central and peripheral thyroid hormone axis (Fig. 47.1, Brown & Dobs, 2002; Porcella et al., 2002; Pagotto et al., 2006). Former reports have shown that acute administration of Δ^9-tetrahydrocannabinol (THC), the major psychoactive cannabinoid ingredient of cannabis, transiently reduced levels of thyroxine (T4) and thyroid-stimulating hormone (TSH) to a great extent, in rats (Nazar, Kairys, Fowler, & Harclerode, 1981). Furthermore, cannabis decreased the release of radioactive iodine from rats' thyroid (Lomax, 1970). Both depressing effects were reversed by exogenously applied TSH, which pointed to a hypothalamic site of action (Lomax, 1970; Nazar et al., 1981). Data about the effects of cannabis on thyroid function in humans are increasing. The author is aware of four studies, which addressed this subject (Table 47.1). These cohort-studies analyzed the thyroid function in patients who abused cannabis regularly, and did not consume any other illegal drug or alcohol (Rubin & Comitas, 1972; Parshad, Kumar, & Melville, 1983; Herning, Better, & Cadet, 2008; Bonnet, 2013). All investigated subjects were current nicotine smokers, or used tobacco to build cannabis-containing joints.

TABLE 47.1 Studies on the Thyroid-Function of Chronic Cannabis Consumers

Study	Study type and *N*	Population	Results	Comments
Rubin and Comitas (1972)	Epidemiologic study, *N* = ?	Jamaican chronic cannabis consumers (predominantly African-Americans)	No relevant functional impairment in the thyroid glands (reported in Parshad et al., 1983)	Study is no longer available, according to a request of the author to NIHM
Parshad et al. (1983)	Case-control study: 26 marijuana smokers versus 30 nonsmokers	Jamaican chronic cannabis consumers (predominantly African-Americans)	Serum total T4, TSH and T3-uptake were found to be not significantly different between both groups and also were all within normal limits	
Herning et al. (2008)	Case control study: 108 cannabis consumers versus 33 control subjects "cannabis group" was subdivided into two groups, one consuming marijuana less than 8 years ("MJ-short," *N* = 56) and the other consuming marijuana longer than 8 years ("MJ-long," *N* = 19)	Chronic cannabis consumers from US (75% African Americans)	"MJ-long"-group showed significantly lower total serum T4 levels and higher T3 uptake levels in comparison to the "MJ-short"-group and the control group. TSH remained stable in the whole active sample	Study primarily focused on EEG-abnormalities
Bonnet (2013)	Cohort study: 39 cannabis consumers seeking inpatient detoxification treatment	German chronic cannabis consumers (all Caucasian)	None of the patients had serum TSH, T3, and free T4 tests outside normal limits at admission	Serum levels of thyroid hormones did not correlate significantly with serum levels of THC, THC-OH or THC-COOH at admission

EFFECT OF CHRONIC CANNABIS USE ON HUMAN THYROID FUNCTION

The first two studies were performed on Jamaican chronic cannabis smokers, and found no relevant functional impairment in the thyroid glands in this population (Rubin & Comitas, 1972; Parshad et al., 1983). However, the study of Parshad et al. (1983), which compared 26 marijuana smokers with 30 nonsmokers, described significantly lower serum total T3-levels in smokers (Parshad et al., 1983). Serum total T4, TSH, and T3-uptake were found to be not significantly different between both groups, and also were all within normal limits (Parshad et al., 1983). In the case of the study of Parshad et al. (1983), the validity was weakened by vague description of the amount of the recent cannabis intake, and strengthened by a comparison with a control group .

The study of Herning et al. (2008), which primarily focused on EEG-abnormalities, comprised 108 individuals (22.8 ± 5.3 years old, 53% women, 75% African American). Among them, there were 75 marijuana-smoking individuals, and 33 control subjects (Herning et al., 2008), all of whom were not seeking treatment, and were selected from a larger National Institute on Drug Abuse (NIDA) sample. All subjects of the active "cannabis group" smoked marijuana between 15 and 30 days before study entry, a fact that ensured an actual burden with cannabis. Furthermore, this "cannabis group" was subdivided into two further groups, one consuming marijuana for less than 8 years ("MJ-short," $N = 56$), and the other consuming marijuana for longer than 8 years ("MJ-long," $N = 19$) (Herning et al., 2008). The following thyroid function tests were investigated in the serum of all groups: TSH, total T4, and T3-uptake, which also corresponds well with the concentration of thyroxin-binding-globulin (TGB) that carries free T4 and free T3 in blood.

There were no statistical significant differences between the control group and "MJ-short"-group, with respect to these thyroid function tests. However, the "MJ-long"-group showed significantly lower total T4 levels, and higher T3 uptake levels, in comparison to the "MJ-short"-group, and the control group. In the whole active sample, TSH remained stable, and there were only two subjects with abnormal thyroid function tests. Both subjects were in the "MJ-long"-group, and had lower total T4-levels and higher T3-uptake levels than normal (Herning et al., 2008). The latter reflected a reduced T4-level, or increased activity of hormone binding proteins. The validity of this study is strengthened by the control group, and weakened by the vague definition of the amount of the recent cannabis consumption in active groups.

The most recent study was performed by the author, with 39 cannabis-dependents, (28.6 ± 8 years old, 20.5% women, all Caucasian), according to ICD-10 (Bonnet, 2013). The patients were seeking treatment, and were voluntarily admitted for inpatient detoxification because of serious problems with cannabis. On average, this cohort reported to have smoked 2.5 ± 1.2 g cannabis nearly daily, for a period of 54.2 ± 62.5 months, and to be 9.9 ± 6.7 years dependent on cannabis. The patients were included in the study if they (1) had consumed cannabis by inhalation daily or almost daily during the 6 months before admission, (2) had consumed cannabis within 24 h before admission, (3) had used no other psychotropic substances (except tobacco) during 4 weeks before admission, and (4) had no active comorbid psychiatric or somatic disorder that could noticeably affect the course of cannabis detoxification treatment.

Thyroid function tests (TSH, total T3, free T4) were determined directly at admission. Simultaneously, the serum levels of THC and its two major metabolites, water-soluble THC-OH and lipid-soluble THC-COOH (Fig. 47.2; Grotenhermen, 2003) were measured. None of the patients had THC-levels below the detection limit (1.0 ng/mL). On average, levels of THC, THC-OH, and THC-COOH were 13.1 ± 23.8 ng/mL ($N = 30$), 4.3 ± 8.6 ng/mL ($N = 16$), and 146.4 ± 149.9 ng/mL ($N = 30$), respectively. These values underlined a substantial and sustained ("chronic") cannabis intake (Musshoff & Madea, 2006), and reflect the self-reported nearly daily abuse in the last weeks (Bonnet, 2013).

None of the included 39 patients had thyroid function tests outside normal limits. Furthermore, the serum levels of the thyroid hormones did not correlate significantly with the serum levels of THC or its metabolites, which suggested no relevant interplay between thyroid-hormones and the measured cannabinoids after chronic cannabis abuse. The validity of this study is

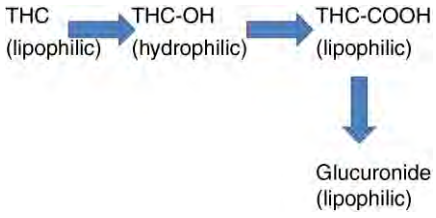

FIGURE 47.2 Main metabolic route for THC. THC is oxidized in humans mainly to 11-hydroxy-delta-9-tetrahydrocannabinol (THC-OH). This metabolite is also psychoactive, and degraded to non-psychoactive 11-nor-delta-9-tetrahydrocannabinol-9-carboxylic acid (THC-COOH). More than 100 different THC-metabolites have been identified, nearly all of which are not psychoactive. The metabolism takes place in the liver and substantially via the cytochrome P450 enzymes 2C9, 2C19, and 3A4. Due to their lipophilic properties, residual THC and metabolites are then stored in adipose tissue, from which they are removed only very slowly. More than 65% of the initial THC is excreted as metabolites in the feces, and approximately 25% in urine, a small part is broken down in the body itself. The main metabolites in urine are free THC-COOH and THC-COOH esterified with glucuronic acid, whereas THC-OH dominates in the feces (Musshoff & Madea, 2006).

strengthened by the clear definition of the amount of the recent cannabis consumption, and weakened by the missing control group.

DISCUSSION

Serum TSH values were within normal limits in the cannabis consuming cohorts of all studies (Rubin & Comitas, 1972; Parshad et al., 1983; Herning et al., 2008; Bonnet, 2013). A somewhat closer look is allowed by the studies of Parshad et al. (1983) and Herning et al. (2008), which found no significant differences between the TSH levels of regular cannabis smokers and normal controls. Even sustained heavier cannabis use was unable to put TSH-levels out of norm (Bonnet, 2013). In support, THC-levels from this sample were not significantly correlated with the thyroid function tests. Thus, regular cannabis intake seems to be not associated with appreciable changes in the thyroid function in human beings, as found in various ethnic cohorts, two with Jamaicans of African origin (Rubin & Comitas, 1972; Parshad et al., 1983), another dominated by African Americans (Herning et al., 2008), and a further with Caucasians (Bonnet, 2013).

In one study, the total T4-levels were found to be reduced, however, not before 8 months of cannabis consumption, while the T3-uptake increased (Herning et al., 2008). Because this study did not determine the free, nor the protein bounded hormone levels, the results might be influenced by an effect of cannabis on hormone-binding proteins, such as TGB.

The most recent study had the opportunity to determine the free T4 levels, which were all within the normal limits in patients with long-lasting and pronounced cannabis abuse (Bonnet, 2013).

Of note, all these studies on chronic cannabis abusers (Rubin & Comitas, 1972; Parshad et al., 1983; Herning et al., 2008; Bonnet, 2013) did not find any evidence for central hyperthyroidism, which has been described in two females suffering from cannabis hyperemesis syndrome (cyclic emesis that improved with hot bathing), after chronic cannabis abuse (Bonnet, Chang, & Scherbaum, 2012). Subclinical elevated TSH, free T4, and total T3 levels returned to normal within a few days of abstinence (Bonnet et al., 2012). In the light of the studies mentioned earlier, these abnormalities in the females' thyroid function tests could be based most likely on their emesis and loss of appetite, than on their chronic cannabis intake. Furthermore, there are experimental data that the activity of thermosensitive neurons is coupled to the activity of thyrotropin releasing hormone (TRH) in the hypothalamus (Salzman & Beckman, 1981) which would provide an explanation for a relationship between central hyperthyroidism and hot bathing, which is a typical feature of the cannabis hyperemesis syndrome (Allen, de Moore, Heddle, & Twartz, 2004; Wallace, Andrews, & Garmany, 2011).

Current nicotine smoking is associated with a slight dose-dependent fall of serum TSH, likely secondary to an increase of serum free T4 and free T3, induced by activation of the sympathetic nervous system (Wiersinga, 2013). This effect was not found in the studies mentioned earlier, which might be due to the inhibitory effect of repeated cannabis exposure on sympathetic activity (Jones, 2002).

Altogether, the results of the human studies argue against a relevant influence of regular or chronic cannabis consumption on thyroid function. An acute effect of cannabis on human thyroid function is not sufficiently investigated hitherto (Brown & Dobs, 2002). With respect to the results from animal experiments (Nazar et al., 1981; Brown & Dobs, 2002), one might suppose an acute depressant effect of cannabis also on human T4-release. Nonetheless, an acute pronounced fall in T4-levels could have been weakened by the development of tolerance in the regularly cannabis smoking cohorts, just as it was found in rats (Nazar et al., 1981).

Future detoxification studies with chronic cannabis addicts, which also analyze several thyroid function tests over time should give more insights in the finer effects of cannabis on human thyroid function. There exists no ultrasonography study of the thyroids of chronic cannabis addicts. Occurrence of goiter was not described in the studies presented previously.

MINI-DICTIONARY

Autonomic nervous system Part of the peripheral nervous system; acts largely below the level of consciousness to control visceral functions, such as digestion, heart rate, perspiration, breathing, salivation, swallowing, pupillary dilatation, and sexual arousal.
Cannabinoid receptors There are at least two known subtypes of cannabinoid receptors (CB1 and CB2); activation of CB1-receptor by THC mediates psychotropic (psychoactive) effects.
Cannabis hyperemesis syndrome Cyclic vomiting and emesis that improved with hot bathing. It emerges after chronic cannabis abuse, and shares many features with the cyclic vomiting syndrome.
Hyperthyroidism Overactive thyroid, develops when the thyroid gland produces and secretes excessive amounts of the free (not protein bound) thyroid hormones. Serum TSH is low, and free T4 is elevated. Graves' disease is the most common cause of hyperthyroidism.
Hypothalamus Located below the thalamus, and forms the ventral part of the diencephalon. It links the nervous system to the endocrine system, and is responsible for activities of the autonomic nervous system, including thermoregulation, sleep, and circadian rhythms.
Hypothyroidism Underactive thyroid, develops when the thyroid gland fails to synthesize or secrete as much thyroid hormones as the body needs, one of the most common diseases. Serum TSH is elevated, and serum free T4 is low.
Δ^9-Tetrahydrocannabinol (THC) Principal psychotropic constituent of cannabis; stimulates CB1-receptors.

Thyroid hormone Triiodthyronine (T3) and thyroxin (T4) are produced by the thyroid gland, and primarily responsible for regulation of metabolism. Iodine is necessary for the production of T3 and T4.

Thyroxin-binding globulin (TBG) One of three proteins (together with transthyretin and albumin) that bind T3 and T4 in blood. Of these three proteins, TBG has the highest affinity for thyroid hormones, and carries the majority of T4 in circulation.

CONFLICT OF INTEREST

The author received fees for lectures and the organization of training courses by the following pharmaceutical companies: Actelion, Boehringer-Ingelheim, Bristol-Myers Squibb, esparma, Glaxo-SmithKline, Janssen, Lilly, Lundbeck, Merz, and Servier.

Department of Psychiatry, Psychotherapy and Psychosomatics, Evangelisches Krankenhaus Castrop-Rauxel, Academic Teaching Hospital of the University of Duisburg-Essen, Castrop-Rauxel, Germany

SUMMARY POINTS

- Since its first description in 2004, the reports on CHS are mounting.
- In its core, CHS consists of cyclic periods with vomiting and, often, epigastric pain.
- Both symptoms improve with hot bathing or showering.
- CHS is often resistant to usual antiemetics.
- Haloperidol or lorazepam may be beneficial to suppress vomiting.
- Fluid and electrolyte replacements are essential basics in the treatment of CHS.
- Typically, CHS is remitted within 2–3 days after cessation of cannabis.
- In mysterious nausea or vomiting, a drug screen should be made.

KEY FACTS OF CHANGES IN CANNABIS POTENCY

- While cannabis users in the 1970s mainly smoked the leaves, cannabis users today prefer to smoke the more potent flowering tops, or buds of the plant (http://ncpic.org.au/ncpic/publications/factsheets/pdf/cannabis-potency).
- In 2009, the reported mean THC-content of hashish and marijuana (including sinsemilla—the form of herbal cannabis with the highest potency) ranged from 3% to 17%, and from 1% to 15% in Europe, respectively (http://www.emcdda.europa.eu/online/annual-report/2011/cannabis/2).
- Recent analysis of the cannabinoid-content of cannabis plants suggests a shift toward use of high potency plant material with high levels of THC and low levels of cannabidiol, in Australia (Swift, Wong, Li, Arnold, & McGregor, 2013).

KEY FACTS OF CYCLIC VOMITING SYNDROME

- Patients with cyclic vomiting syndrome (CVS) share many features with patients with CHS, such as compulsive hot water bathing to alleviate episodic nausea and vomiting.
- CVS can deteriorate over time to persistent symptoms lasting for weeks or even months (coalescent CVS) (Venkatesan et al., 2014).

LIST OF ABBREVIATIONS

CB1-receptor	Cannabinoid 1-receptor
CHS	Cannabis hyperemesis syndrome
CVS	Cyclic vomiting syndrome
THC	Δ^9-Tetrahydrocannabinol

INTRODUCTION

Since its first description, in Australia (Allen, de Moore, Heddle, & Twartz, 2004; de Moore, 2005), a mass of reports on cannabis hyperemesis syndrome (CHS) have been published worldwide (Patterson et al., 2010; Galli, Sawaya, & Friedenberg, 2011; Wallace, Andrews, & Garmany, 2011; Bonnet, Chang, & Scherbaum, 2012; Nicolson, Denysenko, Mulcare, Vito, & Chabron, 2012; Simonetto, Oxentenko, Herman, & Szostek, 2012; Gupta,

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00055-7

TABLE 48.1 Features of the CHS

Cyclical vomiting and emesis (core symptom)
Improvement by compulsive hot showering or bathing
Probable resistance to usual antiemetics
Complete resolution after cessation of cannabis (usually within 2–3 days)

Ojo, & Muruthettuwegama, 2013; Mohammed, Panchoo, Bartholemew, & Maharaj, 2013). CHS occurs after regular and, as a rule, longer lasting cannabis abuse. Its features are shown in Table 48.1.

Prodromal nausea prior to the onset of vomiting occurs in one-third of the cases (Nicolson et al., 2012). "Vomiting crises" itself are regularly accompanied by pronounced epigastric pain and, sometimes, by polydipsia and diaphoresis (Wallace et al., 2011; Nicolson et al., 2012; Simonetto et al., 2012). Hyperemesis can last over several days, and up to 6 months (Nicolson et al., 2012), before self-limiting, and it can reemerge with shorter symptom-free intervals, between the cycles. The patients would have usually gone several times through regional emergency and medical health service systems, often with extensive medical workup, before the physicians or the patients themselves attributed the symptoms to cannabis (Galli et al., 2011; Nicolson et al., 2012). CHS was found to occur in one out of a hundred detoxification treatments from cannabis (Bonnet et al., 2012). This certainly underestimates the true prevalence in real life, because most cases did not seek an addiction treatment (Wallace et al., 2011; Nicolson et al., 2012; Simonetto et al., 2012). CHS is not restricted to adults. In 2010, the first two pediatric cases were published (Miller et al., 2010). Most recently, the first case of "familial" CHS was described in father and daughter (Gupta et al., 2013).

PATHOGENESIS

The pathogenesis of CHS is not understood. As medical marijuana and its main psychoactive ingredient, Δ^9-tetrahydrocannabinol (THC), are antiemetic (Machado Rocha, Stéfano, De Cássia Haiek, Rosa Oliveira, & Da Silveira, 2008), the CHS can be assumed to be a paradoxical reaction to cannabis or THC (Patterson et al., 2010; Galli et al., 2011; Wallace et al., 2011). In contrast to the rather prompt antiemetic effect of medical marijuana, for example, in chemotherapy-induced vomiting (Machado Rocha et al., 2008), CHS occurred after regular, and often heavier cannabis consumption. This possibly points to a sensitization process (Bonnet et al., 2012). According to a large case series ($N = 98$), cannabis consumption prior to the onset of CHS lasted ≤1 year, 2–5 years, and ≥6 years in 32, 44, and 24% of the cases, respectively (Simonetto et al., 2012). The frequency of the cannabis consumption was daily in 59%, and 1–3 times per week in 25% of the cases (Simonetto et al., 2012).

Most hypotheses of the pathogenesis of CHS considered effects of chronic THC: (1) on the autonomic nervous system (inhibition of peristalsis, gastroparesis, and splanchnic vasodilatation). and (2) on the central nervous system (modulation of thermoregulatory and rhythm-forming relays in the hypothalamus, as well as emetic- and compulsion-controlling networks) (Patterson et al., 2010; Galli et al., 2011; Wallace et al., 2011; Bonnet et al., 2012; Nicolson et al., 2012; Simonetto et al., 2012). Chronic cannabis consumption may sensitize and stimulate the cannabinoid network in the gut to override the central antiemetic effect of THC, thereby inducing hyperemesis in susceptible individuals (Galli et al., 2011; Nicolson et al., 2012; Simonetto et al., 2012). Most recently, it was hypothesized that CHS is a subtype of cyclic vomiting syndrome (CVS), speculated to result from abnormal central regulation of predominantly gastrointestinal autonomic function. Exposure to adverse early life events, chronic stress, sleep deprivation, mood disorders, and chronic cannabis and/or opiate use, might lead to neuroplastic changes in central neural structures promoting chronically increased sympathetic responsivity that characterizes CVS-attacks (Levinthal & Bielefeldt, 2014). Moreover, cannabinoids other than THC, in crude cannabis, or the contamination of cannabis with, for example, lead, solvents, or pesticides, are speculated to be involved in the genesis of CHS (Galli et al., 2011; Nicolson et al., 2012).

The worldwide increase of cannabis consumption in combination with the simultaneously rising THC—and falling cannabidiol—contents in marijuana, due to selective breeding of the *Cannabis sativa* plant (Licata, Verri, & Beduschi, 2005; Knight et al., 2012; UNDOC, 2013; Swift et al., 2013) may have unmasked the CHS in cannabis addicts, in the last 10 years (Patterson et al., 2010; Galli et al., 2011; Wallace et al., 2011; Bonnet et al., 2012; Nicolson et al., 2012; Simonetto et al., 2012). In support, intravenous injection of THC or inhalation of herbal blends with admixed synthetic cannabinoids with stronger affinity to CB-1 receptors than THC, such as JWH 122 or JWH 210, were found to induce emesis (Vaziri et al., 1981; Hermanns-Clausen, Kneisel, Szabo, & Auwärter, 2013).

There are some ideas with respect to the improvement of the vomiting during hot baths. An increase of body temperature should (1) influence endocannabinoid-modulated thermoregulatory networks in the hypothalamus, which might readjust the sensitized emesis threshold (Chang & Windish, 2009; Bonnet et al., 2012), or (2) divert blood from the gut to the periphery, thereby

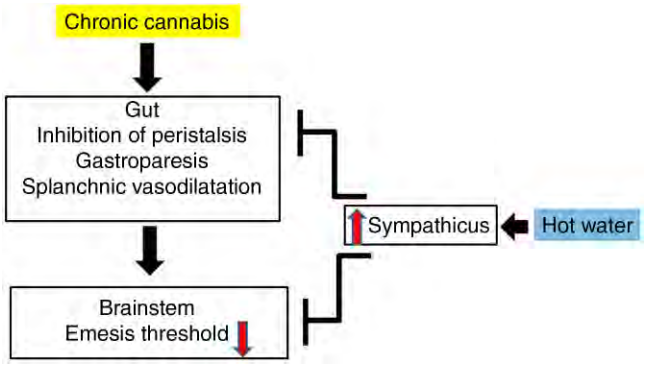

FIGURE 48.1 **Hypothetical mechanism of CHS.** Long-term repetitive (chronic) cannabis consumption repeatedly stimulates parasympathetic afferences, which are associated with a sensitization of the emesis threshold in the human brainstem. Hot water activates the sympathetic nervous system, which raises and readjusts emesis threshold.

limiting the effect of THC-induced splanchnic vasodilatation (cutaneous steel phenomenon) (Patterson et al., 2010), or (3) activate the sympathetic nervous system, which might increase the emesis threshold (Fig. 48.1).

TABLE 48.2 Differential Diagnoses of CHS

Psychogenic vomiting
Cyclic vomiting syndrome (CVS)
Intoxication or withdrawal symptoms
Hyperemesis gravidarum
Drug-seeking behavior
Eating disorders
Migraine
Elevated intracranial pressure
Gastrointestinal motility disorders, such as in Parkinson disease or diabetes mellitus
Pancreatitis
Gallbladder inflammation
Porphyria
Heart diseases
Renal diseases
Addison disease

DIAGNOSIS, COMPLICATIONS, AND TREATMENT

The physical and neurological examinations of patients suffering from CHS are strikingly unremarkable, so that a pure psychosomatic disease, such as psychogenic vomiting or cyclic vomiting, might be assumed (Allen et al., 2004; Wallace et al., 2011). A mild esophagitis or *Helicobacter pylori*-negative gastritis was frequently described (Galli et al., 2011; Nicolson et al., 2012), and suggested to be secondary to the often-pronounced vomiting. CHS did not improve with proton pump inhibitors (Galli et al., 2011). However, the differential diagnoses in Table 48.2 should be considered (Wallace et al., 2011; Nicolson et al., 2012; Bonnet et al., 2012).

Mental status may be influenced by the sequels of long-term cannabis consumption, such as cognitive and motivational impairments, psychosis, affective symptoms, or reduced drive (Hall & Degenhardt, 2009; Bonnet & Scherbaum, 2012). Chronic cannabis consumption is also associated with schizophrenia, bipolar disorder, and addiction to other illegal drugs or alcohol (Hall & Degenhardt, 2009; Bonnet & Scherbaum, 2012). It is assumed that alcohol may play a greater role in the vomiting of cannabis-addicted patients than they concede to their physicians (Nicolson et al., 2012).

Pronounced vomiting could be complicated with massive dehydrations, causing acute prerenal failure, and life-threatening electrolyte imbalances (Bramstedt & Dissmann, 2011). Therefore, fluid and electrolyte replacements are essential basics in the treatment of CHS (Bramstedt & Dissmann, 2011; Wallace et al., 2011). As the patients realized that their "vomiting crises" could be mitigated by hot bathing or showering, some of them showed self-inflicted skin scalds by hot tap water (Allen et al., 2004; Bonnet et al., 2012), or produced enormous water-bills (Fleig & Brunkhorst, 2011). One patient has possibly spent 300 of 365 days in the bathtub (Wallace, Martin, & Park, 2007).

Usual antiemetics, such as metoclopramide, domperidone, ondansetron, or promethazine, probably fail to relieve the vomiting (Wallace et al., 2011). There are some positive experiences with haloperidol (Hickey, Witsil, & Mycyk, 2013) and lorazepam (Cox, Chhabra, Adler, Justin Simmons, & Randlett, 2012) in emergency settings (Table 48.3).

The symptoms of the CHS could be a diagnostic conundrum, when the patients hide their cannabis consumption, and refuse to undergo regular urine or serum

drug-screenings. Characteristically, CHS disappeared with ongoing cessation of cannabis, and did not reoccur under this abstinence condition (Bonnet et al., 2012; Nicolson et al., 2012; Simonetto et al., 2012). Taken altogether, CHS is a somatic sequel of chronic cannabis abuse. Its prognosis clearly depends on the treatment of the cannabis addiction.

MINI-DICTIONARY

Autonomic nervous system Part of the peripheral nervous system; acts largely below the level of consciousness to control visceral functions, such as digestion, heart rate, perspiration, breathing, salivation, swallowing, pupillary dilatation, and sexual arousal.
Cannabidiol Nonpsychotropic phytocannabinoid in cannabis. It acts in some experimental models as an antiinflammatory, anticonvulsant, antioxidant, antiemetic, anxiolytic, and antipsychotic agent.
Cannabinoid receptors At least two known subtypes of cannabinoid receptors (CB1 and CB2); activation of CB1-receptor by THC mediates psychotropic (psychoactive) effects.
Endocannabinoids Specific neuromodulatory lipids endogenously produced in the brain, involved in a variety of physiological processes, including regulation of appetite, affect, pain sensation, and memory; ligands to cannabinoid receptors.
Helicobacter pylori Bacterium found in the stomach, associated with chronic gastritis and gastric ulcers, and also linked to the development of stomach and duodenal cancer. There is some evidence that it also has a protective effect against gastroesophageal reflux disease and its complications such as Barrett's esophagus, and esophageal adenocarcinoma.
Hypothalamus Located below the thalamus; forms the ventral part of the diencephalon. It links the nervous system to the endocrine system, and is responsible for activities of the autonomic nervous system, including thermoregulation, sleep, and circadian rhythms.
Medical cannabis Use of cannabis as medical therapy to treat disease or alleviate symptoms, such as nausea and vomiting in chemotherapy, or anorexia associated with AIDS, or pain and muscle spasticity in multiple sclerosis.
Prevalence The proportion of a population found to have a condition.
Sensitization Nonassociative learning process in which repeated administrations of a stimulus results in the progressive amplification of a response.
Synthetic cannabinoids Research chemicals to investigate the endocannabinoid system, for example, JWH 122 and JWH 210 bind 60- and 88-times stronger to CB1-receptor than THC, respectively.
Δ^9-Tetrahydrocannabinol (THC) Principal psychotropic constituent of cannabis; stimulates CB1-receptors.

CONFLICT OF INTEREST

The author received fees for lectures, and the organization of training courses by the following pharmaceutical companies: Actelion, Boehringer-Ingelheim, Bristol-Myers Squibb, esparma, Glaxo-SmithKline, Janssen, Lilly, Lundbeck, Merz, and Servier.

Cannabis and Cannabinoids and the Effects on Gastrointestinal Function: An Overview

M. Sałaga*, R. Abalo**,†, J. Fichna*

*Department of Biochemistry, Faculty of Medicine, Medical University of Lodz, Lodz, Poland
**Area of Pharmacology and Nutrition, Faculty of Health Sciences, University Rey Juan Carlos, Alcorcón, Madrid, Spain
†Associated Unit I+D+i of the Institute of Medicinal Chemistry (IQM) and of the Institute of Research in Food Sciences (CIAL), Spanish National Research Council (CSIC), Madrid, Spain

SUMMARY POINTS

- This chapter focuses on the role of both exo- and endogenous cannabinoids in gut homeostasis.
- It also refers to the localization of the endocannabinoid system (ECS) in the gut and its organization at the molecular level, and to the details of endocannabinoid degradation pathways involving enzymes, such as fatty acid amide hydrolase and monoacyl glycerol lipase.
- Various components of ECS, such as cannabinoid receptors, endogenous ligands, and degrading enzymes are located throughout the gastrointestinal tract.
- Not only "classical" components of the ECS, but also other receptors (such as GPR55) or ligands (such as *N*-palmitoylethanolamide) play important functions in the gastrointestinal tract.
- ECS modulates physiological functions of the gastrointestinal tract, such as food uptake, motility, and visceral sensation.
- Stimulation of cannabinoid receptors may alleviate pathological states in the gastrointestinal tract, such as inflammation and tumorigenesis.
- ECS is strongly involved in pain signaling, and cannabinoid receptors agonists may be used to alleviate abdominal pain.

KEY FACTS OF INFLAMMATORY BOWEL DISEASES

- Diagnosed in 1–2% of population.
- The prevalence of inflammatory bowel diseases (IBD) is higher in developed countries.
- Extraintestinal manifestations of IBD occur in 30% of patients.
- Crohn's disease (CD) may occur in all parts of the gastrointenstinal (GI) tract, while ulcerative colitis (UC) is located specifically in the colon.
- There are several disease susceptibility genes found on chromosomes 3, 7, 12, and 16.
- Smoking is an important environmental factor in IBD with different effects in UC and CD. Never smoking and formerly smoking increase the risk of UC, whereas smoking exacerbates the course of CD.

KEY FACTS OF IRRITABLE BOWEL SYNDROME

- The concept of an "irritable bowel" first time appeared in the Rocky Mountain Medical Journal, in 1950.
- Irritable bowel syndrome (IBS) symptoms may be reduced following antibiotic therapy for small intestinal bacterial overgrowth.
- Alternative methods, such as yoga and acupuncture, may alleviate the symptoms of IBS.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00056-9
Copyright © 2017 Elsevier Inc. All rights reserved.

- IBS is diagnosed more frequently in patients with mental disorders, such as depression, anxiety, or schizophrenia.
- Women are approximately 2–3 times more likely to be diagnosed with IBS than men. These differences likely reflect a combination of both biological and social factors.

LIST OF ABBREVIATIONS

Δ^9-THC	Δ^9-Tetrahydrocannabinol
2-AG	2-Arachidonoylglycerol
2-OG	2-Oleolylglycerol
AA-5-HT	Arachidonic acid–serotonin
AEA	*N*-arachidonoylethanolamine, anandamide
CB	Cannabinoid
CBD	Cannabidiol
CD	Crohn's disease
CNS	Central nervous system
CRC	Colorectal cancer
DNBS	Dinitrobenzene sulfonic acid
DSS	Dextran sodium sulphate
ECS	Endogenous cannabinoid system
EMT	Endocannabinoid membrane transporter
ENS	Enteric nervous system
FAAH	Fatty acid amide hydrolase
GI	Gastrointestinal
GLP-1	Glucagon-like peptide 1
GPCR	G-protein coupled receptors
IBD	Inflammatory bowel diseases
IBS	Irritable bowel syndrome
LPS	Lipopolysaccharide
MAGL	Monoacyl glycerol lipase
MAPK	Mitogen-activated protein kinase
OEA	*N*-oleoylethanolamide
PEA	*N*-palmitoylethanolamine
PGE2	Prostaglandin E2
PI3K-AKT	Phosphoinositide 3-kinase-protein kinase B
PPAR	Peroxisome proliferator-activated receptor
TLR4	Toll like receptor 4
TNBS	Trinitrobenzene sulfonic acid
TRPV1	Transient receptor potential vanilloid type 1
UC	Ulcerative colitis

INTRODUCTION

For centuries, it has been observed that the symptoms of several gastrointestinal (GI) diseases may be alleviated by plant-based remedies, such as those derived from the marijuana plant *Cannabis* sp., which can be used to treat a wide range of GI disorders, from enteric infections and inflammatory conditions, to functional and motility disorders, as well as emesis, and abdominal pain (Izzo & Sharkey, 2010).

Since Δ^9-tetrahydrocannabinol (Δ^9-THC), the major psychoactive compound of *Cannabis* was identified and isolated, molecular and mechanistic studies that focused on its effects emerged, and lead to the identification of its site and mechanism of action in the GI tract, long before the specific receptor was cloned in 1990 (for review see Izzo & Coutts, 2005; Izzo & Sharkey, 2010). Studies by Gill, Paton, and Pertwee (1970), and afterward by Roth (1978), showed that Δ^9-THC is able to inhibit electrically evoked cholinergic transmission in the myenteric plexus of the guinea pig ileum. They also demonstrated that the site of action of Δ^9-THC is located presynaptically or prejunctionally. These early observations, together with later in vitro and in vivo studies evidenced that cannabinoids (CBs) inhibit GI motility throughout the gut, which—at least partially—explained some of the therapeutic features of *Cannabis* (Izzo & Sharkey, 2010; Abalo, Vera, López-Pérez, Martínez-Villaluenga, & Martín-Fontelles, 2012).

Thereafter, the endogenous cannabinoid system (ECS), including endogenous CB agonists (AEA, 2-AG), endocannabinoid-like compounds (PEA, OEA, which are products of endocannabinoid turnover), and biosynthesis and degradation enzymes (phospholipase D, FAAH, and MAGL), were demonstrated in the gut. Exogenous as well as endogenous CBs are pleiotropic molecules, and activation of other receptors (TRPV1, PPAR, and GPCR-like GPR119), may contribute to their actions. In addition, endocannabinoid levels may be altered with the use of pharmacological tools, in particular inhibitors of enzymes responsible for their degradation, leading to potentially significant functional consequences in both physiological (eg, regulation of appetite) and patophysiological (eg, reduction of inflammation) conditions.

Herein, we will overview the role of the ECS in gut homeostasis, pharmacological actions of CBs, and the potential application of ECS-targeting drugs in the treatment of GI tract diseases.

LOCALIZATION OF ECS COMPONENTS IN THE GUT

Cannabinoid receptors type 1 and 2 (CB1 and CB2) are present in the enteric nervous system (ENS), as shown using immunohistochemical stainings. CB1 receptors are most abundant in myenteric and submucosal plexuses of the ENS (Izzo & Sharkey, 2010). Moreover, double-staining of CB1 receptors with markers of specific types of neurons (eg, calretinin, substance P) confirmed their presence on excitatory motor neurons, interneurons, and intrinsic primary afferent neurons, but not on inhibitory neurons expressing nitric oxide synthase (Coutts, Irving,

Mackie, Pertwee, & Anavi-Goffer, 2002; Izzo & Sharkey, 2010; Kulkarni-Narla & Brown, 2000). Importantly, both CB receptors are located on cholinergic neurons, as well as on epithelial cells of the colon crypts and lamina propria mononuclear cells of the colon (Salaga, Sobczak, & Fichna, 2014b; Di Sabatino et al., 2011).

Besides the "classical" CB receptors, there are other targets for CBs in the gut, including TRPV1 and PPARα, as well as GPR55 and GPR119 receptors. AEA and—to a lesser extent—OEA bind to TRPV1 receptors, with affinity lower than that for CB1 receptors. TRPV1 receptors are involved in visceral hypersensitivity signaling, and were found on the terminals of extrinsic primary afferent fibers, within the innervation of muscle layers, in cells adjacent to blood vessels and, at the highest density, in the myenteric plexus. Although most of the TRPV1 nerves are of spinal afferent origin, some of them originate from the vagal nerve. In certain conditions (eg, inflammation), activation of TRPV1 receptors by AEA may result in functional changes opposite to those observed upon activation of "classical" CB receptors, such as increased intestinal secretion and contractility (Izzo & Camilleri, 2009).

PPARα receptors, which share features of both "classical" ligand-activated receptors and ligand-activated transcriptional factors, are expressed throughout the whole GI tract. PPARα receptors may be found in enterocytes of the small intestine, and in enteric neurons of the myenteric and submucosal plexuses (Izzo & Sharkey, 2010). PPARα receptors are also expressed on enteric glial cells, where they may be indirectly activated by PEA through TLR4-dependent pathway; such activation results in improvement of colitis (Esposito et al., 2013).

GPR55 and GPR119 are, to date, the newest among all discovered targets for ECS-related compounds. GPR55 were found in several peripheral tissues, including the GI tract (jejunum, ileum, colon, pancreas), both in GI epithelial cells and enteric neurons (Godlewski, Offertaler, Wagner, & Kunos, 2009). GPR119 display a relatively narrow expression pattern, and were found predominantly on pancreatic β cells and intestinal tissues, within the villi in a close proximity to GLP-1, indicating the association between these receptors and enteric L-cells (Godlewski et al., 2009). In fact, OEA (the main biolipid activating GPR119) may stimulate the release of GLP-1 by these cells (Godlewski et al., 2009; Izzo & Sharkey, 2010).

The enzymatic machinery involved in the synthesis and degradation of endocannabinoids in the GI tract is probably not different from that in other tissues. However, there is limited data about topography of endocannabinoid biosynthetic and degradation enzymes in the gut, therefore the cellular sources of endocannabinoids are yet to be fully elucidated. FAAH, which breaks AEA and 2-AG intracellularly, is a membrane-bound hydrolase, and it is localized on cell bodies in the myenteric plexus, both in stomach and intestine (Izzo & Sharkey, 2010; Salaga et al., 2014b). MAGL breaks down 2-AG, and is present in the nerve cells and nerve fibers, throughout the muscle and mucosal layers of the duodenum, ileum, and colon (Izzo & Sharkey, 2010). Interestingly, the activity of MAGL varies throughout the GI tract: the highest is observed in the upper GI tract (duodenum), and decreases, reaching the lowest level in the distal colon (Izzo & Sharkey, 2010).

CBs are transported by specific proteins, endocannabinoid membrane transporters (EMT), whose cellular localization and distribution in the organism is yet to be elucidated. Inhibition of EMT results in an increased level of extracellular AEA (up to 200%) and 2-AG (up to 110%) (Chicca, Marazzi, Nicolussi, & Gertsch, 2012). Moreover, inhibition of EMT may produce antiinflammatory effects in the GI tract, similar to that observed after blockade of FAAH (Salaga et al., 2014b).

CANNABINOIDS IN PHYSIOLOGICAL STATES

Food Intake and Obesity

CBs regulate energy balance and food intake, acting both in brain and GI tract. Δ^9-THC increases food uptake via CB1 receptor activation. Starvation increases both AEA levels and CB1 receptor expression in the vagus nerve; on the contrary, satiety reduces CB1 expression and signaling. These observations indicate that CB1-expressing neurons located on the vagus nerve are involved in transmission of CB-dependent signals modulating appetite (Fig. 49.1). Thus, AEA seems to be an important mediator of hunger in the organism (Izzo & Sharkey, 2010). Interestingly, whereas AEA enhances food intake and energy storage, OEA reduces food intake and promote lipolysis (Izzo & Camilleri, 2009; Tourino, Oveisi, Lockney, Piomelli, & Maldonado, 2010).

Since CBs are strong modulators of appetite, it was postulated that ECS may be targeted in the treatment and prevention of obesity. To date, several in vivo studies showed that CB1 receptors signaling was upregulated in animals prone to obesity, and fed with high fat diet (Paulino et al., 2009). Moreover, it was shown that AEA is upregulated in the small intestine and duodenum of obese rats (Izzo & Sharkey, 2010). Extrinsic sensory neurons that relay information from the gut to the brain exhibit increased sensitivity to orexigenic compounds, including cannabinoids in diet-induced obese rodent models. These data demonstrate the potential of endocannabinoids for strong appetite enhancement through peripheral receptors, which may result in an increased food intake and, in longer time periods, obesity. CB1 receptor antagonists were thus imagined as effective agents

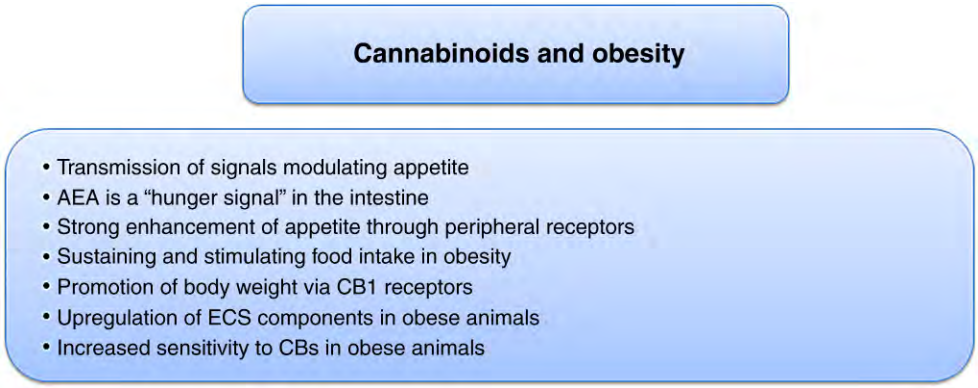

FIGURE 49.1 **Actions of the endogenous cannabinoid system in the course of obesity.**

in limiting food intake, and reducing body weight. Indeed, it was shown that rimonabant, a selective CB1 antagonist/reverse agonist diminishes food intake, and its actions were blocked after chemical vagus nerve deafferentation (Gomez et al., 2002). Another CB1 receptor antagonist, URB447, was shown to reduce food intake and body weight in genetically obese ob/ob mice (Izzo & Sharkey, 2010). However, despite the success in preclinical and clinical trials, rimonabant, the first member of this class of drugs, was withdrawn from the European market in 2008 because of an increased risk of depression due to centrally-mediated actions. The second generation of selective CB1 antagonists, unable to cross the blood–brain barrier, as well as other ECS-focused strategies, are now in the pipeline. In the next few years, we will hopefully know whether ECS can be successfully targeted without significantly affecting other vital processes related to mood and sense of wellbeing (Romero-Zerbo & Bermudez-Silva, 2014; Izzo & Sharkey, 2010).

GI Motility

Cannabinoid effects on GI motility are described in more depth in another Chapter 98 (*Cannabinoids and effects on the gastrointestinal tract: a focus on motility*) within this book.

CANNABINOIDS IN PATHOPHYSIOLOGICAL STATES

Functional Disorders of the Lower GI Tract

Irritable bowel syndrome (IBS) is a heterogeneous disorder, characterized by altered stool habits and abdominal discomfort or pain that lasts for at least 3 days per month, in 3 months prior to diagnosis, in absence of another organic disease. The prevalence of IBS is 10–20% worldwide (Sobczak, Salaga, Storr, & Fichna, 2013). IBS may involve a dysregulation of interactions between central and peripheral nervous system, so called brain-gut axis (Fichna & Storr, 2012; Sobczak et al., 2013). Patients with IBS suffer from altered bowel habits, ranging from diarrhea (IBS-D), constipation (IBS-C), or alternating diarrhea and constipation (IBS-A). The treatment of IBS is still symptomatic, without a well-defined first-line therapy.

ECS may be involved in the pathophysiology of functional diseases like IBS, with CB receptors implicated in the regulation of impaired water and electrolyte secretion, intestinal motility, and pain sensation (Fig. 49.2). CB1 receptors are involved in the reduction of net electrogenic ion transport in the bowel and, thus, may reduce intestinal secretion induced by activation of secretomotor submucosal neurons (Tyler, Hillard, & Greenwood-Van, 2000). In vivo studies indicated the potential role that ECS plays in the pathophysiology of functional diseases. Nonselective CB receptor agonists inhibit cholera toxin-induced fluid accumulation in the bowel, and this effect is blocked by selective CB1, but not CB2 antagonists (Izzo et al., 2003). Interestingly, CB1 receptors are overexpressed in the model of croton oil-induced ileitis, and the CB1 agonists were more effective in reducing transit, compared to control animals (Izzo et al., 2001). In line, Fichna, Sibaev, Salaga, Sobczak, and Storr (2013a) demonstrated that the inverse CB1 agonist, taranabant, increases motility and reduces pain in a mouse model of IBS-C . Also, indirect elevation of endogenous CBs, achieved by blockade of FAAH, may be used to inhibit gut motility in physiologic conditions, and during hypermotility states (Fichna et al., 2014). A potent and irreversible FAAH inhibitor, PF-3845 inhibited mouse colonic motility through CB1-mediated mechanisms, while this effect was not observed in FAAH-knockout mice (Fichna et al., 2013b; Nasser, Bashashati, & Andrews, 2014).

Abdominal pain, together with altered motility and bowel habits, is one of the main symptoms of IBS. ECS may be targeted in order to reduce visceral sensation and abdominal pain induced by various stimuli

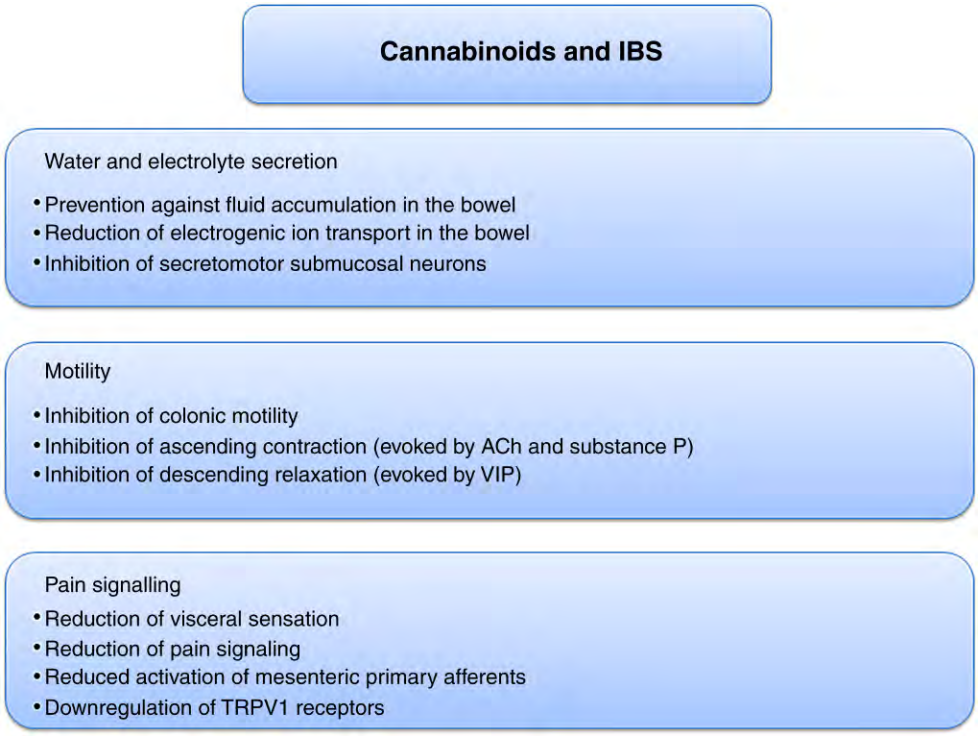

FIGURE 49.2 **Cannabinoid-mediated effects in the course of IBS.** *ACh*, Acetylcholine; *VIP*, vasoactive intestinal peptide; *TRPV1*, transient receptor potential vanilloid type 1.

(Alhouayek & Muccioli, 2012; Izzo & Coutts, 2005; Izzo & Sharkey, 2010; Salaga et al., 2014b). Both direct and indirect CB1 receptor activation, as well as direct CB2 receptor activation, inhibits visceral sensitivity and pain, in rodents. Moreover, antinociceptive effects may be also achieved by blockade of FAAH. Recently, Fichna et al. (2014) showed that PF-3845 produced a potent antinociceptive effect in the writhing test, and a mouse model of abdominal pain induced by mustard oil . Interestingly, these effects were observed after peripheral and central administration. Based on these studies, it seems that ECS is an attractive target for drugs that could treat abdominal pain, either through direct interaction with cannabinoid receptors or inhibition of endogenous cannabinoid degradation. Further translational studies are needed to validate this thesis in humans. Of note, some efforts have been already made in this direction. Fichna et al. (2013b) compared the plasma levels of endocannabinoids and colonic FAAH mRNA expression in IBS patients and healthy controls. The study showed that IBS-D patients had elevated levels of plasma 2-AG. Moreover, FAAH mRNA level was lower in patients with IBS-C, compared to healthy controls (Fichna et al., 2013b). These results suggest that ECS may become a target for future anti-IBS drugs which modulate the activity of endocannabinoid-degrading enzymes.

To date, only some compounds targeting the ECS have been tested on humans, and the results are only partially satisfactory. In a randomized double-blind placebo-controlled study, dronabinol (a synthetic nonselective CB receptor agonist) decreased fasting colonic motility, and increased compliance to colorectal distension, in healthy patients (Esfandyari et al., 2007). However, patients who received dronabinol also reported increased pain during colorectal distension, possibly due to CNS-related effects, such as modulation of perception (Esfandyari et al., 2007). In another study, dronabinol decreased fasting proximal and distal left colonic motility index, compared with placebo, and increased colonic compliance (Wong et al., 2011). The effects of dronabinol were most significant in patients with IBS-D or IBS-A. Moreover, the effects of dronabinol were influenced by genetic polymorphisms of FAAH and CB1. These data indicate that ECS plays an important role in the pathophysiology of functional GI disorders, and further translational studies are urgently needed to close the gap between animal and clinical trials on the novel ECS-targeting drugs for IBS.

Inflammatory Bowel Diseases

Inflammatory bowel diseases (IBD) are idiopathic, relapsing, and chronic disorders, which affect the GI system. Within this group of diseases, the most common are Crohn's disease (CD) and ulcerative colitis (UC), which are diagnosed in 1–2% of population (Schirbel & Fiocchi, 2010). The IBD incidence is highest between 15 and

30, and then 50–70 years of age. The major symptoms of IBD include abdominal pain, fecal bleeding, diarrhea, and weight loss. Moreover, there are extraintestinal manifestations occurring in 30% of IBD patients. The etiology of IBD remains unknown; however, several genetic and environmental factors, as well as nonbalanced immunological response, are believed to trigger its development (Salaga, Sobczak, & Fichna, 2013; Sobczak et al., 2013; Scharl & Rogler, 2012). The major therapeutic goals in IBD include control of the intestinal inflammation, and treatment of the most common symptoms, mainly abdominal pain and diarrhea.

To date, many in vitro and in vivo studies have been performed to elucidate the role of ECS in the course of IBD; here, we will summarize only the most relevant (Fig. 49.3; for a detailed review, please see Izzo & Camilleri, 2009). ECS signaling is enhanced during intestinal inflammation, as revealed by an increased expression of CB1 and CB2 receptors, altered endocannabinoid levels, and decreased expression of endocannabinoid degrading enzymes. Patients with untreated CD and UC had 2-times higher level of AEA in mucosal biopsies than healthy controls. Moreover, AEA levels significantly correlated with clinical activity of the disease (D'Argenio et al., 2006; Izzo & Camilleri, 2009). Immunostaining for CB receptors in healthy and inflamed colonic tissues revealed that CB2 receptor immunoreactivity, faintly detected in normal tissues, was significant in colonic mucosal samples from acute-phase IBD patients. Moreover, CB2 expression in ulcerated tissues was enhanced, compared to noninflamed samples from CD patients (Wright et al., 2005). Based on animal models, it was also reported that the level of FAAH mRNA is altered during the course of colitis. At the beginning of the inflammation (1 day after TNBS administration), the expression of FAAH mRNA was reduced, and when the damage was maximal (3 days after TNBS), FAAH mRNA levels increased (Storr et al., 2008).

Direct activation of CB1 and/or CB2 receptors produces a protective effect in animal models of experimental colitis, induced by mustard oil, DNBS, TNBS, DSS, and LPS (D'Argenio et al., 2006; Izzo & Camilleri, 2009; Kimball, Schneider, Wallace, & Hornby, 2006; Mathison, Ho, Pittman, Davison, & Sharkey, 2004; Storr et al., 2008). Moreover, CB1-deficient mice are less resistant to colonic inflammation than wild type (Massa et al., 2004). Indirect activation of CB receptors through inhibition of FAAH or EMT also provides protection against inflammatory stimuli (Salaga et al., 2014b). In addition, the EMT inhibitor VDM-11 not only increased the level of AEA, but also abolished inflammation (D'Argenio et al., 2006). The blockade of FAAH and EMT (with URB597 and VDM-11, respectively) protected against TNBS-induced colitis in wild type, but not in CB1- and CB2-deficient mice (Storr et al., 2008). Furthermore, the blockade of FAAH may alter the levels of non-"classical" CB receptor ligands, such as 2-OG, PGE2, and glycerol-derived biolipids (Salaga et al., 2014a). These findings highlight the protective role of all components of the ECS in inflammatory GI disorders.

Colorectal Cancer

One of the most threatening risks to which IBD patients are exposed is that of development of colorectal cancer (CRC) as a result of the chronic inflammatory

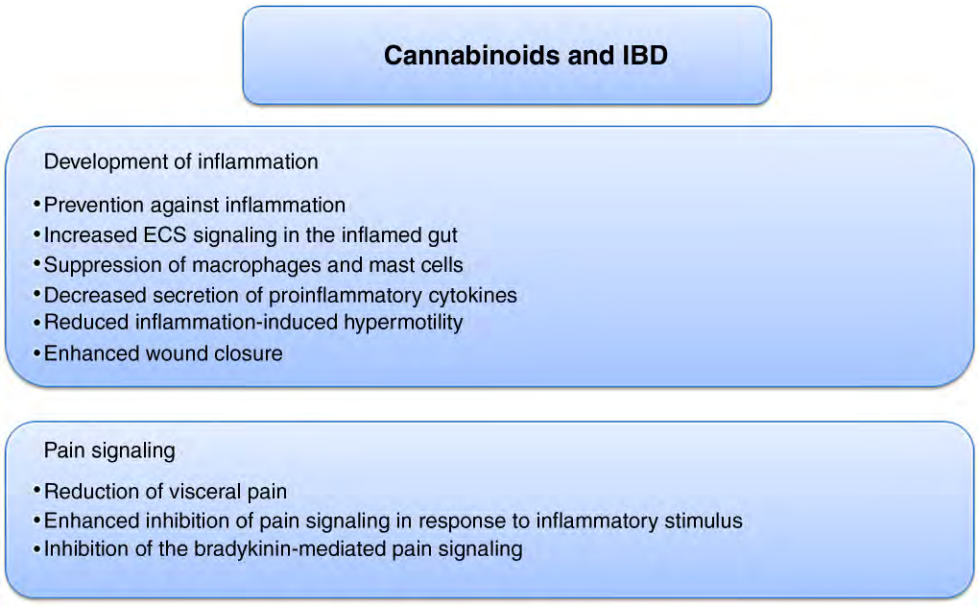

FIGURE 49.3 **Cannabinoid-mediated effects in the course of IBD.**

state in the lower GI tract. Chronic inflammation, which underlies colitis-associated colorectal cancer, may contribute to the development of up to 25% of all diagnosed colorectal tumors (Itzkowitz, Greenwald, & Meltzer, 1995). Currently, the most effective methods for colitis-associated colorectal cancer treatment are cytotoxic drugs, radiotherapy, or resection of tumor area. Low selectivity between cancer and healthy cells, and a major risk of side effects, often combined with poor efficacy and the risk of relapse, are the main reasons for which new therapies against CRC are urgently needed (Kumar et al., 2012).

Both natural and endogenous cannabinoids exert anticancer activities, as indicated in in vitro and in vivo studies (Fig. 49.4). CBs reduce proliferation, and promote apoptosis in colorectal carcinoma epithelial cells, and inhibit development of tumors in animal models of CRC (for review, see Izzo & Camilleri, 2009; Izzo & Sharkey, 2010). Studies on human intestinal biopsies revealed that ECS undergoes adaptive changes in the course of CRC. In adenomas and colorectal cancer, AEA and 2-AG levels are three- and two-fold higher, respectively, than in normal mucosa (Izzo & Camilleri, 2009). Moreover, the expression of CB1 receptors in human cancer specimens is downregulated, due to the methylation of its promoter (Wang et al., 2008). Downregulated CB1-dependent signaling in cancer cells may stimulate their growth into a tumor. On the contrary, recognizable pattern of CB2 mRNA expression can be found in tumor tissues (Izzo & Sharkey, 2010).

Activation of CB1 and, to a lesser extent, CB2 receptors exert antiproliferative and proapoptotic activity in various cancer cell lines (Izzo & Camilleri, 2009). The exact mechanism of such effects is not completely elucidated, but experimental data suggest the involvement of caspase-3, which is associated with activation of CB receptors. Moreover, experimental data demonstrate that Δ^9-THC promote apoptosis by inhibition of MAPK and PI3K-AKT (Izzo & Camilleri, 2009). Another hypothesis considers the involvement of ceramide, a well-known proapoptotic biolipid, and also a second messenger of ECS signaling. Activation of both CB receptors stimulates the synthesis of ceramide in the carcinoma cell lines. In line, it was shown in HT-29 CRC cells that the activation of CB receptors was associated with increased ceramide levels, and pharmacological blockade of ceramide-synthesizing enzymes reversed the proapoptotic changes, which occurred after CB receptor activation (Cianchi et al., 2008). There is also some evidence that antitumor actions of CBs may be mediated by non-CB mediated mechanism, such as prostamide production (Izzo & Camilleri, 2009).

Natural CBs, such as Δ^9-THC and CBD, also exhibit antiproliferative actions in human CRC (Caco-2) cells with IC50 value in low micromolar range (Izzo & Sharkey, 2010). The quinone derivative of CBD, named HU-331, has been shown to be highly effective against tumor xenografts in nude mice. Additionally, HU-331 was found to be much less cardiotoxic than doxorubicin. In HU-331 treated group, the tumor weight was 30% smaller than in doxorubicin-treated animals (Kogan et al., 2007).

CBs may also prevent metastasis. Nonselective CB receptor agonists, as well as selective CB1, but not CB2 agonists, inhibited norepinephrine-induced migration of human colon carcinoma cells SW480 (Joseph, Niggemann, Zaenker, & Entschladen, 2004).

Treatment with the FAAH inhibitor AA-5-HT reduced the formation of aberrant crypt foci in the mouse colon, via caspase-3 activation (Izzo & Camilleri, 2009). Moreover, AA-5-HT also increased AEA and 2-AG levels, indirectly activating both CB receptors.

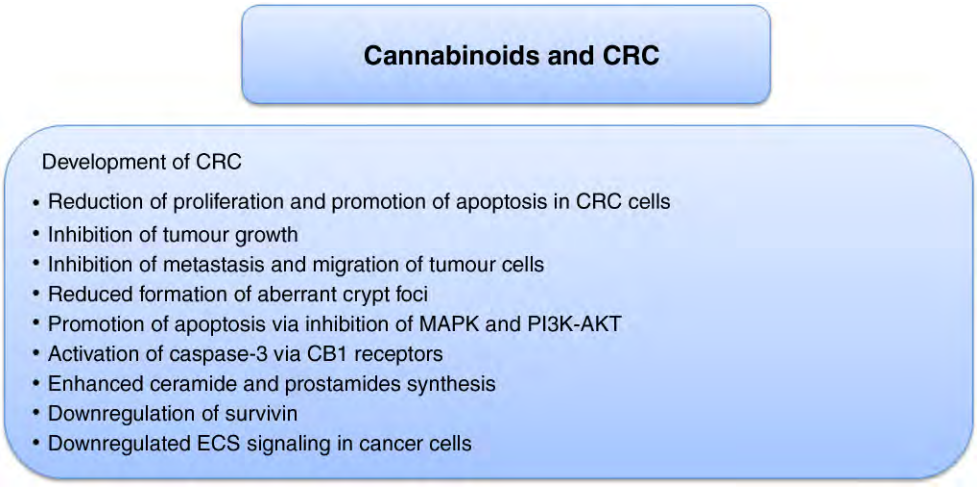

FIGURE 49.4 Cannabinoid-mediated effects in the course of CRC. *MAPK*, Mitogen-activated protein kinase; *PI3K-AKT*, phosphoinositide 3-kinase-protein kinase B.

Several studies were also performed on Apc mice, which possess a germ-like mutation in the APC gene, which is a tumor suppressor gene. These mutants spontaneously develop multiple polyps in the intestine. It has been shown that, in the CB1-deficient Apc mice, the growth rate of intestinal adenoma is significantly higher than in control animals. Moreover, the activation of CB1 receptors attenuated intestinal tumor growth through downregulation of survivin, a protein involved in prevention against apoptosis by inhibition of caspase activation (Wang et al., 2008).

CANNABIS HERBAL LEAF AND RESIN USAGE IN THE GASTROINTESTINAL TRACT

People used various *Cannabis*-derived preparations a long time before its chemical composition has been elucidated. The most popular were those made of *Cannabis* leaves and the resin, which can be obtained from flowers, stem, and leaves. Nowadays, these preparations are popular mostly among recreational users, and are forbidden in many countries due to their addictive properties.

There is limited scientific data on the effect of *Cannabis* leaves and resin on the GI tract, mostly originating from occasional reports of recreational users rather than actual scientific investigations. Bhatia, Manhas, Kumar, and Magotra (2014) points out that the whole plant of *Cannabis sativa* L. (either fresh or dry) may cause nausea and vomiting. These adverse effects of *Cannabis* significantly hamper its clinical use, even though it may be helpful in the treatment of several conditions, such as pain and muscle spasms (Borgelt, Franson, Nussbaum, & Wang, 2013). On top of the obvious legal issues and adverse events, the use of medical *Cannabis* faces a number of challenges. First, the route of administration (smoked, oral, inhaled) and individual condition of the patient (functional lung capacity, GI absorption) may both cause significant variability in the observed effects. Another serious problem is the weak quality control of *Cannabis* preparations (ie, contaminated products, nonstandarized doses). Therefore, emphasis should be put on the isolation of novel and safe therapeutic compounds from *Cannabis*, rather than the search for a safe way of using leaf or resin preparations. To date, many scientific reports showed beneficial properties of *Cannabis*-derived compounds on GI diseases and cancer (see above). Modification and improvement of these compounds is the preferred strategy in this field.

CONCLUDING REMARKS

ECS is one of the most influential endogenous systems in the GI tract, and has a tremendous impact on gut homeostasis, being involved in the regulation of motility, food intake, and intestinal secretion (Fig. 49.5). Moreover, various pathophysiological processes, such as inflammation, pain, and even colorectal cancer, are modulated by ECS-dependent pathways. Compounds targeting ECS have a great potential to become pharmacological tools to study the pathophysiology of GI diseases, as well as being used in treatment of GI diseases in the future. However, given the disappointing experience with the clinical studies on CBs, it will be essential for future drug development programs to screen for the psychotropic or depressant potential of this class of medications. Nevertheless, novel treatment strategies for GI diseases, based on the activation of CB receptors, and the regulation of endogenous cannabinoid levels in the GI tract, are currently under investigation. As more attention is paid currently to the ECS, the discovery and validation of effective therapies against GI diseases in the near future is warranted.

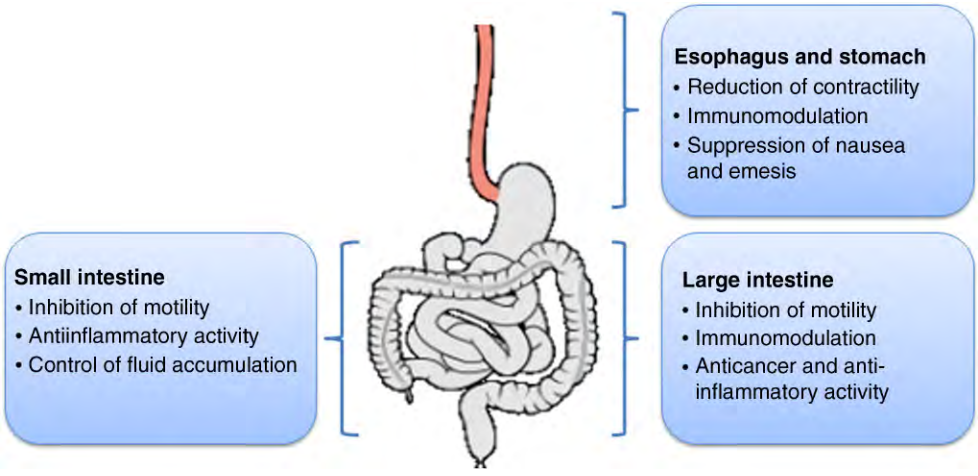

FIGURE 49.5 **A summary of cannabinoid-related actions in the gastrointestinal tract.**

MINI-DICTIONARY

Apc mice Genetically modified mice characterized by spontaneous development of polyps in the intestine.
Colitis-associated colorectal cancer A colon cancer caused by a chronic, sustained inflammatory state.
EMT A putative endocannabinoid membrane transporter, a protein that carries endocannabinoids through cell membranes.
ENS The part of the peripheral nervous system that resides in, and innervates, the gut.
GPR55 and GPR119 Non-"classical" GPCRs that may be activated by endocannabinoids.
Inflammatory bowel diseases Chronic inflammatory disorders affecting the intestine. Encompass Crohn's disease and ulcerative colitis.
Irritable bowel syndrome A functional disorder affecting the GI tract, manifested mainly by altered motility and abdominal pain.
L-cells Enteroendocrine cells located in the intestine that produce peptide hormones, such as incretins.
TNBS Trinitrobenzenesulfonic acid. Sometimes called a hapten. It is one of the chemical agents used to induce experimental colitis.
Vagus nerve The longest of the cranial nerves, it is a mixed nerve, leading to sensory and motor parasympathetic fibers. Belongs to the autonomic nervous system.

CHAPTER

50

Cardiovascular Effects of Cannabis Usage

S. Menahem

Paediatric Cardiology Unit, Monash Health, Melbourne, VIC, Australia; Faculty of Medicine, Nursing and Health Sciences, Monash University, Clayton, VIC, Australia

SUMMARY POINTS

- The major active cannabinoid in marijuana is Δ^9-tetrahydrocannabinol (THC). Its physiological effects are mediated through the cannabinoid receptors CB1 and CB2.
- A low dose leads to tachycardia and blood pressure rise, while a high dose to bradycardia and hypotension.
- There is clear documentation of an increased incidence in both the morbidity and mortality of marijuana users, especially if its usage is chronic or heavy. That may result from an increased incidence of myocardial ischemia and/or infarction, the development of a cardiomyopathy, and the risk of sudden death through a probable malignant arrhythmia and/or reduced coronary blood flow.
- There is also an increased incidence of transient ischemic episodes and stroke.
- There is an increased incidence of intermittent claudication arising from peripheral vascular disease.
- All the above should suggest *caution* against *chronic* and/or *heavy* usage.

KEY FACTS OF CARDIOVASCULAR EFFECTS OF CANNABIS USAGE

- Cannabis usage is frequent and widespread.
- Excessive and/or chronic usage results in significant cardiovascular morbidity and/or mortality.
- That includes involvement of the heart, brain, and limbs.
- That may result in:
  - Angina, myocardial infarction, and/or sudden death.
  - Transient ischemic episodes and/or strokes.
  - Intermittent claudication and/or peripheral gangrene.
- All the above highlight the ill effects of excessive and/or chronic usage of cannabis and caution against its abuse.

LIST OF ABBREVIATIONS

CB1	Cannabinoid receptor 1
CB2	Cannabinoid receptor 2
THC	Δ^9-Tetrahydrocannabinol

INTRODUCTION

Marijuana use is common and widespread, especially in the developed countries (Substance Abuse & Mental Health Services Administration, 1999; Bachs & Morland, 2001; Thomas, Kloner, & Rezkalla, 2014). While often touted as being safe or the least toxic of the so-called recreational drugs, there is a substantial literature which documents potential ill effects and increasing morbidity, and often mortality—especially in its chronic users. This chapter will focus on the described physiological and pathological cardiovascular effects of marijuana, especially if taken in high dosage over a prolonged period of time.

At the outset, it is difficult to separate out the potential effects of cannabis usage, whether by inhalation or ingestion, when it is often accompanied by nicotine inhalation, alcohol, and other chemically active drugs such as cocaine, opiates, ecstasy, etc., and further compounded by at times unknown contaminants (Aryana

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00058-2

& Williams, 2007; Suttout & Nicole, 2009). Accurate estimation of the level of cannabis and its metabolites is often lacking, and can only be inferred by reviewing the history, where there is a tendency to underestimate the quantity taken, and the frequency of the inhalations or ingestions (Menahem, 2013).

PHYSIOLOGICAL EFFECTS

The major active cannabinoid in marijuana is Δ^9-tetrahydrocannibol (THC) (Sydney, 2002). Jones (2002) described in detail the physiological cardiovascular effects of marijuana. THC can lead to a rapid and substantial dose-dependent increase in heart rate up to 100%, and a modest increase in blood pressure probably mediated by sympathetic simulation, and reduced parasympathetic activity peaking within 15 min, and lasting for up to 3 h (Aryana & Williams, 2007; Sydney, 2002; Jones, 2002; Hollister, 1986). The cardiac output is increased by 30% or more (Sydney, 2002; Benowitz, Rozenberg, Rogers, Bachman, & Jones, 1979). THC is also described as facilitating atrioventricular node conduction, reducing left ventricular ejection time, and decreasing the peripheral vascular resistance, especially in skeletal muscle (Aryana & Williams, 2007; Sydney, 2002; Jones, 2002; Benowitz et al., 1979), which may result in orthostatic hypotension which may lead to dizziness, near syncope, or syncope (Aryana & Williams, 2007; Sydney, 2002). Kunos et al. (2000) give a more detailed account of the biological basis of action of marijuana, emphasizing that THC is the primary psychoactive ingredient of the marijuana plant. The high affinity binding of radiolabeled synthetic cannabinoids to stereoselective sites in the brain suggests the existence of specific cellular receptors for cannabinoids (Devane et al., 1992). Two cannabinoid receptors have been identified by molecular cloning—CB1, primarily in the brain, but also in some peripheral tissues, and CB2 receptors in immune cells (Metsuda, 1997). Intravenous injection of endocannabinoid anandomide into rats produced a triphasic response similar to THC. Initially, there was a brief vagally mediated drop in heart rate and blood pressure, followed by a brief pressor response, probably from vasoconstriction in certain vascular beds, followed by more prolonged hypotension and bradycardia, where CB1 appears to be involved. However, there is the possibility that there may be a decrease in sympathetic tone, or direct vasodilator action resulting in cannabinoid induced hypotension (Kunos et al., 2000). The biphasic response to cannabinoids may be dose-dependent, a low to moderate dose causing tachycardia and blood pressure rise, whereas a higher dose may lead to bradycardia and hypotension (Suttout & Nicole, 2009).

CARDIOVASCULAR CONSEQUENCES OF MARIJUANA USAGE

There are well recognized complications associated with marijuana usage, including important adverse cardiovascular disorders well described by Bachs and Morland (2001), Thomas et al. (2014), and Jones (2002). It behoves all clinicians, especially cardiologists and primary care physicians, to be aware of the potential serious consequences of prolonged and heavy use of marijuana. These adverse cardiovascular effects are summarized under the following headings.

Myocardial Ischemia/Infarction

Myocardial ischemia may lead to myocardial infarction (Arora, Goyal, Aggarwal, & Kukar, 2012; Saffan, Markham, & Jayasinghe, 2012) despite apparently normal coronary arteries on angiography. The mechanism may result from an increase in oxygen demand secondary to an increased heart rate and a decreased oxygen supply, because of a rise in the carboxyhemoglobin levels post smoking (Suttout & Nicole, 2009), or reduced coronary blood flow secondary to coronary artery vasospasm (Rezkalla, Sharma, & Kloner, 2003; Karabulut & Cakmak, 2010). Again, it is difficult to separate out the direct action of marijuana versus other drugs or contaminants involved, such as nicotine, alcohol, cocaine, etc. (Thomas et al., 2014).

Myocardial infarction is well described in autopsy series (Tormey, 2012; Caldicott, Holmes, Roberts-Thompson, & Maher, 2005), even in young subjects with apparently normal coronary arteries (Arora et al., 2012; Saffan et al., 2012). It also appears to occur more frequently in those patients with coronary artery disease who use marijuana (Aryana & Williams, 2007; Rezkalla et al., 2003; Gaziano, 2008). There is also statistical evidence that, within an hour of marijuana usage, there is a 4.8 times increase in the risk of myocardial infarction (Mittleman, Lewis, Maclure, Sherwood, & Muller, 2001). To that may be added a probable increase in mortality after myocardial infarction, in recognized users (Mukamal, Maclure, Muller, & Mittleman, 2008; Frost, Mostofsky, Rosenbloom, Mukamal, & Mittleman, 2013). There is little evidence, however, to suggest that there is either the development or acceleration of atherosclerosis, even in chronic users (Thomas et al., 2014).

Cardiomyopathy and Sudden Death

Case reports have described a possible direct action of marijuana on myocardial function (Ting, 2007; Kaushik, Alla, Madan, Arouni, & Mohiuddin, 2011). Those subjects who die suddenly with apparently normal coronary arteries and myocardium raise the possibility of a malignant cardiac arrhythmia (Suttout

& Nicole, 2009; Menahem, 2013; Lindsay, Foeli, Warren, & Henry, 2005) or possible other causes (Montisci, Thiene, Ferrara, & Basso, 2008; Daisley, Jones-Le Cointe, Hutchinson, & Simmons, 1998). Tachyarrhythmias have been frequently reported following cannabis usage (Thomas et al., 2014; Aryana & Williams, 2007; Lindsay et al., 2005; Singh, 2000). This may be related to the initial component of the biphasic response to cannabinoids producing a tachycardia (Suttout & Nicole, 2009); a higher dose may produce a sudden increase in parasympathetic tone, and parasympathetic activity which may lead to a bradycardia and/or an asystolic arrest (Suttout & Nicole, 2009; Menahem, 2013). That may be the cause of sudden death in those patients where the autopsy findings are negative (Bachs & Morland, 2001). Suttout and Nicole (2009) reported an asystolic arrest documented within 3 min of the collapse of a healthy 15 year old who had consumed alcohol and cannabis. Following cardiac pulmonary resuscitation, he developed ventricular fibrillation which was successfully cardioverted. Menahem (2013) documented, in a 25 year old heavy marijuana user, prolonged and repeated episodes of cardiac asystole, the longest lasting 5.6 s, and coinciding with the inhalation of marijuana (Fig. 50.1). His 24-h Holter returned to normal once he stopped using marijuana.

Cerebrovascular Effects of Marijuana Usage

While the psychotropic effects of marijuana use are well described elsewhere within this handbook, there does appear to be strong evidence that suggests that cerebral vascular effects can occur with chronic marijuana usage. A possible vasoconstriction effect or, alternatively, a brief hypertensive episode resulting in recurrent ischemic episodes, have been described during use of marijuana (Mouzak, Agathos, Kerezoudi, Mantas, & Vourdeli-Yiannakoura, 2000; Wolff et al., 2011). In addition, multiple reports have highlighted the development of strokes, especially in heavy users of marijuana, during marijuana inhalation (Wolff et al., 2011; Zachariah, 1991; Geller, Loftus, & Brink, 2004). In the series of Singh, Pan, Muengtaweeponsa, Geller and Cruz-Flores (2012), reexposure to marijuana resulted in recurrent stroke, as well as being described as being an important risk factor for ischemic strokes (Thomas et al., 2014; Phillips et al., 2011).

Peripheral Vascular Disease Following Marijuana Usage

Peripheral atherosclerotic disease, so-called cannabis arteritis, has been well described following marijuana usage (Grotenhermen, 2010; Noel, Ruf, & Panizzon, 2008). While it appears to be similar to thromboangiitis obliterans (Thomas et al., 2014), the latter tends to occur earlier in those individuals using marijuana (Martin-Blondel, Koskas, Cacoub, & Sene, 2011). Patients with cannabis arteritis tend to develop the usual symptoms of peripheral vascular disease, namely intermittent claudication, Reynaud phenomena, ischemic ulcers, and digital necrosis resulting from atherosclerotic changes readily demonstrated angiographically (Noel et al., 2008). Symptomatic improvement has been described, following the cessation of marijuana usage.

CONCLUSIONS

While, as stated earlier, there is little evidence to suggest that marijuana usage increases the risk of atherosclerosis, there is considerable evidence, however, to suggest that acute and/or chronic heavy usage has significant cardiac and peripheral vascular effects that may result in sudden death, a higher incidence of myocardial dysfunction, cardiac arrhythmias, acute myocardial infarction with a probable higher mortality, cerebral and peripheral vascular disease with resultant ischemic episodes, and/or stroke, or intermittent claudication and peripheral ulceration, respectively. Greater dissemination of this information describing the increased morbidity and the significant mortality from both acute and chronic marijuana usage may lead to a more cautious approach to its widespread reported usage.

MINI-DICTIONARY

Arrhythmia Describes the (electrical) activity of the heart which controls the heart rate. The rhythm may become irregular, become abnormally fast or slow, which may result in the more serious cases, a loss of cardiac output with a drop in blood pressure, or even cessation of the heart beat (contraction), resulting in a cardiac arrest leading to the (sudden) death of the person if he/she is not able to be resuscitated.

Cardiomyopathy Describes any condition that affects the heart muscle—often of unknown cause, but may be related to chronic myocardial ischemia (reduced myocardial blood supply), infarction, toxic agents or poisons, genetic disorders affecting the heart muscle, etc. That may result in reduced myocardial (heart) function, obstruction to the outflow of one or both ventricles (pumps), or the development of significant or life-threatening arrhythmias and sudden death.

Myocardial infarction Commonly known as a "heart attack," where there is irreversible necrosis or death of myocardium (heart muscle) from partial or complete occlusion or blockage of one or more coronary arteries which supply blood to the heart itself.

Myocardial ischemia Blood flow to the myocardium (heart muscle) is decreased by partial or complete blockage of the coronary arteries which supply the myocardium. Results in chest pain at rest or exercise (angina), but potentially reversible.

Peripheral vascular disease Sometimes referred to as peripheral arteritis, it results from narrowing of the peripheral (that is, outside the heart and brain) blood vessels. That may lead to intermittent claudication, that is, pain in the calf muscles on walking or running, resulting from ischemia or the reduced blood supply to the muscles of the lower limbs. Occasionally, if there is severe narrowing of the peripheral blood vessels, the skin and underlying tissue may ulcerate and/or develop gangrene (death of tissue) with loss of toes, feet, and even part of a limb.

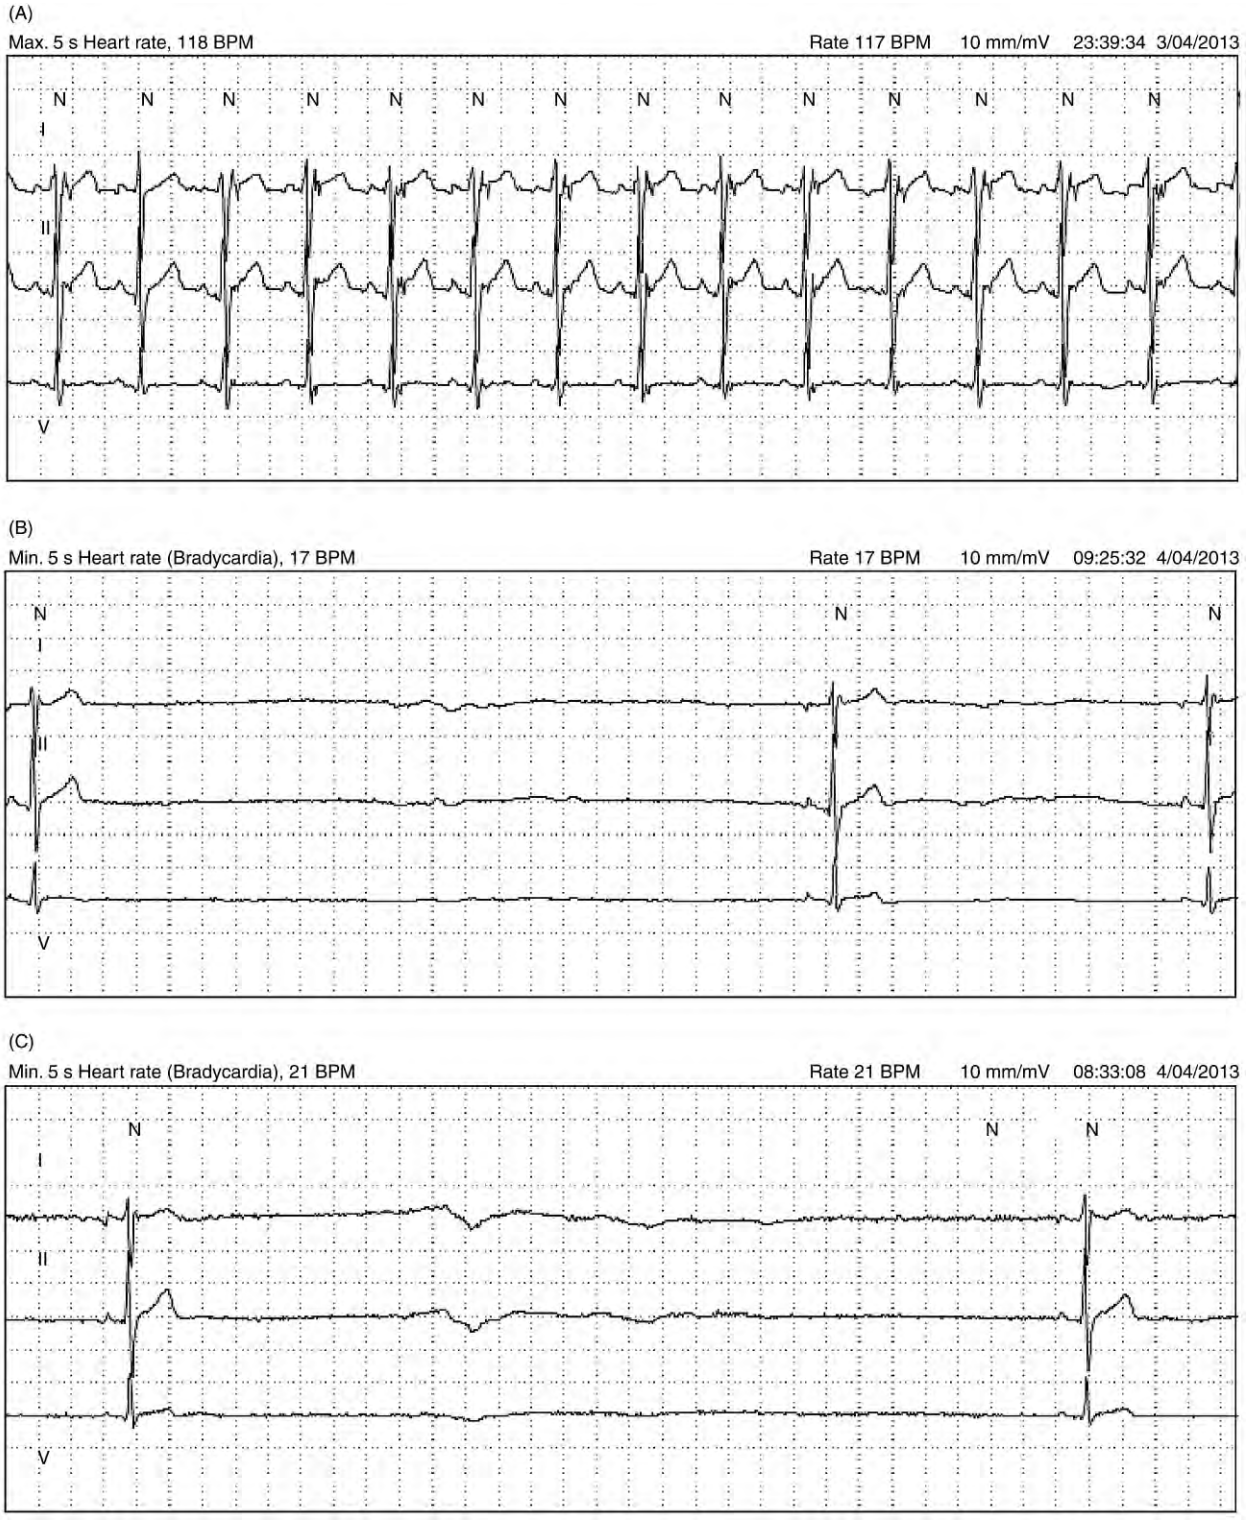

FIGURE 50.1 **Electrographic trace from a 25-year-old heavy marijuana user.** Strips from a 24-h Holter showing (A) sinus rhythm/tachycardia, (B) repeated and prolonged pauses related to cardiac asystole, associated in timing with marijuana usage; (C) longest pause: 5.8 s. *Source: From Menahem, S. (2013). Cardiac asystole following cannabis (marijuana) usage—additional mechanism for sudden death.* Forensic Science International, 233, *1–3. With permission from Elsevier.*

Stroke Sometimes called a cerebrovascular accident, occurs as a result of the loss of brain function, due to disturbance in the blood supply to the brain. That may result in ischemia (lack of blood flow) to the brain, and may occur from a thrombus or clot developing in a blood vessel supplying the brain, or from an embolism or clot dislodged from elsewhere in the body, and ending up in such a vessel. Occasionally, an affected cerebral (brain) blood vessel may rupture or leak, resulting in a hemorrhage which may also affect the brain function, leading to the loss of the use of a limb, speech, swallowing ability, comprehension, etc. Generally, recovery is often incomplete if at all, as there may be infarction or death of the affected brain tissue.

Sudden death Usually implies sudden unexpected cardiac death, often resulting from undiagnosed heart disease, possibly related to myocardial ischemia/infarction, a cardiomyopathy, or a malignant arrhythmia.

Transient ischemic attack Sometimes called a "mini-stroke," where the blood supply to the brain is interrupted for a short period of time, with generally recovery of full function.

Cannabis and Stroke

P.A. Barber

Department of Medicine, Centre for Brain Research, University of Auckland, Auckland, New Zealand

SUMMARY POINTS

- There have been multiple case reports, case series, and population-based studies that have shown an association between cannabis use and ischemic stroke and transient ischemic attack (TIA).
- People with stroke who have used cannabis:
  - are more likely to be younger men,
  - have recently increased cannabis intake,
  - have stroke symptoms that usually come on during or soon after cannabis use,
  - have strokes that are more likely to be in the posterior circulation.
- A causal association between cannabis and ischemic stroke and TIA is plausible for a number of reasons.
  - Cannabis is associated with myocardial infarction, atrial fibrillation and accelerated atherosclerosis, all major risk factors for ischemic stroke.
  - Cannabis may lead to a reversible cerebral arteriopathy, with segmental and multifocal narrowing of arteries, which may, in turn, lead to cerebral ischemia and infarction.
- It is important that future research clarifies whether there is a causal association, as the numbers of people presenting with ischemic stroke and TIA, after cannabis use, is increasing, and will likely continue to do so.
- Physicians should consider screening younger stroke and TIA patients for cannabis, particularly when there are no other risk factors, so that they are able to make informed decisions on future use.

KEY FACTS

- Cannabis is used by 11–27% of younger ischemic stroke and transient ischemic attack (TIA) patients.
- There is unlikely to be an association between intracerebral hemorrhage and cannabis.
- No study has shown a causal association between cannabis use and stroke, independent of tobacco use.
- The numbers of people presenting with stroke who have used cannabis is increasing, and will likely continue to do so.

LIST OF ABBREVIATIONS

ICH	Intracerebral hemorrhage
MIS	Multifocal intracranial stenosis
OR	Odds ratio
RCVS	Reversible cerebral vasoconstriction syndrome
SSRI	Selective serotonin reuptake inhibitors
TIA	Transient ischemic attack

THE ASSOCIATION BETWEEN CANNABIS USE AND STROKE

It is likely that there is an association between cannabis and ischemic stroke and transient ischemic attack (TIA). There are multiple reports of mainly younger men, with no vascular risk factors other than tobacco and alcohol use, with symptom onset during or soon after cannabis use. This often follows a marked increase in cannabis intake. The strokes are mainly in the posterior circulation, possibly reflecting a greater susceptibility to cannabis-induced autonomic changes. Population-based

studies and retrospective audits have also found an association between ischemic stroke and TIA and cannabis. The numbers of patients using cannabis and presenting with stroke has been increasing in recent years, and moves toward legalization for medical and recreational reasons will further increase these numbers.

However, a causal association between cannabis and ischemic stroke has not been proven. One of the major confounding factors is tobacco, which is often smoked with cannabis. A causal link between cannabis and stroke is plausible, and a number of lines of evidence point to such a link. These include the temporal association between cannabis use and stroke, and recurrent stroke with cannabis reexposure. Cannabis is associated with myocardial infarction and atrial fibrillation. Myocardial infarction and atrial fibrillation both increase the risk of cardiac embolism, which in turn accounts for 20–25% of ischemic strokes. There is also a reversible cerebral cannabis arteriopathy with vasospasm, seen with reversible vasoconstriction syndrome (RCVS), and (possibly) a more prolonged stenosis of cerebral arteries that has been called multifocal arterial stenosis (MIS). In this chapter, the evidence linking stroke and cannabis, and the lines of evidence pointing to a causal link, will be summarized (Table 51.1).

Cannabis Ischemic Stroke and Transient Ischemic Attack

The first possible report of ischemic stroke and TIA associated with cannabis use appeared in 1964. This was the case of an 18-year-old male who developed "giddiness" and conjugate gaze deviation to the right, after ingesting cannabis (Mohan & Sood, 1964). The patient recovered over the next 6 weeks. There were no imaging studies available, and so a diagnosis of stroke wasn't confirmed. There have been approximately 100 patients reported as single cases, or in small case series since that time (Garrett, Braithwaite, & Teale, 1977; Zachariah, 1991; Cooles & Michaud, 1987; Barnes, Palace, & O'Brien, 1992; Lawson & Rees, 1996; McCarron & Thomas, 1997; Mouzak, Agathos, Kerezoudi, Mantas, & Vourdeli-Yiannakoura, 2000; White, Martin, Geller, & Pittman, 2000; Mittleman, Lewis, Maclure, Sherwood, & Muller, 2001; Mesec, Rot, & Grad, 2001; Marinella, 2001; Mateo, Pinedo, Gomez-Beldarrain, Basterretxea, & Garcia-Monco, 2005; Finsterer, Christian, & Wolfgang, 2004; Bal, Khurana, Lal, & Prabhakar, 2009; Singh, Pan, Muengtaweeponsa, Geller, & Cruz-Flores, 2012; Wolff et al., 2011; Barber et al., 2013)

There have been three larger case series. In a retrospective study, 17 of 831 patients with ischemic stroke were reported with positive urine screens for cannabis (Singh et al., 2012). It is not clear how patients were selected for cannabis screening. Thirteen of 17 (76%) were men, and the mean age was 41 (range 15–63) years; 10 (58%) of the patients had stroke in the posterior circulation. Five had a history of alcohol use, but no alcohol was detected in blood samples, four had a history of hypertension, three had prior stroke, three used tobacco, and two used cocaine. In a prospective study, 13 of 48 (27%) consecutive ischemic stroke patients aged younger than 45 years had positive urine cannabis screens (Wolff et al., 2011). All of the patients smoked tobacco. Seven had strokes in the posterior circulation, and 10 (77%) had multifocal intracranial stenosis, and all of whom had "binged" on cannabis in the days prior to the stroke.

In a prospective case-control study, 25 out of 160 (16%) consecutive ischemic stroke (150) and TIA (10) patients aged 18–55 years had positive cannabis urine screens (Barber et al., 2013). These patients were more likely to be male, and tobacco smokers. Stroke patients were compared with 160 age, sex, and ethnicity matched control participants admitted to hospital with noncardiovascular diagnoses. Positive urine cannabis tests were obtained in 25 (16%) of the patients, and 13 (8%) control participants. In a logistic regression analysis adjusted for age, sex, and ethnicity, cannabis use was associated with increased risk of ischemic stroke and TIA (OR 2.30, 95% CI 1.08–5.08).

An association between cannabis and stroke has also been reported in population-based studies. A state-wide study of stroke hospital admissions in 18–44 year olds in Texas found an increased risk of ischemic stroke in those with a history of cannabis abuse or dependence (OR 1.76, 95% CI 1.15–2.71) (Westover, Mcbride, & Haley, 2007). An Australian study reported cannabis use in 36 out of 326 (11%) first ever ischemic stroke patients aged 15–50 years (Phillips et al., 2011). A retrospective

TABLE 51.1 Cannabis and Stroke: Summary

What we know
Multiple studies have found an association between cannabis and ischemic stroke
11–27% of younger ischemic stroke patients have recently used cannabis
Cannabis is not associated with intracerebral hemorrhage
What we don't know
Whether cannabis causes stroke, or if the association is a chance or bystander effect?
Why we need to know this
Significant numbers of younger ischemic stroke patients have recently used cannabis
These numbers are increasing, and will continue to do so
We need to know what to advise stroke patients who use cannabis

TABLE 51.2 Characteristics of Ischemic Stroke and TIA Patients Who Use Cannabis

Patients are more likely
Younger (mean age in the mid-30s)
Male (63–86%)
To have posterior circulation strokes (50–58%)
To have no vascular risk factors, apart from tobacco, alcohol and/or illicit drug use
Cannabis use more likely to be
Heavy (often more than once per week)
Increased recently
Used with tobacco, alcohol, and occasionally other illicit drugs

population-based study in the Greater Cincinnati and Northern Kentucky Study region reported cannabis use in 11% of 501 stroke patients aged 18–54 years (de Los Rios et al., 2012). This study also found increasing numbers of younger stroke patients using cannabis, in recent years, with cannabis use increasing from 0.6% in 1993, to 6% in 1999, and to 11% in 2005.

There are a number of similarities between people presenting with ischemic stroke and TIA, and who use cannabis (Table 51.2). They tend to be younger, with a mean age in the mid-30s, although some of the studies limited screening to younger patients only (Desbois & Cacoub, 2013). Most (63–86%) patients are male, possibly reflecting greater cannabis use in men. Ethnic differences have also been found (Barber et al., 2013). Patients are usually heavy users, with up to 86% reporting cannabis use more than once per week (Desbois & Cacoub, 2013). Stroke often occurred after a sudden increase in cannabis intake (Mouzak et al., 2000; Mateo et al., 2005; Renard, Taieb, Gras-Combe, & Labauge, 2012). Most patients also used tobacco and alcohol at the same time, with smaller numbers of patients using other illicit drugs. Cerebral infarction involved the vertebrobasilar arterial territories in 50–58% of patients, possibly due to less robust autoregulatory mechanisms in the posterior circulation (Desbois & Cacoub, 2013; Wolff et al., 2011, 2013). In a case-control study, no differences in age, stroke mechanism, or most vascular risk factors (apart from sex, tobacco use, and ethnicity) could be found between those with and without positive cannabis tests (Barber et al., 2013).

Cannabis and Intracerebral Hemorrhage

There is unlikely to be an association between cannabis and intracerebral hemorrhage (ICH). In a Texas-wide study of hospital admissions of 18–44-year-olds, no association was found between cannabis abuse or dependence and ICH (OR 1.36, 95% CI 0.90–2.06) (Westover et al., 2007). There is only a single case report in the literature linking cannabis use with ICH (Wolff et al., 2011). In the author's unit, only one of 25 (4%) consecutive ICH patients had a positive urine cannabis screen, compared with 13 out of 160 (8%) control patients presenting at the same time to the Internal Medicine service with nonvascular diagnoses. We have subsequently admitted a 48-year-old man with reversible cerebral vasoconstriction syndrome (RCVS) and ICH, who had smoked cannabis laced with amphetamine.

Not All Studies Have Found an Association Between Cannabis and Stroke

In a large population-based study in the Baltimore and Washington area of the United States, 783 younger adults with stroke, and 794 controls, were interviewed about cannabis use (Dutta, Ryan, Cheng, Kittner, & Cole, 2014). There were no differences between the cases and controls, after adjusting for age, sex, and tobacco use, at any time point. However, there was a nonsignificant trend to an association with stroke among frequent, but not infrequent, cannabis users (defined as cannabis use more or less than 1.88 times per month). The authors concluded that additional studies are warranted, examining the effect of heavy or frequent cannabis use. The methodology of this study is not clear, as it has only been reported in abstract form. But there is a potential for bias in studies that rely on self-report, as patients may not volunteer using what is still, in most jurisdictions, an illegal substance.

No study has found an association between stroke and cannabis that is independent of tobacco (Barber et al., 2013; Dutta et al., 2014). In a case-control study, all but three stroke patients with positive cannabis screens used tobacco (which is often mixed and smoked with cannabis), and an association independent of tobacco was unable to be confirmed (OR 1.59, 95% CI 0.71–3.70). However, cannabis does have cardiovascular effects over and above those of tobacco and nicotine, so that an association independent of tobacco is plausible. In people with established coronary artery disease, the time to angina with exercise was reduced by 50% after smoking cannabis, compared with an 8% reduction after smoking a placebo cannabis cigarette (Aronow & Cassidy, 1974), and 23% after smoking tobacco (Aronow, Kaplan, & Jacob, 1968).

One of the arguments against an association is the relative paucity of reports of patients with stroke who use cannabis, despite the widespread use of drug around the world (Thanvi & Treadwell, 2009). Surely the numbers of patients reported would be greater if a causal association existed? This is a reasonable argument, but it is not clear if clinicians routinely ask stroke patients about

cannabis use. Asking patients about, or even screening for, cannabis would likely identify more cannabis associated strokes (Barber, Roberts, Spriggs, & Anderson, 2014). Stroke patients weren't asked about cannabis use in the author's unit until the late 2000s. Once this became part of the routine assessment of patients in whom no clear cause of stroke could be identified, it became clear that one in six had recently used cannabis (Barber et al., 2013). Patients with positive screens are now routinely counselled about the potential risk of cannabis reexposure, so that they can make an informed choice about further use.

A CAUSAL LINK BETWEEN CANNABIS AND STROKE IS PLAUSIBLE

There are a number of lines of evidence that, while not proof, favor a causal association between cannabis and stroke (Table 51.3). This evidence includes the strong temporal association between cannabis and stroke onset, and recurrent stroke with cannabis reexposure, following periods of abstinence. There is an association between cannabis and heart disease, which is one of the major risk factors for stroke. A reversible cerebral cannabis arteriopathy, with RCVS and multifocal intracranial stenosis (MIS) may lead to hypoperfusion and brain ischemia.

TABLE 51.3 Evidence Suggesting a Causal Link Between Cannabis and Ischemic Stroke/TIA

Case-control study evidence
Double the rate of positive cannabis screens in stroke patients compared with controls
Temporal link between cannabis use and stroke or TIA onset
Stroke/TIA onset during or shortly after cannabis use
Stroke/TIA onset following recent increase in cannabis use
Cannabis reexposure leading to recurrent stroke/TIA
Increased risk of cardiac embolism and stroke: cannabis leads to
Shorter time to angina
Increased risk of myocardial infarction
Increased risk of atrial fibrillation
Arterial disease and vasospasm: cannabis leads to
Accelerated atherosclerosis
Reversible cerebral vasoconstriction syndrome
Multifocal intracranial stenosis
Cerebral vasculitis?[a]

[a] *To date, there is no pathological evidence that cannabis leads to cerebral vasculitis.*

Temporal Association Between Stroke Onset and Cannabis Use

A causal relationship between cannabis and stroke is strongly suggested by the close temporal link with stroke onset (Finsterer et al., 2004; Singh et al., 2012; Wolff et al., 2011). Stroke occurred while smoking cannabis in 13 of 17 (76%) patients, and during or within 30 min of last exposure in 16 (94%) patients (Singh et al., 2012). There are also multiple reports of recurrent strokes and TIAs following reexposure to cannabis. A 22-year-old man presenting with ischemic stroke had symptoms consistent with TIA while smoking cannabis 2 months, and again 4 days, prior to presenting with an ischemic stroke (Lawson & Rees, 1996). A 36-year-old man with sporadic cannabis use and no other vascular risk factors developed bilateral cerebral infarction after unusually heavy cannabis use (Mateo et al., 2005). He presented 1 year later with bilateral cerebral infarction immediately after using cannabis following a period of abstinence. He presented for a third time with an ischemic stroke, following heavy cannabis use after a further 1 ½ years of abstinence. In another study, 5 of 17 (29%) patients experienced recurrent stroke during reexposure to cannabis (Singh et al., 2012). In the study by Wolff et al. (2011), one of 10 patients with stroke and MIS did not stop using cannabis, and had a recurrent ischemic stroke.

Cannabis, Heart Disease, and Stroke

Cardiac embolism causes 20–25% of ischemic strokes. Thrombi develop in the heart as a complication of myocardial infarction or atrial fibrillation, and then embolize to the brain. Anything that increases the risk of myocardial infarction or atrial fibrillation can therefore lead to ischemic stroke and TIA.

In a case-crossover design study, the risk of myocardial infarction was elevated almost 5 times over baseline in the 60 min after cannabis use, and then rapidly tailed off with time (Mittleman et al., 2001). Bilateral cerebral infarction was reported in a 33-year-old man who had a myocardial infarction following a significant increase in his longstanding cannabis use (Renard et al., 2012).

Cannabis has also been associated with paroxysmal atrial fibrillation (Singh, 2000; Kosior, Filipiak, Stolarz, & Opolski, 2001; Fisher, Ghuran, Vadamalai, & Antonios, 2005; Charbonney, Sztajzel, Poletti, & Rutschmann, 2005; Korantzopoulos, Liu, Papaioannides, Li, & Goudevenos, 2008). The patients are younger, and the atrial fibrillation tends to be of short duration, and comes on during or shortly after cannabis use. In one review, none of six atrial fibrillation patients who had used cannabis had structural heart disease

(Korantzopoulos et al., 2008). In one of the more interesting cases, a 32-year-old medical doctor performed a provocative test by smoking cannabis during Holter monitoring, and developed paroxysmal tachycardia and atrial fibrillation lasting for 2 min (Kosior et al., 2001). He remained in sinus rhythm with cannabis abstinence over the next 12 months.

A detailed discussion of how cannabis may lead to heart disease is beyond the scope of this chapter. However, in brief, cannabis has a number of cardiovascular effects, including a dose-dependent increase in heart rate, supine hypertension, postural hypotension, and an increase in cardiac output (Jones, 2002). This is mediated through changes in autonomic tone with increases in sympathetic, and decreases in parasympathetic, activity. This increase in cardiac work, coupled with increased carboxyhemoglobin concentration and reduced blood oxygen carrying capacity, may lead to an imbalance between myocardial oxygen demand and supply (Aronow & Cassidy, 1974).

Chronic cannabis use is associated with increased cerebrovascular resistance through changes mediated through blood vessels or the brain parenchyma (Herning, Better, Tate, & Cadet, 2005). Cannabis increases apolipoprotein C levels and triglycerides, and may lead to atherosclerosis by recruiting monocytes to the vascular endothelium. This has led one group to suggest that the vasculature of 18–30-year-old cannabis users is "comparable to that of 60 year olds" (Herning, Better, Tate, & Cadet, 2001).

REVERSIBLE CEREBRAL CANNABIS ARTERIOPATHY

Vasospasm induced by cannabis may lead to ischemic stroke (Zachariah, 1991; Mesec et al., 2001; Ducros et al., 2007). In 1991, Zachariah reported two men in their 30s who developed cerebral infarction during or within 30 min of smoking cannabis (Zachariah, 1991). They had no vascular risk factors apart from tobacco use, but both patients had elevated blood pressure at presentation. The author postulated that a marked, cannabis-induced increase in blood pressure resulted in cerebral vasospasm and stroke. This couldn't be confirmed, as both patients declined angiography. In a later study of 62 RCVS patients, 20 (30%) had used cannabis, and many had also used other vasoactive substances such as selective serotonin reuptake inhibitors (SSRIs), and nasal decongestants (Ducros et al., 2007).

Patients with imaging-proven RCVS and stroke following cannabis use have been reported. A 46-year-old man was reported with recurrent thunderclap headaches and multifocal cerebral infarction, after cannabis use (Calabrese, Dodick, Schwedt, & Singhal, 2007). Vascular imaging showed multifocal segmental stenoses of the middle cerebral, posterior cerebral, basilar, and superior cerebellar arteries that resolved on follow-up imaging. One of 25 (4%) cannabis positive stroke patients in another study had clear clinical and radiological evidence of RCVS (Barber et al., 2013). This was a 54-year-old woman admitted with recurrent thunderclap headaches, and right sided weakness (Fig. 51.1). She used cannabis daily, and was treated for depression with the SSRI fluoxetine. She had left anterior circulation territory infarction and vasoconstriction in the branches of both middle cerebral arteries. She continued to use cannabis, and presented again with further thunderclap headache, and new left-sided sensory symptoms. Repeat imaging showed bilateral cerebral infarction, and more extensive cerebral vasoconstriction. At this point, it was realized that she was going outside the hospital in the evenings to smoke cannabis. The SSRI and cannabis were stopped, the headaches resolved, and repeat vascular imaging showed resolution of the cerebral vasoconstriction. Patients such as these confirm the temporal relationship between cannabis use, cerebral vasoconstriction, and stroke, with a cessation of clinical syndrome and resolution of vasospasm with abstinence (Calabrese et al., 2007). However, only a minority of cannabis-associated stroke patients have the full spectrum of clinical and imaging features of RCVS.

MIS has been reported in 10 out of 13 (77%) patients presenting with ischemic stroke and with positive cannabis screens, compared to only one of 35 (3%) patients with negative cannabis screens (Wolff et al., 2011). The stenoses preferentially involved arteries in the posterior cerebral circulation. Six patients stopped cannabis, with no evidence of relapse over the next 3–6 months, and full or partial reversal of the MIS on repeat vascular imaging. Three patients continued to smoke cannabis, and the MIS persisted in all three, and one had a recurrent ischemic stroke. The authors suggested that the persistence of arterial stenoses with ongoing cannabis exposure argued against vasospasm, although they still thought MIS could be considered a variant of RCVS (Wolff et al., 2013). This work needs to be replicated. In the meantime, the term reversible cerebral cannabis arteriopathy may be a better term to use until the exact nature of the cannabis-associated vascular changes have been clarified.

Cerebral Vasculitis and Cannabis-Associated Stroke

Cerebral vasculitis has also been postulated to cause stroke, following cannabis use (Thanvi & Treadwell, 2009). Cannabis can lead to a severe peripheral arteritis similar to thromboangiitis obliterans, in young male cannabis users (Disdier et al., 2001; Peyrot et al., 2007). A toxic or

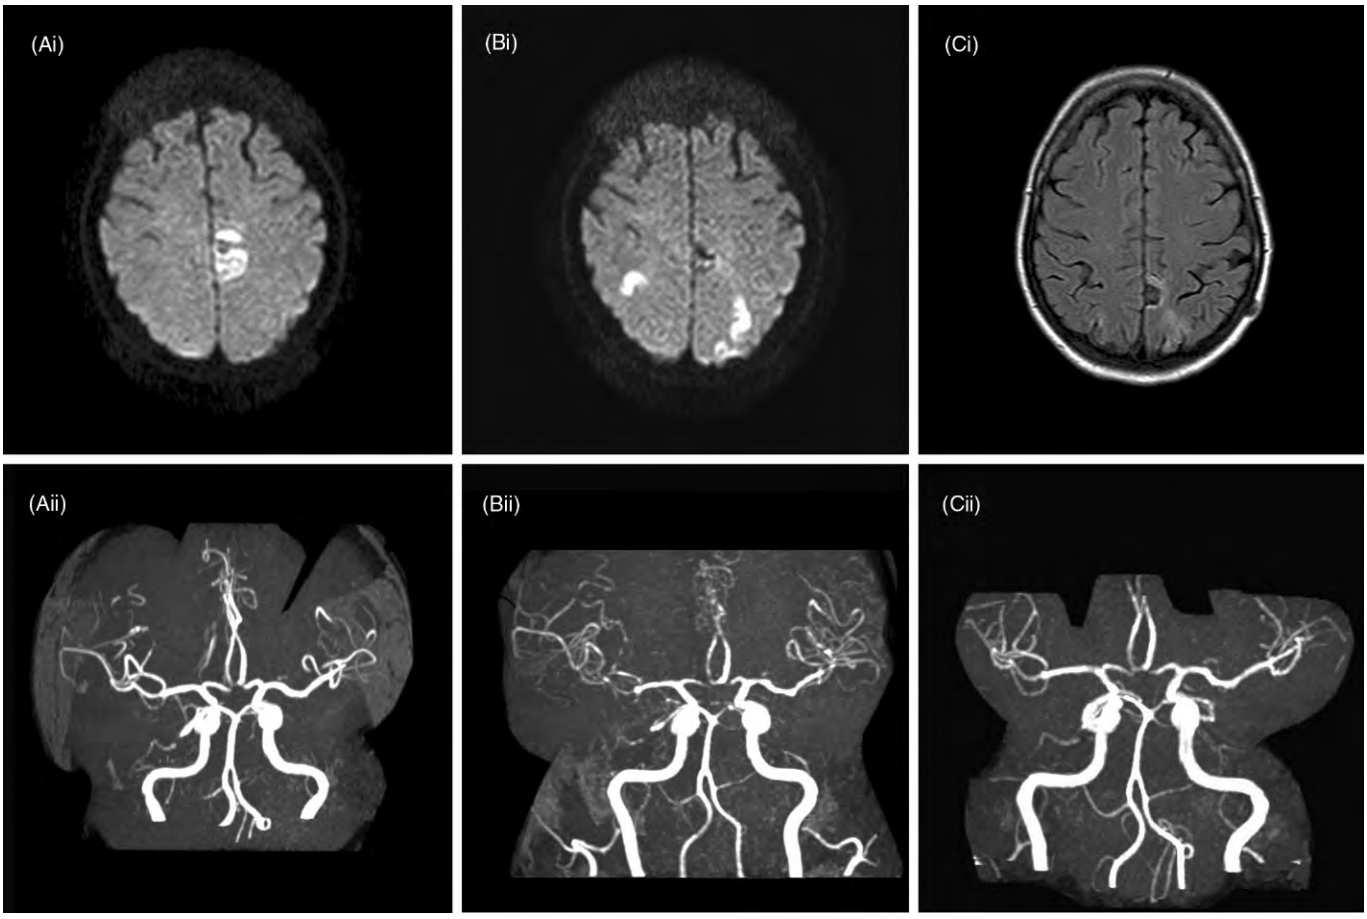

FIGURE 51.1 MRI diffusion-weighted imaging (DWI) (Ai and Bi), and FLAIR imaging (Ci) and angiography (MRA) (Aii, Bii, and Cii), in a 54-year-old woman presenting with recurrent thunderclap headaches and right-sided weakness, and a clinical and imaging course consistent with reversible cerebral vasoconstriction syndrome. The patient used cannabis daily, and was treated for depression with the SSRI antidepressant medication, fluoxetine.

- At presentation (A), the DWI shows left anterior circulation territory infarction and vasoconstriction in the branches of right middle cerebral artery (MCA).
- Ten days after admission (B), she had a further thunderclap headache, and developed new left-sided sensory symptoms. Repeat imaging showed bilateral cerebral infarction on the DWI, and more extensive segmental and multifocal stenosis of the branches of both MCAs. It became clear that the patient was continuing to use cannabis. The SSRI and cannabis were stopped, and the headaches resolved.
- Six weeks after admission (C), repeat imaging showed bilateral cerebral infarction on FLAIR imaging, and resolution of the cerebral vasoconstriction.

immune inflammatory cannabis induced vasculopathy has been suggested in the report of a 36-year-old man presenting with bilateral ischemic strokes, and reduced caliber of the distal temporal branches of the left MCA, following an unusually heavy intake of cannabis (Mateo et al., 2005). These vascular changes were still present when the patient presented 1 year later, with further cerebral infarction. Wolff et al. (2013) suggested that the long duration of stenoses seen in patients with MIS was in favor of a drug-induced immunoallergic vasculitis (Wolff et al., 2013). However, there has never been any pathological evidence of cerebral vasculitis, with no infectious or noninfectious vasculitis seen in autopsies (two patients) or biopsy (one patient) of three adolescent men with cerebellar infarction, following cannabis use (Geller, Loftis, & Brink, 2004).

CONCLUSIONS

Cannabis is used by 11–27% of younger stroke patients. In recent years, the numbers of people with stroke using cannabis has been increasing, reflecting increased use in the wider community. Cannabis has been legalized for medicinal use in many US states, and the District of Columbia, and at the time of writing, can be bought legally for recreational use in Colorado and Washington State, Uruguay, and The

TABLE 51.4 Future Research Questions

Is there an association between cannabis use and stroke/TIA independent of tobacco?
Association independent of tobacco not shown to date
Confounded by the fact that most people who use cannabis also use tobacco
Are the reports of increasing cannabis use in stroke patients due to
A true increase in cannabis use?
Greater willingness of patients to volunteer cannabis use?
Greater willingness of clinicians to ask about cannabis use?
Does counselling stroke/TIA patients who have used cannabis reduce recurrent stroke?
Does cannabis lead to cerebral vasculitis?
Studies with biopsies required
Is multifocal intracranial stenosis simply a form of RCVS?
More studies with serial, high quality vascular imaging required

Netherlands. Use will further increase, as pressure to legalize cannabis elsewhere has an effect.

A causal link between cannabis and ischemic stroke, independent of tobacco, has not been proven, but is plausible. The high and increasing rates of cannabis use in people presenting with stroke makes it imperative that research is carried out to determine whether or not there is a link independent of other vascular risk factors (Table 51.4). This will require documentation of the timing, amount, and mode of cannabis use. Urine or blood should be tested, as questioning people is likely to obtain unreliable responses, and is prone to bias. Study design will be complicated by the fact cannabis is still, in most jurisdictions, illegal.

In the meantime, it is important for physicians caring for people with vascular disease to be aware of this potential association. Consideration should be given to screening younger stroke and TIA patients for cannabis, particularly where there are no other vascular risk factors found. Patients with positive tests could then be counseled about the association between cannabis and stroke, so that they are able to make informed decisions on future use.

MINI-DICTIONARY

Cardiac embolism Thrombi (blood clots) that form in the heart in people with atrial fibrillation, or after myocardial infarction (heart attack) that break off into the systemic circulation. These thrombi may block arteries in the brain or body, leading to ischemia and infarction of the tissue downstream to the blockage.
Infarction Death of tissue in the brain (cerebral) or heart muscle (myocardial) due to ischemia.
Intracerebral hemorrhage (ICH) Sudden onset of focal neurological deficit due to hemorrhage into brain parenchyma. In Caucasian populations, ICH accounts for 10–15% of all strokes.
Ischemia Reduced blood flow to the brain (cerebral ischemia), heart (coronary ischemia), or limbs (peripheral vascular ischemia).
Ischemic stroke Sudden onset of focal neurological deficit due to loss of blood supply to part of the brain, with evidence of cerebral infarction on brain imaging. In Caucasian populations, ischemic stroke accounts for 80–85% of all strokes.
Multifocal intracranial stenosis (MIS) Multifocal stenosis (narrowing) of intracranial arteries that may persist with continued cannabis exposure.
Reversible cerebral cannabis arteriopathy A term to describe the segmental and multifocal stenosis of arteries in patients presenting with stroke after using cannabis, which may be due to RCVS or MIS.
Reversible cerebral vasoconstriction syndrome (RCVS) A group of disorders where patients present with severe, often "thunderclap onset" headaches, with or without focal neurological deficits or seizures, and with reversible segmental and multifocal vasoconstriction (narrowing or occlusion) of cerebral arteries. Previously known as Call–Fleming syndrome.
Transient ischemic attack (TIA) Stroke symptoms and signs that usually disappear within minutes, with no evidence of infarction on brain imaging. TIAs may precede, and have the same causes, as ischemic stroke.
Vasculitis A disorder that damages arteries (arteritis) and veins by inflammation, leading to stenosis or occlusion of the affected vessel, and resulting in ischemia and infarction. In the brain, this is called cerebral vasculitis.

Cannabis Smoking and the Lung

D.P. Tashkin

Division of Pulmonary and Critical Care, Department of Medicine, David Geffen School of Medicine at UCLA, Los Angeles, CA, United States

SUMMARY POINTS

- Nearly all systematic studies of the relationship between habitual cannabis smoking and chronic respiratory symptoms and/or lung function have consistently shown that cannabis is significantly associated with an increased prevalence of symptoms of chronic bronchitis (chronic cough and sputum, often with wheezing).
- On the other hand, the association with lung function impairment has been mixed, some studies showing no abnormalities in lung function in users of cannabis without tobacco, compared to the lung function of nonsmokers in either cross-sectional and/or longitudinal analysis, while others have suggested the presence of mild airflow obstruction; an exception is the finding of a modest, clinically insignificant reduction in specific airway conductance (increased resistance to airflow mainly in larger airways) in all three of the studies in which this measurement was made.
- The weight of evidence to date, therefore, does not suggest that regular cannabis use, in the absence of tobacco, is a significant risk factor for the development of chronic obstructive pulmonary disease.
- Habitual smoking of cannabis has been shown to be associated with evidence of microscopic injury to bronchial lining cells, including precancerous histopathologic alterations, and increased expression of molecular markers of pretumor progression.
- Several cases of lung cancer have been reported in relatively young patients with a history of heavy cannabis use, and some case-control studies have reported significantly positive associations with cannabis use, but these have been flawed by the inability to control for the confounding influence of tobacco, or small sample sizes among the heavier users, resulting in imprecise estimates of risk.
- In contrast, a large prospective cohort study and a case-control study that included large numbers of heavy cannabis users among both the cases and controls have failed to show any positive association with cannabis use, even heavy use; these negative findings need to be replicated.
- The immunosuppressive effect of Δ^9-tetrahydrocannabinol (THC), and the cannabis-associated bronchial epithelial injury that results in increased numbers of mucus-secreting cells, and the loss of ciliated bronchial epithelium, are likely to impair the lung's defense against infection.
- Case series and older observational studies suggest a possible association between cannabis use and both fungal and bacterial pneumonia, as well as pulmonary tuberculosis; however, large-scale epidemiologic studies have yet to be performed to test the significance of an association between cannabis and pneumonia.
- Several cases of pneumothorax and/or pneumomediastinum, as well as bullous lung disease, have been reported in mostly heavy users of cannabis, in association with variable lifetime cumulative tobacco smoking, but a cause-and-effect relationship with cannabis has not been established.

KEY FACTS

- Regular smoking of cannabis (in the absence of tobacco) has been associated with symptoms of chronic bronchitis (cough and sputum) in most observational or community-based studies.
- Regular use of cannabis without tobacco has been variably associated with mild, if any, physiologic evidence of airflow obstruction but without any evidence of an abnormality in gas transfer (diffusing capacity).
- A majority of heavy habitual smokers of cannabis alone have widespread histopathological abnormalities involving the bronchial mucosa, including destruction of ciliated epithelial cells, and increased numbers of mucus-secreting surface epithelial cells, possibly accounting for the prevalent symptoms of chronic bronchitis.
- While cannabis smoke contains the same carcinogens found in tobacco and while some of the histopathological changes in the bronchial mucosa are considered precancerous, most well-controlled case-control studies have failed to find an association with lung cancer after controlling for tobacco.
- Some case series and older epidemiologic studies have suggested as association between cannabis use and fungal, bacterial, or mycobacterial infection, but well-designed epidemiologic studies are lacking.
- A few case series of pneumothorax/pneumomediastinum or bullous lung disease in smokers of cannabis (most often along with tobacco) have been reported, but a causal relationship has not yet been established.

LIST OF ABBREVIATIONS

AIDS	Acquired immune deficiency syndrome
CI	Confidence interval
COPD	Chronic obstructive pulmonary disease
CS	Smoker of cannabis only
CTS	Smoker of cannabis plus tobacco
D_LCO	Diffusing capacity of the lung for carbon monoxide
EGRF	Epidermal growth factor receptor
FEV_1	Forced expired volume in 1 second
FRC	Functional residual capacity
FVC	Forced vital capacity
HIV	Human immunodeficiency virus
HRCT	High resolution computed tomography
Ki-67	A cellular marker associated with cell proliferation
NS	Nonsmoker
OR	Odds ratio
PAHs	Polycyclic aromatic hydrocarbons
RV	Residual volume
SG_{aw}	Specific airway conductance
THC	Δ^9-Tetrahydrocannabinol
TLC	Total lung capacity
TS	Smoker of tobacco only

INTRODUCTION

Since the contents of cannabis smoke include an array of noxious and carcinogenic chemicals, similar to that found in tobacco smoke, there is understandable concern that habitual cannabis smoking might injure the lung in the same manner as tobacco smoking, and thereby predispose to the same pulmonary disorders associated with tobacco. The latter include simple chronic bronchitis, chronic obstructive pulmonary disease (chronic obstructive bronchitis and emphysema), lung cancer, and a heightened risk of pneumonia. This review will focus on the evidence concerning the potential associations of regular cannabis smoking, and the occurrence of these tobacco-related disorders, after adjusting for concomitant use of tobacco and other relevant risk factors. In addition, the evidence pertaining to other potential respiratory risks of cannabis use will be reviewed.

ACUTE EFFECTS OF CANNABIS ON AIRWAY DYNAMICS

In contrast to tobacco cigarette smoking, which causes temporary bronchial constriction mediated via a cholinergic reflex in response to irritants in the smoke (Nadel & Comroe, 1961), cannabis smoking produces acute bronchial dilatation that is directly proportional to the concentration of Δ^9-tetrahydrocannabinol (THC) (Tashkin, Shapiro, & Frank, 1973; Vachon, Fitzgerald, Solliday, Gould, & Gaensler, 1973). Smoked cannabis also causes bronchodilation in patients with asthma (Tashkin, Shapiro, & Frank, 1974) and, furthermore, reverses experimentally induced bronchospasm (Tashkin, Shapiro, Lee, & Harper, 1975). The mechanism of THC-induced bronchodilation involves stimulation of prejunctional cannabinoid-type 1 (CB1) receptors on efferent vagal nerves in the airway, resulting in inhibition of release of acetylcholine from these nerve endings, and of cholinergically mediated airway smooth muscle contraction (Calignano et al., 2000; Grassin-Delyle et al., 2014).

CHRONIC EFFECTS OF CANNABIS ON THE LUNG

Effects on Chronic Respiratory Symptoms

Several studies involving smokers and nonsmokers of cannabis and/or tobacco recruited from the general community have examined possible associations of cannabis alone, tobacco alone, cannabis plus tobacco, and

no smoked substance, with self-reported chronic respiratory symptoms (chronic cough, sputum production, wheeze, chest tightness and shortness of breath) (Tashkin et al., 1987; Bloom, Kaltenborn, Paoletti, Camilli, & Lebowitz, 1987; Taylor, Poulton, Moffitt, Ramankutty, & Sears, 2000; Aldington et al., 2007; Moore, Augustson, Moser, & Budney, 2004; Tan et al., 2009) (Table 52.1). All but one of these studies showed a significant increase in symptoms of chronic bronchitis (chronic cough and/or sputum), along with wheeze, in smokers of cannabis alone (CS), compared with nonsmokers of any substance (NS); in two studies (Tashkin et al., 1987; Aldington et al., 2007) in which comparisons were made with smokers of tobacco alone (TS), the increase in these symptoms were compared to those noted in TS, without evidence of additive effects in the combined smokers of both cannabis and tobacco (CTS). Increases in chest tightness and shortness of breath in the CS, compared to NS, were variably observed. In one other study (Tan et al., 2009), a survey of a random sample of residents of Vancouver, Canada, an increase in the odds ratio (OR) for self-reported chronic respiratory symptoms was found for TS and CTS (but not for CS) versus NS. Taken together, the findings from these studies provide mostly consistent evidence of an association between cannabis use itself (apart from tobacco) and symptoms of chronic bronchitis.

An 8-year follow-up study of habitual smokers of cannabis demonstrated that CS who quit smoking cannabis subsequently experienced a significant reduction in their symptoms of cough, sputum, and wheeze, compared to those who continued to smoke, indicating that cannabis smoke-induced symptoms of chronic bronchitis are reversible (Tashkin et al., 2012). The latter possibility is supported by self-reported data from an internet survey of 6883 cannabis users which revealed that switching from smoking cannabis to using a vaporizer was followed by a reduction in self-reported respiratory symptoms; however, these results could have been influenced by reporting bias (Earleywine & Barnwell, 2007).

Two studies have examined the risk of cannabis for acute respiratory illnesses. Daily smokers of cannabis who did not smoke tobacco (n = 452), followed for ≥2 years in a health maintenance organization, had a small but significantly increased risk of outpatient visits for acute respiratory illnesses, compared to nonsmokers of either substance (n = 450) (relative risk 1.19; 95% CI 1.01–1.41) (Polen, Sidney, Tekawa, Sadler, & Friedman, 1993). In a convenience sample of nonsmokers and smokers of cannabis and/or tobacco, CS (n = 144) had a significantly higher incidence of episodes of acute bronchitis, compared to the nonsmokers (n = 99) ($p < 0.01$) (Tashkin et al., 1987).

Effects on Lung Function

Measurements of lung function were performed in most of the previously cited studies. In addition to these studies, lung function was also measured in a convenience sample of heavy, habitual cannabis smokers (Tashkin, Calvarese, Simmons, & Shapiro, 1980), a longitudinal extension of a birth cohort study already cited (Hancox et al., 2010; Taylor et al., 2000), and in another cohort study in which participants were followed for 20 years (Table 52.2). In two of the studies in which lung function was assessed cross-sectionally (Bloom et al., 1987; Taylor et al., 2000), a slight decrease was noted in the ratio of the forced expired volume in 1 s (FEV_1) to the forced vital capacity (FVC), suggesting possible early airflow obstruction in the CS, compared to the NS. In five other studies involving cross-sectional analysis, no association was found between spirometric evidence of airflow obstruction (as defined by a reduced FEV_1/FVC ratio) and cannabis, after adjusting for tobacco (Tashkin et al., 1980, 1987; Aldington et al., 2007; Tan et al., 2009; Hancox et al., 2010). Moreover, in one of the latter studies, a significant increase in FVC was noted in the CS (Hancox et al., 2010), consistent with possible stretching of the lung by the deep breathing maneuvers characteristic of cannabis smoking topography; thus, an elevated FVC could spuriously reduce the FEV_1/FVC ratio, so that the reduced FEV_1/FVC ratio noted in the two studies cited previously might not reflect the presence of true airflow obstruction. In longitudinal follow-up studies (Tashkin, Simmons, Sherrill, & Coulson, 1997,

Definition of abbreviations: FEV_1, forced expired volume in 1 second; FVC, forced vital capacity; FEV_1/FVC, ratio of FEV_1 to FVC (the preferred measure for defining the presence of airflow obstruction); TLC, total lung capacity; FRC, functional residual capacity; RV, residual volume; SG_{aw}, specific airway conductance; D_LCO, single-breath diffusing capacity of the lung for carbon monoxide; ns, no significant difference from nonsmokers; NR, not reported; ↓, significant decrease compared to nonsmokers ($p < 0.05$); significant ↑ compared to nonsmokers ($p < 0.05$).

[a] *No significant ↓ in current cannabis smokers.*

[b] *Assessments over 20 years of follow-up; model includes lifetime exposure in joint-years.*

[c] *Among those with > 20 joint-years, significant ↓ in FEV_1/FVC but significant ↑ in FVC and a trend toward significant ↑ in FEV_1.*

Hancox et al., 2010; Pletcher et al., 2012), no significant association was found between cannabis use alone and the decline in FEV_1 with age, in contrast to an accelerated decline in lung function (characteristic of chronic obstructive pulmonary disease, COPD) associated with tobacco smoking. In one of these longitudinal studies (Pletcher et al., 2012), a nonsignificant trend toward decreases in FEV_1 over 20 years was noted only in the heaviest smokers of cannabis (50 joint-years), although the latter smokers comprised less than 1% of the study participants. In three studies in which airway resistance was measured with a body plethysmograph (Tashkin et al., 1980, 1987; Aldington et al., 2007), a modest increase in airway resistance (denoting some obstruction in the large central airways) was observed in the CS; however, this finding is probably of little clinical significance, given that the major site of obstruction in COPD is in the smaller, peripheral airways, and sensitive tests of small airways function have been found to be normal in CS (Tashkin et al., 1980, 1987). No physiologic evidence of pulmonary emphysema, for which the diffusing capacity of the lung for carbon monoxide (D_LCO) is a sensitive, if nonspecific, test, was found in the two studies in which the D_LCO was measured (Tashkin et al., 1987; Aldington et al., 2007). In summary, most published studies failed to find a positive association between cannabis use (in the absence of concomitant tobacco smoking) and the development of significant or clinically meaningful airflow obstruction or impairment in diffusing capacity, implying that regular use of cannabis, in contrast to tobacco, does not appear to be a significant risk factor for the development of COPD.

Given the similarity in the smoke contents of cannabis and tobacco, it is unclear why most studies fail to demonstrate evidence of significant airflow obstruction in habitual cannabis smokers, in contrast to consistently reported findings in regular tobacco smokers. It is unlikely that the acute bronchodilator effect of the THC within cannabis, in contrast to the acute bronchoconstrictor effect of tobacco, would account for this difference. A possible explanation is that the well-documented antiinflammatory effect of THC, including impairment of the activation of alveolar macrophages (the major immune effector cell residing in the air spaces) (see later), may counteract the proinflammatory effects of other components within the smoke, thus inhibiting the inflammatory cascade underlying the development of COPD in regular tobacco smokers.

Effects on Thoracic High-Resolution Computed Tomography

Aldington et al. (2007) obtained thoracic high-resolution computed tomography (HRCT) scans in 75 CS, 91 CTS, 92 TS, and 81 NS, and noted a small but significant increase in the percentage of CS and CTS with very

low levels of lung attenuation (suggesting enlarged air spaces) in the lung apices, compared to both NS and TS. However, no evidence of macroscopic emphysema was found in the CS.

Effects on Lung Pathology: Animal Studies

Only few long-term animal exposure studies have been reported. Cannabis smoke-inhaling dogs have been shown to develop evidence of bronchiolitis, and squamous metaplasia of the trachea (Roy, Magnan-Lapointe, Huy, & Boulet, 1976). Rats chronically exposed to the inhaled smoke of cannabis have developed a dose-related focal pneumonitis with some areas of early scarring (Fleischman, Hayden, Braude, & Rosenkrantz, 1975; Fleischman, Baker, & Rosenkrantz, 1979). It is noteworthy, however, that control animals in these same studies developed at least qualitatively similar histopathologic changes. In a study in which rhesus monkeys inhaled smoke from high or low amounts of cannabis (7 vs 2 days a week, respectively) or placebo (cannabis-extracted smoke) versus sham smoke, over 12 months, a higher frequency of several histopathological alterations (alveolitis, alveolar cell hyperplasia, and granulomatous inflammation) were found in the lungs of all smoking groups (irrespective of the cannabis amount), compared to the sham group (Fligiel et al., 1991). In another study, exposure of rats to comparable amounts of cannabis or tobacco smoke, for up to 1 year, failed to reveal any morphological or physiological evidence of emphysema in the cannabis-exposed animals, in contrast to the tobacco-exposed rats, which did develop emphysematous changes (Huber & Mahajan, 1987).

Effects on Human Bronchial Pathology

Videobronchoscopy was performed in 40 habitual smokers of cannabis and/or tobacco or nonsmokers (ages 20–49) to assess visual, as well as microscopic, evidence of airway injury and inflammation; the videotapes were blindly scored by an objective observer (Roth et al., 1998). Scores for visual changes of bronchitis (erythema, edema, increased secretions) were significantly higher in all of the smoking groups, compared to the nonsmokers. The visual changes correlated well with histopathologic evidence in endobronchial biopsies of vascular hyperplasia, submucosal edema, inflammatory cell infiltrates, and hyperplasia of mucus-secreting surface epithelial (goblet) cells. These findings indicate that regular cannabis smoking by young adults is associated with significant airway inflammation that is similar in frequency, type, and magnitude to that found in regular tobacco smokers.

Endoscopic biopsies of bronchial mucosa obtained in a total of 40 CS, 44 CTS, 31 TS, and 53 NS revealed significantly higher percentages of histopathologic alterations, including basal and goblet cell hyperplasia, squamous metaplasia, inflammation, cellular disorganization, and increased nuclear/cytoplasmic ratio in the CS that were comparable to the changes in the TS, with the suggestion of additive abnormalities in the combined smokers of both cannabis and tobacco (Fligiel et al., 1997). The increased numbers of goblet (mucus-secreting) cells, and the loss of ciliated bronchial epithelium replaced by basal, goblet and squamous cells, might explain the association between cannabis use and symptoms of chronic bronchitis; the combination of increased mucus production from the hyperplastic goblet cells, and the diminished capacity of the airways to clear the increased mucus, due to the loss of ciliated epithelium, leaves cough as an alternative mechanism to eliminate the increased mucus from the airways.

Effects on Alveolar Macrophage Number and Function

Bronchoalveolar lavage performed during bronchoscopy has revealed a threefold increase in the numbers of alveolar macrophages in both CS and TS, compared to NS, and a sixfold increase in CTS, as well as increases in neutrophils in all the smoking groups (Barbers, Gong, Tashkin, Oishi, & Wallace, 1987), documenting the impact of cannabis on lung inflammation, and the additive effects of combined smoking of both cannabis and tobacco. On the other hand, functional studies have revealed an impairment in both the phagocytic and microbicidal activity of alveolar macrophages in CS, but not TS (Baldwin et al., 1997). The mechanism of the cannabis-related impairment in alveolar macrophage bactericidal activity appears to be related to the immunosuppressive effect of THC that is mediated by cannabinoid type 2 (CB2) receptors on immune cells (Roth, Whittaker, Salehi, Tashkin, & Baldwin, 2004). THC-related immunosuppression leads to impairment in stimulated production by alveolar macrophages of proinflammatory cytokines (Roth et al., 2004) that are required during infection for upregulation of inducible nitric oxide synthase (Shay et al., 2003) that leads, in turn, to the production of nitric oxide as an effector molecule in bacterial killing. A consequence of THC-related inhibition of alveolar macrophage function is an impairment in the lung's defense against infection (see below).

RELATIONSHIP TO LUNG CANCER

A positive association of cannabis use with lung cancer is suggested by the following lines of evidence (Table 52.3). Cannabis smoke contains procarcinogenic chemicals, including the polycyclic aromatic hydrocarbons (PAHs), benzpyrene and benzanthracene, in concentrations not dissimilar to those found in tobacco

TABLE 52.3 Evidence Supporting a Positive Association Between Cannabis Use and Lung Cancer

- Presence of procarcinogens in the tar phase of mainstream cannabis smoke (eg, polycyclic aromatic hydrocarbons, including benz(a)pyrene and benz(a)anthracene) (Moir et al., 2008)
- Fourfold increase in lung deposition of insoluble smoke particulates (tar) from a single marijuana joint, compared to a single tobacco cigarette of the same weight (Wu et al., 1988)
- Precancerous histopathologic alterations in the bronchial epithelium of habitual cannabis smokers (Fligiel et al., 1997)
- Upregulation of molecular markers of pretumor progression (eg, EGFR and Ki-67) in the bronchial epithelium of habitual cannabis smokers (Barsky et al., 1998)
- Case series of an unexpectedly higher proportion of cannabis smokers (compared to the general population) among individuals diagnosed at an unusually young age with respiratory cancer (lung and upper aerodigestive tract cancers) (Sridhar et al., 1994; Fung et al., 1999)
- Case-control studies showing a significantly positive association of cannabis use with lung cancer (Berthiller et al., 2008—review of three separate North African studies; Aldington et al., 2008; Callaghan, Allebeck, & Sidorchuk, 2013)

smoke (Moir et al., 2008). While cannabis is generally smoked in lower amounts than tobacco, the prolonged breath-holding time during cannabis smoking, and the reduced rod filtration due to more loosely packed cannabis, leads to a fourfold increase in the respiratory deposition of tar, which contains the carcinogenic PAHs (Wu, Tashkin, Djahed, & Rose, 1988). Several of the histopathologic alterations within the bronchial epithelium of smokers of cannabis, even in the absence of tobacco, including squamous metaplasia, cellular atypia, and increased nuclear/cytoplasmic ratio, are considered to be premalignant (Fligiel et al., 1997; Auerbach, Stout, Hammond, & Garfinkel, 1961). Moreover, bronchial biopsies from habitual smokers of cannabis alone have shown significantly increased expression of molecular markers of pretumor progression, including EGRF (epidermal growth factor receptor) and Ki-67 (a nuclear proliferation protein), compared to nonsmokers (Barsky, Roth, Kleerup, Simmons, & Tashkin, 1998). Furthermore, several small case series have indicated an unusually high proportion of regular cannabis smokers among young persons (<40–45 years of age) with lung and upper airway cancer (Taylor, 1988; Sridhar et al., 1994; Fung, Gallagher, & Machtay, 1999), although such case series do not serve as evidence of causality.

A pooled analysis of three North African hospital-based case-control studies from Morocco, Tunisia, and Algeria (Berthiller et al., 2008) found a positive association of cannabis use with lung cancer, after adjustment for age, occupational exposure, and lifetime pack-years of tobacco smoking (not including the tobacco admixed with cannabis in the smoked product), with OR (95% CI) of 2.2 (1.1–4.5), 4.1 (1.8–9.0), and 2.0 (0.7–5.3), respectively. However, none of these studies could fully adjust for the confounding influence of tobacco, since cannabis is typically admixed with tobacco in the form of a "kiff," and smoked.

A population-based case-control study from New Zealand compared 79 lung cancer cases identified between 2001 and 2005 in individuals aged ≤55 years, with randomly selected controls matched for age (Aldington et al., 2008). OR for the association of cannabis use and lung cancer determined by multivariate logistic regression, with adjustments for age, gender, ethnicity, family history of lung cancer, and pack-years of tobacco, showed no difference between smokers of cannabis with a cumulative lifetime history of ≤10.5 joint-years, and nonsmokers (OR point estimates 0.3–0.9), but a significantly increased risk of lung cancer for cannabis smokers with >10.5 joint-years (OR 5.7; 95% CI 1.5–21.6). It is noteworthy, however, that the latter subgroup of heaviest cannabis smokers included only 14 cases and 4 controls; this very small sample size, therefore, likely led to imprecise and inflated estimates.

A possible association between cannabis and lung cancer has more recently been examined in a Swedish population-based cohort study of 49,321 men who had been questioned about tobacco and cannabis use during military conscription at age 18–20 years, and subsequently tracked for up to 40 years for incident lung cancer, using nationwide linked medical registries (Callaghan et al., 2013). Cox regression was used to assess relationships between lifetime use of cannabis *prior* to the time of conscription, and the risk of subsequent lung cancer, adjusted for cumulative tobacco use up to (but not beyond) the age of 18–20 years, chronic lung disease, and socioeconomic status. Whereas no association was found between smoking cannabis up to 50 times (lifetime use prior to the age of 18–20 years) and subsequent lung cancer incidence, a positive association was observed between lung cancer and smoking cannabis >50 times prior to conscription (hazard ratio 2.12; 95% CI 1.08–4.14). The major weakness of this study is the inability to adjust for true lifetime use of tobacco, including use during the ≤40-year follow-up period, as a crucially important confounder, or to take true lifetime use of cannabis into account.

Other evidence does not support a link between cannabis and lung cancer (Table 52.4). A retrospective cohort study of 64,855 enrollees, aged 15–49 years, in a health management program in California, United States, examined the association of self-reported cannabis use with cancer incidence over a mean of 8.6 years of follow-up (Sidney, Quesenberry, Friedman, & Tekawa, 1997). Ever- and current use of cannabis was not found to be associated with an increased risk of tobacco-related cancers, after adjustment for tobacco, alcohol use, and socioeconomic status in either men (relative risk 0.9; 95% CI 0.l7–1.2) or women (relative risk 1.0; 95% CI 0.8–1.1). A

TABLE 52.4 Evidence *Not* Supporting a Positive Association Between Cannabis Use and Lung Cancer

- Demonstration by several investigators of antitumoral effects of THC and other cannabinoids on a variety of malignancies (lung, glioma, thyroid, lymphoma, skin, pancreas, uterus, breath, prostate) in cell culture systems and animal models (reviewed in part by Bifulco, Laezza, Pisanti, & Gazzerro, 2006)
- Large retrospective cohort study failing to demonstrate an association between ever- or current use of cannabis, and any increased risk of lung or other tobacco-related cancers (relative risk ≤1.0) (Sidney et al., 1997)
- Large, prospective population-based case-control study failing to observe any positive association of cannabis use—even heavy, long-term use—with lung cancer (OR <1.0 for all quantity-duration categories of cannabis use), in contrast to a strong dose-response relationship for tobacco (Hashibe et al., 2006)

criticism of this study is that the enrollees were relatively young, and the follow-up period was relatively short, so that, over the period of observation, most of the cohort had not reached the age when cancer incidence is especially prominent, thereby limiting the power of the study to detect a statistically significant association between cannabis use and cancer.

The largest case-control study to estimate the effects of cannabis use on the risk of lung cancer was carried out in residents of Los Angeles county, aged 18–59 years (Hashibe et al., 2006). Over a 5-year period, 611 lung cancer cases and 1040 controls (matched on age, gender, and neighborhood as a surrogate for socioeconomic status) were enrolled and administered a detailed history of drug and alcohol use, occupational exposures, diet, and family history of cancer. Cases included 649 ever-smokers of cannabis, of whom 183 had a cumulative lifetime history of ≥10 joint-years, while controls included 557 ever-smokers of cannabis, of whom 112 had accumulated ≥10 joint-years of smoking. In unconditional logistic regression analyses, with age and gender as covariates, and adjustments for race, educational level, tobacco, and alcohol, no positive association was noted between any level of cannabis use (including ≥60 joint-years) and lung cancer incidence. Adjusted odds ratios (95% CI) ranged from 0.63 (0.46–0.87) for >0 to <1 joint-year to 0.62 (0.32–1.2) for ≥60 joint-years. In contrast, a strong dose-response relationship was observed between tobacco use and lung cancer: adjusted ORs ranged from 1.3 (0.96–1.8) for 1–20 pack-years, to 7.8 (5.5–11) for >30–40 pack-years, and 21 (12–32) for >40 pack years. While these findings argue against a link between cannabis use (when adjusted for concomitant tobacco smoking) and lung cancer, the study had limitations, including the large nonparticipation rate among individuals identified with lung cancer that could have led to selection bias, recall bias concerning how much cannabis was smoked, and errors in measuring the lifetime use of cannabis. Moreover, since the upper limit of the confidence intervals for the association of cannabis use and lung cancer exceeded 1.0, the possibility cannot be excluded that cannabis use might have contributed to the development of lung cancer in a small subgroup of cannabis smokers, particularly heavier users, who might have been unusually susceptible to the development of lung cancer for reasons other than cannabis (eg, genetic); however, these risks appear to be small, relative to the extensively documented hazards of tobacco smoking.

It is tempting to speculate on the reasons that might account for a null association between cannabis use (even heavy use) and lung cancer, in view of the fact that cannabis smoke contains carcinogens in amounts fairly comparable to those found in tobacco smoke. The generally smaller amounts of cannabis that are regularly smoked, compared to tobacco, do not appear to be entirely explanatory, since no dose-response relationship between cannabis use and lung cancer was observed in the large study of Hashibe et al. (2006), in contrast to the strong dose-response relationship observed for tobacco. A more likely explanation is the well-documented antitumoral effects of THC and other cannabinoids that have been demonstrated in both cell culture systems, and animal models of a variety of malignancies, as reviewed by Bifulco et al. (2006). These antitumoral effects (antimitogenic, proapoptotic, and antiangiogenetic) might be capable of counteracting the tumor-initiating or tumor-promoting effects of the carcinogens contained within the smoke of cannabis.

ASSOCIATION WITH LOWER RESPIRATORY INFECTION (TABLE 52.5)

THC-related impairment in the fungicidal and bactericidal activity of alveolar macrophages (the principal immune effector cell in the lung) (Baldwin et al., 1997; Shay et al., 2003) may compromise the lung's defense against microbial infection. Cannabis-related injury to the bronchial epithelium, manifested by loss of ciliated epithelial cells and hyperplasia of mucus-secreting goblet cells (Fligiel et al., 1997) can lead to further compromise of the lung's defense system by impairing mucociliary clearance, with accumulation of excess mucus in the airways that may serve as a substrate for microbes colonizing the airway.

As a consequence of cannabis-related impairment in the lung's defenses against infection, cannabis use could predispose to lower respiratory tract infection. Since cannabis has also been shown to be frequently contaminated with *Aspergillus fumigatus* (Kagen et al., 1983), and potentially pathogenic gram-negative bacteria (Ungerleider et al., 1982), introduction of these microorganisms into the lung by smoking provides an additional mechanism

TABLE 52.5 Evidence Implicating Cannabis Use as a Possible Risk Factor for Pneumonia

- Immunosuppressive properties of THC leading to inhibition of the phagocytic and microbicidal activity of alveolar macrophages, the primary immune effector cells in the lung responsible for the lung's defense against infection
- Destruction by regular cannabis smoking of ciliated epithelial cells in the bronchial mucosa, with replacement by mucus-secreting surface epithelial (goblet) cells, leading to excess mucus production and a diminished capacity to cleanse the airways of the mucus, which could serve as a substrate for infection
- Contamination of marijuana with *Aspergillus fumigatus* (Kagen, Kurup, Sohnle, & Fink, 1983) and potentially pathogenic gram-negative bacteria (Ungerleider, Andrysiak, Tashkin, & Gale, 1982)
- Case reports of *Aspergillus* pneumonia in cannabis smokers immunocompromised due to AIDS (Denning et al., 1991), chronic granulomatous disease (Chusid et al., 1975), bone marrow or renal transplantation (Hamadeh, Ardehali, Locksley, & York, 1988; Marks et al., 1996), chemotherapy for treatment of lung cancer (Sutton, Lum, & Torti, 1986)
- Acquisition of infection with tuberculosis by immunocompetent individuals sharing a cannabis bong with cases of active cavitary tuberculosis (Munckhof, Konstantinos, Wamsley, Mortlock, & Gilpin, 2003; Thu, Hayes, Miles, Tierney, & Foy, 2013)
- Older epidemiologic studies suggesting cannabis as an independent risk factor for opportunistic infection or bacterial pneumonia in HIV+ individuals (Newell et al., 1985; Tindall et al., 1988; Caiaffa et al., 1994). *However, an older AIDS cohort study has failed to implicate cannabis use as an independent risk factor for the development of an AIDS-defining opportunistic infection* (Kaslow et al., 1989)

whereby cannabis could increase the risk of pneumonia. This possibility is supported by case reports of *Aspergillus* pneumonia in smokers of cannabis who were immunocompromised by AIDS (Denning et al., 1991), chronic granulomatous disease (Chusid, Gelfiand, Nutter, & Fauci, 1975), bone marrow transplantation (Hamadeh et al., 1988), renal transplantation (Marks et al., 1996), or lung cancer treated with chemotherapy (Sutton et al., 1986). Although the underlying immuocompromised state could have been a factor contributing to opportunistic fungal infection in these patients, it is also possible that further immunosuppression by cannabis, particularly if contaminated by *Aspergillus*, could have added to the risk of fungal pneumonia. A report from Queensland, Australia, identified a cluster of five young men with cavitary tuberculosis (TB), among whom, along with their contacts, cannabis bong use was found to be common (Munckhof et al., 2003). Of the contacts, 114 were screened for TB, of whom 57 (50%) were TB skin-test positive. In multivariate logistic regression, sharing a cannabis water pipe with one of the cases of active cavitary TB was one of the only two variables associated with the risk of acquiring TB infection (OR 2.22; 95% CI 0.96–5.17). In a more recent report from Australia, a cluster of three additional cases of open cavitary TB infection was identified in individuals who smoked cannabis using a bong. Four of the five contacts who shared a bong with one of these cases (80%), and one of the two contacts who shared a bong with another case (50%) were found to be skin-test positive for TB (Thu et al., 2013). Sharing a bong with one of the cases of cavitary TB was associated with a more than sixfold increased risk of transmission (OR 6.5; 95% CI 01.4–30.4; $p = 0.016$). In these instances, however, it is not possible to determine whether the transmission of infection with tuberculosis resulted from close contact with the patients with cavitary TB and/or cannabis-related impairment in the lung's defenses against infection.

The results of a few older epidemiologic studies suggest that cannabis may be a significant independent risk factor for opportunistic pulmonary infection in HIV+ individuals (Newell et al., 1985; Tindall et al., 1988; Caiaffa et al., 1994). In contrast, however, preliminary analysis of data from the multicenter AIDS cohort study failed to find any evidence for a role of cannabis or other psychoactive drugs in accelerating immunodeficiency in HIV+ individuals (Kaslow et al., 1989). Further studies in immunocompromised individuals, over a longer period of observation, are required to resolve the controversy as to the true impact of cannabis use on pneumonia risk.

ASSOCIATION WITH PNEUMOTHORAX, PNEUMOMEDIASTINUM, AND BULLOUS LUNG DISEASE (TABLE 52.6)

A number of cases of pneumothorax and/or pneumomediastinum (dissection of air from the lung into the pleural and/or mediastinal space) have been reported in association with cannabis smoking (Miller et al., 1972; Mattox, 1976; Birrer & Calderon, 1984; Luque, Cavallaro, Torres, Emmanual, & Hillman, 1987; Herrejon Silvestre et al., 1992; Feldman, Sullivan, Passero, & Lewis, 1993; Hazouard et al., 2001; Goodyear et al., 2004; Beshay, Kaiser, Niedhart, Reymond, & Schmid, 2007). It has been hypothesized that the deep inhalation technique followed by a long breath-holding time characteristic of the cannabis smoking profile might explain this association, particu-

TABLE 52.6 Miscellaneous Potential Effects of Cannabis on the Lung

- High resolution computed tomography findings of significantly lower lung density (suggesting enlarged air spaces) in the lung apices of regular smokers of cannabis with or without tobacco. *However, no evidence of macroscopic emphysema was found in the cannabis smokers* (Aldington et al., 2007)
- Isolated cases of pneumothorax and/or pneumomediastinum in regular cannabis users
- Several cases of large lung bullae (pathologically enlarged air spaces—more than 1 cm—in the lung parenchyma) in mostly heavy smokers of cannabis along with varying amounts of tobacco

larly if the smoker performed a Valsalva maneuver during the breath-hold (Birrer & Calderon, 1984), potentially leading to alveolar rupture with leakage of air through the visceral pleural surface. Several cases of large lung bullae (pathologically enlarged air spaces in the lung parenchyma, measuring more than 1 cm) have been reported in smokers of mostly large amounts of cannabis, all of whom also smoked varying quantities of tobacco (Johnson, Smith, Morrison, Laszlo, & White, 2000; Thompson and White, 2002; Phan, Lau, & Li, 2005; Hii, Tam, Thompson, & Naughton, 2008). Since case series represent uncontrolled observations, and the prevalence of bullous lung disease in the general population is not known, a cause-and-effect relationship between cannabis use and lung bullae has not been established (Tan, Hatam, & Treasure, 2006).

MINI-DICTIONARY

Airflow obstruction Defined as an abnormally reduced ratio of FEV1 to FVC (ie, a ratio less than 70%).
Alveolar macrophages These are the most numerous cells residing in the distal respiratory tract, and serve as immune effector cells that are principally important for defending the lung against infection.
Bronchodilation Involves an increase in the diameter of the bronchial airways due to relaxation of airway smooth muscle.
Bronchoscopy A technique involving the insertion of a lighted fiber-optic scope through the larynx into the tracheobronchial tree, thereby allowing (1) visualization of the mucosal lining of the central airways (trachea and larger bronch), (2) the performance of bronchoalveolar lavage (instilling saline to rinse out cells and fluid from within the lung), and (3) the performance of biopsies of the bronchial tissue for microscopic examination.
Bullous lung disease Consists of one or more bullae, focally enlarged airspaces of >1 cm, within the lung parenchyma.
Chronic bronchitis Defined by the presence of cough and sputum on most days, for at least 3 months of the year, for 2 or more years; symptoms of chronic bronchitis do not necessarily imply the presence of chronic obstructive pulmonary disease.
Chronic obstructive pulmonary disease Consists of chronic obstructive bronchitis and emphysema, in varying proportions, and is characterized by the presence of significant airflow obstruction (as defined previously), which does not fully reverse to a normal FEV1/FVC ratio after administration of a bronchodilator (ie, the obstruction is not fully reversible).
Forced vital capacity in 1 second (FEV1) The maximum amount of air that can be exhaled in 1 s after a maximal inhalation.
Forced vital capacity The maximal amount of air than can be exhaled after a maximal inhalation.
Pneumothorax and pneumomediastinum Terms used to describe a leakage of air from the airspaces in the lung into the surrounding pleural space, either between the lung and the chest wall (pneumothorax) or the lung and the mediastinum, the structures between the two lungs (pneumomediastinum).
Pulmonary emphysema Defined by pathologically enlarged distal airspaces in the lung that can be quantitated by high-resolution computed tomography (HRCT) of the lung; the presence of pulmonary emphysema is also suggested by a significantly reduced diffusing capacity of the lung for carbon monoxide (D_LCO), a function of the rate of transfer of carbon monoxide from the distal airspaces in the lung (alveoli) to the blood in the alveolar capillaries.

SUMMARY POINTS

- The aim of this chapter is to summarize the findings pertaining to the effect of cannabis and/or different cannabinoids in the context of liver disease.
- Elevated serum liver enzymes is a frequent finding in chronic users of cannabis.
- Smoking cannabis is an important issue in liver transplantation because of the possible fungal infection, and immunity-related effects, of cannabinoids
- Smoking cannabis has been implicated in increasing fibrosis and steatosis in liver of patients infected with hepatitis C virus.
- The effect of cannabis and/or cannabinoids in the liver could be separated into hepatoprotective CB2 receptor mechanisms versus CB1 fibrogenic and steatosis enhancing mechanisms.
- CB1 antagonists or CB2 agonists might find utility in the treatment of liver steatosis, fibrosis and in improving the hemodynamic changes in advanced liver disease.

KEY FACTS OF FIBROSIS

- Fibrosis is a wound-healing process in response to chronic liver injury and inflammation, for example, in response to hepatitis B- and C-mediated liver disease.
- With repeated inflammation, excessive scar formation occurs, termed liver fibrosis.
- This will result in compression and death of liver cells, and shrinkage of the liver and liver failure.
- The attempted regeneration of the liver cells results in disorganized nodules (cirrhosis).
- Finally, the patient will require liver transplantation.

KEY FACTS OF HEPATITIS C VIRUS

- Hepatitis C is a major cause of chronic liver disease that affects more than 170 million people worldwide.
- The primary source of transmission is *via* blood transfusions, and sharing of nonsterilized needles and syringes (illicit drug injection).
- Results in slowly progressive liver fibrosis and hepatitis C are the most common indication for liver transplantation.
- Is an important cause of liver cancer.
- Currently, the standard treatment is injectable pegylated-interferon used in combination with ribavirin, with overall viral clearance rate of approximately 55%. Newer agents, such as sofosbuvir, added to this combination therapy are expected to achieve much higher eradication rates.

KEY FACTS OF FATTY LIVER

- Fatty liver results from the accumulation of fat within the liver cells (steatosis).
- Causes include alcohol, hepatitis C virus, diabetes mellitus, obesity, excessive caloric intake, or drugs.
- It is a common form of chronic liver disease, and a frequent cause of abnormal liver enzymes.
- It is reversible, but if the causative agent is not removed, it might result in inflammation, fibrosis, or the development of cirrhosis.

LIST OF ABBREVIATIONS

Δ^9-THC	Δ^9-Tetrahydrocannabinol
Δ^9-THCV	Δ^9-Tetrahydrocannabivarin
2-AG	2-Arachidonoylglycerol
ACEA	Arachidonyl-2-chloroethylamide
AEA	*N*-Arachidonoylethanolamine (anandamide)
CCl_4	Carbon tetrachloride
CB1	Cannabinoid receptor subtype 1
CB2	Cannabinoid receptor subtype 2
ConA	Concanvalin-A
FAAH	Fatty acid amide hydrolase
HCV	Hepatitis C virus
HSCs	Hepatic stellate cells
IL-6	Interleukin-6
NF-κB	Nuclear factor κB
TGF-β1	Hepatic transforming growth factor-beta 1
TNF-α	Tumor necrosis factor-alpha
TRPV1	Transient receptor potential vanilloid type-1

INTRODUCTION

The discovery of the cannabinoid receptors and their endogenous ligands have paved the way toward our understanding of the involvement of the endocannabinoid system in the regulation of different physiological and pathological processes in the body. Among these, the effect of cannabis/cannabinoids on the liver has received particular interest. There is evidence that the endocannabinoid system is activated in liver disease. In human active cirrhotic liver, cannabinoid subtype 2 receptors (CB2) were expressed in hepatic fibrogenic cells. CB2 receptors were also detected in cultured hepatic myofibroblasts and in activated hepatic stellate cells (HSCs) (Julien et al., 2005). In liver samples from patients with alcoholic liver disease, CB1 expression was restricted to areas with advanced fibrosis only (Patsenker et al., 2011). In patients with primary biliary cirrhosis, CB1 receptors were upregulated in hepatocytes and biliary epithelial cells, while CB2 were expressed in hepatocytes and in cholangiocytes (Floreani et al., 2010). Circulating levels of anandamide were increased in plasma of cirrhotic patients (Fernández-Rodriguez et al., 2004).

HUMAN STUDIES

Smoking cannabis is common in patients with chronic liver disease, including those who are potential candidates for liver transplantation (Hézode et al., 2005; Coffman, 2008; Ranney et al., 2009). In patients who were potential liver transplant, marijuana users were significantly younger, more likely to be male, and have hepatitis C (Ranney et al., 2009). The effect of smoking cannabis on liver disease is somewhat controversial. In HIV/AIDS patients undergoing retroviral therapy, there was no statistically significant change in liver enzymes in dronabinol and/or marijuana users, followed up for 12 months (Whitfield, Bechtel, & Starich, 1997). Other studies suggested that smoking cannabis possibly damages the liver. Borini, Guimarães, and Borini (2004) found that chronic marijuana usage, on its own or in association with other drugs of abuse, was associated with hepatomegaly, splenomegaly, and slightly elevated alanine aminotransferase, aspartate aminotransferase, and alkaline phosphatase activities in serum. Other researchers also observed increased alanine aminotransferase and gamma glutamyltransferase activities, total bile acids, and bilirubin in sera of chronic marijuana smokers with no history of liver disease (Toson, 2011).

Liver steatosis is a common finding in patients with hepatitis C virus (HCV) infection, and is an independent risk factor associated with severe hepatic fibrosis (Cholet et al., 2004). Smoking cannabis has been implicated in accelerating liver fibrosis and steatosis severity in untreated patients infected with HCV (Hézode et al., 2005, 2008; Ishida et al., 2008). Hézode et al. (2005) found that cannabis use was independently related to increased fibrosis progression rate, and to the severity of fibrosis (on liver biopsy). Compared with nondaily cannabis users, daily use was significantly associated with moderate to severe fibrosis. The study included 270 patients (14% were occasional users, and 33% were daily users) (Hézode et al., 2005). In another study, on 315 patients (12.4% were occasional users, and 24.1% were daily users), marked steatosis (on liver biopsy) was more frequent in daily cannabis users, compared with occasional users and nonusers (Hézode et al., 2008). In subjects with chronic HCV infection, Ishida et al. (2008) found that daily compared with nondaily cannabis use was significantly associated with moderate to severe fibrosis (fibrosis score on biopsy). The study comprised 204 persons (13.7% were daily users, and 45.1% occasional users, within prior 12 months). Thus daily cannabis smoking emerged as a novel independent predictor of fibrosis and steatosis severity during chronic HCV infection, necessitating cessation of cannabis in these subjects (Hézode et al., 2005, 2008; Ishida et al., 2008).

More recently, however, Brunet et al. (2013) reported no adverse effect for cannabis on liver fibrosis (AST-to-platelet ratio), or disease progression in HIV/HCV coinfected individuals. 53% of patients had smoked marijuana in the past 6 months (a median of 7 joints/week), while 40% smoked daily (38% used injection drugs at baseline, and about half the participants used alcohol, among whom 15% reported alcohol abuse at baseline). Each 10 additional joints/week smoked resulted in 33% increase in the risk of progression to clinically diagnosed cirrhosis, or 13% increase in cirrhosis and end stage liver

disease. This association was attenuated after lagging marijuana exposure to 6–12 months before the diagnosis.

Beneficial effects for cannabis in liver disease have also been reported. Thus, smoking cannabis was found to improve the tolerability to antiviral therapy with interferon-α (IFN-α) plus ribavirin (Sylvestre, Clements, & Malibu, 2006). The standard treatment for HCV is the combination of pegylated IFN-α and ribavirin. This regimen, however, is associated with significant side effects resulting in a discontinuation of significant proportion of patients. Flu-like symptoms, hematological toxicity, elevated transaminases, nausea, fatigue, depressive symptoms, and psychiatric sequelae, are the most frequently encountered (Sleijfer et al., 2005). Sylvestre et al. (2006) found that modest cannabis users were more likely to adhere to the antiviral treatment, compared with nonusers. This resulted in an increase in the duration of time that patients remain on therapy, and in more sustained virological response (54%), compared with nonusers (18%). In patients (n = 3) with cholestatic liver disease and intractable pruritus that has failed conventional (and unconventional) remedies, the situation improved following treatment with Δ^9-THC (Marinol: 5 mg at bedtime). The antipruritic effect of Marinol lasted only for 4–6 h, suggesting the need for more frequent dosing. Nevertheless, sleep improved, and patients were able to resume their work (Neff et al., 2002).

Marijuana use in liver transplant recipients is not uncommon. In these patients, contamination of fungal spores in cannabis might increase the risk of developing aspergillosis. Thus, in many transplant centers, the use of cannabis in liver transplant patients is discouraged (McGuire et al., 2009). Interestingly, in one study, the use of marijuana had no effect on survival rate in potential liver transplant candidates; patients who did and did not use marijuana had similar survival rates (Ranney et al., 2009).

ANIMAL STUDIES

Ethanol-Induced Hepatic Damage

In alcohol-induced fatty liver in mice, there is evidence to suggest a protective role of CB2 receptors in contrast to a fibrogenic and steatosis enhancing effect for CB1 receptors. Thus, Osei-Hyiaman et al. (2005) observed that high-fat diet intake in mice increased liver anandamide, CB1 density, and de novo fatty acid synthesis. Moreover, treatment with a CB1 agonist increased the hepatic gene expression of the lipogenic transcription factor sterol response element-binding protein-1c (SREBP-1c), and its targets acetyl-CoA carboxylase-1 and fatty acid synthase, as well as de novo fatty acid synthesis in the liver or in isolated hepatocytes. The effect of high fat diet on fatty acid synthesis could be blocked by CB1 receptor antagonist rimonabant. Thus, anandamide acting peripherally on hepatic CB1 is involved in diet-induced obesity. Mice fed high-sucrose, high-fat diet and then treated with the rimonabant exhibited reduced fat mass, insulin levels, and liver triglycerides. Rimonabant restored serum adiponectin levels, induced expression of scavenger receptor class B type I, and hepatic lipase genes. In visceral fat, rimonabant also counteracted upregulation of genes involved in transport, synthesis, oxidation, and release of fatty acids (Jourdan et al., 2010).

$CB1^{-/-}$ mice or hepatocyte-specific CB1 knockout mice were resistant to ethanol-induced steatosis and the increase in lipogenic gene expression. Ethanol feeding resulted in increased hepatic expression of CB1 receptors, and upregulation of the endocannabinoid 2-arachidonoylglycerol (2-AG) in HSCs, the main fibrogenic cell type in the liver. Thus, it was suggested that HSCs release 2-AG, leading to paracrine stimulation of hepatocyte CB1 receptors that mediates ethanol-induced steatosis (Jeong et al., 2008). In vitro, 2-AG and Δ^9-THC induced CB1 mRNA expression in HSCs, whereas CB1 blockage with rimonabant inhibited HSCs proliferation, and downregulated mRNA expression of fibrosis mediated genes PCα1(I), TIMP-1, and MMP-13 (Patsenker et al., 2011).

Other studies confirmed that ethanol effect was attenuated in CB1 knockout mice (Patsenker et al., 2011; Trebicka et al., 2011). In contrast, $CB2^{-/-}$ mice ethanol intake exhibited more steatosis and inflammation, compared with wild-type animals and $CB1^{-/-}$ mice. $CB2^{-/-}$ mice showed marked HSC activation and collagen production (Trebicka et al., 2011; Louvet et al., 2011). Moreover, in alcohol-induced fatty liver in mice, stimulation of CB2 receptors with JWH-133 reduced hepatocyte steatosis (Louvet et al., 2011). CB2 receptor stimulation reduced alcohol-induced inflammation by regulating Kupffer cell polarization, thereby reducing hepatocyte steatosis *via* paracrine interactions between Kupffer cells and hepatocytes (Louvet et al., 2011).

In fatty immortalized human hepatocytes, De Gottardi et al. (2010), however, found that not only the CB1 receptor agonist ACEA, but also the CB2 receptor agonist AM1241 increased lipid accumulation of oleic acid-treated fatty hepatocytes. The cannabinoid receptor agonists altered the expression of key enzymes of lipid synthesis and transport (fatty acid synthase, carnitine palmitoyltransferase 1, and lecithin-cholesterol acetyltransferase).

ISCHEMIA-REPERFUSION INJURY

Bátkai et al. (2007a) found that hepatic ischemia-reperfusion (I/R) injury was associated with markedly increased hepatic levels of anandamide and 2-AG (originating from hepatocytes, Kupffer, and endothelial cells). This increase in tissue endocannabinoids correlated with

the degree of hepatic damage and with serum TNF-α, MIP-1α, and MIP-2 levels. JWH133 (CB2 agonist) protected against I/R damage by decreasing oxidative stress, inflammatory cell infiltration, tissue and serum inflammatory cytokines. Moreover, $CB2^{-/-}$ mice showed increased I/R-induced tissue damage, and proinflammatory phenotype. The study suggested a role for endocannabinoids in liver I/R injury, and also indicated a protective role for CB2 receptors (Table 53.1).

Similarly, the CB2 receptor agonist HU-308, given prior to I/R, attenuated tissue injury, lipid peroxidation, neutrophil infiltration, DNA fragmentation, and caspase 3 activity. Serum and tissue TNF-α, MIP-1α, and MIP-2 levels decreased as well. HU-308 given after the ischemic episode also protected against liver damage (Rajesh et al., 2007). When given before ischemia, HU-910, a novel CB2 receptor agonist attenuated hepatic proinflammatory chemokines (CCL3 and CXCL2) and TNF-α level. HU-910 also decreased neutrophil infiltration, intercellular adhesion molecule-1, oxidative stress, and cell death. HU-910 effects were independent of cannabinoid receptors, since the agonist was also protective in CB2 knockout mice, and its effects were not prevented by CB1/2 antagonists in vitro (Horváth et al., 2012).

Attenuation of I/R injury was also obtained by the prior administration of Δ^8-tetrahydrocannabivarin (Δ^8-THCV). This synthetic cannabinoid exerts antiinflammatory effects *via* CB2 receptors. In liver tissue, oxidative stress, chemokines (CCL3 and CXCL2, TNF-α), intercellular adhesion molecule 1, neutrophil infiltration, caspase activity, and DNA fragmentation were all decreased by Δ^8-THCV. The cannabinoid also showed protective effects, when given at the beginning of reperfusion (Bátkai et al., 2012).

The nonpsychotropic cannabidiol was also found to decrease liver inflammation, oxidative/nitrosative stress, and cell death in mouse I/R injury, independently of cannabinoid receptors. The action of cannabidiol involves decreased NF-κB activation, and TNF-α production from Kupffer cells. It also decreased the adhesion molecule expression in liver sinusoidal endothelial cells, and attachment of human neutrophils to the activated endothelium (Mukhopadhyay et al., 2011).

JZL184 is an inhibitor of 2-AG inactivation by monoacylglycerol lipase. The latter hydrolyzes 2-AG to generate the arachidonic acid precursor pool for prostaglandin production. When given to mice, JZL184 suppressed inflammation and oxidative stress and protected against hepatic I/R injury. Increased endocannabinoid signaling *via*

CB2 and reduced production of eicosanoids in the liver were the likely proposed mechanisms (Cao et al., 2013).

CARBON TETRACHLORIDE-INDUCED HEPATIC DAMAGE

In mice, CB2 was induced in the nonparenchymal cell fraction by carbon tetrachloride (CCl_4) (Teixeira-Clerc et al., 2010), while CB1 and CB2 receptor expression was increased in CCl_4-treated cirrhotic rats (Giannone et al., 2012). Teixeira-Clerc et al. (2010) found that the CB2 agonist JWH-133 reduced liver injury, and accelerated liver regeneration. In contrast, $CB2^{-/-}$ mice showed accelerated liver injury and delayed liver regeneration, in response to CCl_4. These mice exhibited decreased iNOS and TNF-α expression, lower levels of hepatic IL-6 messenger RNA, and increased matrix metalloproteinase 2 (MMP-2) activity. Treatment with a nitric oxide donor partially reversed these changes (Teixeira-Clerc et al., 2010). In rats with CCl_4-induced cirrhosis, treatment with rimonabant reduced fibrosis. The likely underlying mechanisms are induction of CB2 receptor expression, and suppression of profibrogenic and inflammatory mediators. CB1 antagonists might thus be an efficient antifibrotic therapeutic modality, even in advanced liver disease (Giannone et al., 2012) (Table 53.2).

In our studies we used total extract from *Cannabis sativa*, consisting mainly of Δ^9-THC. The effect of the whole plant differs from that of Δ^9-THC, in view of its content of other cannabinoids, terpenoids, and flavonoids (McPartland & Russo, 2001). The administration of only cannabis for 2 days had no significant effect on serum liver enzymes, or the oxidative status of the liver (tissue levels of malondialdehyde, reduced glutathione or nitric oxide). In rats intoxicated with CCl_4 (or acetaminophen), however, cannabis at 5 or 10 mg/kg (expressed as Δ^9-THC) significantly increased serum liver enzymes, liver oxidative stress, histological tissue damage, and decreased DNA content of liver cells (Abdel-Salam et al., 2013). Cannabis given to rats at high dose of 20 mg/kg for 1 month increased liver DNA fragmentation, caspase-3 positively stained cells, and was associated with fibrosis, vacuolar degeneration, and cellular infiltration in the portal area (Abdel-Salam, Youness, & Shaffee). Thus, a whole cannabis extract induced liver damage and exacerbated other liver toxicants – findings which are in line with observations in some human studies (Borini et al., 2004; Hézode et al., 2005).

Autoimmune Hepatitis

Autoimmune hepatitis can be induced in mice by the administration of concanvalin-A (ConA). In this model, Δ^9-THC, anandamide, as well as increasing endogenous endocannabinoid levels *via* fatty acid amide hydrolase inhibitors given after challenge with ConA, were able to decrease liver enzymes and tissue damage. Δ^9-THC or anandamide suppressed inflammatory cytokines, and Δ^9-THC increased the number of T regulatory cells in

liver. Δ^9-THC effect was reversed by both CB1 and CB2 antagonists (Hegde et al., 2008). Cannabidiol also inhibited liver inflammation when given after ConA challenge in mice. Cannabidiol decreased proinflammatory cytokines and tissue neutrophil infiltration. The mechanism is likely to involve induction of myeloid-derived suppressor cells, and consequently suppression of T cell proliferation *via* TRPV1 receptors (Hegde, Nagarkatti, & Nagarkatti, 2011). The study thus links TRPV1 receptors and cannabidiol in suppression of autoimmune hepatitis. In liver disease, where immunity has a role in the pathogenesis of liver injury, Schwabe & Siegmund (2005) suggested that the immune-modulatory effects of cannabis ingredients are likely to affect disease progression and fibrogenesis in chronic hepatitis C, by suppressing antiviral immunity.

Effect of Cannabinoids on Liver Fibrosis

CB2 receptors are expressed in cultured hepatic myofibroblasts and in activated HSCs, and CB2 receptor stimulation resulted in growth inhibition and apoptosis (Julien et al., 2005). Studies indicated that endocannabinoids are upregulated during liver fibrogenesis, and these might act as an antifibrogenic agent in the liver by selectively inducing cell death in activated HSCs, but not in hepatocytes (Siegmund et al., 2005, 2007, 2013; Wojtalla et al., 2012) (Table 53.3). Thus, anandamide blocked the proliferation and, at high concentrations, induced cell death of activated HSCs in primary culture and in vivo. Anandamide-mediated HSCs death was caspase independent, and showed typical features of necrosis such as rapid ATP depletion. This effect of anandamide depended on membrane cholesterol, and was associated with increased intracellular Ca^{++} and reactive oxygen species (attenuated by glutathione or Ca^{++} chelation) (Siegmund et al., 2005). The endocannabinoid 2-AG might act as an antifibrogenic agent in the liver by inducing cell death in activated HSCs (but not primary hepatocytes). The effect was mediated through increased mitochondrial release of reactive oxygen species, and was independent of cannabinoid receptors (Siegmund et al., 2007).

Moreover, Wojtalla et al. (2012) demonstrated that, in culture-activated primary murine or human HSCs, incubation with another endocannabinoid, that is, *N*-arachidonoyl dopamine (NADA), resulted in HSCs death. The effect of NADA was independent of cannabinoid receptors CB1 and CB2, or transient receptor potential cation channel subfamily V, member 1. Increased reactive oxygen species formation in HSCs was the likely mechanism since NADA-induced death decreased by treatment with glutathione. On the other hand, primary hepatocytes were resistant to NADA or anandamide, probably due to their high content of glutathione (Wojtalla et al., 2012). It was also suggested that the ability of hepatocytes to resist the AEA-induced injury is due to their higher expression of the AEA-degrading enzyme fatty acid amide hydrolase (FAAH) in contrast to HSCs. Interestingly, adenoviral mediated FAAH overexpression was found to exert protective actions against

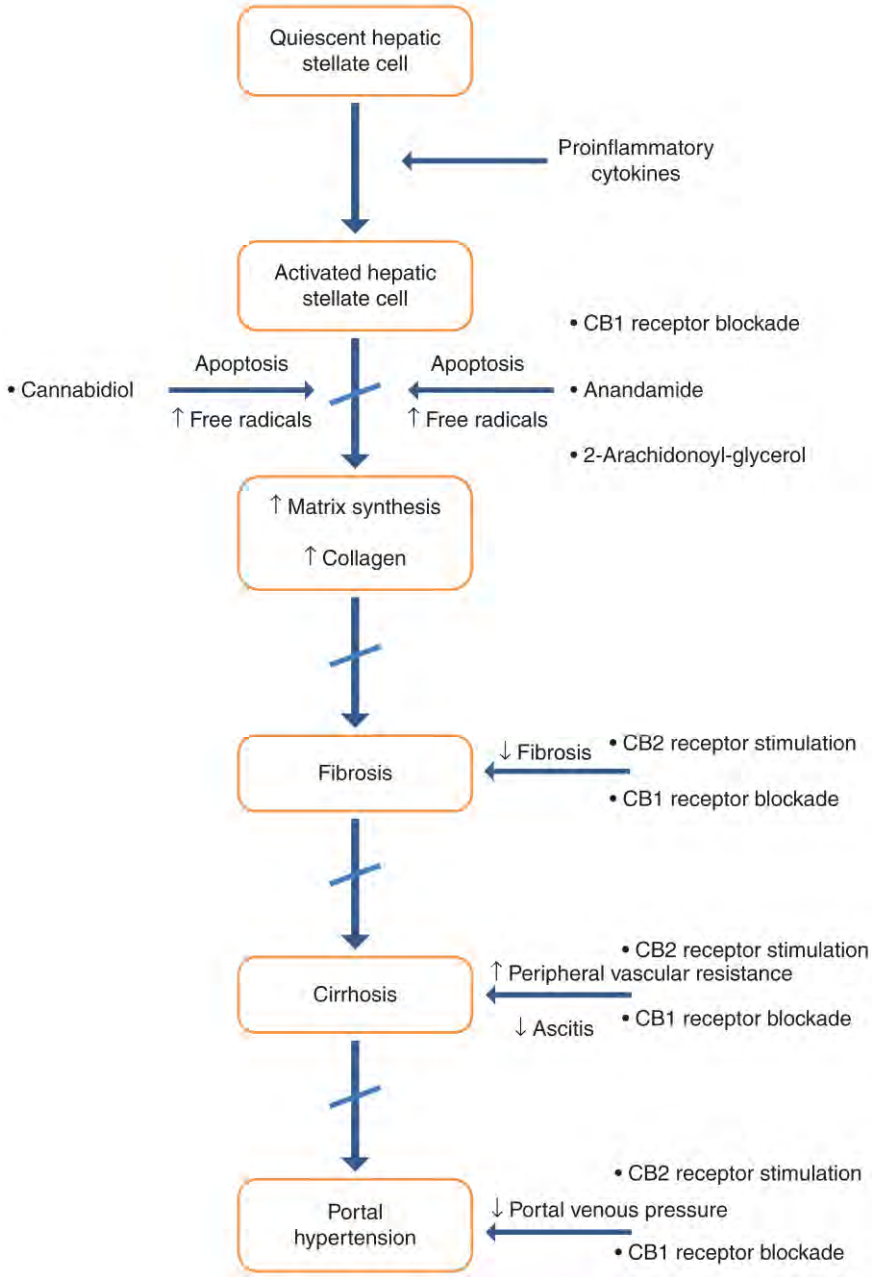

FIGURE 53.1 Effect of cannabinoids on the progression of liver disease. Cannabinoids and/or cannabinoid receptor stimulation modulate the progression of liver disease at different stages.

2-AG induced death in HSCs. Moreover, hepatocytes pretreated with FAAH inhibitor, $FAAH^{-/-}$ hepatocytes, or hepatocytes depleted of glutathione were susceptible to 2-AG induced death (Siegmund et al., 2013) (Fig. 53.1).

It has been suggested that CB1 and CB2 receptors exert opposing effects on liver fibrogenesis; CB1 receptors enhance fibrosis (Yang et al., 2007a; Trebicka et al., 2011) while CB2 mediate hepatic protective and antifibrogenic effects (Julien et al., 2005; Bátkai et al., 2007b; Muñoz-Luque et al., 2008). Mice lacking CB2 receptors showed enhanced liver fibrosis following chronic CCl_4 treatment (Julien et al., 2005). Moreover, hepatic CB1 receptor blockade with rimonabant (SR141716A) decreased the wound healing response to acute liver injury, and inhibited the progression to fibrosis in chronic models of liver injury. CB1 receptor antagonism lowered hepatic TGF-β1, reduced the accumulation of fibrogenic cells in the liver, and inhibited the growth of hepatic myofibroblasts (Teixeira-Clerc et al., 2006). Selective suppression of CB1 expression using lentivirus-mediated small interfering RNA was associated with decreased HSCs proliferation, and extracellular matrix production. It also meliorated dimethylnitrosamine-induced hepatic fibrosis. This occurred through reversal of epithelial-to-mesenchymal

TABLE 53.4 Effect of Cannabinoids on Hepatic Stellate Cells (HSCs)

Cannabinoid	Effect	Suggested mechanism/CB receptor involvement	References
2-AG (endocannabinoid) and Δ^9-THC	Induced CB1 mRNA expression in HSCs in culture	—	Patsenker et al. (2011)
Rimonabant (selective CB1 receptor antagonist)	Inhibited HSCs proliferation Downregulated mRNA expression of fibrosis mediated genes	—	Patsenker et al. (2011)
Anandamide	Induced HSCs death in HSCs primary culture-activated and in vivo-activated HSCs	↑ Reactive oxygen species formation ↑ Intracellular Ca(2+) (cannabinoid-receptor-independent mechanism)	Siegmund, Uchinami, Osawa, Brenner, and Schwabe (2005)
N-arachidonoyl dopamine (NADA) (endocannabinoid)	Induced HSCs death in culture-activated primary murine or human HSCs	↑ Reactive oxygen species formation (cannabinoid-receptor-independent mechanism)	Wojtalla et al. (2012)
2-AG (endocannabinoid) Culture-activated HSCs	Induced HSCs death (apoptotic) in culture-activated HSCs	↑ Reactive oxygen species (cannabinoid-receptor-independent mechanism)	Siegmund et al. (2007)
Cannabidiol	Induced death (apoptosis) of activated HSCs in culture	Endoplasmic reticulum stress response (cannabinoid receptor-independent mechanism)	Lim, Devi, and Rozenfeld (2011)

transition of HSCs. In contrast, the CB1 antagonist AM251 was without effect on epithelial-mesenchymal transitions of HSCs (Chen et al., 2012) (Table 53.4).

Muñoz-Luque et al. (2008) investigated the effect of daily treatment with CB2 receptor-selective agonist JWH-133 in cirrhotic rats with ascites. Mean arterial pressure increased following CB2 stimulation with JWH-133. In the liver tissue, there were decreased inflammatory infiltrates, and reduced number of activated stellate cells and decreased fibrosis. JWH-133 resulted in decreased alpha-smooth muscle actin and collagen I, and increased MMP-2 in hepatic tissue. Thus CB1 receptor antagonists or CB2 receptor agonists might find utility in the treatment of established liver fibrosis. There is evidence also that CB1 antagonism could reverse fibrosis, with this effect of CB1 receptor involving the induction of CB2 receptor expression (Giannone et al., 2012).

Finally, cannabidiol was shown to induce endoplasmic reticulum-mediated apoptosis in activated HSCs (but not in quiescent cells) independently of cannabinoid receptors (Lim et al., 2011).

CANNABINOIDS AND HEMODYNAMIC CHANGES IN LIVER CIRRHOSIS

The endocannabinoid system has been implicated in the systemic vasodilatation, hyperdynamic circulation, and cardiac muscle abnormalities that occur in advanced liver cirrhosis. Anandamide induces marked vasodilatation in isolated vascular preparations (White et al., 2001; Zygmunt et al., 1999) and these involved the activation of vanilloid receptors, since they were blocked by the vanilloid receptor antagonist capsazepine (Zygmunt et al., 1999). Another endocannabinoid, that is, virodhamine, caused endothelium-dependent relaxation of the rat isolated small mesenteric artery (Hoi & Hiley, 2006). In rats with CCl_4-induced cirrhosis, anandamide tissue levels increased in the heart, while both 2-AG and anandamide were markedly elevated in liver tissue (Bátkai et al., 2007a). Cirrhotic mesenteric arteries showed an overexpression of CB1 receptor associated with increased relaxation response to anandamide, which was suppressed by combinations of vascular Ca(2+)-dependent K(+) channel blockers (Yang et al., 2007b).

Ros et al. (2002) found that in cirrhotic rats with ascites (but not in control rats), the administration of a CB1 receptor antagonist significantly increased arterial pressure and peripheral resistance. Anandamide was detected in monocytes of cirrhotic animals, and this induced fall in blood pressure in recipient rats. It is likely that, in cirrhotic rats with ascites, monocytes are activated to produce anandamide that, in turn, contributes to arterial hypotension. The endocannabinoid system participates in the extreme mesenteric vasodilation, portal hypertension, and systemic hypotension present in advanced liver cirrhosis. Anandamide produced a drop in systemic vascular resistance, and decreased mean arterial pressure and the compensatory rise in cardiac output. Anandamide also increased portal venous flow and pressure, and decreased mesenteric vascular resistance.

These effects were partially prevented by the CB1 antagonist SR-141716A (Garcia, Járai, Mirshahi, Kunos, & Sanyal, 2001). Anandamide increased portal perfusion pressure in normal as well as in cirrhotic liver of bile duct-ligated (BDL) rats. In cirrhotic livers, anandamide increased intrahepatic resistance. These effects were associated with increased cysteinyl leukotrienes and thromboxane(2) production. The anandamide-induced increase in intrahepatic resistance was attenuated by the cyclooxygenase inhibitor indomethacin, as well as by a thromboxane A(2) synthase inhibitor (Yang et al., 2006). In BDL rats, the specific CB1 receptor antagonist AM251, given for 1 week, resulted in a decrease in portal venous pressure, intrahepatic resistance, and in superior mesenteric artery blood flow. The hepatic levels of TGF-β1, 5-lipoxygenase and cyclooxygenase-2, and the eicosanoids thromboxane B2 and cysteinyl leukotrienes were decreased, along with decreased hepatic collagen deposition (Yang et al., 2007b).

Gaskari et al. (2005) provided data suggesting a role for increased local neuronal production of endocannabinoids via a CB1 responsive pathway in cirrhotic cardiomyopathy. The authors observed that in isolated left ventricular papillary muscle from BDL cirrhotic rats, the CB1 antagonist AM251 restored the blunted response to beta-adrenergic stimulation. Increasing endogenous anandamide by the reuptake inhibitors VDM11 and AM404 enhanced muscle relaxation, which was completely blocked by AM251 and pertussis toxin. In rats with CCl_4-induced cirrhosis (but not in control rats), the CB1 antagonist AM251 acutely (intravenously) increased mean blood pressure, and the indexes of cardiac systolic function. CB1 receptor antagonists might therefore be of value to contractile function in cirrhotic cardiomyopathy (Bátkai et al., 2007a). In rats with CCl_4-induced cirrhosis and ascites, CB1 antagonism with rimonabant decreased ascites formation and volume, improved sodium balance, and decreased liver fibrosis. Rimonabant increased mean arterial pressure, peripheral vascular resistance, and renal blood flow. Improvement in systemic and renal hemodynamics, as well as antifibrotic effect, have accounted for the ascites reducing effect of CB1 antagonism in experimental cirrhosis (Domenicali et al., 2009).

In BDL cirrhotic rats, the CB2 agonists JWH-015 or JWH-133 decreased portal venous pressure, alleviated portosystemic shunting, and mesenteric vascular density. These effects were mediated via CB2 receptors (abolished by the CB2 antagonist AM630). JWH-015 decreased mesenteric COX-1 and COX-2 messenger RNA expressions, eNOS protein expressions, and decreased intrahepatic angiogenesis and fibrosis (Huang et al., 2012). Data suggested a modulatory effect for CB2 agonists (JWH-133 and GPla) on Kupffer cells activation. In BDL rats whose Kupffer cells were activated by zymosan or LPS, these CB2 agonists attenuated portal pressure. JWH-133 attenuated thromboxane B2 production following Kupffer cells activation, and increased heme oxygenase-1 expression. The inhibition of heme oxygenase-1 enhanced portal hypertension, thus heme oxygenase-1 induction by JWH-133 plays an important role (Steib et al., 2013) (Table 53.5).

TABLE 53.5 Summary of the Effect of Cannabinoid CB1 and CB2 Receptor Stimulation or Antagonism in the Liver

CB1 receptor activation	References
• ↑ De novo fatty acid synthesis in the liver or in isolated hepatocytes	Osei-Hyiaman et al. (2005)

MINI-DICTIONARY

Ascites The accumulation of fluid within the abdominal cavity in liver cirrhosis.
Autoimmune hepatitis Liver damage caused by perturbed immunoregulation resulting in autoimmune attack on liver.
Cirrhosis The formation of diffuse fibrosis and regenerative nodules giving the liver nodular, irregular appearance. It is the end stage of different disease processes affecting the liver.
Hepatic stellate cell The cell which derives hepatic wound healing and fibrosis. In the normal human liver, stellate cells store vitamin A. In response to oxidative stress and various inflammatory signals, these cells become activated, and synthesize and secrete extracellular matrix proteins.
Kupffer cell The resident immune cell of the liver. Kupffer cell activation during liver injury is an important step in progression of liver tissue damage.
Steatosis The accumulation of lipid droplets in liver cells.
Sustained virological response A measure of virus eradication. It is the absence of virus nucleic acid in serum at the end of treatment and 6 months later.

Cannabis Allergy: More Than a Bad Trip

A.L. Van Gasse, V. Sabato, M.M. Faber, C.H. Bridts, D.G. Ebo

Faculty of Medicine and Health Science, Department of Immunology-Allergology-Rheumatology, University of Antwerp, Antwerp, Belgium

SUMMARY POINTS

- An allergy is defined as an immune-pathological, mostly IgE-mediated, reaction that ultimately results into a hypersensitivity reaction toward one or more foreign compounds, that is, an allergen.
- The exact prevalence of cannabis allergy is not known, it seems to be an increasing problem in the past few years.
- Active use, as well as passive exposure to cannabis could lead to sensitization to cannabis allergens, and eventually to cannabis allergy if this sensitization is of clinical relevance.
- The clinical manifestations of cannabis allergy can vary from mild to life-threatening reactions, often depending on the route of exposure.
- Sensitization to cannabis could also lead to secondary allergies, such as allergies to fruit and vegetables, designated as the "cannabis-fruit/vegetable syndrome," but also to *Hevea* latex, cereals, tobacco, and alcoholic beverages, such as beer and wine.
- At present, diagnosis generally rests upon history, skin testing, and an IgE test with an industrial hemp variety.
- Recently, the basophil activation test (BAT) has been proven to be a reliable additional diagnostic.
- For the time being, there is no cure for cannabis-related allergies. Strict avoidance of cannabis and other allergens implicated in the individual cross-reactivity syndrome is imperative.

KEY FACTS OF CONTACT DERMATITIS

- Contact dermatitis is a delayed hypersensitivity reaction mediated by T cells, instead of antibodies (Coombs & Gell, 1963).
- Although cannabis related-allergies are generally IgE-mediated, a delayed T cell mediated reaction is also possible (Williams et al., 2008).
- Contact dermatitis is characterized by a local inflammation of the skin due to skin contact with a substance originating from outside the body, for example, an allergen or irritant.
- A red and itchy rash can be seen as clinical manifestation.
- Diagnosis of delayed hypersensitivity reactions is made by placing the contact allergens on the surface of the skin, and subsequently evaluating the skin after 24, 48, and 72 h; a method known as a patch test.
- The treatment comprises strict avoidance of skin contact with the culprit allergens, but when the contact dermatitis had already arisen, local corticosteroid creams can be used.

LIST OF ABBREVIATIONS

Act d	*Actinidia deliciosa* (kiwi fruit)
Ara h	*Arachis hypogaea* (peanut)
ATP	Adenosine triphosphate
BAT	Basophil activation test
Bet v	*Betula verrucosa* (birch)
Can s	*Cannabis sativa*
CCD	Cross-reactive carbohydrate determinants
Cit s	*Citrus sinensis* (orange)

Cor a	*Corylus avellana* (hazelnut)
CRD	Component resolved diagnosis
Cup a	*Cupressus arizonica* (cypress native to the southwest of north America)
DC	Dendritic cell (professional antigen presenting cell)
FEIA	Fluorescent enzyme immunoassay
Hev b	*Hevea brasiliensis* (natural rubber tree)
IL	Interleukin
Lyc e	*Lycopersicom esculentum* (tomato)
Mal d	*Malus domestica* (apple)
MALT	Mucosa associated lymphoid tissue
Mus a	*Musa acuminate* (banana)
Ns-LTP	Nonspecific lipid transfer protein
OAS	Oral allergy syndrome
Phl p	*Phleum pratense* (Timothy grass)
PR	Pathogenesis-related
Pru av	*Prunus avium* (cherry)
Pru p	*Prunus persica* (peach)
RuBisCo	Ribulose-1,5-biphosphate carboxylase/oxygenase
sIgE	Specific immunoglobulin E
Th	T helper
TLP	Thaumatin-like protein
Tri a	*Triticum aestivum* (wheat)
Vit v	*Vitis vinifera* (grape)

INTRODUCTION

The main function of the immune system is to provide defense against pathogenic microorganisms and toxins. Although immune responses are regulated in order to avoid excessive responses, and development of autoimmune conditions, potential harmful immune-pathologic reactions can occur. "Allergy" is a typical example of such an immune-pathological reaction in which an undesired immune response is mounted against a harmless foreign compound.

In the literature, allergies to food, aeroallergens, Hymenoptera venoms, and medicines are well described. In contrast, mainly by their illegal nature, little is known about allergy to illicit drugs and narcotics (Anselme, Metz-Favre, & de Blay, 2011; Swerts et al., 2014). This chapter focuses on the current knowledge and management of cannabis-related allergies.

THE ALLERGIC REACTION

An "allergy" is defined as an immune-pathological reaction that results into a hypersensitivity reaction to one or more foreign compounds, that is, an allergen. According to the underlying humoral or cellular pathomechanisms and clinical manifestations, allergic reactions are classified in four classes, as initially described by Coombs and Gell (1963). Describing these immune pathologic reactions is beyond the scope of this review that focuses on IgE-dependent cannabis-related allergies.

THE IgE-MEDIATED REACTION

Principles

Primary IgE-Mediated Allergy

Exposure to foreign proteins or products (antigens and allergens) predominantly occurs via skin and mucosae, where immunologic and nonimmunologic mechanisms prevent allergens entering the body and/or eliciting immune responses. However, some allergenic components evade these surveillance mechanisms and will encounter resident specialized antigen-presenting dendritic cell (DC) populations. After uptake of allergens, these DCs migrate to the T-cell zones of secondary lymphoid organs (eg, lymph nodes, mucosa associated lymphoid tissue, and spleen) and present antigenic peptides to naïve T helper (Th)-cells, that will proliferate and polarize into interleukin (IL)-4/IL-13 producing Th2 cells (Fig. 54.1A). These Th2 cytokines trigger immunoglobulin isotype switching, and the synthesis of allergen-specific IgE (sIgE) antibodies by B cells and plasma cells. These sIgE antibodies bind to effector cells, mainly tissue-resident mast cells and peripheral blood basophils. Upon re-exposure to the sensitizing allergen, the allergen that triggered the immune system to produce sIgE antibodies can cross-link at least two adjacent sIgE antibodies bound to the surface high-affinity IgE receptor (FcεRI), inducing the effector cells to release a broad variety of mediators, such as histamine, leukotrienes, prostaglandins, and cytokines. These mediators are responsible for the symptoms of the allergic reaction (Table 54.1). Most of the time, allergens triggering IgE-mediated reactions are glycoproteins (Kumar & Bhatia, 2013). Allergens are not recognized as a whole component by the immune system. There are only specific regions of the allergen that elicit the immune response. These specific regions are called B-cell epitopes, as they are complementary to the allergen-binding site of the corresponding specific antibodies (Kumar, Verma, Das, & Dwivedi, 2012).

Secondary IgE-Mediated Allergy (Cross-Reactivity)

Unlike primary IgE-mediated allergy, in which the allergenic determinants responsible for direct sensitization of the immune system and subsequent triggering of effector cells are the same, secondary IgE-mediated allergies are acquired indirectly, that is, via immunologic cross-reactivity. This immunologic cross-reactivity occurs when an antigen (or allergen) triggers the production

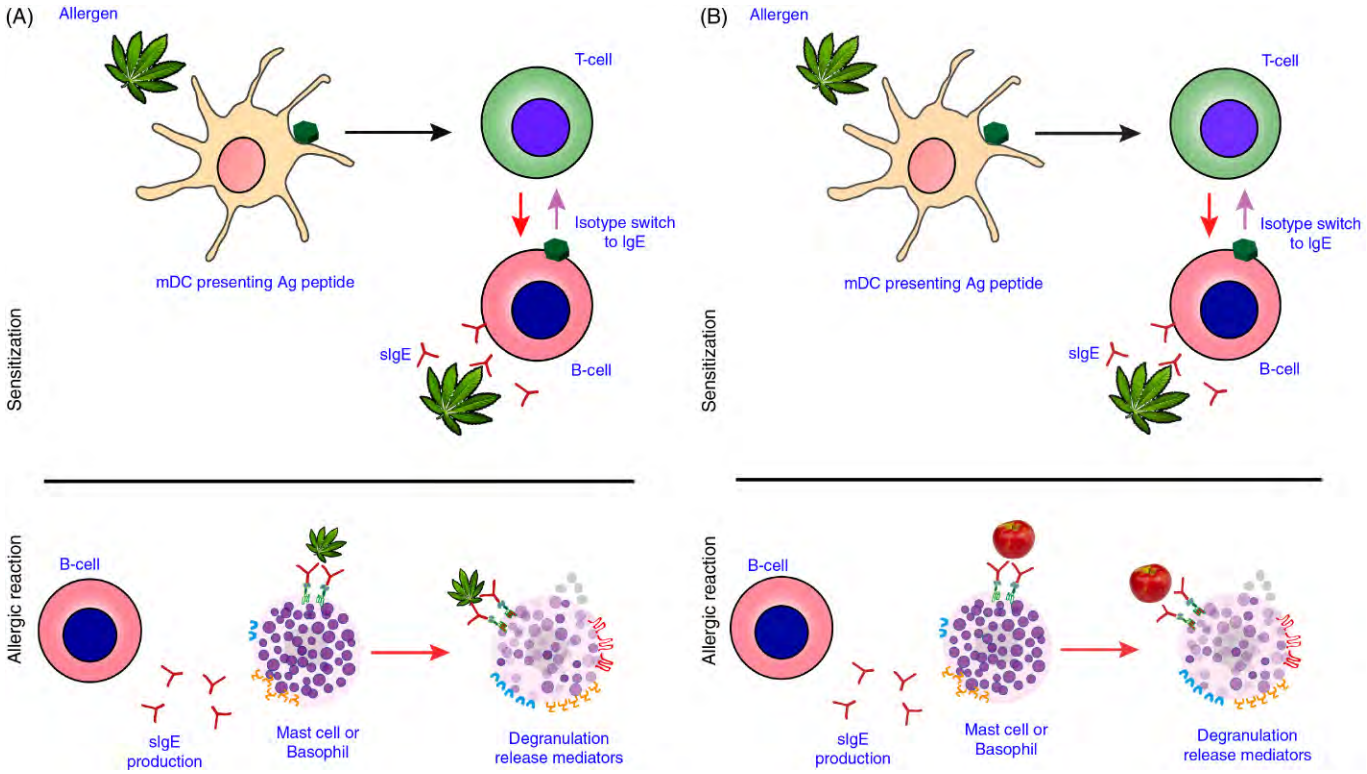

FIGURE 54.1 (A) Pathogenesis of a primary (genuine) IgE-mediated allergy against cannabis. The epitopes responsible for sensitization and subsequent triggering of the effector cells, that is, basophils and mast cells, are identical. (B) Pathogenesis of a secondary IgE-mediated (cross-) allergy. The allergenic determinants responsible for initial sensitization are different from the allergenic determinants that trigger mast cells and basophils. In this particular example, the sensitizing allergen is cannabis, the cross-reacting allergen is apple.

TABLE 54.1 IgE-Mediated Allergy: Clinical Manifestations

Skin	Pruritus (itching) Erythema Nonspecific rash Wheals Urticaria Angioedema
Eyes	Conjunctivitis (tearing, itching, redness)

Intestinal	Cramps Nausea, vomiting Diarrhea
Cardiovascular	Tachycardia Hypotension (collapse) Shock
Death	

of sIgE antibodies that can bind to structural similar or identical epitopes and components present in allergens originating from taxonomically related and distant sources (Fig. 54.1B). Noticeably, these cross-reactive antibodies are not of clinical relevance per se, that is, induce cross-allergy between the allergens originating from the various sources. Depending on the presence or absence of clinical manifestations, cross-reactive allergenic components can roughly be divided into three groups.

A first group of cross-reactive components comprises structures and epitopes frequently having clinical significance. This means that these allergenic components often trigger a cross-allergy. In our regions, the best-known example of cross-allergy is the birch pollen-related food syndrome (Ebo & Stevens, 2001). In this syndrome, patients are initially sensitized to Bet v 1, the major allergenic component from birch pollen (*Betula verrucosa*), and can subsequently display a broad cross-allergy to plant-derived foods, mainly pit and stone fruit, tree nuts, soy, and carrot. In this birch pollen-related food syndrome, along with their respiratory symptoms upon exposure to birch pollen, these patients will complain of symptoms in the oral cavity and throat, also known as an oral allergy syndrome (OAS) after ingestion of the different

foods involved. Another example, predominantly observed in southern Europe, is the "ns-LTP syndrome" governed by peach. In this syndrome, sensitization to Pru p 3, the nonspecific lipid transfer protein (ns-LTP) of peach (*Prunus persica*), entails the risk for severe allergic reactions, such as anaphylaxis, to multiple plant-derived foods (Van Winkle & Chang, 2014).

A second group of cross-reactive components includes allergenic structures that seldom evoke clinical manifestations, such as profilins (Ebo, Hagendorens, Bridts, De Clerck, & Stevens, 2004). This means that patients sensitized to profilins will predominantly display a broad in vitro cross-reactivity, but only a minority of these patients will present a clinically relevant cross-allergy. The most prevalent profilin-related cross-allergies are allergies to banana and melon, secondary to grass pollen allergy.

Finally, a third group of cross-reactive components comprises the cross-reactive carbohydrate determinants (CCD). These immunogenic, nonmammalian carbohydrate moieties are ubiquitous in plant kingdom and invertebrates (eg, hymenoptera venom), but sIgE antibodies raised against CCD are generally believed not to cause clinical symptoms (Ebo et al., 2004; Ebo et al., 2002).

CANNABIS ALLERGY

Prevalence

Allergic reactions to certain members of the *Cannabaceae* family, such as industrial hemp and hop (*Humulus lupulus*) have repeatedly been described (Herzinger, Schopf, Przybilla, & Rueff, 2011; Spiewak, Gora, & Dutkiewicz, 2001; Williams, Thompstone, & Wilkinson, 2008). In contrast, reports of IgE-mediated reactions to cannabis remain rare. A possible explanation for this low number of reports probably relates to the illegal status of cannabis use, which makes the patients reluctant to report their abuse and associated allergic symptoms (Nayak et al., 2013). Today, no information is available about the prevalence of cannabis allergy. However, it seems to be an increasing problem since a few years (Van Gasse, Sabato, Bridts, & Ebo, 2014).

Cannabis Allergens

To date, the allergenic composition of *Cannabis sativa* (Can s), the plant from which proteins can be extracted, remains relatively elusive (Nayak et al., 2013). Larramendi et al. (2013) found that six different bands with a molecular weight of 10, 14, 20, 35, 38, and 60 kDa were recognized by the individual patients' sera. The 10-kDa IgE-binding band was already described in other reports (de Larramendi et al., 2008; Gamboa et al., 2007; Tanaka, Degawa, Kawata, Hayashi, & Shoyama, 1998), and probably corresponds to Can s 3, the nonspecific lipid transfer protein (ns-LTP) of *C. sativa* (Gamboa et al., 2007) that belongs to the pathogenesis-related proteins (PR)-14 group. Pathogenesis-related proteins are plant host proteins induced specifically in response to pathological situations, such as an infection by fungi, bacteria, viruses, and other means of stress (Van Loon, 1999). The 38-kDa band corresponds with a thaumatin-like protein (TLP) that belongs to the PR-5 family (Larramendi et al., 2013). Although in the study of Larramendi et al. (2013) no homology was found between the 14-kDa band and any known allergen, this band probably corresponds with a profilin (de Larramendi et al., 2008).

In an American study of Nayak et al. (2013), 23 kDa and 50 kDa seem to be the most prominent bands. The 23-kDa band corresponds with "oxygen-evolving enhancer protein 2," an enzyme involved in the photosynthesis. The 50-kDa band corresponds with the heavy chain subunit of ribulose-1,5-biphosphate carboxylase/oxygenase. Other possible allergens identified by Nayak et al. (2013) are glyceraldehyde-3-phosphate and adenosine triphosphate synthase. Finally, they observed that CCDs might be the cause of some IgE reactivity. Unlike the European studies, in this American study no ns-LTP sequences were identifiable, and no IgE reactivity to this panallergen was demonstrable, even though IgE reactivity at approximately 10 kDa was observed in two patients. In contrast to the European series, most of the American patients did not suffer from a cannabis-related cross-reactivity syndrome as is described later. The most important cannabis allergens are displayed in Table 54.2.

Routes of Exposure/Sensitization

Possible ways of exposure and sensitization to allergens are so called *routes of exposure*. Regarding cannabis, multiple routes of exposure/sensitization might exist.

First, people may be exposed to cannabis through active use, such as smoking, vaporizing, chewing, oral ingestion, or intravenous use of the drug. Second, cutaneous contact could be a possible route. This could be important in cannabis growers, for example. An alternative route of exposure and sensitization could be passive by proxy when allergens become airborne or are transferred via contact. Therefore, children can also be exposed to cannabis allergens, for example, through parental smoking (Ebo et al., 2013).

Finally, it should be kept in mind that *C. sativa* is an anemophilous plant that produces wind-borne pollen, in case of a male plant. The pollen can be transported over extreme distances (Swerts et al., 2014). For example, in Nebraska, where industrial *C. sativa* is cultivated, Can s pollen account for 36% of the total pollen count during mid- to late-August (Stokes, Hartel, Ford, & Casale, 2000). In European countries, such as France (Anselme et al., 2011), Spain (Mayoral, Calderon, Cano, & Lombardero, 2008),

and Italy (Torre et al., 2007), quite similar observations were made. Noticeably, only female (nonpollinating) plants are cultivated for illicit use. Therefore, it is unlikely that abusers of cannabis, who grow their own plants, are becoming sensitized to marihuana through pollen.

CLINICAL MANIFESTATIONS

Genuine Cannabis Allergy

Symptoms of cannabis allergy can vary from mild to life-threatening reactions that generally relate to the route of exposure.

First, respiratory reactions, such as rhinoconjunctivitis, asthma, and palpebral angioedema have been described. These reactions predominantly occur when cannabis is consumed by smoking or vaporizing (Ebo et al., 2013; Swerts et al., 2014; Van Gasse et al., 2014). Respiratory symptoms may also arise from passive exposure to cannabis smoke, or inhalation of *C. sativa* pollen. However, the latter is unlikely to induce sensitization or trigger symptoms in patients growing their own plants.

Handling of Can s plants may lead to contact urticaria (Majmudar, Azam, & Finch, 2006; Williams et al., 2008) and contact dermatitis (Williams et al., 2008). Nevertheless, urticaria and angioedema may also occasionally be triggered by cannabis allergens that became airborne (Swerts et al., 2014).

At last, anaphylaxis can result from ingestion of hempseed (Stadtmauer, Beyer, Bardina, & Sicherer, 2003) and from drinking marihuana tea (Tessmer et al., 2012).

Cross-Reactivity Syndrome

Patients with IgE-mediated cannabis allergy can display distinct sensitization profiles with sensitization toward Can s 3 to be frequent in Europe and almost absent in the United States. Nonspecific lipid transfer PR-14 proteins are panallergens ubiquitously present throughout the plant kingdom (Egger, Hauser, Mari, Ferreira, & Gadermaier, 2010). Consequently, sensitization to Can s 3 could be an explanation for the high variety of secondary plant-derived food allergies seen in European patients with a cannabis allergy. This (sometimes extensive) cross-reactivity between cannabis and plant-derived food has been described in the study by Ebo et al. (2013), and was recently designated as the "cannabis-fruit/vegetable syndrome" (Van Gasse et al., 2014). In our case-control series (Ebo et al., 2013), 10 out of 12 patients with a documented cannabis allergy were sensitized to different ns-LTPs, including Pru p 3, the ns-LTP of peach (*P. persica*). The food allergies most commonly implicated in the cannabis-fruit/vegetable syndrome were allergies to peach, banana, apple, cherry, nuts, tomato, and occasionally citrus fruits, such as orange and grapefruit. Important to note is that these allergic reactions were more severe than the OAS generally observed in food allergy related to sensitization to Bet v 1(Ebo & Stevens, 2001). This could be explained by the fact that ns-LTPs resist to gastroduodenal proteolysis (Cavatorta et al., 2010; Wijesinha-Bettoni et al., 2010) and thermal processing (Matejkova et al., 2009; Sancho et al., 2005; Scheurer et al., 2004). It should also be kept in mind that, in addition to plant food allergies, sensitization to Can s 3 might also explain cross-reactions to *Hevea* latex (Beezhold et al., 2003; Faber et al., 2015; Rihs et al., 2006), alcoholic beverages such as beer and wine (Asero, Mistrello, Roncarolo, Amato, & van Ree, 2001; Jegou, Douliez, Molle, Boivin, & Marion, 2000) and tobacco (*Nicotinia tabaccum*) (Carnes et al., 2013).

Fig. 54.2 gives a nonexhaustive overview of this cannabis-fruit/vegetable syndrome.

As already exemplified in Table 54.2, thaumatin-like proteins (TLP), belonging to the PR-5 family, constitute

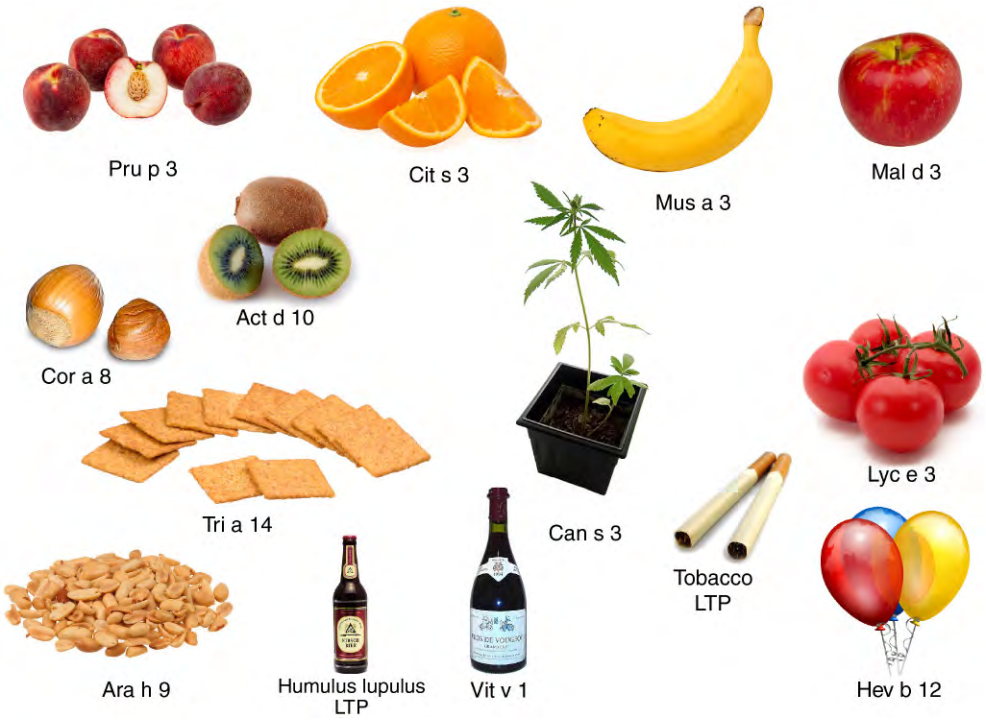

FIGURE 54.2 **The cannabis-fruit/vegetable syndrome and other cross-allergies.** Nonspecific lipid transfer proteins (ns-LTPs) are ubiquitously present in the plant kingdom. Consequently, sensitization to Can s 3, the ns-LTP from *C. sativa*, could lead to a broad variety of cross-reactions. Cross-reactive substances displayed in the figure: cherry (*Prunus avium*), tangerine (*Citrus reticulata*), orange (*Citrus sinensis*), peach (*P. persica*), apple (*M. domestica*), tomato (*Lycopersicom esculentum*), hazelnut (*Corylus avellana*), walnut (*Juglans regia*), banana (*Musa acuminate*), wheat (*Triticum aestivum*), latex (*Hevea brasiliensis*), tobacco and alcoholic beverages, such as wine (grapes: *Vitis vinifera*) and beer (common hop: *Humulus lupulus*). *Source: Adapted from Van Gasse et al. (2014).*

another group of components that might explain cross-reactivity between cannabis and plant-derived food in European patients (Larramendi et al., 2013). These TLPs can be found in pollen and different foods, such as NP24 proteins from tomato (*Solanum lycopersicon*) (Sharma, Singh, Singh, Gaur, & Arora, 2011), Cup a 3 from cypress (*Cupressus arizonica*) (Breiteneder, 2004), Act d 2 from kiwi fruit (*Actinidia deliciosa*) (Bublin et al., 2004), and Mal d 2 from apple (*Malus domestica*) (Hsieh, Moos, & Lin, 1995). Like ns-LTP hitherto, sensitization to TLP has been only observed in south European patients (Larramendi et al., 2013).

DIAGNOSIS

At present, diagnosis of a cannabis allergy rests upon a history, skin testing, and a sIgE antibody test with the industrial hemp variety. However, as will emerge from the following paragraphs, correct diagnosis of cannabis allergy is not always straightforward.

History Taking

Although a thorough anamnesis is essential for correct diagnosis, it appears that history is frequently pieced together from inadequate description and recall by patients reluctant to admit or simply denying illicit drug abuse. In a series of 50 patients with a cannabis allergy who attended our outpatients' clinic, none was consulted because of respiratory or cutaneous symptoms upon exposure to the drug. Actually, all had their diagnosis established because of a plant-derived food and/or vegetable allergy. History might also be misleading because of misinterpretation or misconception of symptoms related to active or passive exposure.

Confirmatory Testing

Skin Prick Test

The principles of skin prick tests (SPT) are displayed in Fig. 54.3. Briefly, a fresh or processed allergen extract is placed on the skin (mostly of the forearm), and pricked with a lancet or similar device. The SPT is considered positive when a wheal with a diameter of at least 3 mm appears. In each test, there also has to be performed a positive (histamine) and negative (saline buffer solution) control to check for skin anergy and dermographism, respectively.

For the time being, sensitization and allergy to cannabis is almost exclusively studied or documented by prick-prick skin testing using a broad variety of raw materials,

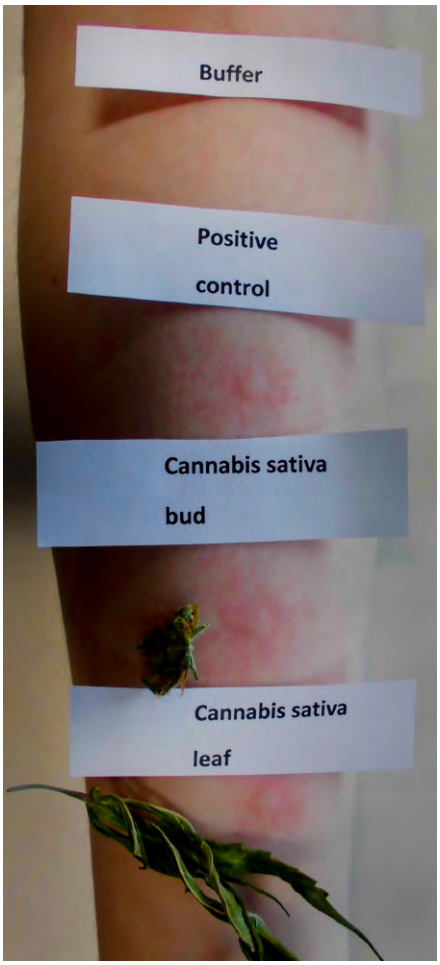

FIGURE 54.3 **Principle of the skin prick test.** Two skin prick tests with *C. sativa* were performed: the first one with the bud and the second one with the leaves of the *C. sativa* plant. In addition, also a positive (histamine) and negative (saline buffer solution) control were performed. The two prick tests with *C. sativa* were positive as a wheal from more than 3 mm appeared.

such as *C. sativa* leaves, buds, and flowers (de Larramendi et al., 2008; Ebo et al., 2013; Gamboa et al., 2007; Larramendi et al., 2013; Metz-Favre, Pauli, Bessot, & De Blay, 2011; Nayak et al., 2013; Stadtmauer et al., 2003; Tessmer et al., 2012) (Figure 54.3). Needless to say that, at this moment, this approach is flawed by many issues, and is virtually impossible to standardize because of unpredictable variations in composition, and potential contaminations with other allergens of the raw material.

Measurement of Total and Allergen-Specific IgE Antibodies

Quantification of total IgE is a prerequisite in order to allow correct interpretation of sIgE, mainly because of unspecific binding to the solid-phase in case of elevated titers. However, quantification of total IgE is not informative for identification of the culprit allergen (Laske, Bunikowski, & Niggemann, 2003).

Today, sIgE is usually measured using the fluorescent enzyme immunoassay ImmunoCAP (Thermofisher Scientific, Uppsala, Sweden). As displayed in Fig. 54.4 (right panels), the antigen (or allergen) of interest is covalently coupled to a solid phase. When sIgE antibodies that recognize this antigen are present in the patients' serum, these antibodies will bind the antigen to form an antigen-antibody immune complex. Subsequently, nonbound sIgE is rinsed away, and an enzyme-conjugated antihuman-IgE antibody is added. This so-called secondary antibody will bind the sIgE-antigen complex. Finally, after washing, a substrate is added. This substrate will be metabolized by the bounded enzyme producing a quantifiable fluorescence. In traditional assays, sIgE results of $\geq$ 0.35 kUA/L are considered positive. However, some issues should be kept in mind for correct interpretation of sIgE results. First, none of the available sIgE assays demonstrates an absolute predictive value. A negative sIgE result does not preclude allergy. Alternatively, a positive sIgE result should always be interpreted with prudence, because it is not per se an indication of the presence of an allergic disease, but can merely reflect cross-sensitization.

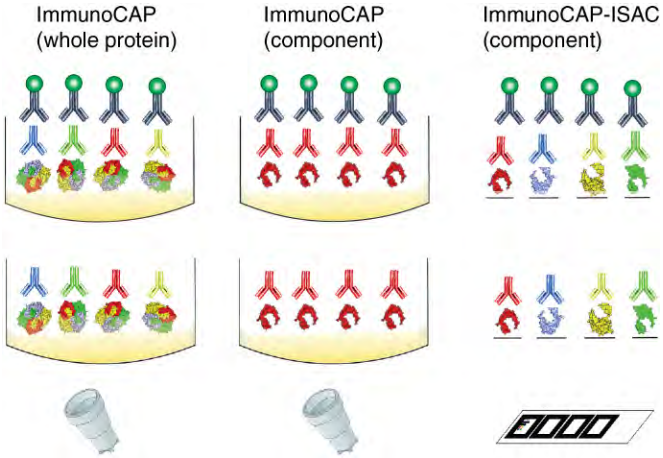

FIGURE 54.4 **Principle of measurement of sIgE.** In traditional ImmunoCAP (left panels), the antigen (a heterogeneous protein extract containing different components) of interest is coupled on a CNBr-activated cellulose solid phase. sIgE antibodies in the patients' serum recognizing the antigen will bind to form a so-called antigen-antibody immune complex. Subsequently, an enzyme-conjugated antihuman-IgE antibody is added. This secondary antibody will bind the antigen-antibody immune complex. Finally, a substrate is added that will be metabolized to produce a quantifiable fluorescence. In component-resolved diagnosis (CRD), two techniques are frequently used. First in a singleplex assay single native or recombinant components (eg, proteins or peptide components) (De Knop et al., 2010; Ebo et al., 2012; Valenta et al., 1999) are coupled to a solid phase as described previously (center panels) and detection of sIgE is exactly the same as in the traditional technique. In the multiplex assay, single native and/or recombinant components are spotted on a polymer coated slide (right panels), sIgE from the patient blood sample bind to the components and these antibodies are detected with a fluorochrome labeled anti-IgE. Finally, the reaction is scanned in a laser scanner and results are evaluated by image analysis software.

This concern relates mainly to the fact that traditional sIgE assays use heterogeneous protein extract-based allergens from different sources. As already exemplified in the section *Secondary IgE-Mediated Allergy*, ubiquitous cross-reactive structures, such as CCD, present on glycoproteins of plants and hymenoptera venom, and profilins present in plant allergens can easily elicit positive, but clinically irrelevant serology with a broad spectrum of cross-reactivity, including *C. sativa* (Ebo et al., 2013). In our series, three out of eight pollen allergic patients, without cannabis allergy, demonstrated a false positive industrial hemp sIgE test (Ebo et al., 2013).

During the last two decades, advances in biochemistry and molecular biology enabled the characterization, cloning, and recombinant production of relevant allergenic components and epitope-emulating peptides, allowing quantification of sIgE antibodies to these components or sequential epitopes; this is a method known as component resolved diagnosis (CRD) (Fig. 54.4, center and left panels). In contrast to traditional sIgE tests, CRD does not rely upon whole extract preparations, but upon single native or recombinant components (eg, proteins or peptide components) (De Knop et al., 2010; Ebo, Hagendorens, Bridts, & Stevens, 2012; Valenta et al., 1999). Briefly, CRD involves unique marker components to study the genuine sensitization of patients toward a particular allergen, and the presence of sIgE antibodies to cross-reactive components (eg, profilins and CCD) that point to cross-reactivity. CRD not only enables to discriminate between genuine allergy and cross-reactivity, but also allows to establish individual predictive sensitization profiles.

Unfortunately, at present, no *C. sativa* components are readily available, but Can s 3 has been cloned recently (Rihs et al., 2014). However, multiplex CRD using the ISAC 112 can help to confirm sensitization toward ns-LTP as an important cause of the cannabis-fruit/vegetable syndrome (Ebo et al., 2013).

Basophil Activation Test

In 1991, the discovery of the basophil degranulation marker, CD63 (Knol, Mul, Jansen, Calafat, & Roos, 1991), induced the development of a novel method to quantify allergen-specific in vitro activated basophils (BAT). This flow cytometric technique relies upon identification and quantification of alterations of particular surface markers such as CD63/CD107a and CD203c (Fig. 54.5). At present, this technique has proven to be a reliable diagnostic aid for various allergies, such as allergy to food, inhalant allergens, medicines, hymenoptera venom, and most recently also cannabis.

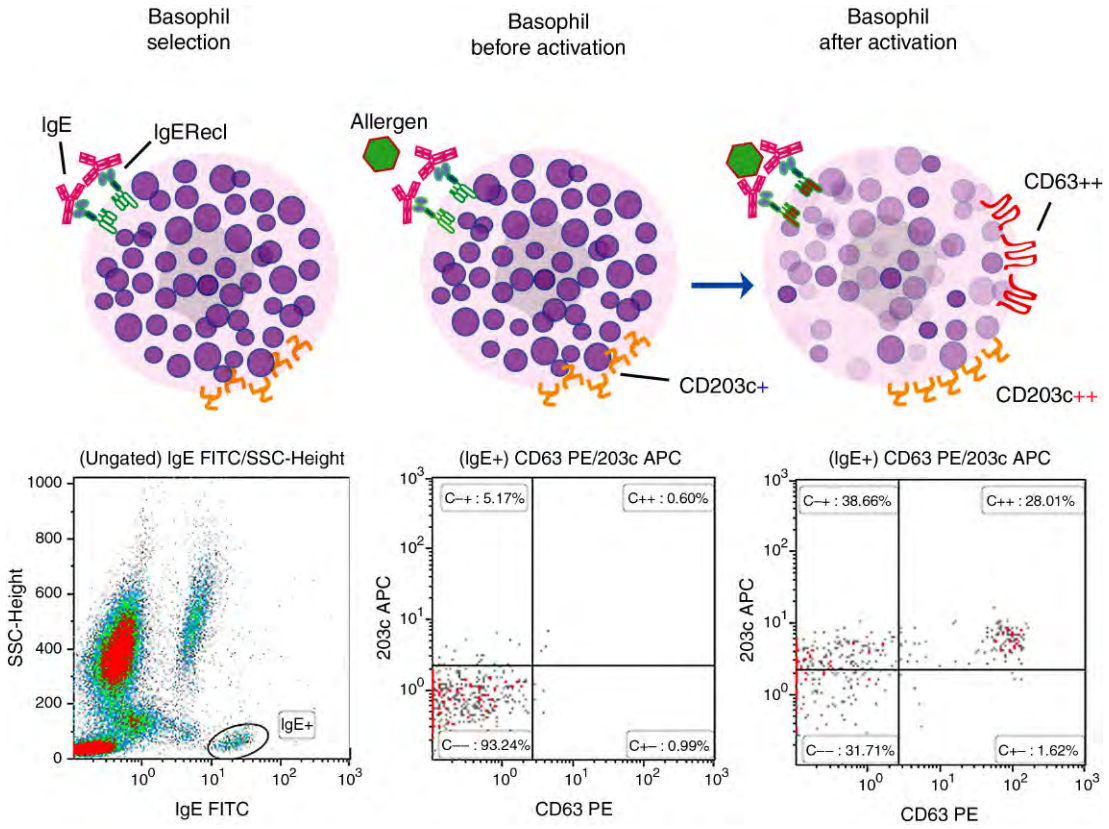

FIGURE 54.5 **Principle of the basophil activation test (BAT).** The allergen of interest is added to a blood sample of the patient. When the allergen is able to cross-link at least two specific IgE molecules bound on the surface of the basophil, activation of the basophil occurs. This activation leads to an upregulation of activation markers that can be measured using flow cytometry. Important surface markers are CD63 and CD203c.

TREATMENT

For the time being, there is no cure for cannabis allergy or for the cannabis-fruit/vegetable syndrome. Therefore, avoidance measures are of utmost importance. These measures comprise an absolute stop of further abuse of the drug and eventually also avoidance of exposures to allergens implicated in the individual cross-reactivity syndrome.

NATURAL HISTORY

The natural history of a cannabis allergy is unknown. Nevertheless, from an own study we observed that, although the patient stopped cannabis exposure, secondary food allergies can still increase.

MINI-DICTIONARY

Allergen/antigen A foreign compound that is recognized by the immune system. An allergen/antigen should be regarded as a collection of different epitopes (antigenic determinants) that can trigger specific humoral and/or cellular immune responses.
Anaphylaxis A generalized allergic reaction to an allergen, for example, foods, latex, drugs, or insect venoms. It is an acute and potentially life-threatening condition.
Angioedema An abrupt deep dermal, subcutaneous, or mucosal swelling. Pain and tenderness are often present, whereas itching is not obligatory.
Autoimmune condition A disorder due to an abnormal immune response against healthy body tissue.
Cross-reactivity/cross-allergy The in vitro reaction between an antigen and antibody due to sensitization to a different but structurally similar antigen (sensitizing antigen). A cross-reaction, however, is not always clinically relevant, but can merely represent an in vitro phenomenon. In cross-allergy, cross-reactivity is clinically relevant, that is, the patient will suffer from a reaction to both the sensitizing and cross-reacting antigen. The principles of cross-reactivity are displayed in Fig. 54.1B.
Cytoskeleton A network of microtubules, microfilaments, and intermediate filaments that gives structure to a cell.
Hymenoptera An order of insects comprising honeybees, bumblebees, wasps, and ants.
ISAC 112 A microarray technique enabling the measurement of 112 allergen components at the same time.
Native compound A substance, chemically processed or not, of natural origin (source material).
Panallergen A native compound, mostly a protein, that is widely distributed in nature, and often leads to cross-reactivity.
Photosynthesis A chemical process in which (green) plants and other photosynthetic organisms use the energy of the sun to transform carbon dioxide and water into oxygen and glucose.
Primary prevention Interventions that attempt to avoid the development of a certain condition.
Recombinant compound A substance produced by altering genetic material in a living organism, that is, genetic engineering.
Rhinoconjunctivitis An inflammation of the mucosa of the nose and eyes. It is characterized by itching of the eyes and nose, a runny nose, nasal congestion, sneezing, and red eyes.
Skin anergy The skin is not able to respond to any stimulus.
Urticaria A skin rash characterized by red or pale elevated wheals associated with severe itching. It is also known as hives.

CHAPTER

55

Marijuana and Breastfeeding

M.G. Hill, K.L. Reed

The University of Arizona, Tucson, AZ, United States

SUMMARY POINTS

- Maternal marijuana use does result in presence of THC and its metabolites in the breastmilk.
- The concentration of THC in breastmilk, after different levels of use, has been inadequately studied.
- Marijuana use does not seem to inhibit milk letdown in postpartum women.
- There is not sufficient evidence to confirm immediate physical harm to the neonate breastfeeding from a woman who uses marijuana.
- There is some evidence that there are long-term effects of neonatal exposure to marijuana in certain areas of reasoning. However, there is not sufficient evidence to conclude that overall Intelligence Quotient is affected in human offspring.

KEY FACTS ABOUT MARIJUANA AND BREASTFEEDING

- Women who use marijuana during breastfeeding do produce milk with marijuana and its metabolites present in detectable quantities. It is not known how much of the drug is absorbed in the gastrointestinal tract of the infant.
- There is a lack of evidence pertaining to outcomes of children exposed exclusively to marijuana (and not other drugs), and exclusively through breast milk (and not in utero). This makes clinical recommendations difficult.

LIST OF ABBREVIATIONS

SIDS	Sudden infant death syndrome
THC	Tetrahydrocannabinol

INTRODUCTION

Marijuana is the most frequently used illicit drug in many areas of the world. In the United States, Colorado and Washington legalized in 2014 the commercial sale and use of marijuana. Studies from multiple countries have suggested that the rate of use is approximately 5–20% in pregnant and breastfeeding women (Scragg et al., 2001; Fried, Watkinson, Grant, & Knights, 1990; Wallace, Burns, Gilmour, & Hutchinson, 2007). An internet search regarding marijuana and breastfeeding yields many confidently written, yet contradictory opinions on the benefits and risks of this activity. There remain gaps in understanding of the clinical utility and the risk of marijuana use in pregnant and breastfeeding women. This chapter focuses on what is known about the effects of marijuana use in this population.

ROUTES OF MATERNAL INGESTION

Marijuana can be inhaled or ingested. The inhalation route is the most common way for marijuana to be accessed (Huestis, 2007). Inhalation yields varying amounts of absorbed marijuana (Huestis, 2007). Absorption of active drug appears to be dependent on multiple factors. One of these is the use of smoking aids. For example, the smoking of a "joint" (rolled cigarette of marijuana, often combined with tobacco) allows a larger proportion of the THC (tetrahydrocannabinol) to be released into the surrounding environment between breaths taken by

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00064-8
Copyright © 2017 Elsevier Inc. All rights reserved.

the user, whereas a "bong" device ensures that a larger portion of the smoke produced from the marijuana is collected in a canister for inhalation. There is also some evidence that users more experienced in smoking marijuana inhale a greater proportion of smoke from a standardized amount of marijuana (Huestis, 2007). This may be related to breathing techniques and tolerance to the irritation of smoke on the airways (Huestis, 2007).

Oral intake of marijuana is another common route of administration. Users will frequently cook leaves and buds of the marijuana plant inside foods, wherein the baking process releases the active ingredients from the marijuana. In some populations, marijuana tea is more common. Resins of marijuana can also be produced for human consumption. The effects of marijuana occur later after oral ingestion than with inhalation, as complete absorption takes several hours (Sharma, Murthy, & Bharath, 2012).

With the advent of medical marijuana, methods for dosing including rectal administration and patch administration are now also being investigated. The commonly marketed form of synthetic medication is dronabinol (Marinol) for oral administration. Several synthetic compounds are accessible to patients, some of which stimulate the endocannabinoid system, producing effects on appetite without producing the same significant effects on mental state that marijuana is known for (Fride, Bregman, & Kirkham, 2005). These are not the focus of this chapter, though their use is becoming increasingly common.

FACTORS THAT INFLUENCE INITIATION AND CONTINUATION OF BREASTFEEDING

Women tend to make the decision to breastfeed before pregnancy or during pregnancy (Kools, Thijs, & de Vries, 2005). One large survey addressing breastfeeding attitudes illustrated that women make decisions based on their own understanding of the benefits of breastfeeding, as well as other factors (work commitments, convenience) that may make formula feeding a better option for their situation (Kools et al., 2005). The success of breastfeeding seems not to be related to the age of the mother or her level of education (Kools et al., 2005). Most women do not make their decision about method of feeding based upon physician or midwife advice (Kools et al., 2005). In fact, there is evidence that the introduction of intensive postpartum clinical support in women using drugs does not modify parental behavior. A study from Australia found that home visits for "at risk" women did not increase the rates of continuation of breastfeeding; the control group breastfed for longer, in spite of the fact that the home visit group arguably had more breastfeeding support (Bartu, Sharp, Ludlow, & Doherty, 2006).

The strongest predictor for initiation and continuation of breastfeeding is previous experience with breastfeeding (Kools et al., 2005). Women who have previously breastfed an infant are much more likely to be successful in initiating and continuing breastfeeding (Kools et al., 2005). Women who have never had an infant, or who have previously fed their children with formula, are less likely to breastfeed (Kools et al., 2005). Use of marijuana does not seem to heavily influence the decision of most women as to method of newborn feeding. Survey-based research has indicated that many women who use marijuana and cigarettes will decrease or stop use in pregnancy (Fried et al., 1990). However, some will then increase use again after delivery. Theoretically, women who choose to breastfeed may be doing so at a time when they are increasing the use of marijuana.

MARIJUANA USE, MILK PRODUCTION, AND WILLINGNESS TO BREASTFEED

A concern cited regarding the use of marijuana in breastfeeding women is that it may delay the production of breastmilk. This is poorly studied in humans.

One study identified changes in prolactin levels in nonpregnant human females in response to marijuana inhalation (Mendelson, Mello, & Ellingboe, 1985). This experiment included 16 females who served as their own controls. Serum prolactin levels were measured in the follicular and luteal phases of the menstrual cycle, after inhalation of a marijuana cigarette or a placebo cigarette. Intriguingly, the patients had no difference in prolactin levels in the follicular phase in response to marijuana inhalation, but did have a decrease in prolactin levels in the luteal phase of the cycle (Mendelson et al., 1985). The implication is that marijuana may cause a decrease in prolactin levels in lactating women. However, as stated, this study was performed on women who were not pregnant or breastfeeding, who were having menstrual cycles. Additionally, other important hormones for the production of milk in humans, such as oxytocin, were not studied.

There are several longitudinal studies assessing the continuing health of mother–infant dyads with marijuana exposure both during pregnancy and breastfeeding (Astley & Little, 1990; Dreher, Nugent, & Hudgins, 1994; Hayes, Lampart, Dreher, & Morgan, 1991; Tennes et al., 1985). The results of marijuana use on infant development will be discussed later, however, the very existence of these studies confirms that milk production and letdown does occur in these women. Additionally, studies from multiple countries show equivalent rates of breastfeeding initiation and continuation in mothers using and abstaining from marijuana. One study

from Colorado followed 62 infants who were breastfed (Tennes et al., 1985). 27 infants had been exposed to marijuana through the mother's breastmilk. The age of weaning in infants was no different between groups (Tennes et al., 1985). This suggests that marijuana use probably does not significantly impair a mother's physiologic ability to nurse an infant.

Some authors suggest that marijuana use leads women to become apathetic, sedated, and less alert to the needs of their infants (Liston, 1998), or that the drug causes immediate adverse effects similar to an intoxication in the infant (Garry et al., 2009). These claims have a poor scientific basis, and seem to be rooted in the bias that people using marijuana have impaired functioning.

The effects of marijuana on infant appetite are unknown. The anorexia associated with multiple medical conditions has been treated with marijuana with encouraging results (Fride et al., 2005). Animal studies suggest that stimulation of the endocannabinoid system increases suckling behavior in juveniles (Fride et al., 2005). These findings indicate that marijuana exposure during infancy likely does not cause a decrease in appetite. Multiple cohorts reporting on marijuana exposure of the fetus and infant have not shown slower growth (an indication of decreased milk intake) in newborns (Dreher et al., 1994; Hayes et al., 1991; Tennes et al., 1985). Likewise, overall growth into the teen years does not seem to be affected by early life exposure to marijuana. However, the lifelong effects of appetite manipulation in the newborn via the endocannabinoid system are unknown.

LEVELS OF NEONATAL EXPOSURE THROUGH BREASTFEEDING

In spite of many resources touting the risks of marijuana to the breastfed infant, there is a concerning lack of scientific studies related to this subject. An important publication on the subject detailed the maternal serum, maternal breast milk, and neonatal fecal THC concentrations and the metabolites of THC; 11-OH-THC and 9-carboxy-THC (Perez-Reyes & Wall, 1982). This 1982 publication had two subjects.

The first subject used marijuana via a pipe once per day. Levels of THC in the milk of this subject were 105 ng/mL. The metabolites of THC were not detected in her milk. Additionally, the urine testing of her infant was also negative for the metabolite 9-carboxy-THC.

The second subject in this study had heavier use of marijuana, with inhalation via a pipe seven times per day. Her milk level of THC was 340 ng/mL, the metabolite 11-OH -THC was found at a level of 4 ng/mL. The second metabolite, 9-carboxy-THC was absent. The urine of her infant also tested negative for the metabolite 9-carboxy-THC (Table 55.1).

TABLE 55.1 Concentrations of THC and THC Metabolites in Human Milk

Concentration	Subject 1 (1 pipe per day)	Subject 2 (7 pipes per day)
Milk concentration of THC	105 ng/mL	340 ng/mL
Milk concentration of 11-OH-THC	Not detected	4 ng/mL
Milk concentration of 9-carboxy-THC	Not detected	Not detected

Unsatisfied with these results, the investigators requested that the second subject, with heavier use, provide serum, milk, and infant fecal samples for comparison. On the second testing of this subject, the investigators discovered that THC levels were higher in the infant's feces (347 ng in the total fecal sample), as compared to the maternal plasma (7.2 ng/mL) or milk (60.3 ng/mL). There were also higher levels of the metabolites (Table 55.2). The authors assessed the proportional increases in THC and its metabolites found in the neonatal feces (compared to the maternal milk), and concluded that the neonates were metabolizing and excreting the drug into the feces.

Though this was important work, the leaps in thinking based on these two clinical cases are problematic. This research has been used as justification for statements that marijuana "concentrates" in breastmilk, and is accumulated in the neonate.

The publication of only two clinical cases with only one parent–infant pair being studied is insufficient investigation on which to base practice recommendations. It is curious that the authors chose to report concentrations as ng/mL in the maternal serum and milk, but as "total fecal sample" for levels in the neonate. The authors do not comment on the volume of the fecal sample provided, or whether it was from a single bowel movement of from several samples. Obviously, the larger the sample from which a "total level" was obtained, the larger the amount of active and metabolized drug. Additionally, the presence of THC and its metabolites in infant feces does not necessarily imply absorption by the infant, just that it ingested breastmilk that contained these substances. Another confounding variable is that this infant may very well have inhaled second hand smoke from the mother's intake of marijuana via a pipe seven times per day, and excreted the metabolites

TABLE 55.2 Levels of THC in Mother and Neonate

	Maternal plasma	Maternal milk	Neonatal feces
Level of THC	7.2 ng/mL	60.3 ng/mL	347 ng (total fecal sample)

via the feces. Lastly, more than 65% of marijuana is excreted in the feces (Huestis, 2007). Hence, a fecal sample should not be compared to a serum or urine sample, as the marijuana is preferentially excreted into the feces. It is likely that the maternal feces would have had a higher concentration of the THC and metabolites, had it been tested.

The levels of THC absorbed by infants via breastfeeding with THC present in the maternal milk, as well as the amount the typical infant is exposed to via secondhand smoke, are important topics of future study. This is a challenging area, considering that many women may be reticent to allow their and their infant's participation in such a study for fear of loss of custody of their children, loss of work, or inferior medical treatment because of physician bias resulting from their participation. The current public bias seems to remain that these parents are not "doing the best" by their children (discussed in the next section). However, more evidence is needed to further clarify infant exposure and outcomes following ingestion of marijuana during breastfeeding.

MARIJUANA AND SUDDEN INFANT DEATH SYNDROME

There is an established role of the use of cigarettes (not just by the mother, but cigarette use in the home) in cases of sudden infant death syndrome (SIDS) (Schoendorf & Kiely, 1992). Studies assessing use of marijuana and SIDS risk are inevitably confounded by the concurrent use of tobacco, as marijuana is most often inhaled via smoking, and marijuana smokers are more likely than controls to also use cigarettes. In addition to this, there is also the confounding introduced by polydrug and alcohol use, in most studies assessing the use of marijuana during breastfeeding and risk of SIDS.

One study from New Zealand assessed the use of marijuana in breastfeeding with the outcome of SIDS being investigated (Scragg et al., 2001). 393 cases (patients who used marijuana) and 1592 controls (patients who did not use marijuana) were included. This study found an increased risk of SIDS in patients who used marijuana, when results were adjusted for use of tobacco and ethnicity of the study population OR 2.23 (1.39–3.57). After the multivariate analysis was employed, which adjusted for additional factors, the results were less compelling, with the confidence interval crossing 1.0 – OR of 1.55 (0.87–2.75).

Even if the results of this study were accepted without further investigation, the risk of using marijuana and SIDS occurrence is equivalent to the use of tobacco during breastfeeding. Additionally, the importance of recall bias in a case control study should be considered. It is possible that women who had experienced the loss of a child would have already performed their own analysis of the likely reason this may have happened. Self-blame for the death of an infant may lead to more complete reporting of drug use in the group of women who had lost a child to SIDS than those in the group who had living children.

Studies pertaining to smoking and breastfeeding have indicated that infants of women who smoke are exposed to the smoke (and chemicals contained within the smoke) of the mother, whether the mother chooses to breastfeed or formula feed (Shulte-Hobein, Schwartz-Bickenbach, Abt, Plum, & Nau, 1992). Cotinine levels (easily detected in the urine of women and infants exposed to cigarette smoke) remain elevated in infants of women who smoke, irrespective of whether they were breast or formula fed (Shulte-Hobein et al., 1992). Multiple authors and organizations have recommended that women who smoke tobacco should breastfeed (Australian Breastfeeding Association, 2014; Dorea, 2007). This mode of feeding is recommended during for the first year of life, and provides infants with nutritional and immunologic benefits (D'Apolito, 2013; Hauck, Thompson, Tanabe, Moon, & Vennemann, 2011; Ip et al., 2007). The "protection" of their infant afforded by abstaining from breastfeeding is a false one, in which the infant remains exposed to the second hand smoke and the smoke particles on the mothers skin, hair, and clothes, without the protections provided by breastfeeding (Australian Breastfeeding Association, 2014).

A concerning phenomenon is the recommendation put forward by multiple clinicians and academic societies that women who use marijuana should not breastfeed. A recommendation to feed with formula because of maternal use of marijuana should be undertaken with caution. The clinician should consider the overwhelming evidence of the benefits of breastfeeding, and the lack of evidence that breastfeeding in the setting of marijuana use risks immediate harm to the infant. There is a lack of evidence that neonatal exposure to smoke from marijuana in conjunction with formula feeding is superior to breastfeeding while using marijuana.

SHORT AND LONG-TERM EFFECTS ON THE NEONATE

Studies pertaining to the neonatal and childhood outcomes in the breastfed baby exposed to marijuana have two important sources of confounding. These are the influence of prenatal marijuana exposure (women who used marijuana during pregnancy in addition to during breastfeeding), and the use of substances other than marijuana. The other substances are most commonly cigarettes, alcohol, and cocaine.

Two large cohorts, the MHPCD (Maternal Health Practices and Child Development Study) and the OPPS (Ottawa Prenatal Prospective Study) are of interest. Each is a prospective cohort, the first from the United States, and the second from Canada. These studies did not look only at marijuana use during breastfeeding. Women were asked about drug use during pregnancy, as well as after a pregnancy. The results of these studies suggest that there is no effect of marijuana use on motor development or intelligence quotient, after adjustments are made for confounding variables. However, there was some evidence that the children of heavy users had a detrimental effect in the area of visual perception and reasoning. This difference was not dramatic between those exposed and unexposed in the cohorts, and was the only effect found after a battery of developmental tests (Fried, 1995). When growth was assessed in the OPPS, there was a difference in head circumference in early teenage years. This finding, in isolation, is difficult to interpret (Fried, Watkinson, & Gray, 1999).

There was one prospective cohort from Jamaica in which children were exposed to marijuana in a more culturally accepted pattern of use (Dreher et al., 1994; Hayes et al., 1991). Women in this cohort smoked marijuana, and also drank marijuana tea (Dreher et al., 1994). Specific information on feeding practices after delivery was not reported. However, it is likely that in rural Jamaica, most of these infants were breastfed, and that their mothers continued their daily consumption in the socially accepted practice for that region. In the first month of life, the infants of mothers who used marijuana had better outcomes, and their mothers seemed to transition to their new role with more ease (Dreher et al., 1994). This may have been related to the fact that the mothers who used marijuana also seemed to have more financial control in their lives (investigators reported that marijuana use in this population was associated with a higher average income) (Dreher et al., 1994). In a 5 years' follow-up, there were no detrimental effects in the marijuana-exposed group in this cohort (Hayes et al., 1991).

A cohort from Colorado also showed no adverse effects in children exposed to marijuana in utero and during breastfeeding (Tennes et al., 1985). However, the length of assessment did not exceed 1 year.

Lastly, a report exists detailing poorer motor development at the age of 1 year in infants exposed to marijuana during breastfeeding than controls (Astley & Little, 1990). This cohort included 68 mother–infant dyads per group. However, only 14 infants were exposed only during breastfeeding (the other 54 infants were exposed both during the pregnancy and breastfeeding). Additionally, the mothers in the marijuana exposure group were three times more likely to use cocaine, both during pregnancy and lactation, and had a lower average income than the controls. Considering these factors, a conclusion should not be drawn that the isolated use of marijuana is solely responsible for these effects.

LEGAL CONCERNS

Pregnancy and motherhood expose women to legal vulnerability. The use of marijuana, while legal or decriminalized in many parts of the world, can still cause a significant disadvantage to a woman in relation to her rights. The use of drugs, including marijuana, can lead to investigation of a family by social services, even if no concerns about parental behavior exist, and can also be discussed during custody proceedings. Some regions of the United States require that physicians and healthcare workers report any illicit drug use to child protective services. This requirement persists, in spite of a lack of evidence of immediate harm related to the use of marijuana while breastfeeding.

Health care workers should be aware of the laws that exist within their geographic region pertaining to reporting of substance use. If serum or urine screening tools are used, they should be employed only with the informed consent of patients. Ideally, patients should be made aware that there are very few instances in which the use of marijuana will impact their immediate health or the health of their child. However, a positive finding on screening may create legal concerns for the patient. Physicians may choose to opt for screening that excludes detection of marijuana, seeing the evidence regarding harm is inconsistent.

Likewise, the neonate should not be tested for illicit substances without the express consent of the parents. Testing in the absence of parental consent is unethical, opens family units to legal costs (both financial and emotional), and damages the doctor–patient relationship. Healthcare workers should be cognizant that screening of women and infants has historically been biased toward ethnic minorities and those with socioeconomic disadvantage. Focusing on nonconsensual testing of these populations serves to further increase the divide between the advantaged and disadvantaged, and the perception of victimization by these groups.

CONCLUSIONS

There is a lack of evidence regarding the relative benefits and risks of marijuana use during breastfeeding. Marijuana is illegal in many areas of the world, and its use remains socially unacceptable in other areas, making study of the effects of the drug during lactation difficult.

The most common mode of marijuana dosing is via inhalation, often mixed with tobacco. Considering the known health risks of smoke exposure to the neonate,

TABLE 55.3 Benefits of Breastfeeding

Nutritionally complete for newborns
Provides immunologic protection
Encourages time for bonding between mother and infant
Eliminates need to purchase supplies for infant feeding

TABLE 55.4 Effects of Marijuana Use During Pregnancy and Breastfeeding

Potential adverse effects of marijuana use while pregnant and breastfeeding	Supporting evidence
Maternal sedation and negligence	Opinion only
Failure of milk letdown	Opinion only
Neonatal sedation and intoxication	Opinion only
Sudden infant death syndrome	Risk may be equivalent to infants of mothers who smoke tobacco
Abnormal infant growth	Several prospective cohorts found no significant difference in infant growth

including sudden infant death syndrome and respiratory infections, it is optimal that women not smoke marijuana or tobacco during breastfeeding. This being said, breastfeeding offers many benefits, and formula feeding does not protect the infant from the dangers of maternal smoking. Rather it allows for continued smoke exposure without the immunologic, nutritional, and financial benefits of breastfeeding. If a woman is going to smoke tobacco, she should be encouraged to continue breastfeeding. There is a lack of evidence to suggest that the recommendation to a mother who uses marijuana should be any different (Tables 55.3 and 55.4).

Hypocretins/Orexins and Addiction: Role in *Cannabis* Dependence

Á. Flores, R. Maldonado, F. Berrendero

Department of Experimental and Health Sciences, Laboratory of Neuropharmacology, School of Health and Life Sciences, Pompeu Fabra University, Barcelona, Spain

SUMMARY POINTS

- Hypocretins/orexins are hypothalamic neuropeptides that regulate physiological processes, such as energy balance, stress and arousal, sleep/wake cycle, and reward.
- The hypocretinergic system modulates the addictive properties of several drugs of abuse (ie, alcohol, nicotine, opioids, psychostimulants, and cannabinoids).
- Anatomical, biochemical and functional cross-talks exist between hypocretinergic and endocannabinoid systems, the latter being the main target of cannabis compounds.
- The hypocretin receptor 1 is necessary for the rewarding properties of the synthetic cannabinoid WIN55,212-2.
- Chronic exposure to THC or WIN55,212-2 affects the activity of hypocretin neurons.
- The dopaminergic transmission in the mesolimbic system is disrupted if the hypocretin receptor 1 is not present.

KEY FACTS OF DRUG SELF-ADMINISTRATION PARADIGMS

- Drug self-administration is a form of operant conditioning used for assessing drug-seeking and drug-taking behavior.
- This method allows us to directly evaluate the reinforcing properties of a drug, and hence to predict its rewarding (and presumably addictive) effects.
- Drug self-administration protocols are performed in operant conditioning chambers, generally equipped with two levers (or holes), one active and one inactive, distinguishable for the presence of a cue light above the active one.
- A correct lever-pressing or nose-poking response results in the contingent presentation of reward: the delivery of an intravenous drug infusion by a syringe pump.
- Different reinforcement schedules can be employed, depending on the type of response to be evaluated:
  - Fixed-ratio (FR). A determined number of operant responses are required to dispense one unit of reinforcer, that is, FR5 requires 5 active lever-presses to receive one drug infusion. Commonly used during the acquisition of drug-taking.
  - Progressive ratio (PR). The number of operant responses required to receive one reinforcer are gradually increased. This schedule provides information about the motivation to obtain the drug, since it reveals at which amount of effort the subject ceases drug self-administration.
- Drug self-administration allows the study of diverse stages present in the addictive behavior:
  - Initial acquisition of drug-taking behavior.
  - Extinction of this behavior during the absence of the drug.
  - Reinstatement of drug-seeking after exposure to stress, associated context/cues, or the drug itself.
- Drug self-administration is considered to be the most reliable model of addiction and to have a high predictive value.

LIST OF ABBREVIATIONS

2-AG	2-arachidonoylglycerol
cAMP	Cyclic adenosine monophosphate
CB1	Cannabinoid receptor 1
CB2	Cannabinoid receptor 2
CNS	Central nervous system
DAG	Diacylglycerol
DMH	Dorsomedial hypothalamus
GABA	γ-Aminobutyric acid
HcrtR1	Hypocretin receptor 1
HcrtR2	Hypocretin receptor 2
HcrtRs	Hypocretin receptors
IP3	Inositol triphosphate
LH	Lateral hypothalamus
MAP	Mitogen-activated protein
mRNA	Messenger ribonucleic acid
NAc	Nucleus accumbens
PFA	Perifornical area
THC	Δ^9-Tetrahydrocannabinol
VTA	Ventral tegmental area

THE HYPOCRETIN/OREXIN SYSTEM

Hypocretin-1/orexin-A and hypocretin-2/orexin-B are two neuropeptides proteotically cleaved from the same precursor, prepro-hypocretin/prepro-orexin (de Lecea et al., 1998; Sakurai et al., 1998). Two closely related G protein-coupled receptors that respond to hypocretins have been cloned, hypocretin or orexin receptor 1 (HcrtR1/OXR1) and hypocretin or orexin receptor 2 (HcrtR2/OXR2) (Fig. 56.1). Hypocretin-1 binds to both receptors with similar affinity, whereas hypocretin-2 binds to HcrtR2 with ten-fold greater affinity than to HcrtR1. The intracellular signaling pathways that mediate the effects of hypocretins have been intensively investigated, but remain still to be completely elucidated. Stimulation of both hypocretin receptors (HcrtRs) leads to a prominent increase in intracellular Ca^{2+} concentrations through the activation of Gq proteins, followed by phospholipase and subsequent protein kinase C (PKC) stimulation (Xu, Yang, Ward, Gao, & Liu, 2013). The Ca^{2+} elevation induced by hypocretin receptor activation explains the commonly reported neuroexcitatory nature of hypocretin peptides on the brain. In addition, hypocretins have been reported to activate the MAP kinase pathway (Xu et al., 2013) (Fig. 56.2).

In the central nervous system (CNS), hypocretin expression is restricted to a few thousand neurons in some particular regions of the hypothalamus: the perifornical area (PFA), the dorsomedial hypothalamus (DMH), and the dorsal and lateral hypothalamus (LH) (Peyron et al., 1998). Although hypocretin-containing neurons represent a relatively small number of cells, their projections are widely distributed throughout the brain (Peyron et al., 1998) (Fig. 56.1). The widespread extension of the hypocretin system in the CNS is in agreement with the variety of physiological functions of hypocretin peptides that includes energy homeostasis, behavioral arousal, sleep/wake cycles, and emotional regulation (Li, Hu, & de Lecea, 2014). Moreover, numerous studies demonstrate a role for hypocretins in reward-seeking and addiction (Plaza-Zabala, Maldonado, & Berrendero, 2012). Consistent with this, hypocretin neurons send significant efferent projections to structures related to addiction, such as the paraventricular nucleus of the thalamus, the septal nuclei, the bed nucleus of the stria terminalis, the anterior and central amygdaloid nuclei, and the ventral tegmental area (VTA). Disperse axons are also found

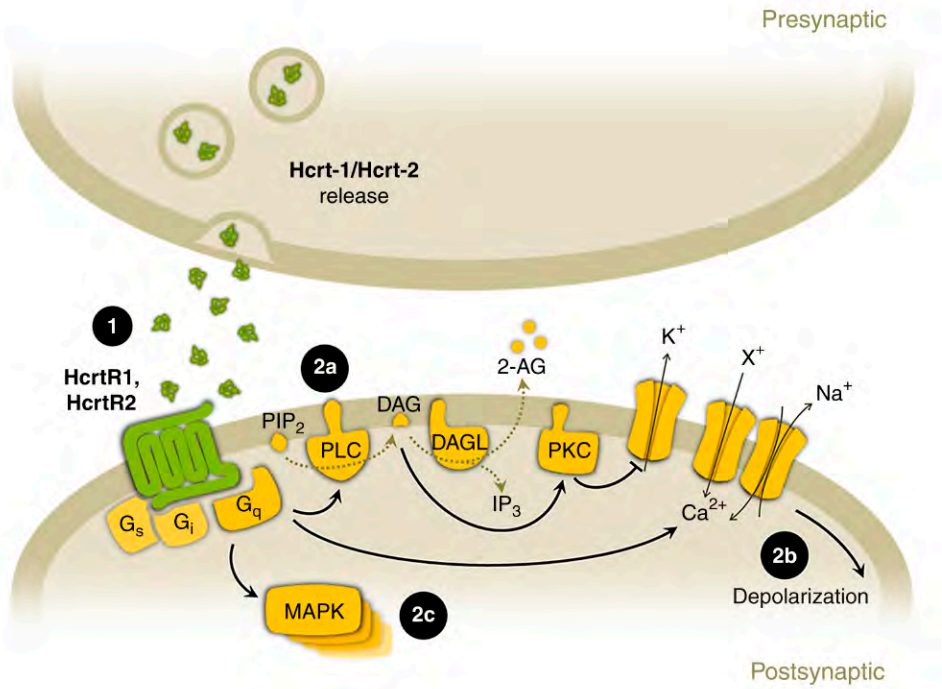

FIGURE 56.2 **Hypocretin-mediated synaptic signaling.** (1) Hypocretins are released from presynaptic terminals and stimulate postsynaptic HcrtR1 and HcrtR2. (2) HcrtR activation is mainly associated with Gq-protein stimulation, but it can activate also other G-protein subtypes. The key downstream outcomes from HcrtR activation and subsequent Gq-protein stimulation are: (2a) activation of PLC activity, and preceding DAG and 2-AG synthesis; (2b) membrane depolarization due to the modulation of K^+ channels, nonspecific cationic channels and $Na^+/Ca2^+$exchanger; and (2c) activation of protein kinase cascades such as the MAPK pathway. *PIP_2*, phosphatidylinositol bisphosphate; *DAG*, diacylglicerol; *2-AG*, 2-arachidonoylglycerol; *PLC*, phospholipase C; *DAGL*, diacylglycerol lipase; *MAPK*, mitogen-activated protein kinase; *Hcrt-1*, hypocretin-1; *Hcrt-2*, hypocretin-2; *PKC*, protein kinase C; *X^+*, unspecific cation. *Source: Adapted with permission from Flores et al. (2013).*

throughout the cortex and the medial part of the nucleus accumbens (NAc) (Peyron et al., 1998). Moreover, hypocretin-1 injected into the VTA increases dopamine in the NAc (España et al., 2010), suggesting that these neuropeptides play a role in the regulation of the dopaminergic mesocorticolimbic system and reward learning.

ROLE OF THE HYPOCRETIN/OREXIN SYSTEM IN THE ADDICTIVE PROPERTIES OF DRUGS OF ABUSE

As mentioned previously, the hypocretin system plays a crucial role in the regulation of the addictive properties of several major drugs of abuse (Fig. 56.3). Hypocretin transmission regulates the primary reinforcing effects of opioids, nicotine, and alcohol (Plaza-Zabala et al., 2012). Recent evidence also suggests a role for these neuropeptides in cannabinoid reward (Flores, Maldonado, & Berrendero, 2014). However, in the case of psychostimulants, an involvement of the hypocretin system is revealed only when effort requirement to obtain the drug is high (España et al., 2010). The differential participation of hypocretins in the reinforcing properties of psychostimulants could be explained by the different action upon the mesolimbic system. Thus, opioids, nicotine, alcohol, and cannabinoids increase dopaminergic cell firing in the VTA, whereas psychostimulants directly inhibit dopamine uptake in the NAc. These differences suggest that the VTA might be a crucial site of action for hypocretins to mediate the rewarding effects of different drugs of abuse (Aston-Jones, Smith, Moorman, & Richardson, 2009). Therefore, behavioral effects that depend on increased VTA dopaminergic activation (opioid/alcohol/nicotine/cannabinoid reinforcement) would be attenuated by HcrtR1 antagonist because they may require hypocretin transmission. However, behaviors that are independent of the activation of VTA (primary cocaine reinforcement) could avoid this critical site of actions of hypocretins. Moreover, hypocretins regulate the reinstatement of drug-seeking behaviors induced by drug-associated cues, as described for cocaine, alcohol, heroin, and nicotine. Stress-induced reinstatement of cocaine and alcohol is also mediated by hypocretin transmission (Khoo & Brown, 2014). As a whole, these data suggest that HcrtR1 antagonists might be of potential interest for the treatment of drug addiction (Figure 56.3). The possible usefulness of HcrtR2 antagonists should be considered cautiously, since this receptor seems to be mainly involved in the regulation of sleep-wake cycle.

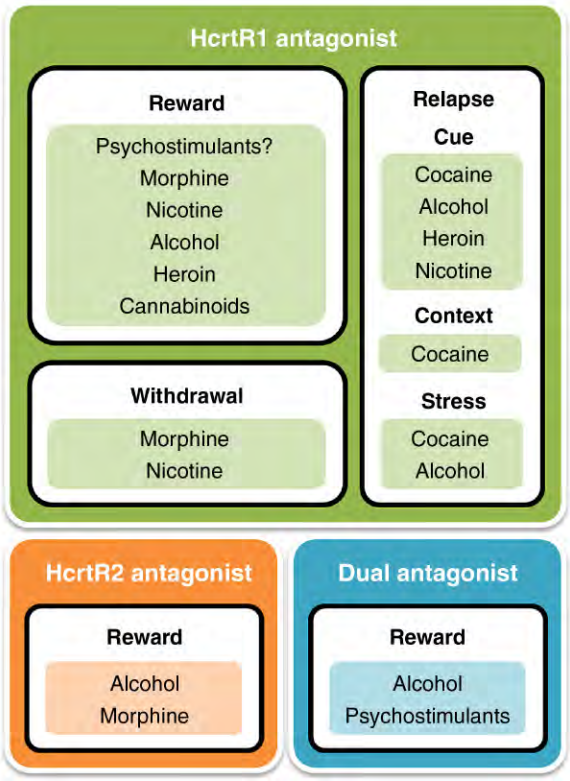

FIGURE 56.3 Potential therapeutic utility of hypocretin/orexin receptor antagonists. Diagram showing the different stages of drug addiction in which hypocretin/orexin receptor antagonists constitute potential therapeutic tools. *Source: Adapted with permission from Plaza-Zabala et al. (2012).*

NEUROBIOLOGICAL MECHANISMS OF CANNABINOID DEPENDENCE

The neurochemical processes by which cannabinoid addiction is developed are similar to those reported for other drugs of abuse. The endocannabinoid system is the leading site of action for the rewarding and pharmacological responses induced by cannabinoids. In fact, this system fulfils a general modulatory effect on the reward circuitry, participating in the rewarding and addictive properties of all classical drugs of abuse.

CB1 receptors are abundantly expressed in the diverse regions of the brain reward system, including the VTA, the NAc, the prefrontal cortex, and the amygdala. However, it is known that VTA dopaminergic neurons are unlikely to express CB1 receptors (Julian et al., 2003). Indeed, CB1 receptors present in the VTA are located on presynaptic glutamatergic and GABAergic neurons. Endocannabinoids modulate the excitatory and inhibitory synaptic inputs into the VTA, acting as a retrograde messenger. Thus, the activation of CB1 receptors in the VTA present in GABAergic interneurons, or in glutamatergic terminals mainly from prefrontal cortex neurons, would remove, respectively, these inhibitory or excitatory inputs on dopaminergic neurons. The final effect on the modulation of VTA dopaminergic activity by endocannabinoids would depend on the functional balance between these GABAergic and glutamatergic inputs (Maldonado, Valverde, & Berrendero, 2006; Fattore, Fadda, Spano, Pistis, & Fratta, 2008). Accordingly, exogenous cannabinoid agonists stimulate the activity of mesencephalic dopaminergic neurons by altering this balance. Both Δ^9-Tetrahydrocannabinol (THC) and the synthetic cannabinoid WIN55,212-2 enhance the firing rate and bursting activity of dopaminergic neurons in the VTA, subsequently enhancing dopamine release in terminal regions, such as the NAc and the prefrontal cortex (Chen et al., 1990; Tanda, Pontieri, & Di Chiara, 1997), a fact that has been associated to their reinforcing properties.

Parallel dopamine-independent mechanisms in the development of cannabinoid addiction may also be modulated by the endocannabinoid system. For instance, CB1 receptors present in the prefrontal cortex might explain the involvement of the endocannabinoid system in the motivation to seek the drug, since this brain area integrates sensory information, emotional processing, and hedonic experience. Besides, reinstatement of drug-seeking behavior is probably influenced by the endocannabinoid system because of its capacity to modulate synaptic plasticity, consolidating the reward-driven behavior required to establish addictive processes (Maldonado et al., 2006).

In summary, endocannabinoid and dopaminergic systems are crucially involved in the neurobiological mechanisms underlying the addictive effects of the main classical drugs of abuse, including cannabinoids. Likewise, other neurochemical systems have also been involved in the addictive processes induced by cannabinoids, including endogenous opioids, GABA, glutamate, monoamines, and several neuropeptides (Maldonado, Berrendero, Ozaita, & Robledo, 2011). Lately, hypocretins have been reported to contribute also to cannabinoid dependence, revealing a new potential therapeutic target for the treatment of this disorder.

INTERACTION BETWEEN HYPOCRETIN/OREXIN AND ENDOCANNABINOID SYSTEMS

In later years, research has shown the possible existence of a cross talk between hypocretinergic and endocannabinoid systems. Although few investigations have analyzed this interaction, emerging neuroanatomical and biochemical evidences strongly suggest the existence of such cross-modulation (Flores, Maldonado, & Berrendero, 2013). Hence, CB1 and HcrtRs show an overlapping distribution in several areas of the CNS (Marcus et al., 2001; Mackie, 2005).

The common expression of HcrtRs and CB1 within the entire hypothalamus denotes an important modulation of energy homeostasis, and neuroendocrine and autonomic functions by both hypocretin and endocannabinoid systems. They are also abundant along the mesocorticolimbic system, denoting their regulation of reward processing and addiction. Likewise, the mutual involvement of these neuromodulators in the control of anxiety-like responses, sleep/wake cycle, and nociception is supported by the presence of HcrtRs and CB1 within diverse brainstem nuclei. However, HcrtRs location among different neuronal populations and therefore direct synaptic connections between HcrtRs and CB1, are not well defined yet. On the other hand, the recent detection of multifocal CB2 expression in the brain opens a new range of possibilities for hypocretin–cannabinoid interaction.

CB1 and CB2, as well as HcrtR1 and HcrtR2, are classified as rhodopsin-like G-protein coupled receptors. Although most cellular signals triggered upon cannabinoid receptor activation differ from those initiated following the stimulation of hypocretin receptor, it seems that cannabinoid and HcrtRs share diverse signaling pathways (Demuth & Molleman, 2006; Kukkonen, 2013). CB1 and CB2 receptors are coupled to the Gi/o family of G-proteins and, subsequently, inhibit adenylyl cyclase activity, and decrease cAMP levels. In contrast, HcrtRs are mainly associated with Gq-proteins, inducing the activation of phospholipase C that produces the second messengers DAG and IP3. Additionally, stimulation of both HcrtRs has been suggested to modulate adenylyl cyclase activity by coupling other G-proteins, in certain experimental conditions. One of the most relevant differences between hypocretin and cannabinoid cellular signaling is the effect on transmembrane potential as a consequence of their divergent modulation of effector ion channels triggered upon receptor stimulation. Thus, CB1 activation triggers the plasmatic membrane repolarization that results in neurotransmitter release inhibition, whereas HcrtRs stimulation induces membrane depolarization, facilitating the formation of action potentials. On the other hand, the main cellular pathway activated by both cannabinoid and hypocretinergic stimulation is the phosphorilation and activation of the MAP kinase cascade that regulates neuronal gene expression and synaptic plasticity. Additionally, recent in vitro and in vivo studies report that HcrtR1 stimulation can lead to 2-arachidonoylglycerol (2-AG) release activating CB1 receptors in nearby cells, since DAG produced upon phospholipase C stimulation is used by diacylglycerol lipase as a substrate for 2-AG synthesis (Turunen, Jäntti, & Kukkonen, 2012). This hypocretin-induced endocannabinoid release might be a relevant mechanism by which hypocretins could mediate synaptic inhibition in certain conditions.

CB1 receptors have a significant propensity to make homo- and heteromeric complexes. Indeed, the existence of CB1-HcrtR1 and CB1-HcrtR2 heteromers in diverse in vitro models has been demonstrated by electron microscopy colocalization, and fluorescence and bioluminiscence resonance energy transfer (FRET and BRET) imaging studies (Hilairet, Bouaboula, Carrière, Le Fur, & Casellas, 2003; Ellis, Pediani, Canals, Milasta, & Milligan, 2006). The functional impact of this heteromerization has been associated with HcrtRs and CB1 receptor trafficking, as well as cross-agonism/-antagonism phenomena. However, whether HcrtR-CB1 heteromers actually exist within the CNS tissue, and if they are indeed of physiological relevance, remains to be further elucidated.

So far, various functional studies have revealed the existence of a mutual regulation between the hypocretin and endocannabinoid systems, mainly regarding the areas of nociception, appetite, and reward. Thus, systemic administration of the CB1 antagonist AM251 reverses the antinociceptive effect of hypocretin-1 microinjection into the periaqueductal gray, during the hot-plate test in rats (Ho et al., 2011). Similarly, it has been suggested that hypocretin-1 exerts its orexigenic action through CB1 receptor activation, since pretreatment with a nonanorectic dose of the CB1 antagonist rimonabant blocks the orexigenic effect of hypocretin-1 administered by intracerebroventricular route in rats (Crespo, Gómez de Heras, Rodríguez de Fonseca, & Navarro, 2008). In the same line, it has been shown that conditioned place preference induced by chemical stimulation of the LH, which depends on HcrtR1 activation in the VTA, is reduced in a dose-dependent manner by previous intra-VTA administration of rimonabant (Taslimi, Haghparast, Hassanpour-Ezatti, & Safari, 2011). Moreover, coadministration of effective doses of both HcrtR1 and CB1 antagonists into the VTA reduces conditioned place preference in a nonadditive manner, suggesting that these receptors regulate this effect by a common mechanism (Taslimi et al., 2011). This goes in line with the idea that hypocretins and endocannabinoids may share a common site of action for reward modulation, since primary rewarding effects of drugs of abuse that depend on increased VTA dopaminergic activity, such as opioids, nicotine, and alcohol, require both hypocretinergic transmission and presence of CB1 receptors. A possible explanation for this cannabinoid-mediated effect of hypocretins is the synthesis and release of 2-AG upon HcrtR1 activation, mentioned previously. However, this mechanism has been only confirmed to occur in the periaqueductal gray (Ho et al., 2011), and in the dorsal raphe nucleus (Haj-Dahmane & Shen, 2005), and further studies will be necessary to better understand the interaction between the endocannabinoid and hypocretin systems in the regulation of the reward circuit.

ROLE OF HYPOCRETINS/OREXINS IN CANNABINOID DEPENDENCE

Despite the evidence supporting the hypocretin-cannabinoid cross talk in the CNS and the undeniable regulation of the addictive properties of several drugs of abuse by the hypocretinergic system, there is little information regarding the role of hypocretins in cannabinoid dependence. The main data available are focused on the rewarding properties of cannabinoids, whereas other relevant aspects of cannabinoid dependence, such as relapse and withdrawal, remain unexplored.

The initiation of cannabis addiction has been related to its capacity to induce rewarding effects. There are several predictive animal models to study responses related to the rewarding effects produced by cannabinoids. Among these paradigms, drug self-administration procedures currently represent the most reliable models of drug consumption in humans and have a high predictive value by directly evaluating the reinforcing properties of the drug (Maldonado et al., 2011). Recent studies have revealed persistent cannabinoid self-administration under different experimental conditions. Thus, intravenous self-administration of THC has been described in squirrel monkeys (Justinová, Tanda, Redhi, & Goldberg, 2003). Although operant responding for self-infused THC has not been consistently demonstrated in rodents, intravenous self-administration of the synthetic and short half-life cannabinoid agonist WIN55,212-2 has been reported in rats and mice (Solinas et al., 2007; Mendizábal, Zimmer, & Maldonado, 2006).

A recent study has investigated the contribution of hypocretins to the reinforcing properties of cannabinoids, by using the intravenous WIN55,212-2 self-administration paradigm in mice (Flores et al., 2014). In this study, animals were trained to self-administer the synthetic cannabinoid during 12 days, and the role of HcrtRs was evaluated by diverse pharmacological and genetic approaches (Fig. 56.4). The study showed that a chronic treatment with the HcrtR1 antagonist SB334867 during the acquisition phase of WIN55,212-2 self-administration reduced the number of animals reaching the acquisition criteria for this operant response. Moreover, acute SB334867 administration, after a successful acquisition of WIN55,212-2 self-administration, impaired the reinforcing properties of this synthetic cannabinoid. An acute HcrtR1 antagonist injection also reduced the maximal effort required to obtain a WIN55,212-2 infusion in a progressive ratio schedule session, suggesting a decrease in the motivation for the drug. On the contrary, the administration of the HcrtR2 antagonist TCSOX229 did not modify WIN55,212-2 self-administration in any of the reinforcement schedules tested. These data point to a specific role for HcrtR1 in the modulation of the reinforcing properties of cannabinoids. In fact, HcrtR2 appears to be of minor relevance in the regulation of the rewarding properties of drugs of abuse, although both hypocretin receptor subtypes are abundant in brain areas relevant in reward processing, such as the VTA, NAc, and bed nucleus of the stria terminalis (Plaza-Zabala et al., 2012). In agreement with the pharmacological data previously mentioned, HcrtR1 knockout mice showed an impaired WIN55,212-2 self-administration behavior in comparison with wild-type animals (Flores et al., 2014). Thus, the acquisition of the operant behavior was successfully reached by a minor percentage of mutant mice. The amount of WIN55,212-2 self-infused by these knockout animals was reduced, as well. Mice lacking HcrtR1 also showed diminished motivation for the cannabinoid, since their maximal effort to obtain a WIN55,212-2 infusion was reduced, when compared to wild-type mice in a progressive ratio schedule session. It is worth mentioning that the impairment of WIN55,212-2 self-administration was not attributable to other unspecific effects, such as locomotion alteration or possible learning deficits in the acquisition of an operant behavior, since none of the treatments or genetic manipulations altered operant responding for a natural reward such as water. As a whole, these behavioral data suggest that the primary reinforcing properties of cannabinoids, as well as motivation to obtain the drug are modulated by HcrtR1 signaling (Flores et al., 2014).

Little information is available regarding the possible changes of the hypocretinergic activity in response to a chronic cannabinoid exposure. It has been recently shown that chronic THC administration during the adolescent period of male rats decreases hypothalamic prepro-hypocretin mRNA levels in adulthood (Llorente-Berzal et al., 2013). Interestingly, hypothalamic prepro-hypocretin mRNA levels remain unaffected in adult female rats receiving THC during adolescence (Llorente-Berzal et al., 2013). This sexual dimorphism results are interesting, since female rats also acquire stable WIN55,212-2 self-administration more rapidly and at higher rates than males (Fattore et al., 2007). Thus, lower hypocretin levels could be related to phenotypes less vulnerable to cannabinoid dependence. On the other hand, it has been observed that hypocretin-1 expression in peripheral blood cells is reduced in cannabis-dependent smokers, when compared to nicotine-dependent smokers and nonsmokers (Rotter et al., 2012). However, this information should be carefully interpreted, since peripheral hypocretin mRNA levels do not necessarily reflect the situation in certain areas of the CNS. Moreover, these differences could be related to peripheral effects of THC, and not to the central modulation of cannabinoid dependence (Flores et al., 2013).

Operant yoked-control models of drug self-administration are essential to understanding whether neurochemical changes are attributable to the effects of drug

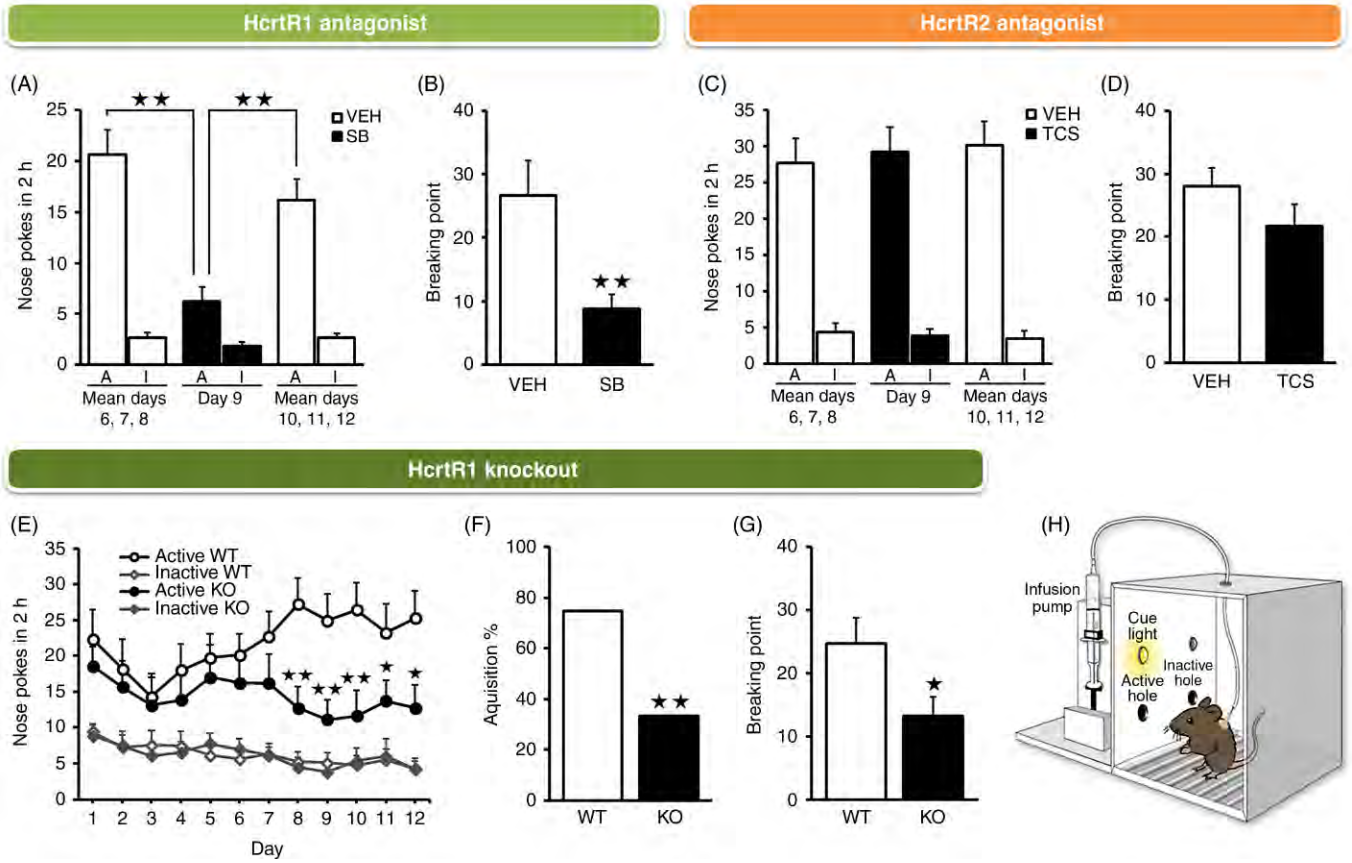

FIGURE 56.4 Effects of HcrtR1 and HcrtR2 pharmacological blockade or HcrtR1 gene deletion in WIN55,212-2 self-administration. HcrtR1 antagonization or gene deletion reduces operant WIN55,212-2 self-administration, and motivation to obtain the drug, whereas HcrtR2 pharmacological blockade has no effect on this behavioral response. In the pharmacological approach (A–D) mice were trained to self-administer the synthetic cannabinoid WIN55,212-2 under fixed ratio 1 (FR1) until stable behavior was acquired. SB334867 (10 mg/kg, intraperitoneal) or TCSOX229 (10 mg/kg, intraperitoneal) was administered 30 min before a FR1 session on day 9, or before the progressive ratio (PR) session. (A, C) Number of active and inactive responses displayed after acute (A) SB334867 or (C) TCSOX229 pretreatment on day 9, and during the 3 days before (mean days 6–8), and after (mean days 10–12) these pharmacologic challenges. (B, D) Breaking-point values achieved in the PR schedule after acute (B) SB334867 or (D) TCSOX229 pretreatment. In the genetic approach (E–G) HcrtR1 knockout and wild-type mice were trained to self-administer WIN55,212-2 during 12 days, and underwent a PR session on day 13. The time course (E) and the percentage of acquisition (F) of WIN55,212-2 self-administration in wild-type and knockout mice is shown, as well as the breaking-point values achieved in the PR schedule (G). (H) Schematic diagram of operant chambers where drug self-administration procedures are performed. Values are represented as mean + SEM. *SB*, SB334867; *VEH*, vehicle; *TCS*, TCSOX229; *WT*, wild-type; *KO*, HcrtR1 knockout; *A*, active hole; *I*, inactive hole; ★, $p < 0.05$; ★★, $p < 0.01$ when compared to the control group. *Source: Adapted with permission from Flores et al. (2014).*

seeking, or to the pharmacologic actions of the drug. Interestingly, contingent (active) and noncontingent (passive) WIN55,212-2 self-administration have been reported to modulate differently the activation of hypocretin neurons (Flores et al., 2014). Thus, immunofluorescence studies showed that contingent self-administration of the cannabinoid induced an increase in the percentage of hypocretin cells expressing FosB/ΔFosB in the LH, a transcription factor considered a marker of neuronal activity (Fig. 56.5). Notably, hypocretin cells were not activated in mice receiving passive infusions of the cannabinoid, suggesting that the recruitment of hypocretin cells within the LH is mainly due to operant seeking for the reinforcing effects of this drug. Moreover, these neurons were not recruited due to the learning process inherent to the acquisition of an operant behavior, since operant conditioning maintained by water did not modify the activation of hypocretin cells within the LH. In contrast, operant WIN55,212-2 self-administration had no apparent effect on FosB/ΔFosB expression in DMH/PFA hypocretin neurons, although mice receiving passive infusions of the drug showed a lower activation of these cells, in comparison with those receiving the drug contingently (Fig. 56.5). Activation of hypocretin cells located within the LH, but not those in the DMH/PFA, has been related also with the exposure to other drugs of abuse, such as morphine (Richardson & Aston-Jones, 2012) and ethanol (Lawrence, Cowen, Yang, Chen, & Oldfield, 2006). In fact, it has been proposed the existence of a functional dichotomy between the diverse

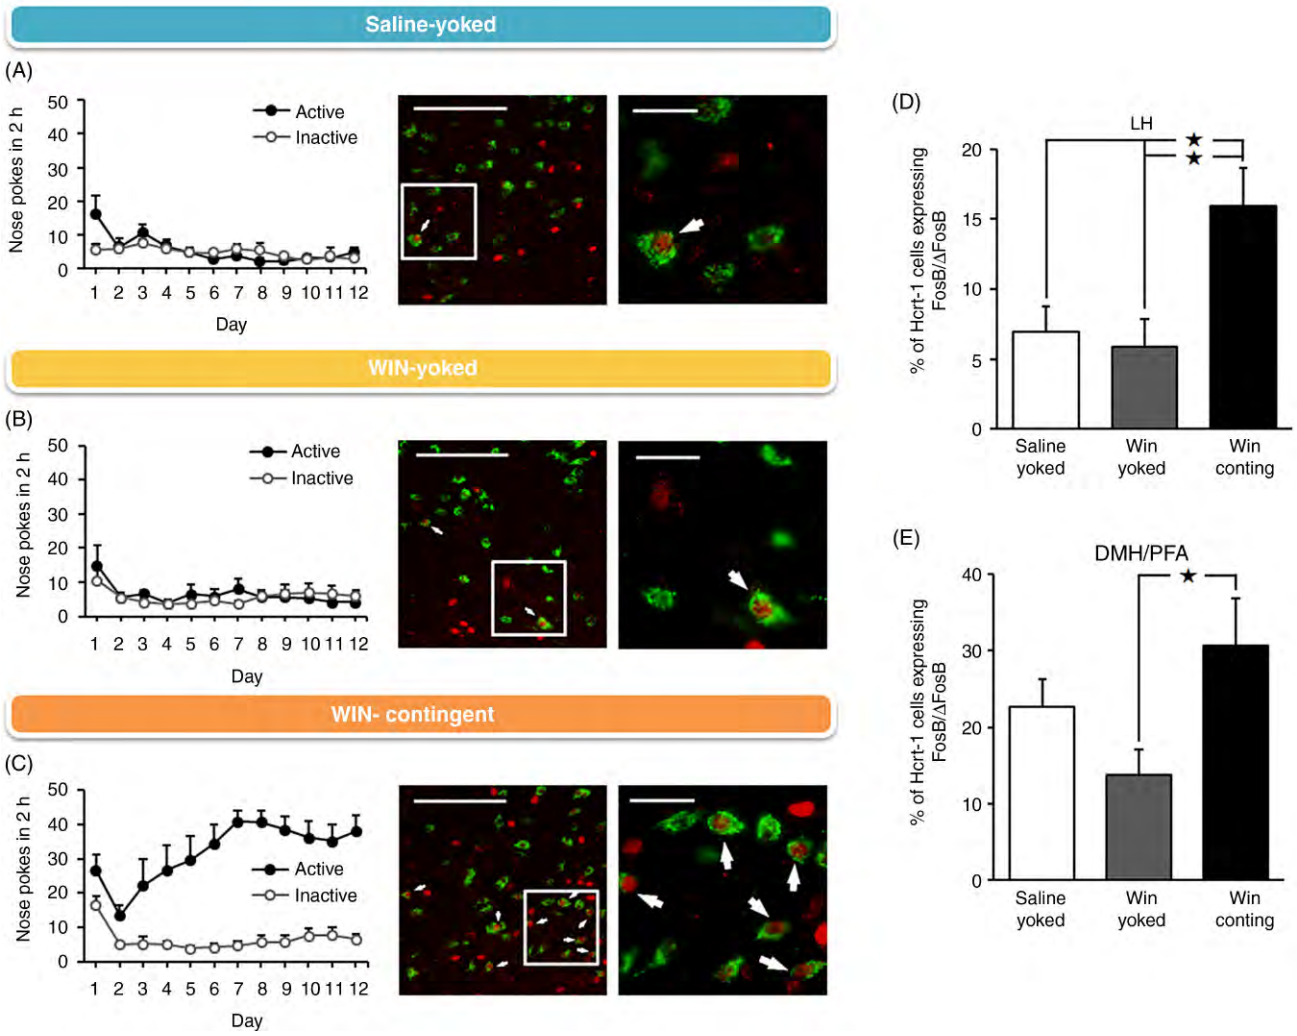

FIGURE 56.5 **Hypocretin/orexin neurons in the lateral hypothalamus are activated during contingent, but not noncontingent, WIN55,212-2 self-administration.** Double-label immunofluorescence of FosB/ΔFosB with hypocretin-1 was performed in the lateral as well as dorsomedial and perifornical hypothalamic area of mice that had underwent a contingent/noncontingent WIN55,212-2 self-administration paradigm during 12 days. (A–C) Operant responding on the active and inactive holes in mice receiving (A) passive saline infusions (saline-yoked mice), (B) passive intravenous WIN55,212-2 infusions (WIN-yoked mice), and (C) contingent intravenous WIN55,212-2 infusions (WIN-contingent). Each group is illustrated with their corresponding representative images of sections of the LH obtained via fluorescence microscopy. Arrowheads indicate FosB/ΔFosB positive hypocretin-1 expressing neurons. The scale bar represents 100 μm in left-side images and 25 μm in right-side images. (D,E) Percentage of FosB/ΔFosB positive hypocretin-1 expressing neurons after contingent/noncontingent WIN55,212-2 self-administration in the LH (D) and the DMH/PFA (E). Values are represented as mean + SEM. *LH*, lateral hypothalamus; *DMH/PFA*, dorsomedial and perifornical area; *WIN*, WIN55,212-2; *, $p < 0.05$ between groups. *Source: Adapted with permission from Flores et al. (2014).*

hypocretin neurons subpopulations, being those located in the LH mainly involved in reward processing, whereas those located in the DMH/PFA are more related with regulation of arousal and stress (Harris & Aston-Jones, 2006). However, some divergent findings suggest that further studies are required to support a differentiated role for each hypocretin cell subpopulation.

As previously mentioned, the modulation of VTA dopaminergic transmission by hypocretins seems to be especially important in the regulation of reward processing, particularly in drug seeking behavior (Mahler, Smith, Moorman, Sartor, & Aston-Jones, 2012). Accordingly, cannabinoid-induced release of dopamine in the NAc, which correlates with the rewarding effects of the drug, seems to be modulated by HcrtR1 signaling. Thus, increased extracellular dopamine levels in the NAc, induced by an acute systemic injection of THC, was observed in wild-type mice but not in HcrtR1 knockout animals, as revealed by in vivo microdialysis studies (Fig. 56.6) (Flores et al., 2014). Although the neuronal mechanism remains unclear at present, it seems that cannabinoid exposure could activate hypocretin transmission in the VTA. The subsequent activation of HcrtR1 in the VTA might be contributing to the rewarding

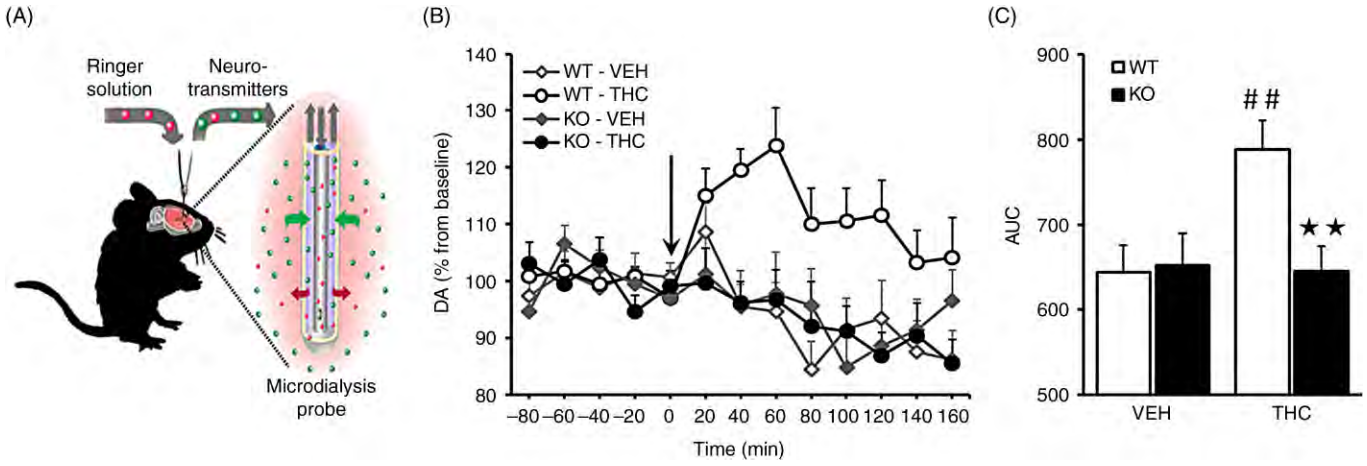

FIGURE 56.6 **THC-induced enhancement in dopamine extracellular levels in the nucleus accumbens is blocked in HcrtR1 knockout mice.** (A) Schematic diagram of in vivo microdialysis principles. (B) Time course of basal and stimulated levels of dopamine (percentage from baseline) in the nucleus accumbens. Dialysates were collected 80 min before and 160 min after a challenge injection of THC (0.3 mg/kg, intraperitoneal; arrow at time 0) or vehicle in wild-type and HcrtR1 knockout mice. (C) Area under the curve (AUC) values for levels after THC or vehicle injection (from 0 to 160 min) for the different groups of mice. Values are represented as mean+SEM. *DA*, dopamine; *WT*, wild-type; *KO*, knockout; *VEH*, vehicle; **, $p < 0.01$ between genotypes; $^{\#\#}$, $p < 0.01$ between treatments. *Source: Adapted with permission from Flores et al. (2014).*

properties of cannabinoids through the modulation of the dopamine mesolimbic pathway.

In summary, hypocretin transmission at HcrtR1 is a critical component involved in the reinforcing and motivational properties of cannabinoids. Therefore, HcrtR1 antagonists could represent an interesting pharmacologic tool for cannabis dependence in humans, as this is a major clinical need devoid of available treatment at the present moment.

MINI-DICTIONARY

Conditioned place preference Behavioral paradigm used to determine the rewarding or aversive effects of a drug, performed in a two-compartment box. Mice are administered with a drug in one of the compartments, and with vehicle in the other compartment, during several days. The time spent in each compartment during the test day gives an idea of the reward or aversion induced by the drug.

Fluorescence and bioluminescence resonance energy transfer (FRET and BRET) In vitro technique used to determine if two components are close enough to form a complex, based on the distance at which different types of energy is able to be transferred from one to another.

G-protein coupled receptor Receptor located in the cellular membrane that activates an intracellular pathway through stimulation of a G protein.

Heteromer A complex formed by different types of subunits. In this case, this complex is formed by diverse receptors, and shows features distinct from those of its components.

In vivo microdialysis Technique used to measure in vivo the amount of a determined compound (eg, a neurotransmitter) released to the extracellular space, in a small volume of tissue (eg, a defined brain structure). It requires the implantation of a probe containing a semipermeable membrane that will be crossed by small solutes by passive diffusion.

Mesocorticolimbic system Group of brain structures involved in the processing of reward and hedonic experiences, including the ventral tegmental area in the brainstem, and its target structures, such as nucleus accumbens, prefrontal cortex, amygdala, and bed nucleus of stria terminalis.

Reinforcement A term used in operant conditioning to refer to a stimulus that increases the probability that a response will occur. For instance, in an attempt to increase the likelihood of a behavior occurring in the future, an operant response is associated by the presentation of a reward.

Synaptic plasticity Group of processes that confer to a synapse the ability to strengthen or weaken its capacity of transmission.

Regulatory Role of Cannabinoids for Skin Barrier Functions and Cutaneous Inflammation

T. Tüting, E. Gaffal

Laboratory of Experimental Dermatology, Department of Dermatology and Allergy, University Hospital of the Friedrich-Wilhelm-University Bonn, Bonn, Germany

SUMMARY POINTS

- This chapter focuses on the role of endogenous and exogenous cannabinoids for the regulation of skin inflammation in allergic contact dermatitis and atopic dermatitis.
- The endogenous cannabinoid system with its receptors, lipid ligands, and enzymes for their synthesis and degradation can be found in human skin.
- Endogenous and exogenous cannabinoids have been shown to downregulate allergic inflammation in the skin. In particular, CB1 receptors on keratinocytes help limit inflammation, and promote the homeostatic regeneration of epidermal integrity.
- These insights have important implications for the future development of strategies to harness cannabinoids for the treatment of inflammatory skin diseases.

KEY FACTS OF ALLERGIC CONTACT DERMATITIS AND ATOPIC DERMATITIS

- Allergic contact dermatitis occurs in about 11% of women and 5% of men in industrialized countries, and is one of the most common occupational diseases.
- Contact allergy remains for a lifetime. Treatment includes the local application of steroids. Furthermore, contact to known allergens should be avoided.
- Up to 10% of children and 1–3% of adults in industrialized countries are affected by atopic dermatitis. Genetic factors play an important role in the pathogenesis of this inflammatory skin disease.
- Patients with atopic dermatitis often also suffer from allergic asthma, and they tend to develop food allergies.
- Common treatments of atopic eczema include skin moisturizers, topical and systemically application of steroids, topical immunomodulators (eg, Tacrolimus, Pimecrolimus), and UV-light therapy.

LIST OF ABBREVIATIONS

ACD	Allergic contact dermatitis
CB	Cannabinoid
CCL, CXCL	Chemokine subfamilies
CHS	Contact hypersensitivity
Cnr	Gene ID for cannabinoid receptor
DNFB	2,4-Dinitro-1-fluorobenzene
ECS	Endogenous cannabinoid system
FITC	Fluorescein isothiocyanate
IFN	Interferon
IgE	Immunoglobulin E
IL	Interleukin
KC	Keratinocyte

NOD	Nucleotide-binding oligomerization domain
PEA	Palmitoylethanolamide
TGF	Transforming growth factor
TLR	Toll-like receptor
TNF	Tumor necrosis factor
TSLP	Thymic stromal lymphopoietin

THE SKIN AS A BARRIER ORGAN

With a size of approximately 1.5–2.0 m^2, the skin is the largest organ of the human body. Similar to lung and intestinal mucosal tissue, it forms a barrier between the organism and its surrounding environment that protects from harmful physical, chemical, or biological influences such as UV radiation, toxic substances, or pathogenic microorganisms (outside-in barrier). In addition, our skin regulates body temperature and prevents excessive loss of water and electrolytes (inside-out barrier). The skin can be divided into three layers: the epidermis (outer layer), the dermis, and the subcutaneous tissue (hypodermis). The epidermis is a stratified squamous epithelium which constantly renews itself under physiological and pathophysiological conditions, and forms the first physical and immunological barrier. It mostly consists of keratinocytes which are arranged in four layers: the stratum basale (basal cell layer), spinosum, granulosum, and corneum. The basal cell layer contains undifferentiated keratinocytes attached to the basal membrane by keratin filaments (keratin 5, keratin 14). The stratum spinosum is named after the spine-like shape of keratinocytes in this part of the epidermis. Here, keratinocytes slowly begin to differentiate, keratin 5 and 14 are replaced by the differentiation-specific keratins 1 and 10 (Fuchs & Green, 1980; Waseem et al., 1999). Lamellar bodies, which contain lipids and hydrolytic enzymes, can now be detected. The stratum granulosum is characterized by basophilic keratohyalin granules found in further differentiating keratinocytes. They contain profilaggrin, loricrin, and keratin filaments which are important components for the formation of the cornified cell envelope, and are crucial for cell stability. Finally, keratinocytes undergo a specialized form of programmed cell death to form the stratum corneum. This outermost layer consists of dead lipid-depleted keratinocytes (corneocytes) surrounded by a lipid matrix predominantly made of ceramides and cholesterol (Houben, De Paepe, & Rogiers, 2007; Kalinin, Kajava, & Steinert, 2002). This structure is also known as "bricks" and "mortar." It helps to protect the skin from water loss, and prevents the penetration of environmental toxins, allergens, and pathogens.

Keratinocytes not only maintain a physical barrier, but also play a central role in the regulation of immunological barrier functions in the epidermis. Damage to the skin leads to the secretion of numerous cytokines and chemokines such as TNF, IL1, IL8, IL18, CXCL2, CXCL10, and CCL2. These mediators activate local immune cells and endothelial cells, initiate antigen-specific immune responses, and recruit various immune cells into the skin (Albanesi, 2010; Cataisson et al., 2006; Ryckman, Vandal, Rouleau, Talbot, & Tessier, 2003; Wetzler, Kampfer, Pfeilschifter, & Frank, 2000). On the surface of keratinocytes, there are numerous cytokine and chemokine receptors which modulate inflammatory immune responses. Their activation also regulates the proliferation and differentiation of keratinocytes. In addition, keratinocytes secrete antimicrobial peptides (AMPs), such as beta-defensins and cathelicidin, which prevent the invasion of microbes by direct killing of pathogens, and activation of the innate immune system. Furthermore, they are able to recognize invading viruses, parasites, bacteria, and fungi in the skin through Toll-like (TLR) and NOD-like receptors. Perturbations in the physical and immunological functions of keratinocytes are of major importance for the development of allergic inflammatory responses in the skin (Fig. 57.1).

THE ENDOGENOUS CANNABINOID SYSTEM IN KERATINOCYTES

The endogenous cannabinoid system (ECS) with its specific receptors, endogenous ligands, and enzymes for their synthesis and degradation can be found in human and murine skin (Maccarrone et al., 2003; Stander, Reinhardt, & Luger, 2006). The CB1 receptor is expressed on keratinocytes in the stratum spinosum and stratum granulosum of the epidermis, and can be found in differentiated cells of the hair follicle. CB2 receptors were detected in undifferentiated cells of the stratum basale, and in hair follicles (Stander, Schmelz, Metze, Luger, & Rukwied, 2005). Cultured immortalized and normal human keratinocytes (HaCaT, NHEK) also express cannabinoid receptors, and possess a fully active biochemical machinery to metabolize endogenous cannabinoids. The ECS of the skin plays an important role for the growth and differentiation of keratinocytes. The endogenous cannabinoid anandamide inhibits the differentiation of keratinocytes in vitro by downregulating the expression of epidermal structure proteins like keratin 1, keratin 10, and transglutaminase 5 in a CB1-dependent way (Paradisi, Pasquariello, Barcaroli, & Maccarrone, 2008). Plant-derived cannabinoids like Δ^9-tetrahydrocannabinol (THC) exert an antiproliferative effect on human keratinocytes and NHEKs in vitro (Wilkinson & Williamson, 2007). The pharmacological blockade of CB1 receptors on human keratinocytes induces an increased production of inflammatory mediators like IL8 and CCL2/MCP1.

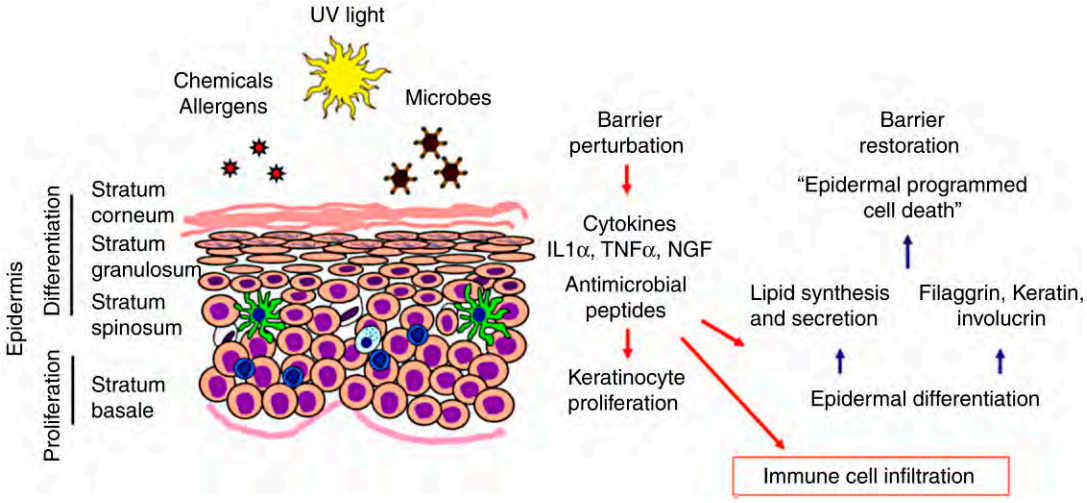

FIGURE 57.1 **Regulation of epidermal barrier functions.** Schematic diagram of the epidermis. It mostly consists of keratinocytes, organized in four layers: the stratum basale, spinosum, granulosum, and corneum. Basal keratinocytes proliferate, and slowly move to the upper layers of the skin. During this time, they differentiate and undergo a defined "epidermal" programmed cell death to form the outermost lipid-rich corneal layer that protects the body from chemicals, and prevents excessive water loss. Through the secretion of various cytokines, chemokines, and antimicrobial peptides, keratinocytes also actively participate in the regulation of immune responses in the skin.

ALLERGIC CONTACT DERMATITIS

The clinical term "allergic contact dermatitis" describes an inflammatory response of the skin after contact to certain highly reactive chemicals with a low molecular weight, which can penetrate the skin barrier. Key findings about the underlying pathophysiology were obtained with the help of experimental mouse models for contact sensitization ("contact hypersensitivity" or CHS). Here, obligate contact sensitizers like 2,4-dinitro-1-fluorobenzene (DNFB) are commonly used to induce contact hypersensitivity. Allergic contact dermatitis develops in three phases. In the sensitization phase, chemicals react with epidermal proteins to form so-called haptens, and stimulate the innate immune system via TLRs (Kaplan, Igyarto, & Gaspari, 2012; Schmidt et al., 2010), as well as the inflammasome (Watanabe et al., 2007) on resident skin cells. The production of proinflammatory mediators (TNF, IL1, IL18) leads to the activation of cutaneous dendritic cells (DC) and Langerhans cells. They take up the haptenized proteins and migrate to the draining lymph nodes. Here, they present the allergen to antigen-specific naive CD8+ and CD4+ T-lymphocytes which get activated, and differentiate toward Th1/Th17 phenotypes. In the effector phase, repeated exposure to the hapten leads to the recruitment of allergen-specific T lymphocytes in the skin. They secrete IL17 and IFNg which induce the production of proinflammatory mediators including CXCL1, CXCL2, CXCL10, and CCL2 by keratinocytes and endothelial cells. These inflammatory mediators support the cutaneous infiltration of neutrophil granulocytes and macrophages. Together with keratinocytes, they initially amplify the infiltration with effector cells (Engeman, Gorbachev, Kish, & Fairchild, 2004; Kish, Li, & Fairchild, 2009; Kish, Gorbachev, Parameswaran, Gupta, & Fairchild, 2012). In this inflammatory environment, keratinocytes initiate a regenerative proliferative response which contributes to the restoration of epidermal barrier functions. When the individual is no longer exposed to the allergen, inflammation gradually decreases in the resolution phase. Now, regulatory CD4 + T cells secrete cytokines such as IL-10 and TGF which downregulate proinflammatory mediators, and inhibit further activation of dendritic cells, neutrophils, and macrophages (Cavani et al., 2000; Cavani, De Pità, & Girolomoni, 2007; Grimbaldeston, Nakae, Kalesnikoff, Tsai, & Galli, 2007).

THE ENDOGENOUS CANNABINOID SYSTEM ATTENUATES CONTACT ALLERGIC INFLAMMATION

Using the model of experimental contact allergy, we were able to show for the first time that the endogenous cannabinoid system participates in the regulation of allergic skin inflammation. Mice with a genetic deletion of CB1 and CB2 receptors ($Cnr1/2^{-/-}$ mice) display stronger signs of inflammation, including increased allergic ear swelling and elevated infiltration of inflammatory immune cells, when compared with wild-type animals. The pharmacological blockade of CB receptors using specific antagonists (SR141716 and SR144528) also resulted in a gain of allergic ear swelling in wild-type mice. In contrast, mice genetically lacking enzymes that degrade endocannabinoids ($FAAH^{-/-}$ mice) displayed

reduced signs of allergic ear swelling. A whole-genome mRNA expression analysis of contact allergic inflamed ear tissue revealed a significantly increased expression of the proinflammatory chemokine CCL8/MCP2 in Cnr1/2$^{-/-}$ mice, when compared to wild-type animals. Interestingly, especially CB1 receptors seemed to play a central role in modulating cutaneous inflammation since Cnr1$^{-/-}$ animals developed an allergic reaction that was nearly as strong as that observed in Cnr1/2$^{-/-}$ mice (Karsak et al., 2007).

CB1 RECEPTORS ON KERATINOCYTES DOWNREGULATE THE SECRETION OF PROINFLAMMATORY CHEMOKINES IN CONTACT ALLERGIC INFLAMMATION

CB1 receptors are primarily expressed in the central nervous system (Matsuda, Lolait, Brownstein, Young, & Bonner, 1990). Here, they are important for the sensation of pain (Zimmer, Zimmer, Hohmann, Herkenham, & Bonner, 1999), the extinction of aversive memories (Marsicano et al., 2002), and for protection against excessive neuronal activity (Marsicano et al., 2003). However, in the last years, evidence has accumulated that CB1 receptors also modulate protective and inflammatory processes in peripheral organs. In an experimental model of inflammatory bowel disease, the activation of CB1 receptors on peripheral nerve fibers resulted in a reduction of gastrointestinal inflammation, and inflammation-induced hypermotility (Massa et al., 2004). In addition to their functions in the central and peripheral nervous system, CB1 receptors are also involved in the regulation of T-cell-specific immune responses. In a murine model for multiple sclerosis (experimental autoimmune encephalitis, EAE), it could be shown that the activation of neuronal CB1 receptors attenuated T-cell-mediated inflammation in the brain (Maresz et al., 2007). These observations suggest that CB1 receptors are expressed in peripheral tissues, and their activation protects against excessive T-cell-dependent inflammatory responses.

To further evaluate the role of CB1 receptors for the regulation of contact allergic inflammation, we generated mice with a tissue-specific knockout of CB1 receptors on peripheral sensory neurons (SNS-CB1$^{-/-}$), on immune cells (LysM-CB1$^{-/-}$), and on keratinocytes (KC-CB1$^{-/-}$). In the model of experimental contact allergy, only KC-Cnr1$^{-/-}$ animals developed an allergic inflammation almost as strong as observed in Cnr1$^{-/-}$ and Cnr1/2$^{-/-}$ animals. Keratinocytes play a central role in the regulation of T-cell-dependent immune responses in the skin. They are attacked by infiltrating T-lymphocytes, which leads to an increased production of proinflammatory cytokines and chemokines, and initiates the recruitment of myeloid immune cells, especially of neutrophils. This initially amplifies the inflammatory response, but also contributes to the repair and regeneration of epidermal barrier functions (Albanesi, 2010; Gaffal et al., 2013a; Wittmann & Werfel, 2006). In our model, the infiltration of myeloid immune cells into inflamed ear tissue and the proinflammatory chemokine CCL8/MCP2 were also significantly increased in KC-Cnr1$^{-/-}$ mice, in comparison to wild-type animals. In the skin, CCL8 is secreted by epidermal keratinocytes and fibroblasts in an IFNγ-dependent manner, in the context of a Th1-driven inflammatory response (Struyf et al., 1998). CCL8 increases the recruitment of myeloid immune cells (Zaidi et al., 2011) and Th2 type lymphocytes into the skin (Islam et al., 2011). In vitro studies on primary keratinocyte cultures confirmed that CB1 receptor-deficient cells produce higher levels of CCL8 after stimulation with IFNγ. Additionally, CCL8 was chemotactic for bone marrow-derived macrophages (Gaffal et al., 2013a). Taken together, these results provide the first in vivo evidence for the importance of CB1 receptors on epidermal keratinocytes for the regulation of T-cell-dependent immune responses in the skin.

ATOPIC DERMATITIS ASSOCIATED WITH IMPAIRED BARRIER FUNCTIONS

Atopic dermatitis (atopic eczema) is a chronic inflammatory skin disease. Early genetic linkage studies found an association of atopic eczema with polymorphisms in genes for immunoregulatory proteins which control IgE receptor synthesis, IL-4 production, and IL-4 receptor synthesis. These findings support the so-called "inside-out" hypothesis, where the genetic predisposition to an enhanced Th2-dependent inflammatory response leads to impaired epidermal barrier functions. But geneticists also discovered an association with polymorphisms in genes for epithelial structural proteins, such as filaggrin or claudin, which are important for composing and maintaining the epidermal barrier. Thus, a genetically induced barrier defect in the epidermis also promotes the development of atopic inflammation ("outside-in" hypothesis) (Barnes, 2010; Eyerich & Novak, 2013).

The unaffected skin of patients with atopic dermatitis can already show differences to healthy skin, and contains increased numbers of mast cells, and discrete perivascular T-cell infiltrates secreting Th2 cytokines, such as IL4 and IL13. Disruption of the epidermal barrier caused by allergens, scratching, or microbial toxins in the acute phase of atopic eczema initiates the secretion of inflammatory mediators like IL1, TNF, and GM-CSF through dendritic cells, mast cells, and epidermal keratinocytes. These mediators upregulate adhesion molecules on endothelial cells, which in turn, support the infiltration of immune cells. Skin lesions in the early

phase of atopic inflammation are mainly characterized by the presence of CD4+ Th2 cells, as well as increased IL4, IL5, and IL13 levels. The cytokine "thymic stromal lymphopoietin" (TSLP) produced by keratinocytes additionally supports the development of a Th2-mediated inflammation through its effect on dendritic cells and mast cells in the skin. Chemokines like CCL5/RANTES, CCL13/MCP4, and CCL11/eotaxin also induce the recruitment of eosinophils and macrophages into the skin. In the chronic phase of atopic eczema, the initially Th2-dominated inflammation is replaced by a Th1-, Th17-, and Th22-dominated immune cell infiltrate. The exact molecular mechanisms which control this conversion are not fully understood. Centrally important cytokines are IL12 and IL18, secreted by activated epidermal dendritic cells and macrophages. The germ colonization of the skin also plays an important role. In chronic skin lesions, the number of dermal macrophages is significantly increased, and IgE-bearing Langerhans cells and activated dendritic cells can be found in the epidermis. Compared to acute eczema, IL5, IL12, and IFNγ levels in the skin are elevated (Boguniewicz & Leung, 2011; Homey, Steinhoff, Ruzicka, & Leung, 2006). Different experimental mouse models helped to elucidate the pathophysiology of atopic dermatitis. One possibility to induce atopic-like inflammation in mice is the repetitive epicutaneous application of the contact sensitizer fluorescein isothiocyanate (FITC), which induces a Th2-dependent immune response in the skin, and increases serum IgE levels. In transgenic mouse models, proinflammatory mediators like TSLP or IL-4 are overexpressed in the skin to investigate their importance for the development of atopic eczema. Furthermore, there are models in which mice spontaneously develop the symptoms of atopic eczema. These include the so-called "flaky-tail" mice with a spontaneous null mutation in the filaggrin gene, resulting in impaired epidermal barrier functions (Dearman & Kimber, 2000; Fallon et al., 2009; Jin, He, Oyoshi, & Geha, 2009; Oyoshi, Murphy, & Geha, 2009; Spergel, Mizoguchi, Oettgen, Bhan, & Geha, 1999; Takeshita, Yamasaki, Akira, Gantner, & Bacon, 2004).

CB1 RECEPTORS ON KERATINOCYTES PARTICIPATE IN THE REGULATION OF ATOPIC-LIKE INFLAMMATION

Using the experimental model for Th2-driven, atopic-like contact allergic inflammation against FITC, we discovered that CB1 receptors in keratinocytes are also important for the preservation of physical barrier functions. We found that $Cnr1^{-/-}$ and KC-$Cnr1^{-/-}$ mice show increased transepidermal water loss and delayed repair responses, following epidermal barrier disruption, when compared to wild-type animals. These findings were associated with an elevated epidermal penetration of FITC, and reduced expression of epidermal structural proteins such as filaggrin and involucrin in the inflamed skin. Furthermore, $Cnr1^{-/-}$ and KC-$Cnr1^{-/-}$ mice showed increased allergic skin inflammation, and significantly higher mRNA levels for IL4, TSLP, and CCL8, when compared to wild-type controls. $Cnr1^{-/-}$ and KC-$Cnr1^{-/-}$ mice also displayed enhanced infiltration with eosinophils into FITC-challenged ear skin. In vitro studies with cultured primary keratinocytes revealed that CB1 receptor deficient cells produced higher levels of TSLP under basal and inflammatory conditions (Gaffal, Glodde, Jakobs, Bald, & Tüting, 2014). Similar results have independently been observed by another group studying skin barrier repair responses in CB1 receptor-deficient mice (Roelandt et al., 2012). Using electron microscopy, these investigators found that the naïve skin of $Cnr1^{-/-}$ mice already shows alterations in the composition of the stratum corneum lipid bilayer. The fact that endogenous cannabinoids also regulate the expression of genes for epidermal differentiation in human keratinocytes in a CB1-dependent manner further supports the important role of the endogenous cannabinoid system in the regulation of epidermal barrier functions (Pasquariello, Oddi, Malaponti, & Maccarrone, 2009) (Fig. 57.2).

THERAPEUTIC POTENTIAL OF CANNABINOIDS FOR THE TREATMENT OF ALLERGIC SKIN DISEASES

Due to their antiinflammatory potential, cannabinoids have been considered for the treatment of inflammatory skin diseases (Klein, 2005; Kupczyk, Reich, & Szepietowski, 2009; Nagarkatti, Pandey, Rieder, Hegde, & Nagarkatti, 2009). We found that the systemic and local administration of the CB receptor agonist Δ^9-tetrahydrocannabinol (THC) can significantly reduce inflammatory responses in the model of DNFB-induced contact hypersensitivity. THC not only decreased allergic ear swelling and the number of infiltrating immune cells in inflamed ear tissue in vivo, but also the secretion of IFNγ-induced proinflammatory chemokines CXCL10 and CCL8 by keratinocytes, in vitro. Migration experiments with macrophages using supernatants from IFNγ-activated keratinocyte cultures supported our hypothesis that the THC-mediated inhibition of chemokine production decreases the recruitment of myeloid immune cells (Gaffal, Cron, Glodde, & Tuting, 2013b; Karsak et al., 2007). Similar observations were reported using the endogenous cannabinoid-like lipid palmitoylethanolamide. Palmitoylethanolamide was shown to reduce the secretion of proinflammatory chemokines in human keratinocytes in vitro, and diminish the signs of acute dermatitis in vivo (Petrosino et al., 2010). In a clinical study in

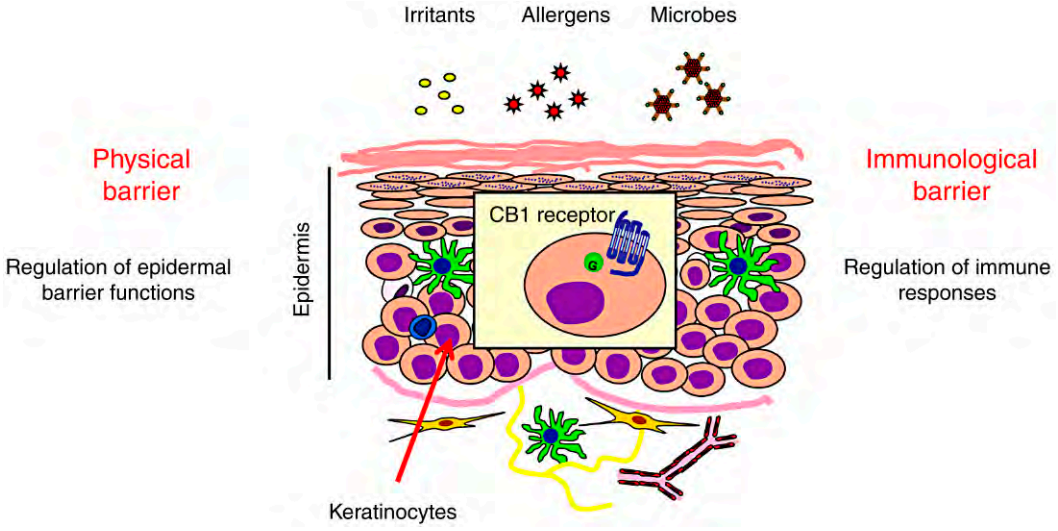

FIGURE 57.2 **Role of the endocannabinoid system in epidermal barrier functions.** Cannabinoid-1 receptors in keratinocytes help to maintain physical and immunological barrier functions of the skin.

patients with chronic pruritus, a strong itch-relieving effect was described after local application of palmitoylethanolamide (Stander et al., 2006). Taken together, these findings open up new possibilities for the topical treatment of inflammatory skin diseases with cannabinoids and other antiinflammatory lipids.

MINI-DICTIONARY

Allergic contact dermatitis Clinical term for the inflammatory response of the skin after repeated contact to sensitizing chemicals which can be found in cosmetics, jewelry, or clothes. Affected patients develop local redness, itching, edema, and blisters. Typical locations are hands, feet, eyelids, and lips.

Atopic dermatitis Chronic inflammatory skin disease characterized by the occurrence of relapsing eczema, chronic dry skin, severe itching, and an increased tendency to develop cutaneous infections.

Chemokines Chemical messengers attracting immune cells to areas of inflammation (chemotaxis).

Contact hypersensitivity Experimental model for allergic contact dermatitis.

Keratinocytes Predominant cell type of the epidermis with important immunological and physical barrier functions.

Cannabis and Oral Health: Deleterious Effects on Periodontitis and Dental Implants

G. Nogueira-Filho

School of Health Sciences, University Salvador, Laureate International Universities, Salvador, Bahia, Brazil

SUMMARY POINTS

- *Cannabis* smoke decreases bone filling around titanium implants.
- *Cannabis* smoke impairs cancellous bone formation.
- *Cannabis* does not affect the cortical bone around the implants.
- *Cannabis* smoke increases bone loss in teeth with induced periodontitis.
- *Cannabis* smoke had no effect on bone physiology in periodontally healthy teeth.
- The deleterious impact of *Cannabis* on bone healing represents a new concern for dental implants success/failure.
- There is a lack of evidence to prove the role of *Cannabis* as an etiologic risk factor for periodontitis.
- Further investigations are necessary to determine whether smoking *Cannabis* can be considered a real threat to oral health.

KEY FACTS

- Cannabis sativa can enhance an established inflammatory response in periodontitis sites
- Cannabis sativa can enhance bone loss around dental implants
- Cannabis sativa is not able to initiate disease at the gingival and bone levels

LIST OF ABBREVIATIONS

CB1	Cannabinoid receptor-1
CB2	Cannabinoid receptors-2
CBD	Cannabidiol
D9-THC	D9-tetrahydrocannabinol
IFNg	Interferon gamma
IL-1	Interleukin 1
IL-6	Interleukin 6
IL-10	Interleukin 10
NK cells	Natural killer cells
Th1	T helper 1 lymphocyte
Th2	T helper 2 lymphocyte
THC	Tetrahydrocannabinol
TNFa	Tumor necrosis factor alpha

INTRODUCTION

Cannabis sativa (marijuana) is a plant that contains more than 60 types of cannabinoids produced by small glands on its leaf surface (Grotenhermen, 2004). *Cannabis* and its cannabinoids can affect the immunological human functions (Peeke, Jones, & Stone, 1976). Cannabinoids seem to attenuate the production of some inflammatory mediators such as interferon-g (IFNg), tumor necrosis factor-a (TNFa), interleukin (IL)-1, IL-6, and IL-10 (Klein, 2005; Massi, Vaccani, & Parolaro, 2006). Cannabinoids activate specific cell-surface cannabinoid receptors-1 and -2 (CB1 and CB2, respectively), which are normally engaged by a family of endogenous ligands so-called

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00057-0

the endocannabinoids (Do, McKallip, Nagarkatti, & Nagarkatti, 2004). Compounds that bind these receptors induce cannabimimetic responses in vivo and in vitro. Indeed, recent evidence indicates that cannabinoids might influence vascular inflammatory diseases in several ways such mediating vasodilatation particularly in lipopolysaccharide (LPS) induced infectious diseases (Grotenhermen, 2004). The cannabinoids can also reduce the immune response, and impair the body defense against viral, bacterial, and protozoa's infections (Do et al., 2004).

Experimental models have been used for host response evaluation in cultures of cells exposed to tetrahydrocannabinol (THC), and in human populations of declared consumers of cannabis. These studies suggest that the cannabinoids can affect the resistance of the host by modifying the primary and secondary immune system, especially the function of lymphocyte T and B, as well as the NK cells and macrophages (Klein, 2005). Moreover, cannabinoids can act as immunomodulators by modifying the production and function of cytokines in the acute phase of the inflammatory process in the phases T helper 1 (Th1) and T helper 2 (Th2). Animal and cell experiments have demonstrated that THC exerts complex effects on cellular and humoral immunity. THC was shown to modulate the immune response of T lymphocytes. It suppressed the proliferation of and Th2 cytokines (Grotenhermen, 2004).

Cannabinoids can influence vascular inflammatory diseases (Powles, te Poele, & Shamash, 2005) in several ways, such as mediating vasodilatation, particularly in LPS-induced diseases. Studies (Davies, Sornberger, & Huber, 1979; Idris, van't Hof, & Greig, 2005; Ofek et al., 2006) have also indicated the association between bone loss and the use of cannabis. Considering bone metabolism, the suspect of cannabis effect was confirmed by molecular studies that demonstrated a negative impact on bone physiology by cannabinoids (Grotenhermen, 2004; Klein, 2005; Tam, Ofek, & Fride, 2006).

Nakajima, Furuichi, and Biswas (2006) suggested a possible role of cannabinoids in periodontitis by reporting expression of cannabinoid receptors (CB1 and CB2) in periodontal tissues, followed by an increase in anandamide, an agonist of the cannabinoid receptor derived from arachidonic acid. Many oral problems have been associated with the use of cannabis, including xerostomia, with predisposition to dental caries and periodontitis, severe gingivitis, oral mucosal disease, abnormal stress response on administration of adrenalin-containing local anesthetics, leukoedema, and increased prevalence of opportunistic microorganisms such as *Candida albicans* (Darling, Arendorf, & Coldrey, 1990; Versteeg, Slot, van der Velden, & van der Weijden, 2008; Veitz-Keenan & Spivakovsky, 2011; Nogueira-Filho et al., 2011; Kayal, Elias, Alharthi, Demyati, & Mandurah, 2014).

Considering the apparent lack of scientific information regarding the effects of cannabis on oral bones, and its impact in oral inflammation, our research group has developed an animal model to study second hand cannabis smoke in rats (Fig. e8.1). So far, we have summarized the main findings of two studies published recently in dental journals (Nogueira-Filho, Cadide, & Rosa, 2008; Nogueira-Filho et al., 2011) that reflect our impressions about the possible relationship between cannabis and the health of oral bones around teeth, and also on the bones around endosseous titanium implants.

STUDIES

STUDY 1. Cannabis sativa smoke inhalation decreases bone filling around titanium implants: a histomorphometric study in rats (Nogueira-Filho et al., 2008)

In this first study, we aimed to investigate if second hand cannabis smoke could impair bone formation and repair around prototypes of dental implants to be inserted in rat tibia (Figs. e8.2 and e8.3).

Thirty Wistar rats were used in this study. After anesthesia, the tibiae surface was exposed, and one screw-shaped titanium implant was placed bilaterally. The animals were randomly assigned to one of the following groups: CTRL (control; $n = 15$), and MSI (cannabis smoke inhalation 8 min/day; $n = 15$), as illustrated in Fig. e8.1. Urine samples were obtained to detect the presence of THC for both groups. After 60 days, the animals were killed. The degree of bone-to-implant contact and the bone area within the limits of the threads of the implant were measured in the cortical (zone A) and cancellous bone (zone B). The experiment finished with 23 animals, instead of 30 (CTRL/$n = 15$, and MSI/$n = 8$), as seven rats died during the experiment because of respiratory failure provoked by intermittent cannabis smoke inhalation. THC was detected in urine samples from all animals from MSI group ($n = 8$). Negative THC detection was found in all samples from control animals. Also, according to the Brazilian Research Protocol for Illegal Drugs, all human researchers that worked directly with the cannabis smoke experiments had also their urine checked. All their samples were negative to THC (Table e8.1), confirming the effectiveness of their personal protective equipment used during cannabis handling and smoke exposure.

This study demonstrated that cannabis smoke inhalation had a deleterious impact on cancellous bone healing around titanium implants by reducing bone filling and bone-to-implant contact inside the implant threads, while no effect was observed in the cortical bone (Figs. e8.2 and e8.3). The negative effects of cigarette smoking on periodontitis and around titanium implants have been demonstrated by the authors (Nogueira-Filho, Froes Neto, & Casati, 2004; Nogueira-Filho, Rosa, Cesar-Neto, Tunes, & Tunes, 2007), where cigarette smoking seems to reduce bone capacity to formation and/or increasing

resorption. Despite the limitations of the present study, it is the first one, to our knowledge, that demonstrates the negative impact of *Cannabis sativa* smoke on bone healing around titanium implants.

According to Tam et al. (2006), bone mass and shape are determined by continuous remodeling consisting of the concerted and balanced action of osteoclasts (the bone resorbing cells), and osteoblasts (the bone forming cells). Firstly, immune cells express endocannabinoids, and cannabinoid receptors (CB1 and CB2) at the surface of immune cells are activated after infection or immune stimulation. The second general principle is that the main immune targets of cannabinoid-based drugs involve the suppression of cytokines and cell-mediated immunity, through cannabinoid receptor-dependent and -independent mechanisms. The results of the present study clearly demonstrated that cannabis smoke could decrease bone mass around titanium implants in the cancellous zone. As a matter of fact, to explain such phenomenon, some observations might be further addressed considering the CB1/CB2 receptor system of the cannabinoids.

Bone is densely innervated by sympathetic fibers (Mach, Rogers, & Sabino, 2002). These fibers release norepinephrine, thus potently mediating central signals that restrain bone formation, and stimulate bone resorption (Schlicker & Kathmann, 2001). Because CB1 is expressed in such nerve fibers elsewhere, its presence in bone sympathetic nerve fibers was further explored, indicating also the presence of CB1 receptors in sympathetic fibers that innervate the cancellous bone (Elefteriou, Ahn, & Takeda, 2005).

On the other hand, CB2 receptors are located principally in immune cells, among them leukocytes, in the spleen, and tonsils. Immune cells also express CB1

receptors, but there is markedly more mRNA for CB2 than CB1 receptors in the immune system. One of the functions of CB receptors in the immune system is modulation of cytokine release. Activation of the CB1 receptor produces cannabis-like effects on psyche and circulation, while activation of the CB2 receptor does not. CB2 is expressed in the vast majority of hematopoietic cells, including macrophages, and attenuates immune responses. CB2 is expressed in osteoblasts, osteocytes, and osteoclasts. It was found that osteoclasts, cells derived from the monocyte-macrophage lineage, have high levels of CB2 mRNA (Ofek et al., 2006). Specific cannabinoids as the CB2 are also characterized by increased activity of osteoblasts (bone-forming cells), increased osteoclast (bone-resorbing cell) numbers, and a markedly decreased number of osteoblast precursors.

Our results were not able to present any disturbance in the cortical bone around the implants placed in the rats that inhaled the cannabis smoke. Interestingly, this phenomenon could be explained by the presence of a CB2-specific agonist that does not have any psychotropic effects enhancing endocortical osteoblast number and activity. Cannabis smoke inhalation somehow seems to impair the healing of the cancellous bone, probably because of a THC effect in inhibiting CB2 expression on osteoblasts and, consequently, reducing bone formation.

In the same way, the reduced bone-to-implant contact values in the cannabis group may also suggest the occurrence of a restraining in the osteoclastogenesis, apparently because of the inhibition of the proliferation of osteoclast precursors, and receptor activator of NF-κB ligand expression in bone marrow-derived osteoblasts/stromal cells (Nakajima et al., 2006). Endocannabinoids could regulate the periodontal inflammation through NF-κB pathway inhibition. The endocannabinoid system seems to participate in bone physiology by regulating bone mass, bone loss, and osteoclast activity by signaling via the peripheral CB2 expressed in bone, and its effect decreased the bone healing around the implants in the experimental rats from cannabis group (Idris et al., 2005).

As long as it is well established that titanium implant success is a reality, and only a few situations, such as cigarette smoking, may cause implant failure, this study was a hallmark as the first in the literature to raise the concern about the consumption of cannabis as a possible risk factor in order to explain some of dental implant failures in patients that not always inform, during anamnesis, that they are marijuana consumers. Nevertheless, further epidemiological and molecular studies are mandatory to confirm such suspect.

STUDY 2. Marijuana smoke inhalation increases bone loss during ligature-induced periodontitis (Nogueira-Filho et al., 2011)

In this second study, we aimed to investigate if second hand cannabis smoke could increase bone inflammation around teeth with induced periodontal inflammation, in a rat model.

30 male Wistar rats were used in the study. A ligature was placed around one of the mandible first molars (ligated teeth) of each animal, and they were then randomly assigned to one of two groups: CTRL (control; $n = 15$), or MSI (marijuana smoke inhalation for 8 min/day; $n = 15$), as illustrated in Fig. e8.1. Urine samples were obtained to detect the presence of THC. After 30 days, the animals were killed, and decalcified sections of the tooth furcation area were obtained and evaluated according to the following histometric parameters: bone area, bone density, and bone loss.

Seven rats in the MSI group died during the experimental period, probably because of respiratory failure provoked by intermittent cannabis smoke inhalation; however, no further investigations were performed to confirm the cause of death. At the end of the 30 days of cannabis inhalation, the remaining animals from the MSI group presented abnormal behavior, as noted by erratic movements in the cage, and excessive food ingestion. The teeth ligatures that promoted periodontitis were kept in place in all 23 animals that completed the experimental period, and served as a retention device for oral microorganisms.

This study demonstrated that cannabis smoke inhalation increased bone loss in the furcation area of teeth with induced periodontitis in rats, whereas no effect was observed in periodontally healthy sites, confirmed by the histomorphometric analysis that showed the highest values of bone loss into the furcation area from cannabis-exposed teeth (Fig. e8.4). Despite the studies by Davies et al. (1979) on the effect of marijuana inhalation on alveolar macrophages, by the use of a smoke exposure chamber, to the best of our knowledge, this is the first study evaluating the influence of cannabis smoke on healthy periodontal tissues, and during experimental periodontitis.

Though our results and the biologic plausibility that cannabis use could be considered a possible risk factor for periodontitis, some limitations of the present study have to be emphasized. Some animals from the cannabis group probably died because of respiratory difficulties because the smoke that was produced looked very dense and dusty, and may not be comparable to the doses inhaled by human cannabis consumers. Also, regardless of our interesting results, contradictory findings may be observed in other studies. Conversely, Napimoga, Benatti, and Lima (2009) demonstrated experimentally that the administration of cannabidiol (CBD), a cannabinoid component from *Cannabis* that does not induce psychotomimetic effects, and possess antiinflammatory properties, significantly inhibited bone loss in experimental periodontitis in rats. The study by Napimoga et al. (2009) suggests that such

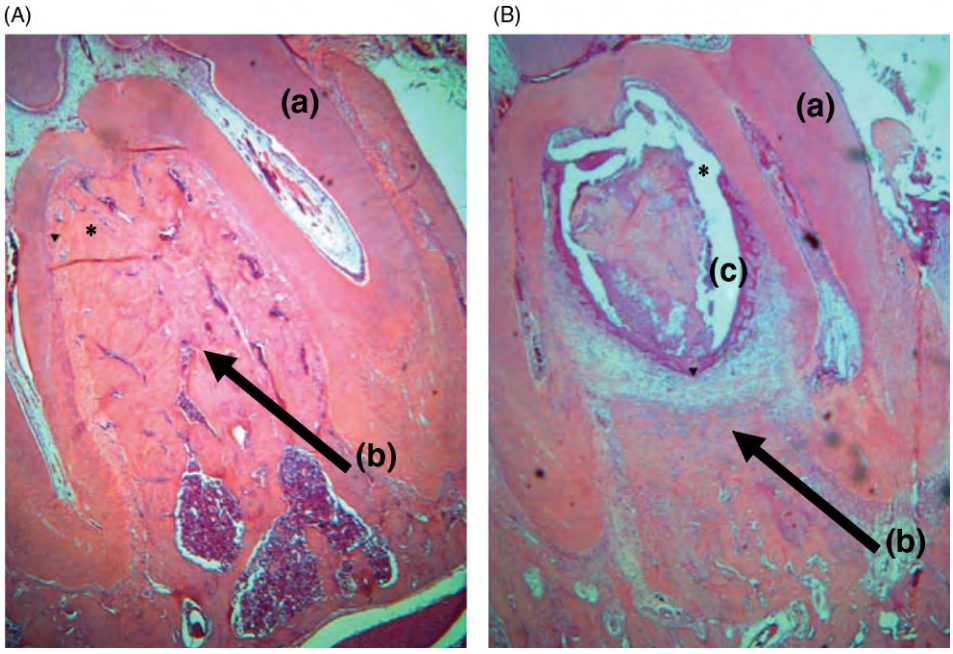

FIGURE e8.4 Photomicrographs illustrating the furcation region of a rat molar showing no bone loss in the control group with no cannabis smoke exposure (hematoxylin and eosin; magnification = 10×). These photomicrographs correspond to histological sections from the rat teeth. (A) Represents control rats, whereas (B) represents cannabis-exposed rats. For (A) and (B), the zone (a) corresponds to the tooth root, and zone (b) corresponds to the furcation area filled with original bone. For (B), the zone (c) corresponds to furcation bone loss due the cannabis smoke exposure. *Source: Data are from Nogueira-Filho et al. (2011).*

cannabis antiinflammatory effect might be related to drug-induced reduction of bone-related molecules, as receptor activator of NF-κB and receptor activator of NF-κB ligand expression, neutrophil infiltration, and cytokine production at gingival tissues.

Although both studies (Napimoga et al., 2009; Nogueira-Filho et al., 2011) used the same experimental model (ligature-induced periodontitis in rats), a direct comparison between the studies has to be taken with caution. Napimoga et al. (2009) tested just cannabidiol, one of the compounds of *Cannabis* smoke, whereas the study by Nogueira-Filho et al. (2011) evaluated whole *Cannabis* smoke inhalation. Interestingly, cannabis leaves, like tobacco leaves, contain more than 400 compounds, but *Cannabis* presents at least 60 cannabinoids. The noncannabinoid constituents are similar to tobacco (except for nicotine), which carry systemic health risks, and have histopathologic effects similar to those of tobacco smoke. Realistically, in the study by Napimoga et al. (2009) only cannabidiol was administered via intraperitoneal injections in the rats; whereas the animals in the study by Nogueira-Filho et al. (2011) inhaled the cannabis smoke itself. These methodological differences may explain, at least in part, the contradictory results of these two interesting studies.

Two relevant clinical studies have reported the effects of cannabis usage on periodontal tissues. In a prospective cohort study, Thomson, Poulton, and Broadbent (2008) found *Cannabis* smoking to be an independent risk factor for periodontal disease. Contradictorily, López and Baelum (2009) found no evidence associating the use of cannabis with periodontal diseases. The human populations of each investigation may be considered the most important difference, when comparing both studies. The study by Thomson et al. (2008) evaluated only adult patients (~32 years old); however, López and Baelum (2009) evaluated younger patients (~12–21 years old). Notwithstanding this, it is well recognized that in such clinical studies it is difficult to control the frequency, amount, duration, and mode of administration of cannabis in all individuals included in epidemiological evaluations. Personal risk factors, including age, oral hygiene, general health, concurrent tobacco smoking, and multidrug use, may also act as confounding factors, making even more difficult the identification of the specific influence of *Cannabis* on periodontitis.

FINAL CONSIDERATIONS

Our studies propose a methodology widely used to evaluate the influence of cigarette smoke on living tissues, in order to study the impact of *Cannabis* smoke on ligature-induced periodontitis, and on endosseous implants. Cigarette and *Cannabis* smoke are quite similar regarding composition, which may result in similar biologic effects. Cigarette smoking can reduce bone capacity

of formation or increase its resorption. Similarly, the present results demonstrate that *Cannabis* smoke might also alter bone pathophysiologic patterns. Cannabinoids may suppress important biologic pathways related to inflammatory processes, whereas nicotine, a key tobacco constituent, promotes these pathways. However, the biologic pathway by which *Cannabis* smoke exerts its effects on periodontal tissues and bone around dental implants is still not totally understood.

Because the healthy groups did not present changes in the bone levels, the greater bone loss found in the *Cannabis* groups for periodontitis sites, and around titanium implants, might be probably related to impaired immune function during the process of bone repair, or even the activation of specific receptors that might increase bone destruction. In this regard, some speculation has arisen about the endocannabinoid system that seems to play a role in the regulation of bone metabolism. The suspicion of a *Cannabis* effect on bone metabolism was confirmed by some molecular studies that demonstrated a negative impact by cannabinoids on bone physiology. Mice lacking either of the cannabinoid receptors CB1 or CB2 have abnormal bone phenotypes because cannabinoid receptor agonists and inverse agonists reduce bone loss by presenting direct effects on both bone-resorbing cells (osteoclasts) and bone-forming cells (osteoblasts) in vitro. Nevertheless, conflicting results have been reported with regard to the effects of *Cannabis* on the regulation of bone mass via bone resorption and osteoclast function. THC has also demonstrated a direct impact on immune cell activity, leading to immunosuppressive effect on macrophages, natural killer cells, and T and B-lymphocytes.

Undoubtedly, it is wise to consider the fact that many individuals have or will have contact with *Cannabis* as a recreational drug, or as a daily basis usage. The question remains as to how far this *Cannabis* smoking habit may disrupt the bone homeostasis in the oral cavity.

MINI-DICTIONARY

Bone loss Bone loss is the breakdown of bone through a process also called bone resorption, in which bone volume and bone density are decreased physiologically or because of a disease.

Bone resorption Bone resorption is the destruction of bone tissues that promotes bone loss, that is, a decrease in bone mass and bone density.

Furcation region Furcation region of a tooth corresponds to the area filled by bone in between the roots. It is generally found in multiradicular teeth in the oral cavity.

Hematoxylin and eosin (H&E) stain H&E is a common histological staining method for tissues, in which the cell nuclei are stained in a deep blue with hematoxylin, while the cell cytoplasm is stained in a pink color after the counterstaining with eosin.

Periodontal disease Periodontal disease is an inflammation of gingiva and oral bones around teeth. It is called gingivitis when only the gingiva is affected by inflammation, whereas periodontitis involves destruction of alveolar-supporting bone around teeth.

Trabecular bone Trabecular bone is a synonymous with the cancellous bone. It is one of two types of bone tissue in vertebrates.

Xerostomia This is a condition in which there is an extreme decrease of salivary flow in the oral cavity, promoting mouth dryness. It is usually due to physiological and/or pathological decrease of saliva production by the salivary glands present in the oral cavity.

SUMMARY POINTS

- Using a systematic process to identify all eligible studies published from 2004–14, our chapter attempts to answer the following question: "Does marijuana use increase the risk of developing cancer in humans?"
- Seven scientific databases were searched, and the review process identified 19 eligible studies.
- Eligible studies yielded inconsistent results in relation to marijuana use and the development of head and neck cancer, or lung cancer.
- Few eligible studies included sufficient numbers of long-term marijuana users with substantial joint-years of usage (eg, >10 joint-years) and, as a result, a possible connection between long-term and heavy marijuana use and lung cancer or head and neck cancers cannot be ruled out.
- Based on the three available studies, the scant evidence suggests a potential relation between marijuana use and increased risk of nonseminoma testicular germ cell cancers.

KEY FACTS OF LUNG CANCER

- Globally, lung cancer accounts for the biggest proportion of cancer-related mortality.

KEY FACTS OF TESTICULAR CANCER

- Testicular germ cell tumors (TGCTs) are responsible for 95% of testicular tumors.
- TGCTs are classified as either seminomas or nonseminomas.

KEY FACTS OF HEAD AND NECK CANCER

- Globally, head and neck cancers are among the top ten causes of male cancer mortality.
- About 90% of head and neck cancers are squamous cell carcinomas of the head and neck (SCCHNs).

LIST OF ABBREVIATIONS

HNC	Head and neck cancer
TCC	Transitional cell cancer
TGCT	Testicular germ cell tumours
SCCHN	Squamous cell carcinomas of the head and neck

INTRODUCTION

Marijuana is produced and consumed in virtually every country, thus facilitating its status as the most widely used illicit drug worldwide (UNODC, 2014). According to the

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00061-2
Copyright © 2017 Elsevier Inc. All rights reserved.

2014 World Drug Report (UNODC, 2014), approximately 180 million people—or 3.8% of the global population—consumed marijuana in the past year, and it is likely that these numbers are due, in part, to the common perception that its use confers minimal health risks (Berg et al., 2015).

Globally, a range of nations, including countries of the European Union, Australia, and the Americas have recently implemented or proposed reforms to the ways in which they control marijuana use, thereby departing from traditional approaches of criminal prohibition that have dominated throughout most of the 20th century (Room, Fischer, Hall, Lenton, & Reuter, 2010). In light of the global debate about marijuana decriminalization/legalization, as well as its widespread global use, it is critically important to assess the impact of marijuana smoking on human health, especially on the development of cancer. Despite the current lack of data on the prevalence of marijuana use by method of intake, smoking is presumed to be the most common form of consumption (National Institute on Drug Abuse, 2014).

There are a number of good reasons to think that marijuana smoking may facilitate the development of cancer, especially for those cancers identified as directly attributable to tobacco use (Centers for Disease Control and Prevention, 2013). Tobacco smoking is the leading cause of lung cancer (Alberg, Ford, Samet, & American College of Chest Physicians, 2007), and marijuana and tobacco smoke contain many of the same potent carcinogens (Maertens et al., 2009)—but with marijuana-smoke condensates being even more cytotoxic and mutagenic (Maertens et al., 2009). In comparison to tobacco smoking, marijuana smoking is usually associated with deeper inhalation, longer breath-holding times, use of unfiltered marijuana cigarettes (joints), and relatively greater delivery of tar (a known carcinogen) to the lungs (Mehra, Moore, & Crothers, 2006). In addition, studies employing bronchial biopsies have demonstrated that marijuana users not only manifest airway inflammation, but also histopathological and/or molecular changes indicative of precancerous bronchial activity (Tashkin, Baldwin, Sarafian, Dubinett, & Roth, 2002).

In view of the similarity of marijuana smoke to that of tobacco, our narrative review focuses on the following question: "Does marijuana use increase the risk of developing cancer in humans?" Given that the last major systematic review attempting to answer this question was published a decade ago by Hashibe et al. (2005), we provide a narrative assessment of all subsequent articles published from 2004–14.

HOW WERE ALL RELEVANT STUDIES IDENTIFIED?

A Master's-level university librarian (TF) conducted a systematic search of the following databases from the beginning date of the database to Jun. 2014: Medline OvidSP, Embase OvidSP, LILACS, ERIC EBSCO, PsycInfo EBSCO, Web of Science ISI, and ProQuest Dissertations and Theses. The searches incorporated keywords and subject headings for "cannabis," "marijuana," and "cancer" (see Fig. e9.1 for more details).

WHAT WERE THE INCLUSION/EXCLUSION CRITERIA FOR ELIGIBLE STUDIES?

Articles were eligible for our review if they included all of the following items:

1. A cancer diagnosis;
2. Cannabis use assessment;
3. A risk parameter for estimating relation between cannabis use and cancer outcome; and
4. Original estimates or original data.

In addition, the manuscript must have been written in English, conducted in humans, and published between 2004 and 2014.

WHAT WERE THE STEPS IN THE IDENTIFICATION PROCESS OF ELIGIBLE STUDIES?

The search process yielded 878 potentially eligible articles, and the removal of duplicates produced 478 unique papers. The second author (MV) screened the abstracts and text of each of the 478 articles remaining, and identified all those meeting the criteria for potential inclusion. References of included articles were hand-searched by the second author (MV) and considered for inclusion. This screening process identified 21 articles, which the second author (MV) and the lead author (RCC) then reviewed. Agreement was reached on all articles for inclusion to occur, and 19 articles were chosen for our review (Tables e9.1–e9.3).

NARRATIVE ASSESSMENT OF ELIGIBLE STUDIES

The identified articles can be grouped into three main cancer types—lung, head and neck, and testicular germ cell—as well as a miscellaneous category. Within each grouping, a critical analysis of each publication will be presented, followed by an overarching conclusion at the end of the paper.

LUNG CANCER

Critical Analysis of Callaghan, Allebeck, and Sidorchuk (2013)

The only cohort study included in our review (Callaghan et al., 2013) presents the potential association

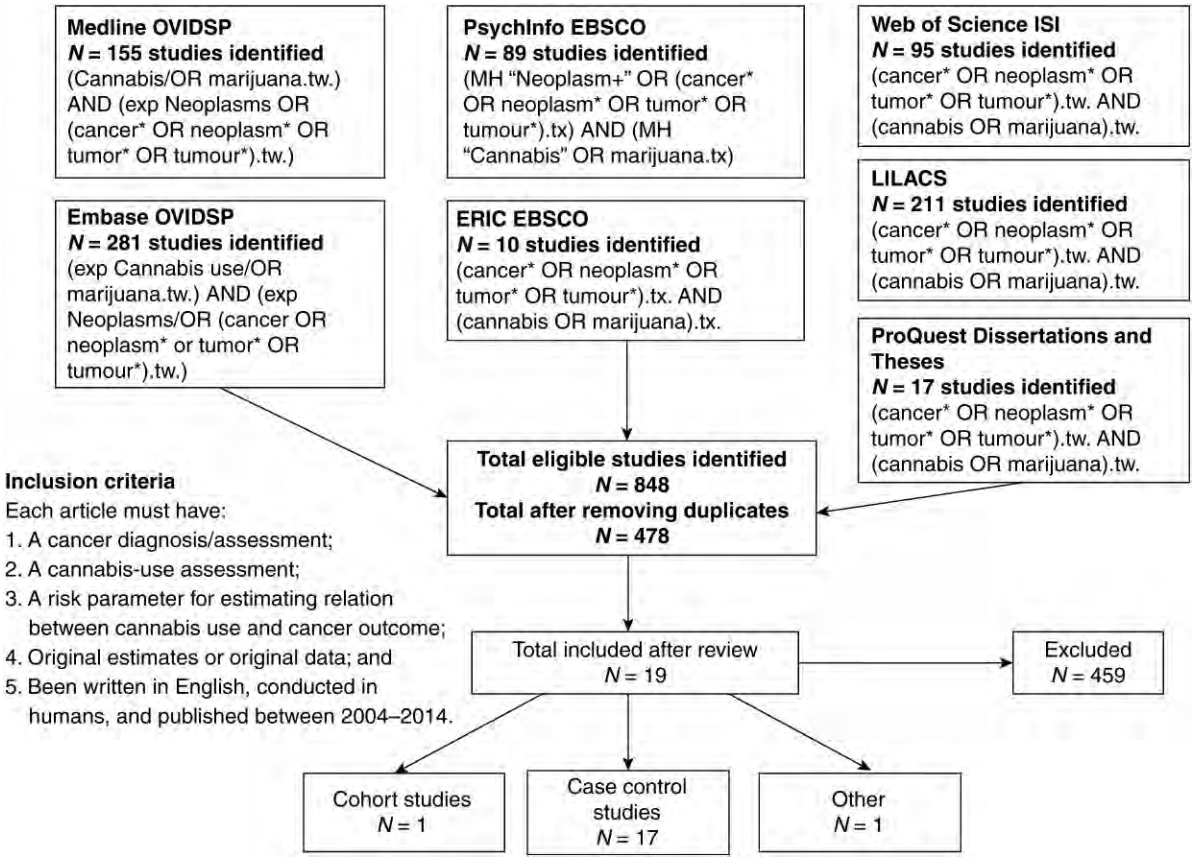

FIGURE e9.1 Flowchart outlining the systematic identification process of eligible studies. The flow chart illustrates how studies were systematically selected for our review.

between marijuana use in late adolescence/early adulthood and the development of lung cancer over a 40-year follow-up period. The sample comprised male Swedish military conscripts (n = 49,321), aged 18–20, who were inducted into military service in 1969–70. Most of those who smoked marijuana had also smoked tobacco, with approximately 91% of the "heavy" marijuana smokers (defined as those using more than 50 times during lifetime) also indicating at least some tobacco use. Heavy marijuana use was associated with more than a twofold increased risk of lung cancer, an association that remained even after adjustment for tobacco and alcohol use, respiratory conditions at conscription, and socioeconomic status (HR = 2.12; 95% CI = 1.08–4.14). It is important to note that no information on the use of marijuana or tobacco is available for the period preceding conscription or following it, and there is a strong possibility of residual confounding by tobacco use, in relation to the study's main findings.

Critical Analysis of Hashibe et al. (2006)

In one of the best designed studies in the field, researchers investigated the association between marijuana use and lung cancer in a large Southern Californian case-control study [611 lung-cancer cases; 1040 controls (Hashibe et al., 2006)]. Despite the study's strength of having a large number of heavy marijuana smokers as participants (defined in this study as >10 joint years, n = 85 for cases, n = 115 for controls), after adjustment for several confounders, including cigarette smoking and alcohol consumption, no evidence of significant relations between joint-years of marijuana smoking and lung cancer were evident. In the subgroup analyses of marijuana users who were not tobacco users, the results showed similar patterns. The findings ran counter to the authors' initial hypotheses, and the researchers suggested that their results may have been affected by selection bias in choosing controls, or error in measuring lifetime exposure/confounder histories.

Critical Analysis of Aldington et al. (2008a)

A population-based case control study was conducted in New Zealand (Aldington et al., 2008a), with 79 cases and 324 controls aged 55 years and younger being administered face-to-face questionnaires regarding possible risk factors for lung cancer. Although marijuana smoking (lifetime use of 20 or more joints) was not associated with increased risk of lung cancer, those in

Chen et al. (2008). California, United States. Data from a prospective cohort study by Sidney et al. (1997) was obtained between 1979 and 1985. Participants were then followed-up until the appearance of a cancer diagnosis, membership termination, diagnosis of HIV/AIDS, death, or the end date 31 Dec. 1993	All cancer	64,855 Kaiser Permanente Medical Care Program (KPMCP) members aged 15 to 49 years. 1421 incident cases of cancer	Self-administered questionnaires	*Total sample* Never 58.8% Ever 41.2% *Incident cancer cases* Never 60.9% Ever 29.1%	*Effects* *Interaction effects of marijuana use alone and tobacco use alone, men* Tobacco alone Marijuana alone *Main effects of marijuana use collapsing across tobacco use, men* Never Ever *Interaction effects of marijuana use alone and tobacco use alone, women* Tobacco alone Marijuana alone *Main effects of marijuana use collapsing across tobacco, women* Never Ever	$r = 0.36$ $r = 0.09$ $X^2 = 10.35$, $p = 0.001$ $r = 0.65$ $r = 0.35$ $X^2 = 31$, $p \leq 0.001$ $r = 0.34$ $r = 0.08$ $X^2 = 34.60$, $p \leq 0.001$ $r = 0.27$ $r = 0.73$ $X^2 = 36.09$, $p \leq 0.001$		

The table presents the key characteristics of studies which used a pooled approach or re-analyzed secondary data ($n = 4$) included in the systematic review.

the highest tertile of marijuana use (>10.5 joint-years) showed significantly higher risk (RR = 5.7; 95% CI = 1.5–21.6), even after adjustment for age, sex, ethnicity, pack-years of cigarette smoking, and a family history of lung cancer. The study also found an increase in lung cancer risk of 8% for each joint-year of marijuana smoked, after adjustment for confounders, such as cigarette smoking. This finding appears to be consistent with previous research showing that smoking a few joints a day causes histological changes in the tracheobronchial epithelium, similar to those caused by smoking 20–30 tobacco cigarettes a day (Roth et al., 1998). The possibility of residual confounding by tobacco use, however, is highly possible in the study, as cases and controls differed dramatically on tobacco pack-years smoked (eg, ≥23.9 tobacco pack-years smoked: cases = 56.9%; controls = 12%).

Critical Analysis of North African (Maghreb) Studies: Voirin et al. (2006); Berthiller et al. (2008)

Using data from the Maghrebian region of North Africa, a pooled study (Berthiller et al., 2008) was conducted, which included the Voirin et al. (2006) Tunisian study, as well as a previously published study completed in Morocco by the same group (Sasco et al., 2002), and additional new data from Algeria. The pooled analysis included a total of 430 cases and 755 controls from all three studies. The studies employed a similar research approach, all were hospital-based, and all used face-to-face interviews administered by trained physicians. However, one of the key issues present in all three studies is the very low number of current marijuana smokers (a total of only 4, all from the Algerian data), likely due to biases in self-reports resulting from the strict marijuana-prohibition laws in the area. Overall, the pooled analysis found an increase in the risk of lung cancer in the "ever" group versus the "never" group (OR = 2.4, 95% CI = 1.5–3.7), after adjusting for age, occupational exposure, country (within the pooled analysis), and tobacco use. Cases were much more likely to have not only a higher prevalence of current or former smoking status (controls: 95%; cases: 76%), but also a substantially greater proportion of individuals who reported tobacco smoking of more than 35 pack-years (cases: 35–45%; controls: 10–17%). As a result, there is a strong possibility of residual confounding of the results by tobacco use. Also, studies based in North African settings encounter the frequently intractable problem of identifying the independent effect of marijuana from tobacco, in regions where smoking mixed tobacco and marijuana products (kiff) is common practice (Hashibe et al., 2005).

Critical Analysis of Han, Gfroerer, & Colliver (2010)

Using cross-sectional data from individuals aged 35–49 in the 2005–07 US National Surveys on Drug Use and Health (NSDUH, a large, population-based survey), Han et al. (2010) estimated the relations between duration of illicit drug use (including marijuana use) on a set of 20 self-reported lifetime health conditions, adjusting for potential confounding factors. Logistic-regression models were adjusted for a range of covariates. The researchers found that duration of marijuana use of ≥11 years was significantly associated with increased likelihood of lung cancer (OR = 7.87, 95% CI = 1.28–48.40). It is surprising that the researchers limited their sample to individuals aged 35–49 in the survey, especially as the median age of lung cancer diagnosis is approximately 70 years of age in the United States (Hayat, Howlader, Reichman, & Edwards, 2007), and relatively few individuals develop lung cancer before the age of 50 (Howlader et al., 2014). The possibility of Type 1 error also must be considered in the interpretation of the significant results, as the authors conducted 300 multivariate tests in the paper.

Critical Analysis of Zhang et al. (2015)

Presenting one of the strongest papers in the field, researchers from the International Lung Cancer Consortium conducted a pooled case-control study based on data from six studies in the United States, United Kingdom, and New Zealand (Zhang et al., 2015). This study has a critical advantage over all previous studies in the marijuana-use and lung cancer field: the project allowed for the analysis of the relation between marijuana use and lung cancer in a large group of nontobacco smokers. Given the strong possibility that tobacco smoking confounds estimates throughout this literature, this is a key development in the field.

Compared with nonhabitual or never marijuana users, the pooled OR for habitual marijuana smokers was 0.96 (95% CI = 0.66–1.38). For those habitual smokers with 1–9.9 joint-years of marijuana usage, the pooled OR was 0.69 (95% CI = 0.41–1.17), and for those with ≥10 joint-years, the pooled OR was 0.94 (95% CI = 0.67–1.32). For marijuana users with 20 years or more duration of use, the pooled OR was 1.03 (95% CI = 0.54–1.98). In the subgroup of marijuana users who did not use tobacco, results were similar. Nonetheless, the researchers did find a small monotonic relation between joint-years of marijuana use and lung cancer, with more joint-years of marijuana use being associated with greater likelihood of lung cancer. It is important to note, however, that the small number of cases in the subgroup analyses with nontobacco-using marijuana smokers produced relatively imprecise estimates with large confidence intervals,

especially for estimates associated with higher exposure levels.

HEAD AND NECK CANCERS

Critical Analysis of Aldington et al. (2008b)

The association between marijuana use and head and neck cancers was examined in a case-control study with 75 incident cases and 319 controls, 55 years of age or younger (Aldington et al., 2008b). Cases were selected from hospital databases and the New Zealand Cancer Registry, and controls were randomly selected from the electoral roll. Both groups completed interviewer-administered questionnaires. Overall, increasing risk of head and neck cancers was associated with increasing alcohol and tobacco use, and decreasing income—but not associated with increasing marijuana consumption. It may have been that the duration of marijuana smoking in cases and controls was too short for long-term effects of marijuana on head and neck cancer to appear (the highest tertile of >8.3 joint-years of cumulative exposure only included 10 cases and 8 controls). Additionally, the small sample size in this study likely undermined statistical power to detect an effect, especially vis-à-vis site-specific head and neck cancers.

Critical Analysis of Gillison et al. (2008)

In light of the possibility that there may be two distinct pathways for the carcinogenesis of head and neck cancers—one facilitated by the mutagenic effects of tobacco and alcohol, and the other driven by HPV-mediated changes—Gillison et al. (2008) undertook two case-control studies, and assessed risk factors associated separately with HPV-positive (cases, $n = 92$; controls, $n = 184$) and HPV-negative (cases, $n = 148$; controls, $n = 296$) head and neck squamous cell carcinomas. The relation between marijuana-use indicators and HPV-16-positive head and neck cancers increased in strength with increasing marijuana-use intensity (joints per month), duration (in years), and cumulative joint-years of exposure, even after adjustment for potential confounders. Marijuana-use categories were not significantly related to HPV-16-negative head and neck cancers in the adjusted models. From these results, the authors suggest that cannabis use may promote the progression of HPV-16-positive head and neck cancers by increasing the risk of infection upon exposure, promoting persistence of an infection, and inhibiting antitumor immunity. Given that HPV-16-positive head and neck cancer cases reported much greater prevalence of sexual behavior and risky sexual behavior (one of the primary mechanisms for the acquisition of HPV-16 virus) and that marijuana use is related to riskier sexual behavior (Andrade, Carroll, & Petry, 2013), it is possible that the significant relations between marijuana-use categories and HPV-16-positive head and neck cancers may be due to residual confounding by sexual behavior.

Critical Analysis of Liang et al. (2009)

Liang et al. (2009) conducted a case-control study in Boston (434 cases, 547 controls), using cases drawn from cancer clinics and controls (matched on age, gender, and town of residence) from population-based registers. After adjustment for several potential confounders, the models demonstrated that current marijuana usage, increasing frequency of weekly marijuana use, and duration of marijuana smoking between 10 and 20 years were all significantly associated with reduced risk of head and neck cancers. The administration of the questionnaires to controls and cases differed, however, and this research-design difference may have affected the results. Cases were administered questionnaires at the initial clinic visit, and their responses were reviewed by study personnel at the clinic. Researchers mailed the questionnaires to controls, and if controls were more likely to report cannabis use because of this data-collection procedure, then this design factor might have led to the significantly reduced risk associated with marijuana use in the cases.

Critical Analysis of Berthiller et al. (2009)

Drawing upon a pooled analysis of five case-control studies from the United States, Cuba, and Argentina, INHANCE Consortium researchers assessed the potential relation between marijuana use and head and neck cancers, in a large group of cases and controls (cases, $n = 4085$; controls, $n = 5125$) (Berthiller et al., 2009). Given the large sample size, the investigators could undertake a critically important analysis for the field: an assessment of marijuana use in these cases of the head and neck cancers in "never" tobacco users (cases, $n = 353$; controls, $n = 1017$). The findings from these analyses showed no evidence of significant positive relations between lifetime marijuana use (ever versus never), daily frequency of marijuana use, duration of marijuana smoking, or cumulative joint-years of exposure. Low numbers of heavy and chronic marijuana users undermined the statistical power to detect even a moderate increased risk associated with these marijuana-use categories. Thus, as the researchers acknowledge, the study lacked the precision to rule out a moderately increased risk of head and neck cancers among marijuana users, especially in those with chronic or heavy usage.

Critical Analysis of Feng et al. (2009)

Employing a case-control study of participants (cases, $n = 636$; controls, $n = 615$) selected primarily from hospital-based settings in Algeria, Morocco, and Tunisia,

Feng et al. (2009) assessed the potential relation between marijuana use and the development of nasopharyngeal cancers. In the models based on male cases and controls (401 controls, 439 cases), and adjusted for age, socioeconomic status, dietary factors, and cigarettes smoked per day, the authors found no evidence that cannabis-use indicators, such as lifetime usage (never versus ever) or frequency of consumption, were significantly related to nasopharyngeal cancers. However, total frequency of lifetime cannabis consumption ≥2000 times was significantly related to increased risk of nasopharyngeal cancers (OR 2.62; 95% CI = 1.00–6.86).

Critical Analysis of Marks et al. (2014)

Recently, researchers from the INHANCE Consortium also conducted a pooled analysis of the possible relation between marijuana use and oropharyngeal cancers, as well as oral tongue cancers (Marks et al., 2014). The pooled analysis involved individuals from nine case-control studies in the United States and Latin America, including 2395 cases (2002 oropharyngeal and 393 oral tongue) and 7798 controls. Tobacco use and alcohol consumption are powerful risk factors for the development of head and neck cancers (Lubin et al., 2010), and a critical advantage of the current study was that it was able to stratify analyses according to these risk factors. The study found that, compared with never marijuana smokers, ever marijuana smokers manifested no evidence of increased risk of oropharyngeal cancer (OR = 0.99; 95% CI = 0.71–1.25), after adjusting for potential confounding variables, including HPV-16 status.

Among never tobacco smokers and never drinkers, there was some evidence of a trend between cumulative marijuana-use exposure (in joint-years) and oropharyngeal cancers—with greater cumulative exposure being more strongly related to oropharyngeal cancer. However, these analyses (shown in Table e9.3 in the Marks et al., 2014 paper) did not account for HPV-16 status—a critically important potential confounder of the outcome. Also, it is important to acknowledge that the stratified analyses including never tobacco smokers and never alcohol drinkers were likely compromised by low statistical power to detect a moderate effect, especially for higher levels of frequency, duration, and cumulative joint-year exposure categories.

In the Marks et al. (2014) paper, the researchers also assessed the possible link between marijuana use and tongue cancers. The adjusted-model results showed that the risk of oral tongue cancer was consistently reduced across the all levels of marijuana-use categories: "ever" (OR, 0.47; 95% CI = 0.29–0.75), higher frequency of usage (eg, >3 times per week: OR = 0.64; 95% CI = 0.23–0.95), duration of use (eg, >10 years: OR = 0.44; 95% CI = 0.21–0.94), and cumulative joint-years of exposure (>10 years: OR = 0.31; 95% CI = 0.11–0.89). The inverse relation between marijuana use and development of oral tongue cancer might be due to the antineoplastic effects of cannabinoids—active ingredients of marijuana (not to be confused with its psychoactive ingredient, tetrahydrocannabinol)—which appear to support antitumor activity (Cridge & Rosengren, 2013).

TESTICULAR GERM CELL TUMORS

Critical Analysis of Daling et al. (2009); Trabert, Sigurdson, Sweeney, Strom, and McGlynn (2011); Lacson et al. (2012)

Recently, researchers have assessed the relation between marijuana use and the development of testicular germ cell tumors (TGCT). This category of cancer is traditionally divided into two broad groups: pure seminoma (which usually accounts for 60% of incident cases), and nonseminoma. Daling et al. (2009) found that current marijuana use (versus "never" as referent), longer duration of cannabis use among current users (≥10 years), high frequency of current marijuana use (daily or ≥1 day per week), and an earlier age of first-use of marijuana (<18 years) were all significantly associated with *only* nonseminoma TGCT—but not seminoma cases. Similar to the Daling et al. (2009) paper, Trabert et al. (2011) found that higher marijuana-use frequency (>1 per day) and longer marijuana-use duration (≥10 years) were significantly associated with nonseminoma cancer, but not seminoma. In the most recent cannabis-testicular cancer study, Lacson et al. (2012) did not find evidence of any significant relations between marijuana use and seminoma, but they did show that marijuana use was significantly associated with nonseminoma/mixed germ cell tumors—a pattern similar to the prior two studies in the field (ever versus never marijuana use: OR = 2.42; 95% CI = 1.08–5.42). At this time, the field lacks a persuasive description of the biological plausibility of marijuana use as a mechanism specific to nonseminoma tumors.

MISCELLANEOUS: CRITICAL ANALYSIS OF CHACKO ET AL. (2006); BLUHM, DANIELS, POLLOCK, AND OLSHAN (2006); CHEN ET AL. (2008)

In our review, we also identified studies assessing the relation between marijuana use and transitional cell carcinoma, and mothers' marijuana use and cancer in their offspring, as well as a reanalysis of secondary data. Using a small, pilot case-control study (52 cases, 168 age-matched controls), Chacko et al. (2006) found that increasing

joint-years of marijuana use was significantly related, in a univariate analysis, to transitional cell carcinoma. However, even though the authors state that "multivariate adjustment" was undertaken in their supplementary logistic regression model (Chacko et al., 2006, p. 102), the important details of the modeling strategy were not provided and, as a result, it is not possible to evaluate this finding. In addition, Bluhm et al. (2006) found that "any use" of marijuana in the first trimester was significantly related to increased risk of neuroblastoma (OR = 4.75; 95% CI = 1.55–16.48). It is surprising, however, that this model was not adjusted for illicit drug use and, as a result, other kinds of illicit drug use (other than marijuana) may have confounded the estimate. Also, Chen et al. (2008) reanalyzed data from a prior study (Sidney, Quesenberry, Friedman, & Tekawa, 1997) and found that marijuana smokers were "at significantly lower risk of cancer relative to those who smoked tobacco and not marijuana" (Chen et al., 2008, p. 271). The Chen et al. (2008) study, however, used log-linear analyses—an extension of chi-square to multi-factorial contingency tables. The key limitation of the log-linear approach is that it cannot account for potentially confounding variables omitted from the contingency table—in this case, age and alcohol consumption.

CONCLUSIONS

In relation to our primary research question, the findings from the lung cancer area do not yield a definitive response. Of the seven eligible studies, five found that marijuana use significantly increased the risk of lung cancer, but the two best-designed studies—which stratified analyses by tobacco-use status—found no evidence of a relation between marijuana exposure and the outcome. The two critical limitations of these studies published between 2004 and 2014 are: the strong possibility of residual confounding by tobacco use, especially in the studies finding elevated risk associated with marijuana use; and the inclusion of only small numbers of individuals with heavy or chronic marijuana consumption (eg, >10 joint-years of usage). Prior systematic reviews of earlier literature (Hashibe et al., 2005; Mehra et al., 2006) also identified these issues as key limitations undermining clear interpretation of the results in this area. An important, recent advance in the field has been the pooling of estimates across case-control studies (eg, Zhang et al., 2015). This approach has allowed for the stratification of key marijuana-use analyses according to tobacco-use status, and it addresses the threat of residual confounding by tobacco use. Future work should include stratification by tobacco-use into the research design or, at least, match cases and controls according to tobacco consumption. Given the strong biological plausibility of an association between marijuana use and lung cancer (Mehra et al., 2006), the mixed results of the seven studies included in the current review, and the inconsistent findings in prior systematic reviews on this topic (Hashibe et al., 2005; Mehra et al., 2006), it seems reasonable to advise caution regarding lung cancer risk associated with marijuana use until further, more definitive evidence arises in the field.

In the last major review of epidemiological studies assessing the potential link between marijuana use and head and neck cancers, Hashibe et al. (2005) found inconsistent results in the field. In the 10-year interim since the publication of that review, the available literature continues to yield mixed results. Of the six studies reviewed, three showed no evidence of a significant relation between marijuana use and head and neck cancer (or subcategories of head and neck cancer) (Aldington et al., 2008b; Berthiller et al., 2009; Marks et al., 2014); two demonstrated a significantly reduced risk of head and neck cancer (Liang et al., 2009) or oral tongue cancer (Marks et al., 2014); and two studies found that marijuana use indicators were associated with significantly increased risk of head and neck cancers (Feng et al., 2009; Gillison et al., 2008). Given that two studies (Feng et al., 2009; Gillison et al., 2008) found that chronic, heavy marijuana use (ie, use ≥2000 times in lifetime; ≥5 joint-years of use) was significantly related to head and neck cancers, and that the critical limitation in this field is the lack of inclusion of individuals with substantial marijuana-use histories (eg, >10 joint-years of exposure), it is important to stress that a true relation between chronic, heavy marijuana use and head and neck cancer cannot be ruled out.

In light of the three available studies assessing marijuana use and the development of testicular germ cell cancers (Daling et al., 2009; Trabert et al., 2011; Lacson et al., 2012), it is possible to suggest some emerging themes, as well as limitations. All three studies have found an association between marijuana use and nonseminoma/mixed germ cell tumors, but not seminoma cancers. This relation may be true, but a number of caveats need to be considered. First, some of the analyses assessing the potential relation between marijuana use and seminoma lacked sufficient statistical power to detect a meaningful effect (primarily because of relatively small sample sizes of seminoma cases), especially in adjusted multivariate models with numerous covariates. In addition, the field has yet to provide a persuasive description of how marijuana use might specifically affect nonseminoma/mixed germ cell tumors, but not seminoma tumors. In the absence of a description of biological plausibility, readers must consider the strong possibility that the relation may be spurious and a result of confounding by factors associated with marijuana use, but not marijuana use per se.

Since the decade-ago publication of Hashibe et al. (2005), systematic review on the topic of marijuana use and cancer, the scientific field has progressed by producing 19 relevant papers. However, many of these studies have substantial limitations that undermine confident interpretation of their results. For the field to continue to advance, researchers need to make strong efforts to include the following: detailed marijuana exposure assessments; information about primary route of marijuana administration; strict account of tobacco smoking, the best being through stratification across tobacco-use history; sufficiently large samples of chronic or heavy marijuana users (eg, individuals with more than 10 joint-years of exposure); and, where possible, pooled analyses or meta-analytic approaches to identify risk patterns across combined samples or studies.

MINI-DICTIONARY

Germ cells In humans, germ cells are reproductive cells: egg cells in females, and sperm cells in males.
Germ cell tumors A mixed grouping of neoplasms usually occurring at the gonads: ovaries in females, or testes in males.
Gliomas A category of primary brain tumors originating in glial cells, common cells serving a supportive function to neurons.
In vitro Refers to an experiment taking place outside of a living organism in a laboratory or experimental environment—for example, in a test tube or culture dish.
In vivo Refers to an experiment or process taking place inside of a living organism.
Joint-years (JYs) A joint-year is equivalent to smoking 1 marijuana "joint" per day, every day, for an entire year.

CHAPTER

e10

Cannabis and the Use of Amphetamine-Like Substances

A. Porcu, M.P. Castelli

Department of Biomedical Sciences, Division of Neuroscience and Clinical Pharmacology, Cittadella Universitaria, Monserrato, CA, Italy

SUMMARY POINTS

- This chapter focuses on coabuse of cannabis and amphetamine-like substances (ALS).
- Cannabis (main psychoactive compound Δ^9-Tetrahydrocannabinol, Δ^9-THC) is consumed by 2.9–4.3% of the global population aged 16–64 in the world.
- Cannabis consumption is frequently associated with simultaneous use of other psychoactive compounds such as alcohol, cocaine, and ALS (ie, amphetamine, methamphetamine, and 3,4-methylenedioxymethamphetamine).
- New psychoactive substances (NPS), such as cathinones and its derivatives, are frequently coabused with cannabis.
- Cannabis + ASL coabuse enhances the subjective effects of the drugs in humans, counteracts the dysphoric symptoms of "coming down" from 3,4-methylenedioxymethamphetamine or methamphetamine (MDMA and METH), and/or improves and mellows the drug experience.
- Both pharmacological and genotype animal studies support the role of the cannabinoid type 1 receptor (CB1R) in the rewarding and addictive properties of MDMA.
- Preclinical and clinical studies investigating the effects of cannabis + ASL and their interaction in METH/MDMA-induced neurotoxicity have reported conflicting findings: cannabis might exacerbate or attenuate METH/MDMA induced neurotoxicity.

KEY FACTS ON THE MONOAMINERGIC TARGET SYSTEM

- Monoamines refer to the particular neurotransmitters dopamine, norepinephrine and serotonin.
- These neurotransmitters are involved in mediating a wide range of physiological and homeostatic functions such as cognition, memory, learning, mood, and behavior.
- These neurotransmitters are synthesized within particular neurons, and exert an effect when they are released into the synapses, where they are able to act on specific receptors.
- The dopamine transporter (DAT), serotonin transporter (SERT), and the norepinephrine transporter (NET) transport monoamines in or out of a cell.
- ALS may increase the activity of dopamine, norepinephrine, or serotonin by either increasing release, blocking reuptake, inhibiting metabolism, or acting directly on a receptor.

KEY FACTS ON NEW PSYCHOACTIVE SUBSTANCES (NPS)

- NPS are known in the drug market under the names of "designer drugs," "legal highs," "herbal highs," "bath salts," or "research chemicals."
- NPS have become a global phenomenon, and they have affected all regions of the world; 70 (out of 80) countries and territories (88%) examined by UNODC (2014) have reported the emergence of NPS.
- The number of NPS on the global market more than doubled over the period 2009–13. Legislation has not

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00066-1
Copyright © 2017 Elsevier Inc. All rights reserved.

been established, making their sale easy and officially legal in almost all countries.
- The most popular of these drugs are based on the substance cathinone (2-amino-1-phenylpropanone) and its synthetic analogs.
- The chemical structure of NPS is similar to that of amphetamine, as well as their physiological and psychological actions.

KEY FACTS ON POLYDRUG USE

- Research on polydrugs use is typically done on relatively small convenient samples (eg, street-based, emergency rooms, and club patrons), where multiple drugs are frequently used consecutively or simultaneously, often for their perceived counteracting or complementary effects.
- It is associated with a higher risk of developing psychiatric and health problems.

LIST OF ABBREVIATIONS

Δ^9-THC	Δ^9-Tetrahydrocannabinol
5HT	Serotonin
ADHD	Attention-deficit/hyperactivity disorder
AMPH	Amphetamine
ALS	Amphetamine-like substances
BDNF	Brain-derived neurotrophic factor
CB1-KO	Cannabinoid type 1 receptor knockout mice
CB1R	Cannabinoid type 1 receptor
CB2-KO	Cannabinoid type 2 receptors knockout mice
CB2R	Cannabinoid type 2 receptor
CPP	Conditioned place preference
DA	Dopamine
DAT	Dopamine transporter
DEA	Drug Enforcement Administration
dUTP	2′-deoxyuridine 5′-triphosphate
ECS	Endocannabinoid system
FDA	Food and Drug Administration
fMRI	Functional magnetic resonance technique
GFAP	Glial fibrillary acidic protein
MAO	Monoamine oxidase
MDMA	3,4-Methylenedioxymethamphetamine
METH	Methamphetamine
MJ	Marijuana
NE	Norepinephrine
NET	Norepinephrine transporter
nNOS	Neuronal nitric oxide synthase
NO	Nitric oxide
NPS	New psychoactive substances
pCREB	Phosphorylated cAMP response element–binding protein
PKA	Protein kinase A
PKC	Protein kinase C
RNS	Reactive nitrogen species
ROS	Reactive oxygen species
SERT	Serotonin transporter
TH	Tyrosine hydroxylase
TTAR1	Activate trace amine associated receptor 1
TUNEL	Terminal deoxynucleotidyl transferase
VMAT-2	Vesicular monoamine transporter-2

INTRODUCTION

Cannabis is the most widely consumed illicit drug worldwide, with an estimated global use by 2.9–4.3% of the population aged 16–64 (UNODC, 2010) (Fig. e10.1).

While the prevalence of illicit drugs such as cocaine, amphetamine-like substances (ALS) [ie, amphetamine (AMPH), methamphetamine (METH), and 3,4-methylenedioxymethamphetamine (MDMA)] appeared to remain stable between 2009 and 2011, since 2009 the extent of cannabis and opioids use has increased. Cannabis consumption is frequently associated with simultaneous and/or concurrent use of other psychoactive compounds such as alcohol, cocaine, and ALS (Gouzoulis-Mayfrank & Daumann, 2006).

A growing body of clinical and preclinical studies has highlighted the simultaneous use of MDMA, also called ecstasy, and cannabis (Parrott, Milani, Gouzoulis-Mayfrank, & Daumann, 2007). Strote, Lee, & Wechsler (2002), surveying a sample of over 10,000 US college students, reported a prevalence of ecstasy use of 4.7%, with 92% of consumers also consuming cannabis. Wish, Fitzelle, O'Grady, & Hsu (2006) confirmed that 98% of recreational MDMA users in a sample of East Coast College students also consume cannabis. Moreover, the presence of a metabolite of the main psychoactive compound Δ^9-tetrahydrocannabinol (Δ^9-THC), 11-nor-9 carboxy-THC, was found in urine samples collected from 198 ecstasy users between 2005 and 2008 (Black, Cawthon, Robert, & Moser, 2009).

In Europe, the prevalence of couse of MDMA + cannabis ranges from 73% to 100% in different countries (Sala & Braida, 2005), and is higher in males and in regular cannabis users than in women and occasional

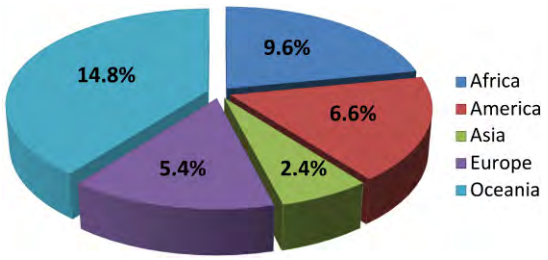

FIGURE e10.1 Estimated number of people who used cannabis at least once in the past year, and its prevalence among the population aged 15–64, by region. *Source: UNODC (2010).*

cannabis consumers (ESPAD, 2000). Due to its low cost, wide availability, and high potential for abuse, METH is the second most frequently abused recreational drug among adolescents, and is often coabused with cannabis (Gonzalez, Rippeth, Carey, & Heaton, 2004).

Several psychosocial and functional reasons can account for the high percentage of concurrent use of Δ^9-THC and METH or MDMA. Cannabis is often considered a "gateway drug," and its consumption might predict a significantly higher risk for subsequent use of heavy illicit drugs such as ALS. However, numerous reports have failed to support this theory, while other studies point to social, environmental, and genetic factors to explain the couse of cannabis and other drugs (Parrott et al., 2007).

MDMA and METH are psychostimulant drugs that induce euphoria, increased sociability, and empathy (Parrott, 2013), while cannabis produces relaxation and feelings of happiness (Green, Kavanagh, & Young, 2003). One of the main reasons for using cannabis in association with MDMA or METH is that the combination of the two drugs enhances the subjective drug effects, and counteracts the dysphoric symptoms of the ecstasy or METH "coming down" (Schulz, 2011). Indeed, MDMA abusers often consume cannabis in the immediate post-ecstasy period as a symptomatic relief against the negative physiological and emotional states (eg, anhedonia, depression) that follow ecstasy's "high." Many ecstasy users also report taking cannabis in the initial acute phase of MDMA to "improve" and "mellow" the experience (Parrott et al., 2007).

In the last few years, many recreational drugs have been synthesized as legal alternatives to scheduled cannabis and AMPH/METH stimulants. New psychoactive substances (NPS) have been found mostly in Europe and North America, but also in Oceania, South America, and Africa. Because they are new, legislation has not been established yet, making their sale easy and officially legal. Their global market has increased dramatically in recent years: by December 2013, the number of NPS reported to UNODC had reached 348, up from 251 as of July 2012, and 166 in 2009 (UNODC, 2014).

The most popular of these drugs are based on the substance cathinone (2-amino-1-phenylpropanone), an analogue of amphetamine, a natural compound of the khat plant (Paillet-Loilier, Cesbron, Le Boisselier, Bourgine, & Debruyne, 2014), which acts on the central dopamine system. Dopaminergic stimulation of the reward system could explain the development of dependence after frequent consumption of cathinone derivatives.

Due to the recent discovery of the NPS, only a few survey studies are currently available on their simultaneous use with cannabis, but no preclinical or clinical studies. On the other hand, despite the high prevalence of cannabis use among MDMA and METH users, the neurobiological interactions between these two drugs are complex, and data regarding their coadministration in human and animal studies are contradictory (Mohamed, Ben Hamida, Cassel, & de Vasconcelos, 2011; Schulz, 2011).

Δ^9-THC and other cannabis derivatives act via cannabinoid type 1 receptors (CB1R) on the endocannabinoid system (ECS), while the ALS, including MDMA, METH and the cathinones, act by increasing synaptic levels of the monoamines dopamine (DA), serotonin (5HT), and norepinephrine (NE).

For a detailed description of the ECS and the mechanism of action of Δ^9-THC and other cannabinoids, see designated Chapters of this book.

In the following paragraphs, we will briefly describe the ALS, including cathinones, their molecular pharmacology, and the pharmacological/neurobiological effects induced by ALS + cannabis.

AMPHETAMINE-LIKE SUBSTANCES: AMPH, METH, MDMA, AND CATHINONES

Amphetamine (AMPH) is the parent compound of a class of molecules with similar chemical structures and biological properties, referred to as amphetamines (Fig. e10.2) (Fleckenstein, Volz, Riddle, & Gibb, 2007).

In 1935, AMPH was introduced to the market by the pharmaceutical company Smith, Kline and French, with the brand name of "Benzedrine." for the treatment of narcolepsy, mild depression, postencephalitic Parkinsonism, and other disorders. Since 1971, AMPH and METH, a substituted amphetamine, due to their addictive potential, have been inserted in Schedule II of the Controlled Substances Act, and are Food and Drug Administration (FDA)-approved for treatment of attention-deficit/hyperactivity disorder (ADHD), narcolepsy, and obesity (DEA Congressional Testimony by Terrance Woodworth; 2000, May 10).

METH is one of the most common ALS; also known as "crystal," "chalk," or "ice," it is taken orally, smoked,

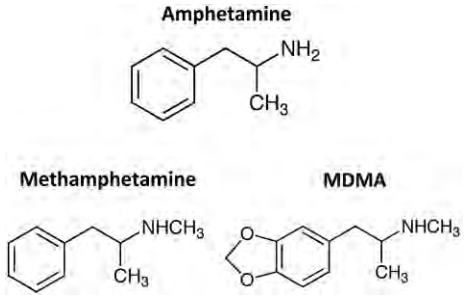

FIGURE e10.2 Chemical structures of amphetamines. Amphetamine, methamphetamine, and MDMA are the amphetamines most frequently coabused with cannabis.

snorted, or dissolved in water or alcohol, and injected. The annual prevalence of METH in the United States was 0.5% of the population aged 15–64 in 2012, similar to that estimated between 2009 and 2011 (SAMHSA, 2013).

MDMA, developed and patented in 1918 by Merck for use in synthesis of styptic drugs, was used in the United States by psychotherapists from 1978 to 1985, when, due to its high abuse potential, the DEA (Drug Enforcement Administration) included it in Schedule I. After cannabis, the second most widely used illegal drugs worldwide are ALS, particularly MDMA (Parrott, 2013). Also known as "ecstasy," "Molly," "lover's speed," or "the love drug," MDMA is used by 10.5–25.8 million people worldwide, corresponding to 0.2–0.6% of the adult population (16–64 years) (UNODC, 2010). MDMA is mostly consumed at late-night parties ("raves," "dance clubs," "techno parties"), where the percentage of users can be up to 95%. The 2009 National Survey on Drug Use and Health reported that the percent consuming MDMA was 1.4% among adolescents (12–17 years old), 3.9% among young adults (18–25 years old) and 0.3% for adults (older than 26 years) (NSDUH, 2010).

Among the NPS, the most abused are derivatives of cathinone, which is a β-cheto analogue of AMPH used as a structural template for the discovery of compounds with a wide range of pharmacological activities (Carroll, Blough, Mascarella, & Navarro, 2010).

NPS are usually marketed as tablets of various colors and shapes, or capsules, powders, and crystals, and sold as "bath salts" or "plant fertilizers." In recent years, several synthetic analogs of cathinone have emerged on the market, and circulate on the Internet or are sold in smart shops with the misleading indication that they are "not for human consumption" (Fig. e10.3).

The general structure of these substituted compounds shows substitution patterns at four locations on the cathinone molecule, for example, on the carbon atom linked to the carbon in the alpha position (R1), on the nitrogen atom (R2 and R3), and on the phenyl group (R4) (Fig. e10.4).

FIGURE e10.3 **Representative packaging of NPS products.** The indication that this substance is "not for human consumption" makes it automatically legal.

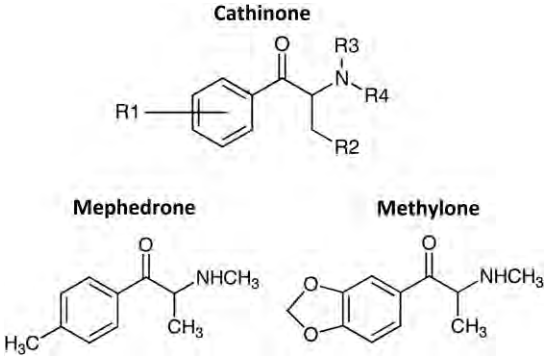

FIGURE e10.4 **Chemical structures of cathinones.** R1, R2, R3, R4 are the various groups that can be substituted to obtain other synthetic derivatives.

ALS Pharmacology

The psychostimulant and rewarding properties of AMPH, METH, and MDMA are due to their ability to enhance neuronal excitability in the brain and, in particular, to increase dopaminergic neuronal activity in the mesolimbic pathway.

Indeed, ALS are historically considered potent indirect monoaminergic agonists, raising the synaptic levels of DA, NE, and, to a lesser extent, 5HT through different mechanisms such as inhibition of: (1) the transporters of DA (DAT), NE (NET), and 5HT (SERT); (2) the vesicular monoamine transporter-2 (VMAT-2); and (3) monoamine oxidase (MAO) activity. Specifically, although with different affinities, AMPH and its derivatives are substrates of plasmalemma DAT, NET, and SERT, with METH and AMPH having greater affinity for DAT, and MDMA having greater affinity for SERT (Sulzer, Sonders, Poulsen, & Galli, 2005).

According to the "exchange-diffusion model," the lipophilic AMPH, METH, and MDMA at high concentrations can diffuse directly across the plasmalemma membrane, while at low concentrations they are transported into the cell by competing with synaptic DA or 5HT at the extracellular site of DAT or SERT. Then, AMPH can disrupt the proton gradient between the inside and outside of the storage vesicle, resulting in an increased release of DA or 5HT from vesicular compartments. At physiological concentrations, AMPH binds to VMAT2, thus inhibiting vesicular monoamine uptake and enhancing cytoplasmic DA levels. As cytoplasmic DA levels rise, DA exits the neuron via reverse transport and/or channel like transport (Fleckenstein et al., 2007).

AMPH can also interact indirectly with DAT. Once entering the neuron, it can bind to and activate trace amine associated receptor 1 (TTAR1), a G-protein

coupled receptor that is important for the regulation of monoamine transporter function and METH's action on DAT activity. In particular, AMPH-induced TTAR1 activation via protein kinase A (PKA) and protein kinase C (PKC) signaling determines DAT phosphorylation and internalization, thereby decreasing DAT DA uptake. METH and MDMA also increase glutamate release in the striatum and hippocampus, respectively (Panenka, Procyshyn, Lecomte, & MacEwan, 2013).

Besides its acute actions, moderate to high doses of ALS administered in a "binge pattern" (repeated administrations at short time intervals) induce long-term effects such as dopaminergic and serotoninergic deficits, including reductions in expression of the enzymes tyrosine and tryptophan hydroxylase and DAT and SERT density, as well as decreases in DA and 5HT tissue content (Marshall & O'Dell, 2012). In addition to damage to DA and 5HT terminals, METH and MDMA cause activation of microglia, and a significant increase in glial fibrillary acidic protein (GFAP), an index of gliosis and central nervous system (CNS) toxicity and cell death. METH increases terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL), a marker of apoptotic cell death and DNA damage, and alters expression of the Bcl2 gene and causes apoptosis by increasing caspase-3 activity, and the Fas/Fasl cell death pathways. MDMA exposure in vitro causes an increase in reactive nitrogen species (RNS) and caspase-3 and, in vivo, an enhancement in protein levels associated with apoptosis (eg, BAX, cytochrome c, caspase-3) (Capela, Carmo, Remião, & Bastos, 2009, Krasnova & Cadet, 2009).

Moreover, the increased extracellular glutamate levels induced by METH-binging activate N-methyl-D-aspartate (NMDA) receptors, promoting an increase in intracellular Ca^{2+} that leads to activation of neuronal nitric oxide synthase (nNOS) and subsequent production of nitric oxide (NO), and activation of apoptotic pathways (Halpin, Collins, & Yamamoto, 2014).

Increasing evidence now suggests the involvement of several interacting mechanisms underlying ALS-induced neurotoxicity, such as hyperthermia, increased production of reactive oxygen (ROS) and RNS, induction of inflammatory responses, apoptotic pathways, DNA damage, and excitotoxic injury. Indeed, ALS-neurotoxicity is associated with long-lasting impairments in mood and cognitive functions in humans and animals (Marshall & O'Dell, 2012).

As concerns synthetic cathinones, data concerning their pharmacological and toxicological properties, mechanisms of action and toxic effects are still inconclusive.

Just as AMPH and cocaine, cathinones in the CNS increase synaptic concentrations of catecholamines by inhibiting their uptake transporters. The meth-cathinone analogs mephedrone and methylone function as substrates for NET, DAT, and SERT at nanomolar concentrations, but are nonselective substrates for monoamine transporters in vitro, exhibiting a potency and selectivity comparable to those of MDMA. Mephedrone and methylone produce concurrent elevations in extracellular DA and 5HT in vivo, and high-dose administration produces hyperthermia and motor stimulation, but no lasting changes in brain tissue monoamines (Baumann, Ayestas, Partilla, & Sink, 2012).

ALS + CANNABIS

Animal Studies

Pharmacological and genotype studies in animals support the existence of interactions between cannabinoid and MDMA/METH related to their rewarding effects, and the role played by CB1Rs in these effects (Sala & Braida, 2005). The reinforcing properties elicited by the simultaneous use of MDMA and Δ^9-THC have been investigated by means of several animal paradigms, such as conditioned place preference (CPP) and intracranial and intravenous self-administration. In particular, in rats trained to self-administer MDMA intracerebroventricularly, the CB1R agonist CP55940 reduced the amount of lever-pressing to obtain MDMA, while the CB1R antagonist SR141617A (SR) increased MDMA-associated lever-pressing, suggesting an increase and a decrease in MDMA's reinforcing effects, respectively. SR decreases MDMA-induced CPP in rats, further supporting the role of the CB1R in reward processes (Sala & Braida, 2005). Accordingly, CB1-KO mice fail to self-administer MDMA, while MDMA induces CPP and enhances extracellular DA levels in the nucleus accumbens of both wild type and CB1-KO mice (Touriño et al., 2008). This discrepancy might be attributed to the different animal species (rats in the pharmacological studies, and mice in the genetic studies), or to the different behavioral paradigms utilized (self-administration vs CPP). Indeed, several brain circuits are involved in the self-administration paradigm, such as those regulating motivation, consciousness, arousal, and learning, while CPP is mostly based on conditioning processes. Intriguingly, subthreshold doses of Δ^9-THC coadministered with a subthreshold dose of MDMA produced CPP in mice, while administration of the same dose of Δ^9-THC with a rewarding dose of MDMA decreased CPP (Robledo et al., 2007). At low doses, the CB1R agonist WIN55212-2 (WIN) increased the rewarding properties of low doses of MDMA, while MDMA reinstated WIN-induced CPP, although WIN was not able to reinstate MDMA-induced CPP in animals with no prior exposure to cannabinoids (Manzanedo, Rodríguez-Arias, Daza-Losada, & Maldonado, 2010).

Accumulating evidence supports the role of the ECS in a crucial phase of the addiction cycle, that is, relapse to drug-seeking after a period of abstinence. Animal studies have shown that a priming with CB1R agonists reinstates not only the extinguished cannabinoid-seeking, but also cocaine-, heroin-, and alcohol-seeking, while reinstatement of cannabinoid-, heroin-, nicotine-, and methamphetamine-seeking is prevented by blockade of CB1Rs (Fattore, Fadda, & Fratta, 2007). Notably, a recent study reported that SR, either alone or coadministered with a priming dose of any of the MDMA, reinstated MDMA-induced CPP. Conversely, WIN had no effect on CPP reinstatement, but potentiated the effects of a subthreshold priming dose of MDMA (Daza-Losada, Miñarro, Aguilar, & Valverde, 2011). Collectively, all these findings supported interactions between the ECS and MDMA regulating either drug-taking or drug-seeking behaviors.

The rewarding effects of Δ^9-THC and MDMA/METH are likely mediated through a common neurochemical system, that is, the mesocorticolimbic pathway. In fact, MDMA raises DA levels by different mechanisms, while cannabinoids influence the synthesis, release, and turnover of DA. In addition, cannabinoid and dopamine receptor expression overlaps in some brain areas, including the nucleus accumbens. Finally, the ECS modulates DAergic transmission by controlling excitatory and inhibitory inputs on dopaminergic neurons. Both cannabinoids and MDMA also modify the glutamatergic system in areas involved in reward and addiction (Maldonado, Valverde, & Berrendero, 2006).

A plethora of data obtained from animal models has shown that administration of high or repeated doses of MDMA and METH results in neurotoxicity to the serotoninergic or dopaminergic system. MDMA neurotoxicity is species-dependent, as in rats and monkeys MDMA mostly affects the serotoninergic pathway, while in mice it targets the dopaminergic one. As revealed by biochemical, histological and immunohistochemical analyses (see the Section "ALS Pharmacology"), administration of high or repeated doses of MDMA or METH causes long-lasting depletion of 5HT and DA in several brain regions.

In association with these neurotoxic effects on the DAergic and 5HTergic systems, binge METH regimens also cause cognitive and behavioral alterations similar to those observed in METH abusers (Marshall, Belcher, Feinstein, & O'Dell, 2007). Recently, our group demonstrated long-term memory deficits and startle responsiveness (index of pathological anxiety) in adult rats, as well as loss of DAergic and 5HTergic brain terminals, following a METH binge neurotoxic regimen (Bortolato, Frau, Piras, & Luesu, 2009). Moreover, the same neurotoxic METH treatment upregulated CB1R expression in brain regions that play an important role in the regulation of emotional and cognitive responses, including the medial prefrontal cortex, striatum, basolateral amygdala, and hippocampal formation (Bortolato, Frau, Bini, & Luesu, 2010).

MDMA-induced neurotoxicity is associated with functional deficits, such as the loss of the ability to thermoregulate, and alterations in locomotor activity in rats (Capela et al., 2009).

The ECS exerts either protective or toxic properties in several in vitro and in vivo models of neuronal injury and neurodegenerative pathologies, including glutamate excitotoxicity, hypoxia, ischemic stroke, brain trauma, oxidative stress, Alzheimer's disease, Parkinson's disease, and Huntington's disease (Fernández-Ruiz, García, Sagredo, & Gómez-Ruiz, 2010).

Given the frequent coabuse of Δ^9-THC and MDMA in humans (see Section "Introduction"), their interaction in MDMA-induced neurotoxicity has also been investigated in terms of neurotoxicity.

Coadministration of Δ^9-THC and CP55940 prevented MDMA-induced hyperthermia, hyperlocomotion, and long-term increase in anxiety measured in the emergence test, but not in the social interaction test in rats (Morley, Li, Hunt, & Mallet, 2004). Accordingly, pretreatment with 3 mg/kg of Δ^9-THC, considered a dose equivalent to that consumed by moderate cannabis users, prevented MDMA-induced hyperthermia in mice receiving a neurotoxic regimen of MDMA (Touriño et al., 2010). This hyperthermic effect was blocked by the CB1R antagonist AM251 and absent in CB1-KO mice, while neither a CB2R antagonist nor deletion of the CB2R gene abolished Δ^9-THC's preventive effect on hyperthermia. Moreover, MDMA-induced microglial and astrocyte activation was abolished by Δ^9-THC in wild-type mice, and partially attenuated in CB2-KO mice, while Δ^9-THC had no effect in CB1-KO and double CB1/CB2-KO mice. Recently, it was demonstrated that an ultra-low dose of Δ^9-THC protects mice from various insults, including ecstasy-induced neurotoxicity and cognitive deficits. This protective effect was long-lasting, and accompanied by increased levels of pCREB (phosphorylated cAMP response element-binding protein) and BDNF (brain-derived neurotrophic factor) in some brain areas (Fishbein, Gov, Assaf, & Gafni, 2012). Altogether, these findings suggest that Δ^9-THC protects an animal from MDMA-neurotoxicity by lowering body temperature and neuroinflammation through both CB1 and CB2Rs.

Chronic administration of Δ^9-THC during adolescence attenuated MDMA-induced hyperthermia, and blunted some behavioral MDMA-induced effects (Shen, Ali, & Meyer, 2011). Additionally, Δ^9-THC prevented MDMA-induced decreases in exploratory behavior, and reductions in 5HT and SERT levels in the striatum, frontal, and parietal cortex, suggesting that chronic coadministration during adolescence might provide some protection

against MDMA-neurotoxicity. Indeed, chronic treatment with Δ^9-THC and MDMA during adolescence produced sex-dependent long-lasting molecular, behavioral, and endocrine-effects, along with modifications of astrocytes, microglia reactive markers, CB1R, and SERT expression. Specifically, coadministration of Δ^9-THC and MDMA impaired working memory in female rats, and attentional capabilities in both sexes, more severely than when administered alone. Moreover, both drugs—either separately or in combination—induced increases in reactive microglia cells, suggesting that chronic administration of these drugs might account for persistent modifications of microglia reactivity.

As regards the METH + cannabis association, only two groups, including ours, have investigated the ability of the ECS to prevent METH-induced neurotoxicity in rats and mice (Castelli et al., 2014; Nader, Rapino, Gennequin, & Chavant, 2014). Specifically, pre- and posttreatment with Δ^9-THC reduced overexpression of nNOS and astrogliosis in the caudate-putamen and prefrontal cortex, respectively, in rats exposed to a neurotoxic regimen of METH. SR reversed the neuroprotective effects of Δ^9-THC on METH-induced nNOS expression, while it failed to counteract the effect of Δ^9-THC on decreasing METH-induced astrogliosis. Our findings indicate that Δ^9-THC prevents METH-induced neurotoxicity through inhibition of nNOS and astrogliosis via both CB1 receptor-dependent and -independent mechanisms (Castelli et al., 2014). According to this, it has been reported that Δ^9-THC, URB597, and JZL184 (inhibitors of degradation of anandamide and 2-arachidonoyl glycerol, respectively) attenuated the decrease in TH levels in the striatum, demonstrating that, in mice, stimulation of the ECS reduced METH neurotoxicity to dopaminergic terminals (Nader et al., 2014).

As concerns cathinone derivatives, no animal studies are currently available on the concomitant use of cannabis.

Human Studies

In contrast to basic research, human studies investigating acute and long-term effects of the consumption of cannabis + MDMA are limited and often contradictory. When consumed acutely, cannabis can enhance MDMA-induced subjective effects and counteract adverse MDMA effects, such as fatigue, insomnia, reduced appetite, irritability, panic attacks, visual hallucinations, and paranoid delusions that appear when "coming off" MDMA. As previously demonstrated in animals (Morley et al., 2004), cannabis can also acutely attenuate body temperature in dance club recreational ecstasy users (Parrott et al., 2007).

Both drugs taken alone may have detrimental effects on memory and cognition (Parrott, 2013; Solowij, Stephens, Roffman, & Babor, 2002), and when taken together can determine neurocognitive deficits in several domains. Noteworthy, while in animal studies MDMA increases oxidative stress, cannabinoids have antioxidative and antiinflammatory properties, supporting the idea that cannabinoids might also have neuroprotective effects against MDMA-neurotoxicity in humans.

The literature on the long-term effects of each substance and/or their combination on cognitive functions, memory, mood, and impulsivity is inconsistent. Indeed, several reports demonstrated that deficits in memory, learning, or verbal fluency, as well as self-reported psychopathological problems such as depression, anxiety, paranoid ideation, and obsessive-compulsive behavior are mainly associated with cannabis use, rather than with ecstasy (Gouzoulis-Mayfrank & Daumann, 2006).

However, other studies revealed a clear relationship between neuropsychobiological deficits and MDMA use, rather than cannabis use, that is, memory/cognitive deficits were related to ecstasy, but not to cannabis use. Indeed, higher self-rated psychiatric symptoms were reported in both light and heavy ecstasy polydrug users than in the control group that included cannabis users (Parrott, 2006). Several factors might explain these conflicting findings, including the relative use of cannabis and ecstasy, the amount of each drug used (heavy versus light users), and the psychobiological function examined. MDMA and cannabis may also influence different cognitive aspects, that is, cannabis use has been associated with everyday memory problems, while MDMA use accentuates prospective memory problems (Parrott, 2006).

As regards the potential neuroprotective effect of cannabis on ecstasy users, cannabis + MDMA users were found to have fewer psychobiological problems (ie, lower rates of anger, hostility, depression, and negative symptoms) than noncannabis users (Gouzoulis-Mayfrank & Daumann, 2006). Moreover, altered brain activation and poor working performance were detected in MDMA users, and the concomitant use of cannabis was suggested to improve the MDMA-induced alterations (Parrott, 2006). Notably, coadministration of these two drugs did not worsen cognitive impairments induced by either drug (Dumont, van Hasselt, de Kam, & Van Gerven, 2011).

Despite the wide consumption of METH + cannabis, only a few clinical studies have investigated the interactions between these two drugs, and their acute and long-lasting effects.

A positron emission tomography study showed that the combined use of these two drugs caused reduced regional cerebral glucose metabolism in the frontal, temporal, and striatal brain areas of METH + marijuana (MJ) users during completion of a continuous performance task, in comparison to individuals that abused METH

alone, but no differences were observed in continuous performance task accuracy between the two groups (Gouzoulis-MayFrank & Daumann, 2006). Accordingly, cognitive functioning in several ability areas (ie, verbal fluency, abstraction/executive functioning, attention/working memory, learning, and delayed recall/retention) in METH + MJ were found not to differ significantly from the control group, or METH users without a history of MJ dependence (Gonzalez et al., 2004). Recently, decreased frontal N-acetylaspartyl glutamate levels, an indicator of intact neuronal integrity, were found in adolescents using METH + MJ, compared to healthy controls and METH groups, supporting the idea that concomitant heavy cannabis and METH use may induce neurotoxicity in the adolescent brain (Sung, Carey, Stein, & Ferrett, 2013).

Further clinical and preclinical studies are needed to clarify if concurrent use of cannabis and MDMA/METH worsens or improves neurocognitive functions.

Finally, a paucity of clinical data are available on the effects of cathinone derivatives given alone or in combination with cannabis. In humans, cathinones induce primarily stimulant effects such as euphoria, elevated mood, mental stimulation, intensification of sensory sensations, increased energy and sociability, empathy connection, and decreased inhibition (Prosser & Nelson, 2012). However, high doses of cathinones lead to hallucinations, paranoia, agitation, self-mutilation, psychosis, tachycardia, increased blood pressure, and hemorrhage.

Chronic khat use is associated with impaired inhibitory control, and long-term use of cathinone is associated with dysfunctions in the prefrontal cortex, and reduced DA levels in the striatum (Colzato, Ruiz, van den Wildenberg, & Bajo, 2011). Even before clubbing (and after recent drug use), mephedrone users performed worse than nonusers on cognitive tasks and, contrary to controls, showed decreased performance in verbal learning and fluency (Herzig, Brooks, & Mohr, 2013). Yet, when subjects were analyzed for their use of other drugs or preexisting factors, it turned out that prior polydrug use (cannabis + alcohol in particular, but also AMPH) and related psychological traits (depression) were likely to affect cognitive functioning in the sample studied.

The presence of some of these substances was detected through surveys/questionnaires, studies on drug samples and biological fluids, and case reports. In one instance, a driver stopped by officers of the Massachusetts State Police and subjected to blood sample analysis revealed the presence of clonazepam, 7-aminoclonazepam, carboxy-THC, diphenhydramine, and MDMA (Elian & Hackett, 2014). The analysis of fluid body samples obtained from suspected NPS intoxication cases detected synthetic cannabinoids of the JHW series and cathinones (methylone, butylone, mephedrone, flephedrone, and methcathinone), often present in combinations of two or more drugs (Papaseit, Farrè, Schifano, & Torrens, 2014). Most worrisome, the recent trend seems to be to mix different types of designer drugs like cathinones (stimulants) or tryptamines (hallucinogens) with synthetic cannabinoids.

MINI-DICTIONARY

Amphetamine-like substances Although there are a variety of amphetamines, in this chapter, amphetamine-like substances (ALS) stands for amphetamine (AMPH), methamphetamine (METH), 3,4-methylenedioxymethamphetamine (MDMA), and cathinones. The first three compounds are frequently coabused with cannabis, while cathinones are the most popular new psychoactive substances (NPS).

Chatinone 2-amino-1-phenylpropanone, a natural compound of the khat plant.

Drug addiction A chronic, relapsing brain disease that causes compulsive drug-seeking and use, despite harmful consequences to the drug addict and those around them.

Dopamine A monoamine neurotransmitter. In particular, the mesolimbic dopamine system that projects from the ventral tegmental area to the nucleus accumbens has been implicated in the rewarding effects of drugs of abuse.

Ecstasy or MDMA This drug is a phenylethylamine, a molecule that belongs to the group of synthetic derivatives of methamphetamine. It is an illegal drug, synthesized for the first time in 1912, with a prevailing action on the serotonergic system.

NPS A new psychoactive substance is defined as a new narcotic or psychotropic drug, in pure form or in preparation.

Polydrug use A common phenomenon defined as the consumption of more than one drug during a specific time period.

Reward system The brain circuit that controls an individual's response to natural rewarding stimuli, such as food, sex, and social interaction.

Cannabinoids and the Cannabinoid Receptors: An Overview

D. Lu, D.E. Potter

Department of Pharmaceutical Sciences, Rangel College of Pharmacy, Texas A&M University, Kingsville, TX, United States

SUMMARY POINTS

- Cannabinoids are a group of biologically active ingredients isolated from cannabis. The representative member of cannabinoids is (−)-Δ^9-tetrahydrocannabinol (Δ^9-THC), which binds to cannabinoid receptors to exert its biological effects, including psychoactive effects.
- So far, at least two types of cannabinoid receptors have been identified and defined respectively as cannabinoid receptor 1 (CB1) and cannabinoid receptor 2 (CB2), which are G-protein coupled receptors specifically responding to phytocannabinoids, endocannabinoids and synthetic cannabimimetic compounds.
- The cannabinoid receptors are widely distributed. The CB1 receptors are primarily found in the central nervous system, whereas the CB2 receptors are mainly found in the cells of immune and hematopoietic systems.
- Activations of the cannabinoid CB1 and CB2 receptors generally lead to the inhibition of adenylyl cyclase, and the activation of mitogen-activated protein kinases (MAPKs).
- The cannabinoid receptors are involved in a large number of physiological processes, such as neuronal development, food intake and energy balance, perception process, and immune modulation.

KEY FACTS

- According to world health organization, about 147 million people worldwide (2.5% of the world population) consume cannabis mainly for recreational purposes.
- Both short-term and long-term uses of cannabis have been linked to certain health hazards such as altered senses, impaired body movement, memory, and learning functions.
- Some synthetic cannabis-mimetics are more potent than natural cannabis ingredients. They may affect the body functions much more powerfully than cannabis. Their actual effects are unpredictable. In some cases, they can be even life-threatening.
- While cannabis is an illicit drug, it has been demonstrated with a number of potential medical usefulness including treatment of asthma and glaucoma, as an antidepressant, appetite stimulant, anticonvulsant, antispasmodic, antiemetic, and analgesic.
- By far, three cannabis-based medications have been developed, which include Dronabinol®, Cesamet®, and Sativex®. The first two were proved by FDA for the treatment of nausea and vomiting in the advanced stages of cancer and AIDS, whilst Sativex® was approved in some European countries for the treatment of spasticity from multiple sclerosis.
- By far in the United Sates, 25 states and Washington D.C. have legalized cannabis for medical uses.

LIST OF ABBREVIATIONS

Δ^9-THC	(−)-Δ^9-Tetrahydrocannabinol
AP-3	Adaptor protein complex-3
BC	Before Christ
cAMP	Cyclic adenosine monophosphate
CB1	Cannabinoid receptor type 1
CB2	Cannabinoid receptor type 2
cDNA	Complementary DNA
CHO	Chinese hamster ovary
CNS	Central nervous system
DNA	Deoxyribonucleic acid
FAAH	Fatty acid amide hydrolase
FAN	Factor associated with neutral sphingomyelinase activation
G-protein	Guanine nucleotide-binding protein
GABA	γ-Aminobutyric acid
GASP1	GPCR-associated sorting protein 1
GPCR	G-protein-coupled receptor
JNK	C-Jun N-terminal kinase
MAGL	Monoacylglycerol lipase
PI3K	Phosphatidylinositide 3-kinase
TM	Transmembrane

INTRODUCTION

Cannabis has a long history for medical application, and is a psychoactive substance for recreational use. Isolation of its major active components (cannabinoids) and the synthesis of potent cannabimimetics led to the discoveries of two G-protein coupled receptors that specifically respond to cannabinoids, and are designated as cannabinoid receptor 1 (CB1) and cannabinoid receptor 2 (CB2). Subsequently, endogenous ligands for the cannabinoid receptors (endocannabinoids) were identified. The cannabinoid receptors and the endocannabinoids are involved in modulation of many physiological functions, not only in the central and peripheral nervous systems, but also in a number of peripheral sites within the human body: endocrine system, immune system, the gastrointestinal tract, cardiovascular system, and the reproductive system. The two described cannabinoid receptors are encoded by different genes, and exhibit a 44% homology in their primary structures. Functionally, they belong to the super family of G-protein coupled receptors, and transduce signals of ligand binding into various biological responses, through both G-protein-mediated and G-protein-independent pathways.

Generally, the major role of the CB1 receptor is to modulate the release of neurotransmitters, whereas the major function of the CB2 receptor is to mediate the immune modulatory effects of cannabinoids, among others. The functions of cannabinoid receptors can be modulated by: (1) a variety of ligands (agonists, partial agonists, neutral antagonists, and inverse agonists) that target the orthosteric binding sites on the receptors, or (2) allosteric modulators that bind to the allosteric binding sites of the receptors. With the development of a variety of new ligands of cannabinoid receptors, intensive research has been carried out in the last two decades to clarify the roles of cannabinoid receptors in physiological and pathological conditions, as well as to determine how the disease states involving the cannabinoid receptors can be treated more effectively and safely. In this chapter, some historical and fundamental aspects about cannabinoids and cannabinoid receptors are reviewed.

CANNABIS AND CANNABINOIDS

The plant *Cannabis sativa* Linne is one of the oldest plants used by humans as folklore medicine. The earliest record of medical use of cannabis appeared around 2737 BC in a Chinese pharmaceutical compendium, *Shennong Bencao Jing* (The Divine Farmer's Materia Medica), in which *Cannabis* was documented as a magic mood- and memory-booster, an antiinflammatory herb, and as a therapeutic for many other conditions, including disorders of the female reproductive tract, constipation, gout, rheumatism, stroke, and absent-mindedness (Yang, 1998). During the long history of agricultural migration of cannabis from China and India to the Middle East and Europe, various medical usefulness of cannabis have been noted (Mack & Joy, 2000). In 1850, cannabis was included in the US pharmacopeia for many ailments, including neuralgia, tetanus, typhus, cholera, rabies, dysentery, alcoholism, opiate addiction, anthrax, leprosy, incontinence, gout, convulsive disorders, tonsillitis, insanity, excessive menstrual bleeding, and uterine bleeding (Boire & Feeney, 2006). The broad pharmacological effects of cannabis stimulated the search for its bioactive ingredients, and led to the isolation and structural characterization of (−)-Δ^9-trans-(6a*R*,10a*R*)-tetrahydrocannabinol (Δ^9-THC) in 1964 (Gaoni & Mechoulam, 1964). Δ^9-THC is the most psychoactive substance present in cannabis. To date, 489 constituents have been isolated from cannabis (Elsohly & Slade, 2005). These natural compounds can be classified into 18 distinct chemical groups such as cannabinoids (~70), terpenoids (~103), hydrocarbons (~50), amino acids (~18), steroids (~11), and flavaniidglycosides (~19), among others (Elsohly & Slade, 2005; Turner, Elsohly, & Boeren, 1980). Cannabinoids is a group of 70 terpenophenolic compounds that generally contain a monoterpene moiety connected to a phenol ring, having a 3- to 5-carbon alkyl chain located in the position meta to the phenolic hydroxyl group. There are 12 major

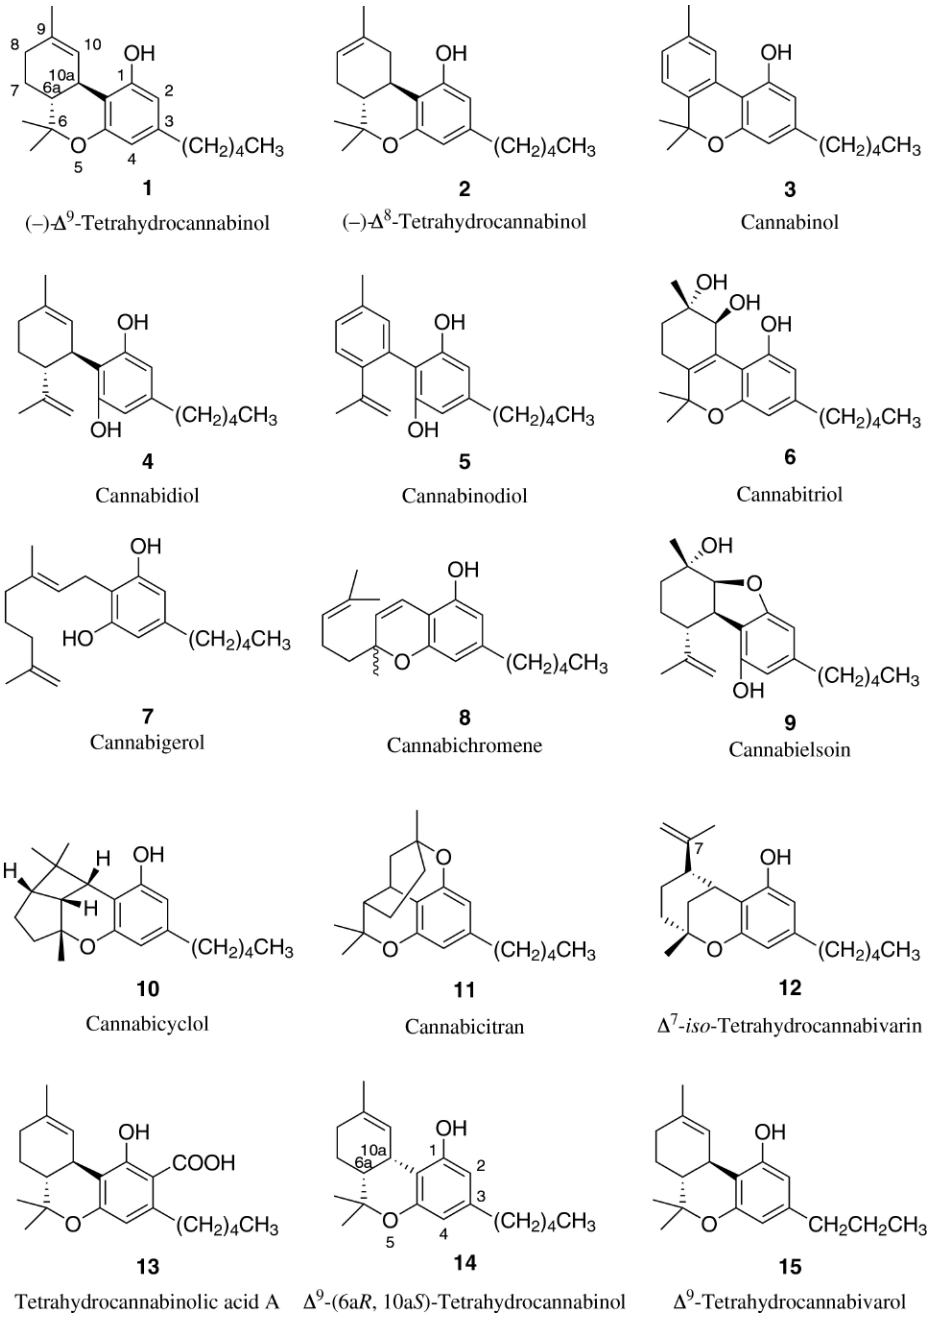

FIGURE 58.1 **Chemical structures of main phytocannabinoids isolated from *Cannabis sativa L.***

types of cannabinoids, all of which are derived from cannabigerol type precursors, and differ mainly in the way how the precursors are chemically cyclized within the structure. The representative members of cannabinoids are illustrated in Fig. 58.1.

The discoveries of endogenous cannabinoids (endocannabinoids) and the development of synthetic cannabimimetic compounds have prompted the use of "phytocannabinoids" to describe plant-derived cannabinoids. Among these phytocannabinoids, (−)-Δ^9-THC (1) and (−)-Δ^8-THC (2) are two psychologically active constituents. Besides the psychoactive cannabinoids, other cannabinoids such as cannabinol (3), cannabidiol (4), and cannabigerol (7) also exhibit a variety of pharmacological effects (Izzo, Borrelli, Capasso, Di Marzo, & Mechoulam, 2009). Notably, cannabidiol (4) and cannabigerol (7) are not psychotropic because of their inability to interact with cannabinoid CB1 receptors in the brain (Izzo et al., 2009).

Consumption of *Cannabis* can lead to a variety of behavioral effects such as sedation, impairment

of short-term memory, motor incoordination; mood alternations that include euphoria, calmness, anxiety, or paranoia. Because of the highly lipophilic properties of phytocannabinoids, early scientific inquires on how cannabis works led to a hypothesis that cannabinoids may elicit their biological effects through nonspecific perturbing the membrane lipids (Lawrence & Gill, 1975). However, this concept was diminished by the discovery of the first cannabinoid receptor in the late 1980s.

CANNABINOID RECEPTORS: WHAT THEY ARE

Discovery of Cannabinoid Receptors

Although nonspecific action of cannabis was thought to be possible, a series of pharmacological studies in late 1980s indicated a receptor-mediated mechanism of action (Howlett & Fleming, 1984; Howlett, Qualy, & Khachatrian, 1986; Little, Compton, Johnson, Melvin, & Martin, 1988). The first evidence for the existence of a brain type cannabinoid receptor came from demonstration of the specific binding sites of synthetic cannabimimetics in rat brain P2 membranes and synaptosomes (Devane, Dysarz, Johnson, Melvin, & Howlett, 1988). This landmark finding was followed by the confirmation of cannabinoid-specific binding sites in the brains of several other mammalian species, including human (Herkenham et al., 1990). The conclusive proof for the existence of a cannabinoid receptor was provided by cloning and expression of a complementary DNA (cDNA), SKR6, from a rat cerebral cortex cDNA library (Matsuda, Lolait, Brownstein, Young, & Bonner, 1990). The protein product of SKR6 differed significantly from any other known receptor in amino acid sequence, and shows high selectivity for binding to phytocannabinoids and cannabimimetic agents. Because the distribution of its mRNA matched well with the binding sites of cannabimimetics in the brain, this receptor was named as cannabinoid receptor, formalized later as cannabinoid receptor type 1 (CB1). Soon after the identification of CB1 receptor, homology cloning disclosed another form of cannabinoid receptor from the human promyelocytic cell line HL60 (Munro, Thomas, & Abu-Shaar, 1993). Because its mRNA could not be detected in the central nervous system during the initial characterizations, this receptor was firstly recognized as a peripheral cannabinoid receptor, and later was formally designated as cannabinoid receptor type 2 (CB2). Following the cloning of human CB2, the rat (Griffin, Tao, & Abood, 2000) and mouse (Shire et al., 1996), CB2 receptors were disclosed. Unlike the CB1 receptor which exhibits high amino acid identity across human, rat, and mouse (>97%) (Abood, Ditto, Noel, Showalter, & Tao, 1997; Gerard, Mollereau, Vassart, & Parmentier, 1991), the CB2 receptor displays only 81% amino acid identity between human and rat, and 82% identity between human and mouse, respectively. Notably, the sequences of human, rat, and mouse CB2 receptors markedly differ at the C-terminus. The mouse CB2 is shorter by 13 amino acids; the rat CB2 is 50 amino acids longer than the human CB2 (Console-Bram, Marcu, & Abood, 2012).

Endogenous Ligands of Cannabinoid Receptors

The cloning of CB1 and CB2 receptors motivated numerous efforts to pursue the endogenous ligands that can activate the cannabinoid receptors. It was then demonstrated that mammalian tissues do synthesize and release lipid-derived molecules that can activate cannabinoid receptors and generate pharmacological effects similar to those from Δ^9-THC (Di Marzo, De Petrocellis, & Bisogno, 2005; Hanuš, 2009; Martin, Mechoulam, & Razdan, 1999). The first identified endogenous cannabinoid, *N*-arachidonoylethanolamine (anandamide), was isolated from porcine brain in 1992 (Hanuš, 2009). Its identity as an endogenous cannabinoid was proven by many in vitro and in vivo studies (Felder et al., 1996; Martin et al., 1999). Later, another lipid derivative, 2-arachidonoylglycerol (2-AG) isolated from canine gut was shown to be a potent endogenous cannabinoid, and binds to the CB1 and CB2 receptors more devotedly than anandamide (Martin et al., 1999). In the brain, the concentration of 2-AG is about 50–500-fold higher than the concentration of anandamide. Additionally, 2-AG behaves as a full agonist for the CB1 and CB2 receptors, whereas anandamide is a partial agonist at both receptors (Di Marzo et al., 2005). The degradation of anandamide is primarily catalyzed by fatty acid amide hydrolase (FAAH), while 2-AG is mainly metabolized by monoacylglycerol lipase (MAGL) (Di Marzo et al., 2005). Other compounds that have been shown as endocannabinoids include noladin ether, *N*-arachidonoyldopamine, *N*-docasatetraenoylethanolamide, dihomo-γ-linolenoylethanolamide, O-arachidonoyl-ethanolamine (virodhamine), and meadethanolamide (Di Marzo et al., 2005; Hanuš, 2009; Martin et al., 1999). The structures of these endocannabinoids are presented in Fig. 58.2. The identification of endogenous ligands completed the discovery of cannabinoid CB1 and CB2 receptors.

The Structural Characteristics of CB1 and CB2 Receptors

The CB1 receptor is a protein encoded by CNR1 gene located on human chromosome 6, whereas the CB2 receptor is encoded by CNR2 gene located on chromosome 1 (Yao & Mackie, 2009). Expressions of the human CNR1 and CNR2 genes, respectively, provide a protein with 472 amino acids (CB1), and a protein with 360 amino acids (CB2). The primary structures of human CB1 and CB2 receptors are illustrated in Fig. 58.3.

FIGURE 58.3 **Primary structures of CB1 and CB2 receptors.** The amino acid sequence of the human CB1 (top panel) and CB2 (lower panel) receptors. The human CB1 receptor comprises of 472 amino acids, whereas the human CB2 receptor contains 360 amino acids. The individual amino acid is presented by one letter abbreviation. The regions shown with *red letters* are transmembrane domains. The length and sequence homology of the third intracellular loop (regions represented with *blue characters*) and the C-terminals (regions represented with *green characters*) of the two receptor subtypes are notably different. The protein sequences and domain assignments were retrieved from the freely accessible protein-sequence database Uniprot (http://www.uniprot.org).

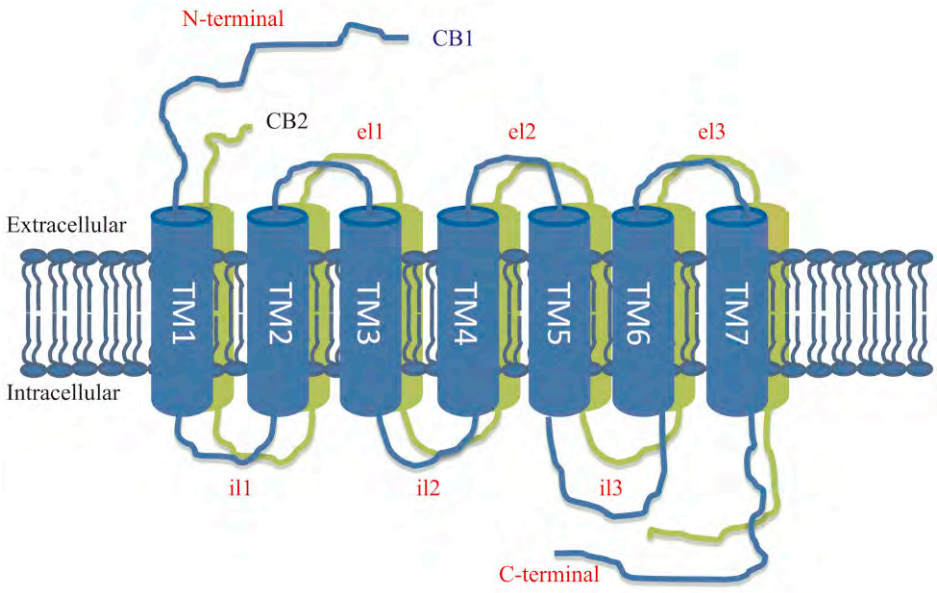

FIGURE 58.4 **Schematic representation of the cannabinoid CB1 and CB2 receptors.** The *blue* model represents CB1 receptor and the *green* model represents the CB2 receptor. *TM*, transmembrane; *el*, extracellular loop; *il*, intracellular loop. The CB1 receptor is a larger protein, and has additional 72 amino acid residues in the N-terminal segment, 13 additional residues in the third intracellular loop, and 14 additional residues in the C-terminal region.

The two cannabinoid receptors belong to the largest family of receptors, which couple to guanine-nucleotide-binding proteins (G-proteins) at their intracellular sites. They share the structural characteristics of all G-protein-coupled receptors (GPCRs), possessing seven hydrophobic domains that transpass the cell membrane seven times, forming helix bundles when embedded in cell membrane. The seven transmembrane domains are linked by three extracellular and three intracellular loops, an extracellular N-terminal, and an intracellular C-terminal (Fig. 58.3). Structurally, the CB1 and CB2 receptors distinguish themselves from many other GPCRs in two aspects (Matsuda, 1997). Unlike many other GPCRs, both CB1 and CB2 receptors do not contain conserved cysteine residues within the second extracellular domain (el1), whereas the third extracellular domain (el2) contains two or more cysteines. The conserved cysteine residues in the second and third extracellular domains of GPCRs appear to stabilize the tertiary structure of the receptor through the formation of intramolecular disulfide linkage with the neighboring transmembrane domains (TMs). Additionally, both CB1 and CB2 lack a highly conserved proline residue in the fifth transmembrane (TM5) domain, by which a structural kink could be formed usually in the helix (Matsuda, 1997). In comparison with the CB2 receptor, the CB1 receptor has an additional 72 amino acid residues in the N-terminal segment, 15 additional residues in the third intracellular loop, and 13 additional residues in the C-terminal region (Figs. 58.3 and 58.4). The sequence homology between the two cannabinoid receptors is 44% in the full-length protein, and ranges from 33% to 82% within the seven transmembrane regions (Fig. 58.4). The highest homology between CB1 and CB2 is found in the transmembrane TM2, TM3, TM6, and TM7 domains (TM1: 50%; TM2: 66%; TM3: 80%; TM4: 33%; TM5: 40%; TM6: 60%; and TM7: 82%) (Matsuda, 1997). The primary structures of CB1 and CB2 receptors show that the length and sequence homology of the third intracellular loops and the C-terminals of the two receptors are considerably different. These variations might affect their cellular response to a ligand, because these regions are known to mediate G-protein signal transduction (Howlett & Shim, 2004), as well as receptor desensitization and internalization (Hsieh, Brown, Derleth, & Mackie, 1999).

At present, X-ray crystallographic structures of cannabinoid receptors remain unknown. In the absence of crystallographic structures for CB1 and CB2 receptors, computational homology models of human CB1 receptor (Shim, Welsh, & Howlett, 2003) and human CB2 receptor (Raitio, Salo, Nevalainen, Poso, & Jarvinen, 2005; Xie, Chen, & Billings, 2003) have been respectively constructed using bovine rhodopsin as the prototype of GPCRs. Site-directed mutation and computer-modeling have been employed to identify the key amino acids (or motif) involved in ligand binding and receptor activation/deactivation. Notable residues identified include Lys192 of CB1 receptor (Song & Bonner, 1996) and Ser112/T116 of CB2 receptor (Tao et al., 1999), which are instrumental for the binding of most cannabinoid ligands. The functional residues/motif involved in ligand binding to the CB1/CB2 receptor has been thoroughly reviewed (Ortega-Gutierrez & Lopez-Rodriguez, 2005).

THE CANNABINOID RECEPTORS: WHERE THEY ARE

The cannabinoid receptors are widely distributed in the human body. CB1 is expressed primarily in the central nervous system (CNS), and is the most abundant G-protein-coupled receptor in the brain (Mackie, 2005). Quantitative autoradiography revealed that the concentration of CB1 receptors in brain is comparable to those of cortical benzodiazepine receptor, striatal dopamine receptor, and whole-brain glutamate receptor (Herkenham et al., 1990). The highest density of CB1 receptors is found in the basal ganglia, particularly in putamen, which is involved in motor control. High levels of CB1 receptors are also detected in cerebellum, hippocampus, and cerebral cortex. These brain regions are involved in coordinating body movements, learning and memory, and higher cognitive functions, respectively (Mackie, 2005; Pertwee, 1997). Moderate levels of CB1 receptors were also found in the brainstem, spinal cord, hypothalamus, amygdala, central gray, and nucleus of the solitary tract (Pertwee, 1997). Besides their presence in CNS, CB1 receptors have been found in periphery, but at much lower level compared to its brain level. Some immunocytochemical analyses of CB1 mRNA indicated the presence of CB1 receptor in a variety of peripheral tissues/organs, including liver, pancreas, testis, fat, skeletal muscle, retina, sperms, peripheral neurons, adrenal gland, heart, lung, prostate, uterus, ovary, bone marrow, spleen, thymus, and tonsils (Bouaboula et al., 1993; Galiegue et al., 1995; Pertwee, 1997; Rice, Shannon, Burton, & Fiedeldey, 1997).

Early investigations of the mRNA of CB2 receptor in the cerebral tissues led to the inference that CB2 receptor is absent in the central nervous system, and predominantly expressed in the tissues/organs of the immune system, such as spleen, tonsil, thymus, and lymphoid tissues (Galiegue et al., 1995; Munro et al., 1993; Schatz, Lee, Condie, Pulaski, & Kaminski, 1997). Of these peripheral sites, tonsils exhibit the highest CB2 mRNA level, which is even higher than the total concentration of CB1 mRNA in the brain (Galiegue et al., 1995). Quantitative analysis of CB2 mRNA reveals that moderate to low levels of CB2 receptors can be found in pancreas, bone marrow, uterus, and lung. Likewise, high concentrations of CB2 receptors can be identified in human leukocytes such as B-cells, NK-cells, monocytes polymorphonuclear neutrophils, $CD8^+$-T-lymphocytes and $CD4^+$-T-lymphocytes (Bouaboula et al., 1993; Galiegue et al., 1995). Although early investigations of CB2 receptor did not detect this receptor in the brain, Van Sickle et al. (2005) have demonstrated that functional CB2 receptors do exist in the central nervous system, albeit in much lower concentration than in the periphery. Several recent reports also disclosed the CB2 immunoreactivity in many brain areas, such as the hippocampal formation, olfactory bulb, cortex, midbrain, and thalamus (Gong et al., 2006; Onaivi et al., 2006, 2008a,b). These results support the conclusion that CB2 receptor is not an exclusively peripheral cannabinoid receptor. Additionally, CB2 receptors show an inducible nature under certain disease conditions. For example, microglial cells in healthy brain do not appear to express CB2. However, in neurodegenerative disorders associated with the activation of brain microglial cells, such as Alzheimer and Huntington diseases, the expression of CB2 receptors in the brain can be significantly elevated (Benito et al., 2003; Palazuelos et al., 2009). The multifocal expressions of CB2 receptors in the brain suggest that CB2 receptors may play broader roles in the central nervous system than previously postulated.

CANNABINOID RECEPTORS: WHAT THEY DO

The cannabinoid receptors as part of the endocannabinoid system have been shown to play important roles in a variety of physiological conditions, including neuronal development, neuronal plasticity, food intake and energy balance, perception process, immune modulation, cell apoptosis, cardiovascular and reproductive functions (Marzo, Bifulco, & De Petrocellis, 2004; Rodriguez de Fonseca et al., 2005). The multifaceted functions of cannabinoid receptors are rooted by their cellular physiology and complex signaling pathways in transducing the binding of cannabinoid ligands into biological responses.

Cell Physiology of Cannabinoid Receptors

Many studies have demonstrated that endocannabinoids function as retrograde messengers in the CNS. They are released from postsynaptic neurons in a calcium-dependent manner, and traverse retrogradely onto presynaptic cannabinoid CB1 receptors. Subsequently, they produce a transient or prolonged reduction in the release of neurotransmitters such as the inhibitory γ-aminobutyric acid (GABA), excitatory glutamate, acetylcholine, and noradrenaline (Piomelli, 2003; Rodriguez de Fonseca et al., 2005). Unlike classical peptide neurotransmitters, endocannabinoids are not presynthesized and stored in vesicles before release. In contrast, they are synthesized "on demand," via enzymatic pathways triggered by a rapid increase of intracellular calcium through cell depolarization or receptor activation. At present, the knowledge concerning the physiology of CB2 receptors is relatively less than that of CB1 receptors. Given the high level of CB2 receptors on the cells of immune and hematopoietic systems, CB2 receptors are most likely involved in inflammation-associated pathologies. In general, CB2 receptors are involved in regulation of immune cells in several ways, including: (1) inducing immune cell apoptosis, (2) suppressing proliferation of immune cells and the

production of proinflammatory cytokines/chemokines, (3) increasing secretion of antiinflammatory cytokines, (4) inducing regulatory T cells, and (5) promoting the trafficking and migration of immune cells (Klein & Cabral, 2006; Rom & Persidsky, 2013).

Signal Transductions of CB1 and CB2 Receptors

Cannabinoid receptors transduce signals through various pathways: G-protein-dependent processes (Demuth & Molleman, 2006; Pertwee, 1997) and G-protein-independent processes (Turu & Hunyady, 2010; Velasco et al., 2005). The major signal transductions of both CB1 and CB2 receptors are primarily mediated through the inhibitory G_i and G_o proteins. However, under certain conditions, signal transductions of CB1 receptor through $G_{q/11}$ and stimulatory G_s are also possible (Turu & Hunyady, 2010). In contrast to CB1 receptors, CB2 receptors do not transduce signals through stimulatory G_s (Demuth & Molleman, 2006). Upon stimulation by agonists, cannabinoid receptors modulate adenylyl cyclase and, consequently, alter the cellular production of cAMP. Although activation of cannabinoid receptors typically suppresses adenylyl cyclase and downregulates signaling responses mediated by second messenger cAMP, evidence suggests that the isoforms of adenylyl cyclase expressed in cells determine the outcome of cAMP production. For instance, in COS-7 cells that coexpress CB1/CB2 with nine isoforms of adenylyl cyclase 1 to 9, activation of the cannabinoid receptors CB1 and CB2 inhibited the activity of adenylyl cyclase isoforms 1, 3, 5, 6, and 8. In contrast, adenylyl cyclase isozymes 2, 4, and 7 were stimulated (Rhee, Bayewitch, Avidor-Reiss, Levy, & Vogel, 1998). In addition, the CB1 and CB2 receptors can carry signal transductions through the activation of phosphatidylinositide 3-kinases (PI3K), but with different mechanisms (Demuth & Molleman, 2006; Howlett & Shim, 2004). Both the CB1 and CB2 cannabinoid receptors regulate the phosphorylation and activation of different members of all three families of mitogen-activated protein kinases (MAPKs), including p44/42 MAP kinase, p38 kinase, and JUN-terminal kinase (Atwood & Mackie, 2010; Turu & Hunyady, 2010). Unlike the activation of CB2 receptor, which generally has no effect on ion channels, activation of CB1 receptor inhibits N- and P/Q-type voltage-gated Ca^{2+} channels and activates A-type and G-protein-coupled inwardly-rectifying K^+ channels (GIRK) (Howlett, 2005). Along with the G-protein mediated signal transductions, the CB1 receptor can interact with a variety of non-G protein partners (eg, β-arrestins, adaptor protein AP-3, GPCR-associated sorting protein 1 (GASP1), and the adaptor protein FAN) to control receptor signaling or trafficking (Howlett, Blume, & Dalton, 2010; Smith, Sim-Selley, & Selley, 2010). The CB1 and CB2 cannabinoid receptors can also transduce signals through G-protein independent pathways that employ ceramide as the second messenger (Velasco et al., 2005). Activation of cannabinoid receptors impacts both the short-term and long-term ceramide accumulation, which is respectively resulted from sphingomylin hydrolysis and ceramide de novo synthesis. Ceramide, in turn, mediates cannabinoid-induced metabolic regulation and cell apoptosis (Herrera et al., 2006; Velasco et al., 2005). The major signaling pathways of the CB1 and CB2 receptors are summarized in Fig. 58.5.

The signaling events of CB1 and CB2 receptors can be attenuated by desensitization of the receptor, followed by an internalization process (Atwood, Straiker, & Mackie, 2012). Desensitization involves G-protein-receptor-kinase-mediated phosphorylation of multiple serine/threonine residues of the receptors, followed by binding of the β-arrestins. The internalized receptors can be either transported to endosomes for dephosphorylation, and then returned to the cell membrane for the next signaling event, or transported to lysosomes for degradation. Apart from the agonist-initiated signal transductions, both CB1 and CB2 receptors can induce cellular responses through constitutive activities (so called "constitutive tone"). In the absence of agonists, the two cannabinoid receptors have been shown to exhibit a spontaneous activation of $G_{i/o}$-proteins, and increased constitutive MAPK-activating properties (Yao & Mackie, 2009). These constitutive activities can be respectively attenuated by inverse agonists that can selectively interact with the CB1 and CB2 receptors.

CONCLUDING REMARKS

The isolation of Δ^9-THC from cannabis, the identification and cloning of the two cannabinoid receptors, and the discovery of endogenous CB ligands, revealed the existence of the endocannabinoid system. In the past three decades, investigation of the molecular biology and pharmacology of the endocannabinoid system has implicated its importance in a large number of physiological functions in human. Modulating the functions of the cannabinoid receptors, either directly or indirectly, holds therapeutic promises for ameliorating a number of pathological conditions, ranging from the diseases of nervous systems, such as psychiatric disorders, Parkinson and Huntington disease, multiple sclerosis and spinal cord and brain injuries, to pain, inflammation, and cancer, as well as some cardiovascular and metabolic disorders including atherosclerosis, myocardial infarction, hypertension, stroke, obesity/metabolic syndrome, and osteoporosis, among others (Pacher, Bátkai, & Kunos, 2006). Further understanding the molecular biology and pharmacology of the cannabinoid receptors will create more opportunities for the discovery of novel and safer medications by targeting of cannabinoid receptors more selectively.

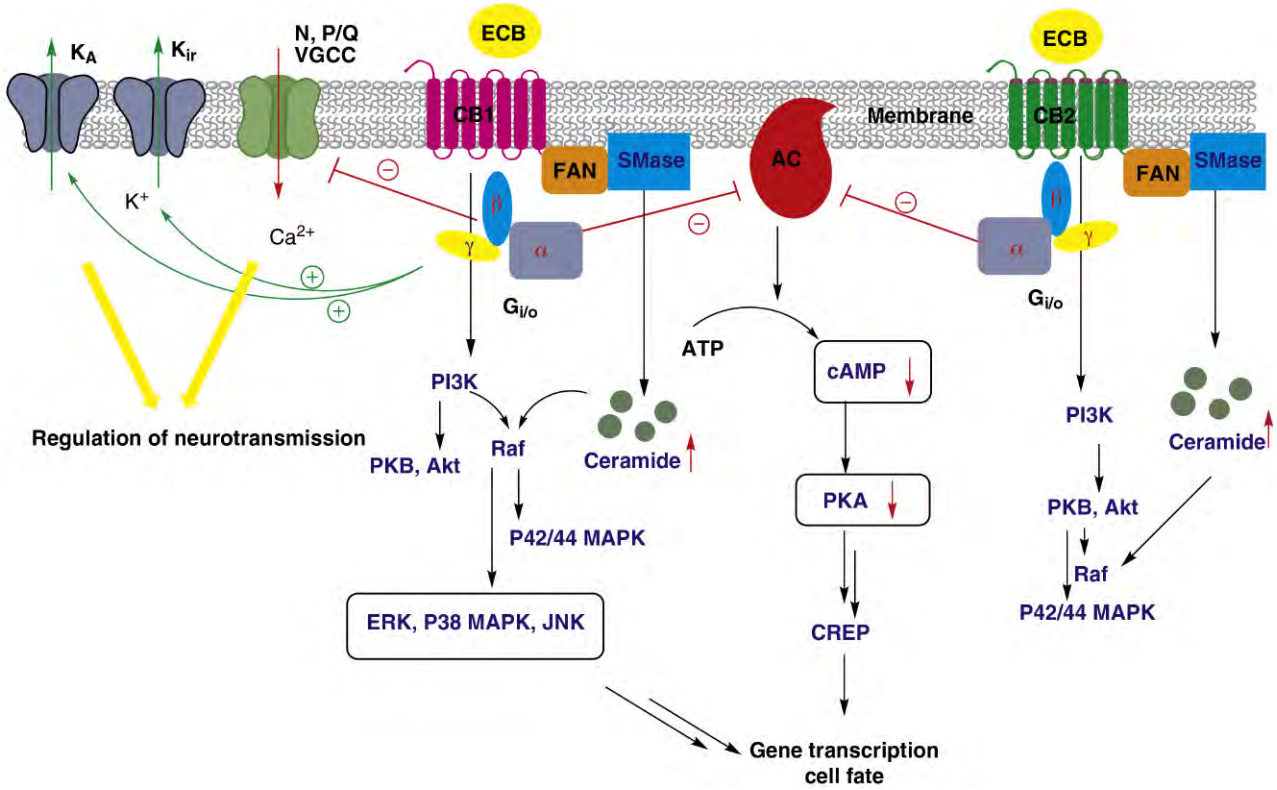

FIGURE 58.5 **Major signaling pathways initiated from activation of the cannabinoid CB1 and CB2 receptors.** The major signaling pathways initiated by the binding of agonists (ECB) to cannabinoid receptors involve the activation and dissociation of the coupled $G_{i/o}$-protein heterotrimers (ie, α and βγ subunits). The released G_α subunits interact with adenylyl cyclase (AC) and inhibit its activity in synthesis of cAMP. This decreases the activation of protein kinase A (PKA), which in turn downregulates PKA-mediated signaling events. The βγ subunits can evoke the phosphatidylinositide 3-kinase (PI3K) and protein kinase B (PKB) pathways, which in turn induce the phosphorylation of P42/44 MAPK and other members of MAPK such as JNK and p38 MAPK. The CB1 and CB2 receptors can also couple to non-G-protein partners such as FAN, which activates neutral sphingomyelinase (SMase) that mediates the generation of ceramide from sphingomyelin. While ceramide is involved in other functions, it can function as a second messenger to activate several downstream effectors, including ERK, JNK, and p38 that are further involved in the control of gene transcriptions and cell fate. Activation of CB1 receptor inhibits N and P/Q types of voltage gated calcium channels (VGCC), while positively regulates A-type K^+ (K_A), and inwardly rectifying K^+ (K_{ir}) channels. The modulations of ion channels by CB1 are independent of the cAMP pathway, and are involved in the regulation of neurotransmitter release. In contrast, activation of CB2 receptors generally does not regulate ion channels.

MINI-DICTIONARY

Cannabinoid receptors Cannabinoid receptors are the G-protein-coupled receptors that mediate the biological effects of phytocannabinoids, endocannabinoids, and synthetic cannabimimetic compounds.

Cannabinoids Cannabinoids are a group of biologically active compounds isolated from the plant cannabis, and are often referred to as phytocannabinoids, some of which are responsible for the psychoactive effects of cannabis.

Endocannabinoids Endocannabinoids are the molecules produced by human and animals which exhibit similar biological activities as phytocannabinoids.

G-protein-coupled receptors G-protein-coupled receptors (GPCRs) are membrane-bound signal transduction proteins that associate with guanosine nucleotide-binding proteins (G-proteins) on their intracellular side. Upon binding to certain type of chemical compounds, the GPCRs change shapes, and cause the disassembly of the associated G-proteins into subunits, which further transduce the signal to the downstream proteins and eventually lead to cellular responses.

Synthetic cannabimimetics Chemical compounds synthesized in laboratories that exhibit similar biological activities as phytocannabinoids.

CHAPTER

59

Signaling and Regulation of the Cannabinoid CB_1 Receptor

M.R. Hunter, D.B. Finlay, M. Glass

Department of Pharmacology and Clinical Pharmacology, Faculty of Medical and Health Sciences, University of Auckland, Auckland, New Zealand

SUMMARY POINTS

- CB_1 primarily signals through $G\alpha_{i/o}$ proteins, resulting in decreased adenylate cyclase activity and phosphorylation of ERK and other mitogen kinases.
- CB_1 can also signal through $G\alpha_s$, $G\alpha_q$, $G\alpha_{12/13}$, and $G\alpha_z$ pathways, depending on the cellular conditions and the agonist applied.
- A wide range of ion channels are modulated in response to CB_1 signaling.
- CB_1 is a constitutively active receptor.
- CB_1 signaling is attenuated by the processes of desensitization and internalization, which ultimately result in receptors being degraded. The cell must repopulate the cell surface with newly-synthesized receptors to regain CB_1-mediated signaling responses.

KEY FACTS ABOUT GPCRs

- Also called seven transmembrane or heptahelical receptors.
- Located in the cell membrane, and transduce signals across the cell membrane.
- Ligands (such as neurotransmitters, hormones or drugs) bind to the extracellular region resulting in a conformational change in the receptor which activates G proteins inside the cell.
- Activation of the G protein triggers a series of intracellular signaling reactions.
- G protein coupled receptors are thought to be desensitized by phosphorylation and internalization.

KEY FACTS ABOUT GPCR PHARMACOLOGY

- A drug which binds to a receptor and activates it is called an agonist.
- A drug which binds to a receptor, but does not activate it, or inactivate it, is called an antagonist. Antagonists produce their effects by preventing agonists from binding to the receptor.
- If a receptor has high basal activity in the absence of agonist (constitutive activity), then inverse agonism can be seen. An inverse agonist is a drug which binds to a receptor and inactivates it, resulting in decreased signaling.

LIST OF ABBREVIATIONS

Δ^9-THC	Δ^9-Tetrahydrocannabinol
2-AG	2-arachidonoylglycerol
cAMP	Cyclic adenosine monophosphate
CB_1	Cannabinoid receptor 1
CB_2	Cannabinoid receptor 2
ERK/pERK	Extracellular signal-regulated kinase/ phosophorylated extracellular signal-regulated kinase
GDP/GTP	Guanosine diphosphate/guanosine triphosphate
GIRK	G protein coupled inwardly rectifying K^+ channels

GRK G protein coupled receptor kinases
PI3K Phosphoinositide 3-kinase
PLC Phospholipase C
PTX Pertussis toxin

INTRODUCTION

Cannabis-like (cannabinoid) agonists such as Δ^9-tetrahydrocannabinol (Δ^9-THC) have long been reported to exert inhibitory effects on the activity of the enzyme adenylate cyclase, which regulates intracellular levels of the second messenger cyclic adenosine monophosphate (cAMP) (Dill & Howlett, 1988). The receptors found to be responsible for this functional effect are G protein coupled receptors (GPCRs). There are currently two confirmed GPCRs which primarily respond to cannabinoids, named the type 1 cannabinoid receptor (CB_1) and type 2 cannabinoid receptor (CB_2). While there is some evidence that a third, or possibly fourth, cannabinoid receptor may exist (Pertwee et al., 2010), this chapter will focus on CB_1 as the receptor mediating the psychoactive effects of Δ^9-THC.

GPCRs signal predominantly by coupling to a family of heterotrimeric G proteins, anchored on the cytoplasmic face of the plasma membrane. Activation of the receptor enables a recruited G protein to exchange a bound GDP molecule for GTP, causing the trimer to dissociate into α and βγ subunits, which proceed to affect a variety of cellular functions. GPCRs in general are capable of activating a large number of intracellular signaling cascades, depending on factors such as the cell type in which they are expressed, the type of G protein bound by the active receptor, and coexpression of the receptor with accessory proteins which may modify the effector coupling. The "coupling" of a GPCR describes the type of G protein α subunit that it activates, as different subunits exert inhibitory ($G\alpha_{i/o}$) or stimulatory ($G\alpha_s$) effects on adenylate cyclase function; cause activation of phospholipase C ($G\alpha_q$); or alter Rho-GTPase signaling pathways ($G\alpha_{12/13}$) (Neves, Ram, & Iyengar, 2002). Both CB_1 and CB_2 are $G\alpha_{i/o}$-coupling receptors (Felder et al., 1995), although this classification is not absolute, and is discussed in detail later in the chapter. The activity of Gβγ subunits is less well characterized, but the various subtypes are able to activate a wide range of effectors, including mitogen-activated protein kinases, ion channels, other receptors, as well as affecting adenylate cyclase function (Dupré, Robitaille, Rebois, & Hébert, 2009). GPCRs also interact with arrestins, and these interactions have intrinsic effects on cell signaling pathways, as well as modifying the activity state of the receptor itself.

CB_1 Agonists

Once the primary psychoactive constituent in marijuana, Δ^9-THC, was elucidated in 1964 (Gaoni & Mechoulam, 1964), a raft of synthetic cannabinoid ligands (such as CP55,940 and WIN55,212-2) were developed. The identification of the endogenous ligands anandamide and 2-arachidonoylglycerol (2-AG) has led to a greater appreciation for the function of the endocannabinoid system. However, it should be noted that cannabinoid receptor pharmacology is largely understood in the context of synthetic agonists, due to their greater potency. Significantly, despite exhibiting high affinity for CB_1 (low nanomolar concentrations), Δ^9-THC is characterized as a partial agonist at this receptor; that is, compared to ligands like HU210, CP55,940, and 2-AG, maximal Δ^9-THC-induced CB_1 signaling is of lower magnitude (eg, Pertwee, 2008; see Fig. 59.1 for structures).

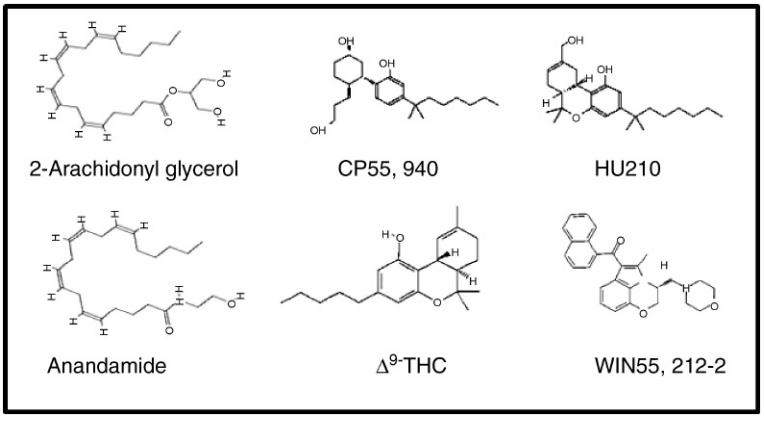

FIGURE 59.1 **Structures of Δ^9-THC; the endocannabinoids 2-arachidonylglycerol (2-AG) and anandamide; and commonly utilized synthetic cannabinoids CP55,940, WIN55,212-2, and HU210.**

CB_1 $G\alpha_I$ PROTEIN COUPLING AND CANONICAL SIGNALING

G Protein Coupling and Modulation of Adenylate Cyclase

Characterization of CB_1 signaling was initiated by Howlett (1984), prior to identification of the cannabinoid receptors. Howlett began investigating the modulatory effects on adenylate cyclase of arachidonic acid derivatives and phytocannabinoids, including Δ^9-THC. This was based on the understanding that cAMP is central to cellular metabolism by, for example, modulating the activity of cAMP-dependent protein kinase A, phosphodiesterases, and ion channels (Antoni, 2012). Δ^9-THC was found to inhibit adenylate cyclase, mediating a cAMP reduction in neuroblastoma cells (Howlett, 1984; Howlett & Fleming, 1984).

Howlett, Qualy, and Khachatrian (1986) also observed that this inhibition of cAMP was sensitive to pertussis toxin (PTX). PTX prevents $G\alpha_i$ protein-receptor interactions by locking the G protein in the GDP-bound state, so this sensitivity implicated $G\alpha_i$-coupling as important in cannabinoid receptor signaling, and suggested that Δ^9-THC was acting upon a GPCR. Indeed, $G\alpha_i$-coupling is today the best-characterized CB_1 signaling phenotype, and is generally considered the canonical signaling pathway for receptor activity (see Fig. 59.2).

The first characterization of brain cannabinoid binding sites was reported by Devane, Dysarz, Johnson, Melvin, and Howlett (1988). However, the molecular identity of CB_1 was only revealed in 1990, upon ligand screening of a novel 473 amino acid protein whose gene was first isolated from a rat cortex cDNA library (Matsuda, Lolait, Brownstein, Young, & Bonner, 1990). In a Chinese hamster ovary K1 (CHO K1) cell line stably expressing this novel GPCR, treatment with the cannabinoid ligands Δ^9-THC and CP55,940 was found to inhibit adenylate cyclase activity. It was further determined that this modulation of adenylate cyclase activity was sensitive to PTX and, therefore, a consequence of $G\alpha_i$ protein coupling.

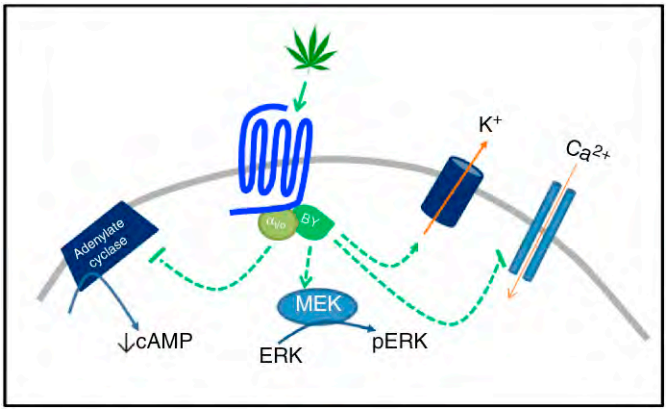

FIGURE 59.2 **Canonical $G\alpha_{i/o}$ mediated CB_1 signaling.** Following activation of CB_1 by an agonist, such as Δ^9-THC (indicated by the cannabis leaf), $G\alpha_{i/o}$ signaling is activated. This results in the activation of inwardly rectifying potassium channels; inhibition of N-, P-, and Q-type calcium channels; activation of MAP-kinase kinase (MEK), leading to phosphorylation of ERK; and inhibition of adenylate cyclase leading to decreased intracellular levels of cAMP.

Although GPCR signaling has traditionally centered around Gα subunit-modulated signal transduction pathways, the role of the Gβγ dimer has become increasingly important in the field of GPCR signaling. Gβγ effectors are now described independently of Gα-mediated signaling, and include modulation of (among others) Gα-independent adenylate cyclase, phosphatidylinositol-3-kinase (PI3K), extracellular signal-regulated kinase (ERK) phosphorylation, and GPCR kinase (GRK) activity (Dupré et al., 2009). Free Gβγ can also selectively activate inwardly rectifying potassium channels and inhibit N-, P/Q-, and R-type voltage-gated Ca^{2+} channels (Currie, 2010; Huang, Slesinger, Casey, Jan, & Jan, 1995).

Phosphorylation of ERK by CB_1

The extracellular signal regulated kinases ERK1/2 are mitogen-activated kinases activated in response to a variety of extracellular signals, and are involved in a wide range of processes, such as cellular proliferation, differentiation, and cell cycle progression. Bouaboula et al. (1995) reported cannabinoid-mediated ERK phosphorylation in CHO cells heterologously expressing CB_1. This pERK stimulation was sensitive to PTX (meaning that the activation pathway was $G\alpha_i$-protein-mediated), but was not Gα or cAMP-mediated, suggestive of a Gβγ-mediated signal. Different researchers have empirically demonstrated CB_1-mediated Gβγ signaling through ERK: nonpigmented ciliary epithelial cells (which endogenously express CB_1) treated with the CB_1 agonist WIN55212-2 induced an outwardly rectifying Cl^- current (Shi et al., 2003). When Gβγ was sequestered, treatment with WIN55212-2 failed to activate this Cl^- current. Interestingly, through pharmacological methods, it was established this effect on Cl^- currents was the consequence of CB_1 signaling, via Gβγ, downstream of phosphorylation of ERK (Shi et al., 2003).

Phosphorylation of ERK has also been reported in hippocampal brain slices on treatment with endocannabinoid ligands (anandamide, 2-AG), in addition to Δ^9-THC. Although CB_1 signaling through pERK has been reported as being PI3K-dependent in other biological systems (Bouaboula et al., 1997), in hippocampal slices the endocannabinoid-induced pERK response was not blocked when PI3K was inhibited with LY294002. Rather, ERK phosphorylation was found to be downstream of cAMP inhibition (Derkinderen et al., 2003). The different pathways for ERK signaling illustrate the complexity

of cannabinoid receptor signaling; receptor activation results in signal transduction through different pathways, depending on the physiology of the host cell type.

Some reports also suggest that CB_1 induces ERK phosphorylation through a pathway involving activation of receptor tyrosine kinases. CB_1 transactivation of vascular endothelial growth factor receptor was shown to induce pERK in a $G\alpha_i$ protein-mediated manner (Rubovitch, Gafni, & Sarne, 2004), and similar effects were induced on cannabinoid-mediated epidermal growth factor transactivation, although the signaling pathway involved was not described (Hart, Fischer, & Ullrich, 2004). Fyn, a member of the Src family of tyrosine kinases, also appears to be involved in the CB_1 pERK response, as Fyn knockout mice demonstrated a loss of cannabinoid-mediated pERK induction (Derkinderen et al., 2003).

CB_1 Associated Ion Channel Modulation

CB_1 mediated modulation of ion channels is well-reported in the current literature, but the large variety of channels influenced by receptor activity makes their characterization complex because, as noted, not all are regulated through the canonical $G\alpha_i$ protein-mediated signaling pathway. In particular, calcium ion channel modulation by CB_1 signaling has layers of complexity. Different pathways are involved in regulation of N-type (Pan, Ikeda, & Lewis, 1996; Mackie & Hille, 1992), L-type (Gebremedhin, Lange, Campbell, Hillard, & Harder, 1999), P/Q-type (Twitchell, Brown, & Mackie, 1997), and T-type (Chemin, Monteil, Perez-Reyes, Nargeot, & Lory, 2001) channels.

Calcium Channels

Cannabinoid inhibition of N-type (neural) Ca^{2+} channels is the most widely established Ca^{2+} ion channel target of CB_1 activity. Mackie et al. discovered that cannabinoid agonists reversibly reduced Ca^{2+} current in differentiated NG108-15 (mouse neuroblastoma) cells. This inhibition was concentration-dependent and $G\alpha_i$ protein-mediated (Mackie & Hille, 1992). The channel responsible for the conduction of these Ca^{2+} currents was determined as N-type, because pretreatment of cells with the selective N-type channel blocker ω-conotoxin-GVIA attenuated cannabinoid-mediated current inhibition (Mackie & Hille, 1992). Similar cannabinoid-mediated inhibition of N-type channels was also reported in superior cervical ganglion neurons (Pan et al., 1996).

Channels conducting Ca^{2+} currents detected in cat arterial smooth muscle cells were identified as L-type (long-lasting), due to their high voltage threshold for channel activation, and blockade by nifedipine and cadmium ions. The effects of cannabinoid agonists on these channels were investigated to probe a possible role in cannabinoid-mediated cerebral vasodilation. Treating cells with cannabinoid agonists resulted in a significant and concentration-dependent inhibition of peak Ca^{2+} current (Gebremedhin et al., 1999). It was also noted that cannabinoid-mediated inhibition of L-type Ca^{2+} currents was unexpected, as other publications have ruled out L-type channels as contributing appreciably to cannabinoid-driven Ca^{2+} currents (Mackie & Hille, 1992), and GPCRs were only seldom associated with Ca^{2+} current modulation via L-type channels. Cannabinoid-mediated L-type Ca^{2+} current inhibition was abolished by PTX pretreatment (Gebremedhin et al., 1999), demonstrating that these effects are $G\alpha_i$ protein-dependent, although the downstream pathways (and whether the effect was Gα- or Gβγ-mediated) were not delineated. L-type Ca^{2+} channel modulation by cannabinoids has been reported more recently, when the Gα subunit of the G protein was found to be responsible for channel conductance in nucleus tractus solitarius neurons, as antibodies against $G\alpha_i$ subunits, but not Gβγ subunits, attenuated WIN55212-2-induced Ca^{2+} current inhibition (Endoh, 2006).

P-(Purkinje) and Q-type Ca^{2+} channels are also inhibited by CB_1 signaling. WIN55212-2 inhibited Ca^{2+} currents in transfected AtT20 cells in a PTX-sensitive manner, but these effects were attenuated when the cells were pretreated with ω-conotoxin-MVIIC (a selective blocker of P/Q Ca^{2+} channels). It was also noted that the extent of cannabinoid-mediated Ca^{2+} current inhibition through P/Q-type channels was subordinate to the influence of cannabinoids on N-type channels: approximately 70% of WIN55212-2-induced current inhibition was carried by N-type channels (Twitchell et al., 1997). Similar P-type channel-directed Ca^{2+} inhibition has been reported for anandamide in Purkinje neurons (Fisyunov, Tsintsadze, Min, Burnashev, & Lozovaya, 2006).

Given the number of Ca^{2+} channels involved in cannabinoid-mediated Ca^{2+} ion conductance, it is challenging to determine the signaling pathways through which these effects are elicited. In general, however, all channels discussed are sensitive to PTX.

Potassium Channels

Cannabinoid-mediated regulation of potassium ion (K^+) channels has also been detailed. In some systems, K^+ conductance is known to be both Gβγ subunit-dependent, and sensitive to changes in intracellular cAMP levels [reviewed by (Yamada, Inanobe, & Kurachi, 1998)], implicating both the α and βγ subunits of G_i in the signaling. For example, CB_1's modulation of inwardly rectifying potassium currents (through G protein coupled inwardly rectifying K^+ channels, GIRKs) were found to be sensitive to PTX, and may be Gβγ-mediated (Ho, Uezono, Takada, Takase, & Izumi, 1999; Mackie, Lai, Westenbroek, & Mitchell, 1995). Specifically, GIRK1 and GIRK4 are implicated in cannabinoid-mediated K^+

conductance, as both increase inward K^+ flux downstream of CB_1 stimulation with WIN55212-2 (Mcallister, Griffin, Satin, & Abood, 1999).

CB_1 CONSTITUTIVE SIGNALING

Traditionally, drug action was interpreted on the basis that receptor systems have no activity unless stimulated by agonist. This notion has been dispelled, as constitutive (ligand-independent) activities have been reported for many GPCRs [reviewed in (Seifert & Wenzel-Seifert, 2002)]. This is supported by the key observation that drugs which had been classified as antagonists (drugs that displace agonists but do not influence receptor activity), are often seen acting as inverse agonists; they are capable of reducing the constitutive activity of their target. In the case of the CB_1 constitutive activity has been detected through a variety of endpoints.

Experiments first demonstrated a constitutive phenotype for CB_1 by revealing inverse agonist action of the drug SR141716A (also known as rimonabant). Firstly, CB_1 mediated G protein turnover in the absence of agonist was demonstrated using the GTPγS assay, which measures G protein cycling through accumulation of radioisotope-labeled GTPγS (a poorly-hydrolysable GTP analog). In this experiment, SR141716A induced a reduction in the extent of GTPγS accumulation (Landsman, Burkey, Consroe, Roeske, & Yamamura, 1997). It has also been observed that in human CB_1-expressing CHO cells, basal levels of ERK phosphorylation were higher than those observed in matched wild-type controls. This effect could be potently attenuated upon treatment with SR141716A (Bouaboula et al., 1997). Similarly, Bouaboula et al. (1997) showed that CB_1 exert basal inhibitory effects on cAMP levels in a manner sensitive to SR141716A. Notably, the potencies with which SR141716A induced ERK inhibition and cAMP increases in unstimulated cells were similar to its binding properties, arguing that the response was directly receptor-mediated, and not due to endogenous agonists present in the culture, or off-target effects on other components of the cell background (Bouaboula et al., 1997).

Furthermore, CB_1 constitutive activity has also been demonstrated in G protein-mediated ion channel conductance, and receptor trafficking, as SR141716A potently blocked agonist-mediated inhibition of Ca^{2+} currents through N-type Ca^{2+} channels. SR141716A also increased Ca^{2+} conductance above basal levels in otherwise unstimulated cells which were microinjected with CB_1 cRNA (Pan, Ikeda, & Lewis, 1998). Recent publications have also reported unstimulated CB_1 trafficking activity, quantifiable in the absence of any drug, and abatable on treatment with multiple CB_1 inverse agonists, including SR141716A (Leterrier, Bonnard, Carrel, Rossier, & Lenkei, 2004; Grimsey, Graham, Dragunow, & Glass, 2010).

CB_1 G PROTEIN COUPLING PROMISCUITY

Alongside the canonical $G\alpha_i$ protein-associated functional consequences of CB_1 signaling, potential for CB_1-mediated activation of other pathways has also been reported in response to specific environmental or pharmacological conditions. In particular, receptor coupling to three non-$G\alpha_i$-type G proteins has been reported, leading CB_1 to be described as a "promiscuous G protein coupler" (see Fig. 59.3).

The most-reported and possibly dominant "secondary" signaling pathway for CB_1 is the coupling of stimulatory $G\alpha_s$ proteins, first reported by Glass and Felder (1997). In cells where CB_1 is coexpressed with D_2 dopamine receptors, costimulation with a CB_1 agonist (HU210) and a D_2 agonist (quinpirole) resulted in an increase in forskolin-induced intracellular cAMP levels (Glass & Felder, 1997)—a finding which challenged the understanding that both receptors couple $G\alpha_i$ proteins. More recent research has revealed that this coupling switch is coexpression-dependent (Jarrahian, Watts, & Barker, 2004), and possibly mediated by a CB_1/D_2 receptor heteromer (Kearn, Blake-Palmer, Daniel, Mackie, & Glass, 2005). PTX pretreatment is sufficient to unmask

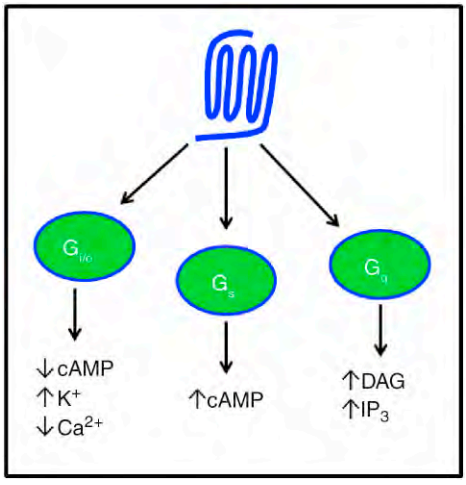

FIGURE 59.3 G protein coupling of CB_1. Activation of CB_1 has been suggested to activate multiple G proteins under particular circumstances, resulting in a diverse range of signaling pathway activation. The predominant pathway is thought to be activation of $G\alpha_{i/o}$ proteins, resulting in decreased cAMP; stimulation of inwardly rectifying potassium channels; and blockade of N-, P-, and Q-type calcium channels. Under conditions of limited G_i, G_s signaling has been described, resulting in increased levels of cAMP. Following activation with some ligands (notably WIN55,212-2), G_q mediated signaling has been reported, consisting of activation of phospholipase C, leading to increased levels of inositol triphosphate (IP3), and diacyl glycerol (DAG).

a CB_1-mediated $G\alpha_s$ response, in both primary striatal neurons (where D2 is coexpressed) and transfected CB_1-CHO cells (Glass & Felder, 1997).

$G\alpha_q$ coupling by CB_1 has also been reported. Unlike $G\alpha_i$ and $G\alpha_s$ signaling, $G\alpha_q$ signaling does not influence adenylate cyclase activity. Rather, $G\alpha_q$ activates phospholipase C (PLC), and its downstream signaling cascade, resulting in Ca^{2+} release from the endoplasmic reticulum into the cytoplasm. Stimulation of CB_1 in hippocampal neurons or transfected HEK293 cells with a high concentration (5 μM) of WIN55,212-2 caused a large, SR141716A-sensitive increase of cytosolic Ca^{2+} (Lauckner, Hille, & Mackie, 2005). This response was PTX-sensitive, and was specific to WIN55,212-2. However, the effect was markedly reduced in cells treated with a PLC inhibitor or expressing a $G\alpha_q$ dominant negative, therefore identifying $G\alpha_q$ as the effector (Lauckner et al., 2005).

$G\alpha_{12/13}$ protein signaling is perhaps the least characterized G protein pathway, and is mainly involved in regulation of the actin cytoskeleton; that is, maintenance and remodeling of cell morphology. The small GTPase RhoA is known to be activated downstream of $G\alpha_{12/13}$ signaling, and is also involved in actin dynamics (Suzuki, Nakamura, Mano, & Kozasa, 2003). Furthering the characterization of CB_1 as a promiscuous coupler of G proteins, anandamide was shown to induce rounding of B103 rat neuroblastoma cells, in a manner consistent with $G\alpha_{12/13}$ protein coupling [insensitive to PTX-treatment, but sensitive to treatment with a Rho inhibitor (Ishii & Chun, 2002)]. Finally, in vivo studies have suggested coupling of CB_1 to the $G\alpha_{i/o}$-related G protein $G\alpha_z$, as mice with reduced levels of $G\alpha_z$ proteins, unlike WT mice, demonstrate attenuated cannabinoid-mediated tolerance to analgesia (Garzon, De La Torre-Madrid, Rodriguez-Munoz, Vicente-Sanchez, & Sanchez-Blazquez, 2009).

CB_1 REGULATION

Desensitization of CB_1

CB_1 receptors lose their responsiveness to ligand (desensitize) within minutes of application of agonist (Jin et al., 1999). As for most GPCRs, this is believed to occur as the result of receptor phosphorylation, followed by removal from the cell surface; this process is illustrated in Fig. 59.4 (Hsieh, Brown, Derleth, & Mackie, 1999; Zastrow, 2003).

GRK proteins act to phosphorylate the intracellular faces of GPCRs, such that G proteins can no longer be activated. Putative phosphorylation sites are found in the C-terminal tail, with mutations of these residues resulting in reduced desensitization in both cell line models and transgenic mice, although phosphorylation of these sites may not be necessary for subsequent receptor internalization (Jin et al., 1999; Straiker, Wager-Miller, & Mackie, 2012; Morgan et al., 2014). Subsequent recruitment of β-arrestins abrogates G protein coupling, and internalization occurs via clathrin-coated pits (Marchese, Paing, Temple, & Trejo, 2008; Hsieh et al., 1999). In cultured rat neurons, CB_1 desensitization is GRK2-dependent (Kouznetsova, Kelley, Shen, & Thayer, 2002), and may also interact with GRK3 (Jin et al., 1999). However,

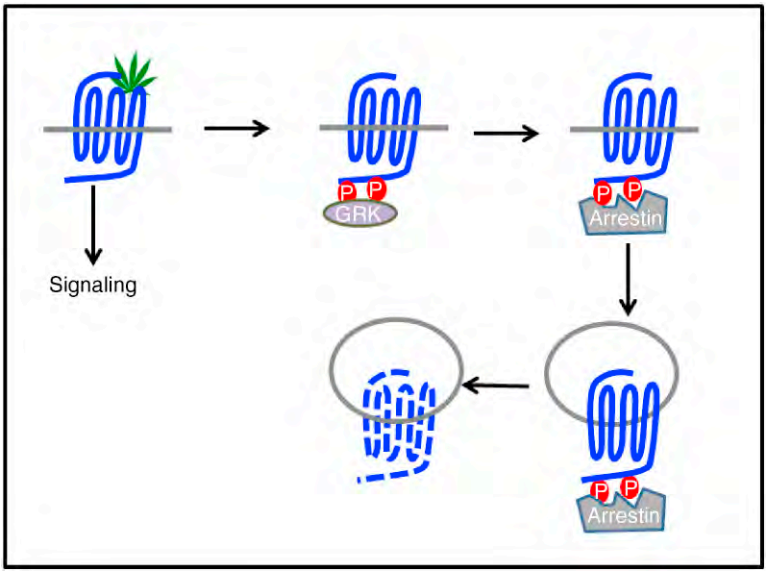

FIGURE 59.4 Regulation of CB_1. Following activation by an agonist, CB_1 (like most G protein coupled receptors) are believed to be phosphorylated and internalized by a conserved pathway. Thus, following activation, the intracellular face of the receptor is phosphorylated by G protein receptor kinase (GRK), leading to arrestin recruitment, and subsequent internalization into a vesicle. Following internalization, CB_1 is thought to undergo lysosomal degradation.

in cultured rabbit smooth muscle cells, GRK5 was found to control phosphorylation (Mahavadi, Sriwai, Huang, Grider, & Murthy, 2014). In the mouse brain, Δ^9-THC treatment results in receptor mediated GRK2 recruitment, and chronic Δ^9-THC treatment results in upregulation of both GRK2 and GRK4 (Rubino et al., 2006). However, it is likely that the exact mechanism of phosphorylation and desensitization may vary between cell types, including standard cell line models, depending on their particular complement of accessory proteins (Atwood, Lopez, Wager-Miller, Mackie, & Straiker, 2011).

Arrestin Recruitment and Signaling

As for other GPCRs, CB_1 is able to interact with β-arrestins, which control aspects of receptor regulation and non-G protein-mediated signaling (Magalhaes, Dunn, & Ferguson, 2012). In general terms, arrestin-mediated signaling can include activation of multiple kinase pathways including Src, ERK, and JNK pathways (Luttrell & Lefkowitz, 2002; Zhan, Kook, Gurevich, & Gurevich, 2014). This provides a second complement of GPCR signaling cascades beyond canonical G protein effects. However, arrestin coupling by CB_1 (and any downstream signaling cascades) is still relatively uncharacterized. In cultured cells, CB_1 is generally observed to interact weakly with β-arrestin2 through a phosphorylation site in the C-terminal tail (Gyombolai, Boros, Hunyady, & Turu, 2013; Daigle, Kwok, & Mackie, 2008), and potentially very weakly with β-arrestin1 (Jin et al., 1999). Furthermore, it has been reported that CB_1 couples to both β-arrestin1 and β-arrestin2 in a ligand-dependent manner (Ahn, Mahmoud, Shim, & Kendall, 2013). Under some conditions, activation of ERK and Src pathways may be solely arrestin-dependent (Mahavadi et al., 2014), although this is not universally observed.

Despite the conflicting data from cell culture experiments, there is some evidence from animal studies that CB_1-arrestin interactions are physiologically important. The behavioral effects of acute doses of Δ^9-THC (eg, antinociception) are increased in β-arrestin2 knockout mice (Breivogel, Lambert, Gerfin, Huffman, & Razdan, 2008; Nguyen et al., 2012), indicating that this arrestin contributes to the desensitization process. However, β-arrestin2 knockout only changes the development of tolerance to chronic Δ^9-THC dosing in some brain regions. For example, receptors in the globus pallidus (which mediate catalepsy) show increased tolerance to stimulation with Δ^9-THC, while receptors in the spinal cord (which mediate nociception) showed reduced tolerance, with behavioral responses reflecting this (Nguyen et al., 2012). Similarly, chronic Δ^9-THC increases β-arrestin1 protein specifically in some (striatum, cerebellum, and hippocampus), but not all, regions of the mouse brain (Rubino et al., 2006). This may reflect the different desensitization-tolerance pathways available in different cell types, which depend on the complement of CB_1-interacting proteins available. It is interesting to note, however, that only Δ^9-THC responses appear to be affected in these β-arrestin2 knockout animals, while responses to synthetic cannabinoids (including synthetic partial agonists) and analogs of the endocannabinoids are unchanged (Breivogel et al., 2008), suggesting a level of complexity yet to be understood.

Internalization and Degradation of CB_1

CB_1 is removed from the cell surface and internalized quickly (Mikasova, Groc, Choquet, & Manzoni, 2008; Grimsey et al., 2010), a process which appears to be controlled by the distal end of the CB_1 C-terminus (independent of the suggested GRK phosphorylation sites) (Straiker et al., 2012). Following internalization into an early endosome, CB_1 is sorted into a degradative pathway (Grimsey et al., 2010). CB_1's helix 8 contains an interaction site for G protein receptor-associated sorting protein 1 (GASP1), a protein which directs receptors to degradative lysosomes (Martini et al., 2007). Indeed, in mice, GASP1 has been observed to be required for the downregulation of CB_1 in response to chronic agonist treatment (Tappe-Theodor et al., 2007). The degradative phenotype of internalized CB_1 affects the cellular regulation of CB_1 signaling, as the state of reduced responsiveness to agonists will persist until new receptors have been synthesized and trafficked to the cell surface.

CONCLUSIONS

CB_1 can signal through a wide range of G protein mediated and independent pathways. Exactly which signaling pathway is activated in a particular cell will depend on the signaling components of the cells. To date, most of our knowledge is based on signaling observed in either transfected cell lines, or primary rodent cells, with a small number of signaling studies in vivo. Further studies will hopefully focus on signaling of CB_1 in primary human cells or tissues, as the culturing of these cells becomes more advanced. Such knowledge should greatly aid in our understanding of how receptors mediate the actions of Δ^9-THC, the endocannabinoids, and the synthetic cannabinoids in the human brain.

MINI-DICTIONARY

Adenylate cyclase/adenylyl cyclase A family of enzymes which convert ATP into cAMP.
Constitutive activity (of a GPCR) GPCR activation which occurs in the absence of agonist.
Desensitization The uncoupling of a receptor from its signaling cascade, resulting in reduced responsiveness to agonist.

ERK (extracellular signal-regulated kinase) pathway Intracellular signaling pathway consisting of a cascade of enzymes which add phosphate groups to the next protein in the pathway. Ultimately, it ends in changes in transcriptional activity in the nucleus.

G proteins A family of GTPases which, when activated by a GPCR, transmit information from the GPCR to downstream effectors (also known as guanosine nucleotide-binding proteins).

G protein coupled receptor A family of seven transmembrane cell surface proteins which respond to external stimuli by coupling (primarily) to intracellular G proteins.

Internalization The cellular process of removing a GPCR from the surface of the cell, thereby decreasing the number of receptors available to extracellular agonist.

Partial agonist A ligand which is able to activate a receptor, but does not elicit the maximum functional response (ie, partial efficacy, even at full receptor occupancy).

CHAPTER

60

Allosteric Modulation of the Cannabinoid CB1 Receptor

E.E. Cawston, M.R. Hunter, M. Glass

Department of Pharmacology and Clinical Pharmacology, Faculty of Medical and Health Sciences, University of Auckland, Auckland, New Zealand

SUMMARY POINTS

- Several allosteric modulators of CB1 cannabinoid receptors have been described.
- The most studied of these are ORG27569 and PSNCBAM-1.
- These compounds have paradoxical action, increasing affinity but decreasing efficacy of orthosteric ligands in most studied signaling pathways.
- These ligands may also show some probe dependence, having greater effect on CP55,940 than on WIN55,212-2 activity.
- Several other ligands have been suggested to act allosterically at CB1 including lipoxin A4, pregnenolone, and pepcans.
- Receptor heteromerization is another mechanism by which receptor signaling can be altered allosterically.
- CB1 forms heteromers with a number of other GPCRs to alter signaling.
- CB1 heteromers may, therefore, provide a means to selectively target only a subset of CB1 receptors.

KEY FACTS OF ALLOSTERIC MODULATION

- Allosteric regulation is regulation of a receptor by binding of a molecule at a site other than the proteins active (orthosteric) site.
- Allosteric modulators bind to the receptor leading to a conformational change in the protein.
- This might enhance or inhibit the activity of the receptor in the absence of an orthosteric ligand, now termed allo-agonism or allo-antagonism.
- Allosteric modulators can alter the response of the receptor to orthosteric ligand, either by enhancing the ligand's affinity and/or efficacy (positive allosteric modulation) or inhibiting it (negative allosteric modulation).

KEY FACTS ABOUT THE THERAPEUTIC POTENTIAL OF ALLOSTERIC MODULATORS OF GPCRS

- If the allosteric modulator has no intrinsic activity at the receptor, then it will only exert its effects when the endogenous ligand is present, thereby maintaining the anatomical and temporal aspects of endogenous signaling.
- Higher sequence divergence in the allosteric site should enable design of subtype selective modulators.
- Allosteric modulation with limited cooperativity produce a ceiling above which there is no further on-target effect, for example, a negative allosteric modulator could decrease signaling without completely preventing it.

LIST OF ABBREVIATIONS

cAMP	Cyclic adenosine monophosphate
CB1	Cannabinoid receptor 1
CP55,940	(−)-*cis*-3-[2-Hydroxy-4-(1,1-dimethylheptyl) phenyl]-*trans*-4-(3-hydroxypropyl) cyclohexanol

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00070-3

ERK1/2	Extracellular signal-regulated kinase 1/2
GPCR	G protein-coupled receptor
[^{35}S]GTPγS	Guanosine 5′-O-(3-[^{35}S]thio) triphosphate binding
MAP kinases	Mitogen-activated protein kinases
mIPSC	Miniature inhibitory postsynaptic currents
ORG27569	5-Chloro-3-ethyl-*N*-[2-[4-(1-piperidinyl)phenyl]ethyl-1H-indole-2-carboxamide
PSNCBAM-1	1-(4-Chlorophenyl)-3-[3-(6-pyrrolidin-1-ylpyridin-2-yl)phenyl]urea
SR141716A	*N*-(piperidin-1-yl)-5-(4-cholrophenyl)-1-(2,4-dichlorophenyl)-4-methyl-1*H*-pyrazole-3-carboxamide
WIN55, 212-2	*R*(+)-[2,3-dihydro-5-methyl-3-(4-morpholinylmethyl)pyrrolo [1,2,3,-de]-1,4-benzoxacin-6-yl]-1-naphtalenylmethanone mesylate

INTRODUCTION

To date, most efforts in G protein-coupled receptor (GPCR) drug design have focused on targeting drugs to the same binding site on the receptor as the endogenous ligand binds to, the orthosteric site. Orthosteric ligands can activate (agonists), inactivate (inverse agonists), or prevent the action of the endogenous ligand (antagonists). Developing specific drugs in this way can be challenging, especially when the target receptor belongs to a larger family that shares high sequence homology at the orthosteric site, as is usually required to bind the endogenous ligand across a family of receptors. Moreover, most GPCR therapies are based on chronic exposure of the receptor to orthosteric ligands, activating regulatory processes, and potentially altering clinical efficacy due to desensitization and up/down regulation of the target receptor. An alternative approach is, therefore, desirable, and targeting of allosteric sites on GPCRs has become an area of intense research (Wenthur, Gentry, Mathews, & Lindsley, 2014).

ALLOSTERIC MODULATION OF GPCRS

The term "allostery" comes from the Greek *allos* meaning "else" or "different" (Kenakin & Miller, 2010). The concept of allosterism was first described over 50 years ago with regard to activity of bacterial enzymes (Umbarger, 1956), with the use of the term "allosteric" being formalized a few years later (Monod, Changeux, & Jacob, 1963); it has expanded to encompass modulatory sites on receptors, including GPCRs (Christopoulos et al., 2014; Kenakin & Miller, 2010).

A GPCR allosteric modulator is a molecule that binds at a topographically distinct site to the orthosteric ligand, and results in a change in receptor conformation, thus creating a receptor with novel binding and/or functional properties (Kenakin & Miller, 2010; Conn, Christopoulos, & Lindsley, 2009). Allosteric modulators have three main modes of action, as illustrated graphically in Fig. 60.1A. First, binding of an allosteric modulator may result in a conformational change that can impact the affinity of the orthosteric binding pocket, such that either the association or dissociation rate (or both) of an orthosteric ligand is modified (affinity modulation). Second, allosteric modulators may modulate the signaling response produced by the orthosteric ligand through altering the efficacy of the receptor conformation induced by the orthosteric ligand (efficacy modulation). Thus, positive allosteric modulators enhance the affinity and/or efficacy of an orthosteric ligand, while negative allosteric modulators decrease the affinity and/or efficacy of the orthosteric ligand (Fig. 60.1B). Finally, the allosteric modulator may have effects on receptor signaling independent of the orthosteric ligand—increasing (allosteric agonism) or decreasing (allosteric antagonism/inverse agonism) signaling (Kenakin & Miller, 2010).

Allosteric modulation of GPCRs is an emerging therapeutic strategy that can potentially provide improved selectivity and safety (Conn et al., 2009). Improved selectivity is predicted as allosteric sites are under less evolutionary pressure to be conserved than would be required to maintain an orthosteric binding pocket capable of accommodating an endogenous ligand across a family of receptors. Furthermore, allosteric modulators that lack intrinsic activity, and only modulate the action of the orthosteric ligand, may overcome some of the receptor regulation produced by orthosteric activation, as well as providing the opportunity to selectively tune up or down the actions of endogenous ligand. Such selective modulation would provide spatial and temporal control not currently possible with orthosteric ligands. Furthermore, allosteric modulation is saturable; thus, once allosteric sites are occupied, no additional on-target effects are observed.

GPCRs have the additional ability to form multireceptor complexes called "heterodimers" or "heteromers," in which two or more GPCRs interact to form a functional unit with modified ligand binding and signaling, compared to monomeric receptors (Fig. 60.4). Therefore, heteromerization can also be considered as a form of allosteric modulation, which is available for pharmacological manipulation, and may be particularly useful for restricting a drug's site of action to a cell type containing a specific heteromer. For the purpose of this review, we will be addressing GPCR allosteric modulation with regard to allosteric ligands and heteromerization.

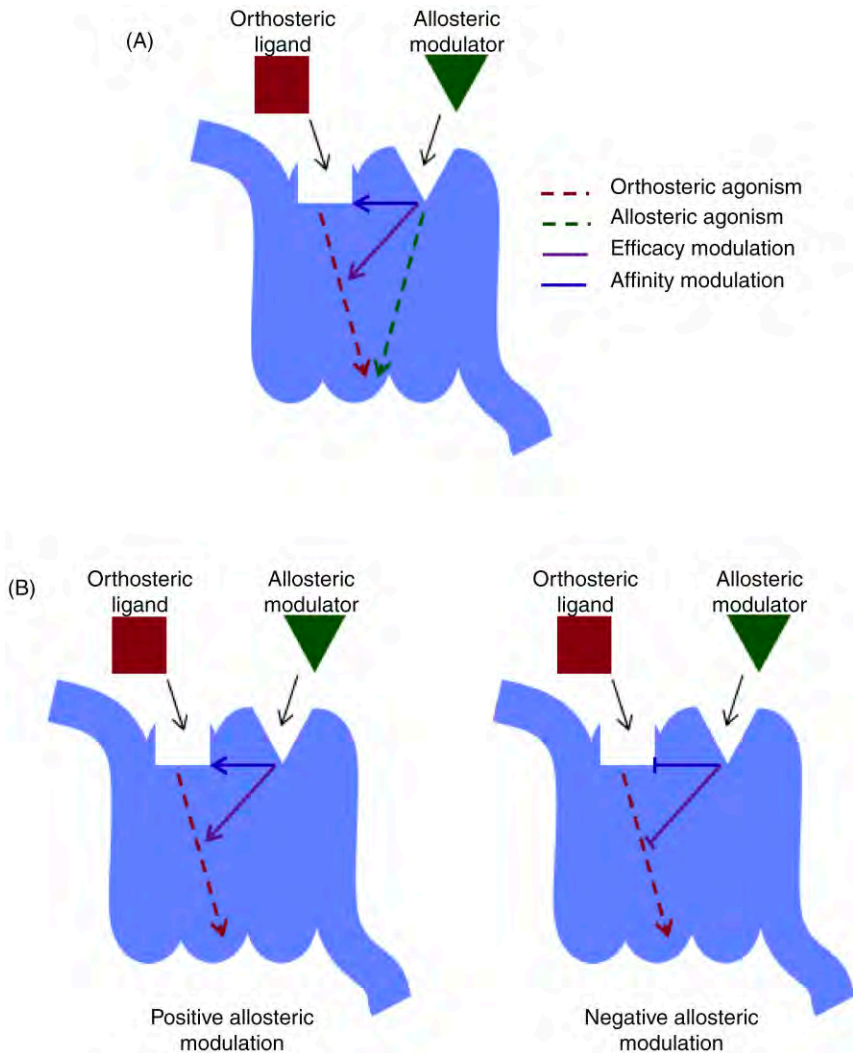

FIGURE 60.1 Different actions of allosteric modulators and how they influence orthosteric function. (A) An allosteric ligand *(green triangle)* binds to topographically distinct sites on the G protein-coupled receptor relative to the orthosteric ligand *(red square)*. An allosteric modulator bound to the allosteric site on a receptor can modulate orthosteric ligand affinity *(blue line)* and/or efficacy *(purple line)*. Additionally, the allosteric modulator may directly modulate signaling in their own right in the absence of orthosteric ligand *(dashed green line)*. (B) Positive allosteric modulators (left) enhance the affinity and/or efficacy of an orthosteric ligand. Negative allosteric modulators (right) decrease the affinity and/or efficacy of the orthosteric ligand.

POTENTIAL ADVANTAGES OF ALLOSTERIC MODULATORS FOR CB1

Cannabinoid receptor 1 (CB1) is of considerable therapeutic interest for the treatment of a range of disorders, including neurodegenerative disorders (Gowran, Noonan, & Campbell, 2011; Scotter, Goodfellow, Graham, Dragunow, & Glass, 2010; Sagar et al., 2009). The widespread distribution of cannabinoid receptors leads to wide-ranging physiological responses to cannabinoid-based therapies, therefore interest is now turning to improved drug therapies for these receptors through development of allosteric ligands, and drugs targeting receptor heteromers.

ALLOSTERIC LIGANDS OF CB1

In 2005, the first description of allosteric modulators for CB1 was reported (Price et al., 2005). Three novel compounds from Organon (ORG27569, ORG27759, and ORG29647) were shown to significantly increase the binding of the orthosteric CB1 agonist [^{3}H]CP55,940, with ORG27569 having the greatest potency (Fig. 60.2A). In 2007, a second CB1 allosteric modulator compound, structurally similar to the Organon compounds, was described through screening of a small molecule library of compounds from Prosidion Limited (PSN) (Horswill et al., 2007). The compound PSNCBAM-1 (Fig. 60.2B) was identified, and was found to produce a similar

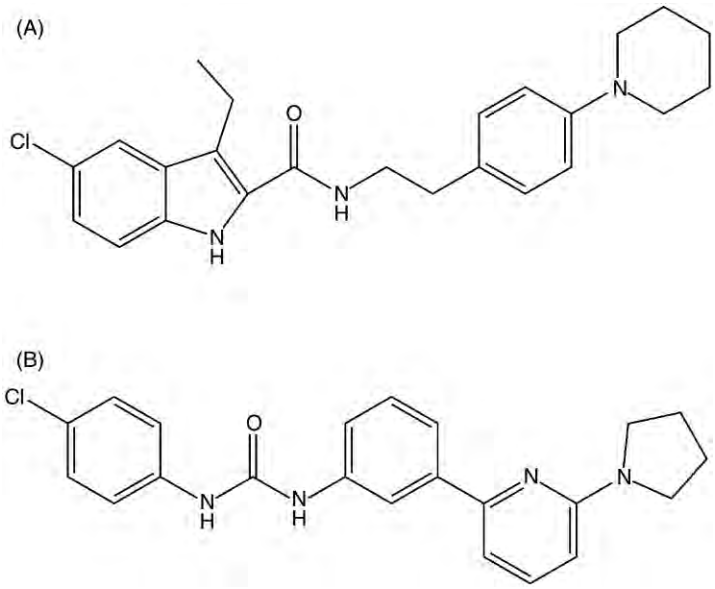

FIGURE 60.2 Structures of CB1 allosteric modulators ORG27569 and PSNCBAM-1. (A) ORG27569: 5-chloro-3-ethyl-*N*-[2-[4-(1-piperidinyl) phenyl]ethyl-1H-indole-2-carboxamide (Price et al., 2005) and (B) PSNCBAM-1: 1-(4-chlorophenyl)-3-[3-(6-pyrrolidin-1-ylpyridin-2-yl)phenyl] urea (Horswill et al., 2007).

increase in binding of [^{3}H]CP55,940 as seen with the Organon compounds (Horswill et al., 2007). The majority of the subsequent studies have focused on the effects of ORG27569 and PSNCBAM-1 on CB1 activity, therefore these will be the main focus of this review.

ALLOSTERIC MODULATORS ALTER THE BINDING OF ORTHOSTERIC LIGANDS TO CB1

Initial studies demonstrated that both ORG27569 and PSNCBAM-1 appeared to increase the binding of the orthosteric agonist [^{3}H]CP55,940 to the receptor (Price et al., 2005; Horswill et al., 2007), as illustrated in Fig. 60.3. Increased radioligand binding suggests positive cooperativity, mediated by an increase in agonist affinity in the presence of the allosteric modulator. This has been further investigated in kinetic studies which have investigated the dissociation rate of [^{3}H]CP55,940 in the presence of ORG27569 or PSNCBAM-1. [^{3}H]CP55,940 has been reported to show biphasic dissociation (Devlin & Christopoulos, 2002), thought to reflect rapid dissociation from low affinity uncoupled receptors, and slow dissociation from high affinity activated receptors. Initial studies with ORG27569 suggested a reduction in both the slow and fast dissociation rate constants, without changing the proportion of receptor in either state (Price et al., 2005). This finding suggests that ORG27569 reduces the orthosteric ligand dissociation without affecting G protein-coupling status (Price et al., 2005). In contrast, more recent kinetic binding assays with PSNCBAM-1 found no alteration in dissociation rates, but rather an increased proportion of receptors undergoing slow dissociation, suggesting that the increased binding observed is not due to a change in affinity, but rather a greater proportion of receptors in a high affinity state (Baillie et al., 2013). This was supported by saturation binding assays, which found no change in affinity (K_d) for [^{3}H]CP55,940 in the presence of either ORG27569 or PSNCBAM, but rather found an increase in total receptor binding (B_{max}), consistent with the suggestion that the ligands increase the available binding sites for the orthosteric ligand, rather than acting directly on ligand affinity (Baillie et al., 2013).

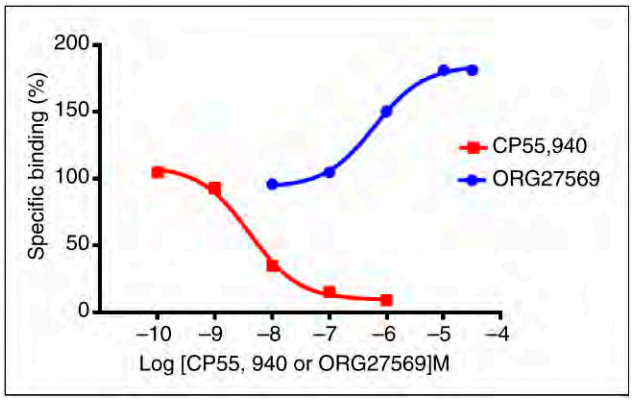

FIGURE 60.3 Influence of ORG27569 on binding of [^{3}H]CP55,940. Classical orthosteric ligands such as CP55,940 cause displacement of the radioligand [^{3}H]CP55,940. In contrast, the allosteric ligand ORG27569 produces a concentration-dependent increase in binding of the radioligand.

An increased proportion of receptors in a high affinity state is also consistent with the finding of Price et al. (2005) that ORG27569 decreased the binding of the inverse agonist SR141716A to rat brain membranes, as inverse agonist is thought to bind preferentially to low affinity receptor conformations. Ahn, Mahmoud, and Kendall (2012) further investigated this with receptor mutations they had previously demonstrated to display enhanced (T201I) or reduced (T210A) constitutive activity (D'Antona, Ahn, & Kendall, 2006). Competition binding assays showed the greatest enhancement of [^{3}H] CP55,940 binding with the inactive state CB1 receptor T210A, while the wild-type receptor showed a slightly lesser increase, and the constitutively active receptor showed no change in [^{3}H] CP55,940 binding, with increasing concentrations of ORG27569 (Ahn et al., 2012). Thus, these findings were again consistent with the concept that the allosteric modulator is driving the receptor into a high affinity agonist binding conformation.

ALLOSTERIC MODULATION OF CB1 RECEPTOR SIGNALING

Despite binding studies demonstrating increased orthosteric ligand binding, as described earlier, a paradoxical decrease in orthosteric ligand efficacy has generally been observed in most signaling pathways. The guanosine 5′-O-(3-[^{35}S]thio)triphosphate binding ([^{35}S]GTPγS) assay measures very early signaling events—the activation of the G protein, in response to agonist binding. Initial functional studies of the effect of the Organon compounds on CB1 receptor showed they acted as insurmountable antagonists of the CB1 receptor in the [^{35}S]GTPγS assay, eliciting a significant reduction in the maximum stimulation achieved by the CB1 agonists (Price et al., 2005). Similarly, PSNCBAM-1 displayed a concentration-dependent blockade of [^{35}S]GTPγS binding stimulated with either CP55,940 or the endocannabinoid anandamide (Horswill et al., 2007). These findings were subsequently confirmed by Baillie et al. (2013), who further extended the signaling assays to include inhibition of adenylate cyclase, a pathway downstream of $G\alpha_i$ activation. This study demonstrated a concentration dependent blockade of CB1-mediated inhibition of adenylate cyclase by ORG27569, a finding confirmed by Cawston et al. (2013). Intriguingly the extent of G protein-coupled inwardly rectifying potassium channel activation induced by CB1 was not inhibited by high concentrations of ORG27569 (Cawston et al., 2013), suggesting biased signaling modulation.

In addition to coupling to $G\alpha_i$, CB1 can also couple to $G\alpha_s$ to stimulate the activation of adenylate cyclase, and this $G\alpha_s$ linkage can be observed in cells following pertussis toxin treatment (Glass & Felder, 1997). Consistent with its effect on $G\alpha_i$, ORG27569 has also been shown to antagonize CB1's $G\alpha_s$-like coupling (Baillie et al., 2013; Cawston et al., 2013).

More complex interactions with signaling pathways have been suggested by studies investigating the effects of the allosteric modulators on MAP kinase signaling pathways (Bouaboula et al., 1995; Derkinderen, Ledent, Parmentier, & Girault, 2001). In contrast to the inhibition of orthosteric agonist signaling observed in other assays, ORG27569 has been suggested to enhance CP55,940-induced pERK stimulation (Baillie et al., 2013) (although see the findings of Ahn et al., 2012 discussed later).

ALLOSTERIC MODULATION OF CB1 RECEPTOR REGULATION

Studies examining the kinetics of blockade of adenylate cyclase inhibition by ORG27569 and PSNCBAM-1 have suggested that rather than purely antagonizing signaling, the blockade of signaling described earlier may be due to enhanced receptor regulation. Thus, Cawston et al. (2013) found that early inhibition of adenylate cyclase by CB1 was not prevented by the allosteric modulators, but that the modulators produced a rapid desensitization of this pathway. Likewise, CB1 mediated recovery of membrane potential following agonist-mediated hyperpolarization was more rapid in the presence of ORG275689 and PSNCBAM-1 (Cawston et al., 2013).

Current receptor theory would suggest that enhanced receptor desensitization is likely to be mediated by enhanced G protein-coupled receptor kinase phosphorylation of the receptor, followed by increased recruitment of β-arrestin and receptor internalization; however, this is not the case with the CB1 allosteric modulators studied to date. Baillie et al. (2013) demonstrated that ORG27569 inhibited β-arrestin recruitment, while Cawston et al. (2013) have shown that ORG27569 and PSNCBAM-1 produce a concentration-dependent decrease in agonist-induced receptor internalization. Interestingly, ORG27569 treatment of the constitutively inactive CB1 variant (T210A) resulted in a robust acceleration in receptor internalization, as compared to CP55,940 alone (Ahn et al., 2012) a finding that is hard to reconcile with the previously mentioned experiments on wild-type receptors, but that may be due to enhanced β-arrestin recruitment by these mutant receptors (Ahn, Mahmoud, Shim, & Kendall, 2013).

ALLOSTERIC AGONISM

There have also been some suggestions in the literature that ORG27569 can act as an allosteric agonist, producing efficacy in signaling pathways in the absence of

orthosteric ligand, although these are by no means consistent. The initial report by Price et al. (2005), suggested no activity of the compounds alone, in a mouse vas deference contractility assay. Similarly, in mouse brain samples, ORG27569 produced no effect on [^{35}S]GTPγS binding; however, in cell lines expressing human CB1, ORG27569 produced a small but significant decrease in basal [^{35}S]GTPγS binding (Baillie et al., 2013), a finding confirmed by Ahn et al. (2012), and consistent with an inverse agonist effect of ORG27569. ORG27569 alone was also found to produce a small stimulation of adenylate cyclase in the presence of forskolin (Baillie et al., 2013), an effect that was confirmed by Cawston et al. (2013). However, this increase was found to be pertussis toxin insensitive in the initial study—suggestive of $G\alpha_s$ coupling (Baillie et al., 2013), but was pertussis toxin-sensitive in the subsequent study (Cawston et al., 2013)—suggestive of inverse agonism. This discrepancy is yet to be resolved.

Ahn et al. (2012) utilized their mutant CB1 receptors with both enhanced and reduced constitutive activity to investigate how ORG27569 influenced additional downstream signaling cascades, including the MAP kinase signaling pathway. Interestingly, ORG27569 alone at high concentrations (10 μM) induced robust ERK1/2 phosphorylation (higher than that of the orthosteric agonist CP55,940). This effect was shown to be pertussis toxin-insensitive, suggesting it was $G\alpha_i$ independent (Ahn et al., 2012), and was subsequently found to be β-arrestin-1 dependent (Ahn et al., 2013). In contrast, Baillie et al. (2013) observed only a small increase in ERK1/2 phosphorylation in response to ORG27569 alone, which was pertussis toxin-sensitive. The cause of these differences between studies is not immediately obvious, particularly as most studies have used transfected HEK293 cells, but could possibly suggest that HEK293 cells in different labs have substantively different β-arrestin expression.

PROBE DEPENDENCE

Probe dependence is when different allosteric effects may be observed for the same modulator, acting at the same receptor, but with different orthosteric ligands (Kenakin, 2005). In the case of CB1, PSNCBAM-1 has been shown to cause noncompetitive antagonism in [^{35}S]GTPγS binding studies, with a higher potency against CB1 receptor agonist CP55,940 than WIN55,212-2 (Wang, Horswill, Whalley, & Stephens, 2011). The electrophysiology studies carried out by Wang et al. (2011), using both WIN55,212-2 and CP55,940, showed a reduction in miniature inhibitory postsynaptic currents (mIPSCs) frequency, but not amplitude. PSNCBAM-1 pretreatment revealed agonist-dependent functional antagonism, abolishing CP55,940-induced reductions in mIPSC frequency, but having no clear effect on WIN55,212-2 actions, suggestive of ligand-dependent effects. In line with these findings, Baillie et al. (2013) showed that both ORG27569 and PSNCBAM-1 displayed a marked ligand selectivity in [^{35}S]GTPγS, β-arrestin and cAMP assays, with both allosteric modulators being significantly less potent as inhibitors of WIN55,212-2 signaling, as compared with CP55,940. This was confirmed for ORG27569 by Cawston et al. (2013) in the cAMP signaling assay; however, they found that PSNCBAM-1 was equipotent for CP55,940 and WIN212-55. However, differences were observed, as when WIN55,212-2 was the orthosteric ligand, ORG27569 was unable to produce the same extent of inverse agonism as CP55,940, suggesting that the presence of WIN55,212-2 prevented the receptor from adopting an inactive conformation (Cawston et al., 2013). Thus, there are suggestions that the allosteric modulators may differentiate between orthosteric ligands, but this still has not been fully investigated.

ELUCIDATION OF ORG27569 BINDING SITE IN CB1

Site-directed fluorescence labeling has been used to gain insight into why the presence of ORG27569 results in increased agonist binding, but also in blockade of agonist mediated signaling (Fay & Farrens, 2012). To do this, a fluorescent label was attached to the cytoplasmic end of CB1's transmembrane 6 (a helix shown to move during activation in other GPCRs by the same method). It was shown that ORG27569 blocks conformational changes in CB1 that accompany G protein binding and/or activation and, thus, inhibits formation of a fully active CB1 structure. It was determined that the reason for this is that the simultaneous binding of ORG27569 and agonist produces a unique conformation resembling an intermediate state (Fay & Farrens, 2012). Furthermore, the binding site of ORG27569 in CB1 has recently been identified via computational, synthesis, mutation, and functional studies as being present in transmembrane 3-6-7 (Shore et al., 2014). The ORG27569 binding site was shown to overlap with the previously determined SR141716A binding site, and extends extracellularly, with an interaction between the ORG27569 piperidine ring nitrogen, and the lysine at position 192 of CB1, enabling ORG27569 to act as an inverse agonist.

IN VIVO STUDIES OF ORG27569

Initial characterization studies with PSNCBAM-1 by Horswill et al. (2007) showed that, in vivo in an acute rat-feeding model, PSNCBAM-1 decreased food intake and body weight. Subsequently, ORG27569 was evaluated

in vivo in the well-established mouse behavioral assays sensitive to CB1 orthosteric agonists and inverse agonist (Gamage et al., 2014). Similar to the orthosteric CB1 antagonist/inverse agonist SR141716A, ORG27569 reduced food intake, however this occurred independently of the CB1 receptor. ORG27569 did not elicit CB1-mediated effects alone, and lacked efficacy in altering antinociceptive, cataleptic, and hypothermic actions of anandamide, CP55,940, or Δ^9-tetrahydrocannabidiol (Gamage et al., 2014). While pharmacokinetic issues cannot be ruled out, this lack of efficacy in common behavioral pathways is surprising, given the complex effects on signaling described earlier, and requires further investigation.

PROPOSED ALLOSTERIC MODULATORS OF CB1

There have been additional reports of potential allosteric modulators for CB1 that have not yet been as extensively investigated as the two compounds described earlier. The endogenous antiinflammatory lipid Lipoxin A4 has been shown as a potential allosteric enhancer of CB1 (Pamplona et al., 2012). Lipoxin A4 enhanced the affinity of anandamide in mouse brain membranes, thus potentiating its effects both in vivo and in vitro. In HEK cells transfected with mouse CB1, Lipoxin A4 increased the potency of anandamide in reducing forskolin-induced cAMP levels ($G\alpha_i$), but had no effect in the [^{35}S]GTPγS assay (Pamplona et al., 2012).

The α-hemoglobin-derived dodecapeptide RVD-hemopressin has been shown to interact orthosterically with CB1 (Heimann et al., 2007). Bauer et al. (2012) investigated this further by raising monoclonal antibodies to the C-terminal part of hemopressin, and screening them on rodent brain extracts, and human and mouse plasma. From this screen, a family of N-terminally extended peptides in addition to hemopressin were identified. The peptides were designated Pepcan-12 and Pepcan-23 (referring to the peptide length). Pepcan-12 was shown to be the most efficacious Pepcan in displacing [^{3}H]CP55,940 and [^{3}H]WIN55,212-2, but only partial displacement occurred, consistent with an allosteric effect. The data was fitted to the allosteric ternary complex model, and revealed a negative cooperativity factor, thus identifying Pepcans as negative allosteric modulators of CB1. Pepcan-12 was shown to be a potent negative allosteric modulator of orthosteric agonist-induced cAMP accumulation, [^{35}S]GTPγS binding, and CB1 internalization (Bauer et al., 2012).

Recently, the inactive precursor of all steroid hormones, pregnenolone has been described as an endogenous negative allosteric modulator of CB1 (Vallee et al., 2014). In rats, Δ^9-tetrahydrocannabidiol CB1 activation was shown to increase the level of brain pregnenolone, which in turn, exerted a negative feedback on the CB1 receptor activity. Binding studies in cell lines expressing human CB1 showed that pregnenolone (up to 100 μM) did not modify equilibrium binding of [^{3}H]CP55,940 and [^{3}H]WIN55,212-2 to CB1 and, thus, the authors have suggested that pregnenolone is acting as a negative allosteric modulator (Vallee et al., 2014).

Finally, several dopamine transporter inhibitor compounds (RTI-370, RTI-371, JWH007, and GBR12909) have been suggested, via a cell-based calcium mobilization assay, to be positive allosteric modulators of human CB1 (Navarro, Howard, Pollard, & Carroll, 2009). The positive allosteric effect on calcium signaling of RTI-370, RTI-371, and JWH007 occurred with very little increase in potency, whereas GBR12909 showed a decrease in CP55,940 potency (Navarro et al., 2009).

CB1 DIMERIZATION AS A FORM OF ALLOSTERIC MODULATION

It has become well-established that GPCRs can interact together to form two- or multireceptor assemblies called "heterodimers" or "heteromers" (Pin et al., 2007). Heterodimerization can be considered as a form of allosteric modulation, which can be exploited pharmacologically for therapeutic advantage (Milligan & Smith, 2007), as illustrated in Fig. 60.4. This could mean designing ligands which disrupt or encourage heterodimer formation, or utilize functional crosstalk within the dimer, therefore targeting tissues specifically where that dimer partnership occurs.

CB1 has been demonstrated to dimerize with many other GPCRs, with functional consequences for CB1's signaling pathways. So far, CB1 has been suggested to dimerize with adenosine A2A (Carriba et al., 2007, 2008); dopamine D2 (Carriba et al., 2008; Glass & Felder, 1997; Marcellino et al., 2008); orexin 1 (Ellis, Pediani, Canals, Milasta, & Milligan, 2006); β2-adenergic (Hudson, Hébert, & Kelly, 2010); and μ-, κ-, and δ-opioid receptors (Rios, Gomes, & Devi, 2006). Here, we will just discuss some better-characterized examples.

The CB1–D2 heterodimer is probably the most well-described cannabinoid receptor heterodimer. These two receptors are coexpressed in neurons, particularly striatal medium spiny neurons (Glass, Dragunow, & Faull, 1997), and within the nucleus accumbens (Pickel, Chan, Kearn, & Mackie, 2006). When coexpressed, these receptors change from their standard $G\alpha_i$ signaling, to one which has been variously reported to either switch to stimulation of cAMP accumulation (Kearn, Blake-Palmer, Daniel, Mackie, & Glass, 2005; Glass & Felder, 1997; Jarrahian, Watts, & Barker, 2004; Maneuf & Brotchie, 1997), or at least nonsynergistic adenylate cyclase inhibition (Meschler & Howlett, 2001; Khan &

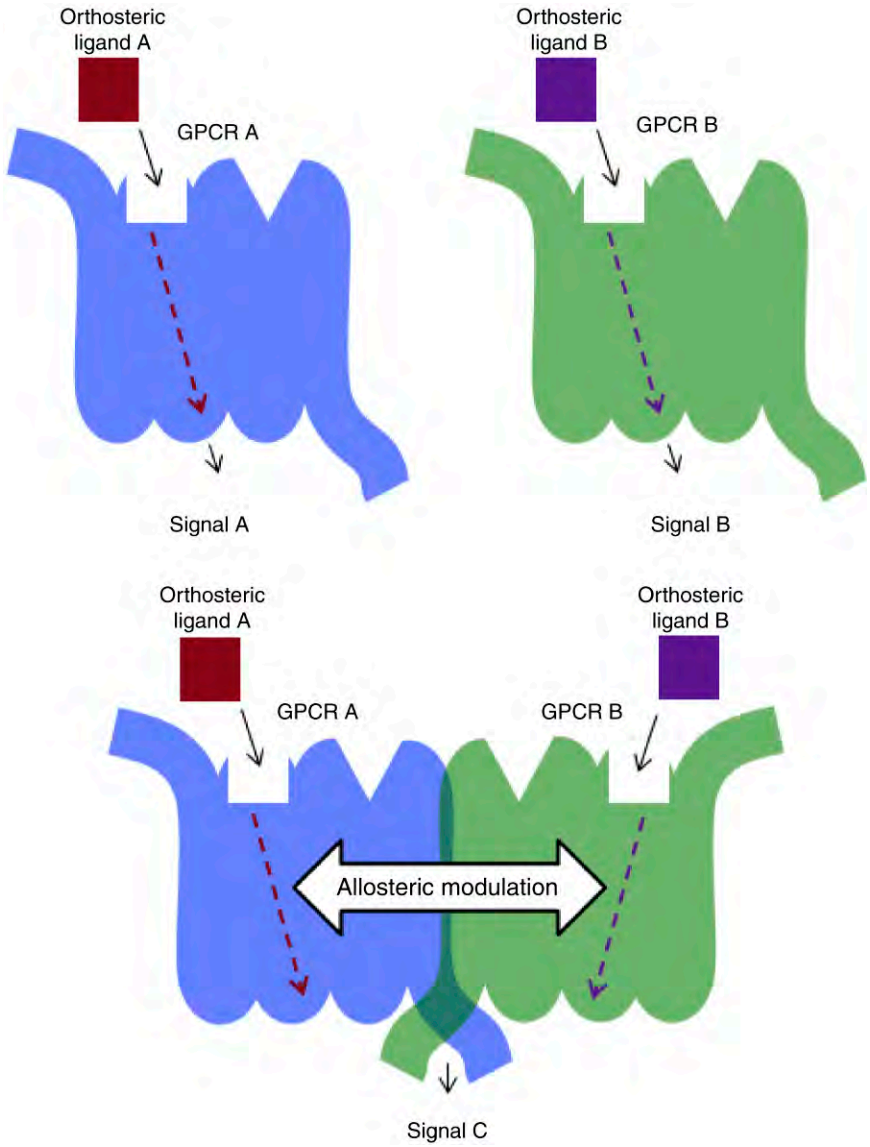

FIGURE 60.4 **Heteromerization as a form of allosteric modulation.** Heterodimerization can be considered as a form of allosteric modulation and, thus, two G protein-coupled receptors A and B can interact together to form a heterodimer, and this results in a change in receptor conformation, thus creating a GPCR heterodimer with novel binding and/or functional properties.

Lee, 2014). Fluorescence resonance energy transfer data (Marcellino et al., 2008; Carriba et al., 2008) and coimmunoprecipitation data (Kearn et al., 2005) strongly suggest that this receptor interaction is due to physical contact between CB1 and D2.

Electron microscopy and FRET data suggest that a CB1–orexin 1 receptor heterodimer can also occur (Ellis et al., 2006; Hilairet, Bouaboula, Carrière, Le Fur, & Casellas, 2003). CB1's dimerization with the orexin 1 receptor affects its constitutive trafficking phenotype (Ellis et al., 2006), and also both receptors' ability to signal through pERK1/2 (Ellis et al., 2006; Hilairet et al., 2003). However, this interaction may not be entirely within the structure of a heterodimer, as orexin receptor stimulation causes 2AG release, which can act at CB1 receptors in an autocrine manner (Jäntti et al., 2013).

The CB1 and μ-opioid receptors are coexpressed in the nucleus accumbens (Pickel, Chan, Kash, Rodríguez, & MacKie, 2004; Schoffelmeer, Hogenboom, Wardeh, & De Vries, 2006), caudate putamen nucleus (Rodríguez, Mackie, & Pickel, 2001), and spinal cord dorsal horn (Salio et al., 2001), allowing for molecular interactions of these receptors. The CB1–μ opioid dimer creates a mutually inhibitory effect on signaling (ie, both receptors signal less), as measured by G protein turnover, pERK1/2, and Src activation pathways (Rios et al., 2006; Canals & Milligan, 2008), and coactivation of both receptors affects neurotransmitter release in nucleus accumbens slices (Schoffelmeer et al., 2006).

The importance of GPCR heteromerization in vivo remains to be elucidated and exploited, largely because of a lack of selective pharmacological tools. Among various efforts to modulate GPCR heteromers, bivalent ligands, are defined as two pharmacophores linked by spacers, represent a promising approach, and may provide such a tool (Berque-Bestel, Lezoualc'h, & Jockers, 2008; Liu, Zhang, & Zhang, 2009). Bivalent ligands are expected to bind with greatly enhanced affinity to ligand recognition sites on heteromers because of the small containment volume for the second pharmacophore after the binding of the first, and the formation of more thermodynamically stable complexes. At the same time, bivalent ligands may display unique properties, since they interact with more than one receptor simultaneously. Indeed, bivalent ligands have been developed for a variety of G protein-coupled receptor targets, and exhibit unique pharmacological properties, compared to their monomeric subunits (Hiller, Kuhhorn, & Gmeiner, 2013).

CONCLUSIONS

In conclusion, CB1 receptor signaling can be modified by allosteric modulation, whether it be by direct binding to allosteric binding sites, or through modulation of the receptor conformation by heteromer partners. Considering the therapeutic potential of cannabinoid receptors, allosteric modulation provides an attractive alternative to orthosteric modulation.

MINI-DICTIONARY

Adenylate cyclase/adenylyl cyclase A family of enzymes which make cAMP, the activity of which can be controlled by GPCRs.
Affinity The strength of interaction between a ligand and its binding site.
Allosteric modulator A molecule that binds at a topographically distinct site to the orthosteric ligand, and results in a change in receptor conformation, thus creating a GPCR with novel binding and/or functional properties.
Efficacy The maximum signaling effect which a ligand can produce.
Heterodimers/heteromers A functional unit formed by the physical interaction of two or more GPCRs, often with modified ligand binding and signaling, compared to monomeric receptors.
MAP kinase signaling A signaling cascade which can be triggered by GPCRs. ERK1/2 phosphorylation is a common experimental endpoint.
Negative allosteric modulator An allosteric modulator that decreases the affinity and/or efficacy of the orthosteric ligand.
Orthosteric agonist An agonist which binds in the same site as the endogenous ligand.
Orthosteric site The binding site on the receptor where the endogenous ligand binds.
Positive allosteric modulators An allosteric modulator that enhances the affinity and/or efficacy of an orthosteric ligand.
Probe dependence When different allosteric effects may be observed for the same modulator, acting at the same receptor, but with different orthosteric ligands.

CHAPTER

61

Polymorphisms of the CB2 Cannabinoid Receptor

P. Kumar, Z.-H. Song

Department of Pharmacology and Toxicology, University of Louisville School of Medicine, Louisville, KY, United States

SUMMARY POINTS

- This chapter focuses on the single nucleotide polymorphisms (SNPs) of the human CB2 cannabinoid receptor (*CNR2*).
- Functional and genetic association studies on SNPs of *CNR2* are reviewed.
- Nonsynonymous SNPs in *CNR2* have been reported to cause changes of the responses of the CB2 to various cannabinoid ligands.
- Nonsynonymous SNPs, synonymous SNPs, as well as SNPs in the noncoding region of *CNR2* have been shown to be associated with a variety of diseases.
- The disorders associated with *CNR2* include autoimmune diseases, liver diseases, osteoporosis, and disorders of central nervous system.

KEY FACTS OF SNPs

- SNPs are single-nucleotide base substitutions that occur in greater than 1% of the population.
- SNPs can be used to predict an individual's susceptibility to environmental factors.
- SNPs play a central role in identifying possible risk factors for diseases.
- SNPs can help predict how an individual will respond a drug treatment.
- SNPs can serve as diagnostic markers to help make informed decisions regarding specific medical treatments.

LIST OF ABBREVIATIONS

2-AG	2-Arachidonoylglycerol
BBRI	Breaking bending resistance index
BMD	Bone mineral density
CB2	Cannabinoid receptor 2
CD	Celiac disease
CHC	Chronic hepatitis C
CNS	Central nervous system
dbSNP	The single nucleotide polymorphism database
GWAS	Genome-wide association studies
ITP	Immune thrombocytopenic purpura
MI	Myocardial infarction
NAFLD	Nonalcoholic fatty liver disease
NASH	Nonalcoholic steatohepatitis
PBC	Primary biliary cirrhosis
SNP	Single nucleotide polymorphism

CB2 CANNABINOID RECEPTOR: DISTRIBUTION AND FUNCTION

The CB2 cannabinoid receptor, cloned in 1993 (Munro, Thomas, & Abu-Shaar, 1993), is a G-protein coupled receptor which is coupled to $G_{i/o}$ protein (Howlett, 2005; Pertwee, 2005; Pertwee & Ross, 2002). Activation of CB2 results in an inhibition of adenylate cyclase through the activation of a pertussis toxin-sensitive G protein (Howlett, 2005; Pertwee, 2005; Pertwee & Ross, 2002).

CB2 has been shown to be expressed on the cells and tissues of the immune system, cardiovascular system, gastrointestinal system, and skeletal system, with recent evidence implicating its expression in the central nervous system (CNS) (Howlett, 2005; Pertwee, 2005; Pertwee & Ross, 2002).

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00071-5
Copyright © 2017 Elsevier Inc. All rights reserved.

In the immune system, CB2 has been shown to mediate immunosuppressive and antiinflammatory effects of cannabinoids (Malfitano, Basu, Maresz, Bifulco, & Dittel, 2014). In the cardiovascular system, CB2 has been shown to play a role in modulating the inflammatory response during myocardial ischemia/reperfusion injury (Steffens & Pacher, 2012). In the gastrointestinal system, the CB2 receptor has been implicated in regulating inflammation in the liver, and playing a hepatoprotective role (Mallat, Teixeira-Clerc, Deveaux, Manin, & Lotersztajn, 2011). In the skeletal system, CB2 receptors have been shown to play a role in bone remodeling (Tam et al., 2005). In the CNS, CB2 may play a role in modulating a variety of diseases such as substance abuse and depression (Onaivi, Ishiguro, Gu, & Liu, 2012).

GENETIC POLYMORPHISMS

Genetic polymorphisms, which are DNA sequence variations in a population, are often the result of mutations. A polymorphism refers to a mutation that displays an allele frequency greater than or equal to 1%. Single nucleotide polymorphisms (SNPs) are the simplest type of polymorphism, and result from a single base mutation which substitutes one nucleotide for another. SNPs are estimated to occur at 1 out of every 1000 base pairs, consist of 80% of all sequence variants, and represent the most common type of polymorphisms and genetic variation among individuals (Gray, Campbell, & Spurr, 2000; Syvanen, 2001).

In a gene, SNPs are typically located in (1) coding sequences, (2) noncoding regions, or (3) intergenic regions between genes (Gray et al., 2000; Syvanen, 2001). SNPs in the coding sequence fall within two categories: synonymous (do not affect protein sequence) and nonsynonymous (affect protein sequence). While synonymous SNPs are typically referred to as silent changes (unable to result in function changes), recently there have been several reports according to which these mutations can result in functional changes. Synonymous SNPs may have altered translation kinetics of a define mRNA which may cause the in vivo folding of the same polypeptide chain into different conformations (Komar, 2007; Sauna, Kimchi-Sarfaty, Ambudkar, & Gottesman, 2007). SNPs that are not in the coding region may still be significant for gene splicing, binding of transcription factors, or the sequence of noncoding RNA (Gray et al., 2000; Syvanen, 2001).

GENOTYPING METHODS

The detection of SNPs can be categorized into two areas: (1) scanning DNA sequences for previously unidentified SNPs and (2) genotyping individuals for known SNPs. SNP genotyping is commonly defined as the measurement of genetic variations of SNPs between members of a species. The most common SNP genotyping methods include hybridization-based (eg, SNP microarrays), enzyme-based (eg, primer extension), oligonucleotide ligation, endonuclease cleavage, or a variation of the aforementioned techniques (Gray et al., 2000; Syvanen, 2001).

TYPES OF INVESTIGATIONS

Association Studies

Genetic association is commonly defined as the relationship between a phenotype and a genetic polymorphism (eg, single nucleotide polymorphism) or between two genetic polymorphisms. Typically, the purpose of genetic association studies is to investigate whether single-locus alleles or genotype frequencies differ between two groups of subjects (patients with disease versus healthy control subjects) (Cargill & Daley, 2000; Farrall & Morris, 2005; Schork, Fallin, & Lanchbury, 2000).

Case–Control Studies

Case–control studies are the most widely employed genetic association studies which compare two groups of subjects (a healthy control group versus a case group displaying the disease). Briefly, all subjects are genotyped (DNA sample analysis) for the known SNPs, and the allele frequency is calculated to determine if it is significantly different between the control and case group. Most commonly, an odds ratio is reported which is the proportion of individuals in the case group exhibiting a specific allele, and the proportion of individuals in the control group exhibiting the same specific allele. An odds ratio significantly greater than one demonstrates that the genetic variant is associated with the disease (Cargill & Daley, 2000; Farrall & Morris, 2005; Schork et al., 2000).

Genome-Wide Association Studies

Genome-wide association studies (GWAS) represent an emerging method to identify important genes which modulate human disease. GWAS primarily focus on relationships between SNPs and disease characteristics (traits). Briefly, this method scans the genome for SNPs, and can analyze hundreds or even thousands of SNPs simultaneously. GWAS typically compare the DNA of two groups of patients: (1) patients who exhibit the disease (cases) and (2) subjects who do no exhibit the disease (controls). This can potentially result in the determination of genes that may contribute to an individual's risk of developing a certain disease (Farrall & Morris, 2005).

THE SINGLE NUCLEOTIDE POLYMORPHISM DATABASE (DBSNP) AND "RS" NUMBERS

One of the most commonly used databases is the dbSNP database, established by the National Center for Biotechnology Information (NCBI), in collaboration with the National Human Genome Research Institute, in 1998. This database serves as the central public source for information regarding genetic variation. The dbSNP is a free public archive for cataloging genetic variation across different species. Reference SNP identification numbers (eg, rs251432) is a unique identification label assigned by NCBI to catalogue a group of SNPs that map to an identical location. The "rs" designation is typically assigned postsubmission, and is always in lower case. The "rs" number does not contain any information regarding position, as it is just an identifier, and is used for all types of variants. It is possible for two different "rs" numbers to refer to the same SNP, if they have not yet been merged (Sherry et al., 2001).

CNR2 GENE LOCATION AND STRUCTURE

The human CB2 cannabinoid receptor gene (*CNR2*) is located on chromosome 1 (1p36.11), and consists of two exons and one intron. The first exon (consists part of the promoter sequence) does not encode for protein, but regulates *CNR2* transcription (Sherwood et al., 2009). In addition, the human *CNR2* has been reported to have two splice variants (Liu et al., 2009).

NONSYNONYMOUS SNPs IN *CNR2*

The following nonsynonymous SNPs in *CNR2* have been shown to cause functional changes of CB2 and/or linked to various diseases:

1. rs2501432, rs35761398: arginine for glutamine at position 63(Q63R) at the beginning of the first intracellular loop.
2. rs4131193: leucine for isoleucine at position 133 (L133I) in the second intracellular loop.
3. rs2501431: alanine for glycine at position 155 (A155G) in the third transmembrane domain.
4. rs2229579: tyrosine for histidine at position 316 (H316Y) at the C-terminal tail.

FUNCTIONAL CONSEQUENCES OF NONSYNONYMOUS SNPs IN *CNR2*

To date, three studies have investigated the functional effects of nonsynonymous SNPs at the *CNR2* gene (Carrasquer, Nebane, Williams, & Song, 2010; Ishiguro et al., 2010b; Sipe, Arbour, Gerber, & Beutler, 2005).

The first study, conducted by Sipe and coworkers, investigated the relationship between the CB2 receptor polymorphism and immune cell regulation and function. They studied a missense polymorphism at the CB2 cDNA position 188-189 which results in the amino acid substitution of glutamine with arginine at position 63 (Q63R). Sipe and coworkers demonstrated that, in T lymphocytes from CB2 188-189 GG/GG homozygotes, there was a twofold reduction of endocannabinoid-induced inhibition of proliferation, compared with cells from CB2 188-189 AA/AA homozygotes. Overall, Sipe et al. (2005) has provided evidence that this missense polymorphism leads to a disruption of the endocannabinoid inhibition of the immune system function, and suggests that the CB2 188-189 variant may be a genetic risk factor for autoimmune diseases.

In 2010, Ishiguro and coworkers investigated the effect of the cannabinoid agonists 2-arachidonoylglycerol (2-AG) and JWH015 on cAMP levels in Q63- or R63-allele *CNR2*-transfected CHO cells. Their results showed that, in cells transfected with the R63-allele, the cAMP response to both 2-AG and JWH-015 was reduced, comparing to cells transfected with Q63 allele. Ishiguro et al. (2010b) concluded that CB2 carrying R63 had a reduced function when activated by cannabinoid agonists.

Carrasquer et al. (2010) investigated if two nonsynonymous SNPs at the *CNR2* gene result in functional consequences at the CB2 receptor. Q63R, H316Y, and Q63R/H316 mutations were generated in recombinant human CB2 and stably transfected in HEK293 cells. Carrasquer and coworkers reported that the CB2 polymorphic receptors were able to bind cannabinoid ligands, and modulate signal transduction. However, in ligand-induced cAMP accumulation assays, the cannabinoid agonists WIN55212-2 and 2-AG exhibited reduced efficacy in cells expressing the polymorphic receptors compared to the CB2 wild-type receptor. Furthermore, in constitutive activity assays, the H316Y and Q63R/H316Y polymorphic receptors displayed higher constitutive activity, compared with the CB2 wild-type receptor. Carrasquer et al. (2010) concluded that the *CNR2* Q63R and H316Y polymorphisms resulted in alterations of receptor function.

CB2 POLYMORPHISM GENETIC ASSOCIATION STUDIES

Association Between CB2 Polymorphisms and Immune System Disorders

This section will review the three studies in which the *CNR2* Q63R variant has been linked to immune system disorders.

Immune thrombocytopenic purpura (ITP) is an acquired autoimmune disorder, and is the most common cause of thrombocytopenia in children. In 2011, Rossi and coworkers genotyped 190 children with ITP and 600 healthy subjects for the *CNR2* rs35761398 variant which results in the missense Q63R. They demonstrated, for the first time, an association between the functional variant of the *CNR2* gene and ITP. The relative odds ratio indicated that the risk of acquiring childhood chronic ITP was more than double in children who were homozygous for the variant. The results from this study indicated that the *CNR2* variant Q63R is significantly linked to childhood chronic ITP. The results from their study confirm the role that CB2 plays in autoimmunity susceptibility, and divulged a previously unknown association between this receptor and childhood chronic ITP (Rossi et al., 2011).

In 2013, Gouda and coworkers investigated the link between the *CNR2* Q63R polymorphism and childhood ITP in a case–control association study consisting of 100 patients. This is the first study to describe this association in a population of Egyptian children. The relative odds ratio indicated that the risk of acquiring childhood chronic ITP was more than double in children who were homozygous for the variant. In contrast, there was no significant difference between the acute ITP patient group and the control group, regarding the Q63R genotype. Therefore, it was concluded that the *CNR2* Q63R polymorphism is a predictor of chronic, but not acute ITP (Mahmoud Gouda & Mohamed Kamel, 2013). The results from this study are consistent with the findings from Rossi et al. (2011).

Celiac disease (CD) is a digestive and autoimmune disorder often characterized by chronic inflammation that damages the lining of the small intestine. CD can be triggered by the consumption of gluten, a protein found in several grain products. In 2012, Rossi and coworkers investigated the association of rs35761398 (CAA/CGG), the Q63R *CNR2* variant, with CD in a cohort of 327 southern Italian children. The finding of this study demonstrated that the Q63R variant was significantly associated with CD. Specifically, the Q63R variant conferred a greater than sixfold risk for developing CD (Rossi et al., 2012a).

Overall, the three studies discussed in this section provide evidence that the Q63R polymorphism of *CNR2* is associated with disorders of the immune system (ie, ITP and CD).

Association Between CB2 Polymorphisms and Cardiovascular Disorders

Reinhard et al. hypothesized that variations within *CNR2* may be linked to myocardial infarction (MI) or cardiovascular risk factors. They conducted a large case–control study involving 1968 individuals from German MI families. Specifically, the association between 13 SNPs (within and near the *CNR2* gene) with MI or cardiovascular risk factors (eg, arterial hypertension, obesity, hypercholesterolemia, and diabetes mellitus) was investigated. Reinhard et al. concluded that, in this large German population, common SNPs within the *CNR2* gene confer no risk to MI or to cardiovascular risk factors. However, it should be pointed out that Reinhard et al. (2008) did not investigate the association between Q63R and MI or cardiovascular factors.

Association Between CB2 Polymorphisms and Liver Disorders

This section will review the three studies in which the Q63R variant has been investigated for its contribution to liver disorders.

Primary biliary cirrhosis (PBC) is a liver disorder involving cholestasis, fibrosis, and biliary cirrhosis. PBC is thought to be modulated by autoimmune processes. In 2010, Floreani and coworkers investigated if the CB2 receptor is modulated in the livers of PBC patients, and if genetic variations in *CNR2* may be associated with PBC. They found that there was no significant increase in the mRNA expression of CB2 in patients with PBC. In addition, since the CB2 polymorphism Q63R (188-189 AA/GG) was observed in 24.4% of Italian patients, 30.4% of US patients, and 28.0% of Italian control samples (p = n.s.), they concluded that the association between CB2 polymorphism and PBC was not significant (Floreani et al., 2010).

Nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH) consist of a broad spectrum of conditions, including steatosis and inflammatory steatohepatitis, which can be associated with differing degrees of fibrosis, and can potentially progress to cirrhosis. The endocannabinoid system has recently been implicated in liver diseases. In 2012, Rossi and coworkers investigated the association of the rs35761398 *CNR2* Q63R variant and liver disease in a population of 118 Italian children with NAFLD, as confirmed by histopathology. They reported that the Q63R variant was not linked to steatosis or fibrosis, but was associated with the severity of the inflammation and appearance of NASH. However, it should be mentioned that the lack of association of Q63R with fibrosis can possibly be due to the young age of the subjects in this study, as the disease simply may have not progressed. Overall, Rossi et al. (2012b) concluded that the Q63R polymorphism may play a role in modulating the inflammatory state in obese children and can potentially predispose these children to liver damage.

In patients with chronic hepatitis C (CHC), CB2 seems to display hepatoprotective properties. Recently,

Coppola et al. conducted the first study to investigate the association between rs35761398 Q63R CB2 polymorphism and CHC, in a cohort of 169 Italian patients with anti-HCV/HCV RNA-positive asymptomatic chronic hepatitis. Coppola et al. (2014) concluded that the Q63R variant of the *CNR2* gene is associated with severe inflammation and hepatocellular necrosis.

Overall, it seems that, whether or not there is an association with *CNR2* Q63R polymorphism, depends on the type of liver disease studied.

Association Between CB2 Polymorphisms and Bone Disorders

Osteoporosis is a skeletal disorder characterized by a decrease in bone mineral density (BMD), reduction in bone mass, and a weakening of the microarchitecture of the bone which results in an increased liability to bone fractures. To date, four studies have investigated the association between SNPs in *CNR2* and bone disorders (Huang, Li, & Kung, 2009; Karsak et al., 2005, 2009; Yamada, Ando, & Shimokata, 2007).

Karsak et al. (2005) were the first to show that the CB2 receptor maybe involved in the etiology of osteoporosis in humans by pursuing a systematic genetic case-controlled association study. The subjects consisted of 388 women of Caucasian and French origin (168 patients with postmenopausal osteoporosis and 220 controls); 26 SNPs in the *CNR2* gene were genotyped and 13 of the SNPs were located in the coding exon. Of the 26 SNPs, 18 are significant for allele and genotype distributions. All 13 SNPs in the coding exon were significant for allele and genotype distributions. Of the 13 SNPs in the coding exon, rs4649124 (synonymous) and rs2501431 (A155G-nonsynmous) showed the most significant *P*-values for allele and genotype distributions. Among the 13 SNPs in the coding exon, 3 were nonsynonymous (rs2501432 Q63R, rs2501431 A155G, rs2229579 H316Y). Karsak et al. (2005) concluded that the CNR2 gene is associated with human osteoporosis.

Yamada et al. (2007) genotyped the rs2501431 (A155G) SNP of *CNR2* in a Japanese cohort of 1110 women and 1128 men, in a population-based prospective cohort study, and the results demonstrated that polymorphisms of *CNR2* were associated with BMD in premenopausal and postmenopausal women.

In 2009, Huang and coworkers conducted an association study of four candidate genes, including *CNR2*, in 1243 case–control Chinese subjects. Six SNPs in the *CNR2* gene were analyzed. Of the six SNPs that were analyzed, only A155G was significant for allelic associations with both trochanter BMD and hip BMD. Of the six SNPs that were analyzed, four are located within exon 2. Among the SNPs in exon 2, only one was nonsynonymous (rs2501431-A155G). Their conclusion was that rs2501431 (A155G) has significant allelic association with both trochanter BMD and hip BMD. Huang et al. (2009) also investigated the nonsynonymous *CNR2* SNP rs2229579 (H316Y), and found it was not significantly associated with trochanter BMD or hip BMD.

In 2009, Karsak et al. investigated the association of polymorphisms in *CNR2* with hand bone strength in a family-based study of 574 subjects (290 men, 277 women) from an ethnically homogeneous healthy family sample of European origin (Chuvashians) living in Russia. Specifically, Karsak et al. genotyped 16 SNPs spanning the extended *CNR2* locus. Of the 16 SNPs, 8 were significantly associated with BMD and breaking bending resistance index (BBRI). Furthermore, of the 16 SNPs, 6 were located in the coding exon and contained 3 nonsynonymous SNPs (rs2501432 Q63R, rs2229579 H316Y, and rs2501431 A155G). Of the SNPs in the coding exon, five were significantly associated with BMD and BBRI which included the two nonsynonymous SNPs (Q63R, A155G), but not H316Y. Overall, there were five SNPs in the coding exon of *CNR2* that are significantly related to both BMD and BBRI. The results from this study confirmed and extended previous studies regarding the association of *CNR2* and bone phenotypes (Karsak et al., 2009).

While the studies described earlier provide evidence that implicates *CNR2* as a candidate gene for osteoporosis, the *CNR2* locus was not reported as loci for BMD or osteoporosis in recent GWAS (Richards et al., 2008; Styrkarsdottir et al., 2008). However, it is worth mentioning that these two GWAS used platforms which showed a gap in SNP coverage of about 200 kb which included *CNR2* and neighboring genes. In other words, the *CNR2* locus was not sufficiently covered in these GWAS, and future studies using novel arrays (covering this locus) are needed to determine the contribution of *CNR2* variants in BMD and osteoporosis (Richards et al., 2008; Styrkarsdottir et al., 2008).

Association Between CB2 Polymorphisms and CNS Disorders

There have been eight published studies that investigated the association between the SNPs in *CNR2* and CNS disorders, including alcoholism, eating disorders, depression, bipolar disorders, and schizophrenia.

Association Between CB2 Q63 Polymorphism and Alcoholism

In 2007, Ishiguro and coworkers published data demonstrating that there is an association (odds ratio = 1.25) between the rs2501432 Q63R polymorphism of the *CNR2* gene and alcoholism, in a Japanese population (667 male

and 118 female and 487 age- and gender-matched controls). Ishiguro et al. (2007) concluded that the Q63R *CNR2* polymorphism may influence the susceptibility for developing alcoholism.

Association Between CB2 Polymorphisms and Eating Disorders

In 2010, Ishiguro and coworkers tested the hypothesis that *CNR2* genetic variants may be important for food consumption by examining the association between the *CNR2* gene and eating disorders (anorexia nervosa and bulimia nervosa) in 204 subjects and 1876 healthy volunteers in a Japanese population. Ishiguro et al. (2010a) demonstrated a link between the R63Q polymorphism of the *CNR2* gene and eating disorders (odds ratio 1.24).

In 2014, Ketterer and coworkers investigated the association between the *CNR2* polymorphisms and body weight in a cross-sectional cohort study of 2006 subjects who were at an increased risk for type 2 diabetes. In this study, five SNPs were analyzed. Of the five SNPs, two were located in exon 2 [rs2229579 (H316Y) and rs3123554]. Of the SNPs in exon 2, only the minor allele of rs3123554 was significant. Ketterer et al. demonstrated that the minor of allele of rs3123554 was associated with reduced body weight. In addition, interestingly, carriers of this allele lose less body weight during lifestyle intervention, which is associated to the lower cerebral insulin sensitivity of these individuals. The authors of this study noted that the reduced body mass index (BMI) in female carriers of this allele may be due to peripheral metabolic mechanisms (Ketterer et al., 2014).

Association Between CB2 Q63R Polymorphism and Depression

In 2008, Onaivi and coworkers hypothesized that genetic variants of the *CNR2* gene may be associated with depression in a Japanese population. They demonstrated, in depressed Japanese subjects, there is a high occurrence of the Q63R, but not H316Y polymorphism in the *CNR2* gene. This study provided the first evidence for a role of CB2 in depression (Onaivi et al., 2008a,b).

In 2012, Mitjans and coworkers conducted a longitudinal study that analyzed the genetic variability in the *CNR2* gene in response to a 12-week treatment to citalopram. They demonstrated that AA allele carriers (rs2501431–A155G) exhibited higher Hamilton Depression Rating Scale, as compared to the G allele carriers. This scale is used by clinicians to determine the level of depression in a patient before, during, and after treatment. Mitjans, Gasto, Catalan, Fananas, and Arias (2012) concluded that the *CNR2* gene is associated more with severity of disease outcome versus treatment response.

Association Between CB2 Polymorphisms and Bipolar Disorder

In 2011, Minocci et al. tested the hypothesis that *CNR2* genetic variants might be associated with BD. Specifically, three *CNR2* missense SNPs, rs2501432 (315ANG; Q63R), rs41311993 (L133I), and rs2229579 (H316Y) were investigated in a case–control study that included 80 patients and 160 healthy subjects. A significant correlation was found between BD and *CNR2* 524C > A (L133I polymorphism). In contrast, no association was observed for the other two SNPs. Overall, Minocci et al. (2011) showed for the first time a link between bipolar disorder and the I133L polymorphism in the *CNR2* gene in a population of patients of Italian descent.

Association Between CB2 Polymorphisms and Schizophrenia

Previously, there have been several reports describing the link between marijuana use and schizophrenia.

In 2010, Ishiguro and coworkers examined genetic associations between *CNR2* gene polymorphisms and schizophrenia in two independent case–control populations. The first group consisted of 1152 East Japanese subjects and 1194 control subjects. The second group consisted of 768 West Japanese subjects and 726 control subjects. Differences in the alleles of associated SNPs were analyzed using postmortem (human) brain tissues, and in cultured cells. They analyzed five SNPs. Three of the SNPs are located in the intron region of *CNR2*, and two SNPs [rs2501432 (R63Q) and rs2229579 (H316Y)] are located in exon 2 of *CNR2*. Among the SNPs analyzed, Ishiguro et al. identified two SNPs in *CNR2* gene that are associated with schizophrenia in Japanese populations: (1) rs2501432, which is the missense polymorphism R63Q; and (2) rs12744386, which is located in the intron region, and was found to be associated with low CB2 mRNA and protein expression levels. Ishiguro et al. (2010b) concluded that individuals who exhibit low CB2 receptor expression or low CB2 function may have an increased risk to schizophrenia.

In 2013, Tong and coworkers investigated the association between 3 *CNR2* gene polymorphisms (rs2501432 Q63R, rs2229579 H316Y, rs2501401 G/A) and schizophrenia in 316 patients and 334 healthy control subjects. The *CNR2* polymorphisms Q63R and H316Y are located on the second exon, while rs2501401 is found in the intron. Tong et al. (2013) demonstrated that the TT genotype and T allele frequencies of Q63R were lower, as compared to controls, indicating a protective effect. In addition, they concluded that the T allele of H316Y may increase the risk for developing schizophrenia. Furthermore, there was no significant difference in the genotype and rs2501401 G/A allele frequencies between the case and control groups, demonstrating that the rs2501401 G/A polymorphism may not be related to the risk of developing schizophrenia (Tong et al., 2013).

POSSIBLE ROLE OF *CNR2* IN PERSONALIZED MEDICINE?

Personalized medicine refers to the determination of an individual's genetic makeup which can result in a more fine-tuned diagnosis and treatment. In addition, by doing so, a more specific treatment can be selected, which may increase the likelihood of a successful outcome and reduce adverse drug reactions (Howland, 2012a,b).

Diagnosis

Recent genetic studies (described earlier) provide evidence that *CNR2* variants are associated with a broad range of conditions (eg, immune disorders, liver disorders, osteoporosis, and CNS diseases), suggesting that high-risk individuals could possibly be identified through genetic testing. For example, Sipe et al. (2005) demonstrated that there is a link between the *CNR2* variant Q63R and immune cell regulation and function in humans. This can potentially be used as a diagnostic marker for individuals who are at higher risk for certain autoimmune diseases.

Treatment

The CB2 receptor represents a novel pharmacological target. Drugs acting specifically on CB2 would not have the psychoactive effects of CB1 agonists. CB2 receptor agonists could be potentially useful for the treatment of a variety of diseases, including autoimmune diseases, liver diseases, osteoporosis, and CNS disorders.

As a potential therapeutic target, CB2 receptor can be genotyped and, based on the presence of a particular SNPs in CB2, health professionals can potentially determine the specific cannabinoid drug and proper dosages of cannabinoids to be administered to the specific patient. For example, Sipe et al. (2005) demonstrated that in T lymphocytes from individuals who are homozygous (GG) for the CB2 188-189 variant, the inhibition produced by the endogenous cannabinoid 2-AG was consistently less, compared with cells from the CB2 188-189 AA/AA homozygotes. Therefore, in individuals who are homozygous for the CB2 188-189 variant, a higher concentration of exogenous cannabinoid will need to be administered to achieve therapeutic response.

MINI-DICTIONARY

Allele A variant form of a gene defined as one of a number of alternative forms of the same gene or same genetic locus.
Case–control studies A term commonly used in genetics which refers to comparing the frequency of alleles or genotypes between cases and control.
Genetic polymorphisms A polymorphism refers to a mutation that displays an allele frequency greater than or equal to 1%.
Genotyping A commonly used method to determine differences in the genetic make-up of an individual by investigating an individual's DNA sequence, and comparing it to another individual's sequence or a reference sequence.
Genome-wide association study (GWAS) A method that involves the rapid scanning of markers across complete sets of DNA or genomes of individuals to determine genetic variations associated with a particular disease. These studies are most commonly performed by comparing cases (affected individuals) and controls (unaffected individuals) unrelated to each other.
Nonsynonymous SNP A coding SNP that alters the protein sequence. Two types of nonsynonymous SNPs are missense (results in a different amino acid) or nonsense (results in a premature stop codon).
Odds ratio A measurement of association typically used in case–control studies. It is defined as the odds of exposure to the susceptible genetic variant in cases compared with the odds of exposure in controls. If the odds ratio is significantly greater than one, the genetic variant is associated with the disease.
Reference single nucleotide polymorphism identification number ("rs" ID) An identification number assigned by NCBI which refers to a cluster of SNPs that map to an identical location.
Single nucleotide polymorphism (SNP) A SNP is a change in a single base pair in a specific position along the genome that may or may not be functionally relevant.
Synonymous SNP A coding SNP that usually does not alter the protein sequence.

Chemistry of Cannabinoid Receptor Agonists

M. Aghazadeh Tabrizi, P.G. Baraldi

Department of Chemistry and Pharmaceutical Science, University of Ferrara, Ferrara, Italy

SUMMARY POINTS

- Cannabinoid ligands are characterized by a wide chemical diversity. This diversity has different consequences. First, it has been fairly complicated to supply a common pharmacophore for all cannabinoid agonists. Second, the structure–activity relationships are not the same in the whole family.
- Conspicuous antinociceptive effects of CB agonists in different models of inflammatory or neuropathic pain have been demonstrated.
- The CB_1 selective agonists include anandamide analogs (ACEA, ACPA) and O-1812, cyano analog of methandamide.
- The CB_2 selective agonists include nonendogenous cannabinoids, traditional cannabinoids such as L-759,633, JWH-133, HU-308, aminoalkylindoles (AM-1241), and several different chemical structures are the purpose of the discussion in this chapter.
- Several cannabinoid receptor agonists show distinct stereoselectivity in pharmacological assays, reflecting the presence of chiral centers in these molecules.

KEY FACTS OF CANNABINOID RECEPTORS

- Cannabinoid receptors are responsible for the mediation of the psychoactive effects of cannabis they are also implicated in a variety of physiological processes.
- The two types of cannabinoid receptors named CB_1 and CB_2 are G protein coupled receptors.
- Activation of the cannabinoid receptors causes inhibition of adenylate cyclase, and a subsequent decrease in the concentration of cyclic adenosine monophosphate in the cell, resulting in the inhibition of neurotransmission.
- Δ^9-Tetrahydrocannabinol (Δ^9-THC), representing the psychoactive principle of *Cannabis*, was identified in 1964.
- The CB_1 receptor is expressed mainly in brain, lungs, liver, and kidneys; the CB_2 receptor is expressed principally in the immune system.
- Cannabinoid receptors are activated by phytocannabinoids (found in *Cannabis*), endocannabinoids (produced naturally in the body by humans and animals), and synthetic cannabinoids (produced chemically by humans).

LIST OF ABBREVIATIONS

2-AG	2 Arachidonoylglycerol
ACEA	Arachidonyl-2′-chloroethylamide
ACPA	Arachidonylcyclopropylamide
AEA	Anandamide
cAMP	Cyclic adenosine monophosphate
CBD	Cannabidiol
CNS	Central nervous system
EC_{50}	Median effective concentration
FAAH	Fatty acid amide hydrolase
K_i	Inhibition constant
SAR	Structure–activity relationship
THC	Tetrahydrocannabinol

INTRODUCTION

Cannabinoids, the active components of *Cannabis sativa* and their derivatives, are known to mediate some of their actions through the cannabinoid receptors. Two distinct cannabinoid receptors, named CB_1 and CB_2, have been cloned and characterized from mammalian tissues. The CB_1 receptor is abundantly expressed in the central nervous system (CNS) and is responsible for the psychotropic side effects. The CB_2 receptor is mainly found in cells of the immune system, though it may be upregulated in the CNS under pathological conditions. The main signal transduction pathway triggered is through G_i proteins, resulting in an inhibition of adenylate cyclase activity, and a decrease in cyclic adenosine monophosphate (cAMP) levels (Pertwee et al., 2010). Several studies have demonstrated noticeable antinociceptive effects of CB agonists in different models of inflammatory or neuropathic pain (Guindon & Hohmann, 2008). These models could be useful for the preclinical evaluation and validation of the therapeutic efficacy of novel putative analgesics (Ashton & Milligan, 2008). However, it was mainly drugs interacting with CB_1 receptors that showed marked central side effects that have disallowed their prevalent acceptance and therapeutic application (Kreitzer & Stella, 2009).

The first part of this chapter describes cannabinoid ligands commonly classified into the following chemical groups: tricyclic and bicyclic analogs of tetrahydrocannabinol (THC); endogenous cannabinoids, and the aminoalkylindoles.

In the second part, we describe the chemical structures of the recent entry of several different cores as cannabinoid ligands.

TRICYCLIC AND BICYCLIC ANALOGS OF TETRAHYDROCANNABINOL

Chemical structures are shown in Fig. 62.1; biological data are shown in Table 62.1.

The tricyclic natural compounds fall into the classical cannabinoids. The prototypical (6aR,10aR)-Δ^9-THC (**1**) is the mainly well-known phytocannabinoid, and it is a nonselective agonist that binds to both CB_1 and CB_2 with a similar affinity in the order of 40 nM (Howlett et al., 2002). This natural product readily isomerizes to thermodynamically more stable isomer (**2**, Δ^8-THC) under acidic conditions, which maintains a similar level of affinity. Classical and nonclassical cannabinoids include the tricyclic and bicyclic derivatives of Δ^9-THC and, in particular, derived from more stable isomer Δ^8-THC. For example, (6aR,10aR)-9-(hydroxymethyl)-6,6-dimethyl-3-(2-methyloctan-2-yl)-6a,7,10,10a-tetrahydrobenzo[*c*]chromen-1-ol **3** (HU-210**)** is the (+)-1,1-dimethylheptyl analog of 11-hydroxy-Δ^8-THC which is more potent than natural THC for both CB_1 and CB_2 receptors. The (−)enantiomer (HU-211) being inactive at cannabinoid receptors highlighted the preference for the 6aR, 10aR enantiomer.

The 1-deoxy-Δ^8-THC derivatives were synthesized by replacing the phenolic hydroxyl function leading to **4** (JWH-051), that exhibited significantly enhanced affinity for both the CB_2 and the CB_1 receptors. Other 1-deoxy-Δ^8-THC compounds such as **5** (JWH-056), and **6 (**JWH-133) showed a total loss of CB_1 affinity. In this series, JWH-133 has very high affinity and selectivity for the CB_2 receptor (K_i 3.4 nM). Alternatively, methylation of the phenolic hydroxyl group also reduced affinity for the CB_1 receptor such as that found in compound **7** (L759,633, K_i CB_1 1043 nM) (Huffman, 2000). The bicyclic compounds fall into the nonclassical cannabinoids and derived from opening of the pyran ring of Δ^9-THC. Cannabidiol (CBD) (**8**) is a bicyclic cannabinoid devoid of any psychoactive properties produced by Δ^8-THC or Δ^9-THC. Interestingly, a 3-phenylcyclohexanol derivative **9** (CP-47,497) which has been described as producing many of the pharmacological effects produced by Δ^9-THC, acts as full receptor agonists for both the CB_1 and CB_2 cannabinoid receptors. Another related bicyclic analog 2-[(1R,2R,5R)-5-hydroxy-2-(3-hydroxypropyl)cyclohexyl]-5-(2-methyloctan-2-yl) phenol **10** (CP-55,940) has been used to identify a cannabinoid binding site (Showalter, Compton, Martin, & Abood, 1996). The bicyclic ligand **11** (HU-308) which has the opposite absolute configuration from all other analogs, is a CB_2 specific agonist. A slight modification of dimethylbicycloheptene leading to the **12** (HU-910), enhanced the affinity of the molecule for CB_2 receptor (Horvath et al., 2012).

ENDOGENOUS CANNABINOIDS AND SYNTHETIC ANALOGS

Chemical structures are shown in Fig. 62.2; biological data are shown in Table 62.1.

Generally, the endocannabinoids show better affinity for the CB_1 than CB_2 receptor. In 1992, the first endogenous ligand cannabinoid receptors was isolated and named anandamide (arachidonoylethanolamide, AEA, **13**) (Howlett et al., 2002). Anandamide exerts its biological effects through both cannabinoid receptors as partial agonist. The endogenous agonist of the CB_1 receptor, 2-arachidonoylglycerol (**14**, 2-AG), is the arachidonic acid ester of glycerol and has higher affinity and efficacy to CB_1 and CB_2 receptors than AEA. 2-Arachidonoylglyceryl ether (**15**, 2-AGE or noladin ether) is an ether-linked analog of 2-AG, binds to CB_1 and very weakly to CB_2 receptor.

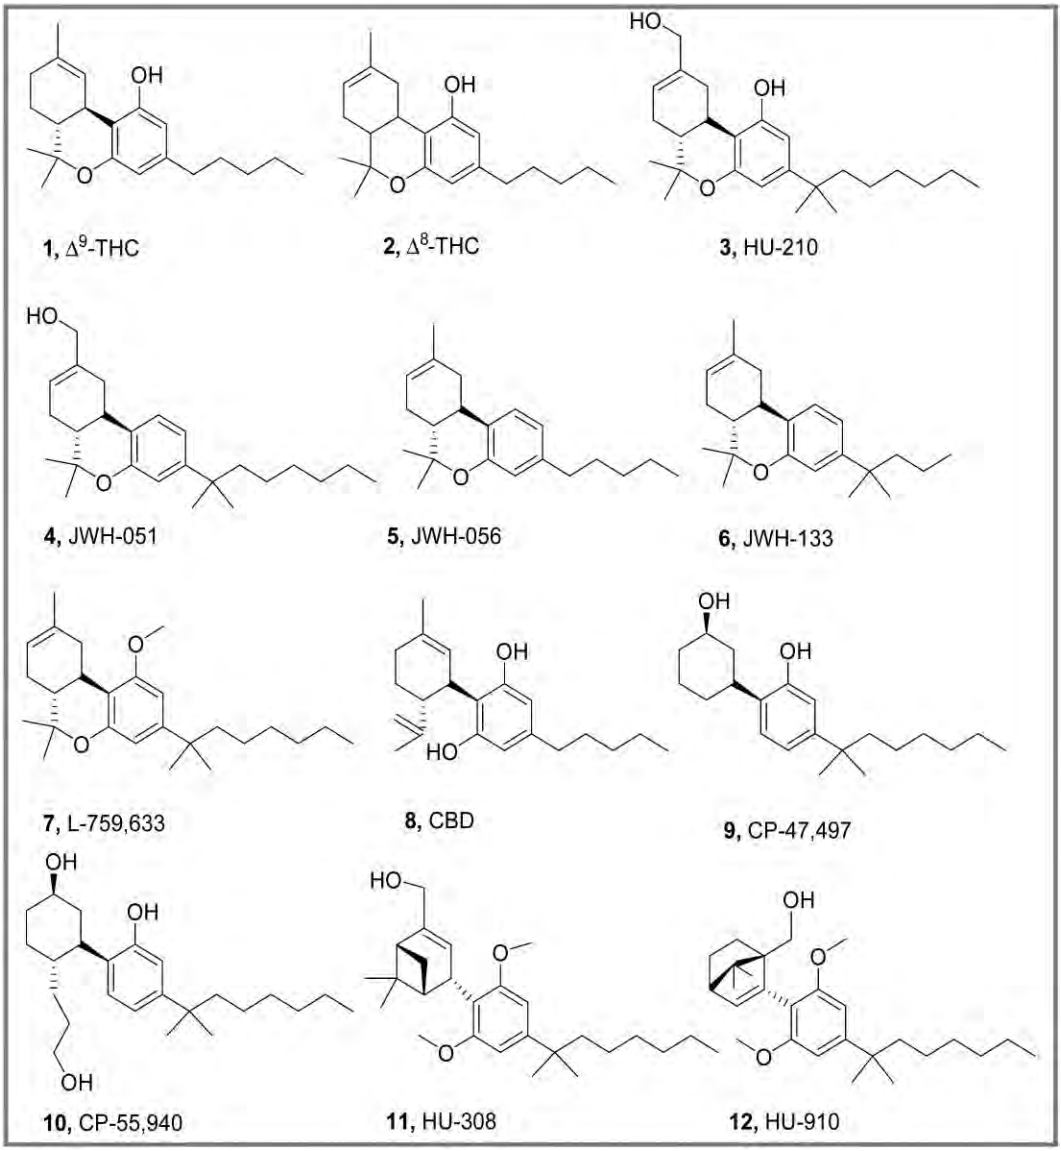

FIGURE 62.1 **Chemical structures of tricyclic and bicyclic analogs of THC.**

To improve metabolic stability and to increase the CB_1 selectivity, the methanandamide series was synthesized. Compound **16** (R-(+)-methanandamide), named also AM356, is a stable chiral analog of anandamide and the CB_1 selectivity of R-(+)-methanandamide derived from the introduction of a methyl group on the 1 carbon of AEA, a structural change that also confers better resistance to the hydrolytic inactivation by fatty acid amide hydrolase (FAAH). O-1812 (compound **17**) is a cyano analog of methanandamide, behaves as potent CB_1 receptor agonist, and acts as a potent and highly selective agonist for the CB_1 receptor (K_i of 3.4 nM at CB_1 and 3870 nM at CB_2 receptors). Unlike most related compounds, O-1812 is metabolically stable against rapid breakdown by FAAH. Arachidonyl-2′-chloroethylamide (**18**, ACEA) and arachidonylcyclopropylamide **19** (ACPA) were prepared by replacement of ethanolamide chain with lipophilic moieties. These analogs are considered to be selective cannabinoid agonists, as they bind primarily to the CB_1 receptor (Pertwee, 2005).

INDOLES

Chemical structures are shown in Fig. 62.3; biological data are shown in Table 62.1.

These ligands consisted of an indole core substituted by the lipophilic aroyl group at C3 and an aminoalkyl side chain at N1 positions (Huffman, 1999). The prototypical **20** (R-(+)-WIN-55,212), is one of the best characterized synthetic cannabinoids from the aminoalkylindole series that has been employed extensively in a number of investigations into the pharmacology of this group of compounds. The R-enantiomer is a potent, full

[b] *Species unspecified.*

agonist of both CB_1 and CB_2 receptors. In contrast, the S-(-)-WIN 55,212 was found to behave as a competitive neutral antagonist of the human CB_2 receptor, and acts as a low potency partial inverse agonist at the human CB_1 receptor (Savinainen et al., 2005).

A summary of SAR described by the research groups indicated that key structural features for potent cannabinoid binding activity of aminoalkylindoles are a bicyclic (particularly l-naphthyl) substituent at the 3-position of the indole, a small substituent, or better, no substituent, at

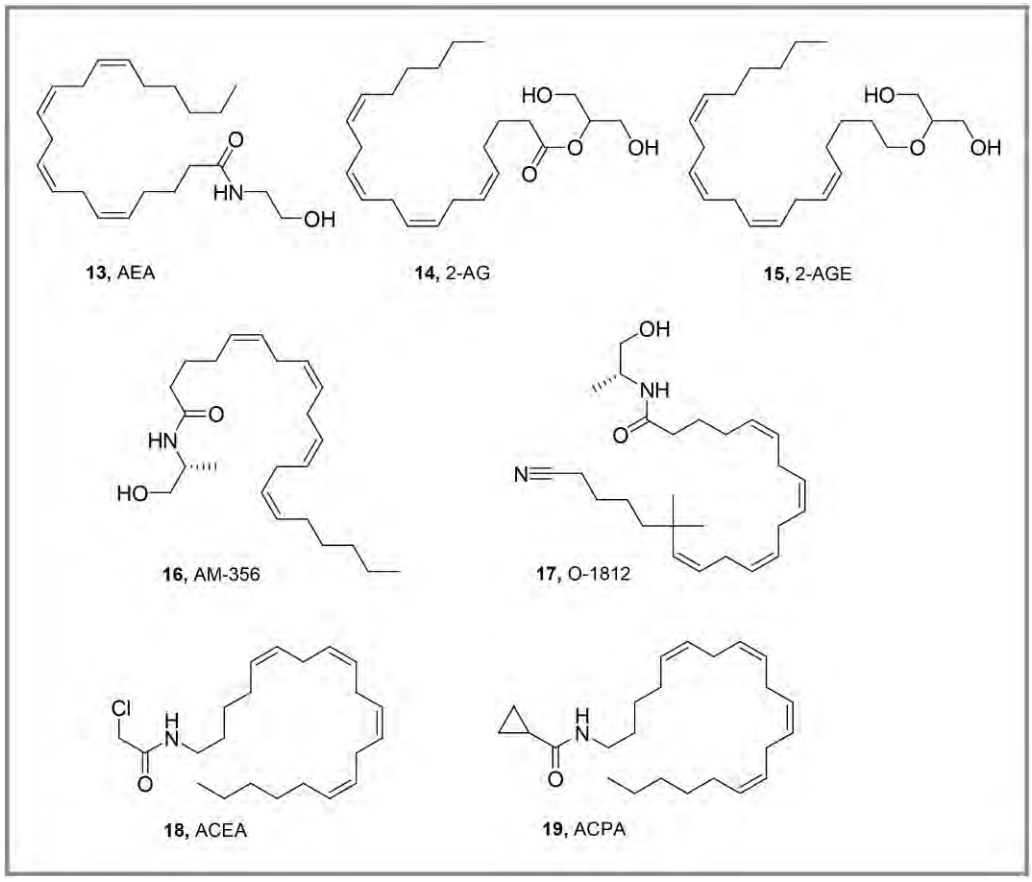

FIGURE 62.2 **Chemical structures of endogenous cannabinoids and synthetic analogs.**

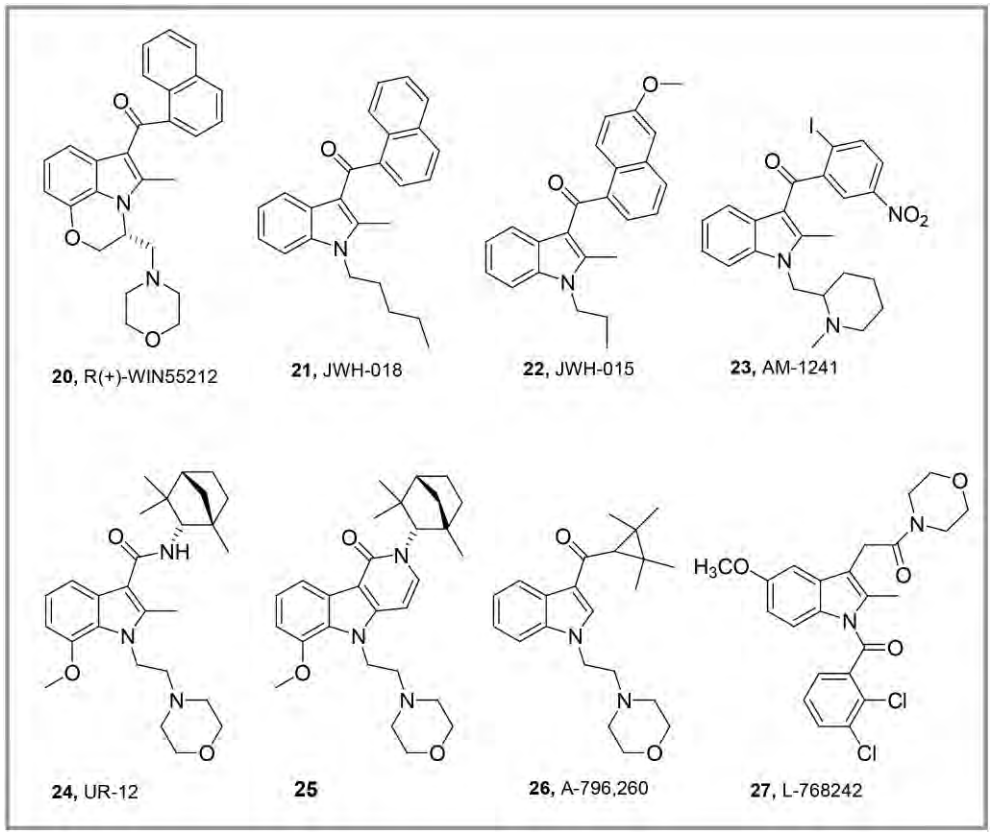

FIGURE 62.3 **Chemical structures of indoles.**

the 2-position of the indole, and a morpholinoethyl or other cyclic aminoethyl substituent at the 1-position. Several studies have been established that the aminoalkyl segment of the molecule could be replaced by an alkyl group. In particular, 1-pentyl-2-methyl-3-(1-naphtoyl)indole **21** (JWH-018) demonstrates modest preference for CB_2, it has high affinity for the brain receptor and exhibits typical cannabinoid pharmacology in vivo. The 1-propyl analog **22** (JWH-015) has selective affinity for the peripheral cannabinoid spleen receptor. In the family of aminoalkylindoles, the 3-benzoyl derivative **23 (**AM-1241, 1-(methylpiperidin-2-ylmethyl)-3-(2-iodo-5-nitrobenzoyl)indole) was prepared as a hydrochloride salt, and showed high selectivity for the human CB_2 receptor versus human CB_1 in recombinant binding assays (Eissenstat et al., 1995). The C3 amido indole and its cyclized and conformationally constrained indolopyridone were found to bind selectively to the CB_2 receptor. Representative compounds are *N*-(S)-fenchyl-1-(2 morpholinoethyl)-7-methoxyindole-3-carboxamide **24** (UR-12**)** and compound **25** (Han et al., 2013). Replacing the aromatic 3-benzoyl or 3-naphthoyl group of indole derivatives with the 3-tetramethylcyclopropylmethanone, enhances selectivity for CB_2 receptors. Compound **26 (**A-796,260) is an example which showed high affinity and selectivity for CB_2 receptor having K_i values of 4.6 and 945 nM in a competition binding assay for human CB_2 and CB_1, respectively (Frost et al., 2010). CB_2 selective cannabimimetic indoles include 1-(2,3-dichlorobenzoyl)-2-methyl-3-(2-[1-morpholine]ethyl)-5-methoxyindole **27** (L-768242) obtained by introduction of benzoyl group on the N1 position (K_i values are 3.92 and 4772 nM for human CB_2 and CB_1 receptors, respectively). The morpholine moiety may be linked to the indole core through an ethylene or acetyl spacer with minimal change in potency on the human CB_2 receptor. In this series, for compounds bearing a morpholine unit at C3, the 2,3-dichlorobenzoyl indole derivative was more active than the another chloro derivatives (30-fold) (Gallant et al., 1996).

The second part of this chapter is focused on advances that have risen with the recent entry of several diverse chemical cores as cannabinoid ligands. Generally, these molecules are characterized by an aromatic heterocyclic core linked to a lipophilic segment, and commonly possess CB_2 receptor affinity.

MONOCYCLIC CORES

Chemical structures are shown in Figs. 62.4 and 62.5; biological data are shown in Table 62.2.

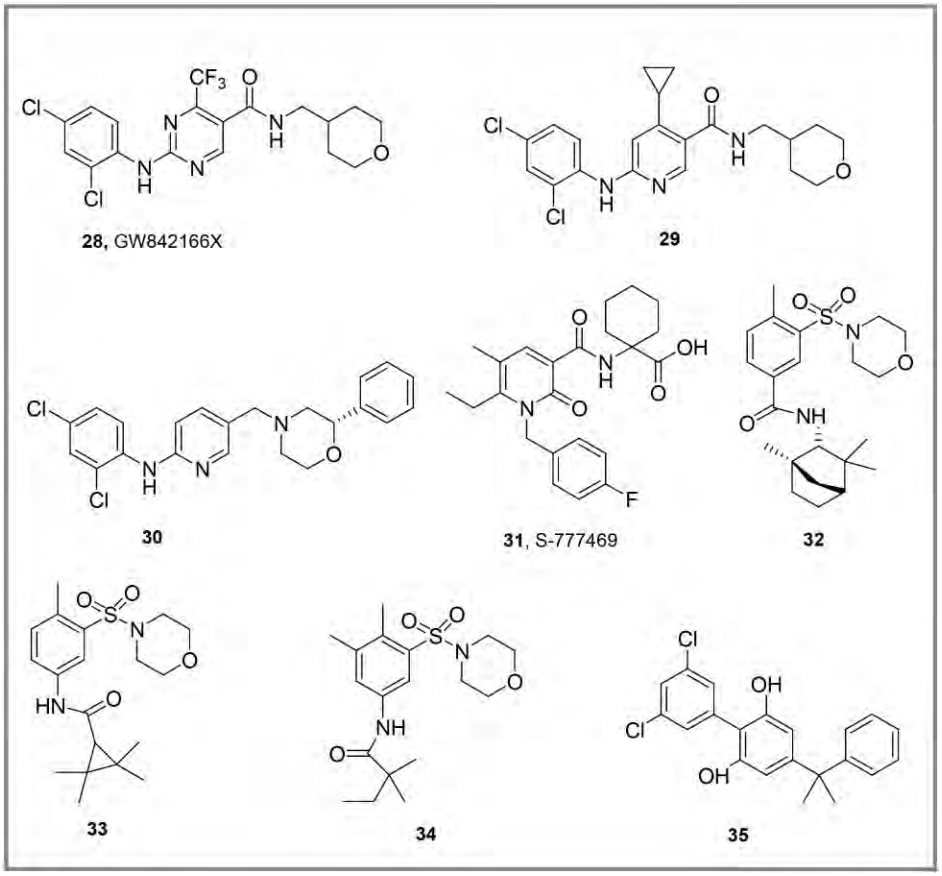

FIGURE 62.4 **Chemical structures of monocyclic cores.**

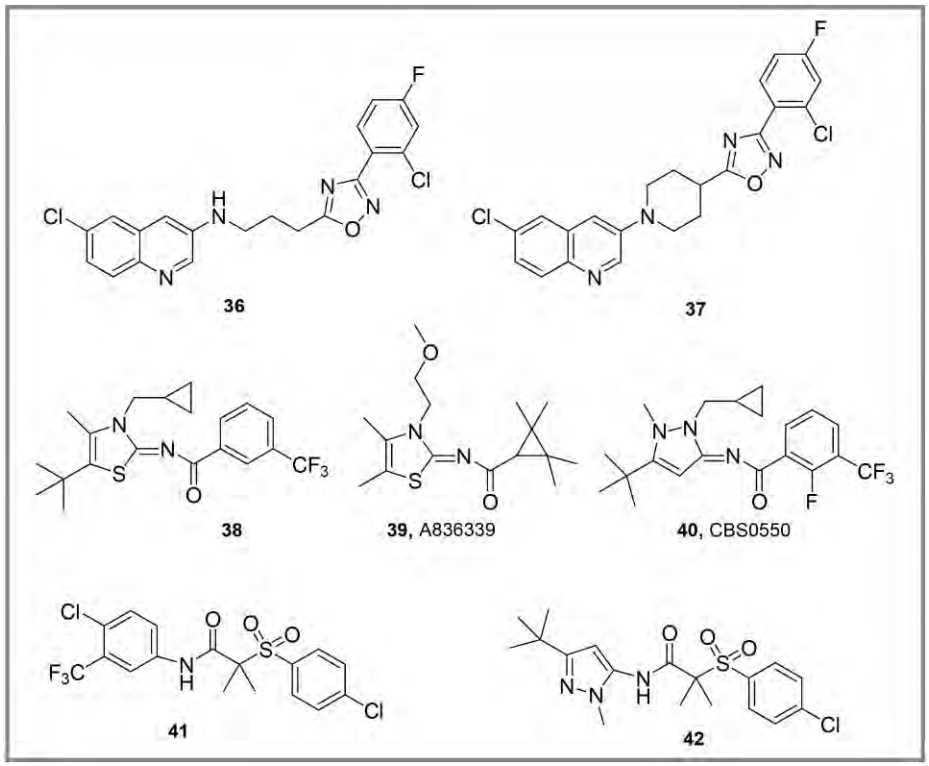

FIGURE 62.5 **Chemical structures of monocyclic cores.**

Pyrimidines and Pyridines

Focused screen identified the pyrimidine ester as a partial agonist at the CB_2 receptor with micromolar potency. Subsequent lead optimization identified **28** (GW842166X) as the optimal compound in the series. GW842166X is a potent and selective full agonist at the CB_2 receptor. Replacement of the pyrimidine core of compound GW842166X with pyridine was investigated to improve the aqueous solubility over GW842166X (Mitchell et al., 2009). An extended SAR of the new pyridine-3-carboxamides template was evaluated, and was concluded in the identification of analog 6-(2,4-dichlorophenylamino)-4-cyclopropyl-*N*-((tetrahydro-2H-pyran-4-yl)methyl)pyridine-3-carboxamide **29** which demonstrated efficacy in an in vivo model of inflammatory pain, despite its low aqueous solubility. Next studies reported a conformationally restricted morpholinyl motif (compound **30**) which retained activity and selectivity (Zindell et al., 2009). A novel CB_2 ligand based on the 3-carbamoyl-2-pyridone derivatives by adjusting the size of side chain at 1-, 5-, and 6-position was discovered. The structure–activity relationship around this template led to the identification of **31** (S-777469) as a selective CB_2 receptor agonist, which exhibited moderate potency for CB_2 receptor (hCB_2 K_i 36 nM) and good selectivity (>120) (Odan et al., 2012).

Sulfamoyl Benzamides

Chemical structures are shown in Fig. 62.4; biological data are shown in Table 62.2.

Several sufamoyl benzamides have been described (Worm et al., 2008), large lipophilic substituents such as S-fenchyl residue, led to improved receptor binding and selectivity for the CB_2 receptor such as compound **32**, with 120-fold functional selectivity for the CB_2 receptor. Small changes in the sulfonamide part of the molecule produced a change from full agonist to inverse agonist. Replacement of the amide moiety with various heterocycles did not significantly improve affinity or selectivity for the CB_2 receptor, in comparison to the lead compound **32**; while reversal of the amide linkage led to the sulfamoyl benzamides with improved affinity and selectivity for the CB_2 receptor. The best compound of this study, the tetramethylcyclopropy derivative **33**, displayed poor metabolic stability in rat pain model (Goodman et al., 2009). Further SAR investigation in the sulfonamide series led to the identification of several compounds, showing potent affinity for the CB_2 receptor (K_i < 10 nM) and improved CB_2 receptor selectivity (>200-fold). Compound **34**, *N*-[3,4-dimethyl-5-(morpholin-4-ylsulfonyl)phenyl]-2,2-dimethyl butanamide, displayed the best overall in vitro profile, and demonstrated robust efficacy in an animal model of postoperative pain (Sellitto et al., 2010).

[a] *Human cannabinoid receptors unless otherwise noted: nM, nanomolar; ND, no data.*

Triaryl Derivatives

Chemical structures are shown in Fig. 62.4; biological data are shown in Table 62.2.

A series of cannabinoid ligands with a structurally triaryl core has been designed. This study was based on the previously observations, wherein an enhancement of CB_2 receptor affinity was observed with a dichlorophenyl substituted ring in the biaryl series. The presence of a gem dimethyl group as a linker (compound **35**) results in a CB_2 selective compound with a K_i value of 1.07 nM at the CB_2 receptor, compared to 93.6 nM at the CB_1 receptor subtype (Bhattacharjee et al., 2009).

N-Arylamide Oxadiazoles

Chemical structures are shown in Fig. 62.5; biological data are shown in Table 62.2.

Targeted library screening and subsequent hit assessment have identified the five-membered oxadiazole core as a novel class of potent and selective CB_2 agonists. SAR investigation into this group of compounds showed that the oxadiazole core was fundamental and substitutions at the 2- and 4-position of the phenyl ring joined to the oxadiazole were important for desired CB_2 activity. The amino quinoline derivative **36** is a highly potent, selective CB_2 agonist that displayed an excellent pharmacokinetic profile, with oral bioavailability in rats (Cheng et al., 2008). Structural modifications in the central portion of the *N*-arylamide oxadiazole scaffold led to the identification of *N*-arylpiperidine oxadiazoles as conformationally constrained analogs that offered improved stability, comparable potency, and selectivity (compound **37**) (DiMauro et al., 2008).

Thiazolylidene, Pyrazolylidene, Amidosulfone

Chemical structures are shown in Fig. 62.5; biological data are shown in Table 62.2.

The five-membered heterocyclic cores such as thiazole ring are reported as CB_2 selective agonists. The SAR study showed that the functional groups at 3- and 5-position in the thiazole ring and the aromatic group in the amide deeply influence the affinity and selectivity for the CB_2 receptor. Thiazolylidene compounds with a bulky functional group like trifluoromethyl, exhibited much high CB_2 affinities (compound **38**, EC_{50} hCB_2 13 nM, 270-fold selectivity) (Ohta et al., 2007). Another thiazolylidene, compound **39** (A-836339), bearing a bulky cycloalkylcarboxamide group, exhibited subnanomolar potency in competition binding assays for human and rat CB_2, with good selectivity against the human and rat CB_1 receptors (425- and 189-fold, respectively) (Dart et al., 2007).

Pyrazole-based CB_2 agonists have also been explored, the SAR study highlighted that heterocycle nucleus operated as a linker, and that the functional groups at the 2-position in the pyrazole ring, and the aromatic group in the amide significantly affected affinity and selectivity for the CB_2 receptor Pyrazolylidene **40** (CBS-0550) has good solubility in water, and in animal studies it was found to produce analgesic and antihyperalgesic effects. It acts as a potent and selective cannabinoid CB_2 receptor agonist (EC_{50} human CB_2 2.9 nM) (Ohta et al., 2008). The strictly correlated α-amidosulfones were found to be potent and selective agonists of CB_2. The effect of the amide substituent on CB_2 activity and selectivity was explored. 3,4-Disubstituted phenyl ring enhanced the potency and selectivity (compound **41**), while disubstituted phenyl rings diminished agonist activity on both CB_1 and CB_2 receptors. For the five-membered heterocycles, it was found that *tert*-butyl group was important for activity, such as in compound 2-(4-chlorophenylsulfonyl)-*N*-(3-*tert*-butyl-1-methyl-1H-pyrazol-5-yl)-2-methylpropanamide **42**. α-Amidosulfones behaved as selective full agonists of CB_2 and showed high functional and cellular activity on CB_2 receptors (Marx et al., 2009).

BICYCLIC CORES

Chemical structures are shown in Fig. 62.6; biological data are shown in Table 62.2.

Benzimidazoles

CB_2 agonists based on benzimidazole template have been reported. One of the first was 2-(4-ethoxybenzyl)-1-(2-(dimethylamino)ethyl)-*N*,*N*-diethyl-1H-benzo[*d*]imidazole-5-carboxamide **43**. This molecule was studied as a starting template to improve the potency of benzoimidazole ligands. SAR studies of the N1 substituent exposed that various alkyl and aromatic groups were tolerated, with a preference for alkyl substituents, and that the binding interactions at the amide position appeared to be essentially hydrophobic (Page et al., 2008). Further investigations around this new class of ligands allowed the discovery of sulfone compounds with CB_2 receptor agonistic activity. Incorporation of neopentyl chain into the 2-position, together with introduction of a sulfonyl group into the 5-position, led to compound 1-(1-(cyclopropylmethyl)-2-neopentyl-1H-benzo[*d*]imidazol-5-ylsulfonyl)cyclopropanecarboxamide (**44**) (Ryckmans et al., 2009), a selective and potent full agonist of CB_2 receptor. In the sulfonyl family, it has been found out that a new class of N-substituted saturated heterocyclic sulfone compounds show CB_2 agonistic activity with little affinity for CB_1, such as 3-(1-(2-(dimethylamino)

ethyl)-2-neopentyl-1H-benzo[*d*]imidazol-5-ylsulfonyl) azetidine-carboxamide **45** (Ando & Iwata, 2010). In this context, 2-*tert*-butyl-substituent benzoimidazole was found to influence both potency and efficacy. Among them, 2-*tert*-butyl-1-(cyclopropylmethyl)-5-(ethylsulfonyl)-1H-benzo[*d*]imidazole **46** was described as a potent and selective CB_2 agonist (>38,000-fold against CB_1) (Ryckmans et al., 2009; Watson et al., 2011). A strictly related class of benzimidazole CB_2 receptor agonists was synthesized, and the SAR was explored. The size of the substituent on the 2-position determined the level of agonism, ranging from inverse to partial or full agonism, which was more pronounced for the rat CB_2 receptor. The benzoimidazole cannabinoid agonists

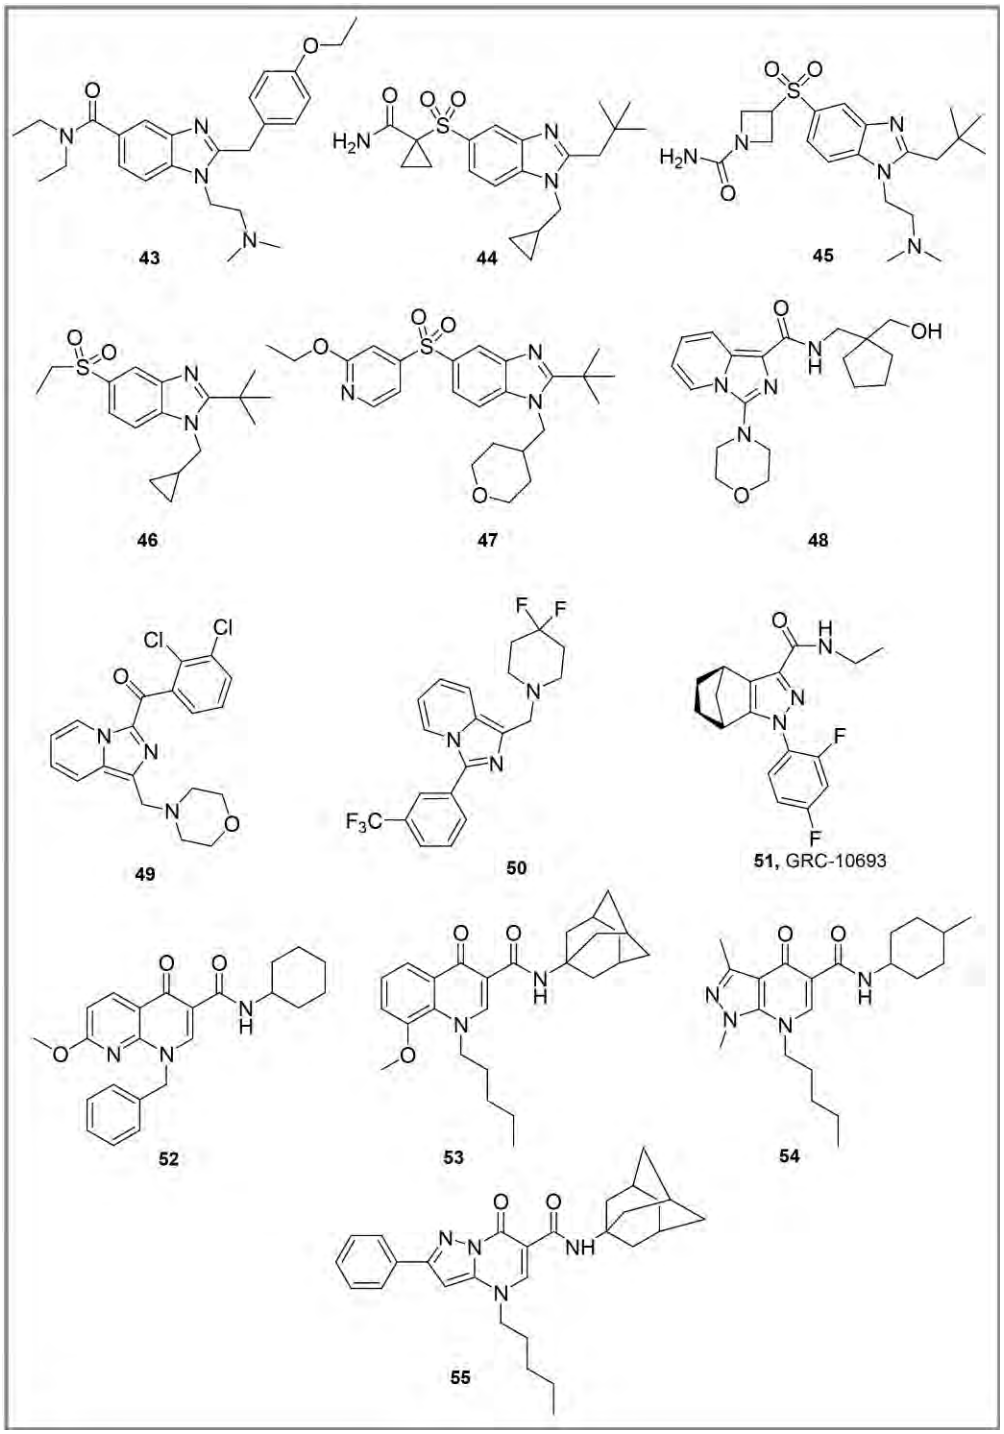

FIGURE 62.6 **Chemical structures of bicyclic cores.**

bearing a substituted aryl group, in particular, the pyridyl sulfone such as compound 2-*tert*-(butyl-5-(2-ethoxypyridin-4-sulfonyl)-1-tetrahydropyran-4-ylmethyl)-1H-benzimidazole. **47** had excellent binding affinity and selectivity for CB_2 (Verbist et al., 2008).

Imidazopyridines

Imidazopyridine-based CB_2 agonists have been described. Exploration of SAR in this chemical series by variation of substituents on both carbon positions of the imidazo ring has produced CB_2 agonists. Compounds *N*-((1-(hydroxymethyl)cyclopentyl)methyl)-3-morpholinoH-imidazo[1,5-*a*]pyridine-1-carboxamide **48** and (2,3-dichlorophenyl)(1-(morpholinomethyl)H-imidazo[1,5-*a*]pyridin-3-yl)methanone **49**, which were completely selective for CB_2 versus CB_1 are representatives of this series. In vivo evaluation of these compounds indicates a significant impact of the degree of selectivity for CB_2 on analgesic effects (Trotter et al., 2011).

A related series of 3-arylimidazopyridine analogs was reported, wherein 3-(3-(trifluoromethyl)phenyl)-1-((4,4-difluoropiperidin-1-yl)methyl)H-imidazo[1,5-*a*]pyridine **50** was the most potent CB_2 agonist disclosed (Wu et al., 2009).

Bicyclic Pyrazoles

The bridged bicyclic pyrazole compounds are reported to be CB_2 agonists. Within this family, (4S,7R)-1-(2,4-difluorophenyl)-*N*-(1,1-dimethylethyl)-4,5,6,7-tetrahydro-4,7-methano-1Hindazole-3-carboxamide (**51**, GRC-10693) has >4700-fold functional selectivity for CB_2 over CB_1, making it one of the most selective CB_2 agonists reported in development (Muthuppalanippan et al., 2006).

Quinolones and Naphthyridines

The CB_2 receptor agonists also include 4-oxo-1,8-naphthyridine-3-carboxamide and 4-oxo-1,4-dihydroquinoline-3-carboxamide derivatives, endowed with high affinity and selectivity toward CB_2 (Manera et al., 2007). Some of these analogs were demonstrated to act as agonists or inverse agonists in functional activity assays, depending on the nature of the substituents on the different positions of the heterocyclic scaffold. In the series of 8-substituted quinolones, the best results in terms of both CB_2 affinity and selectivity were obtained with the introduction of electron-donating groups, such as methyl or methoxy group (compound **52**, K_i human CB_1 > 10,000, human CB_2 0.6 nM). In contrast, the double substitution at positions 6 and 8 of the quinolone nucleus was not favorable. The quinolone derivative **53** is reported to be potent and selective for CB_2 receptor (K_i human CB_1 > 10,000 nM, human CB_2 0.6 nM), and possessed antinociceptive effects (Pasquini et al., 2011).

Pyrazolopyridines

Recently, a related series of heteroaryl-4-oxopyridine derivatives has been described (Aghazadeh Tabrizi et al., 2012). In this family, the core structure of molecules defines the type of activity to be seen, while the substituents around the core structure can be used to modulate the potency of that activity. Compound **54** was among the most potent analogs (K_i values of 4.6 μM for human CB_1 and 11.4 nM for human CB_2 receptor). This compound was found to act as partial agonists while the isoxazolopyridine parent compound behaved as full agonist. Further efforts led to discovery of 7-oxopyrazolo[1,5-*a*]pyrimidine-6-carboxamides, structural isomers of the previously reported pyrazolo[3,4-*b*]pyridines. The novel series exemplified by structure such as compound **55** shows stimulatory effects on forskolin-induced cAMP production acting as inverse agonists (Aghazadeh Tabrizi et al., 2013).

TRICYCLIC CORES

Chemical structures are shown in Fig. 62.7; biological data are shown in Table 62.2.

Rigidifying the CB_1 antagonist *N*-(piperidin-1-yl)-5-(4-chlorophenyl)-1-(2,4-dichlorophenyl)-4-methyl-1H-pyrazole-3-carboxamide (SR141716A) resulted in 1,4-dihydroindeno[1,2-*c*]pyrazol-based CB_2 agonist ligands. Compound **56** exerted affinity and selectivity for CB_2 receptor (mouse K_iCB_2 0.03 nM) (Murineddu et al., 2006). Tricyclic benzoquinolizinone compound **57** (Sch35966) was found to be a potent CB_2 agonist in four different species; it binds with low nanomolar potency to CB_2 in both primates and rodents. It has >450-fold selectivity for CB_2 over central cannabinoid receptor CB_1 in primates (humans and cynomolgus monkeys) and rodents (rats and mice). Sch35966 is an agonist as it effectively inhibited forskolin-stimulated cAMP synthesis in CHO-human CB_2 cells (Gonsiorek et al., 2007).

Several molecules, based on a 1,2,3,4-tetrahydropyrrolo[3,4-*b*]indole moiety, are described as cannabinoid agonists. These ligands demonstrated good binding affinities and potencies toward the CB_2 receptor, showing moderate to good selectivity over the CB_1 receptor. SAR studies showed that the sulfonamide moiety produced higher CB_2 binding affinities (compound **58**) than the corresponding amide or *N*-alkyl analogs, and the piperidine nucleus enhanced CB_2 binding affinity. Compound **58** is described as a full agonist (EC_{50} human CB_2 17.6 nM), and possessed the best binding selectivity in the series (>350-fold over CB_1) (Page et al., 2007).

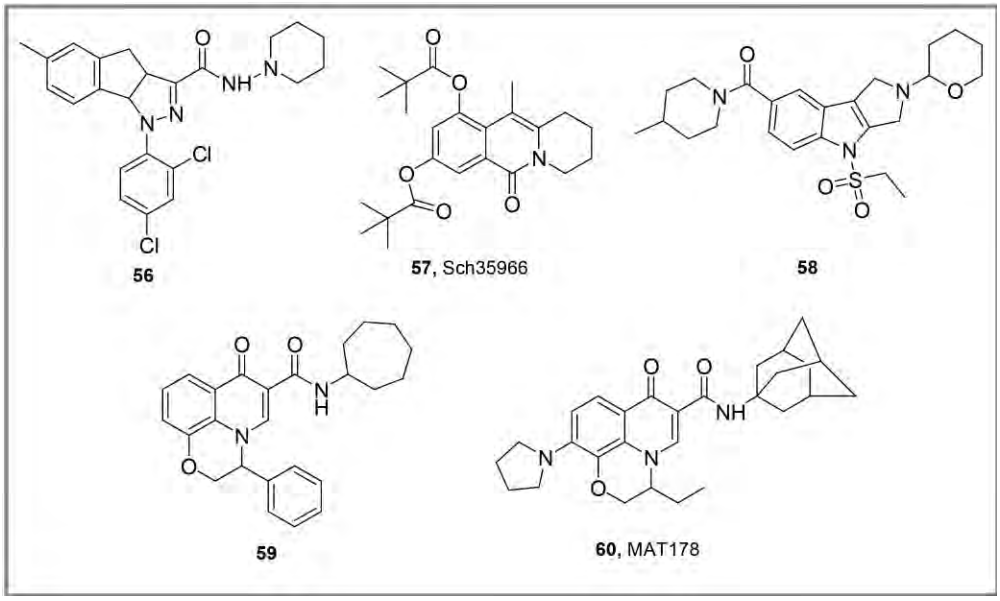

FIGURE 62.7 **Chemical structures of tricyclic cores.**

Very recently, 7-oxo-[1,4]oxazino[2,3,4-*ij*]quinoline-6-carboxamide chemotype is reported as a novel cannabinoid ligand possessing high CB_2 receptor affinity. Structural modifications led to the identification of several compounds as potent and selective cannabinoid receptor agonists (**59**, K_i human CB_2 0.81, human CB_1 310 nM). The effect of a chiral center on the biological activity was also investigated, and it was found that the R-enantiomers exhibited greater affinity at the CB_2 receptor than the S-enantiomers. The novel series behaved as full agonists, exhibiting functional activity at the human CB_2 receptor (Baraldi et al., 2012). Oxazinoqiunolone **60** (MT178) produced a robust analgesia in different pain models via CB_2 receptors, providing an interesting approach to analgesic therapy in inflammatory and chronic pain, without CB_1-mediated central side effects (Vincenzi et al., 2013).

MINI-DICTIONARY

Affinity The affinity of a drug for a receptor is the power with which it binds to the receptor.

Enantiomers Enantiomers are optical isomers that have the same chemical and physical properties, except for their capacity to rotate the plane of polarized light by identical amounts in opposing sense.

Ligand Ligand is a molecule capable to make a complex with a biomolecule to induce a biological function.

Structure–activity relationship (SAR) The relationship between the chemical structure of a molecule and its biological activity is SAR, and allows it to modify the activity of a compound by changing its chemical structure.

The half maximal effective concentration (EC_{50}) The EC_{50} is a measure of the potency of a substance required to produce 50% of the maximal effect.

The inhibitory or affinity constant (K_i) The K_i expresses the binding affinity, and is the direct indicator of affinity between a ligand and a receptor; it could be defined as the concentration of competing ligand that is mandatory to decrease the maximal effect of the reactions by half.

The Endocannabinoid System as a Target for New Antiseizure Drugs

*L.R. Vilela**, *A.C.P. de Oliveira**, *M.F. Moraes*†, *F.A. Moreira**, *R.N. Takahashi***

***Department of Pharmacology, ICB, Federal University of Minas Gerais, Belo Horizonte, Minas Gerais, Brazil; **Department of Pharmacology, CCB, Federal University of Santa Catarina, Florianópolis, Santa Catarina, Brazil, †Department of Physiology and Biochemistry, ICB, Federal University of Minas Gerais, Belo Horizonte, Minas Gerais, Brazil**

SUMMARY POINTS

- Epilepsy is a serious neurological syndrome characterized mainly by the repetitive occurrence of seizures.
- The treatment of epilepsy is limited due to the side effects and resistance to antiseizure compounds.
- *Cannabis sativa* and cannabinoids have been proposed for the treatment of epilepsy.
- Inhibition endocannabinoid hydrolysis promotes on-demand defense against excitotoxicity via cannabinoid receptors type 1 (CB1), and may pave the way for developing new pharmacological treatments for epilepsy.
- Blockade of transient receptor potential cation channel, subfamily vanilloid, member I (TRPV1) channel, similarly to CB1 receptor activation, may restrain seizures. Combining endocannabinoid-hydrolysis inhibition with TRPV1 blockade may lead to more efficacious medicines for controlling seizures and treating epilepsy.

KEY FACTS OF CANNABINOIDS AND SEIZURES

- The phytocannabinoid Δ^9-tetrahydrocannabinol (Δ^9-THC) is the main compound accounting for cannabis activity, including antiseizure effects, although also inducing side effects.
- Other phytocannabinoids, including cannabidiol (CBD), Δ^9-tetrahydrocannabivarin (Δ^9-THCV), and cannabidivarin (CBDV), may be explored for developing safer cannabis-based medicines efficacious against epilepsy.
- Synthetic Δ^9-THC analogs induce inconsistent effects.

KEYS FACTS OF ENDOCANNABINOID HYDROLYSIS INHIBITORS AND SEIZURES

- The endocannabinoid hydrolysis inhibitors facilitate the on-demand functioning of the endocannabinoid system.
- Enhancing the activity of the endocannabinoid system, represents a promising strategy for developing new treatments for epilepsy.
- The effects of fatty acid amide hydrolase (FAAH) inhibitors can be combined with simultaneous blockade of transient receptor potential cation channel, subfamily vanilloid, member I (TRPV1) channel.

LIST OF ABBREVIATIONS

2-AG	2-Arachidonoyl glycerol
Δ^9-THC	Δ^9-Tetrahydrocannabinol
Δ^9-THCV	Δ^9-Tetrahydrocannabivarin
AA-5-HT	*N*-arachidonoyl serotonin
ACEA	Arachidonoyl-2-chloroethylamide
AEA	*N*-arachidonoyl ethanolamide

WAR	Wistar audiogenic rats
WIN55212-2	(R)-(+)-[2,3-Dihydro-5-methyl-3-(4-morpholinylmethyl)pyrrolo[1,2,3-de]-1,4-benzoxazin-6-yl]-1-napthalenylmethanone

INTRODUCTION

The herb *Cannabis sativa* (“marijuana”, “hemp”) has been known for centuries due to its abuse-related effects and possible therapeutic uses, including for the treatment of epilepsies. The experimental and clinical studies in this field, however, have remained scant. The compound Δ^9-tetrahydrocannabinol (Δ^9-THC), which accounts for most of the typical cannabis actions, may have efficacy in attenuating seizures, although its therapeutic use is limited by its psychoactive properties. Other phytocannabinoids, including cannabidiol (CBD), Δ^9-tetrahydrocannabivarin (Δ^9-THCV), and cannabidivarin (CBDV) induce more favorable effects in animal models predictive of antiseizure activity, and in a few and small clinical studies. Synthetic cannabinoids have also been investigated in experimental settings, although with mixed results. As for their mechanisms, Δ^9-THC and other cannabinoids act by directly activating the CB1 cannabinoid receptor. The brain’s own agonists acting upon this target are the lipid compounds *N*-arachidonoyl ethanolamide (anandamide) and 2-arachidonoyl glycerol (2-AG), termed endocannabinoids, recruited on-demand to confer protections against excitotoxicity. Thus, inhibiting the enzymes responsible for terminating their action represents an interesting possibility for developing new antiseizure compounds. Anandamide, however, may also facilitate seizures through transient receptor potential vanilloid type-1 (TRPV1) channels, whose blockade represents another possible potential pharmacological approach. The present review expands on the aforementioned points, and discusses critically whether phytocannabinoids, synthetic cannabinoids, and endocannabinoid-hydrolysis inhibitors represent promising strategies for developing new treatments for epilepsies and related disorders.

EPILEPSY—DEFINITIONS, CLASSIFICATIONS, AND MECHANISMS

Epilepsy is a group of neurological diseases affecting approximately 2–3% of individuals worldwide. It can occur without a well-defined cause, or result from traumatic brain lesions, infections, tumors, and cerebrovascular events (Berg et al., 2010; Fisher et al., 2014). According to the *International League Against Epilepsy* (ILAE), it is a disease of the brain defined by any of the following conditions (Fisher et al., 2014):

- At least two unprovoked (or reflex) seizures occurring >24 h apart;
- One unprovoked (or reflex) seizure, and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years;
- Diagnosis of an epilepsy syndrome.

In addition, the ILAE (Berg et al., 2010) has proposed an international classification for seizures, as presented in Table 63.1:

Partial or focal seizures are characterized by electroencephalographic activity limited to a defined portion of the central nervous system. They can occur with the preservation or loss of consciousness, termed simple or

TABLE 63.1 International Classification of Seizures

1. Partial seizure (focal)
   - 1.1 Simple partial seizure
   - 1.2 Complex partial seizure
   - 1.3 Partial seizure secondarily generalized
2. Generalized seizure
   - 2.1 Absence
     - 2.1.1 Typical/classical
     - 2.1.2 Atypical/abnormal
   - 2.2 Myoclonic
   - 2.3 Clonic
   - 2.4 Tonic
   - 2.5 Tonic-clonic
3. Unclassified

The classification of seizures accordingly to the International League Against Epilepsy (ILAE).
Modified from Berg et al. (2010).

complex, respectively. Generalized seizures are those presenting a wide spectrum of electroencephalographic activity, indicating that a substantial portion of both sides of the brain was committed (Berg et al., 2010). During seizure events, the patient may show lack of consciousness, with no motor activity (simple absence), or diverse types of motor activity along with autonomic alterations and automatisms (Berg et al., 2010). According to the ILAE glossary (Blume-Chair et al., 2001), these motor expressions can occur as follows:

- myoclonic: sudden, brief involuntary muscle contractions with variable topography;
- clonic: myoclonus that is regularly repetitive, and extends to the exact same group of muscles from myoclonic;
- tonic: sustained contraction that lasts a few seconds to minutes;
- tonic-clonic: bilateral symmetric tonic followed by clonic contractions of members.

Regarding the molecular and cellular mechanisms, both synaptic and nonsynaptic processes seem to be involved (McNamara, 1994). Among the synaptic mechanisms, there may occur loss or facilitation of γ-aminobutyric acid (GABA)- and glutamate-mediated neurotransmissions, respectively, resulting in long term potentiation of excitatory synapses. Nonsynaptic mechanisms can be exemplified by the increase in extracellular potassium (K^+), responsible for triggering action potential on pyramidal neurons with a frequency much higher than the physiological rhythm (McNamara, 1994). One concept that has been critical for investigating the epilepsies is *epileptogenesis*. This term refers the dynamic process that begins after the occurrence of an insult, with modification of neuronal excitability that results in the first seizure, and continues with the disease. It may be characterized by neurodegeneration or neurogenesis, gliosis, axon budding, sprouting, and dendritic plasticity (Pitkänen & Lukasiuk, 2011).

THE CURRENT TREATMENT OF EPILEPSIES

Unfortunately, there is no definitive treatment for epilepsy. The main approach consists in the pharmacological control of seizures with substances termed antiseizure drugs, also called anticonvulsant or antiepileptic drugs. A second possibility is a surgical intervention to remove the epileptogenic focus, a far more invasive process, reserved for those cases who do not respond to the pharmacological treatment (Loscher, 2011; Kwan et al., 2010). Epilepsy is considered to be resolved for individuals who had an age-dependent epilepsy syndrome but are now past the applicable age, or those who have remained seizure-free for the last 10 years, with no antiseizure medicines for the last 5 years (Fisher et al., 2014). Currently, approximately 25 antiseizure drugs are available, and grouped according to their mechanisms of action and the type of the pathological condition. Some of them act by diminishing neuronal excitability, mainly though the blockage of voltage dependent sodium (Na^+) or calcium (Ca^{2+}) channels, and reduction of glutamatergic neurotransmission. Others facilitate inhibitory transmission, by indirectly or directly increasing GABA receptor functioning (Fig. 63.1) (Loscher, Klitgaard, Twyman, & Schmidt, 2013).

These medicines prevent or interrupt seizure (such as in status epilepticus), but they not properly "treat" epilepsy, since they are unable to interrupt or reverse the processes causing seizures. This results in the necessity of continuous and long-term treatments. In addition, pharmacoresistant or refractory epilepsy occurs in approximately one-third of patients, a fact defined as failure of adequate trials of two tolerated and appropriately chosen and used AED schedules (whether as monotherapies or in combination) to achieve sustained seizure freedom (Kwan et al., 2010). Therefore, there is an urgent need for new treatments that act by different mechanisms (Loscher et al., 2013). In this context, animal models for studying epilepsy and seizures are indispensable for allowing improvements toward the comprehension of the molecular mechanisms of epilepsy, particularly the course of epileptogenesis, and the characterization of new drug treatments, and their side effects (Loscher, 2011). Some of the main animal models are based on inducing seizures by the following stimuli:

- administration of drugs, such as kainic acid, pilocarpine and pentylenetetrazol (PTZ);
- brain electric stimulation;
- posttraumatic processes;
- brain hypoxia;
- hyperthermia;
- genetic models, such as the Wistar audiogenic rats (WAR).

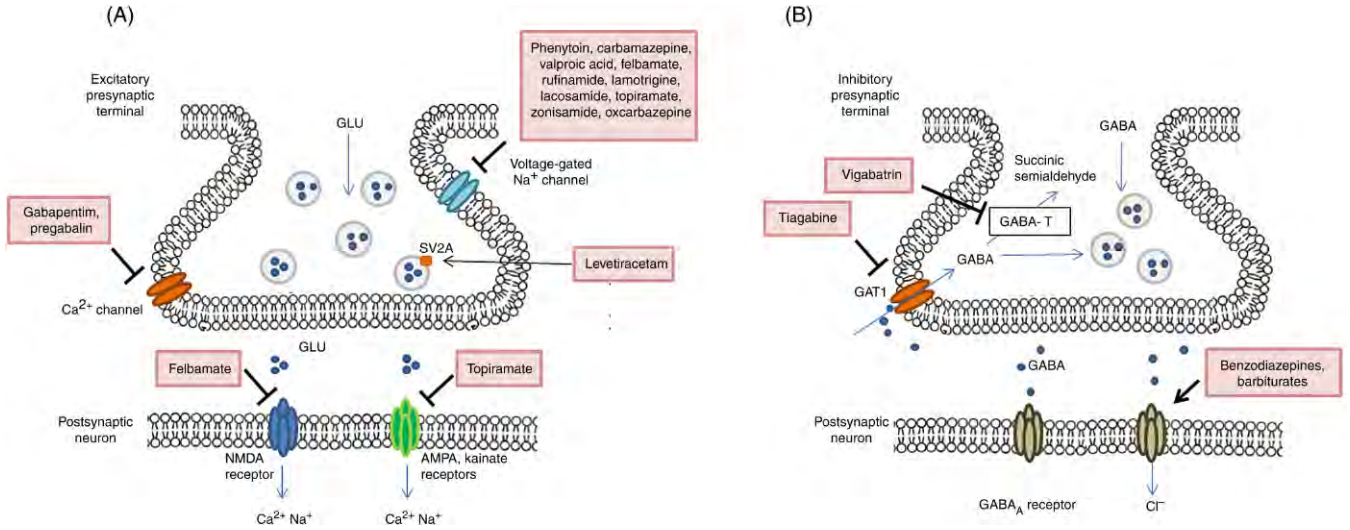

FIGURE 63.1 Mechanisms of action of currently available anticonvulsants through the excitatory and inhibitory synapses. (A) Anticonvulsants that act at excitatory synapse by blocking Na^+ and Ca^{2+} voltage-gated channels, synaptic vesicle glycoprotein and glutamatergic receptors (AMPA and NMDA channels). Some of them have multiple mechanisms of action, but their overall effect is to decrease glutamate (GLU) action; (B) anticonvulsants that acting at inhibitory synapse enhance GABAergic neurotransmission by inhibiting the uptake (mediated by a transporter, GAT) or metabolism (mediated by a transaminase, GABA-T) or by activating GABA-A receptor at specific sites.

THE ENDOCANNABINOID SYSTEM

The endocannabinoid system has been extensively reviewed regarding its biochemistry and physiology. It comprises, in its simplest form, the cannabinoid type-1 (CB1) and type-2 (CB2) receptors; at least two endogenous ligands (endocannabinoids), anandamide and 2-AG; and their metabolizing enzymes (Piomelli, 2003; Pertwee et al., 2010). The endocannabinoids are atypical neurotransmitters in several aspects. Their biosyntheses occur in postsynaptic terminals, where an increase in neural excitability and Ca^{2+} influx promotes the cleavage of membrane lipids, after which the endocannabinoids are immediately released to the synaptic cleft. Thereafter, they activate CB1 receptors located mainly at the presynaptic terminals. Anandamide has other molecular targets, such as TRPV1 channel. The actions of anandamide and 2-AG are terminated by a reuptake process followed by hydrolyses mediated by fatty acid hydrolase (FAAH) and monoacyl glycerol lipase (MGL), respectively (Piomelli, 2003; Pertwee et al., 2010). They serve as substrates for other enzymes, such as those that metabolize arachidonic acid, including cyclooxygenase and lipoxygenase, although the functions of the resulting compounds remain to be understood (Pertwee et al., 2010). The endocannabinoid system, with its main components, is illustrated in Fig. 63.2.

Some of the important compounds that act on the endocannabinoid system are the CB1/CB2 agonist, (R)-(+)-[2,3-dihydro-5-methyl-3-(4-morpholinylmethyl) pyrrolo[1,2,3-de]-1,4-benzoxazin-6-yl]-1-napthalenylmethanone (WIN55212-2); the selective CB1 receptor agonist, arachidonoyl-2-chloroethylamide (ACEA); the CB1 receptor antagonists 5-(4-chlorophenyl)-1-(2,4-dichloro-phenyl)-4-methyl-*N*-(piperidin-1-yl)-1H-pyrazole-3-carboxamide (SR141716, rimonabant), and 1-(2,4-dichlorophenyl)-5-(4-iodophenyl)-4-methyl-*N*-(1-piperidyl)pyrazole-3-carboxamide (AM251). The main compounds that act on endocannabinoid metabolic pathways are [3-(3-carbamoylphenyl)phenyl] *N*-cyclohexylcarbamate (URB597), an FAAH inhibitor, and 4-nitrophenyl-4-[bis(1,3-benzodioxol-5-yl)(hydroxy)methyl] piperidine-1-carboxylate (JZL184), an MAGL inhibitor. Also relevant are the TRPV1 blockers, capsazepine, and 4′-chloro-3-methoxycinnamanilide (SB399791); and the dual FAAH/TRPV1 blocker, arachidonoyl-serotonin (AA-5-HT) (Pertwee et al., 2010).

CANNABINOIDS AND THE ENDOCANNABINOID SYSTEM IN SEIZURES AND EPILEPSY

Effects of Phytocannabinoids

Some experimental studies and early small clinical reports have suggested the efficacy of cannabis and Δ^9-THC against seizures. Marihuana smoking protected patients against tonic-clonic and partial seizures (Consroe, Wood, & Buchsbaum, 1975), although conflicting results have been reported with Δ^9-THC, depending on the dose and types of seizures (Feeney, 1978; Karler, Calder, Sangdee, & Turkanis, 1984). In addition, results also document "rebound" effect following treatment with this compound, facilitating the occurrence of new seizures

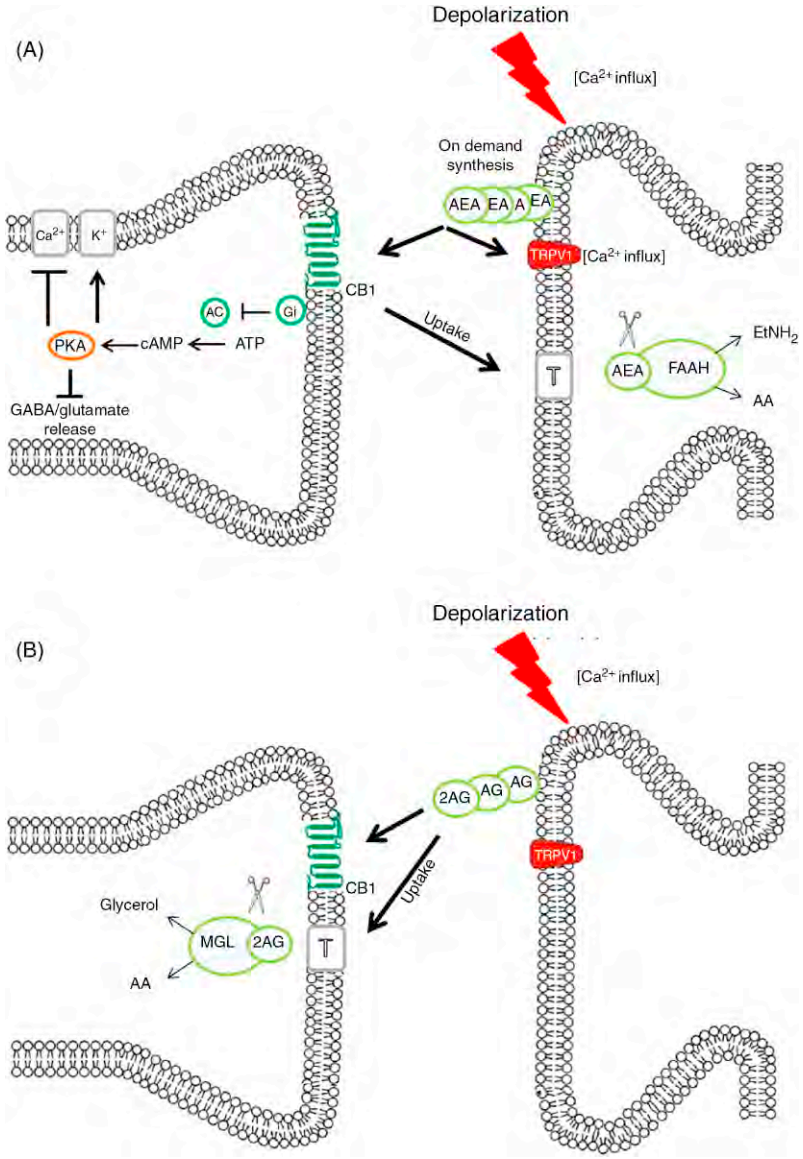

FIGURE 63.2 **Schematic representation of the endocannabinoid system.** (A) Anandamide (*N*-arachidonoyl ethanolamide, AEA) and (B) 2-arachidonoyl glycerol (2-AG) are synthesized from phospholipids at the postsynaptic neuron membrane, after calcium influx. They are immediately released to the synaptic cleft, and bind to presynaptically located cannabinoid type 1 receptors (CB1), whose activation results in decrease in calcium influx and neurotransmitter release. AEA and 2-AG are metabolized by the enzymes fatty acid amide hydrolase (FAAH) and monoacylglycerol lipase (MGL), respectively.

(Karler, Calder, & Turkanis, 1986). Finally, some patients may present significant central and peripheral side effects during treatment with Δ^9-THC, further indicating its therapeutic limitations (Gordon & Devinsky, 2001; Schneir & Baumbacher, 2012). Additional drawbacks are the amnestic, psychotomimetic effects of this and other compounds that act as CB1 receptor agonists (Pertwee et al., 2010).

An alternative could be CBD, the major nonpsychotomimetic component of *Cannabis sativa*, which proved to be effective in certain small experimental clinical reports. Most of them, however, date back to the 1970s, and this compound remained underinvestigated during several years, in part due to legal restrictions (Zuardi, 2008). More recently, interest in CBD has been renewed, with reports of its efficacy in children with pharmacoresistant epilepsy (Cortesi & Fusar-Poli, 2007). In experimental models, it inhibited epileptiform activity in brain slices, and exerted antiseizure activities against PTZ-induced generalized seizures in rats (Jones et al., 2010), in the pilocarpine model temporal lobe seizures, and the penicillin model of partial seizures (Jones et al., 2012), as well as in the PTZ- and electroshock-induced seizures in rats (Shirazi-zand, Ahmad-Molaei, Motamedi, &

Naderi, 2013). Thus, considering the efficacy of CBD, and the fact that it does not share the psychotomimetic, amnestic, and sedative effects of Δ^9-THC, it is an interesting potential treatment for certain cases of epilepsy. A recent clinical study observed that CBD-enriched cannabis extracts significantly reduced seizure frequency in children with treatment-resistant epilepsy, indicating that it could be used as a strategy when other pharmacological treatments fail (Porter & Jacobson, 2013).

It should be noted, however, that more extensive studies are still required to characterize the efficacy of CBD against diverse types of seizures and epileptic syndromes, preferentially in comparison with currently used antiseizure drugs. In addition, the mechanisms of action of this compound have remained elusive, and should be further investigated. CBD is a compound with a plethora of pharmacological actions, including anxiolytic and antipsychotic effects, which may act through diverse mechanisms, including facilitation of the endocannabinoid system, and binding to TRPV1 channels and serotonin type-1A receptors, among others (Izzo, Borrelli, Capasso, Di Marzo, & Mechoulam, 2009; Zuardi, 2008). Finally, other phytocannabinoids have also been investigated regarding their potential application for treating epilepsies, particularly Δ^9- THCV and CBDV (Hill et al., 2010, 2013). Since over 60 phytocannabinoids have been described, they should be further investigated in experimental models. Compounds that act though CB1-independent mechanisms deserve particular attention.

Effects of Synthetic Cannabinoids

Similarly to Δ^9-THC, its synthetic derivatives may either induce favorable effects or facilitate seizures, depending on the animal model and the doses tested (Lutz, 2004). The nonselective CB1 agonist, WIN-55,212-2, had anticonvulsant effects on electroshock model of generalized seizures (Wallace, Wiley, Martin, & DeLorenzo, 2001). In addition, WIN-55,212-2 and ACEA potentiated the effects of the classical anticonvulsants carbamazepine, phenytoin, and phenobarbital in electroshock-induced seizures (Luszczki et al., 2010). WIN-55,212-2 was also effective in the amygdala kindling model of temporal lobe epilepsy in mice (Wendt, Soerensen, Wotjak, & Potschka, 2011).

Several groups have used different models of seizures and a variety of experimental procedures (in vivo and in vitro) to demonstrate that CB1 receptor agonists can modulate both the frequency and severity of seizures (Blair et al., 2006; Bhaskaran & Smith, 2010; Jones et al., 2010; Shafaroodi et al., 2004, 2007). Other studies, however, provide evidence that CB1 receptor activation could have proconvulsant effects (Vilela et al., 2013). Furthermore, long term exposition to WIN-55,212-2 resulted in tolerance and exacerbation of seizures (Blair et al., 2009). Considering these controversies and their possible side effects, CB1 agonists are unlikely to represent the most attractive approach for developing new treatments. Since their effects on experimental seizures have remained poorly investigated, the reasons for these discrepancies are still unclear (Lutz, 2004).

Role of the Endocannabinoid System on Seizure Control, and the Effects of Endocannabinoid Hydrolysis Inhibitors

Some specific features of the endocannabinoid system suggest that it represents an attractive target for developing new drugs for treating epilepsy. The endocannabinoids are produced on-demand after neuronal depolarization to dampen excessive excitatory activity. In line with this notion, some studies have proposed that the endocannabinoid actions upon CB1 receptor may be as a tonic mechanism protecting the brain against seizures. Accordingly, the deletion or pharmacological blockade of this receptor increased KA-induced excitotoxicity (Marsicano et al., 2003). Moreover, conditional deletion of the CB1 receptors in forebrain glutamatergic neurons also facilitated seizure (Monory et al., 2006). Other studies have pointed out that the treatment with CB1 receptor antagonists increases the frequency and duration of seizures, as well as epileptiform discharges (Kozan, Ayyildiz, & Agar, 2009; Deshpande et al., 2007). Reduced levels of anandamide were found in patients (Romigi et al., 2010), and data from positron emission tomography showed that the expression of CB1 receptors was altered in epileptogenic regions (Goffin, Van Paesschen, & Van Laere, 2011). These results support the hypothesis of a primary dysfunction of the endocannabinoid system in patients with epilepsy.

Some contradictory results, however, have been observed. For instance, the treatment with the CB1 antagonists AM251 and SR141716 also prevented antiepileptogenic properties in hippocampal neuron culture in which glutamate agonists were added (Karr, Pan, & Rutecki, 2010). Furthermore, low doses of AM251 enhanced the anticonvulsant effects of ACEA against PTZ-induced seizures in mice (Gholizadeh et al., 2007). The reasons for these discrepancies could be related to the modulation of excitatory and inhibitory neurotransmissions by this receptor, as discussed earlier.

Despite these contrasting results, the observations that anandamide-CB1 signaling may act as an endogenous antiseizure mechanism indicate that FAAH inhibition represents a promising strategy for developing new treatments. Indeed, experimental studies with the kainic acid model of seizures indicate that FAAH inhibitors reduced both in vivo and in vitro excitotoxicity, in addition to inducing neuroprotection

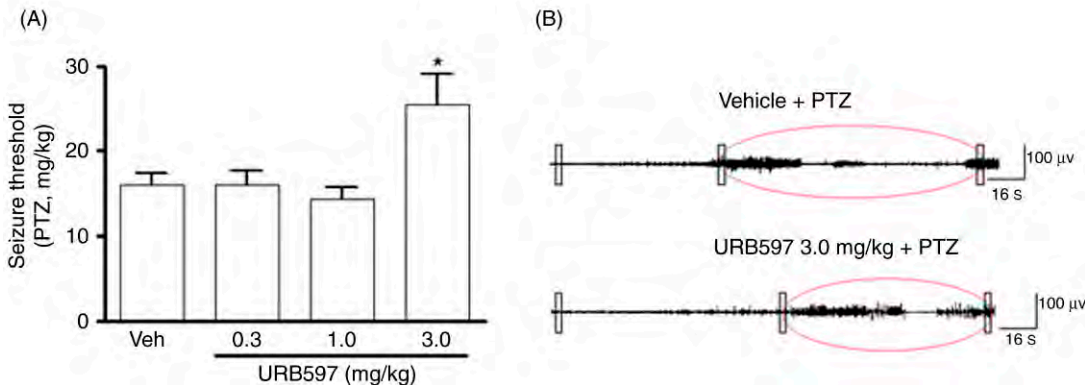

FIGURE 63.3 **Effect of anandamide hydrolysis inhibition on PTZ-induced behavioral and electroencephalographic seizures in rats.** (A) Administration of the FAAH inhibitor, URB597, increased dose of PTZ required to induce seizure in rats; (B) URB597 also reduced the electroencephalographic seizure duration, as shown in this representative EEG recording. The animals received intraperitoneal injections of URB597 30 min before continuous intravenous infusion of PTZ. Bars represent means and standard errors. *$p < 0.05$ as revealed by analysis of variance followed by the Newman–Keuls test; $n = 7–8$/group (for further details, see Vilela et al., 2013).

(Naidoo et al., 2011). Moreover, the FAAH inhibitor, URB597, had an anticonvulsant effect, reducing both seizures and electroencephalographic (EEG) activity induced by PTZ in rats (Fig. 63.3) (Vilela et al., 2013). In addition to anandamide, 2-AG hydrolysis can also be targeted to provide anticonvulsant and neuroprotective effects (Naidoo et al., 2012). Their neuroprotective mechanisms may be explained by a reduced excitatory signaling, reduced calcium influx, buffering of oxidative stress, and activation of intracellular pathways related to cellular survival associated with the production of neurotrophic factors (Bisogno & Di Marzo, 2010; Fernández Ruiz, Garcia, Sagredo, Gomez-Ruiz, & de Lago, 2010). An earlier study, however, observed that FAAH knockout mice exhibited a higher susceptibility to develop seizures after the administration of kainic acid (Clement, Hawkins, Lichtman, & Cravatt, 2003). The reasons for these discrepancies remain unclear.

Interactions Between the Endocannabinoid System and TRPV1 Channel

Although facilitation of the endocannabinoid system represents a promising strategy for controlling seizures, this approach can be hampered by the fact that anandamide binds to other targets, particularly the TRPV1 channel. This ion channel was first characterized as an "orphan receptor" on primary afferents sensory neurons. It is cation permeable, and activated by capsaicin (8-methyl-*N*-vanilil-6-nonanamide, the most irritant component of *Capsicum* sp, popularly known as red pepper), heat and low pH. In the brain, this receptor is thought to be activated mainly by anandamide, resulting in opposite effects to those ascribed to CB1 receptors (Ross et al., 2001; Starowicz, Nigam, & Di Marzo, 2007). Thus, whereas CB1 activation causes inhibition of cation influx, reduction of neural activity, and neurotransmitters release, TRPV1 activation promotes the opposite effects (Starowicz et al., 2007). Remarkably, the events facilitated by TRPV1 are associated with the development of epileptogenic events. Fig. 63.4 illustrates the dual effects of anandamide upon CB1/TRPV1 receptors activation.

In this way, pharmacological targeting of TRPV1 could represent an additional mechanism to modulate seizures. Activation of TRPV1 channels by capsaicin leads to epileptiform activity in vitro and in vivo, while antagonism with capsazepine effectively suppresses electrographic seizures (Gonzalez-Reyes, Ladas, Chiang, & Durand, 2013). Capsaicin also increased the frequency of excitatory postsynaptic potential through the activation of TRPV1 in pilocarpine-treated mice that survived status epilepticus (Bhaskaran & Smith, 2010). In addition, anandamide, at high doses, can facilitate seizures by the activation of TRPV1 in the PTZ model in mice (Manna & Umathe, 2012).

Considering these aspects, a possible strategy for designing new antiseizure drugs is to focus on compounds that simultaneously block TRPV1 and FAAH. A compound that acts through such a mechanism is *N*-arachidonoyl-serotonin (AA-5-HT), which is therefore able to increase the levels of anandamide and redirect the actions of this substance entirely to CB1 receptors (Micale et al., 2009a). Accordingly, the administration of AA-5-HT had efficacious anticonvulsant effect on tonic-clonic seizures in mice (Micale et al., 2009b; Vilela, Medeiros, de Oliveira, Moraes, & Moreira, 2014). This effect was prevented by the CB1 receptor selective agonist AM251. The TRPV1 antagonist, SB366791, however, only partially mimicked the action of the AA-5-HT. These results demonstrate that both TRPV1 blockade and indirect CB1 agonism contribute to the overt effects of AA-5-HT (Fig. 63.5) (Vilela et al., 2014).

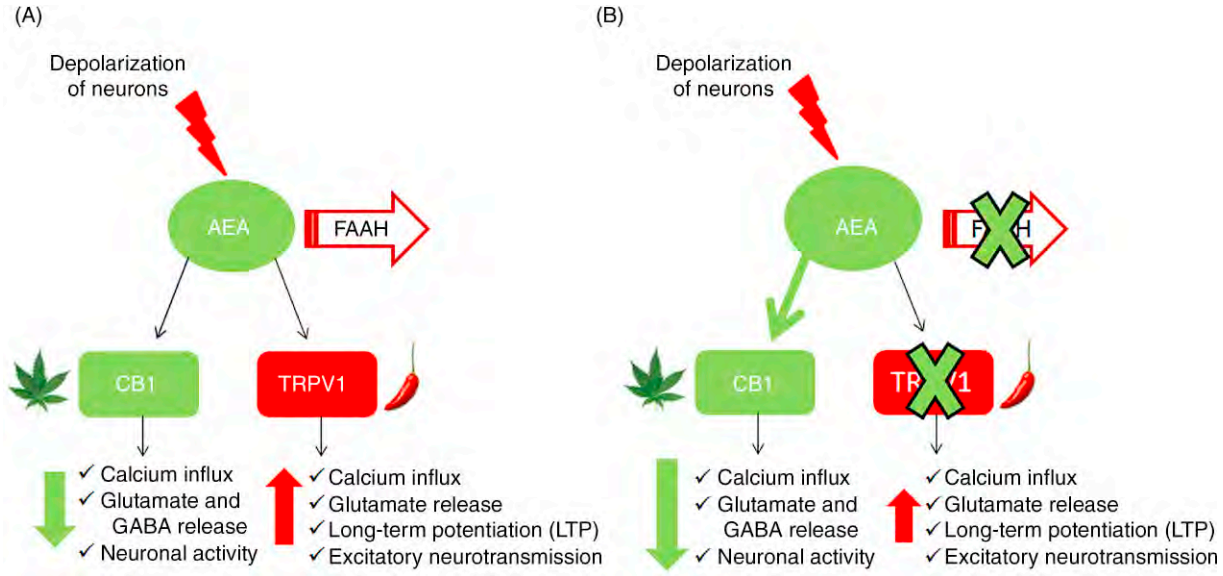

FIGURE 63.4 **Dual effects of anandamide (AEA) on neurotransmission through activation of CB1 receptors and TRPV1 channels.** (A) AEA can exert either anti- or proconvulsant activities, by activating CB1 receptors or TRPV1 channels, respectively. (B) Pharmacological modulation through dual blocking of FAAH and TRPV1 increases on-demand anandamide levels and redirects its actions entirely to CB1 receptor, possibly representing an attractive approach against excitotoxic events.

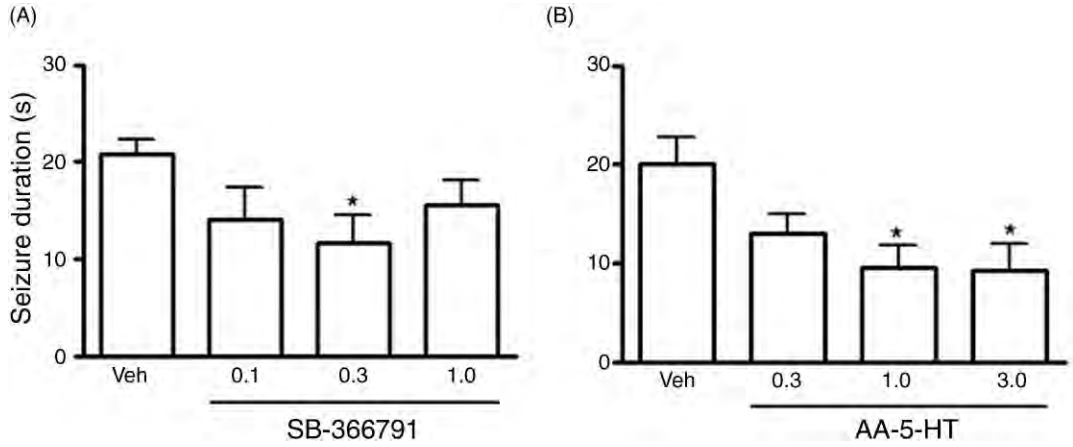

FIGURE 63.5 **Effects of compound that block FAAH and/or TRPV1 on PTZ-induced seizure in mice.** (A) The selective TRPV1 blocker, SB-366791, reduced PTZ-induced seizure. (B) The dual FAAH/TRPV1 blocker, AA-5-HT, reduced PTZ-induced seizure more consistently than the selective TRPV1 blocker. The animals received intraperitoneal injections of SB-366791 or AA-5-HT 30 min before intraperitoneal PTZ. Bars represent means and standard errors. *$p < 0.05$ as revealed by analysis of variance followed by the Newman–Keuls test; n = 9–10/group (for further details, see Vilela et al., 2014).

CONCLUSIONS

In this chapter, we discussed evidence from basic and clinical studies suggesting that cannabinoids and the endocannabinoid system should be further explored for the development of new treatments for epilepsies and related syndromes. Δ^9-THC and synthetic cannabinoids that act as CB1 agonists have discrepant effects, depending on the model and species employed. A possible reason for some seemingly divergent results might be related to the complex role of CB1 receptors in modulating both excitatory glutamatergic and inhibitory GABAergic neurotransmission. As an alternative, other phytocannabinoids, such as CBD, Δ^9-THCV, and CBDV, may represent an interesting strategy. Furthermore, considering that anandamide has been linked to on-demand protection against excitotoxicity, FAAH inhibitors may be employed to induce more favorable effects, as compared to direct CB1 receptor agonists. Finally, considering the possible actions of anandamide upon TRPV1 channels, which counteract CB1-mediated effects, compounds that simultaneously block FAAH and TRPV1 could be

an effective new drug class for seizure treatment. These compounds should be investigated particularly in comparison with clinically used drugs, in terms of both efficacy and side effects. Finally, it should be tested whether they can treat pharmacoresistant epilepsy, and reverse epileptogenesis, hopefully paving the way for new treatments for this devastating syndrome.

MINI-DICTIONARY

Antiseizure drug Any drug efficacious in preventing or interrupting seizures.
Convulsion Rapid and repeated contractions and relaxation of body muscles, usually bilateral, resulting in uncontrolled movements.
Electroencephalography Recording of electrical activity resulting from total ionic current flows in neurons of the brain.
Epilepsy A neurological syndrome characterized mainly by the repetitive occurrence of seizures.
Epileptogenesis Molecular and cellular processes that lead to the increase in neuronal excitability.
Kindling Sensitization to seizure-inducing stimuli after successive exposure.
Pharmacoresistant epilepsy Epilepsy characterized by crises that occurs in spite of the treatment with antiseizure drugs.
Seizure Brief episodes of abnormal excessive or synchronous neuronal activity in the brain.
Status epilepticus A life-threatening condition in which seizures last longer than 5 min, or recurrent seizures without regaining consciousness between seizures for longer than 5 min.
Synchronization Simultaneous firing of groups of neurons in the brain.

Pharmacological Aspects of Anandamide and 2-Arachidonoyglycerol as Bioactive Lipids

M. Alhouayek, G.G. Muccioli

Bioanalysis and Pharmacology of Bioactive Lipids Research Group, Louvain Drug Research Institute, Université catholique de Louvain, Brussels, Belgium

SUMMARY POINTS

- The endocannabinoids *N*-arachidonoylethanolamine (AEA) and 2-arachidonoylglycerol (2-AG) are involved in many pathophysiological processes.
- Classically, endocannabinoids exert their actions by activating the CB_1 and CB_2 cannabinoid receptors, and their actions are terminated by their hydrolysis by specific hydrolases.
- More receptors mediating the effects of AEA and 2-AG have been added over the years.
- Endocannabinoids can also be metabolized by cyclooxygenase (COX)-2, which leads to the synthesis of other bioactive lipids.
- Endocannabinoids and their COX-2 derived metabolites can exert different effects in some settings, a fact that increases the complexity of endocannabinoid signaling.
- Interfering with the metabolism of endocannabinoids opens up a lot of therapeutic opportunities.

KEY FACTS ABOUT ENDOCANNABINOID-RELATED COMPOUNDS

- They are bioactive lipids belonging to the families of *N*-arachidonoylethanolamine (AEA) or 2-arachidonoylglycerol (2-AG) that do not bind cannabinoid receptors.
- They have long been considered as acting via an "entourage effect," by protecting endocannabinoids from degradation, and potentiating their actions; however, they also have receptor-specific effects.
- Among *N*-acylethanolamines: *N*-palmitoylethanolamine (PEA) exerts antiinflammatory, analgesic, and neuroprotective effects, and is a PPAR-α agonist, while *N*-oleoylethanolamine (OEA) is a GPR119 and a PPAR-α ligand known for its anorexigenic properties, and the control of glucagon secretion.
- 2-Oleoylglycerol (2-OG) is a monoacylglycerol related to 2-AG that acts as a GPR119 agonist to increase secretion of glucagon-like peptide 1 (GLP-1).

LIST OF ABBREVIATIONS

2-AG	2-Arachidonoylglycerol
ABHD6	α/β Hydrolase domain 6
ABHD12	α/β Hydrolase domain 12
AEA	*N*-arachidonoylethanolamine or anandamide
CB_1 and CB_2	Cannabinoid receptor 1 and 2
COX-2	Cyclooxygenase-2
cPLA2	Cytosolic phospholipase A2
CYP450	Cytochrome P450
DAGL	Diacylglycerol lipase

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00074-0
Copyright © 2017 Elsevier Inc. All rights reserved.

EET	Epoxyeicosatrienoic acid
EET-EA	Epoxyeicosatrienoic acid-ethanolamide
EET-G	Epoxyeicosatrienoic acid-glycerol ester
FAAH	Fatty acid amide hydrolase
GDE1	Glycerophosphodiester phosphodiesterase 1
HETE	Hydroxyeicosatetraenoic acid
HETE-EA	Hydroxyeicosatetraenoic acid-ethanolamine
HETE-G	Hydroxyeicosatetraenoic acid-glycerol ester
LOX	Lipoxygenase
MAGL	Monoacylglycerol lipase
NAAA	*N*-acylethanolamine-hydrolyzing acid amidase
NAE	*N*-acylethanolamine
NAPE	*N*-acylphosphatidylethanolamine
NAPE-PLD	*N*-acylphosphatidylethanolamine phospholipase D
PG-EA	Prostaglandin-ethanolamine or prostamide
PG-G	Prostaglandin-glycerol ester
PPAR	Peroxisome proliferator activated receptor
TRPV1	Transient receptor potential vanilloid 1

INTRODUCTION

The concept of bioactive lipids stems from the recognition that lipids are not only involved in cell membrane structure and energy storage. Indeed, some lipids bind to specific receptors, leading to signal transduction and biological effects. Accordingly, variations in the levels of such lipids lead to pathophysiological consequences. These are considered bioactive lipids. Eicosanoids, such as the arachidonic acid-derived prostaglandins, are commonly known bioactive lipids.

The endocannabinoids *N*-arachidonoylethanolamine (anandamide or AEA) and 2-arachidonoylglycerol (2-AG) are bioactive lipids that are involved in many physiological processes, such as the regulation of food intake, the control of anxiety, and the modulation of pain and inflammation (Borrelli & Izzo, 2009; Ruehle, Rey, Remmers, & Lutz, 2012; Guindon & Hohmann, 2009; Alhouayek & Muccioli, 2012). As for many bioactive lipids, the activity of endocannabinoids is regulated by their tissue levels and, therefore by the balance between their biosynthesis and their degradation (Muccioli, 2010). In this context, pharmacological modulation of endocannabinoid levels represents an attractive therapeutic avenue for many diseases.

This chapter presents an overview of endocannabinoid metabolism, with many of the intricacies that characterize it, in order to describe the available pharmacological modulators of endocannabinoid signaling, as well as the potential therapeutic opportunities of such modulators.

OVERVIEW OF THE EFFECTS OF ANANDAMIDE AND 2-ARACHIDONOYLGLYCEROL

These endocannabinoids have several beneficial effects that could be used in potential treatments. For instance, endocannabinoids have antiinflammatory effects, which can be beneficial in diseases such as inflammatory bowel diseases and arthritis (Alhouayek & Muccioli, 2012; Mecs, Tuboly, Toth, Nagy, & Nyari, 2010). They are also valuable in neurodegenerative diseases such as multiple sclerosis, or following cerebral trauma, due to their antiinflammatory and neuroprotective properties (Lourbopoulos, Grigoriadis, Lagoudaki, Touloumi, & Polyzoidou, 2011; Panikashvili, Shein, Mechoulam, Trembovler, & Kohen, 2006). Endocannabinoids also exert analgesic effects in many settings (Guindon & Hohmann, 2009), modulate the stress response, reduce anxiety and depression (Ruehle et al., 2012), promote sleep (Murillo-Rodriguez, Poot-Ake, Arias-Carrion, Pacheco-Pantoja, & Fuente-Ortegon, 2011), and decrease nausea and vomiting (Sharkey, Darmani, & Parker, 2014). Generally, increasing endocannabinoid levels is thought to be beneficial, therefore endocannabinoid degradation enzymes constitute interesting targets, and many inhibitors of these enzymes have been developed. However, the endocannabinoid system also exerts some unwanted effects. As an example, cannabis use is associated with psychotropic effects that are reproduced following a chronic increase of 2-AG levels in animals (Long, Li, Booker, Burston, & Kinsey, 2009a; Schlosburg, Blankman, Long, Nomura, & Pan, 2010). Moreover, cannabis use is associated with impaired memory, and this is also observed with administration of cannabinoid receptor agonists to mice. Finally, endocannabinoids have been shown to exert deleterious effects in some settings, such as obesity. Indeed, AEA and 2-AG are orexigenic and adipogenic agents (Bisogno, Mahadevan, Coccurello, Chang, & Allara, 2013; Muccioli, Naslain, Backhed, Reigstad, & Lambert, 2010). In this context, inhibitors of endocannabinoid biosynthesis seem to be interesting therapeutic tools.

CLASSICAL METABOLISM OF ANANDAMIDE AND 2-ARACHIDONOYLGLYCEROL

Although both 2-AG and AEA are arachidonic acid derivatives synthetized from membrane phospholipids, their biosynthetic and degradation routes are quite different, with diverse enzymes implicated.

The most described biosynthetic route for 2-AG (Fig. 64.1A) is through the sequential actions of an activity-dependent phospholipase C-β (releasing diacylglycerols from phosphatidylinositols-4,5-bisphosphate) and diacylglycerol lipases (DAGLα and DAGLβ) to produce 2-AG. However, DAGLs do not constitute the only biosynthesis pathway for 2-AG, as this bioactive lipid is synthetized in DAGL-knockout mice (Aaltonen, Riera,

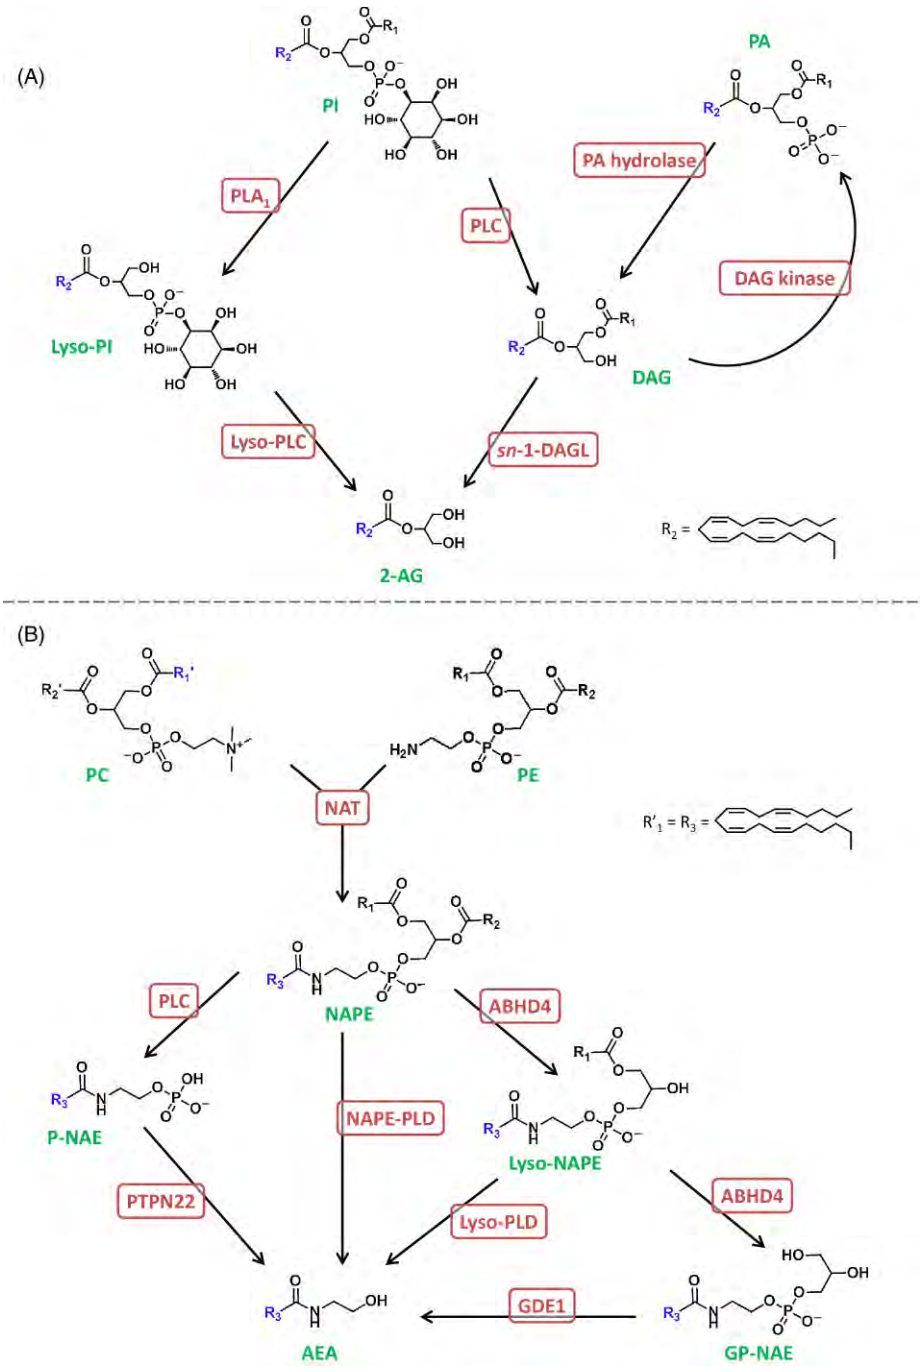

FIGURE 64.1 Biosynthesis of the endocannabinoids 2-AG and AEA. (A) 2-AG is produced through the sequential action of either a phospholipase C (PLC) and diacylglycerol lipase (sn-1-DAGL), or a phospholipase A (PLA1) and a lysophospholipase C (LysoPLC). Diacylglycerol (DAG) levels are also regulated by a phosphatidic acid hydrolase (PA hydrolase) and a diacylglycerol kinase (DAG kinase); (B) *N*-acylphosphatidylethanolamine (NAPE), the key intermediate in the synthesis of AEA, is synthesized from phosphatidylcholine (PC) and phosphatidylethanolamine (PE) by a calcium-dependent *N*-acyltransferase activity (NAT). Several pathways are responsible for the production of AEA from NAPE: (1) directly via a *N*-acylphosphatidylethanolamine preferring phospholipase D (NAPE-PLD); (2) or through a phosphate intermediate (P-NAE) generated by a phospholipase C (PLC) and hydrolyzed by the phosphatase PTPN22; (3) or through a lyso-*N*-acylphosphatidylethanolamine (lyso-NAPE), produced by ABHD4, and which in turn can be hydrolyzed into AEA by a lyso-phospholipase D (lyso-PLD), or converted into the glycerophosphate intermediate (GP-NAE) before its conversion into AEA by glycerophosphodiester phosphodiesterase 1 (GDE1).

Lehtonen, Savinainen, & Laitinen, 2014). 2-AG is then inactivated through its hydrolysis by several lipases into arachidonic acid and glycerol (Fig. 64.2). Monoacylglycerol lipase (MAGL) was the first enzyme described as hydrolyzing 2-AG. This enzyme plays a prevalent role in the brain, where it controls around 80% of 2-AG hydrolysis (Blankman, Simon, & Cravatt, 2007). Two additional α/β-hydrolases—α/β-hydrolase domain 6 (ABHD6) and 12 (ABHD12)—were also shown to hydrolyze 2-AG (Marrs, Blankman, Horne, Thomazeau, & Lin, 2010; Navia-Paldanius, Savinainen, & Laitinen, 2012). These three enzymes exhibit different subcellular localizations, which led to the hypothesis that they have access to different pools of 2-AG (Savinainen, Saario, & Laitinen, 2012). However, contrary to MAGL which only hydrolyzes monoacylglycerols, ABHD6 and ABHD12 also hydrolyze other bioactive lipids, such as lysoglycerophospholipids (Thomas, Betters, Lord, Brown, & Marshall, 2013; Blankman, Long, Trauger, Siuzdak, & Cravatt, 2013).

The primary biosynthetic route for AEA (Fig. 64.1B) is through the sequential actions of a Ca^{2+}-dependent *N*-acyltransferase (to generate *N*-acylphosphatidylethanolamines or NAPEs), and a NAPE-preferring phospholipase D (NAPE-PLD) that leads to the production of *N*-acylethanolamines (NAEs), including AEA (Muccioli, 2010). While NAPE-PLD was first described as responsible for the transition from NAPEs to NAEs, other less direct routes have been described over the years (Fig. 64.1B). AEA is hydrolyzed by two enzymes (Fig. 64.3), the fatty acid amide hydrolase (FAAH) and the more recently described *N*-acylethanolamine-hydrolyzing acid amidase (NAAA), which differ in particular by their catalytic properties and substrate specificity (Ueda, Tsuboi, & Uyama, 2010). FAAH is a serine hydrolase active at neutral and alkaline pH, and has the highest reactivity against AEA, while NAAA is a cysteine amidase active at acidic pH, inactive at alkaline pH, and is more efficient at hydrolyzing another NAE, *N*-palmitoylethanolamine (Ueda et al., 2010; Muccioli, 2010). However, recent studies point to a potential differential role for these enzymes in the regulation of NAE levels, depending on the tissue, or even the condition (Alhouayek & Muccioli, 2014b).

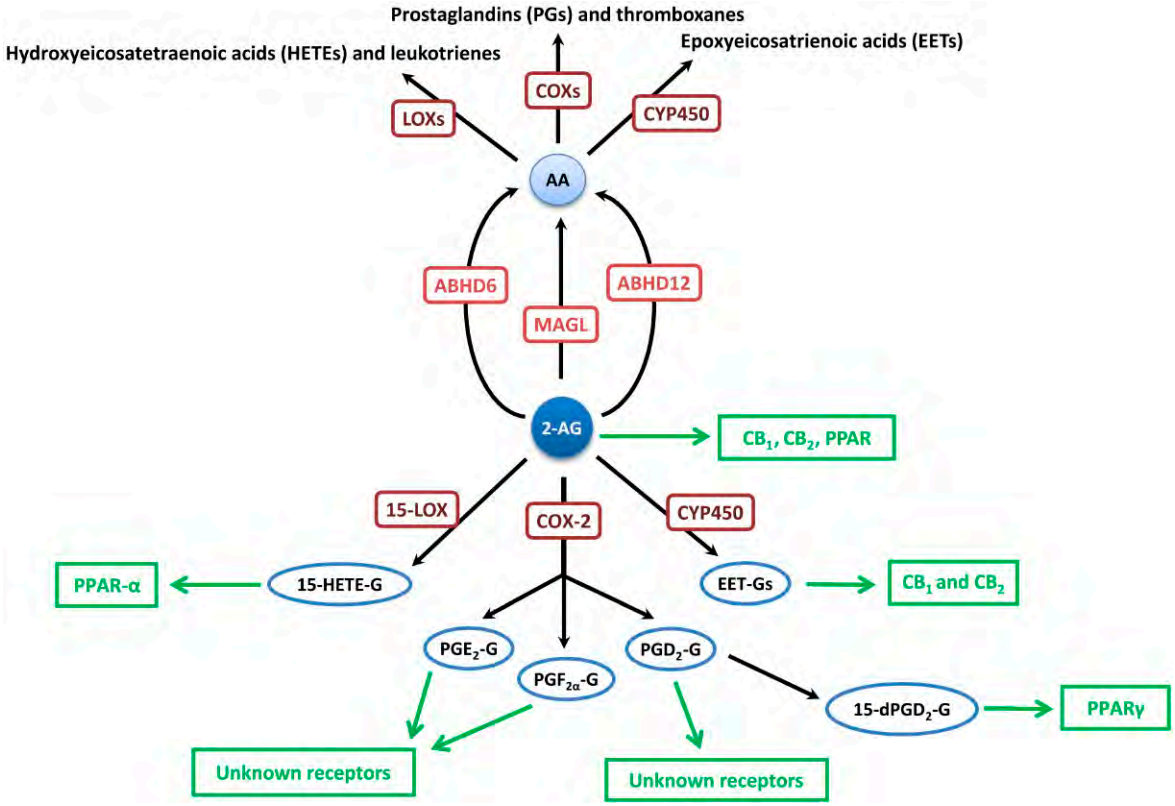

FIGURE 64.2 2-AG is at the center of a bioactive lipid network. 2-AG can be either hydrolyzed, by MAGL, ABHD6, or ABHD12, into arachidonic acid (AA) or oxidized, by 15-lipoxygenase (15-LOX), cyclooxygenase-2 (COX-2), or cytochrome P450 (CYP450) enzymes, to generate 2-AG-derived bioactive lipids. Thus, 15-LOX will generate 15-hydroxyeicosatetraenoic acid-glycerol ester (15-HETE-G), CYP450 will generate epoxyeicosatrienoic acid-glycerol esters (EET-Gs), and COX-2 will produce several prostaglandin-glycerol esters (PG-Gs), depending on the prostaglandin synthase expressed. The AA produced upon 2-AG hydrolysis can also be metabolized through the same pathways. The molecular targets identified so far for these bioactive lipids are presented in *green*.

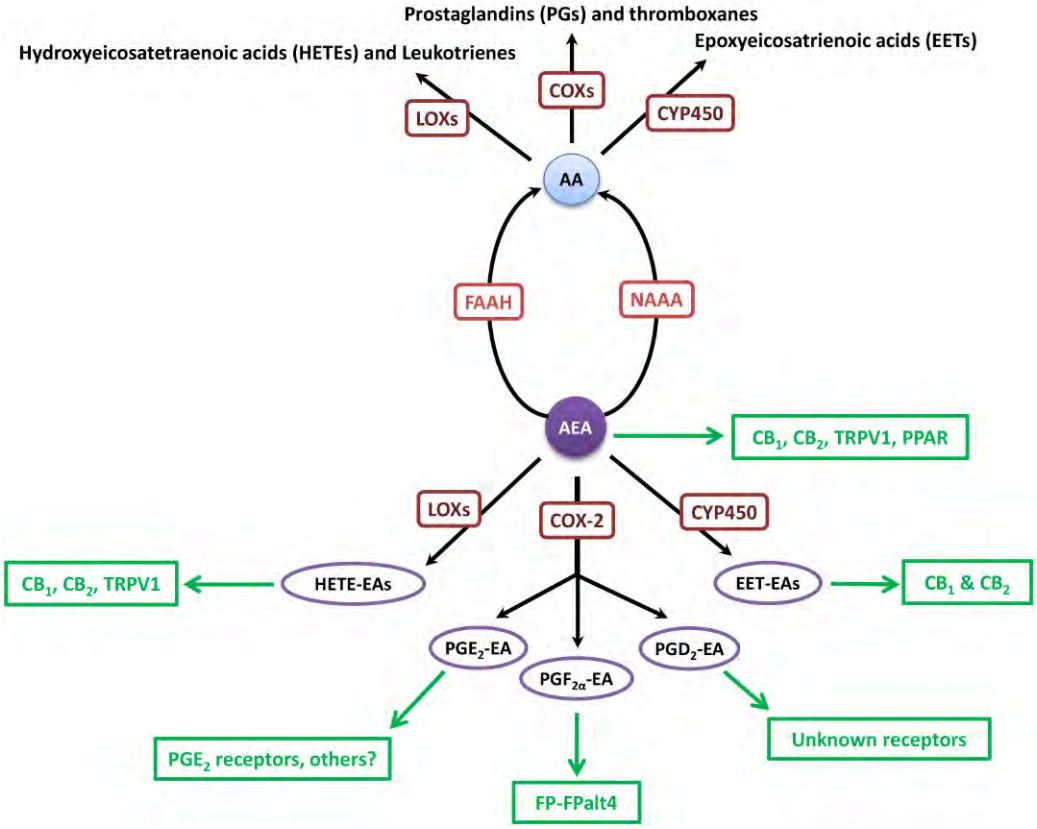

FIGURE 64.3 **AEA is at the center of a bioactive lipid network.** AEA can be either hydrolyzed, by FAAH or NAAA, into arachidonic acid (AA) or oxidized, by lipoxygenases (LOXs), cyclooxygenase-2 (COX-2), or cytochromes P450 (CYP450) enzymes, to generate AEA-derived bioactive lipids. Thus, LOXs will generate hydroxyeicosatetraenoic acid-ethanolamines (HETE-EAs), CYP450 will generate epoxyeicosatrienoic acid-ethanolamide (EET-EAs), and COX-2 will produce several prostaglandin-ethanolamines or prostamides (PG-EAs), depending on the prostaglandin synthase expressed. The AA produced upon AEA hydrolysis can also be metabolized through the same pathways. The molecular targets identified so far for these bioactive lipids are presented in *green*.

ANANDAMIDE AND 2-ARACHIDONOYLGLCEROL AT THE CENTER OF A NETWORK OF BIOACTIVE LIPIDS

The role of MAGL in hydrolyzing 2-AG in the brain was reinforced with the studies by Nomura, Morrison, Blankman, Long, and Kinsey (2011), showing that MAGL inhibition in the brain leads to a drastic increase in 2-AG levels, but also to a reduction in arachidonic acid levels. This study also demonstrated that inhibiting MAGL affects bioactive lipids levels at a larger scale than endocannabinoid hydrolysis, by reducing the levels of arachidonic acid, a major bioactive lipid implicated in inflammation (Nomura et al., 2011). But arachidonic acid is not the only connection between the endocannabinoid and eicosanoid systems. Seminal studies by the Marnett lab put forth the ability of COX-2 to metabolize the endocannabinoids, similarly to arachidonic acid. This is due to the arachidonoyl moiety shared by 2-AG and AEA, and to the ability of COX-2 to accommodate not only free fatty acids, but also their amide and ester derivatives (Rouzer & Marnett, 2011). This COX-2 mediated metabolism of the endocannabinoids will lead to ester (prostaglandin-glycerol esters or PG-Gs for 2-AG) and amide (prostaglandin-ethanolamides, also known as prostamides or PG-EAs for AEA) derivatives of the prostaglandins. These PG-Gs and PG-EAs are bioactive lipids in their own right that exert biological actions different from those of endocannabinoids and prostaglandins (Alhouayek & Muccioli, 2014a).

$PGF_{2\alpha}$-EA is probably the most studied of these metabolites. It has been used, along with its more stable analogs such as bimatoprost, for the treatment of high intraocular pressure (Woodward, Wang, & Poloso, 2013). More recently, $PGF_{2\alpha}$-EA was also shown to negatively regulate adipogenesis (Silvestri, Martella, Poloso, Piscitelli, & Capasso, 2013), and induce hyperalgesic effects in mice (Gatta, Piscitelli, Giordano, Boccella, & Lichtman, 2012). AEA, on the other hand, has analgesic effects, and stimulates adipogenesis (Muccioli et al., 2010; Guindon & Hohmann, 2009). This example is a perfect illustration of

the differential effects exerted by endocannabinoids and their COX-2-derived metabolites.

Adding to the complexity of this system is the fact that all PG-Gs and PG-EAs do not exert the same effects (Alhouayek & Muccioli, 2014a). PGE_2-EA and PGD_2-G exhibit antiinflammatory effects (Alhouayek, Masquelier, Cani, Lambert, & Muccioli, 2013; Brown, Davidson, & Rotondo, 2013), while PGE_2-G and $PGF_{2\alpha}$-G exert proinflammatory and hyperalgesic effects (Hu, Bradshaw, Chen, Tan, & Walker, 2008; Valdeolivas, Pazos, Bisogno, Piscitelli, & Iannotti, 2013; Alhouayek et al., 2013; Ligresti, Martos, Wang, Guida, & Allara, 2014). So, while 2-AG exerts antiinflammatory effects, two of its COX-2-derived metabolites are proinflammatory, and one is antiinflammatory. Therefore, it becomes important to determine under which conditions these PG-Gs are formed, and in which tissues, in order to determine if 2-AG levels should be increased or decreased, and which enzyme(s) to target.

These few examples highlight the intricacy of endocannabinoid metabolism, and the importance of using the right tools, at the right moment, in the right conditions. And this is only the tip of the iceberg. Other enzymes of the eicosanoid system, such as cytochromes P450 (CYP450) and lipoxygenases (LOX), are also able to metabolize the endocannabinoids, leading to glycerol esters and ethanolamide derivatives of epoxyeicosatrienoic acid (EETs) and hydroxyeicosatetraenoic acid (HETEs), respectively (Rouzer & Marnett, 2011; Alhouayek & Muccioli, 2014a).

As the number of endocannabinoid-hydrolyzing enzymes increases, it becomes very important, from a drug discovery standpoint, to understand where and under which circumstances each enzyme is responsible for controlling 2-AG or AEA levels. This entails the availability of potent and selective inhibitors for these enzymes, in order to dissect their contributions.

RECEPTORS AND TARGETS OF ANANDAMIDE, 2-ARACHIDONOYLGLYCEROL, AND THEIR DERIVATIVES

Classically, endocannabinoids exert their actions by activating two G protein-coupled receptors, the cannabinoid receptors 1 and 2 (CB_1 and CB_2). However, over the years, several other targets have been identified. These include the peroxisome proliferator activated receptors (PPARs) for both AEA (PPARα and PPARγ) and 2-AG (PPARγ), and the transient potential vanilloid receptor TRPV1 for AEA (Pertwee, Howlett, Abood, Alexander, & Di Marzo, 2010).

The complexity of endocannabinoid targets and biological effects is increased, when considering the oxidative derivatives of these compounds through enzymes such as COX-2, LOX, and CYP450s. Indeed, some of these derivatives, such as LOX-derived metabolites of AEA, are also agonists of the cannabinoid receptors or the TRPV1 receptor (Fig. 64.3) (Rouzer & Marnett, 2011; Alhouayek & Muccioli, 2014a). Similarly, CYP450-derived metabolites of AEA and 2-AG exhibit high affinity at cannabinoid receptors, while a 15-LOX derived metabolite of 2-AG is a PPARα agonist (Figs. 64.2 and 64.3) (Rouzer & Marnett, 2011; Alhouayek & Muccioli, 2014a). Moreover, the receptors mediating the effects of the endocannabinoid-derived prostaglandins remain elusive for the most part. $PGF_{2\alpha}$-EA was shown to act through a heterodimer of the $PGF_{2\alpha}$ receptor, and one of its splice variants (FP-FPalt4) (Woodward et al., 2013). PGE_2-EA can bind to all four of the PGE_2 receptors, but it is not clear yet whether they mediate its effects (Ross, Craib, Stevenson, Pertwee, & Henderson, 2002). Receptors for the other PG-Gs and PG-EAs have not been described yet, although 15-deoxy-$\Delta^{12,14}$-PGJ_2-G, a metabolite of PGD_2-G, was shown to be a PPARγ agonist (Raman, Kaplan, Thompson, Vanden Heuvel, & Kaminski, 2011).

These numerous targets of the endocannabinoids and their metabolites also add to the complexity of the endocannabinoid system. As interfering with endocannabinoid levels also affects a network of related bioactive lipids, it can be expected that, in some situations, the effects of administering cannabinoid receptor agonists will not have the same effects as increasing the levels of endocannabinoids.

TOOLS AND CONSEQUENCES OF ENDOCANNABINOID LEVELS MODULATION

Interfering with endocannabinoid metabolism offers an array of potential therapeutic applications in the fields of pain, inflammation, anxiety, and obesity, to cite a few. Inhibitors are available to interfere with endocannabinoid biosynthesis or degradation. However, similarly to FAAH which hydrolyzes AEA, the enzymes implicated in the metabolism of 2-AG—that is, DAGL, MAGL, ABHD6, and ABHD12—are all serine hydrolases. This made the identification of selective inhibitors of these enzymes more challenging. Considerable effort is being done to obtain more selective inhibitors. The most studied of these inhibitors, and the latest developments, are summarized in Tables 64.1 and 64.2 and Fig. 64.4. In this section, we will try to highlight the benefits and drawbacks of inhibiting the different enzymes responsible for the metabolism of endocannabinoids.

Inhibitors of the Metabolism of 2-AG

Inhibitors for several enzymes involved in the metabolism of 2-AG have been synthetized and characterized, such as inhibitors for DAGLs, MAGL, and ABHD6.

TABLE 64.1 Selected Modulators of 2-AG Metabolism

	Inhibitor	Structure	MAGL (IC_{50})	ABHD6 (IC_{50})	Other serine hydrolases	DAGLα (IC_{50})	DAGLβ (IC_{50})
MAGL	JZL184		8 nM mouse 262 nM rat 4 nM human	3.3 μM	FAAH: 4 μM ABHD12: no significant inhibition	—	—
	JJKK-048		0.3 nM mouse 0.2 nM rat 0.4 nM human	229 nM	FAAH: 2 μM ABHD12: no significant inhibition	—	—
	MJN110		9.5 nM mouse 9 nM human	260 nM	FAAH: no significant inhibition	—	—
	JZL195		4 nM	50 nM	FAAH: 2 nM	—	—
	OMDM169		1.5 μM mouse 0.9 μM human	—	FAAH: 3 μM	2.8 μM	—
	URB602		30–200 μM	—	FAAH: 17 μM	—	—
ABHD6	WWL70		No inhibition up to 1–10 μM	70–85 nM	FAAH: no inhibition at 10 μM; ABHD12: no inhibition at 1 μM	—	—
	WWL123		No significant inhibition	0.43 μM	FAAH: no significant inhibition; ABHD12: no significant inhibition	—	—

TABLE 64.1 Selected Modulators of 2-AG Metabolism (*cont.*)

	Inhibitor	Structure	MAGL (IC_{50})	ABHD6 (IC_{50})	Other serine hydrolases	DAGLα (IC_{50})	DAGLβ (IC_{50})
	KT185		No significant inhibition	1.3 nM	FAAH: no significant inhibition; ABHD12: no significant inhibition	—	No significant inhibition at 1 μM
DAGLβ	KT109		No significant inhibition	16 nM	FAAH: no significant inhibition; ABHD12: no significant inhibition	2300 nM	82 nM
	KT172		5 μM	5 nM	FAAH: no significant inhibition; ABHD12: no significant inhibition	140 nM	71 nM
DAGLα	RHC80267		No significant inhibition	No significant inhibition	FAAH: 70 μM; ABHD12: no significant inhibition	30–50 μM[a]	
	THL		No significant inhibition	No significant inhibition	FAAH: no significant inhibition; ABHD12: 80 nM	60 nM	100 nM
	OMDM-188		No significant inhibition	—	FAAH: no significant inhibition	16 nM	—
	O-7460		Partial inhibition at 10 μM	Partial inhibition at 10 μM	FAAH: no significant inhibition	690 nM	—

The structures and pharmacological properties of several tools useful to modulate AEA hydrolysis are summarized here.

DAGL inhibition has been proposed as a promising anti-obesity strategy, as reducing 2-AG levels is expected to reduce food intake and adipogenesis (Bisogno et al., 2013). However, as 2-AG is at the center of a network of bioactive lipids, the levels of other lipids can also be affected. DAGLβ inhibition in peritoneal macrophages, for instance, leads to a decrease in 2-AG and arachidonic acid levels (Hsu, Tsuboi, Adibekian, Pugh, & Masuda, 2012). As these two COX-2 substrates are decreased, it is also expected that the levels of prostaglandins and PG-Gs will also be reduced. The reduction of arachidonic acid levels is interesting during inflammation, or in the context of macrophage activation, where a decrease in prostaglandin levels is desired. It remains to be seen whether this decrease in arachidonic acid and prostaglandins will have the same gastric and cardiovascular side effects as nonsteroidal antiinflammatory drugs (NSAIDs). However, as discussed further, several elements point to a

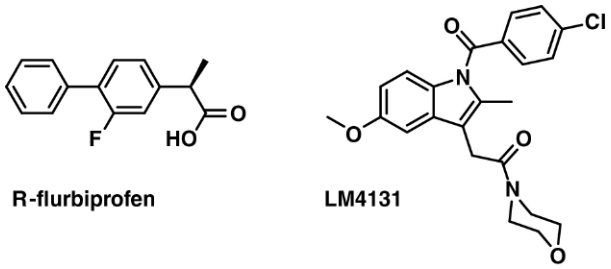

FIGURE 64.4 **Representative substrate-selective COX-2 inhibitors.** R-flurbiprofen and LM4131 preferentially inhibit the oxidative metabolism of endocannabinoids by COX-2, compared to the metabolism of arachidonic acid.

differential regulation of arachidonic acid levels by 2-AG metabolism, or the classical phospholipase A2 (cPLA2) pathway, depending on the tissues.

Indeed, studies with *MAGL inhibitors* led to a drastic increase in 2-AG levels in all the tissues assessed (Long, Nomura, & Cravatt, 2009b; Nomura et al., 2011). However, this was accompanied by a decrease in arachidonic acid levels in some tissues (eg, brain, liver, and lung) but not in others (eg, the gut) (Nomura et al., 2011). Accordingly, MAGL inhibition did not induce gastric ulcers (Nomura et al., 2011), and actually protects against NSAID-induced gastric ulcers, through a CB_1-dependent mechanism (Kinsey, Nomura, O'Neal, Long, & Mahadevan, 2011b). MAGL inhibition was therefore proposed as a potent antiinflammatory and neuroprotective strategy, devoid of the classical side effects of NSAIDs. Accordingly, MAGL inhibition was shown to exert beneficial effects in many models of inflammatory diseases, such as IBD and Parkinson disease in mice (Nomura et al., 2011; Alhouayek, Lambert, Delzenne, Cani, & Muccioli, 2011).

However, things are not so simple, and while MAGL inhibition increased the levels of 2-AG in a murine model of Parkinson disease, and decreased proinflammatory prostaglandin levels, leading to an overall protective effect, this was not the case in a murine model of Huntington's disease (Valdeolivas et al., 2013). In this latter case, MAGL inhibition had a neurotoxic effect. This was blocked by COX-2 inhibition and replicated by PGE_2-G administration, suggesting that the neurotoxic effect is the result of a COX-2 and prostaglandin E synthase metabolism of 2-AG. Accordingly, DAGL inhibition reduced 2-AG levels, and led to a neuroprotective effect, probably due to the decrease in PGE_2-G (Valdeolivas et al., 2013). It is therefore crucial to further understand the pathways mediating the effects of 2-AG in different pathologies.

MAGL inhibition, although very efficient at increasing 2-AG levels and reducing nausea, depression, anxiety, pain, and inflammation in some settings, comes with two major drawbacks: psychotropic side effects due to the drastic increase in 2-AG levels in the brain, as well as functional antagonism of cannabinoid receptors (Long et al., 2009a; Schlosburg et al., 2010). Two strategies can be proposed to circumvent these side effects: the development of peripherally-restricted MAGL inhibitors, and the inhibition of another 2-AG hydrolase, such as ABHD6, to increase peripheral 2-AG levels. Indeed, ABHD6 was shown to control less than 5% of 2-AG hydrolysis in mouse brain (Blankman et al., 2007) and ABHD6 inhibitors, while increasing 2-AG levels in various tissues did not affect 2-AG levels in the brain (Alhouayek et al., 2013). Also, as ABHD6 controls only a fraction of the 2-AG pool, its inhibition does not affect arachidonic acid levels (Alhouayek et al., 2013). Therefore, ABHD6 was proposed as a means for fine-tuning 2-AG levels, and thus avoiding the side effects due to the drastic increase of 2-AG levels. However, both these strategies lead to a loss of some of the beneficial central effects of 2-AG, such as the reduction of nausea, anxiety, and depression. Perhaps one way to deal with that is to increase the levels of the other endocannabinoid, AEA. Indeed, FAAH inhibition is associated with antiemetic and antidepressive effects, without all the side effects observed following MAGL inhibition (Long, Nomura, Vann, Walentiny, & Booker, 2009c).

ABHD6 inhibition increased 2-AG levels in the liver and lung of mice with lipopolysaccharide (LPS)-induced inflammation, and reduced inflammatory parameters (Alhouayek et al., 2013). This effect was partly dependent on cannabinoid receptors activation, and partly on COX-2 metabolism of 2-AG. Indeed, in macrophages activated with LPS, ABHD6 inhibition led to a decrease of several parameters of macrophage activation, and this effect was due to the production of PGD_2-G. Moreover, PGD_2-G was shown to exert antiinflammatory effects in LPS-induced inflammation in mice (Alhouayek et al., 2013). So, in this case, we have a COX-2-derived metabolite of 2-AG with antiinflammatory properties, in opposition with PGE_2-G that was formed in the brain, following MAGL inhibition. It remains to be seen whether this difference in the production of PG-Gs following the inhibition of two different 2-AG hydrolases is due to a different subcellular localization of the prostaglandin synthases, leading to a differential coupling with one enzyme or the other, or to a different regulation of prostaglandin synthases, in different tissues and different disease settings.

Recently, ABHD6 was shown to be more than a monoacylglycerol hydrolase, as it is able to hydrolyze lysoglycerophospholipids (Thomas et al., 2013). In this context, knockdown of ABHD6 in the liver and adipose tissue exerted beneficial effects on high fat diet-induced obesity and hepatic steatosis, probably due to the increase in the levels of other substrates than 2-AG (Thomas et al., 2013).

Identification of selective *inhibitors of ABHD12* proved more difficult. The first identified inhibitor of ABHD12

was tetrahydrolipstatin, which also inhibited DAGL (Hoover, Blankman, Niessen, & Cravatt, 2008). This made it difficult to identify the contribution of ABHD12 to the metabolism of 2-AG. Perhaps the more recently described triterpenoid derivatives, having no effect on DAGL, will allow for a more thorough understanding of this role of ABHD12 (Parkkari, Haavikko, Laitinen, Navia-Paldanius, & Rytilahti, 2014). However, studies with ABHD12 knockout mice point to a role for this enzyme in controlling the levels of lysophosphatidylserines, rather than 2-AG (Blankman et al., 2013).

Inhibitors of the Metabolism of AEA

Currently, there are no known inhibitors of *AEA biosynthesis*. Redundancy in the biosynthetic pathways of NAEs might be a reason for this lack of inhibitors, as several enzymes can make the transition from NAPEs to NAEs (Fig. 64.1B). In this context, it is interesting to note that some NAPE-PLD knockout mice exhibit altered NAE levels, while another NAPE-PLD knockout strain does not exhibit alterations in AEA levels (Leung, Saghatelian, Simon, & Cravatt, 2006; Tsuboi, Okamoto, Ikematsu, Inoue, & Shimizu, 2011). The same goes for GDE1 knockout mice in the brain (Simon & Cravatt, 2010).

In the context of interfering with AEA hydrolysis, the most developed and characterized inhibitors are *FAAH inhibitors* (Table 64.2). FAAH and NAAA profoundly differ in their catalytic mechanisms (Ueda et al., 2010) which allowed for the development of selective inhibitors of FAAH, devoid of activity at NAAA, and vice versa. FAAH inhibitors were shown to increase AEA levels in vivo, in physiological and pathological settings. These can be used for the treatment of pain and inflammatory diseases such as arthritis, as well as more central effects of the endocannabinoids, such as nausea and vomiting and mood disorders (Ahn, Johnson, Mileni, Beidler, & Long, 2009; Kinsey, Naidu, Cravatt, Dudley, & Lichtman, 2011a; Bluett, Gamble-George, Hermanson, Hartley, & Marnett, 2014). FAAH inhibition, and the subsequent increase in AEA levels in the central nervous system, was not associated with the same psychotropic effects observed with MAGL inhibition (Long et al., 2009c). As increasing AEA levels can be accompanied by a subsequent increase in prostamide levels in inflammatory settings, novel FAAH inhibitors that can double as antagonists of the $PGF_{2\alpha}$-EA receptor (AGN 211335) are being considered for the treatment of inflammatory pain (Ligresti et al., 2014). Indeed, as we mentioned earlier, AEA has analgesic and antiinflammatory properties, while $PGF_{2\alpha}$-EA is hyperalgesic and proinflammatory. However, antagonism of the effects of $PGF_{2\alpha}$-EA is not the goal in every situation, as this compound has proven very effective in the treatment of glaucoma (Woodward et al., 2013).

Regarding *NAAA inhibition*, much fewer inhibitors are available, probably due to the more recent molecular identification of NAAA, and the fact that less is known when it comes to the molecular mechanisms of cysteine hydrolases and their inhibitors, compared to serine hydrolases. Among the first described NAAA inhibitors, β-lactone derivatives are relatively potent, but exhibit limited plasma stability (Ponzano, Bertozzi, Mengatto, Dionisi, & Armirotti, 2013). These compounds were mostly tested in local administration schemes, where they increased *N*-palmitoylethanolamine levels, and exerted antiinflammatory and analgesic effects (Solorzano, Zhu, Battista, Astarita, & Lodola, 2009; Sasso, Moreno-Sanz, Martucci, Realini, & Dionisi, 2013). In these cases, the NAAA inhibitor did not affect AEA levels, or this was not reported (Solorzano et al., 2009; Sasso et al., 2013). Therefore, the impact of NAAA inhibition on AEA levels remains to be elucidated. As *N*-palmitoylethanolamine is a well-known antiinflammatory bioactive lipid (Alhouayek & Muccioli, 2014b), NAAA inhibitors are potential therapies in inflammatory diseases.

Dual Inhibitors of the Metabolism of 2-AG and AEA

Following the characterization of the MAGL inhibitor JZL184, another related carbamate inhibitor was developed as a dual FAAH/MAGL inhibitor, JZL195. While increasing the levels of both endocannabinoids seems promising to tackle numerous pathologies, the use of this inhibitor was accompanied by similar psychotropic side effects as those observed following cannabis use (Long et al., 2009c).

Another means to increase the levels of both AEA and 2-AG is *COX-2 inhibition*. Indeed, following the discovery that endocannabinoids can be oxidized by COX-2, it was hypothesized that some of the effects of NSAIDs were not only due to the decreased prostaglandin production, but also to increased endocannabinoid levels. This hypothesis was supported by several observations that COX-2 is able to control AEA levels in the brain, and COX inhibitors can increase endocannabinoid levels in murine models of inflammation (Telleria-Diaz, Schmidt, Kreusch, Neubert, & Schache, 2010). Moreover, some of the effects of NSAIDs can be blocked by CB_1 antagonists (Telleria-Diaz et al., 2010; Staniaszek, Norris, Kendall, Barrett, & Chapman, 2010). Thus, exploiting the endocannabinoid component of COX-2 inhibition might be a way to enhance the benefits of NSAIDs, and reduce their side effects. Indeed, endocannabinoids are analgesic and antiinflammatory compounds, therefore increasing their levels concomitantly with COX-2 inhibition has a synergistic effect, and would allow for a reduction of the doses of NSAIDs. In this context, compounds with

dual inhibitory activity at FAAH and COX are currently being evaluated (Cipriano, Bjorklund, Wilson, Congiu, & Onnis, 2013).

Another way to exploit the endocannabinoid component of COX-2 is the development of substrate-selective inhibitors of COX-2, that is, inhibitors of endocannabinoid metabolism by COX-2, without affecting the metabolism of arachidonic acid. R-flurbiprofen, the R-enantiomer of the NSAID S-flurbiprofen, was shown to increase endocannabinoid levels in vivo, and reduce nerve damage in a murine model of multiple sclerosis (Schmitz, de Bruin, Bishay, Mannich, & Haussler, 2014). Another COX-2 substrate-selective inhibitor, LM-4131, increased endocannabinoid levels, and reduced anxiety in mice (Hermanson, Hartley, Gamble-George, Brown, & Shonesy, 2013).

CONCLUDING REMARKS

The studies outlined in this review point to an ever-increasing complexity of the endocannabinoid system. While, in the early days of its exploration, the system looked relatively simple, it is nowadays clear that it is both complex and highly interconnected with the eicosanoid pathways. Also, what seemed to be two "redundant lipids," with AEA and 2-AG activating the same cannabinoid receptors, now appears as two distinct bioactive lipids characterized by numerous unique properties. While the complexity of the system might appear as a hurdle to its therapeutic exploitation, it is actually a unique opportunity to fine-tune the desired effect depending on the lipid that is modulated.

MINI-DICTIONARY

COX-2 substrate-selective inhibitors COX-2 inhibitors that selectively block endocannabinoid oxygenation by COX-2, without affecting the oxygenation of arachidonic acid. This is in opposition with other COX inhibitors, such as the NSAIDs which inhibit the oxygenation of arachidonic acid and endocannabinoids by COX-2.

Eicosanoids Biologically active lipid mediators, including prostaglandins, thromboxanes, leukotrienes, and other oxygenated derivatives, produced primarily by three classes of enzymes, cyclooxygenases, lipoxygenases, and cytochrome P450. The most studied of the fatty acids is arachidonic acid (C20:4), mostly found in esterified form, mainly to phospholipids and phosphatidylinositol, in particular. Arachidonate is released by the action of the enzyme phospholipase A2 (PLA2). 2-AG and MAGL have also been implicated in the release of arachidonic acid in some tissues and conditions.

Endocannabinoids Endogenous ligands of the two G-protein coupled receptors activated by Δ9-THC, one of the main constituents of cannabis. The two most studied endocannabinoids are the N-acylethanolamine N-arachidonoylethanolamine (AEA or anandamide), and the monoacylglycerol 2-arachidonoylglycerol (2-AG).

Pharmacological Aspects of NMDA Receptors, mGluR5, and Endocannabinoids

Y. Izumi, C.F. Zorumski

Department of Psychiatry; The Taylor Family Institute for Innovative Psychiatric Research, Washington University School of Medicine, St. Louis, MO, United States

SUMMARY POINTS

- Synaptic depression is often mediated by endocannabinoids (eCBs) serving as retrograde messengers at cannabinoid receptor 1 (CB1), and other cannabinoid receptors.
- eCB production and CB1 activation on inhibitory synaptic terminals are essential for DSI.
- Several forms of long-term depression (LTD) are mediated by eCBs serving as retrograde messengers.
- Binding of glutamate to postsynaptic metabotropic glutamate receptors (mGluRs), leading to eCB formation and release, results in activation of specific presynaptic eCB receptors, and induction of several forms of LTD.
- Whereas exogenously administered cannabinoids disrupt long-term potentiation (LTP), eCBs may paradoxically augment LTP induction.
- NMDA glutamate receptors (NMDAR) activation may have additional actions, including adverse effects on CB1 signaling.
- Some NMDAR effects may involve transient receptor potential vanilloid 1 (TRPV1) activation.

KEY FACTS ABOUT ENDOCANNABINOIDS AS RETROGRADE MESSENGERS

- At synapses, neurotransmitters are released from presynaptic sites to activate postsynaptic receptors.
- However, synaptic transmission is not limited to anterograde (forward) transmission.
- Retrograde messengers travel from postsynaptic sites to presynaptic sites and modulate neurotransmitter release.
- Endcannabinoids are known to serve as retrograde messengers.
- Activation of postsynaptic glutamate receptors triggers endocannabinoid release from postsynaptic sites.
- Endocannabinoids play pivotal roles in synaptic plasticity as retrograde messengers.

LIST OF ABBREVIATIONS

2-AG	2-Arachidonoylglycerol
ACPD	Aminocyclopentane-1,3-dicarboxylic acid
AMPA	α-Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor
AP5	2-Amino-5-phosphonovalerate
CB1	Cannabinoid receptor 1
CB2	Cannabinoid receptor 2
CHPG	2-Chloro-5-hydroxyphenylglycine
CNQX	6-Cyano-7-nitroquinoxaline-2,3-dione

CNS	Central nervous system
CPCCOEt	7-(Hydroxyimino)cyclopropa[*b*]chromen-1a-carboxylate ethyl ester
DAG	Diacylglycerol
DHPG	3,5-Dihydroxyphenylglycine
DSE	Depolarization induced suppression of excitation
DSI	Depolarization-induced suppression of inhibition
eCB	Endocannabinoid
EPSP	Excitatory post synaptic potential
FAAH	Fatty acid amide hydrolase
GPCR	G protein coupled receptor
KO	Knockout
LPI	L-alpha-lysophosphatidylinositol
I-LTD	Long-term depression of inhibitory postsynaptic currents
IPSC	Inhibitory postsynaptic current
IPSP	Inhibitory postsynaptic potential
LTD	Long-term depression
LTP	Long-term potentiation
MAGL	Monoacylglycereol lipase
MAPK	Mitogen-activated protein kinases
mGluR	Metabotropic glutamate receptors
MPEP	2-Methyl-6-phenylethynyl)pyridine
NADA	*N*-arachidonoyl dopamine
NBQX	2,3-Dioxo-6-nitro-1,2,3,4-tetrahydrobenzoquinoxaline-7-sulfonamide
NMDA	*N*-methyl-D-aspartate
NMDAR	NMDA glutamate receptors
PLC	Phospholipase C
PND	Postnatal date
SLM	Stratum lacunosum moleculare
THC	Δ^9-Tetrahydrocannabinol
TRPV1	Transient receptor potential vanilloid 1

INTRODUCTION

In this chapter, we review interactions between metabotropic and NMDA glutamate receptors (NMDARs) and the endocannabinoid (eCB) system. We also discuss neuropharmacological aspects of eCBs in the central nervous system (CNS), and the roles of metabotropic glutamate receptors (mGluRs), NMDARs, and eCBs in synaptic plasticity.

OVERVIEW OF GLUTAMATE RECEPTORS AND THE CNS eCB SYSTEM

Glutamate Receptors

Glutamate receptors are divided into two major groups: ionotropic receptors, and mGluRs. Ionotropic receptors are further classified according to specific agonists: AMPA, kainate, and NMDA. AMPA/kainate receptors participate in basal synaptic transmission, whereas NMDARs trigger intracellular events via calcium influx. Calcium, in turn, promotes synaptic plasticity [including long-term potentiation (LTP) and long-term depression (LTD)], but can also trigger excitotoxic neuronal death. mGluRs were previously called quisqualate receptors or ACPD receptors; quisqualate is a potent group I mGluR agonist, with additional actions at AMPA/kainate receptors, whereas aminocyclopentane-1,3-dicarboxylic acid (ACPD) is a group I and group II mGluR agonist. Group I mGluRs include mGluR1 and mGluR5, and activate phospholipase C (PLC) to form inositol 1,4,5-triphosphate and diacylglycerol (DAG). DAG is a precursor of 2-arachidonoylglycerol (2-AG), a major eCB. 3,5-Dihydroxyphenylglycine (DHPG) is an agonist for mGluR1 and mGluR5, whereas 2-chloro-5-hydroxyphenylglycine **(**CHPG) is a selective mGluR5 agonist. In the CA1 region of rat hippocampal slices, 100 μM DHPG induces chemical LTD, even in the presence of 2-methyl-6-phenylethynyl)pyridine (MPEP), a selective mGluR5 antagonist (Izumi & Zorumski, 2012), but chemical LTD induced by 10 μM DHPG is blocked by MPEP (Purgert et al., 2014), suggesting that LTD induced by high concentrations of DHPG involves mechanisms other than mGluR5 activation. CHPG (250 μM) fails to induce chemical LTD in the presence of MPEP (Purgert et al., 2014), suggesting that CHPG is a more specific mGluR5 agonist, though DHPG is the more commonly used agent to induce LTD. LY367385 and 7-(hydroxyimino)cyclopropa[*b*]chromen-1a-carboxylate ethyl ester (CPCCOEt) are specific antagonists against mGluR1. Recent evidence indicates that most mGluRs in the CNS are localized intracellularly, rather than at the cell membrane (Jong, Schwetye, & O'Malley, 2007), and these intracellular receptors contribute to LTD, but not LTP (Purgert et al., 2014).

Endocannabinoids

Endocannabinoids (eCBs) are endogenous lipids similar to active components in cannabinoids (Table 65.1). Anandamide was the first eCB identified (Devane et al., 1992), and is also called *N*-arachidonoylethanolamine (AEA). Anandamide is formed via hydrolysis of *N*-arachidonyl phosphatidylethanolamine, or from arachidonate and ethanolamine, via fatty acid amide hydrolyase (FAAH). FAAH also rapidly degrades anandamide, and is inhibited by URB597. AM404, an active metabolite of acetaminophen, is an uptake inhibitor that can be used to investigate physiological effects of anandamide.

2-AG was the second eCB identified. In the CNS, 2-AG is more abundant than anandamide (Sugiura, Kishimoto, Oka, & Gokoh, 2006). Because 2-AG formation is mediated

TABLE 65.1 Endocannabinoids (eCBs) in the CNS

Endocannabinoids (eCBs)
Anandamide (arachidonylethanolamine, AEA)
2-Arachidonyl glyceryl (2-AG)
2-Arachidonyl glyceryl ether (Noladin ether)
N-Arachidonyldopamine (NADA)
Oleamide

TABLE 65.2 Cannabinoid Receptors and Widely Used Antagonists

Cannabinoid receptor	Commonly used agonist	Commonly used antagonist
CB1	ACEA	Rimonabant (SR141716) AM251 (also agonist of GPR55) AM281
CB2		AM630
GPR55		Cannabidiol
TRPV1	Capsaicin	Capsazepine

by phospholipase C and DAG, it is likely that group I mGluRs stimulate 2-AG production. 2-AG is mainly metabolized by monoacylglycereol lipase (MAGL), which can be inhibited by UR602.

Other possible eCBs include 2-arachidonyl glyceryl ether (noladin ether), an agent that is present at levels lower than 2-AG, but is more stable than 2-AG. In rat substantia nigra, *N*-arachidonoyl dopamine (NADA) is another potential eCB generated by high potassium depolarization (Freestone et al., 2014). Oleamide may also be an eCB, because oleamide activates cannabinoid receptors. Oleamide accumulates in CSF, following sleep-deprivation, and produces sleep if administered to animals.

Synthetic Cannabinoids

In addition to phytocannabinoids, such as Δ^9-tetrahydrocannabinol (THC), other synthetic cannabinoids include CP 55,940, WIN55,212-2, and HU210. CP 55,940 activates classical cannabinoid receptors, but also antagonizes GPR55, a nonclassical cannabinoid receptor (Kapur et al., 2009).

Cannabinoid Receptors

THC induces various symptoms in animals and humans by activating specific CNS receptors. The cannabinoid receptor 1 (CB1), first described by Matsuda, Bonner, and Lolait (1992), is the main CNS cannabinoid receptor, and is densely expressed in cerebellum, hippocampus, cerebral cortex, and basal ganglia (Table 65.2). CB1 localizes presynaptically on glutamatergic axon terminals of most excitatory pathways in the hippocampus (Katona et al., 2006), and inhibits voltage-sensitive calcium channels and adenylyl cyclase, while stimulating mitogen-activated protein kinases (MAPKs) (Turu & Hunyady, 2010). CB1 is also present on mitochondrial membranes, which directly control energy metabolism, and is involved in depolarization-induced suppression of inhibition (DSI) in the hippocampus (Bénard et al., 2012). Rimonabant (SR141716), AM251, and AM281 are CB1 antagonists.

Cannabinoid receptor 2 (CB2), another cannabinoid receptor, is mainly expressed in the immune system and hematopoietic cells. CB2 is also found in CNS microglia and neurons (Gong et al., 2006). In the CA1 hippocampal region and substantia nigra, CB2 is mainly postsynaptic (Brusco, Tagliaferro, Saez, & Onaivi, 2008), and inhibits voltage-gated calcium channels (Atwood, Wager-Miller, Haskins, Straiker, & Mackie, 2012b). In mice, JWH203, a CB2 receptor agonist, reverses MK-801-induced disruptions in sensorimotor gating, suggesting that CB2 may protect against NMDAR hypofunction (Khella, Short, & Malone, 2014).

Nonclassical cannabinoid receptors may also exist in the CNS. GPR55 is one example, and L-alpha-lysophosphatidylinositol (LPI), an agonist of GPR55, transiently increases glutamate release at CA3-CA1 hippocampal synapses via calcium release from presynaptic stores (Sylantyev, Jensen, Ross, & Rusakov, 2013). Cannabidiol, a GPR55 antagonist, blocks this effect. GPR18, another nonclassical receptor, is expressed in microglia (McHugh, 2012).

Transient receptor potential vanilloid 1 (TRPV1) is another nonclassical candidate receptor that is activated by several lipid signaling molecules, including anandamide, NADA, and 12-(S)-HPETE (Marinelli et al., 2007). Capsaicin and capsazepine are selective TRPV1 agonists and antagonists, respectively. In the dorsal horn, TRPV1 and mGluR5 colocalize on presynaptic terminals of nociceptive neurons, suggesting that coupling between TRPV1 and mGluR5 serves spinal nociceptive neurotransmission (Kim et al., 2000). Furthermore, DHPG-mediated calcium responses in the spinal cord involve TRPV1 activation by DAG. In the CA1 region of CB1 knockout (KO) mice, reduction of excitatory postsynaptic potentials (EPSPs) by WIN55,212-2 and CP55940 is capasazepine sensitive, suggesting TRPV1 participates in eCB mediated synaptic depression (Benninger, Freund, & Hájos, 2008).

There may be other cannabinoid receptors. In interneurons of the rat hippocampus, the nonhydrolysable anandamide analog, R-methanadamide, depresses excitatory transmission (Edwards et al., 2012). This depression is not blocked by AM251 or capsazepine, suggesting the existence of CB1/TRPV1-independent, anandamide receptors (Fig. 65.1).

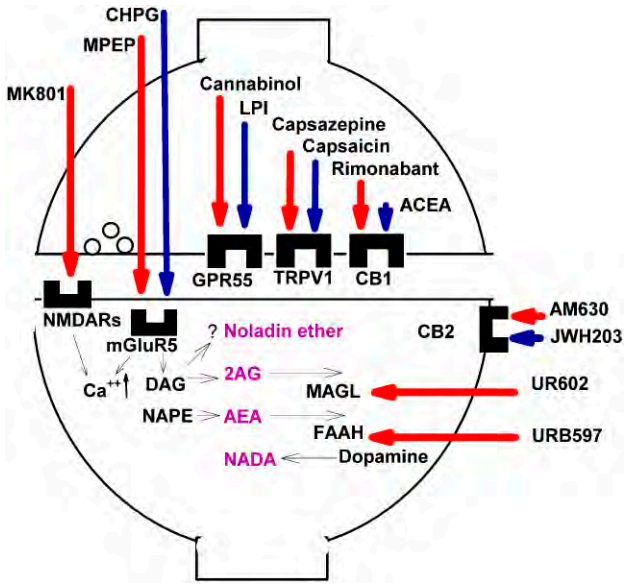

FIGURE 65.1 Pharmacological approach for understanding the eCB system. The upper part depicts the presynaptic site with neurotransmitter vesicles, and the lower part represents the postsynaptic site expressing glutamate receptors. Agonists for each receptor are shown with *blue arrows*, whereas antagonists and inhibitors are shown with *red arrows*. eCBs are shown in *purple*.

SYNAPTIC PLASTICITY AND mGluR5

eCBs are typically formed in postsynaptic neurons, and serve as retrograde messengers to activate presynaptic CB1. The activation of metabotropic receptors, especially mGluRs, plays an important role in eCB formation. In addition to CB1, other receptors may be involved in modulating synaptic transmission, participating in depolarization-induced suppression, and LTP. Furthermore, alteration of inhibitory synaptic transmission may affect LTP induction. Both genetic modifications and pharmacological approaches have helped to define the role of eCBs in synaptic plasticity.

Depolarization-Induced Suppression of Inhibition and the eCB System

Depolarization-induced suppression of inhibition (DSI) is a transient decrease in inhibitory GABAergic postsynaptic potentials or currents (IPSPs or IPSCs), triggered by depolarizing pulses. In hippocampal cultures, DSI is augmented by group I mGluR activation, and is prevented by AM 281 (Ohno-Shosaku, Maejima, & Kano, 2010). Application of 1.5–5 μM DHPG facilitates DSI (Ohno-Shosaku, Shosaku, Tsubokawa, & Kano, 2002). Given that CB1 is expressed presynaptically, retrograde eCB signaling is proposed to play a role in DSI, according to the following scheme: activation of postsynaptic mGluRs, eCB formation, activation of presynaptic CB1, and reduction of GABA release.

In a neuron/synaptic bouton preparation from the basolateral amygdala, a region critical for fear conditioning, a 4 s depolarizing step (–60 to 0 mV) produces robust suppression in the frequency and amplitude of spontaneous IPSPs (Zhu & Lovinger, 2005). MPEP shortens DSI duration but does not block DSI, while AM251 completely prevents DSI. Furthermore, WIN55,212-2 suppresses spontaneous IPSCs, and mimics the effects of depolarization (Zhu & Lovinger, 2005).

In neuron/synaptic boutons from the CA1 region, depolarization alone does not induce DSI, but depolarization combined with DHPG induces short-term depression. WIN55,212-2 depresses this short-term depression in spontaneous IPSCs. Similarly, 2-AG and anandamide also depress spontaneous IPSCs, with anandamide being more effective than 2-AG. The eCB-dependent short term depression is mGluR5-dependent, based on block by MPEP. These observations suggest that the depression in the hippocampus is more dependent on mGluR activation than that in the amygdala (Sheinin, Talani, Davis, & Lovinger, 2008).

In midbrain slices containing substantia nigra, IPSPs are facilitated by rimonabant. This facilitation is blocked by CPCCOEt but not MPEP, indicating that mGluR1, not mGluR5, is linked with eCB-mediated alteration of inhibitory synaptic transmission (Freestone et al., 2014).

Taken together, the role of mGluRs in DSI is variable among brain regions, but eCB production and CB1 activation on inhibitory terminals are essential for temporary reduction of GABA release. When a single neuron is grown on a small island of permissive substrate, it forms autapses (synapses) onto itself. In autaptic neurons from CB1 KO mice, depolarization to 0 mM from –60 mV fails to induce DSI. However, in CB2 transfected autaptic neurons from CB1 KO mice, DSI can be induced, and is prevented by AM630, indicating a possible role for CB2 (Atwood, Straiker, & Mackie, 2012a).

eCBs can also mediate depolarization-induced suppression of excitation (DSE; Ohno-Shosaku et al., 2002). 2-AG is the most likely endocannabinoid mediating DSE in autaptic neurons (Straiker & Mackie, 2005).

Some effects of eCBs in the CNS are not explained by activation of CB1 or CB2, and TRPV1 may be linked with glutamate receptors. The acute depression induced by DHPG in the CA1 region is facilitated by capsazepine, suggesting that TRPV1 may be involved in modulating mGluR-dependent short-term depression (Bennion et al., 2011; Fig. 65.2).

Heterosynaptic LTD

Chevaleyre and Castillo (2003) provided early evidence for the involvement of eCBs in heterosynaptic LTD. In the CA1 region of rat hippocampal slices, high frequency stimulation (HFS) (100 Hz 1 s × 2 strains) in

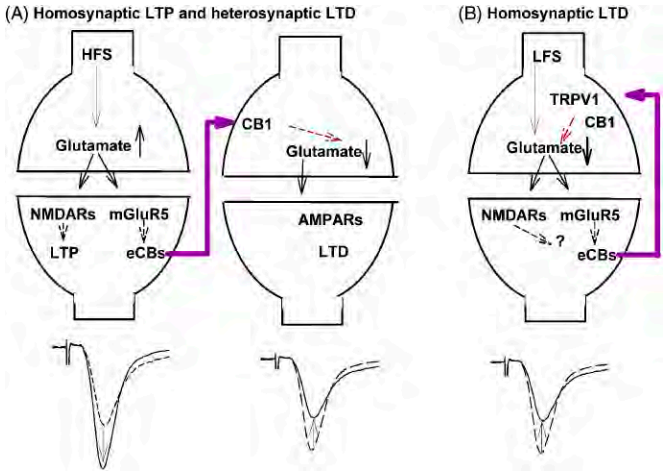

FIGURE 65.2 Schematic representation of heterosynaptic and homosynaptic LTD. (A) Glutamate released following presynaptic HFS activates NMDARs, resulting in homosynaptic LTP. Glutamate also activates postsynaptic mGluR5, leading to eCB formation. As retrograde messengers, eCBs activate presynaptic CB1, and suppress glutamate release on other neurons. The heterosynaptic pathway is independent from NMDARs. (B) Glutamate released during LFS activates both NMDARs and mGluR5 at postsynaptic sites. eCBs formed after activation of these glutamate receptors serve as retrograde messengers at the same synapses. In the CA1 region, eCBs activate presynaptic CB1, and suppress glutamate release. In the dentate gyrus, TRPV1 may be responsible for homosynaptic LTD induction. Traces show how EPSPs are altered after HFS and LFS.

stratum radiatum induces LTD of IPSCs (I-LTD). I-LTD induction is prevented by MPEP plus LY367385, and by U73122, a PLC inhibitor, suggesting that PLC stimulation following activation of group 1 mGluRs is essential. HFS-mediated I-LTD and chemical I-LTD induced by DHPG are not additive. HFS fails to induce I-LTD in the presence of AM251, but AM251 administered after HFS does not reverse I-LTD, indicating that CB1 helps to initiate but not sustain LTD. Chemical I-LTD by DHPG is also blocked by AM251. HFS-mediated I-LTD, and chemical I-LTD induced by WIN55,212-2 are not additive (Chevaleyre & Castillo, 2003). From these findings, a mechanism for I-LTD induction is proposed: glutamate release after HFS activates mGluRs1/5, leading to PLC activation and DAG formation; DAG is then converted into 2-AG, which inhibits GABA release by acting on heteropresynaptic CB1 (Chevaleyre & Castillo, 2004).

Yasuda, Huang, and Tsumoto (2008) showed that, prior to postnatal day (PND) 14, HFS (20 pulses at 100 Hz x 5 trains) in the presence of picrotoxin induced heterosynaptic LTD, in addition to homosynaptic LTP in the CA1 region. The heterosynaptic LTD is not induced in the presence of MPEP plus LY367385. This LTD is not blocked by 2-amino-5-phosphonovaleric acid (AP5), a selective NMDAR antagonist, whereas AP5 blocks homosynaptic LTP, indicating that the LTP is dependent on, but LTD is independent of NMDAR activation. AM251 inhibited heterosynaptic LTD, but did not affect homosynaptic LTP. At PND 2-5, CB1 inhibition is necessary for HFS to induce homosynaptic LTP (Yasuda et al., 2008). Similar findings were observed in mouse visual cortex (Huang, Yasuda, Sarihi, & Tsumoto, 2008). In layer II/III neurons in the visual cortex of young mice (PND 14-20), theta-bust stimulation with postsynaptic depolarization induces homosynaptic LTP and heterosynaptic LTD. AP5 abolishes homosynaptic LTP, but not heterosynaptic LTD; MPEP abolished heterosynaptic LTD, but not homosynaptic LTP. Similarly, AM251 abolishes heterosynaptic LTD, but not homosynaptic LTP. From these findings, the authors proposed a scheme to explain heterosynaptic LTD: postsynaptic activation of group 1 mGluRs stimulates release of eCBs as retrograde messengers that activate heteropresynaptic CB1, and depress neurotransmitter release (Huang et al., 2008).

Homosynaptic LTD

eCBs are involved in autaptic LTD (autLTD) (Kellogg, Mackie, & Straiker, 2009). The autLTD resulting from repeated 4 Hz stimulation is induced in the presence of AP5/CNQX, or even in the presence of 4-carboxyphenylglycine, a group I mGluR antagonist. However, administration of all the three antagonists blocks autLTD. Administration of 2-AG for 3–5 min induces acute suppression, and long-lasting depression of excitatory postsynaptic currents (EPSCs). The 2-AG mediated LTD is reversed by U73122, a PLC inhibitor. This finding suggests that autLTD occurs via activation of presynaptic PLC downstream of CB1 (Kellogg et al., 2009).

In the CA1 region, electrical LTD induced by low frequency stimulation (LFS), and chemical LTD induced by DHPG are both sensitive to chemical and genetic inhibition of CB1 (Xu, Chen, Zhang, & Chen, 2010). CB1 is abundant in stratum radiatum, but is less prevalent in stratum lacunosum moleculare (SLM) (Xu et al., 2010). This may explain why LTD is easier to induce in stratum radiatum than SLM. Consistent with this, LFS of direct perforant path inputs to CA1 SLM does not induce homo- or heterosynaptic LTD, but depotentiates stratum radiatum LTP (Izumi & Zorumski, 2008).

Péterfi et al. (2012) found that excitatory synaptic inputs to both CA1 interneurons and pyramidal cells readily undergo spike timing-dependent LTD. This form of LTD is blocked by a DAG lipase inhibitor, and also by MPEP, suggesting that eCBs formed via DAG lipase after mGluR5 activation are involved in hippocampal LTD induction. Furthermore, LTD was not seen in CB1 KO mice.

In the CA1 region of rat hippocampal slices, WIN55,212-2 and ACEA induce chemical LTD of Schaffer collateral EPSPs (Izumi & Zorumski, 2012). The LTD induced by WIN55,212-2 is blocked by AM251, but not by AM630, indicating that CB1, but not CB2, is required

for LTD induction. Conventional LTD of EPSPs induced by low frequency electrical stimulation is also blocked by AM251. The effect of WIN55,212-2 was best mimicked by noladin ether, but less by 2-AG or anandamide, suggesting that noladin ether rather than 2-AG may be involved in CA1 LTD. These observations also suggest that anandamide and 2-AG may serve roles other than LTD in CA1.

In the rat nucleus tractus solitarius, LTD is prevented by both AP5 and AM 251. Interestingly, LTD was not blocked by intracellular perfusion of MK801, implying an involvement of NMDARs on neighboring cells or presynaptic sites. In addition, FAAH inhibition lowers the threshold for LFS mediated LTD, suggesting the participation of anandamide as the eCB in this nucleus (Khlaifia, Farah, Gackiere, & Tell, 2013). In the striatum, eCB release is also involved in LTD of excitatory transmission (Gerdeman, Ronesi, & Lovinger, 2002).

In addition to CB1, TRPV1 may be involved in LTD induction. In the dentate gyrus, capsaicin triggers LTD that is mediated by anandamide in a CB1-independent manner (Chávez, Chiu, & Castillo, 2010). This TRPV1-mediated LTD also requires mGluR5 activation (Chávez et al., 2010).

Taken together, it is likely that mGluR activation, followed by eCB production and activation of CB1 or TRPV1, is necessary for homosynaptic LTD induction.

Synaptic Potentiation and the eCB System

Compared to the clear participation of eCBs in synaptic depression, their role in synaptic potentiation is less certain. Cannabinoids, however, are known to impair memory acquisition and maintenance (Ranganathan & D'Souza, 2006). Because LTP is thought to be a cellular mechanism of memory, it is hypothesized that cannabinoids block LTP. Indeed, HU201, a synthetic cannabinoid, inhibits LTP induction in rat hippocampal slices (Collins, Pertwee, & Davies, 1994), effects mimicked by WIN55,212-2 and anandamide (Terranova, Michaud, Le Fur, & Soubrié, 1995). Because these effects of WIN55,212-2 and anandamide are overcome by a CB1 antagonist, CB1 is believed to be pivotal for LTP inhibition (Terranova et al., 1995), and LTP is facilitated in CB1 KO mice (Jacob, Marsch, Marsicano, Lutz, & Wotjak, 2012). Another form of LTP induced by exogenous ATP (10 μM for 10 min) is blocked by WIN55,212-2. This inhibitory effect of WIN55,212-2 is overcome by AM251, suggesting again the involvement of CB1 (Ievglevskyi, Palygin, Kondratskaya, Grebenyuk, & Krishtal, 2012).

While exogenous cannabinoids disrupt LTP induction, it is less clear whether endogenously formed eCBs suppress LTP. Administration of URB597, an inhibitor of FAAH, doubles anandamide levels in the hippocampus (30–40 pmol/g) but only partially inhibits LTP (Basavarajappa, Nagre, Xie, & Subbanna, 2014). This depression of LTP is not seen in slices from CB1 KO mice. Although this inhibitory effect of anandamide is mediated by CB1, it is still possible that TRPV1, also activated by anandamide, may be involved in LTP modulation, and capsaicin enhances excitatory LTP in the hippocampus (Bennion et al., 2011).

Because eCBs suppress IPSCs at least transiently, and because GABAergic inhibition modulates excitatory LTP in the hippocampus, an opposite scenario is also plausible: eCBs may paradoxically augment LTP induction. Consistent with this, eCB release by rat hippocampal neurons during DSI allows subthreshold trains of EPSCs to induce LTP in individual cells (Carlson, Wang, & Alger, 2002). The enhancement of LTP can be mimicked by facilitation of iLTD. In area CA1, 10 Hz stimulation induces iLTD via CB1, but does not produce excitatory LTD. After 10 Hz stimulation, weak theta burst stimulation can induce excitatory LTP, suggesting an influence of iLTD on theta burst sensitivity (Chevaleyre & Castillo, 2004). Lin et al. (2011) have reported that AM281, a CB1 inhibitor, blocks LTP induction, and this inhibition was not seen in the presence of picrotoxin. These results suggest that CB1 activation participates in LTP induction via a GABA-A receptor mediated mechanism. However, AM404, an anandamide transport inhibitor, failed to alter LTP, suggesting that anandamide is not the eCB involved in LTP induction.

LFS priming prior to repeated HFS inhibits late phase LTP. This inhibition is prevented by AM251, and mimicked by WIN55,212-2, suggesting that CB1 activation is involved in this form of metaplasiticity (Slanina, Roberto, & Schweitzer, 2005).

In the amygdala, capsaicin inhibits LTP by activating both neuronal nitric oxide synthase (NOS) and CB1 (Zschenderlein, Gebhardt, von Bohlen Und Halbach, Kulisch, & Albrecht, 2011). This study suggests that TRPV1 activation alters LTP induction in a complex manner.

Glutamate receptors are not limited to the CNS. Peripheral injection of capsaicin into rat hind instep causes an increase in glutamate levels in the subcutaneal perfusate. This increase is suppressed by MK801, NBQX, or CPCCOEt (Jin et al., 2009), suggesting that three types of glutamate receptors are involved in nociceptive glutamate release triggered by TRPV1.

eCBS AND NMDARs

Effects of NMDARs on eCB Systems

NMDAR activation enhances eCB formation. This enhancement of eCBs synthesis likely involves calcium influx, and perhaps stimulation of PLC and DAG lipase. Intracranial infusion of NMDA in neonatal rats enhances

anandamide concentrations 13-fold, but does not increase 2-AG levels (Hansen et al., 2001). Similarly, mild brain injury increases anandamide levels via NMDAR activation (Hansen et al., 2001). In rat cortical neurons, administration of 300 μM NMDA alone fails to enhance anandamide formation, but increases anandamide levels 10-fold, when administered in combination with carbachol. This effect is also observed with glutamate and carbachol, and is blocked by MK801, an NMDAR antagonist. These observations indicate that enhanced anandamide formation likely involves synergistic activation of nicotinic receptors and NMDARs (Stella & Piomelli, 2001). In the same setting, NMDA also enhances 2-AG formation but the enhancement does not require carbachol (Stella & Piomelli, 2001).

NMDAR activation may not be sufficient for certain forms of LTD, and may require coincidental CB1 activation. In the rat nucleus tractus solitarius, for example, presynaptic LTD resulting from visceral fiber stimulation is induced by coactivation of NMDARs and CB1 (Khlaifia et al., 2013).

NMDARs may be more closely linked to TRPV1 than CB1. Low doses of anandamide have anxiolytic effects via CB1 (Fogaça, Gomes, Moreira, Guimarães, & Aguiarogaça, 2013). However, a high dose of anandamide masks these anxiolytic effects in a capsazepine-sensitive fashion, suggesting that effects of high dose anandamide involve TRPV1. The masking effects are also prevented by an NMDAR antagonist, suggesting that the actions of TRPV1 are mediated by NMDAR activation. It is also possible that TRPV1 activation and NMDAR activation have synergistic effects against the anxiolytic actions. TRPV1 activation not only masks the anxiolytic effects of anandamide, but also induces depressive behaviors in rats (Fogaça et al., 2013), and TRPV1 activation with resiniferatoxin enhances immobility of rats in the forced swim test. This enhanced immobility is blocked by ketamine. Because ketamine antagonizes NMDARs, it is possible that TRPV1-mediated depressive behaviors depend on NMDARs (Abdelhamid, Kovács, Nunez, & Larson, 2014).

NMDAR Actions May be Affected by eCBs

Just as the eCB system can be modified by NMDARs, the effects of NMDARs are modulated by cannabinoids. For example, anandamide inhibits NMDAR-mediated calcium influx in rat brain slices (Hampson et al., 1998), via effects on CB1. This effect suggests that CB1 activation may be neuroprotective against NMDAR-induced toxicity. Indeed, neuronal death in the dentate gyrus by NMDA is ameliorated by NADA, in a fashion that is blocked by AM251 but not by AM630 or 6-iodonordihydrocapsaicin, indicating a role for CB1, but not CB2 or TRPV1 (Grabiec et al., 2012).

Although anandamide inhibits NMDAR-mediated calcium influx via CB1, anandamide paradoxically enhances NMDA-mediated calcium influx when CB1 is blocked by rimonabant (Hampson et al., 1998). This enhancement is not mimicked by THC. A role for TRPV1 was not examined, although NMDAR activation sensitizes TRPV1 via receptor phosphorylation (Lee, Chung, & Ro, 2012). In the retina, neuronal death after intravitreal injections of capsaicin is partially prevented by AP5 (Leonelli, Martins, & Britto, 2013), suggesting not only participation of NMDARs in TRPV1-mediated retinal cell death, but also that NMDAR-mediated neuronal degeneration is partially mediated by TRPV1. However, actions of TRPV1 in the retina are likely complex, and TRPV1 activation can be neuroprotective. Ganglion cell death by intravitreal NMDA injection is completely prevented by capsaicin (Sakamoto et al., 2014). It is important to note, however, that ketamine was used as an anesthetic during NMDA injection, in this study. Because ketamine may alter TRPV1's actions (Abdelhamid et al., 2014), it is possible that the neuroprotective effect of TRPV1 on NMDAR-meditated ganglion cell death involves interactions with ketamine.

Taken together, it seems likely that both CB1 and TRPV1 are involved in NMDAR-mediated neuronal degeneration. Furthermore, cannabinoids can alter NMDAR-mediated actions, and NMDAR activation modulates the effects of eCBs.

CONCLUSIONS

Current evidence suggests that both mGluRs and NMDARs may alter eCB signaling. Synaptic depression is often mediated by eCBs serving as synaptic retrograde messengers at CB1 and other cannabinoid receptors. While it is known that postsynaptic mGluR5 is likely important for eCB formation, the role of NMDARs is less certain. NMDAR activation may have additional effects, including adverse effects on CB1 actions. Some of these NMDAR actions may involve TRPV1.

MINI-DICTIONARY

DSI A transient suppression of inhibitory GABAergic postsynaptic potentials or currents triggered by a depolarizing pulse. DSI may increase the likelihood of LTP induction.
EPSP An electrical response in postsynaptic neurons in response to the release of glutamate. EPSPs stimulate neurons and promote the firing of postsynaptic action potentials.
IPSP An electrical response in postsynaptic neurons following release of GABA at synapses. IPSPs suppress the occurrence of postsynaptic action potentials.
LTP A form of synaptic plasticity in which synaptic function is persistently enhanced. Hippocampal LTP is a cellular model of learning and memory.

LTD A form of synaptic plasticity that leads to persistently diminished synaptic transmission. Hippocampal LTD may play a role in novelty processing.
Metabotropic receptors A class of neurotransmitter receptors that act on second messengers, such as G-proteins, and alter intracellular signaling.
mGluR5 A type of G-protein coupled glutamate receptor. Like mGluR1, mGluR5 activates PLC. Dysfunction of mGluR5 may be involved in neuropsychiatric illnesses, including depression, drug abuse, and Fragile X syndrome.
NMDARs A type of ionotropic glutamate receptor. NMDARs are voltage dependent, and allow calcium influx into neurons. The calcium influx is critical for many forms of synaptic plasticity.
Retrograde messenger A substance released from postsynaptic sites that travels back to reach presynaptic sites, and activate specific receptors. Endocannabinoids serve as retrograde messengers for some forms of synaptic plasticity.
Synaptic plasticity The adaptability of a synapse to activity-dependent changes in strength.

Peripheral CB1 Receptors and Ghrelin in Feeding Regulation: Pharmacological Implications

L. Orio, R. Gómez de Heras, F. Rodríguez de Fonseca

Department of Psychobiology, Faculty of Psychology, Complutense University of Madrid, Pozuelo de Alarcón, Madrid, Spain

SUMMARY POINTS

- Peripheral signals arising from the gut, and metabolically relevant organs, can control appetite and energy expenditure.
- Ghrelin is an orexigenic signal arising from the gut, mainly from the stomach. It stimulates appetite, acting both at peripheral (vagus nerve) and central (hypothalamus) sites.
- In all peripheral organs, the endogenous cannabinoid system contributes to the regulation of both, appetite and energy expenditure, through the regulatory actions exerted by cannabinoid receptors.
- Drugs modulating signals in the periphery are likely devoid of central nervous system-derived side effects. Orexigenic signals, such as ghrelin and endocannabinoids, are being studied for pharmaceutical development.
- Cannabinoid receptor antagonism in the periphery counteracts the orexigenic actions of ghrelin, suggesting that a combinatory therapy targeting both systems might have synergistic effects in controlling appetite in the periphery.

KEY FACTS OF FEEDING REGULATION

- Nutrients and their components released in the blood can regulate appetite and satiety.
- When these nutrients reach the gut (from the stomach to the small intestine), they promote the release of signals that reach the brain centers controlling appetite.
- These signals can be either orexigenic (like ghrelin or anandamide) or anorexigenic (like cholecystokinin or oleoylethanolamide).
- Peripheral signals arising from the gut, and metabolically relevant organs, such as the muscles, the pancreas, the liver, and the adipose tissue can either reach directly the brain or activate the peripheral sensory system.
- In the brain, the main structure that controls appetite and energy expenditure is the hypothalamus.
- The hypothalamus, in association with the autonomic nervous system to which is heavily connected, also communicates to metabolically relevant organs in order to control the onset and termination of feeding behavior.

LIST OF ABBREVIATIONS

2-AG	2-Arachidonoylglycerol
AEA	Anandamide
AgRP	Agouti-related protein
AMPK	AMP-activated protein kinase
BBB	Blood brain barrier
CNS	Central nervous system
ECS	Endocannabinoid system
GH	Growth hormone
GHRH	Growth hormone releasing hormone
GHS-R1a	Growth hormone secretagogue receptor
NPY	Neuropeptide Y
NTS	Nucleus of the tractus solitarius
PNS	Peripheral nervous system
POMC	Proopiomelanocortin
PVN	Paraventricular nucleus

INTRODUCTION: FEEDING REGULATION BY PERIPHERAL SIGNALS

The maintenance of body weight and the control of energy expenditure is a complex function that stands on a bidirectional flow of information between the brain and the body (Gao & Horvath, 2007). The control of feeding behavior, the management of nutrient processing and storage, the delivery of both fuel molecules and structural components to the different tissues of the body, as well as the maintenance of temperature through heat production, are tightly regulated by dozens of different signals that come and go from the body to the brain. On top of that, motivational processes controlled by the monoaminergic network of the reward circuit help to sustain food search and food selection (Dietrich & Horvath, 2009).

Peripheral signals are either nutrients, including bioactive lipids, such as the endocannabinoids, gut peptide hormones, such as ghrelin or glucagon-like peptide-1, pancreatic hormones, such as insulin, or adipocyte-linked signals, such as leptin or adiponectin (Dietrich & Horvath, 2009; Shirazi et al., 2013). These signaling molecules can either reach directly the brain or activate the peripheral sensory system. In turn, the brain can directly deliver controlling commands to metabolically relevant organs, through the autonomic nervous system (Gao & Horvath, 2007; Merchenthaler, 1991). Because most functions related to body weight and energy expenditure oscillate around homeostatic set points, these signals can be divided on the basis of the direction of the modulatory activity (either activation or inhibition) that they exert.

In the brain, the main structure that controls appetite and energy expenditure is the hypothalamus, in association with the autonomic nervous system to which it is heavily connected (Dietrich & Horvath, 2009; Diéguez, Vazquez, Romero, López, & Nogueiras, 2011). In the ventral hypothalamus, several neuronal groups, especially those from the arcuate nucleus, control the onset and termination of feeding behavior, thanks to the ability to detect these peripheral signals that reach the hypothalamus through the blood. These arcuate neurons are basically distributed into two majors groups, one expressing the neuropeptide Y (NPY), together with agouti-related protein (AgRP), and the other one expressing the opioid gene proopiomelanocortin (POMC), in association with the neuropeptide cocaine, and amphetamine-related transcript, CART. While NPY neurons stimulate appetite, POMC neurons inhibit it. Both NPY/AgRP and POMC/CART neurons are activated by peripheral signals, thanks to the convergent mechanisms on lipid metabolism-regulatory proteins, including the AMP-activated protein kinase, AMPK. These neurons have the ability to reprogram their metabolic substrate utilization away from glycolysis, and toward lipid oxidation, depending first on substrate availability, and second on AMPK activity. AMPK is regulated both by metabolic status and incoming signals and, ultimately, it will regulate the production of orexigenic NPY or anorexigenic POMC. While fasting, endocannabinoids, glucocorticoids, adiponectin, ghrelin, or AgRP activates AMPK, thus promoting feeding, signals, such as leptin, refeeding, insulin, GLP-1, or melanocortin receptor agonists that reduce AMPK activity, resulting in feeding inhibition. Nutrients, such as glucose, citrate, lactate, or alpha-lipoic acid can also modulate AMPK activity and feeding (Gao & Horvath, 2007; Diéguez et al., 2011).

Although this simple mechanism allows to start and stop feeding behavior, additional mechanisms centered in the motivational properties of food are also working in parallel to ensure a correct associative learning (ie, to learn caloric value, organoleptic properties, and adequacy of nutrients), and to provide reinforcing signals that help to organize food choice and meal patterns, whose temporal organization is further arranged by the internal clocks located in the suprachiasmatic nuclei of the hypothalamus. A relevant role for dopaminergic and serotonergic neurons in organizing these aspects of feeding behavior has been clearly determined (Abizaid et al., 2006; Dietrich & Horvath, 2009; Gao & Horvath, 2007).

The existence of these well-identified brain networks that control appetite and energy expenditure led to the development of therapies based on drugs capable to interfere with those central mechanisms (Dietrich & Horvath, 2012). Although being effective in preclinical models, and being apparently safe in early phases of clinical trials, these therapies were either not sufficiently safe, after extensive phase III studies, or withdrawn from

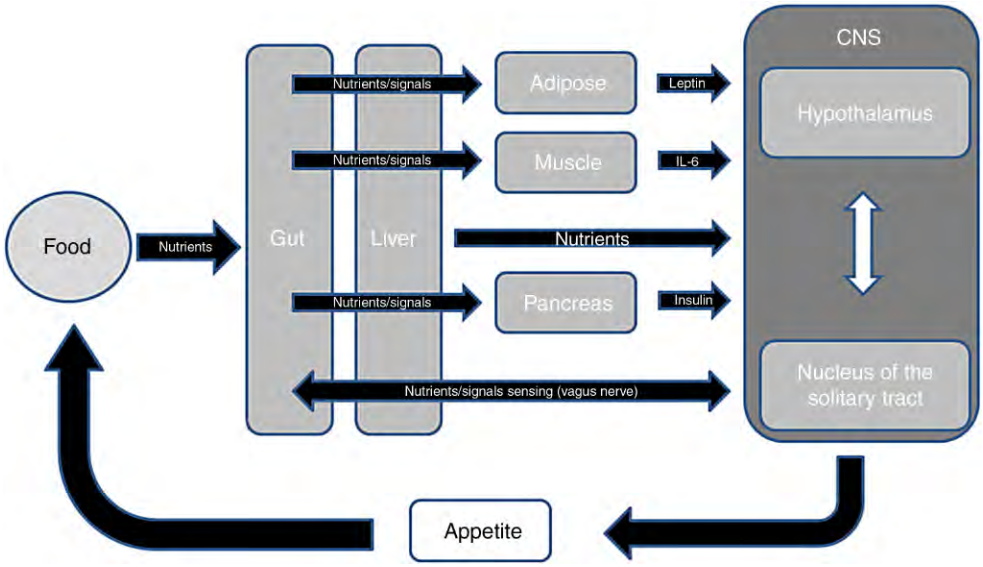

FIGURE 66.1 **Peripheral control of appetite through nutrients/blood-borne signals.** Peripheral control of appetite. Nutrients arriving to the gut elicit multiple signals (peptides, lipids) that, by direct access through the blood stream, by modulation of vagal afferents, or through their action on peripheral organs, such as the adipose tissue, the endocrine pancreas, or the muscles, modulate the activity of CNS nuclei involved in appetite control. In addition, these peripheral organs send additional signals (adipokines such as leptin, myokines, such as IL-6, or pancreatic hormones, such as insulin), that contribute to inform the brain on the metabolic status of the body, and the availability of nutrients.

the market because of unwanted side effects, especially of cardiovascular or psychiatric nature.

Because the control of appetite and energy expenditure is an unmet medical need, a considerable effort has been placed on the development of alternative therapies that avoid the unwanted central effects. A new strategy for treating obesity has been centered in understanding and controlling the actions of orexigenic/anorexigenic signals arising from the peripheral tissues, trying to moderate or even reverse the brain-oriented information that the metabolically relevant signals send from the gut, the adipose tissue, the liver, the pancreas, or the muscles.

As depicted in Fig. 66.1, upon the arrival of nutrients to the gut, a complex set of signals starts to emerge from the different sections of the gut, including mouth, stomach, and intestine. This information is derived from the direct effect of nutrients on sensors located along the different portions of the gut (Ariyasu et al., 2001; Gao & Horvath, 2007; Langhans, Leitner, & Arnold, 2011). In addition, the nutrients that reach the blood are delivered to metabolically relevant organs, where secondary signals help to orchestrate the adaptation to meals, or the response to fasting, in case there were long periods without food availability (Ellingsgaard et al., 2011). All these primary and secondary signals, together with specific nutrients (ie, glucose, aminoacids, fatty acids, such as lipoic acid) are either delivered to the hypothalamus or directly to the sensory terminals of the vagus nerve, that will inform, via the nucleus of the solitary tract, the hypothalamic network (Berthoud, 2008; Dietrich & Horvath, 2009). Because these signals can be either orexigenic or anorexigenic, it is reasonable to think that targeting this activity on the peripheral sites of origin may affect feeding behavior, without producing the unwanted adverse effects observed when brain target-designed drugs were used.

Among these signals, a special attention has been put on both the endocannabinoids and the stomach peptide ghrelin. In the present chapter, we review the interactions of endocannabinoids and ghrelin, both at peripheral and central levels, to control appetite. Combinatorial therapies aimed to antagonize these orexigenic signals might offer alternative approaches devoid of the unwanted side effects of classical central targets (Dietrich & Horvath, 2012).

THE PERIPHERAL ENDOCANNABINOID SYSTEM AND FEEDING REGULATION

The endocannabinoid system (ECS) is composed of a number of endogenous ligands synthesized from membrane phospholipids, mainly anandamide (AEA) and 2-arachidonoylglycerol (2-AG), the corresponding G protein coupled cannabinoid receptors CB1 and CB2, and a large number of enzymes involved in synthesis and degradation. The ECS is widely expressed throughout the body, especially in areas responsible for regulating the homeostatic control (Pagotto, Marsicano, Cota, Lutz, & Pasquali, 2006), helping to keep the tone of response to the requirements of the environment.

The CB1 receptor was originally described as brain receptor because of its wide expression in this organ. These receptors are located in brain areas that play a critical role in the homeostatic regulation of food intake, such as the hypothalamus, brainstem, and mesocorticolimbic system. Presently, we know that CB1 receptors are also expressed in peripheral organs, especially in those related to metabolic control. By contrast, CB2 receptor shows a more restricted distribution, and is mainly present in the immune system, although its presence in the gut and metabolically relevant tissues is documented (Bermúdez-Silva et al., 2008; Piomelli, 2003).

Activation of the ECS induces a large number of physiological responses in the main organs responsible for the regulation of food intake and metabolism, due to the coexistence of ECS in all signaling that regulates central and peripheral control of feeding. The central control of food intake is governed mainly by the hypothalamus, as a structure that receives sympathetic efferent inputs and peripheral hormones (leptin, CCK, ghrelin, GLP-1, glucocorticoids) reporting on the peripheral energy status. Peripheral response also depends on the different hormonal signals and sympathetic efferents. CB receptors are expressed widely in the hypothalamus, the reward system, the brainstem, the nucleus of the tractus solitarius (NTS), and other brain structures involved in feeding.

Increasing evidence indicates that the PNS (both sympathetic efferent branches and parasympathetic vagal afferents) mediates, through the engagement of the ECS, the crosstalk between the CNS and peripheral organs (Fig. 66.2). Endocannabinoids induce overfeeding, delaying the natural satiety induced by the arrival of food at the gut (Kirkham, Williams, Fezza, & Di Marzo, 2002). This effect is elicited by activation of CB1 receptors located in hypothalamic brain areas involved in appetite regulation. However, the peripheral ECS appears to contribute in a significant way to the regulation of feeding behavior. Intestinal AEA levels increase during fasting, and are abrogated by refeeding. Interestingly, the peripheral but not central administration of either anandamide or the synthetic agonist WIN 55,212-2 produce hyperphagia in rats partially satiated, and this effect disappears after vagotomy, indicating that cannabinoids promote food intake beyond the restricted hypothalamic control of the hunger and satiety mechanism (Gomez et al., 2002). Therefore, the administration of CB1 receptor antagonists has suppressive effect on feeding, as a result of the decline of endogenous cannabinoid tone. This reasoning was the basis of the development of clinical trials and the approval of the CB1 receptor antagonist rimonabant for the treatment of obesity, although its central effects generated adverse reactions that eventually led to its withdrawal from the market.

It is important to stress that the effects of pharmacological blockade of CB1 receptors on food intake and body weight are not due exclusively to a central hypothalamic and mesolimbic action. When the administration of the CB1 receptor antagonist, rimonabant, has no restriction effect on feeding by the development of tolerance to the drug, the rats still keep losing weight for 2 weeks (Colombo et al., 1998). Clinical studies have replicated these findings with alternative CB1 antagonists (Addy et al., 2008). All these data show that changes in the regulation of ECS produce a variety of central and peripheral metabolic actions that may be independent of food intake, and that are directly involved in the regulation of lipid and carbohydrate metabolism.

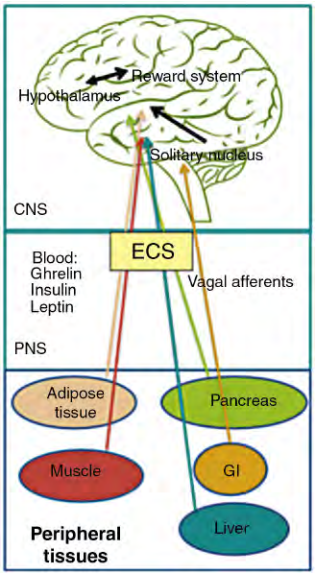

FIGURE 66.2 Schematic representation of the involvement of the endocannabinoid system in the peripheral and central regulation of food intake. The *arrows* represent connections between CNS and peripheral tissues, mediated by endocrine and the PN systems. In all these connections, the ECS plays a fundamental role based on the presence of CB receptors and their endogenous ligands. *CNS*, Central nervous system; *ECS*, endocannabinoid system; *GI*, gastrointestinal system; *PNS*, peripheral nervous system.

As mentioned before, CB1 receptors are extensively expressed in peripheral organs. In the gut, CB1 receptors are at even higher concentrations than in the brain, and they control intestinal motility, facilitate the inhibition of gastric emptying, and regulate from a distance the gustatory neural activity elicited by the sweet taste. This sensorial signal reaches the brain via the vagus nerve (cranial nerve X), which contains branches that communicate efferent and afferent food-related signals between brain and gut. In the adipose tissue, CB1 receptor stimulation facilitates fatty acid accumulation, and an increase in lipoprotein lipase activity, is reversed by CB1 antagonism (Cota et al., 2003). There is also an overexpression of CB1 receptors in adipocytes of obese rats. CB1 activation promotes neolipogenesis in the liver, the release of insulin by the pancreas, or a decrease of

glucose uptake induced by insulin in the skeletal muscle. In general, activation of the ECS occurs in the periphery, in situations where an energy deficit happens in order to activate a set of responses designed to obtain energy storage (Bermúdez-Silva et al., 2008).

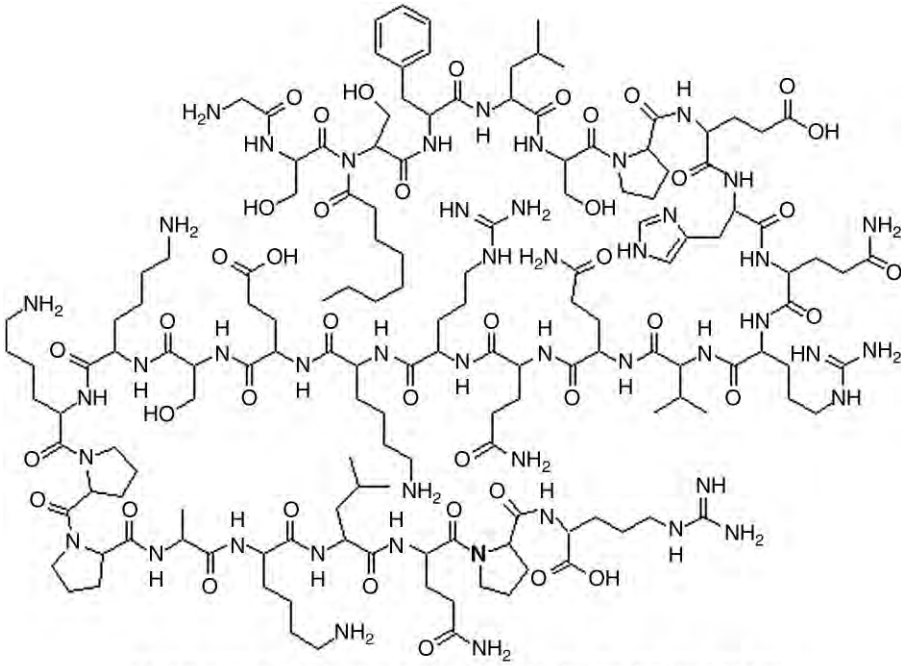
In conclusion, the ECS is expressed in all structures related to feeding, both in the central and peripheral nervous system. Peripheral organs contain their own ECS machinery which modulates its physiology. In general, cannabinoid activity exerts an anabolic effect that, on one hand, promotes food intake and, on the other hand, reduces intestinal and gastric motility, gastric acid secretion, vomiting and nausea, is antidiarrheal, and generates a prolipogenic action. In contrast, agents that block the CB1 receptors (antagonists) cause the opposite effects. All this activity makes the ECS an attractive and potentially effective multidrug target for many diseases involving the gut, the liver, and the control of metabolism and energy expenditure, such as obesity, diabetes, and appetite-related syndromes.

GHRELIN AND INTEGRATIVE SIGNALS FOR APPETITE

One of the peripheral signals that target the brain in order to control our feeding behavior is the hormone ghrelin (Fig. 66.3). Ghrelin is the only peripheral peptide hormone known to date which has orexigenic function, acting in a similar way than anandamide, as described earlier. The major source of ghrelin production is the stomach. Small quantities of ghrelin are also synthesized in other peripheral organs, such as the lower parts of the gastrointestinal tract, the pancreas or thymus, and in the brain, although the major contribution to circulating ghrelin levels appears to come from the stomach (Kojima et al., 1999; Ariyasu et al., 2001).

Levels of circulating ghrelin increase during fasting, and decrease immediately after food ingestion, which suggests that ghrelin may participate in meal initiation (Cummings et al., 2001). Conversely, a drop in circulating ghrelin levels is understood by the brain as a satiety signal. Ghrelin has also a role in the long-term control of body energy homeostasis by suppressing fat utilization, reducing energy expenditure, or promoting gluconeogenesis and adipose tissue deposition. The body mass index of one individual is negatively correlated with ghrelin levels. Indeed, levels of ghrelin are reduced in obese individuals and, conversely, increased in lean subjects, including anorectic patients.

Peripherally-produced ghrelin targets the CNS, specifically hypothalamic areas related to appetite regulation, via the vagus nerve, in order to transmit the hunger signal. Ghrelin may also cross the blood brain barrier (BBB), or reach the brain though circumventricular organs (BBB open areas) surrounding the hypothalamus (Banks, Tschop, Robinson, & Heiman, 2002; Merchenthaler, 1991). Ghrelin was originally found to



Gly-Ser-Ser(octanoyl)-Phe-Leu-Ser-Pro-Glu-His-Gln-Arg-Val-Gln-Gln-Arg-Lys-Glu-Ser-Lys-Lys-Pro-Pro-Ala-Lys-Leu-Gln-Pro-Arg-OH

FIGURE 66.3 **Chemical structure of human ghrelin.** The chemical structure of human ghrelin is represented in the figure. Molecular formula: $C_{149}H_{249}N_{47}O_{42}$. *Source: Reproduced with permission from http://www.chemblink.com/*

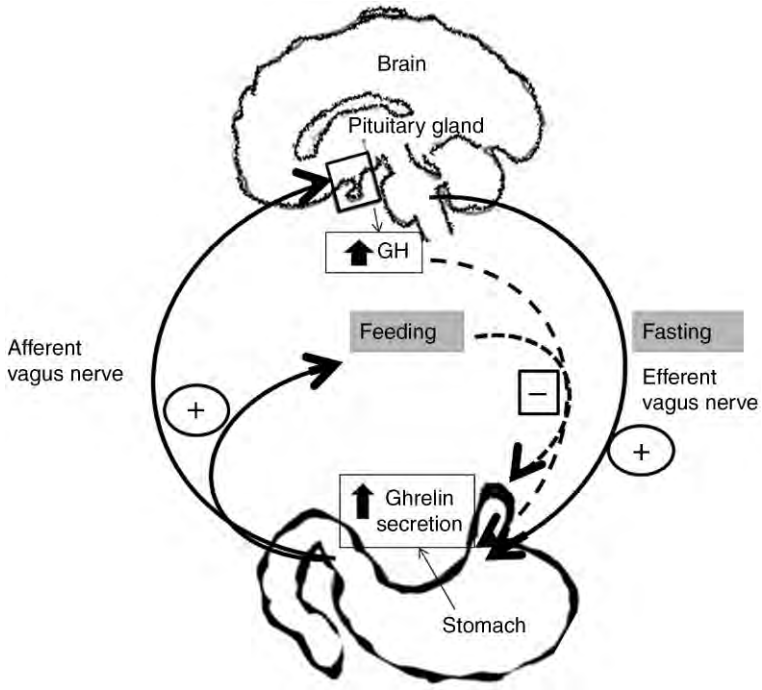


FIGURE 66.4 **Role of the vagus nerve in ghrelin actions and level regulation.** Ghrelin is mainly produced by the stomach, and released in the blood. Circulating ghrelin is increased during fasting, and decreased after feeding. The afferent vagus nerve contains ghrelin receptors that transmit ghrelin signal from the stomach to the hypothalamus, where the centers of appetite are located. Vagotomy eliminates both the ability of ghrelin to stimulate feeding, and GH release from the pituitary gland. The efferent vagus nerve has a role in increasing ghrelin secretion by the stomach, in fasting conditions, but it is not involved in the suppression of ghrelin levels after feeding. This is supported by the observation that vagotomy suppresses the increase in ghrelin production induced by food deprivation, but not baseline blood levels or reduction of ghrelin levels by nutrient infusion. Pituitary GH inhibits ghrelin secretion by the stomach as a feedback mechanism. *GH*, Growth hormone; continuous line and (+), means activation; discontinuous line and (–), means inhibition.

stimulate the release of growth hormone (GH) by binding to growth hormone secretagogue receptor (GHS-R1a) (Kojima et al., 1999). There is a regulatory system that controls GH and ghrelin: while ghrelin stimulates the release of GH from the pituitary, GH decreases ghrelin synthesis by the stomach as a feedback mechanism. The efferent vagus nerve contributes to ghrelin secretion by the stomach in fasting conditions, since vagotomy completely prevents fasting-induced ghrelin increase (Williams, Grill, Cummings, & Kaplan, 2003). Basal levels of ghrelin are not affected by vagotomy (Fig. 66.4).

Ghrelin receptors are located in hypothalamic areas that control appetite, such as the arcuate nucleus or the paraventricular nucleus, but also in the vagal nodose ganglia and the gastrointestinal tract, and their stimulation, as mentioned before, increases food consumption, reduces energy expenditure, and has adipogenic actions (Burdyga, Varro, Dimaline, Thompson, & Dockray, 2006; Guan et al., 1997; Kojima et al., 1999). Ghrelin receptors located in the nodose ganglia of the vagus nerve might be responsible of transmission of ghrelin signal from the stomach to the brain. Both peripheral and central administration of ghrelin increase feeding (Wren et al., 2000), and, inversely, blockade of GHS-R1a reduces food intake (Salome et al., 2009). The availability of nutrients in the gastrointestinal tract (but not its biodisponibility in blood) regulates the release of ghrelin. For example, glucose suppresses ghrelin levels (Overduin, Frayo, Grill, Kaplan, & Cummings, 2005), and interestingly, ghrelin may maintain circulating glucose levels (via GH release) during extreme fasting conditions (Zhao et al., 2010).

At a central level, ghrelin receptors located in NPY/AGPR-expressing neurons in the hypothalamus appear to be responsible of the orexigenic effect of this hormone. Ghrelin may also modulate feeding behavior by affecting the corticostriatal-limbic circuitry related to motivational behavior and reward, with the ventral hippocampus (Kanoski, Fortin, Ricks, & Grill, 2013), amygdala (Alvarez-Crespo et al., 2012), and ventral tegmental area (Abizaid et al., 2006) as the main neurobiological targets for these effects.

INTERACTIONS BETWEEN GHRELIN AND PERIPHERAL CB1 RECEPTORS IN FEEDING REGULATION

As mentioned before, both endocannabinoids (through CB1 receptors) and ghrelin modulate feeding behavior potently. There is a functional interaction between both

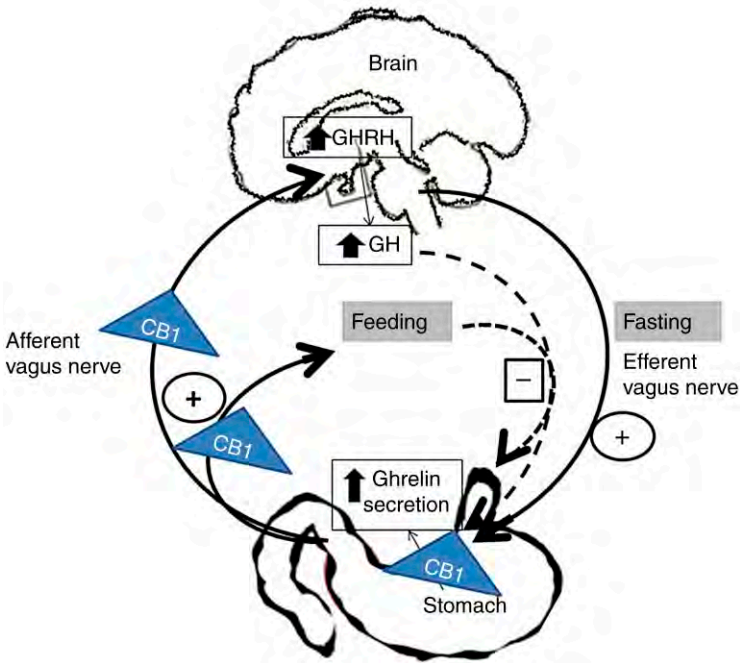

FIGURE 66.5 **Role of peripheral CB1 receptors in the release and activity of ghrelin.** Peripheral CB1 receptors located in the neuroendocrine cells of the stomach modulate gastric ghrelin secretion. CB1 receptors located in the afferent branch of the vagus nerve influence ghrelin-induced feeding, hypothalamic GHRH expression, and pituitary GH release. *GHRH*, Growth hormone releasing hormone; *GH*, growth hormone.

systems that has been described in vivo, although the specific site of such interaction is still not clear. The metabolic status influences both the endocannabinoid system and ghrelin. For example, food restriction increases endocannabinoid levels in the brain (Kirkham et al., 2002), modulates vagal CB1 receptor expression (Burdyga et al., 2006), and influences ghrelin circulating levels. It has been described that the orexigenic effects of ghrelin require the existence of functional CB1 receptors (Kola et al., 2008; Tucci, Rogers, Korbonits, & Kirkham, 2004) and, inversely, endocannabinoid-induced activation of the energy homeostasis regulator AMPK requires GHS-R1 mediated ghrelin signaling in hypothalamus, liver, and adipose tissue (Lim et al., 2013).

The interplay between CB1 receptors and ghrelin has been proposed to take place at central or peripheral levels. Ghrelin increases the endocannabinoid content in the hypothalamus, and a CB1 pharmacological blockade inhibits ghrelin hyperphagic activity in the PVN (Tucci et al., 2004). Additionally, genetic ablation of CB1 receptors abolishes ghrelin's orexigenic effects (Kola et al., 2008). Recently, it has been proposed that central CB1 receptors may simultaneously stimulate or inhibit food intake, depending on the neural circuits activated (Bellocchio et al., 2010). Although the widely assumed role for endocannabinoids is to increase appetite, endocannabinoids may also induce hypophagia, under stimulated conditions, by acting in the PVN. Interestingly, ghrelin influences the neuronal activity in the PVN, and might determine the positive or negative effects of CB1 receptors in feeding (Soria-Gómez, Bellocchio, & Marsicano, 2014).

Peripheral CB1 receptors may also interplay with ghrelin, in the control of food intake (Fig. 66.5). Several studies support a crosstalk between peripheral CB1 receptors and ghrelin, in appetite. Firstly, gastric CB1 receptors modulate the secretion of ghrelin by the stomach (Senin et al., 2013). Secondly, peripheral CB1 receptors located in the vagus nerve influence central ghrelin activity. The vagus nerve has a dominant role in the transmission of the hunger signal induced by endocannabinoids and ghrelin to hypothalamic areas and, ultimately, in the regulation of energy balance. The nodose ganglia (inferior ganglion of vagus nerve) coexpress CB1 and GHS-R1 receptors (Burdyga et al., 2006; Date et al., 2005). Food administration induces a downregulation of CB1 receptors in the human nodose ganglia, prevented by ghrelin administration (Burdyga et al., 2006). Al-Massadi et al. (2010) showed that systemic administration of a CB1 antagonist decreases ghrelin-induced release of GH and hypothalamic growth hormone releasing hormone (GHRH) mRNA expression. Surgical vagotomy or central CB1 antagonist administration abolishes this effect. According to this, peripheral CB1 receptors located in the vagus nerve afferent branch facilitate the hypothalamic release of GHRH, and posterior ghrelin-mediated release of GH by the pituitary gland, which is implicated in energy homeostasis (Al-Massadi et al., 2010). Interestingly, peripheral CB1 receptors may also mediate ghrelin-induced hyperphagia, since an ultra-low dose of a CB1

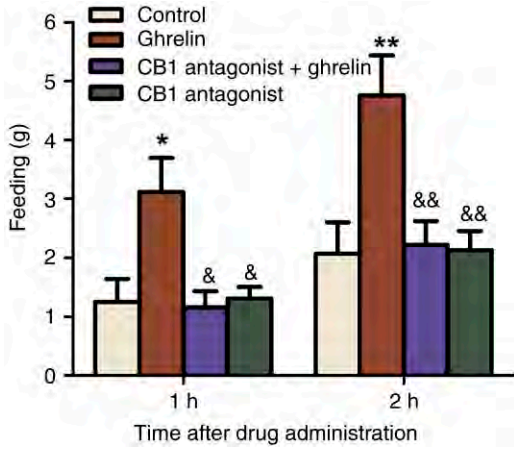

FIGURE 66.6 Peripherally restricted CB1 antagonist (LH-21) counteracts ghrelin-induced hyperphagia in free feeding rats. Intracerebroventricular administration of ghrelin induces an increase in food intake in animals with free access to food. Pretreatment with the compound LH-21, a CB1 antagonist that does not cross the BBB, reduces ghrelin-induced orexigenic effect, with no effect in control animals. *, Statistically different from control group; &, statistically different from ghrelin-treated group. *Source: Modified from data in Alen et al. (2013) (with permission of PLoS One).*

antagonist (that is not centrally active) or a peripherally-restricted CB1 antagonist inhibit the orexigenic effect of ghrelin under balanced energy balance conditions (Alen et al., 2013; Fig. 66.6).

As a conclusion, while targeting CB1 receptors to fight against obesity would be an appropriate pharmacological alternative, the associated central side effects have to be considered. CB1 antagonist-based pharmacotherapies are efficient in reducing body weight and improving metabolic parameters (Pagotto et al., 2006), but they induce undesirable relevant side effects in the CNS, such as depression, anxiety, and even suicidal ideas (Christensen, Kristensen, Bartels, Bliddal, & Astrup, 2007). Because of the psychiatric collateral side effects, CB1 antagonists are no longer allowed as a pharmacotherapy for obesity. In this context, targeting CB1 receptors outside of the blood brain barrier emerges as an attractive alternative to treat obesity, since peripheral restricted CB1 antagonists maintain the benefits on energy homeostasis regulation, avoiding undesirable psychiatric effects. Interestingly, the association of a peripheral cannabinoid CB1 receptor antagonist with a drug targeting additional peripheral signals that regulate feeding offers unexplored alternatives that might lead to safer but effective therapies. In the present review, the identification of ghrelin as a signal that might be counteracted by cannabinoid receptor antagonists indicates that a potential association of these peripheral cannabinoid receptor antagonists with a ghrelin antagonist might have synergistic effects as feeding inhibitors. Other gut peptide that can be considered for this strategy is cholecystokinin (Orio et al., 2011), although the multiplicity of gut peptides controlling appetite and metabolism opens additional possibilities. In addition, other endocannabinoid-like substances that target noncannabinoid receptors may have a beneficial profile to control obesity, when combined with peripheral ghrelin antagonists. For example, oleoylethanolamide (OEA) is a fatty acid ethanolamide that does not bind CB1 receptors, and is emerging as a good candidate to treat obesity, due to the metabolic benefits and its ability to control peptides regulating food intake, including ghrelin (Cani, Montoya, Neyrinck, Delzenne, & Lambert, 2004; Serrano et al., 2008, 2011). A whole research area on combinatorial therapies based in these peripheral signals demands to be considered for future studies.

MINI-DICTIONARY

Combinational therapy A therapy where several targets, usually two, are being modulated by the concurrent administration of several drugs. A combinational therapy searches for synergistic effects. A combinational therapy might reduce unwanted effects without a loss of effectiveness.

Endocannabinoid system A lipid signaling system which includes the cannabinoid receptors, the endogenous lipid ligands (endocannabinoids), and the enzymatic machinery for their synthesis and inactivation. This system regulates a wide range of biological functions, including nociception, motor activity, cognitive and emotional processes, immune function, and energy balance.

Endocannabinoids Family of biologically active lipids that bind to CB1 and CB2 receptors. They include several derivatives of arachidonic acid, generated on demand by neurons and other cells, in response to physiological or pathological stimuli. The two best characterized endocannabinoids are 2-arachidonoyl-*sn*-glycerol (2-AG) and anandamide (AEA).

Ghrelin Peptidic hormone released mainly by endocrine cells of the stomach; it has orexigenic functions. There are receptors for ghrelin in the hypothalamus.

Hypothalamus Brain area located in the diencephalon which integrates central neuropeptides and peripheral hormones involved in feeding and energy homeostasis.

Nodose ganglia Collection of sensorial neurons located in the caudal part of the vagus nerve.

Vagotomy The surgical cutting of the vagus nerve. In research, it is used as strategy to examine the peripheral versus central actions of compounds (such as ghrelin).

Vagus nerve The tenth pair and largest cranial nerve which sends to the brain afferent visceral information related to feeding. It is a mixed nerve, since it also conveys parasympathetic efferents from the brain to the thoracic and abdominal cavities.

CHAPTER

67

Pharmacological Aspects of Novel Antiobesity Agents Related to Cannabinoids

L. Hernandez-Folgado

Institute of Medicinal Chemistry, CSIC, Madrid, Spain

SUMMARY POINTS

- Obesity appears to be associated with a dysregulated and hyperactive endocannabinoid system, in rodents and humans.
- Animal studies and clinical trials have shown that blockade of CB1 cannabinoid receptor induces weight loss, improves cardiometabolic risk factors, and insulin resistance, and causes metabolic benefits in mammals, so blockade of this receptor is considered a challenged strategy in obesity.
- Since rimonabant was withdrawn in 2009, weight-loss strategies were aimed to design and prepare CB1 neutral antagonists, acting either centrally or peripherally, or CB1 inverse agonists acting only at a peripheral level.
- CB1 neutral antagonists and CB1 inverse agonists structurally related to rimonabant, such as AM6545, LH21, NESS038C6, otenabant, and so on, have been reported.
- In addition, novel cannabinoid targets to develop antiobesity drugs, such as CB2 cannabinoid receptor, the putative cannabinoid GPR55 receptor, and 2-monoacylglycerol lipase, are being taken into account.

KEY FACTS OF OBESITY

- Overweight and obesity are defined as abnormal or excessive fat accumulation that may impair health.
- Obesity is one of the greatest public health challenges of the 21st century.
- Its prevalence has tripled in many countries of the WHO European Region since the 1980s, and the numbers of those affected continue to rise at an alarming rate.
- More than 40 million children under the age of five were overweight in 2011.
- Current treatment for obese patients is based on diet and practicing exercise, combined with pharmacotherapy.

WHO	World Health Organization

OBESITY AND WEIGHT-LOSS DRUGS

The global epidemic of overweight and obesity—"globesity"—is rapidly becoming a major public health problem in many parts of the world. According to the WHO (http://www.who.int/mediacentre/factsheets/fs311/en/), obesity is one of the greatest public health challenges of the 21st century. Its prevalence has tripled in many countries of the WHO European Region since the 1980s, and the numbers of those affected continue to rise at an alarming rate.

Obesity is a complex metabolic disorder characterized by an imbalance in energy homeostasis, abnormal increase of adipose tissue, and dysregulation of hormones, cytokines, and other important signaling systems. The increasing prevalence of overweight and obesity is associated with many diet-related chronic diseases, including diabetes mellitus, hepatic steatosis, cardiovascular risk, sleep apnea, stroke, hypertension, and certain cancers.

Current treatment for overweight or obese patients is based on diet and practicing exercise, combined with pharmacotherapy (Table 67.1). In the extreme cases of morbid obesity (BMI > 40), gastric bypass surgery is also considered. A successful weight-loss drug should reduce energy intake and/or increase energy expenditure, without adverse side effects. However, most of the antiobesity drugs commercialized in the last 20 years were withdrawn due to their severe side effects (Adan, 2013). Phentermine, an amphetamine, was combined with fenfluramine in FenPhen. This successful drug was withdrawn because it often induced pulmonary hypertension. Sibutramine, a noradrenalin and serotonin reuptake inhibitor, was withdrawn in 2010 because of cardiovascular side effects, which resulted in increased heart attacks and strokes.

Orlistat is currently the only widely available monotherapy for a long-term treatment of obesity. It is a gastric and pancreatic lipase inhibitor that has poor compliance because of its side effects (eg, fecal incontinence, oily stools). Lorcaserin and Qsymia are novel additions to the limited repertoire of antiobesity drugs. Lorcaserin, a serotonin (5-HT2c) agonist, is not free of side effects such as headache, dizziness, and nausea. Whereas the anticonvulsant topiramate as monotherapy results in 6–7% more body weight loss compared to placebo, when it is combined with phentermine (in Qsymia), it has an efficacy of 9–10% more body weight-loss, compared to placebo, after 1 year of treatment. This combination has a noradrenalin releaser-anticonvulsant mechanism of action, and little is known about where and how it works. It has considerable side effects, which are mainly related to brain function, and even possible teratogenic effects.

Two upcoming drugs are being under clinical trials: one is Contrave, a combination of bupropion (noradrenalin/dopamine reuptake inhibitor) and naltrexone (opioid receptor antagonist), with nausea its most common side effect; and Tesofensine, a serotonin/noradrenalin/dopamine reuptake inhibitor which shows depressed mood and cardiovascular side effects.

As shown earlier, targeting monoaminergic systems (serotoninergic, noradrenergic, and dopaminergic) was the main approach to develop antiobesity drugs. But, in the 1990s, the endocannabinoid system was found

TABLE 67.1 Past and Current Antiobesity Drugs

Drug	Approval	Efficacy	Remarks
FenPhen	In the 1990s	Up to 10% body weight loss	Withdrawn
Sibutramine	In the late 1990s	Loss of 4–5 kg over 1 year	Withdrawn in 2010
Rimonabant	2006 (Europe)	Decrease in body weight and waist circumference	Withdrawn in 2009
Orlistat	1998	Loss of 2–3 kg over 1 year	Only monotherapy for a long-term treatment
Lorcaserin	2012	3–4% weight loss over 1 year	—
Qsymia	2012	9–10% weight loss over 1 year	—
Contrave	In clinical trials	4–5% weight loss over 1 year	Declined in 2011 and refiled
Tesofensine	In Phase III	—	—

Data of antiobesity drugs that were withdrawn, are currently available, or are in advanced clinical trials.

to be involved in food intake and energy homeostasis, so it was considered a promising target for weight-loss drugs.

ENDOCANNABINOID SYSTEM AND OBESITY

Obesity appears to be associated with a dysregulated and hyperactive endocannaboboid system (ECS), in rodents and humans. There is an increase in circulating endocannabinoid levels and altered expression of the components of this system, in cerebral areas such as hypothalamus, hindbrain, and limbic areas, but also in peripheral organs, including adipose tissue, liver, and pancreas.

The widespread presence of the ECS indicates its physiological relevance in the regulation of a variety of biological processes. In the last years, there has been substantial interest in investigating the role of endocannabinoid signaling in the regulation of metabolism and energy homeostasis, mainly due to the abundance of cannabinoid receptor type 1 (CB1) expression in brain regions and peripheral tissues involved in the control of feeding behavior and energy balance (Serrano et al., 2012). CB1 receptors, as well as endocannabinoid producing machinery, have been described in the gut, liver, muscle, endocrine pancreas, and white adipose tissue (WAT). In this regard, animal studies and clinical trials have shown that blockade of CB1 receptor induces weight loss, improves cardiometabolic risk factors and insulin resistance, and causes metabolic benefits in mammals. Therefore, all these data have emphasized the potential of CB1 receptor blockade as a therapeutic strategy in obesity.

Consequently, rimonabant (trade name Acomplia), an inverse agonist at the cannabinoid CB1 receptor acting mainly at the central nervous system (CNS), was developed by Sanofi-Aventis in the 1990s (Rinaldi-Carmona et al., 1994). It was approved by the European Medicines Agency (EMA) and introduced in Europe in 2006 (Table 67.1). Rimonabant, when combined with a hypocaloric diet over 1–2 years, can promote a clinically significant decrease in body weight and waist circumference, an increase in HDL cholesterol, a reduction in triglycerides, and an improvement of cardiovascular risk factors (Pi-Sunyer, Aronne, Heshmati, Devin, & Rosenstock, 2006). Due to its central action, adverse events of severe depression and suicidal thoughts were frequently reported with its use. Therefore, it was withdrawn in 2009 by the European Regulatory Authorities.

It was clear that peripheral blockade of CB1 receptors may induce metabolic advantages for complicated obesity. However, a major goal was to avoid the unwanted central effects. Thus, alternative approaches were searched for blocking CB1 receptors preventing the side effects of rimonabant. One option was to design and prepare CB1 neutral antagonists, acting either centrally or peripherally, or CB1 inverse agonists acting only at a peripheral level; and another option was to develop dual ligands or combinatorial therapies that exploit synergies between CB1 antagonists/inverse agonists and additional targets, by enhancing thermogenesis and blocking lipid mobilization (Fernández-Fernández et al., 2013). Regarding the first option, in the literature, there is a controversy about whether CB1 receptor blocking at only peripheral level achieves the same effects on feeding behavior than at both central and peripheral levels at the same time. Moreover, some authors suggest that, among peripherally restricted compounds, CB1 inverse agonists may offer distinct advantages over neutral antagonists; particularly as far as weight reduction and insulin sensitization are concerned. Meanwhile, other authors demonstrate that a CB1 neutral antagonist, which leaves the constitutive CB1 activity intact is just as efficient in reducing weight gain as a CB1 inverse agonist, but lacks potentially harmful effects on anxiety and motivation.

To further deepen in these issues, the following sections cover the main results reported from 2010 to the beginning of 2014 about developing novel antiobesity agents related to cannabinoids.

ANTIOBESITY DRUGS STRUCTURALLY RELATED TO RIMONABANT

As it was already mentioned, rimonabant, a diarylpyrazole derivative (Fig. 67.1), was the first selective CB1 inverse agonist to be reported (Rinaldi-Carmona et al., 1994). It is a very useful pharmacological tool, being to date the CB1 inverse agonist of reference in most of the preclinical in vitro and in vivo assays. Even after its withdrawal from the European market, many structural analogs have been evaluated in feeding behavior. They are being synthesized and characterized to prevent adverse effects observed with rimonabant while maintaining antiobesity properties.

In this section, the design, molecular structure, and pharmacology of these so-called second generation CB1 antagonists/inverse agonists will be described.

CB1 Antagonists

One of the most interesting compound is AM6545 (Fig. 67.1), a neutral CB1 antagonist with relatively poor penetrability into the brain (Cluny et al., 2010). This drug reduces food intake in animals fed high-fat and high-carbohydrate diets, but it is less effective in reducing

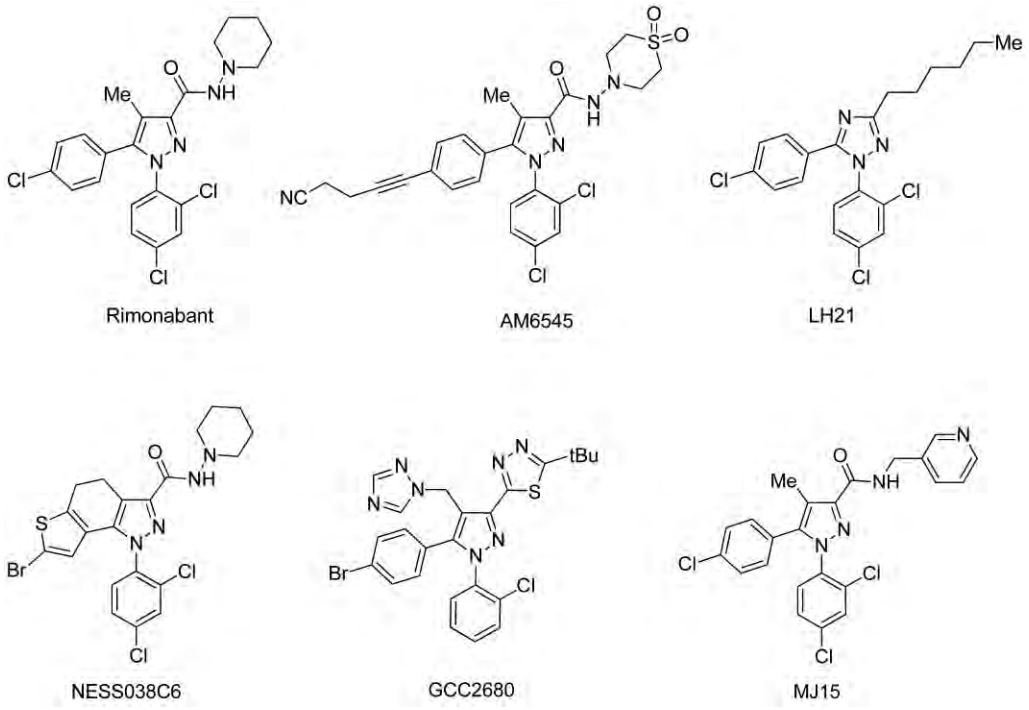

FIGURE 67.1 **Rimonabant and novel CB1 antagonists.** Structures of rimonabant and novel CB1 antagonists related to rimonabant.

regular chow intake. Due to its low brain penetration, AM6545 does not affect behavioral responses mediated by CB1 receptors in the brain, such as catalepsy, hypomotility, hypothermia, and anxiety-like behaviors. AM6545 reduces body weight gain and the adiposity index, improving the metabolic profile of obese mice fed a high-fat diet in a food intake–independent manner. In fact, this drug has been reported to decrease lipogenic and increase lipolytic gene expression in both liver and adipose tissue. Moreover, AM6545 treatment reverses the hepatic steatosis induced by high-fat diet, reducing liver triglycerides and hepatocellular damage. By contrast, AM6545 has no effect on body weight and adiposity in *ob/ob* mice, likely due to leptin signaling deficiency. In addition, AM6545 is also able to reduce food intake and body weight gain in CB1 receptor knockout (KO) mice, indicating the existence of other alternative pathways. Cluny et al. (2010) suggest that hypophagia mediated by cannabinoid receptors is not solely dependent on central activation. In fact, the feeding behavior of AM6545 seems to be dependent only on peripheral effects.

Jagerovic et al. (2004) synthesized and characterized LH21 (Fig. 67.1), a triazole analog of rimonabant, that acts as a CB1 neutral antagonist. LH21 displays a different pharmacological profile than rimonabant. Acute administration of this compound reduces food intake in fasted rats. Similarly, subchronic treatment causes hypophagia and reduces body weight gain in obese rats, but with no metabolic effects. LH21 is more efficacious as an antiobesity drug in obese rats exposed to enriched-fat diet than in control rats, likely due to the dysregulation and overactivation of the ECS associated to obesity. Contrary to the metabolic benefits of rimonabant, obese rats treated with LH21 do not display an improvement of the obesity-associated hepatic steatosis. The poor penetration of LH21 into the CNS indicates that its anorectic effects are mainly mediated by peripheral CB1 receptors located in gut sensory terminals that control satiety, and also with cannabinoid receptors located in metabolically relevant tissues. A study from 2012 has indicated that the antiobesity properties of LH21 may be mediated through modulation of the lipogenic pathways in adipose tissue (Alonso et al., 2012). In adipocytes, LH21 treatment also affects the gene expression of leptin, reducing its transcription, and improving the leptin resistance associated to obesity. In a recent study, Alen et al. (2013) investigated whether peripheral-acting CB1 antagonists, such as LH21, may modulate other signals controlling appetite, such as ghrelin. Ghrelin is an endogenous regulator of energy homeostasis synthesized by the stomach to stimulate appetite and positive energy balance. A subanxiogenic ultra-low dose of LH21 was tested on ghrelin orexigenic actions, finding that it blocked ghrelin-induced hyperphagia in free feeding animals. This study suggests that the peripheral ECS may interact with ghrelin signal in the control of food intake, under equilibrate energy balance conditions, and that therapies using peripheral-restricted CB1 antagonist might be efficacious for the treatment of obesity when ghrelin-inducing food intake signal is overactivated.

NESS038C6 (Fig. 67.1) was highlighted as a novel CB1 antagonist without central effects (Mastinu, Pira, Pani, Pinna, & Lazzari, 2012). Although Mastinu et al. (2012) reported this compound as a CB1 antagonist, no functional assay data were shown both in Mastinu's paper and in the US patent where its chemical synthesis was described (Lazzari, Murineddu, Pinna, & Ruiu, 2009). Thus, there was no accurate information about whether it acted as a neutral antagonist or an inverse agonist. Anyway, the effects induced by a chronic treatment with NESS038C6 in DIO mice were studied. NESS038C6 chronic treatment (30 mg/kg per day for 31 days) determined a significant reduction in DIO mice weight, relative to that of vehicle fat diet. The entity of the effect was comparable to that detected in rimonabant fat diet. Moreover, NESS038C6 fat diet evidenced an improvement of cardiovascular risk factors; a significant decrease in adipose tissue leptin expression; an increase in mRNA expression of hypothalamic orexigenic peptides, and a decrease of anorexigenic peptides; an expression increase of metabolic enzymes and PPARα in the liver; and a normalization of monoaminergic transporters and neurotrophic expression in mesolimbic area. However, in contrast to the case of rimonabant, this CB1 antagonist improved the disrupted expression profile of genes linked to the hunger-satiety circuit, without altering monoaminergic transmission.

Green Cross Corporation disclosed GCC2680 (Fig. 67.1) as a potent, selective and orally efficacious CB1 antagonist with antiobesity properties (Lee et al., 2010). Through a process of lead optimization based on modeling data, it was selected as a candidate for development as a weight-loss agent. Although Lee et al. (2010) claimed GCC2680 as a CB1 antagonist, functional data of this compound were not reported, so the functionality of the compound should be called into question. However, its in vivo efficacy was deeply studied on high fat DIO mice and rats. GCC2680 is substantially more efficacious than rimonabant in both animal models. Moreover, it displayed significant antidiabetic activity through oral administration in various animal models, including *ob/ob* mice, *db/db* mice, and DIO mice. Furthermore, the pharmacokinetic properties of GCC2680 were measured in Sprague Dawley rats. Thus, the off-target activity of this compound was evaluated, demonstrating not to be a significant inhibitor of cytochrome p450 enzymes. Its activity in the hERG potassium channel assay was determined to be higher than that of rimonabant, indicating less risk of increasing QT interval. Besides, GCC2680 proved not to be mutagenic in comet and Ames mutagenicity assays. In addition, when the cytotoxicity of GCC2680 was tested on a panel of cells (Huh-7, Vero, HCT116, and HEK-293) it demonstrated to be safe. Subsequently, in vivo toxicity studies were performed, estimating an LD_{50} greater than 2 g/kg.

Also, through a process of lead optimization, CB1 antagonist MJ15 (Fig. 67.1) was identified as a precandidate for further development as an antiobesity molecule (Chen et al., 2010). Its affinity to CB1 receptor was almost equivalent to that of rimonabant, and its efficacy in selectively antagonizing the CB1 receptor in mammalian cells was a little inferior to that of rimonabant. MJ15 was studied in two animal models, DIO rats and DIO mice. In both models, it demonstrated remarkable effects from 20 to 40 mg/kg, including promoting small intestine peristalsis in ICR mice, and inhibiting food intake and body weight increase. Interestingly, MJ15 not only could prevent the body weight and adipose gain in DIO rats, but could also reduce body weight and fat mass in obesity DIO mice. Moreover, to the accompanied dyslipidemia, MJ15 completely ameliorated it in DIO rats, but only corrected the hypertriglyceridemia of the DIO mice. Additionally, preliminary pharmacokinetics studies showed less distribution of MJ15 in the brain of mice, which indicated that MJ15 displays lowered propensity to pass the blood–brain barrier, and thus may avoid some CNS side effects seen with rimonabant.

CB1 Inverse Agonists

An interesting central acting inverse agonist, developed by Pfizer, is Otenabant (Fig. 67.2) (Hadcock et al., 2010b). In vivo, Otenabant reverses four cannabinoid agonist-mediated CNS-driven responses (hypolocomotion, hypothermia, analgesia, and catalepsy), which involves central effects. This compound exhibits dose and concentration-dependent anorectic activity in two models of acute food intake in rodents, fast-induced refeeding, and spontaneous, nocturnal feeding. It also acutely stimulates energy expenditure in rats, and decreases the respiratory quotient, indicating a metabolic switch to increased fat oxidation. Concentration/effect relationships combined with ex vivo brain CB1 receptor occupancy data were used to evaluate efficacy in behavioral, food intake, and energy expenditure studies.

Three Phase III trials were conducted to evaluate the long-term efficacy and safety of Otenabant in the treatment of overweight or obese patients with or without type 2 diabetes (Aronne et al., 2011). In 2008, Pfizer, as sponsor, elected to discontinue the three trials and the Otenabant development program. The decision was based on changing regulatory perspectives with regard to the risk/benefit profile of CB1 receptor-related drugs, and the likely difficulties of obtaining regulatory approval for them. The most frequent adverse events found for Otenabant in these trials were diarrhea, nausea, nasopharyngitis, and headache. Furthermore, self-reported experiences of anxiety and suicidal thoughts

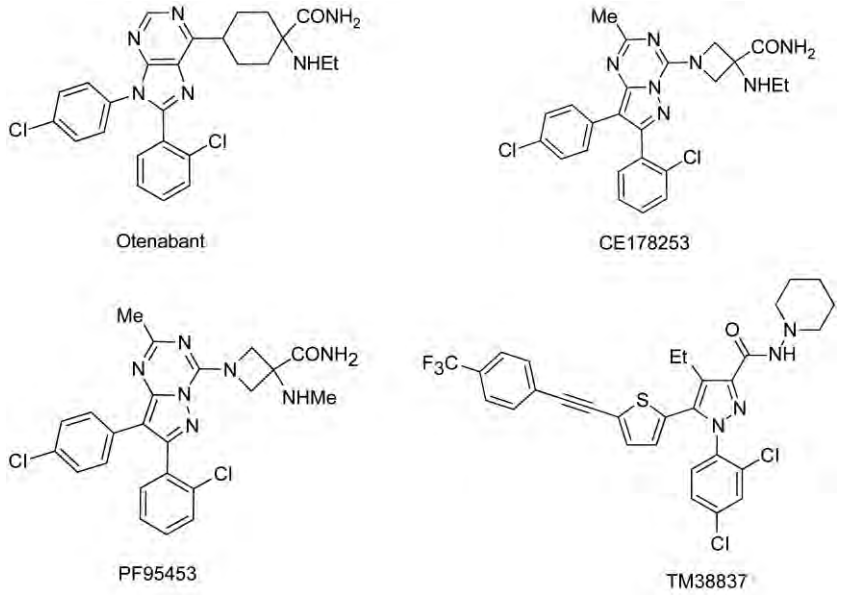

FIGURE 67.2 **Novel CB1 inverse agonists.** Structures of novel CB1 inverse agonists related to rimonabant.

were higher with Otenabant than placebo, as were the incidence of depression and depressed mood.

After discontinuing Otenabant, Pfizer reported the pharmacology and food intake properties of two of their analogs. CE178253 (Fig. 67.2) was described as a centrally-acting CB1 inverse agonist, and its quantitative in vitro and in vivo pharmacological profile was widely reported by Hadcock et al. (2010a). PF95453 (Fig. 67.2) was evaluated in vivo in weight-stable, diet-standardized obese cynomolgus monkeys, using a protocol that involved both a vehicle-treated control group and a pair-fed control group to optimize the ability to differentiate variances related to anorectic behaviors from those related to food intake-independent actions of the compound. Wagner et al. (2010) reported PF95453 as a selective CB1 antagonist, but it was not clear if it was a neutral antagonist or an inverse agonist, like its counterpart compounds. Both CE178253 and PF95453 were discontinued like Otenabant, and no further research about them can be found in the literature. Nevertheless, Pfizer researchers suggested an interesting conclusion from these studies. They found that appetite suppression of CB1 antagonists, and the corresponding anxiety and depressed mood probably were inexorably linked. However, evidence from animal studies indicated that the beneficial metabolic effects of CB1 receptor antagonism were mediated in part by CB1 receptor blockade in peripheral tissues.

A second generation CB1 inverse agonist, TM38837 (Fig. 67.2), was demonstrated to induce comparably significant weight-loss in mice, at the same dose of rimonabant (10 mg/kg), while the dose of TM38837 showed only around 5% of CB1 receptor occupancy in the CNS (Hung et al., 2010). Moreover, TM38837 was tentatively recognized as a peripheral inverse agonist, based on its negative central effects in CB1 receptor-induced hypothermia and analgesia models. Consequently, Hung et al. (2010) suggested that similar levels of antiobesity effects could be achieved even when central CB1 receptor occupancy is rather low. In 2014, a PET study was published, in which in vivo brain CB1 receptor occupancy of TM38837, in comparison with rimonabant in nonhuman primates, was investigated (Takano et al., 2014). Expected clinical therapeutic doses of TM38837 (20 mg) demonstrated only low levels of in vivo brain CB1 receptor occupancy, compared with rimonabant at the comparable doses in nonhuman primates. This low CNS occupancy by TM38837 would reduce the risk of CNS side effects in clinical situations. According to the authors, this nonhuman primate PET study supports further development of TM38837 in clinical trials.

ANTIOBESITY AGENTS NOT RELATED TO RIMONABANT

Phytocannabinoids

Wargent et al. (2013) reported pharmacological in vitro and in vivo experiments of Δ^9-tetrahydrocannabivarin (THCV). THCV is a naturally occurring analog of Δ^9-tetrahydrocannabinol, which behaves as a CB1 neutral antagonist (Pertwee et al., 2007) and, depending on the assays used, also as a CB2 agonist or antagonist (Bolognini et al., 2010). THCV produced therapeutic metabolic effects in two different mouse models of obesity, DIO and genetically (*ob/ob*) obese mice. In particular,

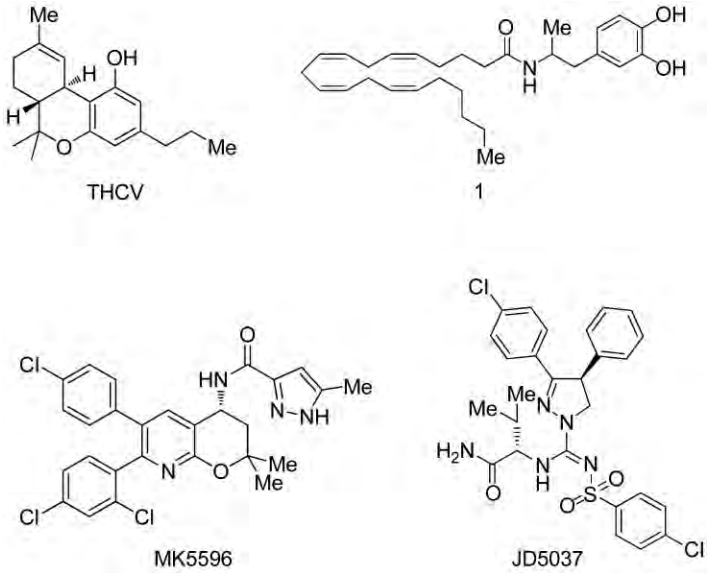

FIGURE 67.3 Novel antiobesity agents not related to rimonabant. Structure of novel antiobesity agents not related to rimonabant.

its strongest effects are exerted on plasma glucose and insulin levels in DIO mice, and on liver triglycerides in *ob/ob* mice. Based on these data, Wargent et al. (2013) suggested that THCV may be useful for the treatment of the metabolic syndrome and/or type 2 diabetes, either alone or in combination with existing treatments.

Fatty Acid Derivatives

Interestingly, studies performed in both rodents and humans have demonstrated that dietary lipids can modulate endocannabinoid levels (Kim, Li, & Watkins, 2013). Specifically, diet n-3 polyunsaturated fatty acids (PUFA) could potentially alter the levels of endocannabinoids (mainly AEA and 2-AG), and the ECS tone. Introducing n-3 PUFA to the diet directly reduced the substrate amount of arachidonic acid (AA) available in membrane phospholipids for the synthesis of AEA and 2-AG. Specific hypothesis tried to explain how long chain n-3 PUFA may function to alter the homeostatic induction of the ECS. The long chain n-3 PUFA derivatives may bind with varying affinities to the cannabinoid receptors, and act as modifiers of AEA and 2-AG bound to receptors in order to diminish overstimulation of this signaling pathway contributing to obesity. In addition, the long chain n-3 PUFA may increase or decrease the expression or activity of enzymes in the synthesis and degradation of endocannabinoids.

Thus, PUFA derivatives have been recently developed as antiobesity drugs. Some fatty acid amides, specifically oleic and arachidonic ones, of several metabolites of 3,4-methylenedioxymethamphetamine (MDMA) resulted in negative modulation of food intake in rats (Almeida et al., 2010). The most active compound (see "1" in Fig. 67.3) showed some affinity for the CB1 receptor, but no data about its functionality were reported. Moreover, it displayed an acute food intake modulation profile.

Heterocycles

From 2010, some heterocyclic structures not related to rimonabant have been reported. At around the same time that rimonabant was withdrawn, Merck announced the withdrawal of its CB1 inverse agonist taranabant from Phase II and III studies for the indications of smoking cessation and obesity, also due to psychiatric side effects including depression, irritability, anxiety, and suicidality. Afterwards, this pharmaceutical company claimed another inverse agonist for the treatment of obesity. It was MK5596 (Fig. 67.3), also a CB1 inverse agonist related to taranabant (Yan et al., 2010). It reduced body weight and food intake in a DIO rat model, at a very low dose of 1 mg/kg. An extensive preclinical study revealed that MK5596 possessed attenuated off-target hERG activity, CB1 receptor-related pharmacological efficacy similar to that of taranabant, good pharmacokinetic profiles in preclinical species (rat, monkey, and dog), acceptable safety margins, and a potentially balanced metabolism profile in human. Despite this excellent preclinical profile, Merck decided to discontinue the clinical evaluation of MK5596 as an antiobesity agent due to the rimonabant and taranabant side effects.

JD5037 (Fig. 67.3), an analog of the brain-penetrant CB1 inverse agonist ibipinabant, was investigated as a peripheral CB1 inverse agonist with weight-loss properties (Tam et al., 2012). The absence of in vivo brain CB1 receptor occupancy following acute or chronic

administration of JD5037 was documented by PET. In mice with DIO, JD5037 was equieffective with its brain-penetrant parent compound ibipinabant in reducing appetite, body weight, hepatic steatosis, and insulin resistance, even though it does not occupy central CB1 receptor or induce related behaviors. Appetite and weight reduction by JD5037 were mediated by resensitizing DIO mice to endogenous leptin through reversing hyperleptinemia. It was performed by decreasing leptin expression and secretion by adipocytes, and increasing leptin clearance via the kidney. Thus, inverse agonism at peripheral CB1 receptor not only improves cardiometabolic risk in obesity, but has antiobesity effects by reversing leptin resistance. Tam et al. (2012) claimed that a key finding of their study was the greater efficacy of peripheral CB1 inverse agonism, compared to neutral antagonism in reducing food intake and body weight. Hyperleptinemia, the target of these effects, was partially reduced by the neutral antagonist AM6545, but completely normalized by JD5037. It is possible that, in obesity, the fraction of CB1 receptor present in the active conformation is increased in peripheral tissues involved in metabolic regulation, a fact that could account for the greater efficacy of inverse agonists over neutral antagonists. Moreover, this study seemed to confirm earlier suggestions that the hypophagic effect of brain-penetrant CB1 inverse agonists may be mediated by peripheral CB1 receptor (Gomez et al., 2002).

CONCLUSIONS AND PERSPECTIVES

As it was shown in the previous sections, some considerable debate remains about the best way in which to target CB1 receptors for weight and metabolic control. Some authors claim that inverse agonism of CB1 receptors at a central and peripheral level is the best approach to achieve weight loss, and others suggest that blocking the CB1 receptor with nonbrain penetrating compounds and neutral antagonism should be the strategy to be chosen. Consequently, many questions remain unanswered about the ideal methods by which to inhibit CB1 receptors for weight and metabolic control, and even novel cannabinoid targets to develop antiobesity drugs are being taken into account.

Cannabinoid CB2 receptors were first described in immune system cells, being involved in modulating immune responses. However, subsequent analysis revealed that this receptor is also expressed in organs controlling metabolism, such as the liver, adipose tissue, skeletal muscle, and the endocrine pancreas. In agreement, changes in their expression have been reported in obesity in both the liver and adipose tissue, and CB2 specific activation potentiated inflammatory markers, insulin resistance, and liver steatosis in obese mice, whereas its blockade did the opposite (Deveaux et al., 2009). Indeed, animals genetically lacking the CB2 receptor in the whole body have shown to increase food intake and body weight with age, displaying less insulin resistance and inflammatory markers than the wild-type. These CB2 KO mice were also more resistant to the development of DIO.

In addition, CB2 receptor has been also detected in several brain areas (Van Sickle et al., 2005), so the putative role of central CB2 receptors in modulating body weight and glucose homeostasis is still under study (Romero-Zerbo et al., 2012).

Recent pharmacological data has demonstrated that certain cannabinoid ligands mediate their biological effects through the GPCR GPR55 (Lauckner et al., 2008), considering it as a novel putative cannabinoid receptor. Regarding obesity, GPR55 exerts some metabolic actions on insulin secretion and gut movement. Importantly, this receptor may be a clinically relevant target because GPR55 expression in WAT is increased in obese subjects, and even more in obese patients with type 2 diabetes. Moreover, LPI, the endogenous ligand of GPR55, showed increased circulating levels in obese patients, and a positive correlation with fat percentage and BMI in women (Imbernon et al., 2014). These preliminary but interesting results require investigating the potential role of GPR55 agonists/antagonists in obesity and insulin sensitivity.

In brain, 2-monoacylglycerol lipase (MGL) works as a primary regulator of the endocannabinoid 2-AG, signaling action via the ECS. Chon et al. (2012) showed that intestinal MGL expression and activity were significantly induced by a high fat diet, but not by fasting, suggesting a potential role for MGL in dietary lipid assimilation. Moreover, they generated transgenic mice that overexpressed MGL in the small intestine, finding that, after 3 weeks of a high fat diet, these mice showed a significant increase of body weight gain and body fat accumulation, accompanied by hyperphagia, as well as reduced energy expenditure. Thus, preliminarily, intestinal MGL may be envisioned as a new metabolic regulator involved in the control of the whole body energy homeostasis.

MINI-DICTIONARY

Adipocytes Cells of the adipose tissue.
Anorectic drug Substance which reduces appetite and food consumption.
Dyslipidemia An abnormal amount of lipids in the blood.
Energy homeostasis It measures the energy intake, so the sum of energy stored, work, and heat.
Hyperleptinemia High serum levels of leptin.
Hypertriglyceridemia High blood levels of triglycerides.
Hypophagia Reduction of food intake.

Leptin Hormone regulating the amount of fat stored in the body.
Liver/hepatic steatosis A process in which fat accumulates in liver cells via an abnormal retention of lipids.
Rimonabant Antiobesity drug whose mechanism involves CB1 receptor blocking.

Cannabinoid Reward and Dependence: Focus on the Main Psychoactive Ingredients of Marijuana in Preclinical Studies

G. Panagis

University of Crete, Department of Psychology, Laboratory of Behavioral Neuroscience, Rethymnon, Crete, Greece

SUMMARY POINTS

- This chapter focuses on the effects of the major phytocannabinoids, Δ^9-tetrahydrocannabinol (Δ^9-THC) and cannabidiol (CBD) in brain reward processes that are believed to play a pivotal role in the development and maintenance of drug abuse and addiction.
- Very low doses of Δ^9-THC lower brain stimulation reward thresholds. The ability of drugs to lower brain stimulation reward thresholds correlates with high abuse potential.
- Δ^9-THC is self-administered intravenously by experimental animals, although the range of conditions under which this occurs is more limited than with other drugs of abuse.
- Δ^9-THC is self-administered intracerebroventricularly, or into the posterior ventral tegmental area and the shell of the nucleus accumbens by experimental animals.
- Depending on a number of experimental parameters (dose, strain of the animal, number of conditioning sessions, timing between injections, previous drug exposure), Δ^9-THC induces both conditioned place preference (CPP) and aversion.
- In experimental animals, abrupt discontinuation of chronic Δ^9-THC treatment does not result in a robust spontaneous withdrawal syndrome. However, challenge with the CB_1 receptor antagonist SR141716A elicits withdrawal signs in animals treated with Δ^9-THC.
- Cannabidiol is not rewarding in experimental animals, since it neither decreases brain stimulation reward thresholds, nor induces conditioned place preference.

KEY FACTS OF CANNABINOIDS AND THE ENDOCANNABINOID SYSTEM

- The plant *Cannabis sativa* contains over 400 chemical compounds, including about 80 terpeno-phenols, unique to the plant of cannabis, known as plant cannabinoids (phytocannabinoids).
- Δ^9-Tetrahydrocannabinol (Δ^9-THC) is the major psychoactive constituent of the plant.
- Plant cannabinoids with very weak or no psychotropic and psychotomimetic activity include cannabidiol (CBD), cannabigerol (CBG), cannabichromene (CBC), Δ^9-tetrahydrocannabivarin (Δ^9-THCV), cannabidivarin (CBDV), Δ^9-tetrahydrocannabinolic acid (Δ^9-THCA), and cannabidiolic acid (CBDA).

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00079-X
Copyright © 2017 Elsevier Inc. All rights reserved.

- Δ^9-THC exerts its effects by interacting with specific receptors. Two major cannabinoid (CB) receptors have been cloned (CB_1 and CB_2), both of which belong to the superfamily of G-protein coupled receptors.
- CB_1 receptors are expressed ubiquitously, but they are preferentially located in the brain and the spinal cord. They can be found in the highest concentrations in areas involved in motor function and coordination (eg, basal ganglia and cerebellum), memory (eg, hippocampus), emotionality (eg, neocortex, and amygdala), and motivation and reward (eg, prefrontal cortex, nucleus accumbens, amygdala). CB_1 receptors are localized preferentially at the presynaptic level, and mediate inhibition of ongoing release of other neurotransmitters, including dopamine.
- The CB_2 receptor has been categorized classically as the peripheral cannabinoid receptor, since it is expressed principally in the immune system. However, recent findings suggest that CB_2 receptors are also expressed in the brain under normal and, in particular, under pathological conditions.
- Endogenous ligands for CB receptors have been discovered and characterized. These endocannabinoids include anandamide (AEA), 2-arachidonoylglycerol (2-AG), noladine ether, virodhamine, and *N*-arachidonoyldopamine (NADA).
- Endocannabinoids are released upon demand from lipid precursors, and their concentrations are regulated in a strict manner through a reuptake process into cells, and a rapid enzymatic inactivation.
- The endocannabinoid system is an important lipid signaling system which modulates various physiological functions, not only in the central nervous system, but also in the autonomic nervous system, the endocrine, the reproductive, the immune, and the cardiovascular system.

LIST OF ABBREVIATIONS

CB_1 receptors	Cannabinoid 1 receptors
CBD	Cannabidiol
CPP	Conditioned place preference
ICSS	Intracranial self-stimulation
KO	Knockout
Δ^9-THC	Δ^9-Tetrahydrocannabinol

INTRODUCTION

Cannabis is by far the most commonly consumed illegal drug worldwide, and it is generally considered to have only modest addictive potential, compared to other drugs of abuse (Ramo, Liu, & Prochaska, 2012). In many countries, more than 50% of young people have used it at least once. The popularity of cannabis as a recreational drug is due to its ability to alter sensory processing, as well as producing clear subjective motivational responses accompanied by a sense of mild euphoria and wellbeing. Indeed, this elation, along with the sense of relaxation produced by cannabis, are among the most cited subjective psychotropic properties of the drug (Green, Kavanagh, & Young, 2003). In Europe today there is a trend toward relaxation of the criminal penalties associated with cannabis use and cannabis users, mainly because it is perceived as relatively safe. However, there is evidence that some users do become dependent on cannabis, consuming the drug in a compulsive fashion, and experiencing withdrawal symptoms upon cessation.

In spite of the well-established abuse properties of cannabis preparations in humans, rewarding effects of cannabinoids in animal models of drug abuse and dependence have been rather difficult to demonstrate. However, several recent findings have demonstrated many commonalities between the rewarding and addictive effects of cannabinoids, and those of other drugs of abuse. Here, we will briefly describe and evaluate the actions of cannabis, its main psychoactive ingredient Δ^9-tetrahydrocannabinol (Δ^9-THC), and cannabidiol (CBD) on brain reward circuitry, that are believed to play a pivotal role in the development and maintenance of cannabinoid addiction.

Δ^9-THC and Cannabidiol Effects on Brain Stimulation Reward

A number of studies have been conducted on the effects of Δ^9-THC in the intracranial self-stimulation (ICSS) paradigm (Table 68.1). According to Gardner and coworkers, 1 and 1.5 mg/kg of Δ^9-THC decreased ICSS thresholds in Lewis rats, but not in Fisher 344 rats, whereas in Sprague-Dawley rats the effect was only marginal (Gardner et al., 1988; Lepore, Liu, Savage, Matalon, & Gardner, 1996). In contrast, other studies failed to show an enhancement of brain stimulation reward with Δ^9-THC in the dose range from 0.5 to 10 mg/kg in Sprague-Dawley rats, under baseline conditions (Katsidoni, Kastellakis, & Panagis, 2013b; Kwilasz & Negus, 2012; Vlachou, Nomikos, Stephens, & Panagis, 2007), or in animals preexposed to stress (Fokos & Panagis, 2010). Similar results have been reported in Long-Evans rats with oral administration of 10 mg/kg Δ^9-THC and various doses of three synthetic analogs structurally related to Δ^9-THC, namely levonantradol, nabilone, and canbisol (Kucharski, Williams, & Kornetsky, 1983; Stark & Dews, 1980). Surprisingly, however, in a recent study we showed that Δ^9-THC can induce both rewarding and anhedonic effects in the ICSS paradigm in

TABLE 68.1 Studies Regarding the Role of Δ^9-Tetrahydrocannabinol (Δ^9-THC) in Reward and Dependence

Model	Dose of Δ^9-THC	Brief result	Animals	References
ICSS	0.12–10 mg/kg	Increased ICSS threshold	Long-Evans rats	Stark and Dews (1980)
ICSS	0.2, 0.3 mg/kg	Increased ICSS threshold	Albino CDF rats	Kucharski et al. (1983)
ICSS	1.5 mg/kg	Decreased ICSS threshold	Lewis rats	Gardner et al. (1988)
ICSS	1 mg/kg	Marginal decrease in ICSS threshold No effect Decreased ICSS threshold	Sprague-Dawley rats Fischer 344 rats Lewis rats	Lepore et al. (1996)
ICSS	1–2 mg/kg	Increased ICSS threshold	Sprague-Dawley rats	Vlachou et al. (2007)
ICSS	0.5, 1 mg/kg	No effect	Sprague-Dawley rats	Fokos and Panagis (2010)
ICSS	0.32–1 mg/kg	No effect	Sprague-Dawley rats	Kwilasz and Negus (2012)
ICSS	0.1 mg/kg 1 mg/kg	Decreased threshold Increased threshold	Sprague-Dawley rats	Katsidoni et al. (2013b)
Intravenous self-administration	0.02–0.3 mg/kg	No effect (self-administration in no higher than vehicle levels)	Rhesus monkeys (with previous drug experience)	Harris, Waters, and McLendon (1974)
Intravenous self-administration	6.25–50 µg/kg per injection	Self-administration in food restricted rats	Wistar albino rats	Takahashi and Singer (1979)
Intravenous self-administration	12.5 µg/kg per injection	Self-administration in food restricted rats	Wistar albino rats	Takahashi and Singer (1980)
Intravenous self-administration	0.4 mg/kg per injection	Self-administration after withdrawal from forced automatic intravenous injections of Δ^9-THC (drug naive monkeys did not self-administer Δ^9-THC)	Rhesus monkeys (with previous drug experience)	Kaymakcalan (1981)
Intravenous self-administration	17–100 µg/kg per injection	No effect (self-administration in no higher than vehicle levels)	Rhesus monkeys (with previous drug experience)	Mansbach, Nicholson, Martin, and Balster (1994)
Intravenous self-administration	2 and 4 mg/kg per injection	Self-administration	Squirrel monkeys (with previous drug experience)	Tanda, Munzar, and Goldberg (2000)
Intravenous self-administration	2, 4, 8 mg/kg per injection	Self-administration	Naive squirrel monkeys	Justinova, Tanda, Redhi, and Goldberg (2003)
Intravenous self-administration	2–8 µg/kg per injection	Self-administration	Squirrel monkeys (with previous drug experience)	Justinova, Tanda, Munzar, and Goldberg (2004)
Intravenous self-administration	20–80 µg/kg	Self-administration under second order schedule	Squirrel monkeys (with previous drug experience)	Justinova et al. (2008)
Intravenous self-administration	0.0032–0.032 mg/kg per infusion	No effect (self-administration in no higher than vehicle levels)	Rhesus monkeys (with previous drug experience)	Li, Koek, and France (2012)
Intravenous self-administration	4 µg/kg per injection	Self-administration	Squirrel monkeys (with previous drug experience)	Justinova et al. (2013)
Intracerebroventricular self-administration	0.01–1 µg/2 µL per infusion	Self-administration	Wistar rats	Braida, Iosue, Pegorini, and Sala (2004)
Intracerebral (posterior ventral tegmental area and posterior shell of the nucleus accumbens) self-administration	100 nL injection of 66 or 200 pmol	Self-administration	Sprague-Dawley rats	Zangen, Solinas, Ikemoto, Goldberg, and Wise (2006)

CPP	1, 10 mg/kg	No effect (but reversed the CPA in mice treated with 10 mg/kg Δ^9-THC)	ICR mice	Vann et al. (2008)
CPP	1, 3, 10 mg/kg	Tendency for CPP only when administered in combination with 10 mg/kg Δ^9-THC	Albino Wistar rats	Klein et al. (2011)

Sprague-Dawley rats, depending on the dose used (Katsidoni et al., 2013b). Indeed, a low dose of 0.1 mg/kg decreased ICSS thresholds, and caused clear parallel leftward shifts in the rate-frequency function, whereas a higher dose of 1 mg/kg increased ICSS thresholds, and produce rightward shifts. These effects are specifically mediated by cannabinoid 1 (CB_1) receptors, since they have been reversed by a low dose of the CB_1 receptor antagonist SR141716A. These results therefore need to be interpreted with caution. These seemingly contradictory results could be attributed to differences in the dose range of the tested compounds, the strain of the animals used, and the methods followed. More importantly, it is possible that Lewis rats may have a differential sensitivity to Δ^9-THC, compared to Sprague-Dawley and Fisher 344 rats, and it could conceivably be hypothesized that the dose-response function of Δ^9-THC on brain stimulation reward is not linear, but rather biphasic.

CBD is a nonpsychotomimetic constituent of *Cannabis sativa*, which induces central effects in rodents. Although CBD has been shown to affect emotional responses, to date, only one study has been undertaken to evaluate its effects on brain stimulation reward (Table 68.2). According to the findings of this report, low doses of CBD did not affect brain stimulation reward, whereas higher doses increased ICSS thresholds, and produce rightward shifts (Katsidoni, Anagnostou, & Panagis, 2013a). Thus, CBD lacks hedonic properties and abuse potential, but can reduce brain reward function, producing an anhedonic-like state. Interestingly, it has been also shown that CBD blocks the reward-facilitating effect of morphine in the ICSS paradigm (Katsidoni et al., 2013a), and attenuates cue-induced reinstatement of heroin-seeking behavior (Ren, Whittard, Higuera-Matas, Morris, & Hurd, 2009).

Δ^9-THC Self-Administration

Most drugs abused by humans, including psychostimulants, opiates, ethanol, and nicotine, support reliable and persistent self-administration behavior in drug naive experimental animals, under normal experimental conditions. However, for many years, demonstrations of cannabis or Δ^9-THC self-administration in drug naive rodents or primates had been limited and unconvincing. Interestingly, in many studies, the procedures of the self-administration experiments have been varied in order to demonstrate reliable, persistent, and dose-dependent self-administration of Δ^9-THC in experimental animals (Table 68.1).

Kaymakcalan (1981) was the first who demonstrated successful self-administration of Δ^9-THC in two monkeys out of six studied, but only after withdrawal from forced automatic intravenous injections of Δ^9-THC, when signs of physical dependence on Δ^9-THC occurred. Furthermore, one monkey exhibited Δ^9-THC self-administration behavior following cocaine self-administration. In the same study, drug-naive monkeys did not self-administer Δ^9-THC (Kaymakcalan, 1981). Similarly, other studies have shown self-administration of Δ^9-THC in experimental animals with a previous self-administration experience of phencyclidine, amphetamine, cocaine, or food (Justinova et al., 2004; Justinova et al., 2008, 2013; Tanda et al., 2000; Thompson & Pickens, 1975). However, these studies suffer from some serious limitations. Indeed, previous drug exposure may affect acquisition and maintenance of self-administration of various abused drugs in experimental animals, since the motivational state in naive animals, compared with animals that self-administer other drugs, could be different, and therefore their corresponding response could also vary accordingly. Interestingly, there are studies that have failed to show robust Δ^9-THC self-administration, even in animals preexposed to other drugs of abuse, such as cocaine, phenobarbital, phencyclidine, ethanol, or amphetamine (Harris et al., 1974; Li et al., 2012; Mansbach et al., 1994).

Food deprivation was another frequently used manipulation in the study of Δ^9-THC self-administration. Indeed, Takahashi and Singer reported Δ^9-THC self-administration in food-restricted rats (Takahashi & Singer, 1979, 1980). Interestingly, however, self-administration immediately decreased to placebo levels, when food-restriction was discontinued. Thus, a criticism of this research is that self-administration Δ^9-THC

was demonstrated under special conditions that may have altered the functional or motivational state of the animals.

In a seminal article, Justinova et al. (2003) showed for the first time that low doses of Δ^9-THC can initiate and sustain high rates of intravenous self-administration in drug-naive squirrel monkeys. In their study, they used three drug naive squirrel monkeys, low doses of Δ^9-THC (1–8 μg/kg per injection) that, according to the authors, were several times lower than the doses generally used in previous attempts to demonstrate Δ^9-THC self-administration in monkeys, and comparable to those delivered by an average marijuana cigarette. The self-administration behavior was rapidly extinguished, either by substituting vehicle injections for Δ^9-THC injections, or by administering the CB_1 receptor antagonist SR141716A before the session, indicating that this effect was mediated through the CB_1 receptor. Interestingly, Justinova et al. (2008) were also the first to report Δ^9-THC self-administration using a drug-seeking procedure (second-order schedule), although in that study the monkeys had a previous experience with self-administration of amphetamine, cocaine, or food.

Two studies investigated the possibility that Δ^9-THC is self-administered intracerebrally by experimental animals. Braida et al. (2004) were the first to report intracerebroventricular self-administration of Δ^9-THC in water-deprived rats. Subsequently, Zangen et al. (2006) reported Δ^9-THC self-administration directly into the posterior ventral tegmental area and the shell of the nucleus accumbens.

To conclude, studies with self-administration of Δ^9-THC under normal experimental conditions have not always been consistent. Thus, it could be argued that self-administration of Δ^9-THC occurs under more limited conditions than self-administration of other drugs of abuse. However, a number of studies report robust self-administration of Δ^9-THC under normal conditions, either in squirrel monkeys or, intracerebrally, in rodents. These findings provide some evidence that Δ^9-THC produces rewarding effects through the same reward brain circuitry as other drugs of abuse.

Δ^9-THC and CBD Effects on Conditioned Place Preference (CPP)

Although most drugs abused by humans produce a clear CPP in experimental animals, the corresponding data on Δ^9-THC are not very consistent. Indeed, Δ^9-THC can induce appetitive effects under some conditions, but aversive effects under others (Table 68.1). This is determined at least partly by the particular dose used, the administration of a priming injection, and the timing between injections. Surprisingly, in the studies reporting CPP, the preference is connected to a single dose. Since this is not the case with other drugs of abuse, in which CPP can be obtained over a range of doses, it has been suggested that cannabis is an atypical or anomalous drug of abuse.

In the study by Lepore et al. (1995), 2–4 mg/kg Δ^9-THC produced CPP in Long Evans rats when the CPP pairing interval was 24 h; using the same experimental design, 1 mg/kg of Δ^9-THC did not produce any preference). However, when the schedule of daily injections was changed, allowing a longer washout interval between injections (48 h), Δ^9-THC produced a clear place aversion in the dose of 2–4 mg/kg, but CPP in the dose of 1 mg/kg. Thus, Δ^9-THC induced CPP was dependent upon the dose and the injection schedule. In this regard, increasing the time interval between Δ^9-THC injections might have changed the effects of Δ^9-THC due to a postdrug dysphoric rebound effect. That is, at the shorter pairing interval, the post Δ^9-THC rebound dysphoria might have attenuated Δ^9-THC's rewarding effect, while at the longer pairing interval, where the post Δ^9-THC rebound effect subsided, the effects of all doses were accentuated, allowing the 1 mg/kg to be rewarding, and the highest doses to be aversive.

Similar results have been reported in subsequent studies. Braida et al. (2004) demonstrated Δ^9-THC induced CPP in Wistar rats, in a dose range between 0.075 and 0.75 mg/kg; in the same study, higher doses produced aversive effects. The authors suggested that the low doses of Δ^9-THC used in their experiment could have minimized any dysphoric effects of the drug that might lead to aversion. In another study, Le Foll et al. (2006) reported that a low dose of Δ^9-THC (0.1 mg/kg) produced CPP, while doses lower (ie, 0.01 mg/kg) or higher (ie, 1 mg/kg) than this did not produce any preference. However, more recently, the Goldberg group did not find any rewarding or aversive effects of Δ^9-THC in the CPP paradigm in Sprague-Dawley rats, and in the dose range of 0.1–3 mg/kg (Scherma et al., 2012).

Valjent and Maldonado (2000) reported Δ^9-THC induced CPP bypassing the dysphoric/aversive effects of Δ^9-THC that has been reported in naive animals, with a priming injection 24 h before the first conditioning session. However, Vlachou et al. (2007), using the same experimental manipulation, did not found CPP with the 1 mg dose of Δ^9-THC. These differences can be explained, in part, by the different strain of animals used, the number of pairings, or the periods of conditioning and administration of the drugs. Although Maldonado's group replicated their findings in a subsequent study (Soria et al., 2004), it is worth noting that they also report conditioned place aversion with the dose of 5 mg/kg of Δ^9-THC.

A number of studies reported clear aversive effects of Δ^9-THC in the CPP paradigm, in rats or mice (Hutcheson et al., 1998; Mallet & Beninger, 1998; Parker & Gillies, 1995; Sanudo-Pena et al., 1997; Vann et al., 2008).

Two studies have investigated whether adolescent rats are more vulnerable to Δ^9-THC than adult rats. Quinn et al. (2008) found that Δ^9-THC (5 mg/kg) produced CPA in adult rats, whereas in adolescent rats there was only a nonsignificant trend toward aversion. Interestingly, the aversive effect reported in adult rats was long-lasting, since the animals still avoided Δ^9-THC paired environment 16 days following the last drug exposure. Surprisingly, in a more recent study in adolescent Wistar rats, although Δ^9-THC (10 mg/kg) did not induce CPP when administered alone, it tended to produce a preference when administered in combination with cannabidiol (Klein et al., 2011). Surprisingly, however, when administered alone, CBD lacks hedonic properties because it does not induce CPP (Parker et al., 2004; Vann et al., 2008) (Table 68.2).

In conclusion, while almost all drugs abused by humans are able to produce a clear and reliable CPP (ie, increase the time spent in the drug paired compartment) over a wide range of doses, results with Δ^9-THC have not always been consistent. The studies reporting a CPP associated with administration of Δ^9-THC have used particular experimental methodology, and the preference often occurs at only a single dose, complicating the interpretation of the results.

Δ^9-THC Physical Dependence and Withdrawal

Although experimental animals treated chronically with most drugs of abuse exhibit typical withdrawal reactions, either following drug cessation or upon the administration of the appropriate receptor antagonist, data on Δ^9-THC are largely controversial. Indeed, several studies failed to report spontaneous withdrawal symptoms following abrupt cessation of chronic Δ^9-THC administration in experimental animals (Aceto et al., 1996; Chesher & Jackson, 1974; Dewey et al., 1972; Diana et al., 1998; Harris et al., 1974; Leite & Carlini, 1974; McMillan et al., 1970). It has been proposed that the main reason for this is the particular pharmacokinetic properties of Δ^9-THC (high lipophilicity, long duration of action, and slow elimination) that may prevent the development of a pronounced withdrawal syndrome, when the drug is abruptly discontinued (Gonzalez et al., 2005). Kaymakcalan et al. (1977) published a paper in which they reported a spontaneous withdrawal reaction after chronic Δ^9-THC treatment. However, the authors treated the rats for 5 weeks with extremely high doses that, in the last 2 weeks, reached 40 mg/kg twice daily.

In spite of the failure to observe clear spontaneous withdrawal reactions following Δ^9-THC cessation, Beardsley et al. (1986) reported a suppression of operant behavior for food reinforcement in monkeys. The authors interpreted this finding as a manifestation of spontaneous withdrawal, since it returned to normal after readministration of the drug. In a latter study, they replicated the same behavioral pattern in rats (Beardsley & Martin, 2000). Similarly, Fredericks and Benowitz (1980) suggested a cannabis abstinence syndrome following cessation of Δ^9-THC in monkeys, with core symptoms being an increased frequency and/or duration of gross movement, eye contact, and tooth bearing. However, these manifestations deviate from the view of the classical withdrawal syndrome observed with other drugs of abuse.

In the absence of a clear spontaneous withdrawal from Δ^9-THC in experimental animals, a number of investigators have tried to demonstrate physical dependence and withdrawal signs by challenging chronically treated animals with a CB_1 receptor antagonist, such as SR141716A. Indeed, administration of the CB_1 receptor antagonist SR141716A in experimental animals chronically treated with Δ^9-THC precipitates specific withdrawal reactions. The signs observed are largely somatic (mainly of motor nature), with no relevant vegetative changes. The most characteristic withdrawal signs are wet-dog shakes, head shakes, facial rubbing, front paw tremor, body tremor, ataxia, eyelid ptosis, piloerection, hyperlocomotion, retropulsion, licking, scratching, and mastication (Aceto et al., 1995; Aceto et al., 1996; Anggadiredja et al., 2003; Gonzalez et al., 2004; Huang et al., 2009; Hutcheson et al., 1998; Ledent et al., 1999; Lichtman et al., 2001; Schlosburg et al., 2009; Soria et al., 2004; Stewart & McMahon, 2010; Tzavara et al., 2000). These somatic signs, even if they appear very mild, are mediated through the CB_1 receptor, since in CB_1 KO mice receiving chronic treatment with Δ^9-THC administration of the CB_1 receptor antagonist SR141716A did not precipitate any signs of abstinence (Ledent et al., 1999). However, the most serious disadvantage of many of the studies cited earlier is that the authors used extremely large doses of Δ^9-THC and/or SR141716A. This may have complicated the obtained results and, thus, the generalizability of much published research on this issue is problematic.

Although most drugs of abuse upon withdrawal after chronic treatment exhibit a clear "anhedonic" state, as reflected in elevated ICSS thresholds (Paterson & Markou, 2007), this has not been investigated properly with Δ^9-THC. Gardner and Vorel (1998) report that "withdrawal from as little as a single 1.0 mg/kg dose of Δ^9-THC produces significant elevations in electrical brain stimulation thresholds." However, one major criticism of this work is that we cannot explain how a single and relatively low dose of Δ^9-THC could produce dependence, so that withdrawal anhedonia can be observed. Since Gardner et al. (1988) adopt in their studies a very strict criterion of stable responding (ie, 0.01 log units for three consecutive days), it is possible that the observed effect of Δ^9-THC in their study could reflect normal baseline variation over days.

In summary, there is no conclusive evidence for a robust spontaneous withdrawal in experimental animals treated chronically with Δ^9-THC. The precipitated withdrawal has been shown using very high doses of Δ^9-THC, which exceed the relevant dose range in human cannabis users.

CONCLUSIONS

From a wide variety of data, it appears that Δ^9-THC activates brain reward circuitry and enhances reward-related behaviors in similar fashion to other drugs of abuse, although the range of conditions under which this occurs is more limited than with drugs such as cocaine, heroin, alcohol, and nicotine. The rewarding properties of Δ^9-THC are clearly shown by a decrease in brain stimulation reward thresholds, and self-administration behavior. However, particular experimental conditions are required to induce Δ^9-THC place preference, and many studies have reported aversive-like responses of Δ^9-THC in the CPP paradigm. Similarly, the doses of Δ^9-THC required to induce physical dependence and withdrawal in experimental animals are very high, and are not comparable with those consumed by humans. Moreover, there is no conclusive evidence for a robust spontaneous withdrawal in experimental animals treated chronically with Δ^9-THC. Thus, withdrawal reactions have been only observed after challenge with the CB_1 receptor antagonist SR141716A. On the other hand, the other major phytocannabinoid, cannabidiol, does not produce rewarding effects in experimental animals, as evident by a lack of effect on the ICSS and the CPP paradigm. Interestingly, cannabidiol exerts a wide range of pharmacological effects, many of which are of potential therapeutic interest, without exerting significant intrinsic activity upon CB_1 receptors. Presumably, for this reason, cannabidiol lacks hedonic properties. In general, these animal behavioral models have provided a better understanding of the rewarding effects of Δ^9-THC, and have revealed commonalities between Δ^9-THC and other drugs of abuse. We believe that more precise examination of the actions of Δ^9-THC in brain areas of the reward circuitry will advance our understanding of the process of drug addiction. On the other hand, cannabidiol which is devoid of Δ^9-THC-like psychoactive effects represents a phytocannabinoid with high potential for therapeutic use.

MINI-DICTIONARY

Antagonist-precipitated withdrawal Withdrawal from long term administration of an addictive drug, caused by the administration of an appropriate antagonistic drug. Precipitated withdrawal is similar to spontaneous withdrawal, but is more intense and has a much faster onset.

Cannabidiol (CBD) A major nonpsychotomimetic constituent of *Cannabis sativa*. It exerts a plethora of pharmacological effects, many of them associated with central actions.

Cannabinoid 1 (CB_1) receptor The most common G-protein coupled receptor in the brain through which Δ^9-THC elicits its psychological effects.

Cannabinoids A class of diverse chemical compounds that bind to cannabinoid receptors.

Cannabis sativa The hemp plant, which is the source of marijuana. It contains over 400 chemical compounds, including about 80 terpenophenols, known as plant cannabinoids (phytocannabinoids).

Conditioned place preference (CPP) paradigm A procedure that assesses an experimental animal's preference for environments (contexts) in which it has previously experienced drug effects. Although this procedure does not directly measure drug reinforcement, it can be used to infer the motivational value of addictive drugs. Thus, CPP produced by a drug indicates that it exhibits rewarding properties, and that it might therefore have abuse potential in humans.

Intracranial self-stimulation (ICSS) paradigm An operant behavioral paradigm in which animals press a lever to administer brief electrical pulses to their own brains. It has been shown that most drugs of abuse are able to lower brain stimulation reward threshold, indicating that they activate the same substrate with electrical stimulation in a synergistic manner.

Physical dependence A state in which the discontinuation of drug taking will induce typical withdrawal reactions.

Self-administration paradigm A behavioral paradigm in which animals are given the opportunity to self-administer a drug intravenously, orally, or intracerebrally, by making an operant response, such as pressing a lever in an operant chamber, or inserting their nose into a hole.

Spontaneous withdrawal A procedure in which the chronic administration of an addictive drug is abruptly discontinued, and the physical signs that emerge are evaluated.

SR141716A (also known as rimonabant) A highly potent and selective CB_1 receptor antagonist that has been used extensively in many studies as pharmacological tool.

Δ^9-Tetrahydrocannabinol (Δ^9-THC) The major psychoactive constituent of the plant *Cannabis sativa* that was isolated in 1964 by Gaoni and Mechoulam.

Withdrawal syndrome The appearance of symptoms opposite to those produced by an addictive drug when the drug is administered repeatedly and then is no longer readministered, or is administered in smaller quantities.

SUMMARY POINTS

- This chapter focuses on cannabinoids as PPARγ ligands.
- Cannabidiol, a nonpsychotropic cannabinoid, is a promising candidate for the management of neuroinflammatory and neurodegenerative diseases.
- Cannabinoids are valid templates for the development of novel chemical entities with superior activities on well-defined molecular targets.
- Oxidation of CBD and CBG leads to the paraquinones HU-311 and VCE-003, respectively.
- HU-311 and VCE-003 bind and activate PPARγ.

KEY FACTS OF CANNABINOIDS

- Plant-derived cannabinoids represent a class of natural products endowed with pleiotropic activities and low toxicological profile.
- Endocannabinoids are produced in the brain and periphery.

KEY FACTS OF PPARγ

- PPARγ is expressed in all type of cells present in the CNS.
- PPARγ is a validated target for the development of novel therapies against neuroinflammatory and neurodegenerative diseases.
- There is evidence showing that cannabinoids exert their bioactivities through PPARγ-dependent and PPARγ-independent mechanisms.

KEY FACTS OF POLYPHARMACOLOGY

- Polypharmacology defines drug molecules interacting with multiple targets.
- Phytocannabinoids are pleiotropic by nature and polypharmacology is behind the benefits of this class of compounds.

KEY FACTS OF BLOOD–BRAIN BARRIER

- Blood–brain barrier is a diffusion barrier, which impedes influx of most compounds from blood to brain.
- Phytocannabinoids such as Δ^9-THC, CBD, and CBG are lipophilic, and penetrate into the brain where they can activate cannabinoid receptors, including PPARγ.

LIST OF ABBREVIATIONS

2-AG	2-Arachidonoylglycerol
AEA	Anandamide
AjA	Ajulemic acid
BBB	Blood–brain barrier
CB 2	Cannabinoid receptors type 1 and 2
CBD	Cannabidiol
CBG	Cannabigerol
EAE	Experimental autoimmune encephalopathy
eCB	Endocannabinoids
IL	Interleukin
NRs	Nuclear receptors
OLs	Oligodendrocytes
PPARs	Peroxisome proliferator activated receptors
ROS	Reactive oxygen species
RXR	Retinoid X receptor
T2D	Type 2 diabetes
Δ^9-THC	Δ^9-Tetrahydrocannabinol
TRP	Transient receptor potential

INTRODUCTION

Cannabinoids and Biological Receptors

Plant-derived cannabinoids (phytocannabinoids) refer to nearly 100 lipid-soluble compounds found exclusively in the plant *Cannabis sativa*, and different plant varieties differ in their content of phytocannabinoids. The two major substances, Δ^9-tetrahydrocannabinol (Δ^9-THC, the main psychoactive ingredient), and cannabidiol (CBD) are derived from the common synthetic precursor cannabigerol (CBG). These plant metabolites are synthesized from fatty acid precursors through metabolic pathways, involving specific transferases and synthases (de Meijer et al., 2003).

The use of *Cannabis sativa* preparations for ceremonial, recreational, and medical use has been common throughout history, but the psychotropic activity of Δ^9-THC has dampened the medical use of *Cannabis* since the early 20th century. Δ^9-THC was isolated, identified, and synthesized in 1964 (Gaoni & Mechoulam, 1964), and, 30-years later, the first cannabinoid receptor (CB), a G-protein coupled receptor named CB_1, was described and cloned from brain tissues (Matsuda, Lolait, Brownstein, Young, & Bonner, 1990). Thereafter, a second cannabinoid receptor, CB_2, was cloned and found to have only a 45% homology to the CB_1 receptor (Munro, Thomas & Abu-Shaar, 1993). These CB receptors are widely distributed throughout mammalian tissue, and early studies have revealed that CB_1 receptors are the most abundant receptors in neural tissue, and responsible for the psychotropic effect of Δ^9-THC and *Cannabis* preparations. CB_2 is considered the peripheral cannabinoid receptor since it is expressed at high concentrations in cells and organs of the immune system (Mackie, 2006). However, evidence of neural CB_2 expression has been emerging only in the past few years, and its functionality is still largely unknown (Atwood, Straiker, & Mackie, 2012).

The cloning and characterization of endogenous CB_1 and CB_2 receptors led to the identification and isolation of the growing family of endogenous ligands collectively named endocannabinoids (eCBs), composed of amides, esters, and ethers of long chain polyunsaturated fatty acids. The first discovered eCBs were anandamide (AEA) and 2-arachidonoylglycerol (2-AG), but other endolipids such as noladin ether, virodhamine, *N*-palmitoylethanolamine (PEA), *N*-oleoylethanolamine, and *N*-arachidonoyl-dopamine are also considered relevant members of the eCBs family (Di Marzo, De Petrocellis, & Bisogno, 2005). eCBs are synthesized upon demand, and bind to and activate their target receptors mediating several biological effects on different tissues. The main target receptors for both phytocannabinoids and eCBs are CB_1 and CB_2, but many other receptors have been identified to respond to them (Pertwee et al., 2010). For instance, the transient receptor potential (TRP) superfamily of cation channels is targeted by different cannabinoids (Pertwee et al., 2010). Phytocannabinoids such as CBD and CBG were shown to act as full agonists of human TRPV1 (De Petrocellis et al., 2011). Recent evidence indicates that both AEA and NADA act as TRPM8 antagonists, while CBD, CBG, and Δ^9-THC were found to activate this receptor (De Petrocellis et al., 2011). In addition, TRPA1 is also activated by phytocannabinoids such as Δ^9-THC, cannabinol, and cannabichromene, as well as synthetic cannabinoids such as AM1231, HU331, and WIN55212 (Jordt et al., 2004; De Petrocellis et al., 2011).

In the past few years, it has been demonstrated that peroxisome proliferator activated receptors (PPARs), a family of nuclear receptors able to regulate lipid turnover and metabolism, are also targeted by cannabinoids of different nature (Pistis & Melis, 2010).

Nuclear Receptors

Nuclear receptors (NRs) comprise a family of 49 members sharing a highly conserved amino-terminal activation domain, a carboxy-terminal ligand binding domain, a zinc-finger DNA-binding domain, and a second activation C-terminal domain. NRs act as ligand-inducible transcription factors, and are classified into two categories (www.nursa.org). Type I NRs include estrogen, glucocorticoid, progesterone, mineralocorticoid, and androgen receptors, which undergo nuclear translocation upon ligand activation, and bind as homodimers to DNA. Type II NRs are localized in the nucleus, and bind to DNA as heterodimers with the retinoid X receptor (RXR). PPARs, thyroid hormone

receptor, liver X receptors and Vitamin D receptors fall into this category (Sladek, 2011).

PPARs

PPARs heterodimerize with RXR, and bind to PPAR responsive element (PPRE) in the regulatory region of target genes that function in diverse biological processes, such as lipid metabolism, insulin sensitivity, cell growth and differentiation, and immune response. They are also the targets of drugs that are effective in the treatment of metabolic syndrome, including insulin resistance, glucose intolerance, obesity, dyslipidemia, hypertension, atherosclerosis, and renal dysfunction (Chen, Jia, & Yang, 2014).

So far, three isoforms of PPARs have been identified, namely PPARα PPARδ (also known as PPARβ), and PPARγ (PPARγ_1 and PPARγ_2), all of which have been treated as attractive targets for developing drugs to treat type 2 diabetes (T2D). Although they share structural similarity, and exhibit high homology in amino acid sequence, the three isoforms are differentially expressed among tissues. In general, PPARα is abundant in the liver, brown adipose tissue, heart, and kidney; PPARγ is highly expressed in the adipose tissue and other tissues, and PPARδ is ubiquitously expressed. Their differential distributions, as well as different affinities to ligands, are attributed to their distinct roles. PPAR ligands vary from endogenous fatty acids such as leukotriene B4, 8-S-hydroxy eicosatetraenoic acid, and prostaglandin J2, to pharmaceutical drugs such as fibrates and thiazolidinediones (TZDs). Lipid-lowering fibrate drugs like clofibrate and fenofibrate have been shown to activate preferentially PPARα, and insulin sensitizers TZDs are selective agonists of PPARγ (Willson, Brown, Sternbach, & Henke, 2000). In addition to the beneficial effects in diabetes, specific PPARγ agonists have also been investigated as a potential therapy against several chronic diseases, such as rheumatoid arthritis, liver fibrosis, inflammatory bowel diseases, neurodegenerative and neuroinflammatory disorders, and some type of cancers (Lehrke & Lazar, 2005).

TZDs such as rosiglitazone and pioglitazone have been largely used so far in clinical practice. They provide similar effects on glycemic control, as well as a range of similar adverse effects, such as weight gain, fluid retention, and increased risk of heart failure, which seem to be PPARγ-mediated. Indeed, rosiglitazone was recently withdrawn in Europe, and its use has been restricted in the United States, as a consequence of increased risk of cardiovascular events in T2D patients.

The development and use of PPAR ligands in the past decades have greatly advanced our understanding of the physiological and pathological role of PPARs, and the therapeutic implication of targeting them. In this sense, although TZDs are potent PPARγ full agonists (PPARγ-fa) their mechanism-based side effects have limited the full therapeutic potential of those compounds (Ciudin, Hernandez, & Simó, 2012). Moreover, the use of TZDs for CNS treatments is also dampened because of their poor blood–brain barrier (BBB) permeability. Nevertheless, the physiologic and therapeutic relevance of the PPARγ pathway has promoted new studies to develop newer classes of molecules that reduce or eliminate adverse effects. Therefore, a lot of progress has been achieved in the discovery and development of selective PPARγ modulators (PPARγ-m), as safer alternatives to PPARγ-fa. This class of compounds can only activate a subset of the functions induced by the cognate ligand, or those that act in a cell-type-selective manner. The preclinical and clinical findings clearly suggest that selective PPARγ-m have the potential to become the next generation of PPARγ agonists: effective insulin sensitizers with a superior safety profile to that of PPARγ-fa (Doshi, Brahma, Bahirat, Dixit, & Nemmani, 2012). In this sense, natural and synthetic cannabinoids are considered PPARγ-m that readily transverse the BBB because of their lipophilicity. Preclinical evidence shows that cannabinoids alleviate neuroinflammatory and neurodegenerative processes through the activation of PPARγ (Fernández-Ruiz et al., 2013).

PPARγ and Neuroinflammation

The immune response evoked during noninfectious CNS diseases such as multiple sclerosis, Alzheimer disease, Parkinson disease, trauma, and ischemia/stroke often leads to the development of neuroinflammatory processes , which in turn, accelerate neurodegeneration in the majority of cases. In the last decade, there have been an increasing number of experimental studies supporting the use of PPARγ ligands to treat major disabling brain diseases.

The therapeutic effects of PPARγ agonists have been tested in many different neuroinflammatory diseases (Heneka & Landreth, 2007). Loss of function of PPARγ results in an exacerbated experimental autoimmune encephalopathy (EAE), with increased CNS inflammation and demyelination in mice (Natarajan, Muthian, Barak, Evans, & Bright, 2003), and treatment with PPARγ agonists such as glitazones and 15d-PGJ2 ameliorates EAE (Storer, Xu, Chavis, & Drew, 2005). On the other hand, PPARγ agonists reduce inflammation and the amyloid burden in animal models of Alzheimer disease (Esposito et al., 2011), regulate the inflammatory response in trauma, and reduce infarct size in animal models (Culman, Zhao, Gohlke, & Herdegen, 2007). Moreover, pioglitazone treatment effectively reduced inflammation, and restored mitochondrial function in different animal models of dopaminergic neurodegeneration (Heneka & Landreth, 2007).

The beneficial effects of PPARγ agonists in brain pathologies are mediated by different mechanisms that

may be disease-specific, and involve both peripheral and central antiinflammatory activities, by affecting crucial functions of peripheral (macrophages and/or lymphocytes) and central immune cells (microglial cells). As well as microglia, PPARγ agonists can act on other neural cell types, including astrocytes, neurons, and oligodendrocytes (Bernardo & Minghetti, 2008). While the exact mechanisms for the antiinflammatory activity of PPARγ agonists are not completely identified, it seems that this mechanism is multifactorial, and involves transcriptional and posttranscriptional mechanisms. In addition, PPARγ agonists inhibit interleukin (IL)-12 induced differentiation of Th1 cells, and alleviate EAE (Bright, Kanakasabai, Chearwae, & Chakraborty, 2008).

Oligodendrocytes (OLs) are the myelin-forming cells of the CNS. Their differentiation from precursor to mature cells occurs through a series of stages that can be defined by morphological and antigenic changes. Although PPARβ/δ has been long considered the PPAR type mainly expressed in OLs, and involved in myelination, recent findings suggest a key role of PPARγ in OL protection and differentiation (Bernardo, Bianchi, Magnaghi, & Minghetti, 2009).

Astrocytes are the most abundant glial cells in the CNS, and are essential to maintain brain homeostasis. In addition, astrocytes also exert important roles in brain inflammation and immunity. Similar to microglia, astrocytes react rapidly to external insults and/or damaging events, and represent an important target for antiinflammatory and neuroprotective therapeutic strategies. In this sense, there is large evidence showing that PPARγ agonists modulate astrocyte functions, and attenuate astrogliosis (Kielian & Drew, 2003; Drew, Xu, Storer, Chavis, & Racke, 2009). For instance, TZD compounds were reported to be neuroprotective in vivo (Luna-Medina et al., 2007). In addition, 15d-PGJ2, a natural ligand of PPARγ, suppresses the release of the proinflammatory cytokine IL-12 in LPS-stimulated astrocytes (Xu & Drew, 2007). In line with the role of PPARγ in regulating cytokines' mediated functions, it has also been observed that troglitazone increases IL-4 expression in glia cells (Loane et al., 2009).

Microglia in the CNS are the major population of brain resident macrophages. In the healthy brain, microglia maintain homeostasis by continuously interacting with the environment. When CNS infection and/or inflammation occurs, microglia respond appropriately by changing their activation state. Microglia exhibit a range of activation states associated with pathogen defense, wound healing, and tissue repair. PPARγ agonists have been extensively studied for their therapeutic potential to prevent the undesired toxic effects of microglial activation (Bright et al., 2008).

Cannabinoids as PPARs Ligands

In this review, we focus on cannabinoid-based PPARγ ligands that have been shown to exert neuroprotective activities. The effects of cannabinoids on other PPARs have been reviewed elsewhere (Mechoulam & Ross, 2010; Pertwee et al., 2010; O'Sullivan, 2007). Thus, a number of cannabinoids and endocannabinoids have been reported to be PPARγ agonists (Table 69.1). In general, the potency of cannabinoids is several orders of magnitude lower at PPARγ than the reference drugs pioglizatone and rosiglitazone, which act at low nanomolar concentrations. In addition, the activity of cannabinoids on PPARγ can be dissected from its ability to bind and activate or inhibit other cell surface receptors, such as CB_1, CB_2, GPR55, and TRPs (Pertwee et al., 2010).

It has been shown that Δ^9-THC binds to PPARγ, and activates its transcriptional activity at relatively high concentrations, compared to those required to activate CB_1 and CB_2 (Granja et al., 2012; O'Sullivan et al., 2005). Δ^9-THC activates PPARγ through CB_1- and CB_2-independent pathways, and causes PPARγ-dependent vasodilatation (O'Sullivan et al., 2005). It has been suggested that this mechanism is mediated by an increase in superoxide dismutase activity that scavenges NO by endogenous superoxides, and also to catalyze the conversion of

superoxides to H_2O_2 (O'Sullivan et al., 2005; O'Sullivan, Kendall, & Randall, 2006). More recently, it has been reported that the PPARγ antagonist GW9662 prevented in vivo the antitumor effect of Δ^9-THC in hepatocarcinoma tumor xenografts (Vara, Morell, Rodríguez-Henche, & Diaz-Laviada, 2013). In the CNS, there is clear evidence that Δ^9-THC mediates neuroprotective effects by acting on CB_1 and PPARγ. For instance, Δ^9-THC showed neuroprotective effects through PPARγ activation in an in vitro model of Parkinson disease, where the CB_1 antagonist AM251 did not block this effect. In contrast, the PPARγ antagonist T0070907 blocked the neuroprotective effects of Δ^9-THC (Carroll, Zeissler, Hanemann, & Zajicek, 2012). Thus, it is possible that the neuroprotective effects of Δ^9-THC may be mediated not only through CB_1 signaling, but also through activation of PPARγ, thereby exemplifying the polypharmacological profile of the major phytocannabinoids.

CBD is a nonpsychotropic component of marijuana that binds to CB_1 receptors with very low affinity. Biochemical studies indicate that CBD may enhance endogenous AEA by inhibiting its intracellular degradation catalyzed by the enzyme fatty acid amide hydrolase (FAAH). However, CBD still remains enigmatic with respect to its precise mode of action. CBD targets PPARγ and some TRPs, and it is also an agonist of the $5\text{-}HT_{1A}$ receptor, as well as an antagonist of the GPR55 receptor (Pertwee et al., 2010). Although the PPARγ binding activity of CBD is relatively weak, with an EC50 ranging from 5 to 20 μM (O'Sullivan & Kendall, 2010; Granja et al., 2012), there is mounting evidence that many biological activities of CBD are mediated through PPARγ. In this sense, it cannot be discarded that CBD metabolites account for the PPARγ-mediated activity of CBD in vivo.

The interest of CBD as a therapeutic option to manage a plethora of different diseases has substantially increased in recent years. Thus, CBD is neuroprotective in rat Alzheimer disease models, and the blockade of PPARγ was able to significantly blunt CBD effects on reactive gliosis and, subsequently, on neuronal damage (Iuvone et al., 2004; Esposito et al., 2011). In the same study, CBD was observed to stimulate hippocampal neurogenesis through a PPARγ-dependent pathway (Iuvone et al., 2004). CBD, as well as Δ^9-THC, also induces adipogenesis, and causes a time-dependent vasorelaxant effect that is partially inhibited by a PPARγ antagonist (O'Sullivan, Sun, Bennett, Randall, & Kendall, 2009).

CBD has been shown to promote proapoptotic effects on different types of tumor cells, and it has been proven to exert antiinvasive and antimetastatic activities (Ramer, Merkord, Rohde, & Hinz, 2010; Ramer et al., 2012). More recently, it has been shown that CBD increases the expression of COX-2 and PPARγ at the protein level, in lung cancer cells, and both proteins converge in a coordinated fashion via activation of PPARγ by the COX-2 derived products PGD_2 and $15d\text{-}PGJ_2$, which in fact, may be responsible for the antitumor activity of CBD (Ramer et al., 2013).

CBG, the precursor of Δ^9-THC and CBD, is another major phytocannabinoid present in some varieties of *Cannabis sativa*. CBG has been less investigated than Δ^9-THC and CBD, but it is also endowed with pleiotropic activities. In vitro studies have revealed that CBG is an α2-adrenoceptor agonist, antagonizes 5HT1A receptor, activates TRPV1, TRPV2, and TRPA1, and is an antagonist of TRPM8 (Russo, 2011). Interestingly, CBG outperforms Δ^9-THC and CBD in the binding to PPARγ, showing an EC50 of 12.7 μM (Granja et al., 2012). However, no direct evidence of the involvement of CBG on PPARγ activation has been investigated in vivo. Several reports have suggested that PPARγ is a potential target for the development of novel anti-Huntington disease drugs. In this sense, we have shown that CBG was neuroprotective in mice intoxicated with 3-nitropropionate, improving motor deficits and preserving striatal neurons, and we also found that CBG partially reversed the downregulation of PPARγ in R6/2 transgenic mice expressing the HD gene with 150 CAG repeats. In the same study, it was shown that CBG activated PPARγ in cultured striatal cells expressing endogenous wild type and mutant huntingtin (Valdeolivas et al., 2014).

There is evidence that agents interacting with the endocannabinoid system in the body can also interact with PPARγ. For instance, CB_1 activation by 2-AG enhances PPARγ expression (Du, Chen, Zhang, & Chen, 2011) and, conversely, PPARγ agonists may enhance the tissue levels of AEA by inhibiting its catabolism (Lenman & Fowler, 2007). It has been described that AEA, as well as some other endocannabinoids, can mediate some of its biological activities through PPARγ signaling. AEA binds to PPARγ, induces its transcriptional activity with an EC50 of 8 μM, and mediates fibroblast differentiation into adipocytes (Bouaboula et al., 2005). In addition, AEA and *N*-arachydonoyl-dopamine cause a PPARγ-dependent mediated vasorelaxation in rat aorta, suggesting that activation of PPARγ in endothelial vascular cells may represent a novel mechanism by which endocannabinoids can regulate the vascular tone (O'Sullivan, Sun, Bennett, Randall, & Kendall, 2009). Palmitoylethanolamide (PEA), another endogenous fatty acid amide, reduces inflammation and pain associated to spinal cord trauma through mechanisms involving both PPARα and PPARγ signaling (Paterniti et al., 2013).

It is well known that PPARγ ligands are endowed with potent antiinflammatory and immunosuppressive activities. Accordingly, in mouse splenocytes, AEA evoked a concentration-dependent inhibition of IL-2 secretion that was blocked by the PPARγ antagonist T0070907 (Rockwell & Kaminski, 2004). In the same sense, 2-AG is metabolized by COX-2 to 15-Deoxy-$\Delta^{12,14}$-prostaglandin J2-glycerol ester that binds to PPARγ, and suppresses

IL-2 gene transcription by targeting the binding of the transcription factor NFAT to the IL-2 gene promoter (Raman, Kaplan, & Kaminski, 2012).

Ajulemic acid (AjA) is a nonpsychotropic analog of the Δ^9-THC metabolite THC-11-oic acid that was described more than 20 years ago (Burstein et al., 1992). AjA has potent analgesic and antiinflammatory activity, acting as a dual agonist for CB_2 and PPARγ. Activation of PPARγ by AjA requires the AF-2 helix of the receptor, suggesting that AjA activates PPARγ through its ligand-dependent AF-2 region and, therefore, AjA binding enables PPARγ to recruit nuclear receptor coactivators (Ambrosio et al., 2007). Phase II clinical trials have shown that AjA is orally available, and was effective in reducing chronic neuropathic pain, compared with placebo, and no major adverse effects were observed (Burstein, 2005). More recently, it has been shown that AjA prevents progression of fibrosis in vivo, and inhibits fibrogenesis in vitro, through a PPARγ-dependent pathway (Gonzalez et al., 2012).

Other synthetic cannabinoids, such as WIN55212-2 and CP55940, are able to activate PPARγ, as measured in reporter gene assays, but the pharmacological significance of these findings remains to be investigated (Pertwee et al., 2010).

Cannabinoid Quinones as a Novel Class of PPARγ Agonists

Hemp tissues have long been known to give a purple color when treated with bases (Beam, 1911). This unique color reaction is at the basis of the Beam test, one of the simplest forensic tests to detect marijuana. The chemistry underlying this color reaction was elucidated by Mechoulam, who, in a seminal work published almost 50 years ago (Mechoulam, Ben-Zvi, & Gaoni, 1968), identified the colored pigment as a mixture of monomeric and dimeric cannabinoid quinols, characterizing the structure of the compounds formed from CBD (Fig. 69.1). Paradoxically, Δ^9-THC and CBN, the psychoactive principles of marijuana, do not give the color reaction, which requires the presence of a resorcinyl moiety with free hydroxyls. Therefore, the Beam test actually detects the presence of the nonpsychotropic cannabinoids typical of fiber hemp, rather than the psychotropic cannabinoids typical of marijuana.

From a mechanistic standpoint, the reaction involves the activation of the resorcinyl system by deprotonation, and then reaction with atmospheric oxygen to form an α-hydroperoxy ketone. The nucleophilic distal hydroperoxyl oxygen next reacts with the keto form of the *p*-enolic hydroxyl, to generate a peroxyhemiacetal, whose fragmentation by cleavage of the weak oxygen–oxygen bond eventually affords the quinol derivative (Fig. 69.2). This mechanism rationalizes the need to have two free phenolic hydroxyls to give the color reaction, the first one being necessary for the activation of the aromatic system by deprotonation, and the second for the tautomerization and the generation of an electrophilic carbonyl sink paralocated to the hydroperoxyl group.

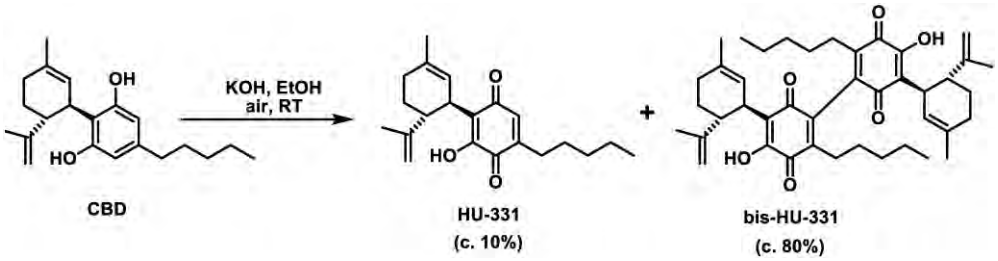

FIGURE 69.1 **Base-catalyzed air oxidation of CBD.**

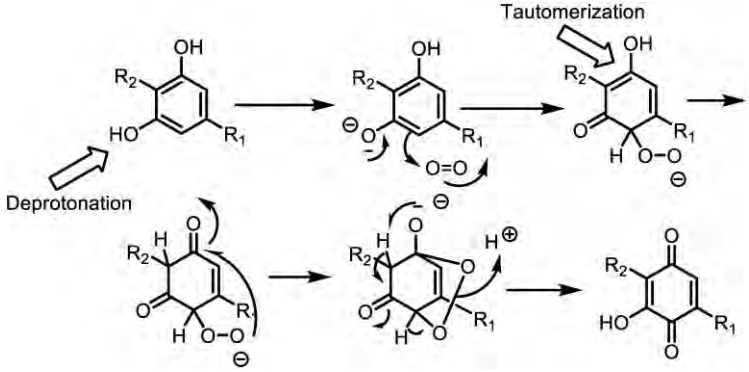

FIGURE 69.2 **Possible mechanism for the formation of quinol cannabinoids by base-promoted air oxidation of cannabinoids (R_1 = pentyl, R_2 = sesquiterpenyl).**

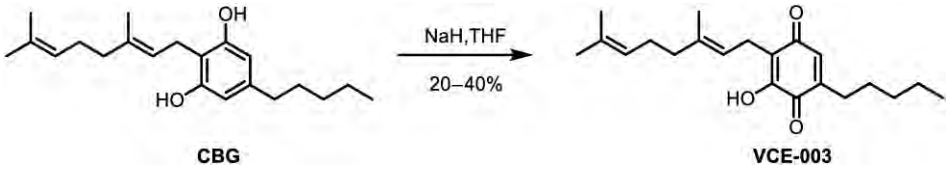

FIGURE 69.3 **Synthesis of VCE-003.**

Despite the forensic relevance of cannabinoid quinones, the biological profile of these compounds has long been overlooked because of the difficulty of their purification, their chemical instability, and uncertainties on their structure, long debated between a *p*- or *o*-quinone nature. Interest in cannabinoid quinols was rekindled in the past decade by Mechoulam, who confirmed their *p*-quinone structure by X-ray, improved their synthesis, and discovered the potent cytotoxic activity of the quinol from CBD, a compound known under the name of HU-331 (Kogan et al., 2004). HU-331 is a selective and potent (nanomolar IC_{50}) inhibitor of DNA topoisomerase II, with antitumor activity (Peters & Kogan, 2007). Interestingly, this compound was described previously to be generated during hepatic microsomal metabolism of CBD, and capable of generating reactive oxygen species (ROS) inducing cell toxicity (Watanabe, Usami, Yamamoto, & Yoshimura, 1991; Usami, Yamamoto, & Watanabe, 2008). We have also found that HU-331 induces ROS and the collapse of mitochondrial membrane potential in human leukemia cell lines (unpublished results).

The quinol derivative denbinobin occurs in some varieties of fiber hemp (Sánchez-Duffhues et al., 2008), but cannabinoid quinols have never been isolated from *Cannabis* plant samples, presumably because of their instability. However, an acetylated form of the quinol of CBG was described from a high-potency marijuana sample (Radwan et al., 2009). This report inspired the synthesis of the quinol of CBG (VCE-003), a compound that was prepared by oxidation of CBG under a variety of basic conditions, as well as with hypervalent iodine reagents (Granja et al., 2012) (Fig. 69.3).

We found that oxidation of CBD and CBG to HU-311 and VCE-003, respectively, greatly enhances its binding activity to PPARγ (Granja et al., 2012). VCE-003 has potent immunosuppressive activities by targeting both PPARγ and CB_2, and ameliorates the neurological defects and the severity of MOG-induced EAE in mice (Carrillo-Salinas et al., 2014). Regarding structure–activity relationships, the quinol hydroxyl is critical for activity, since its methylation or acetylation gave substantially inactive analogs (unpublished results).

More recently, a class of CBD quinones, chromenopyrazolediones, inspired by HU-345, have also been described and shown to exert antitumor activity on prostate cancer cells, and on tumor xenografts (Morales et al., 2013). In the same study, it was shown that chromenopyrazolediones 4 inhibits cell viability through a mechanism involving ROS generation and PPARγ activation.

MINI-DICTIONARY

Cannabinoids A complex group of lipophilic molecules that comprise phytocannabinoids, endocannabinoids, and synthetic cannabinoids.
Endocannabinoids A class of lipid mediators that are essential to maintain the homeostasis of the endocannabinoid system.
Nuclear receptors A superfamily of protein hormones that serve as transcription factors.
Peroxisome proliferator activated receptors A family of nuclear receptors able to regulate lipid turnover and metabolism. They have a role in the resolution of inflammatory processes.
Phytocannabinoids Defined as the terpenophenolic constituents of *Cannabis sativa* L.
PPARγ ligands Small molecules that bind and activate the nuclear receptor PPARγ
Thiazolidinediones (glitazones) Potent PPARγ agonists used in the treatment of diabetes.
TRP receptors Transient receptor potential multigene superfamily encoding integral membrane proteins that function as ion channels.

The Protein–Protein Interactions of Cannabinoid Receptor Interacting Protein 1a (CRIP1a) and Cannabinoid 1 Receptor: The Molecular Mechanism Study Through an Integrated Molecular Modeling Approach

M.H. Ahmed, Y. Zhang

Department of Medicinal Chemistry, School of Pharmacy and Institute for Structural Biology and Drug Discovery, Virginia Commonwealth University, Richmond, VA, United States

SUMMARY POINTS

- This chapter focuses on developing an atomic model for the interaction between cannabinoid receptor interacting protein 1a (CRIP1a) and the cannabinoid type-1 receptor (CB_1R).
- CRIP1a was experimentally shown to bind to, and decrease, the constitutive activity of CB_1R.
- Unfortunately, there is no experimental data for the details of how that interaction occurs.
- Molecular modeling offers valuable information that might explain the molecular mechanism of that interaction.
- The primary sequence of CRIP1a was used to generate a three-dimensional (3D) model that was subsequently used to dock the C-terminus of CB_1R, in order to construct a model of CRIP1a–CB_1R interaction.
- Several computational techniques were used during the process, most importantly: homology-modeling, protein threading, and ab initio, for construction of the CRIP1a model, followed by protein–protein docking to the CB_1R C-terminus and, finally, molecular dynamics for model refinement.
- The model suggests several putative key interactions that might contribute to the experimentally observed CRIP1a–CB_1R interaction.
- This model may be useful to guide future site directed mutagenesis, and to improve the crystallization process of CRIP1a protein.

KEY FACTS OF CANNABINOID RECEPTOR INTERACTING PROTEINS

- Cannabinoid receptor interacting proteins is a family of two structurally related proteins: CRIP1a and CRIP1b.
- They were first discovered by Niehaus et al. (2007).
- CRIP1a and CRIP1b are generated by alternative splicing of the *Cnrip1* gene located on chromosome 2 in humans.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00081-8
2017 Published by Elsevier Inc.

- CRIP1a is a protein 164 amino acids long, while CRIP1b is 128.
- Orthologs of CRIP1a occur throughout the vertebrates, while CRIP1b is unique to primates.
- Both proteins bind to the C-terminus of cannabinoid type-1 receptor.

KEY FACTS OF HOMOLOGY MODELING

- Also known as comparative modeling of protein, referring to a computational method for the construction of a 3D atomic-resolution model of a protein.
- Homology modeling relies on the concept that similar amino acid sequences adopt similar protein structures.
- An experimental 3D structure of a related homologous protein (template) to the target protein is required for this process.
- Homologous proteins (templates) are identified by having an amino acid sequence identity of at least 20% to the target protein.
- A sequence alignment between the template's and the target's amino acid sequences is produced that maps residues in the target's sequence to residues in the template's sequence, which is subsequently used for the actual model construction of the target protein.

KEY FACTS OF PROTEIN THREADING

- Also known as fold recognition, referring to a computational method for the construction of a 3D atomic-resolution model of a protein.
- This method is used for proteins that do not have homologous proteins (templates) with known structure.
- Protein threading relies on two concepts: (1) many unrelated sequences fold into similar structures, and (2) there is only a relatively small number of unique structural folds, when compared with the number of proteins in nature.
- An experimental 3D structure of a protein (template) of the same fold as the target protein is required for this process, regardless of their sequence identities.
- Protein threading relies on using statistical knowledge to analyze the relationship between the currently available experimentally determined 3D protein structures (potential templates) and the sequence of the protein in question (target).
- The 3D model of the target protein is constructed by threading each amino acid in the target sequence to a position in the template structure, and assessing how well the target fits the template.
- After selecting the best-fit template, the actual model of the target protein is constructed, based on its sequence alignment with the chosen template.

KEY FACTS OF PROTEIN–PROTEIN DOCKING

- Protein–protein docking is the computational modeling of the 3D structure of complexes formed by two or more interacting proteins.
- The 3D structures of the interacting proteins are used to produce plausible candidate structures that are subsequently ranked using scoring functions to identify structures most likely to occur in nature.
- The term "docking" originated in the late 1970s, a period that witnessed the development of scoring functions that were able to discriminate between good and bad candidate protein–protein interaction models, as well as the first computational attempts to predict protein–protein complexes' 3D structures.
- Protein–protein docking can be broadly categorized into rigid-body docking and flexible docking.
- Rigid-body docking is carried out with all bond angles, bond lengths, and torsion angles of the interacting proteins fixed, which is sometimes inadequate. However, it is computationally fast.
- Flexible docking permits conformational change by intelligently selecting a small subset of possible conformational changes of the interacting proteins for docking calculations, which is computationally expensive. However, it is more accurate than rigid-body docking.

KEY FACTS OF THE HINT FORCE FIELD

- HINT is short for hydropathic interactions.
- HINT is a novel empirical molecular modeling system with new methods for de novo drug design, and protein or nucleic acid structural analysis.
- HINT is being developed by Dr Glen Kellogg of the Medicinal Chemistry Department at Virginia Commonwealth University in Richmond, USA.
- HINT translates the well-developed Medicinal Chemistry and QSAR formalism of LogP and hydrophobicity into a free energy interaction model for all biomolecular systems, based on the experimental data from solvent partitioning.
- The partition coefficient (LogP) is a thermodynamic parameter that, because of its unprocessed and unbiased experimental nature, encodes all noncovalent interactions in the biological environment, as well as solvent effects, and entropy.

LIST OF ABBREVIATIONS

CB_1R	Cannabinoid type-1 receptor
CB_2R	Cannabinoid type-2 receptor
Cnrip1	Cannabinoid receptor interacting protein gene
CRIP1a	Cannabinoid receptor interacting protein 1a
CRIP1b	Cannabinoid receptor interacting protein 1b
HINT	Hydropathic interactions
MD	Molecular dynamics

INTRODUCTION

Ever since their discovery in the mid-1980s, cannabinoid receptors have been receiving increasing attention due to the fact that their roles in an expanding array of vital human physiological processes are elucidated. For example, regulation of motivation, motor function, memory, appetite, energy homeostasis, pain perception, immune function, gastrointestinal and cardiovascular function, and bone mass maintenance have all been attributed to cannabinoid receptors. Most notably, cannabinoid type-1 receptor (CB_1R) signaling and regulation have been implicated in a wide range of diseases, including substance abuse disorders (as the major targets of Δ^9-tetrahydrocannabinol, the main psychoactive constituent in marijuana) and neurodegenerative diseases such as Parkinson, Alzheimer, Huntington diseases, cancer, obesity, inflammatory bowel disease, and neuropathic and inflammatory pain (Lee, Choi, & Pak, 2009; Miller & Devi, 2011; Oesch & Gertsch, 2009; Thakur, Tichkule, Bajaj, & Makriyannis, 2009).

The CB_1R signals mainly through the activation of $G_{i/o}$ proteins family, which inhibits adenylyl cyclases, and regulates ion channels, including calcium and potassium channels (Hudson, Hébert, & Kelly, 2010). Evidence also exists that, in certain cell types, CB_1Rs can stimulate adenylyl cyclase via G_s, which can induce receptor-mediated Ca^{2+} fluxes, and stimulate phospholipases (Turu & Hunyady, 2010). Moreover, stimulation of CB_1Rs results in the phosphorylation and activation of mitogen-activated protein kinases (MAPKs) that regulate nuclear transcription factors (Howlett, 2005). In recent years, it has become evident that CB_1Rs also interact with various non-G protein GPCR-interacting proteins that can modulate CB_1R function (Smith, Sim-Selley, & Selley, 2010). In addition, CB_1Rs have the ability to form homo- and heterodimers/oligomers, resulting in altered pharmacological properties, which might contribute to the diverse pharmacological effects of cannabinoids observed in various tissues (Turu & Hunyady, 2010). However, one mechanism that appears to be unique to CB_1Rs is related to their binding to CRIP1a and CRIP1b, the cannabinoid receptor interacting proteins (Niehaus et al., 2007).

CRIP1a/b are globular proteins first discovered by the Lewis group, when they observed that the deletion of the CB_1R C-terminus resulted in delaying the time required to peak Ca^{2+} current inhibition, augmented the tonic CB_1R-mediated inhibition of Ca^{2+} currents, and promoted the ability of CB_1R to sequester G-proteins (Nie & Lewis, 2001a,b). These findings suggested that the C-terminal tail could be serving as an autoinhibitor. Searching for additional proteins that might be involved in regulating CB_1R activity, they used the CB_1R distal C-terminus as bait in a yeast two-hybrid screen, and identified two proteins: CRIP1a and CRIP1b. Later, CRIP1a was shown to bind to a GST-labeled CB_1R-C-terminal tail fusion protein and to coimmunoprecipitate with CB_1R, although no interaction of CRIP1a with the CB_2R has been observed (Niehaus et al., 2007).

CRIP1a and CRIP1b are generated by alternative splicing of the *Cnrip1* gene, located on chromosome 2 in humans (Niehaus et al., 2007). CRIP1a is most highly expressed in the brain, and its homologs are found throughout the vertebrates. Interestingly, CRIP1a was shown to selectively reverse basal, but not CB_1R agonist-induced, inhibition of voltage-gated Ca^{2+} channels when cotransfected with CB_1R in superior cervical ganglion neurons, which suggests that CRIP1a inhibits constitutive CB_1R activity (Niehaus et al., 2007). Supporting this interpretation, the ability of the CB_1R inverse agonist rimonabant (SR141716A) to stimulate basal Ca^{2+} channel activity in CB_1R-transfected neurons was eliminated by coexpression of CRIP1a (Niehaus et al., 2007).

Interestingly, CRIP1a possesses a palmitoylation site and a C-terminus PDZ class I ligand domain (Niehaus et al., 2007; Howlett, Blume, & Dalton, 2010; Smith et al., 2010). The palmitoylation site may play a role in localizing CRIP1a to the plasma membrane (Niehaus et al., 2007). The PDZ ligand domain may play several roles: (1) allowing CRIP1a to interact with other proteins, act as a scaffolding site, and/or enabling the formation of heterodimers between CB_1Rs and other receptors; and (2) potentially modulating the localization, desensitization, or internalization of CB_1Rs (Howlett et al., 2010; Smith et al., 2010).

CRIP1a may also be involved in the balance between neuroprotection and degeneration. Katona's group employed quantitative PCR to compare the levels of CB_1R and CRIP1a mRNA in epileptic and healthy post-mortem human hippocampal tissue. Reduced levels of both CRIP1a and CB_1R mRNA were found in sclerotic hippocampi (Ludányi et al., 2008). Alternatively, CRIP1a mRNA was found to be elevated following kainic

acid–induced seizures in rats (Bojnik et al., 2012). Both reports suggest that CRIP1a plays a role in modulating CB_1R function in the pathogenesis or neuroadaptive response to epilepsy. Moreover, in a model of glutamate excitoxicity in cultured cortical neurons, virally mediated expression of CRIP1a inhibited the protective effects of a cannabinoid agonist while conferring a protective effect to an antagonist (Stauffer et al., 2011). In addition to its putative roles in the brain, CRIP1a is presynaptically expressed along with CB_1Rs in the retina, and the *Cnrip1* gene exhibits hypermethylation in a subset of colorectal carcinomas and adenomas (Hu et al., 2010; Lind et al., 2011; Oster et al., 2011).

While none are definitive, the previously mentioned findings suggest potentially important functions of CRIP1a in multiple physiological systems, yet very little is known about the exact mechanisms by which CRIP1a binds to the CB_1R, which is crucial to understanding its regulation of CB_1R signaling. In this chapter, we apply a palette of complementary computational techniques, including homology modeling, ab initio, and protein threading, to generate all-atom molecular models for CRIP1a. Then, using protein–protein docking methods, the resulting CRIP1a model is docked to the C-terminus of the CB_1R, and further refined by means of molecular dynamics to generate a model for the CRIP1a–CB_1R interaction.

Using the CRIP1a amino acid sequence, the secondary structure pattern of CRIP1a was predicted. Then, three different methods were used to build 3D models for CRIP1a (homology modeling, ab initio, and protein threading). Hydrogen atoms were added to the CRIP1a models followed by energy minimization. Next, all models were evaluated with multiple scoring paradigms, and compared against the predicted secondary structure patter, in order to choose the best model to carry forward into succeeding stages. The best model for CRIP1a was then docked to the C-terminus of the CB_1R. The protein–protein complex model was then refined and optimized. The final stage was to subject the model to a 10 ns all-atom molecular dynamics simulation in explicit solvent, for further refinement.

CRIP1A SECONDARY STRUCTURE PREDICATION

CRIP1a secondary structure pattern was predicted using the amino acid primary sequence by different algorithms available in the GeneSilico Metaserver (Kurowski & Bujnicki, 2003), which provides a consensus secondary structure. Predictions by the majority of algorithms suggest that CRIP1a is composed almost exclusively of β-sheets and loops, which make CRIP1a a member of all β proteins class (data not shown). This was supported by the prediction of CRIP1a structural class and fold type using the 1D protein structure prediction software from Kurgan's lab (Chen, Kurgan, & Ruan, 2008) that predicts structural class and fold type information from the primary sequence of a protein; it also predicted CRIP1a is of the concanavalin A-like lectins/glucanases all β strands sandwich fold.

CRIP1A 3D STRUCTURE PREDICTION

Several algorithms available in the GeneSilico Metaserver (Kurowski & Bujnicki, 2003) were used for identifying templates suitable for homology modeling of CRIP1a, in addition to BLAST (Altschul et al., 1997). However, all such identified protein templates were of low homology, relative to CRIP1a (data not shown). For the prediction of distant homologs, protein threading algorithms were used, which are pDomTHREADER (Lobley, Sadowski, & Jones, 2009), I-TASSER (Roy, Kucukural, & Zhang, 2010), RaptorX (Källberg et al., 2012), LOMETS (Local Meta-Threading-Server) (Wu & Zhang, 2007); and MUSTER (Multi-Sources Threader) (Wu & Zhang, 2008), in addition to the algorithms available in the GeneSilico Metaserver (Kurowski & Bujnicki, 2003). These methods yielded 111 different sequence alignments of 74 different protein chains. Each algorithm has its own scoring method, so it is difficult to compare the results directly. However, it was clear that most of the generated alignments were in the low range of their respective algorithm's scoring scales. Only pDomTHREADER, an algorithm generally regarded as precise and sensitive in discriminating superfamilies, yielded two alignments in the high range. pDomTHREADER combines information from both sequence and structure to produce domain alignments. The highest scoring alignment thus produced was for PDB ID 1DS6 Chain B, (human Rho-specific guanine nucleotide dissociation inhibitor 2, RhoGDI 2), which covers amino acids 1–152 of CRIP1a's 164 amino acids, that is, all but the last of CRIP1a's β-sheet (see Fig. 70.1).

RhoGDI is also an all β protein of sandwich fold type that plays an important role in G-protein coupled receptor (GPCR) signaling, including that of CB_1R (Dovas & Couchman, 2005). The pDomTHREADER analysis also suggested CRIP1a to be somewhat homologous to RhoGDI 1, implying the possibility of CRIP1a sharing a similar function with the RhoGDIs. RhoGDI decreases the activity of Rho by preventing guanine nucleotide exchange, and membrane association. RhoGDI may also act as a positive regulator for Rho activities by providing spatial restriction, guidance, and availability signals to effectors, functions that are essential for the correct targeting and regulation of these effectors (Dovas & Couchman, 2005). RhoGDI 2 has an identity of 15.9%

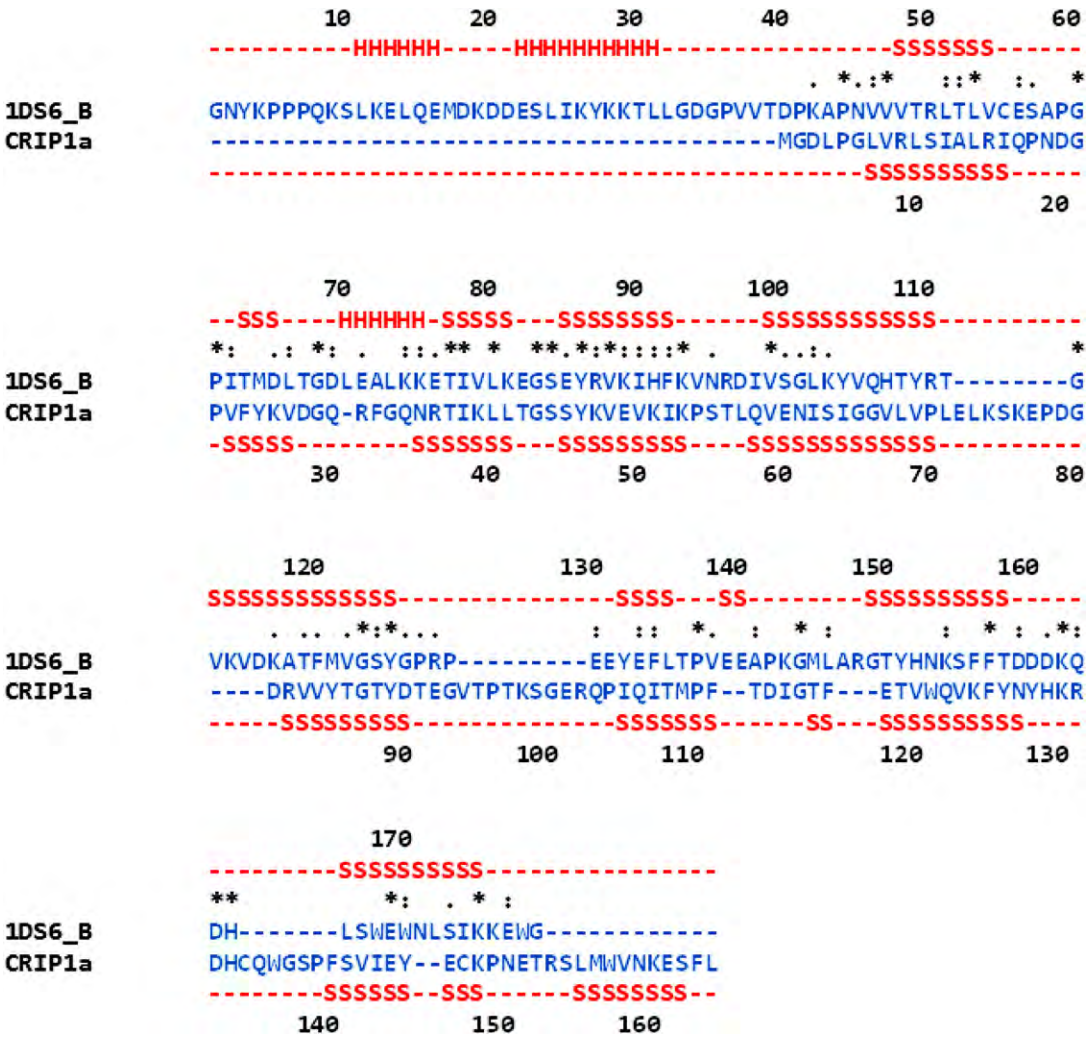

FIGURE 70.1 **CRIP1a and RhoGDI 2 sequence alignment.** RhoGDI 2 (PDB ID 1DS6 chain B) was the best-found scoring template. The RhoGDI 2 secondary structure and the predicted (consensus) secondary structure for CRIP1a are shown in *red*, above and below the sequence alignment, respectively. *S*, β-Sheet; *H*, α-helix; and –, unordered.

to the CRIP1a sequence, which is quite low; however, pDomTHREADER (Lobley et al., 2009) uses the primary sequence of a protein to infer distant relationships to other protein families that are not detectable by simple percentage identity. These relationships often suggest common function, and can often provide templates for the construction of high quality 3D structural models.

While other alignments with higher percentage identity were found, they had low scores, and did not cover as large a fraction of the CRIP1a sequence. For example, 1AOZ (ascorbate oxidase) chain A, and 1AYO (alpha 2-macroglobulin) chain A both have 20% identity with CRIP1a. Their alignment scores, however, were lower than that of RhoGDI 2, and did not provide templates for several of CRIP1a's β-sheets.

Based on the produced alignments, we used MODELLER to generate CRIP1a models, and ranked them according to the DOPE score (Shen & Sali, 2006). The highest scoring model was that based on the RhoGDI 2 template (Fig. 70.2A). The constructed model for CRIP1a follows the predicted secondary structure; however, residues 153–162 were removed, since they exceeded the extents of the template. Thus, to produce a complete model, residues 153–162 were remodeled using the next best scoring template—fibrinogen-binding protein SdrG (PDB ID 1R17) chain B. After energy minimizing and scoring this model, it had the highest score of all generated models (Fig. 70.2B). To ensure no major modeling defects, a Ramachandran plot was generated by MOLPROBITY (Chen et al., 2010) for the model, and was found to be within the acceptable limits (Fig. 70.2C).

The QUARK algorithm for ab initio protein folding and structure prediction (Xu & Zhang, 2012) was used to generate models using replica-exchange Monte Carlo simulation, guided by an atomic-level knowledge-based

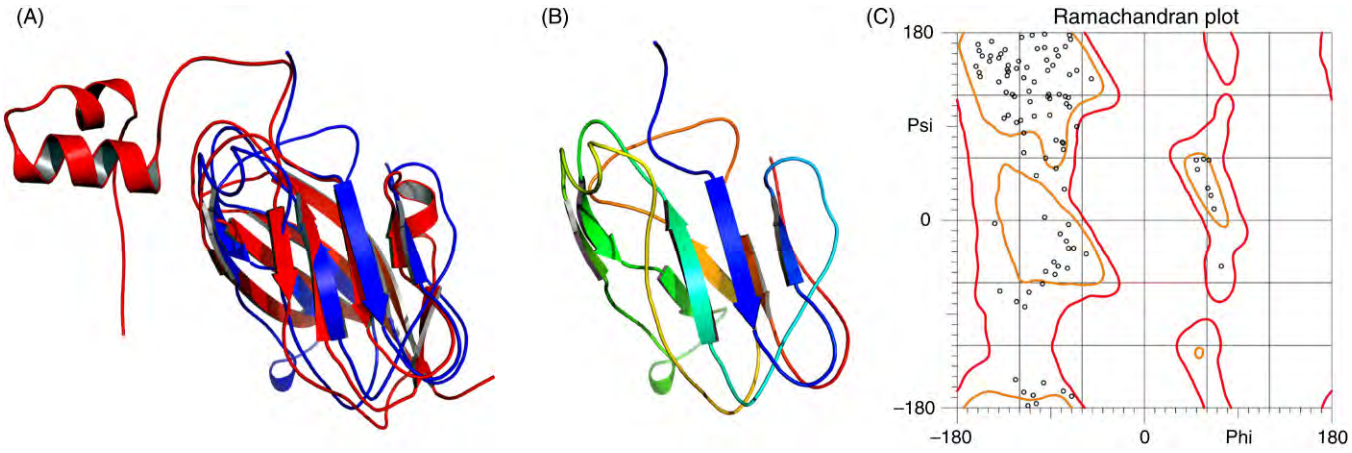

FIGURE 70.2 **CRIP1a protein threading based model.** CRIP1a generated model based on RhoGDI 2 (PDB ID 1DS6 chain B). (A) Superimposition of backbone atoms of CRIP1a model *(blue)* and the RhoGDI 2 crystal structure *(red)*. (B) 3D structure constructed for CRIP1a colored as a rainbow, starting from the N-terminus *(blue)* and ending with the C-terminus *(red)*. (C) Ramachandran plot for the full CRIP1a model and, as can be seen, all of the residues are within the allowed regions of the plot.

force field. Furthermore, hybrid methods combining ab initio with other techniques were used: Bhageerath (incorporating bioinformatics tools) (Jayaram et al., 2006) and Robetta's algorithm (incorporating comparative models of protein domains) (Chivian et al., 2003).

The various models generated by ab initio methods, all of which were β proteins, were evaluated using the DOPE method. The DOPE score of a protein can be viewed as a conformational energy that measures the relative stability of a conformation with respect to other conformations of the same protein. It can be used to choose the best model out of a set of predicted model structures for a particular protein sequence. Because the DOPE energy (Shen & Sali, 2006) is not normalized based on the size of the protein, the absolute score for a protein is not meaningful, but the *relative* energies of different conformations are useful in model evaluation. According to DOPE scoring, models built using ab initio methods were found to have high scores (data not shown); however, none of them had a score better than the model generated using RhoGDI 2 as a template. It is interesting to note that the hybrid bioinformatics/ab initio Bhageerath algorithm generated the best scoring model of this set.

CB_1R C-TERMINUS MODELING

According to Niehaus et al. (2007), the last nine amino acids on the C-terminus of CB_1R are the minimum residues required for CRIP1a binding (Niehaus et al., 2007). PEP-FOLD, which is a de novo approach for prediction of peptide structures from amino acid sequences (Beaufays, Lins, Thomas, & Brasseur, 2012), was used to build the 3D structure of this nine amino acid peptide.

CRIP1A–CB_1R PROTEIN–PROTEIN DOCKING

Protein–protein docking was performed using the HADDOCK (High Ambiguity Driven DOCKing) algorithm (de Vries, van Dijk, & Bonvin, 2010). The site on CRIP1a where the CB_1R C-terminus binds is unknown, so this nine amino acid peptide was docked to all possible sites encompassing amino acids 34–110 of CRIP1a. This range was chosen because these amino acids are common between CRIP1a and CRIP1b, and thus most likely critical for CB_1R binding (Niehaus et al., 2007). Docking results were individually inspected, after which high scoring models were passed into the refinement step.

All docked poses were refined with FireDock (Fast Interaction Refinement in a molecular Docking) (Mashiach, Schneidman-Duhovny, Andrusier, Nussinov, & Wolfson, 2008) algorithm, and then rescored using the HINT force field (Kellogg & Abraham, 2000; Sarkar & Kellogg, 2010) that describes and quantifies all interactions in the biological environment by exploiting the interaction information implicit in $LogP_{o/w}$ (the partition coefficient for 1-octanol/water solute transfer). HINT is known as a "natural" force field because it is based on empirical energetic terms defined by real experiments, and thus encodes interaction types including Coulombic, hydrogen bond, and hydrophobic interactions expected to be found between molecules in the biological environment. It is a free energy force field that includes solvation/desolvation and entropy, in addition to the other enthalpic terms.

The best scoring CRIP1a–CB_1R model according to HINT is shown in Fig. 70.3. The nine amino acids of the CB_1R C-terminus are mostly polar; therefore, polar interactions are the dominant type of interaction between

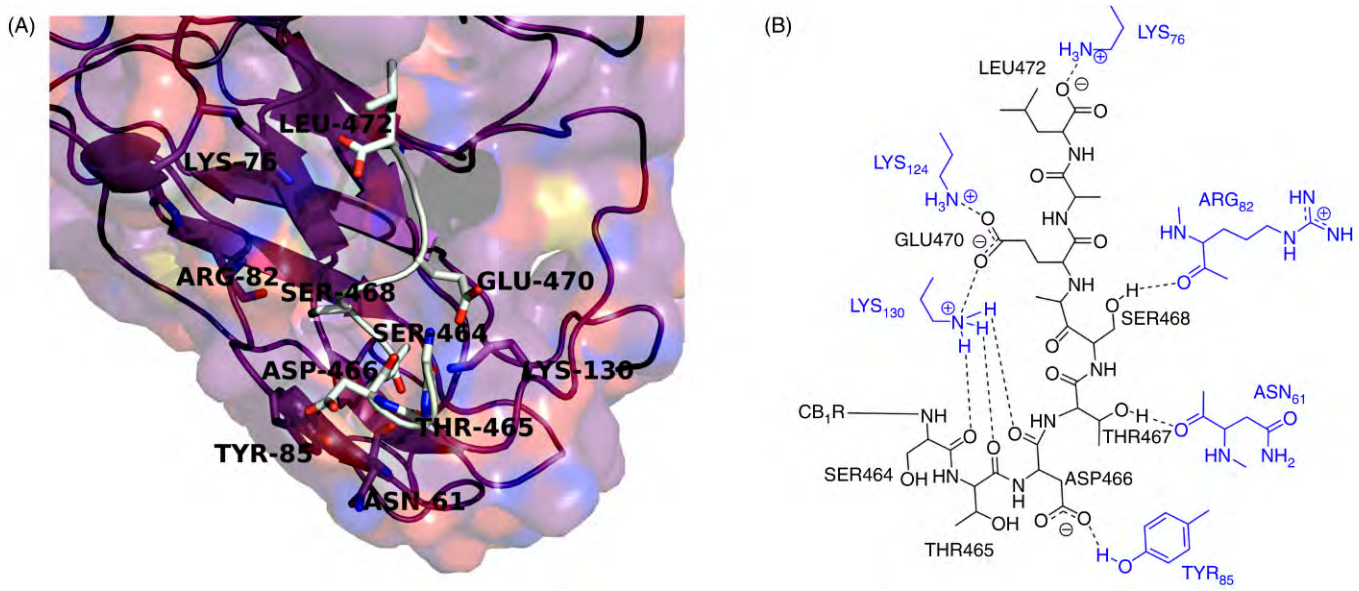

FIGURE 70.3 **Key interactions between the CB_1R and CRIP1a, as predicted by the model.** (A) Model showing CRIP1a *(purple)* bound to C-terminus of CB_1R *(gray)*. (B) 2D representation of the key interactions between CRIP1a *(blue)* and the C-terminus of CB_1R *(black)*.

CRIP1a and CB_1R. Most notably, the model suggests that hydrogen bonds are formed between the CB_1R backbone carbonyl oxygens of Ser464 and Thr465 and Asp466, with the terminal amine in Lys130 from CRIP1a, between one of the CB_1R carboxyl oxygens of Asp466 and the phenolic oxygen of Tyr85 from CRIP1a, and between the Thr467 hydroxyl group from CB_1R and the backbone carbonyl oxygen of Asn61 from CRIP1a. The model suggests that Lys130 from CRIP1a has a quite significant role in the interaction between CRIP1a and CB_1R (Fig. 70.3). In addition, there are some hydrophobic interactions, for example, between Val67 from CRIP1a and Ala471 from CB_1R.

The electrostatic properties of the CRIP1a–CB_1R complex interface was evaluated using Adaptive Poisson–Boltzmann Solver (APBS) tools plug-in developed by Lerner & Carlson from the University of Michigan, Ann Arbor for PyMOL. This tool uses APBS to solve the Poisson–Boltzmann equation (PBE) to assess electrostatic properties (Baker, Sept, Joseph, Holst, & McCammon, 2001). All images were created using the PyMOL Molecular Graphics System, Version 1.2r3pre, from Schrödinger, LLC. As can be seen in Fig. 70.4, the electrostatic complementarity analysis reveals the high complementarity in both CRIP1a and CB_1R interfaces.

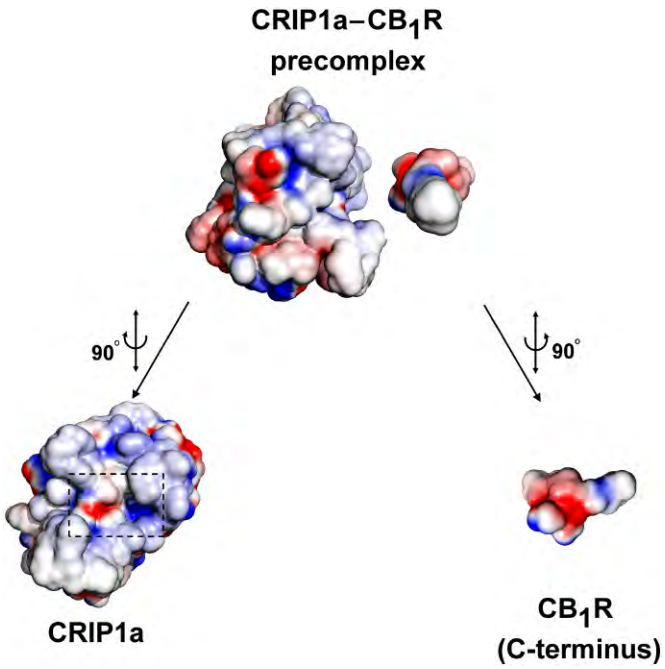

FIGURE 70.4 **Complementarity of electrostatic potentials at the interface of the predicted CRIP1a–CB_1R complex.** In the top middle, CRIP1a and CB_1R C-terminus are aligned in a precomplex position to better show the spatial complementarity of electrostatic potentials of the molecules. Positive potential is shown as *blue*, and negative potential is shown as *red*. Bottom left, CRIP1a is shown; the CB_1R binding site is enclosed in a *back dashed rectangle*. Bottom right, the binding interface of the C-terminus of CB_1R is shown. It can be clearly seen the complementarity of electrostatic potentials at the interface of the complex, as the area of the positive potential *(blue)* on CRIP1a faces the negative potential *(red)* on CB_1R C-terminus, and vice versa.

MOLECULAR DYNAMICS

The CRIP1a–CB_1R complex 3D model was further refined by subjecting it to an all-atom Molecular Dynamics (MD) simulation. MD simulations were carried out

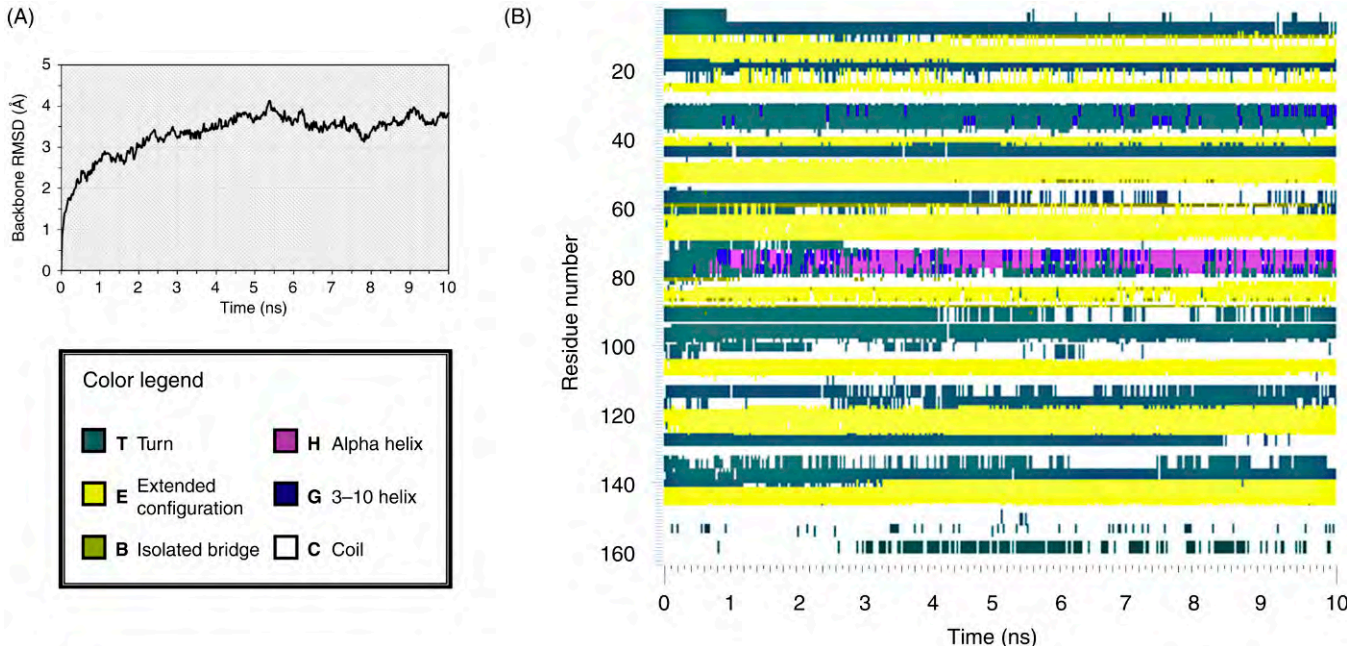

FIGURE 70.5 **Structural analysis of the MD trajectory.** (A) The root mean square deviation of atomic positions (RMSD) plot of the MD trajectory, as can be seen a rapid increase occurs during the first 2 ns, and then the RMSD levels off and becomes stable for the remainder of the simulation. (B) The change in secondary structure of CRIP1a throughout the MD simulation [generated by the Timeline Plugin, Version 2.3. in VMD (Humphrey et al., 1996)].

with the NAMD 2.8 package developed by the Theoretical and Computational Biophysics Group in the Beckman Institute for Advanced Science and Technology at the University of Illinois at Urbana-Champaign (Phillips et al., 2005). CHARMM (Charmm-27) was used as the force field (MacKerell et al., 1998). The initial MD setup was done using the MDWeb's (Hospital et al., 2012) "NAMD FULL MD Setup" workflow. The CRIP1a–CB_1R complex 3D model was first solvated in an equilibrated TIP3P water box with the dimensions of 91.8 Å × 81.8 Å × 73.8 Å, using the center of mass of the complex as the origin. Then Cl^- and Na^+ ions were added to neutralize the system, and appropriate amounts of ions were added up to a concentration of 50 mM. Solvent molecules were first minimized for 500 steps of conjugate gradients minimization method, keeping the protein molecules fixed to allow favorable distribution of water molecules on the complex surface. Subsequently, the system was coupled to a heat bath from 0 to 300 K, and the constraints applied to the solute atoms were gradually decreased, after which the system was allowed to be simulated without restraints for over a period of 10 ps. Finally, a 10 ns molecular dynamics production phase was carried out on the entire system. The analysis of the MD trajectory was done in VMD (Humphrey, Dalke, & Schulten, 1996).

To obtain an estimate of the MD trajectory quality and convergence, the backbone root mean square deviation (RMSD) values relative to the starting structures were plotted as shown in Fig. 70.5A. This analysis shows that, after a rapid increase in RMSD during the first two ns, the trajectory is stabilized with average RMSD values of 3.56 ± 0.21 Å. This suggests that the protein was undergoing modest equilibration in the first two ns of the production phase. The secondary structure of CRIP1a was examined to characterize any instabilities or conformational changes during the MD simulation. Throughout the entirety of the 10 ns simulation, CRIP1a's extended β-sheets were found to be well maintained (Fig. 70.5B). Amino acids 30–35 were alternating between a 3–10 helix, (which matches the secondary structure of the same aligned area in the template, Fig. 70.1) and a turn. Amino acids 73–76, corresponding to a gap in the template in the original sequence alignment (Fig. 70.1), were changed from a turn to an α-helix by the end of the simulation. The rest of the amino acids, which were originally involved in loops, were alternating between pure coils and turns. The binding region of the CB_1R C-terminus was highly maintained throughout the simulation.

As indicated by the root mean square fluctuation (RMSF) calculated over the entire simulation (Fig. 70.6B), the most flexible regions of CRIP1a correspond to the N-terminus (residues 1–5), the A-loop (residues 15–23), the B-loop (residues 68–80), the C-loop (residues 95–100), and the C-terminus (residues 148–160). All these regions correspond to the amino acids that alternate between a pure coil and a turn, with the exception of the B-loop, which changed from a turn to an α-helix. Crystallization

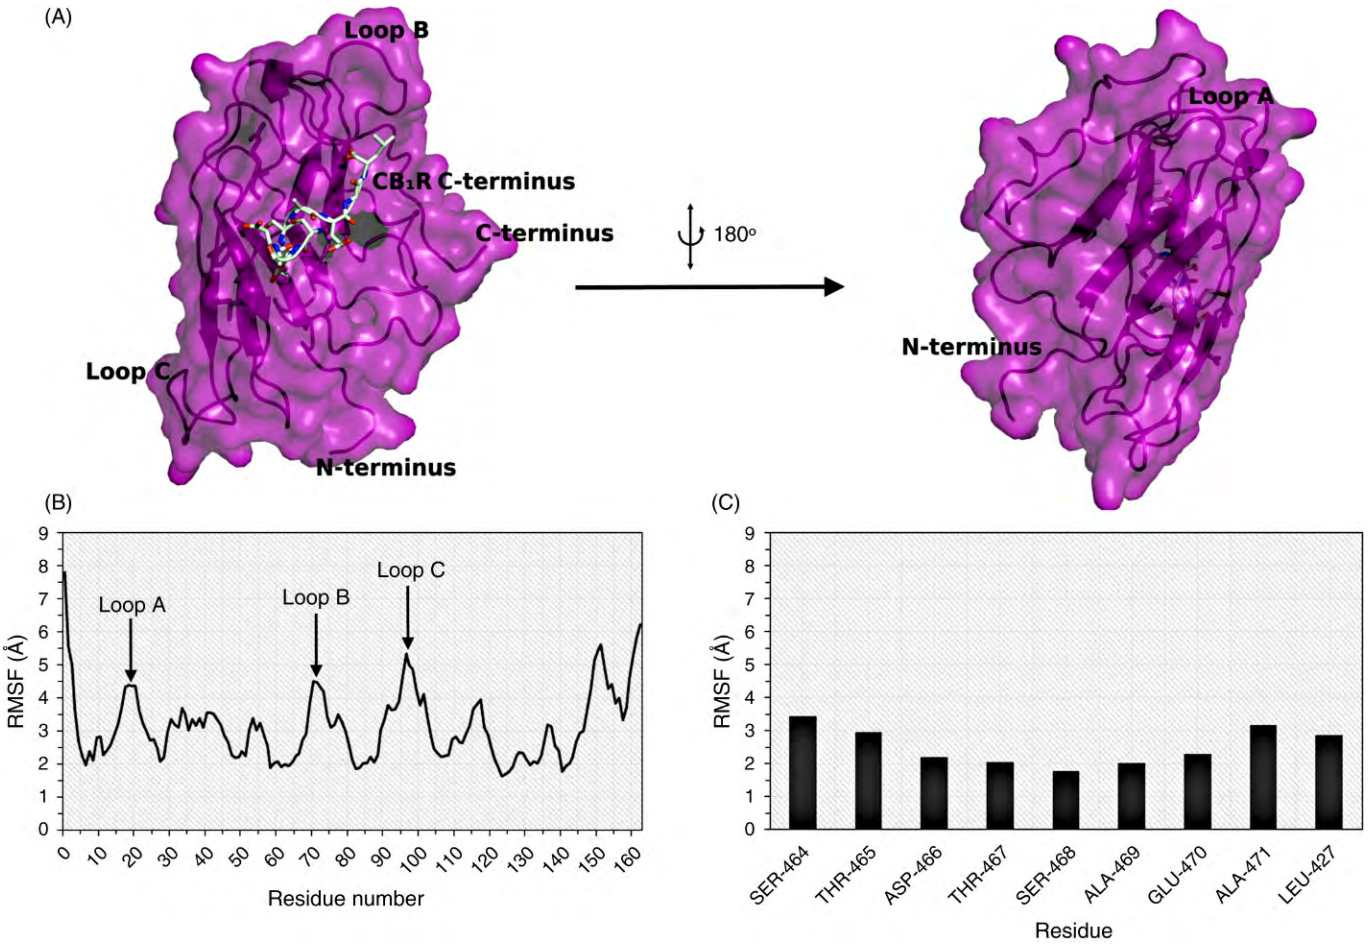

FIGURE 70.6 **The MD simulation results.** (A) The 3D binding mode of CB_1R C-terminus *(gray)* to the CRIP1a protein *(purple)*. (B) Cα-based root mean square fluctuations (RMSFs) calculated over the entire period of 10 ns of the MD production simulation for CRIP1a. (C) Cα-based RMSFs calculated over the entire period of 10 ns of the MD production simulation for the last nine amino acids of the CB_1R C-terminus.

experiments for CRIP1a are currently undergoing, however, it proved to be a difficult task (data not shown). The high flexibility of these regions might be contributing to such difficulties. The RMSF analysis of the nine amino acids CB_1R C-terminus (Fig. 70.6C) showed no significant fluctuations, compared to the whole complex.

Since the trajectory analysis suggested that the protein was undergoing modest equilibration in the first 2 ns of the production phase, as mentioned earlier, it seemed more appropriate to analyze the interactions between CRIP1a and the CB_1R C-terminus in the region between 2 and 10 ns of the trajectory. Among the H-bonds that were observed more than 50% of the time, during the analyzed region of the simulation: CRIP1a-Ser63 and CB_1R-Thr467 sidechains with an average distance of 2.91 ± 0.18 Å, and CRIP1a-Arg82 backbone and CB_1R-Ser468 sidechain with an average distance of 2.87 ± 0.22 Å. In addition, the following salt bridge interactions were observed more than 50% of the time, during the analyzed region of the simulation: CRIP1a-Lys76 sidechain and CB_1R-Leu472 terminal carboxylic group with an average distance of 2.87 ± 0.23 Å, and CRIP1a-Lys130 and CB_1R-Glu470 with an average distance of 2.76 ± 0.17 Å. Finally, hydrophobic interactions were observed more than 50% of the time, during the analyzed region of the simulation for residues Val67, Val69, Val83, Leu163, and Phe162 from CRIP1a, and Ala469, Ala471 and Leu472 from CB_1R.

This CRIP1a–CB_1R interaction model supports the assertion that CRIP1a might be responsible for blocking the coupling of CB_1R to specific $G_{i/o}$ proteins that are responsible for the tonic inhibition of Ca^{2+} channels, but not to other $G_{i/o}$ proteins that could inhibit Ca^{2+} channels, in response to agonist activation (Niehaus et al., 2007). The concept of CB_1R differential G-protein coupling, and the subsequent selective signal transduction mechanisms, was previously discussed by Anavi-Goffer et al. (2007), who found through $G_{i/o}$ protein reconstitution experiments that the combination of CB_1R and $G\alpha_{i3}$(C351G) significantly enhanced the tonic inhibition of Ca^{2+} channels, while CB_1R and $G\alpha_{oA}$(C351G) abolished the tonic inhibition of Ca^{2+} channels (Anavi-Goffer et al., 2007). An earlier study of Nie and

Lewis (2001b) also reinforces the differential coupling concept: they showed that D164N point mutation of CB_1R blocked tonic inhibition of Ca^{2+} channels, whereas agonist-dependent Ca^{2+} channel inhibition was not affected (Nie & Lewis, 2001b). The possibility that CRIP1a blocks the coupling of CB_1R to specific $G_{i/o}$ proteins, without affecting the binding of other $G_{i/o}$ proteins, may provide an explanation for the finding that CRIP1a selectively blocks basal CB_1R modulation of Ca^{2+} channel activity, but not CB_1R agonist-induced modulation of this activity (Niehaus et al., 2007).

In conclusion, previous work has explored the effects of binding CRIP1a to CB_1R; however, this interaction has never been examined at the atomic level, as there are no available X-ray crystal structures for the complex, or either of the interacting proteins. Here, we used three different types of computational techniques, comparative, ab initio, and protein threading, to build 3D models of the CRIP1a protein. The best scoring model was obtained through protein threading, using RhoGDI 2 as a template. RhoGDI 2, another effector with a significant role in G-protein coupled receptor signaling (including CB_1R), is an all β protein of the sandwich fold type, which is the same fold predicted for CRIP1a. Also modeled was the nine amino acid C-terminal end peptide of CB_1R. The peptide was docked as a ligand to the best-scored model of CRIP1a, resulting in mostly favorable polar interactions. The constructed model was then subjected to an all-atom MD simulation for further refinement. The energetics and binding mode analyses suggest that Lys130 of CRIP1a may play a significant role in this interaction. Our model identified potential areas of the CRIP1a that are highly disordered, which is important information for crystallization efforts. In addition, the model may be used to guide the design of future site-directed mutagenesis experiments. Understanding the structures of these proteins and, particularly, their interactions, will form the foundation for understanding mechanisms of CB_1R regulation in the CNS, and may also lead to advances in drug development for the treatment of disorders involving modulation of CB_1R activity.

MINI-DICTIONARY

Concanavalin A-like lectin/glucanases superfamily A family of proteins characterized by having a domain similar to the concanavalin A lectin, which mostly consist of a sandwich of 12–14 β-strands in two sheets with a complex topology.
Homology modeling Constructing an atomic-resolution model of a target protein from its amino acid sequence and a template (an experimental 3D structure of a related homologous protein). Also known as comparative modeling.
Huntington disease A devastating, hereditary, degenerative brain disorder that affects muscle coordination, and leads to cognitive decline and psychiatric problems in mid-adult life. Unfortunately, at present there is no cure.
Palmitoylation site A site on the protein that can undergo a posttranslational modification by binding to palmitate (C16) in this case, which can be reversible or irreversible.
PDZ class I ligand A specific C-terminal sequence recognized by protein interaction modules (PDZ domains), which is a common structural domain of 80–90 amino-acids found in the signaling proteins. PDZ is an acronym combining the first letters of three proteins–post synaptic density protein, drosophila disc large tumor suppressor, and zonula occludens-1 protein, which were the first proteins discovered to have this domain.
Protein threading A method of constructing an atomic-resolution model of a target protein using a template protein that has the same fold. It is used in cases where a closely homologous protein is unavailable. Protein threading is based on the basic observation that the number of different folds in nature is small (approximately 1300).
Root-mean-square deviation (RMSD) It is the measure of the average distance between the atoms of superimposed proteins.
Root-mean-square fluctuation (RMSF) It is a measure of the deviation between the position of an atom and some reference position (a measure of the average atomic mobility).

Synthetic Cannabinoids: a Summary of Selected Phenomena With Respect to Behavioral Pharmacology and Abuse Liability

B.T. Burrows, L.R. Watterson*, J. Egnatios**, M.F. Olive**

***Department of Psychology, Arizona State University, Tempe, AZ, United States**
****School of Medicine, University of California San Diego, La Jolla, CA, United States**

SUMMARY POINTS

- While "Spice" and "K2" are the most known, over 100 different synthetic cannabinoids have been marketed for recreational use, and identified as having Δ^9-tetrahydrocannabinol (THC) like activity.
- Numerous different structural formations have been identified as synthetic cannabinoids, including naphthoylindoles (JWH-018, JWH-073, AM-2201), naphthylmethylindoles (JWH-185), naphthoylpyrroles (JWH-030), naphthylmethylindenes (JWH-176), phenylacetylindoles (JWH-250, RCS-4), cyclohexylphenols (CP47,497), tetrahydrocannabinols (HU-210), and tetramethylcyclopropyl ketone indoles (UR-144, XLR-11).
- The common paradigm for identifying THC-like effects, the cannabinoid tetrad, suggests that many synthetic cannabinoid effects are mediated primarily by the CB_1 receptor. This receptor undergoes downregulation and desensitization through repeated stimuli, but can be recovered within days to weeks of cessation.
- JWH-018, the primary compound of brand names "K2" and "Spice," appears to be significantly more potent, and to have higher affinity for the CB_1 receptor than THC. JWH-018 also appears more potent based on drug discrimination paradigm in rats and rhesus monkeys.
- Tetramethylcyclopropyl ketone indoles such as UR-144 and XLR-11 appear to also be more potent than THC, as assessed in the cannabinoid tetrad paradigm, but equipotent as assessed via drug discrimination testing.
- THC and synthetic cannabinoids produce evidence of cross-tolerance to other cannabinoid molecules.

KEY FACTS OF SYNTHETIC CANNABINOIDS

- Use of synthetic cannabinoids in the general public, through primarily adolescents and young adults, has drastically increased in the last decade.
- Many designer drugs and synthetic cannabinoids are not detected by common toxicology screens, a situation that leaves healthcare providers and law enforcement with limited quantitative tools to confirm use.
- Synthetic cannabinoid use has been linked to acute kidney injury, cardiovascular events and collapse, psychosis, and death.
- Nearly 12% of United States high school seniors admit to having tried a synthetic cannabinoid such as "Spice" or "K2" in the past year.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00082-X
Copyright © 2017 Elsevier Inc. All rights reserved.

- Empirical evidence appears consistent with published literature, suggesting a more significant response to synthetic cannabinoids, with a seemingly higher rate of induced anxiety, dysphoria, agitation, bizarre behavior, and psychosis in patients with prior history of psychiatric disease or mood disorder.
- Parents and healthcare providers are less likely to have knowledge or awareness of synthetic cannabinoids, when compared to classical illicit drugs abused by adolescents.
- SCBs differ not only structurally, but also in their pharmacodynamics, where they display a range of actions including full or partial agonist, antagonist/inverse agonist, and varying affinities at CB_1 and CB_2 receptor sites.

LIST OF ABBREVIATIONS

AM2389	9β-Hydroxy-3-(1-hexyl-cyclobut-1-yl)-hexahydrocannabinol
AM251	*N*-(piperidin-1-yl)-5-(4-iodophenyl)-1-(2,4-dichlorophenyl)-4-methyl-1*H*-pyrazole-3-carboxamide
AM356	(R)-(+)-arachidonyl-1′-hydroxy-2′-propylamide
CB_1	Cannabinoid receptor type 1
CB_2	Cannabinoid receptor type 2
CP55,940	5-(1,1-Dimethylheptyl)-2-[(1R,2R,5R)-5-hydroxy-2-(3-hydroxypropyl) cyclohexyl]-phenol
HU-210	1,1-Dimethylheptyl-11-hydroxytetrahydrocannabinol
HU-308	4-[4-(1,1-Dimethylheptyl)-2,6-dimethoxyphenyl]-6,6-dimethylbicyclo[3.1.1]hept-2-ene-2-methanol
JHW-018	(1-Pentyl-1*H*-indol-3-yl)-1-naphthalenylmethanone, also referred to as AM678
MPE	Maximum possible effect
SCB	Synthetic cannabinoid
THC	Δ^9-Tetrahydrocannabinol
WIN 55,212-2	(R)-(+)-[2,3-dihydro-5-methyl-3-(4-morpholinylmethyl)pyrrolo[1,2,3-*de*]-1,4-benzoxazin-6-yl]-1-naphthalenylmethanone mesylate

INTRODUCTION

Following the isolation and identification of THC as the principal psychoactive component of marijuana, in 1964 (Gaoni & Mechoulam, 1964), and the recognition of cannabis' potential medicinal value, efforts commenced toward development of novel synthetic THC analogues (synthetic cannabinoids, or SCBs) as potential therapeutic agents, as well as pharmacological tools to further study endogenous cannabinoid systems (Watson, Benson, & Joy, 2000). While SCBs have greatly improved our understanding of cannabinoid systems, and led to the development of various pharmacotherapeutics, underground chemists throughout the world have also used the scientific literature to create illicit SCBs intended to be used recreationally as "legal" alternatives to cannabis (Castaneto et al., 2014; Rosenbaum, Carreiro, & Babu, 2012; Seely, Lapoint, Moran, & Fattore, et al., 2012). These more recently developed SCBs have infiltrated international drug markets, and are often sold as herbal marijuana alternatives, herbal incense, or "potpourri" blends under brand names such as "K2," "Spice," "California Spice," "Spike," etc. (Fig. 71.1).

Along with the recent influx of SCBs into drug markets, the number of case reports of psychological impairment and systemic toxicity has increased in parallel (Castaneto et al., 2014; Rosenbaum et al., 2012; Seely et al., 2012; see Fig. 71.2). In addition to their desired euphorigenic effects, SCBs can induce agitation, irritability, anxiety, confusion, psychosis, and impairments in short-term memory, speech, and other cognitive functions. As detailed in examples of case incidents from emergency room visits of self-reported SCB users (Table 71.1), adverse clinical effects of SCB include mydriasis, reddened conjunctivae, nausea, vomiting, hyperventilation, hypertension, tachycardia, angina, diaphoresis, and various hematological abnormalities (de Havenon, Chin, Thomas, & Afra, 2011; Meijer, Russo, & Adhvaryu, 2014; Quan, Haase, & Levitan, 2011; Simmons et al., 2011; Patton et al., 2013).

The SCBs available on drug markets to date come primarily from one of seven different structural classes including naphthoylindoles (JWH-018, JWH-073, AM-2201), naphthylmethylindoles (JWH-185), naphthylpyrroles (JWH-030), naphthylmethylindenes (JWH-176), phenylacetylindoles (JWH-250, RCS-4), cyclohexylphenols (CP47,497), and tetrahydrocannabinols (THC, HU-210). However, newer structural classes such as tetramethylcyclopropyl ketone indoles (UR-144, XLR-11) have emerged as replacements in response to recent legislative actions. The SCBs from these various classes differ not only structurally, but also in their pharmacodynamic effects, where they display a range of actions including full or partial agonism, antagonist/inverse agonist activity, and varying efficacies at CB_1 and CB_2 receptors in the brain and peripheral organs, respectively (Palmer, Thakur, & Makriyannis, 2002; Tai & Fantegrossi, 2014). The potential actions of SCBs on other receptor systems in the brain and periphery, however, are largely unknown.

FIGURE 71.1 **Common packaging of SCB cannabinoid products.** *Source: Reproduced with permission from Penn, Langman, Unold, Shields, & Nichols (2011).*

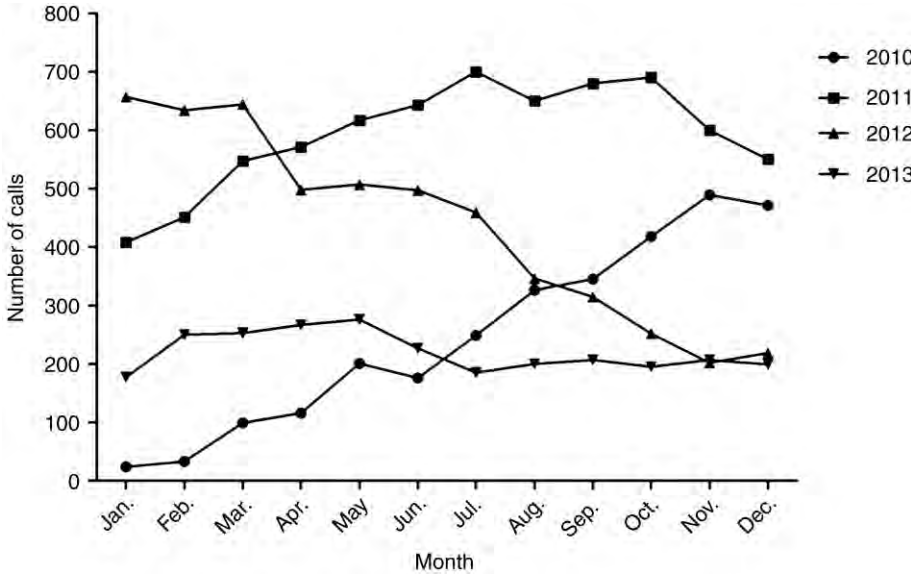

FIGURE 71.2 **Number of calls to US poison control centers regarding SCBs, by month, from 2010 to 2013.** *Source: Reproduced with permission from Castaneto et al. (2014).*

Historically, one of the first SCBs to be developed was WIN 55,212-2 (Fig. 71.3; Huffman, Dai, Martin, & Compton, 1994), an aminoalkylindole cannabinoid that served as a chemical backbone for subsequent development of synthetic indole cannabinoids such as JWH-018 (Wiley, Marusich, & Huffman, 2014b). While THC, WIN 55,212-2, and JWH-018 appear chemically distinct (Fig. 71.3), they possess common moieties and functional groups that have been proposed to interact with cannabinoid receptors at distinct sites on the receptor molecule (Wiley et al., 2014b).

A comprehensive discourse covering all aspects of the chemistry and pharmacology of SCBs is beyond the scope of the present chapter. The reader is therefore directed to several recent and comprehensive reviews for supplemental information (Fattore & Fratta, 2011; Hudson & Ramsey, 2011; Seely et al., 2012; Spaderna, Addy, & D'Souza, 2013; Wiley et al., 2014b; Zawilska & Wojcieszak, 2014; also see Chapter 87). This chapter represents a summary of selected well-characterized and consistent phenomena that have emerged in the literature with respect to the behavioral pharmacology and abuse liability of SCBs. Specifically, these phenomena include: (1) CB_1 receptor mediated characteristic tetrad effects in laboratory animals following exposure to SCBs; (2) discriminative stimulus effects of SCBs relative to THC; and (3) tolerance and cross-tolerance to the effects of SCBs.

CB_1 RECEPTOR MEDIATED CHARACTERISTIC TETRAD EFFECTS IN LABORATORY ANIMALS FOLLOWING EXPOSURE TO SCBs

To date, over 100 SCBs have been detected on international drug markets (United Nations Office on Drugs and Crime, 2014). However, only a handful of these

TABLE 71.1 Emergency Room Case Reports of Adverse Health Effects in Self-Reported SCB Users

Case	Cause for medical evaluation	Clinical presentation	Physical findings	Treatment	Resolution
21-Year old male (Meijer et al., 2014)	Seizure-like activity	Altered mental status, somnolence, confusion, emesis	Sinus tachycardia, tachypnea, minimally reactive dilated pupils, hyperreflexia, leukocytosis, hyperglycemia, negative urine toxicology	Observation, IV 0.9% saline and diphenhydramine	Return to baseline state
27-Year old male (Meijer et al., 2014)	Altered mental status	Emesis, confusion, agitation, combativeness	Sinus tachycardia, tachypnea, leukocytosis, negative urine toxicology	Observation, IV 0.9% saline	Return to baseline state
21-Year old male (Meijer et al., 2014)	Altered mental status	Agitation, emesis	Leukocytosis, hypokalemia, normal pupillary reflexes	Observation, lorazepam, IV 0.9% saline	Return to baseline state
29-Year old male (Meijer et al., 2014)	Panic attack	Feelings of imminent doom, palpitations, shortness of breath, abdominal pain, agitation	Reddened conjunctivae, sinus tachycardia, hyponatremia, slightly elevated leukocyte count, negative urine toxicology	2 Day observation, IV and PO lorazepam every 8 h, CT head scan and blood/urine cultures to rule out other causes	Return to baseline state
26-Year old male (Simmons et al., 2011)	Self-injury	Disorientation, severe agitation	Severe bilateral burns to hands and forearms, 14.5% total body surface area burns from 2nd to 4th degree severity	Emergency irrigation and debridement, amputation of fingers at metacarpo-phalangeal joints	Significant postamputation health impairment
24-Year old male	Generalized tonic-clonic seizure	Suspected postictal confusion, somnolence	No laboratory abnormalities or physical exam findings of significance	MRI, CT scan, CSF analysis, EEG (all negative), observation with IV saline infusion	Return to baseline state
36-Year old male (de Havenon et al., 2011)	Status epilepticus	Unresponsive, seizure activity	Leukocytosis	Intubation, IV lorazepam, etomidate, vecuronium, propofol, levetiracetam, phenytoin. X-ray, urinalysis, blood cultures, CSF analysis, MRI, EEG, CT head scan all negative	Return to baseline state
Grouped case review (Quan et al., 2011)	Altered mental status	Diaphoresis, tremor, anxiety, agitation	Hypertension, sinus tachycardia, mydriasis, leukocytosis	IV saline and benzodiazepine administration	Return to baseline state

This table highlights case reports to illustrate the clinical presentation and acute medical treatment of SCB toxicity in self-reported users. Cases were obtained from the published literature of emergency room reports.
IV, Intravenous; PO, oral.

SCBs have been assessed for their behavioral effects in laboratory animals, and effects reported in humans are largely anecdotal. One of the most common behavioral methods to assess novel SCBs for THC-like effects is termed the "cannabinoid tetrad" (Little, Compton, Johnson, Melvin, & Martin, 1988), and is characterized by a collection of physiological effects including hypothermia, analgesia, catatonia, and locomotor suppression. This collection of physiological and behavioral effects reliably occurs in mice given THC, is largely specific to ligands acting at CB_1 receptors, and is therefore used to predict THC-like effects in humans (Wiley et al., 2014b). As an illustrative example, dose-dependent induction of cannabinoid tetrad behaviors by WIN 55,212-2 is shown in Fig. 71.4 (Wiley et al., 2014b). Overall, the cannabinoid tetrad has been extremely useful in the characterization of biochemical and physiological effects of various ligands on the cannabinoid system, and various recent

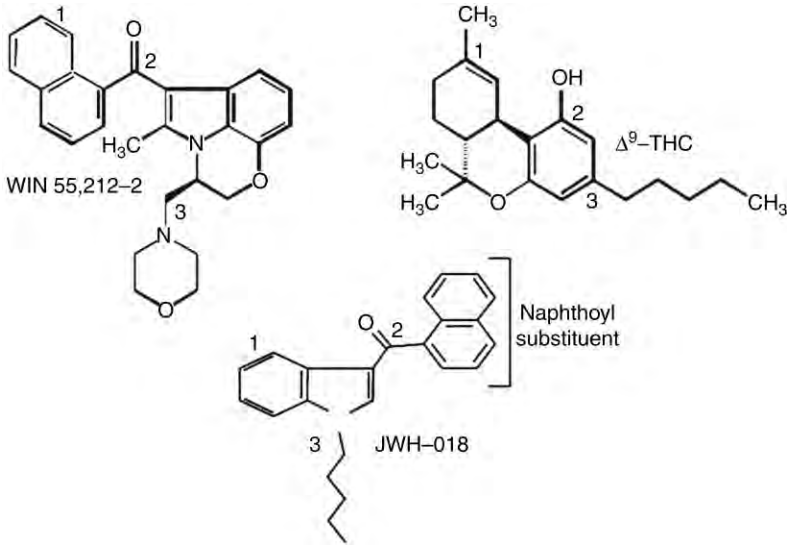

FIGURE 71.3 **Chemical structures of WIN 55,212-2, THC, and JWH-018.** Numerals adjacent to functional groups represent predicted binding sites of the molecule to CB receptors. *Source: Reproduced with permission from Wiley et al. (2014b).*

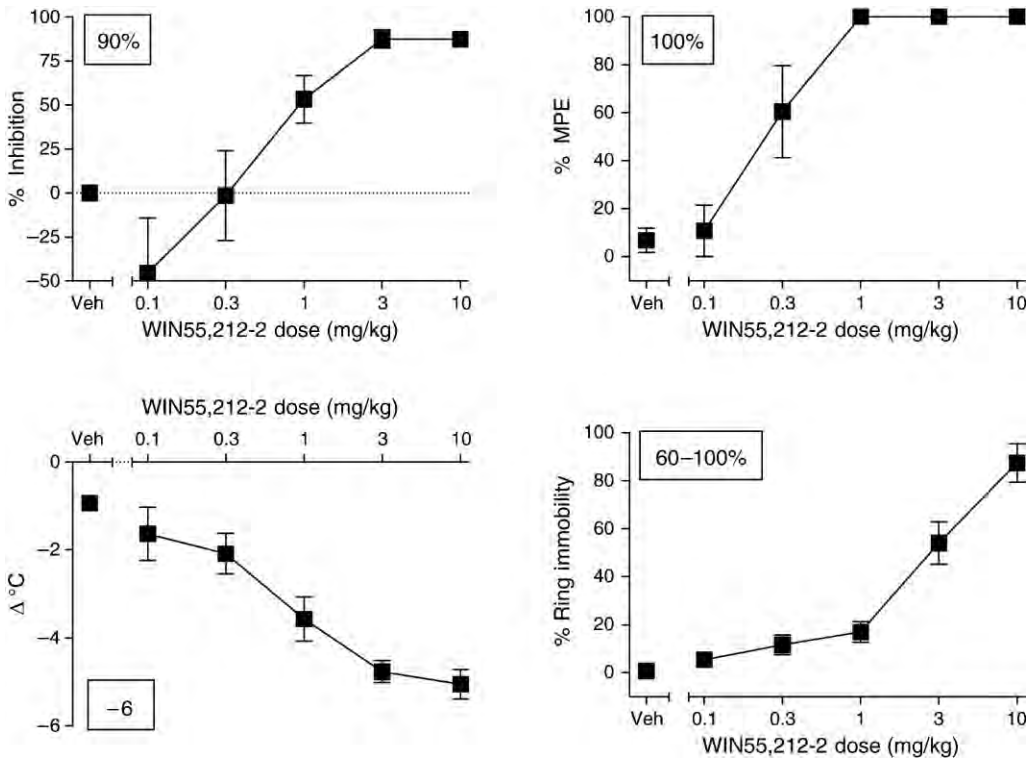

FIGURE 71.4 **Dose-dependent induction of cannabinoid tetrad effects by the SCB WIN 55,212-2 in adult male mice.** *Top left graph*, inhibition of spontaneous locomotor activity. *Top right graph*, antinociception as assessed in the tail flick assay. MPE, maximum possible effect. *Bottom left graph*, rectal temperature. *Bottom right graph*, catalepsy as measured in a ring testing apparatus. *Source: Reproduced with permission from Wiley et al. (2014b).*

studies have shown that some of the commercially available SCBs appear to elicit effects similar to those of THC (Gurney, Scott, Kacinko, Presley, & Logan, 2014; Wiley et al., 2014b).

Early work with the synthetic cannabinoids CP 55,940 and WIN 55,212-2 revealed that these SCBs produce tetrad effects similar to those elicited by THC, but both do so at much lower doses, indicating greater potency (Fan, Compton, Ward, Melvin, & Martin, 1994). JWH-018, one of the earliest SCBs found in "K2/Spice" products (see Chapter 87), has high affinity for CB_1 receptors, and displays full tetrad effects in mice at 2–50 times lower doses than

THC. Tetrad effects also occur in mice exposed to smoke produced from a commercially available "spice" product containing 5.4% JWH-018 (Wiebelhaus et al., 2012). In addition, several structurally related compounds in which the naphthoyl moiety in JWH-018 is replaced with a phenylacetyl group retains CB_1 receptor mediated tetrad effects (Wiley, Marusich, Martin, & Huffman, 2012a; Wiley, Smith, Chen, Martin, & Huffman, 2012b). Not surprisingly, a subset of 1-pentyl-3-phenylacetylindoles, such as JWH-250, has also emerged on drug markets (Rosenbaum et al., 2012; Vardakou, Pistos, & Spiliopoulou, 2010; Wiley et al., 2012a). JWH-073, the alkyl homologue of JWH-018 prominent in "Spice," displays CB_1 mediated tetrad effects in mice, possibly mediated by several of its potential active metabolites (Brents et al., 2012). The bicyclic SCB, CP-47,497, is a potent CB_1 agonist found in commercial preparations, and it also displays potent tetrad-like effects in mice, along with several structurally related bicyclic analogues (Compton, Johnson, Melvin, & Martin, 1992b). HU-210, a highly potent full agonist at CB_1 receptors also causes tetrad-like effects of catalepsy and suppressed locomotion in rats (Bosier et al., 2010). Finally, UR-144 and XLR-11, which are two novel tetramethylcyclopropyl ketone indoles and full CB_1 receptor agonists, have emerged as popular replacements to earlier banned SCBs. In tetrad tests, UR-144 was 3–15 times more potent, and XLR-11 was 4–17 more potent than THC, respectively, across the various tetrad measures. Furthermore, results revealed that UR-144 and XLR-11 are approximately equipotent (Wiley, Marusich, Lefever, Grabenauer, Moore, 2013).

DISCRIMINATIVE STIMULUS EFFECTS OF SCBs, RELATIVE TO THC

Another behavioral method commonly used to assess the THC-like effects of SCBs is drug discrimination. Drug discrimination procedures provide a measure of similarity between the interoceptive cues produced by a novel compound in relation to a drug with known pharmacological properties (Ator & Griffiths, 2003). Drug discrimination has proven extremely useful at predicting marijuana-like effects in humans, as previous research has revealed a high correspondence between THC-like subjective effects in humans and THC-like responding in drug discrimination tests (Ator & Griffiths, 2003). Furthermore, cannabinoids with high CB_1 receptor affinity share discriminative properties with THC, whereas substances from other drug classes such as psychostimulants typically do not support THC-like responding. Therefore, drug discrimination is a pharmacologically selective method for determining the likelihood that novel SCBs will produce THC-like subjective effects in humans (Gold, Balster, Barrett, Britt, & Martin, 1992; Wiley, Huffman, Balster, & Martin, 1995). In drug discrimination procedures, laboratory animals are trained in an operant conditioning apparatus to respond on one lever (eg, right lever) in order to receive a food reinforcer following administration of a drug (Fig. 71.5). Conversely, responding on a different lever (eg, left lever), following administration of saline, results in the presentation of a food reinforcer. Training typically alternates between drug and vehicle sessions until lever-appropriate responding reaches a designated stability criterion (usually ~80%). Thus, interoceptive cues produced by the drug/vehicle serve as discriminative stimuli that guide lever appropriate responding, in order to receive food reinforcement. Following stabilization of responding with the training drug, stimulus generalization tests are conducted after administration of a novel drug, during which both levers are reinforced (Fig. 71.5). A test drug is interpreted as

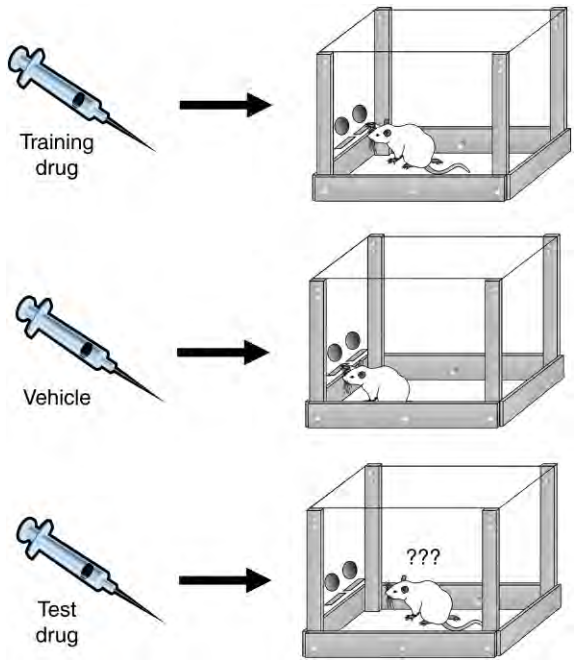

FIGURE 71.5 Drug discrimination procedures. Laboratory rodents are trained in operant conditioning chambers to respond for food reinforcement. During discrimination training, rodents are administered training drugs (eg, THC, top diagram), after which they are placed into the chambers and required to press one of two levers (eg, right lever) in order to receive food reinforcement. Prior to alternate sessions, rodents are administered the corresponding vehicle, and during the ensuing training session, rodents are required to press the opposite lever (eg, left lever, middle diagram) in order to receive food reinforcement. Training alternates between drug and vehicle sessions until lever-appropriate responding reaches a designated stability criterion (~80%). Next, stimulus generalization tests are conducted following administration of a test drug (bottom diagram), during which both levers are reinforced. A test drug (eg, a novel SCB) is interpreted as producing interoceptive effects similar to the training drug (eg, THC) when lever responding occurs more frequently on the training drug-associated lever versus the vehicle-trained lever. When responding following administration of the test drug is ≥80% of that following the training drug, the test drug is interpreted as fully substituting for the training drug.

producing interoceptive effects similar to the training drug when lever responding occurs more frequently on the drug-trained lever versus vehicle-trained lever. Moreover, when responding following administration of the test drug is ≥80% of that following the training drug, the test drug is interpreted as fully substituting for the training drug (Watterson, Watterson, & Olive, 2013).

In one of the first studies of its kind, Gold and colleagues (1992) showed that the SCB CP 55,940, a bicyclic analogue of THC, fully substituted for THC in rats (training dose of THC 3.0 mg/kg, i.p.) and rhesus monkeys (training doses of THC 0.04–0.1 mg/kg, i.m.). In both rats and rhesus monkeys, doses that led to full substitution were much lower than those required for THC, revealing that CP 55,940 was at least 20-fold more potent than THC in eliciting THC-appropriate lever responding (Gold & Balster, 1996). In another set of early studies, full substitution for THC was also found with the full CB_1 agonist WIN 55,212-2 (Compton et al., 1992b; Wiley et al., 1995). In the study by Wiley et al. (1995), the stereoisomers (+)-WIN 55,212-2 and (–)-WIN 55,212-2 displayed differential substitution for THC (3 mg/kg) in rats, such that the (+)-isomer (11.5 μmol/kg) fully substituted for THC, whereas the (–)-isomer was inactive and showed negligible effects at doses up to 57 μmol/kg. Furthermore, the (+)-isomer fully substituted for THC with an ED50 value (0.17 mg/kg) much lower than that produced by THC itself (0.6 mg/kg), revealing increased potency compared to THC (Compton, Gold, Ward, Balster, & Martin, 1992a). In the study by Compton et al. (1992a), WIN 55,212-2 was found to fully substitute in THC trained rhesus monkeys. Interestingly, however, WIN 55,212-2 was less potent than THC in rhesus monkeys than in rats, with ED50 values of 0.1 μmol/kg versus 0.03 μmol/kg for THC (Wiley et al., 1995). With regard to JWH-018 (occasionally referred to as AM678 in earlier studies), drug discrimination in rats revealed full substitution of this compound for both THC and methanandamide, an analog of the endogenous cannabinoid anandamide (Hudson & Ramsey, 2011; Vardakou et al., 2010; Järbe, Li, Vadivel, & Makriyannis, 2010). Furthermore, compared to THC, JWH-018 was approximately 11.3 times as potent as THC in producing full substitution. Following administration of a CB_1 receptor antagonist, a rightward shift in the dose-response curve was observed, indicating CB_1 receptor agonism as the likely mechanism mediating THC-like responding. JWH-018 also fully substituted for methanandamide, and was approximately 57 times more potent. In another study using rhesus monkeys trained to discriminate between THC (0.1 mg/kg, i.v.) and vehicle, or the CB_1 receptor antagonist rimonabant (1 mg/kg, i.v.) and vehicle, JWH-018 was approximately 3.4 times as potent as THC in producing full substitution for THC (Ginsburg & Schulze, 2012). JWH-018 failed to substitute for rimonabant, and coadministration with the CB_1 receptor antagonist rimonabant caused a rightward shift in the dose response curve during THC generalization tests, suggesting surmountable antagonism (Ginsburg & Schulze, 2012). In another recent study (Wiley, Lefever, Cortes & Marusich, 2014a), rats were initially trained to discriminate either JWH-018 (0.3 mg/kg, i.p.) from vehicle, or THC (3.0 mg/kg, i.p.) from vehicle. In THC trained rats, JWH-018 fully substituted for THC at approximately 4–5 times the potency as THC. In JWH-018 trained rats, THC fully substituted for JWH-018, and interestingly, was about 30 times as potent as THC in causing full JWH-018-like responding.

The SBC JWH-073 has also been shown to substitute for THC in a number of studies. In the first (Ginsburg & Schulze, 2012), JWH-073 produced full substitution in rhesus monkeys trained to discriminate THC (3.0 mg/kg, i.p.) from vehicle. While this study also showed that JWH-018 was more potent than THC, JWH-073 was demonstrated to be approximately equipotent to THC, and approximately 4 times less potent than JWH-018 (Ginsburg & Schulze, 2012). In addition, rimonabant caused a rightward shift in the dose response curve, indicting surmountable antagonism and CB_1 receptor-mediated effects. In another study, JWH-073 also fully substituted for THC, yet, despite a much greater affinity for CB_1 receptors, was again shown to be approximately equipotent to THC (Wiley et al., 2014a). Recently, the replacement SCBs XLR-111 and UR-144 have also been shown to fully substitute for THC in mice trained to discriminate THC (5.6 mg/kg, i.p.) from vehicle. XLR-11 was shown to be approximately 1.5 times more potent than both THC and UR-144. UR-144 was found to be approximately equipotent to THC, with both drugs showing full substitution at the 5.6 mg/kg dose (Wiley et al., 2013). Finally, THC substitution was blocked at the 5.6 mg/kg doses by administration of rimonabant (3 mg/kg, i.p.), again suggesting CB_1 mediated responding.

TOLERANCE AND CROSS-TOLERANCE TO THE EFFECTS OF SCBs

With repeated activation by exogenous ligands, CB_1 receptors undergo significant downregulation and desensitization in multiple regions of the brain (Rubino, Vigano, Massi, Spinello, Zagato, 2000). These adaptations are thought to contribute to tolerance to SCB-mediated behavioral effects. However, CB_1 receptor downregulation and desensitization have been shown to recover within days to weeks, following cessation of ligand administration (Hirvonen, Goodwin, Li, Terry, Zoghbi, 2012; Sim-Selley, Schechter, Rorrer, Dalton, Hernandez, 2006), suggesting that long-term neurophysiological changes produced by SCBs may be, at least in part, reversible.

Only a small number of SCBs have been assessed for their ability to lead to tolerance or cross-tolerance to other cannabinoids, most commonly THC. In a 2011 study (McMahon, 2011), rhesus monkeys were initially trained to discriminate THC (0.1 mg/kg, i.v.) from vehicle. Next, the discriminative stimulus effects of THC, WIN 55,212-2, and CP 55,940 were assessed both before and after 1 day of THC treatment. Discriminative stimulus effects of THC were also assessed after 3 and 6 days of repeated treatment. While THC fully substituted for itself, 1 day of THC treatment did not produce significant effects, and repeated treatment with THC for both 3 and 6 days produced a rightward shift in the dose effect curves, revealing tolerance-like effects. Similarly, 1 day of THC treatment did not produce cross-tolerance to WIN 55,212-2 or CP 55,940, although the 3 and 6 day treatment regimens were not tested. However, this study also provided evidence of cross-tolerance of THC to WIN 55,212-2 and CP 55,940.

In a study by Hruba, Ginsburg, and McMahon (2012), rhesus monkeys were initially trained to discriminate THC from vehicle. These investigators observed that CP 55,940, JWH-018 and JWH-073 fully substituted for THC. When tested after 1 and 3 days of repeated treatment with THC, no changes in drug discrimination were observed. However, 14 days of chronic THC treatment (1 mg/kg per day, s.c.) produced significant rightward shifts in the dose-response curve for THC, CP 55,940, JWH-018, and JWH-073 that were 9.2-, 3.6-, 4.3-, and 5.6-fold, respectively. Thus, chronic THC treatment produced cross-tolerance to each of the CB_1 receptor agonist JWH-018 and JWH-073, two of the most commonly abused recreational SCBs.

CONCLUSIONS

The scientific assessment of the behavioral pharmacology and abuse liability of SCBs is still in its infancy, and a great deal of additional work is needed to establish acute and lasting behavioral, psychological, and neurological effects. Of the over 100 SCBs that have appeared on international markets, their effects in humans remain largely anecdotal, and only a handful have been assessed in animal models. Furthermore, continued governmental bans on specific compounds, combined with the multitude of possible structural modifications, will likely lead to the emergence of potentially hundreds of additional SCBs on international markets. Of the SCBs scientifically assessed in animal studies to date, experiments have generally revealed behavioral effects similar to THC, but often with much greater potency and specificity at CB_1 receptors. Thus, the most common recreationally used SCBs, to date, appear to have high abuse potential at least comparable to, and often greater than, cannabis or THC itself. False marketing as safe alternatives to cannabis, ease of procurement, low cost, and failure to produce positive results on traditional drug screens make SCBs attractive to both existing and new drug users, further increasing their potential for abuse. This combination of factors has created a new unique challenge to scientists, educators, and legislators responsible for reducing societal harm that, thus far, has been less than adequate. Given the multitude of SCBs already available on drugs markets, and the hundreds of potential new compounds likely to emerge, it is clear that newer strategies are desperately needed to curb SCB abuse.

MINI-DICTIONARY

Cannabinoid subtype 1 (CB_1) receptor The receptor believed to be most linked to the effects of cannabis and cannabis-mimicking drugs. The CB_1 receptor is a G-protein coupled receptor that is highly expressed in central nervous system tissue.

Downregulation Reduction in the expression and/or function of a particular protein.

Drug discrimination Relating to the ability of test subjects (most commonly rodents or primates) to distinguish between the subjective (interoceptive) effects of drugs, as inferred from operant responding.

Interoceptive effects Internal bodily signals relevant to a designated effect or response to a drug.

Synthetic cannabinoids (SCBs) A collective term referring to research chemicals and "designer" illicit drugs that behave similarly in action and biological effect to THC. Spice and K2 are two of the most popular SCBs.

Tetrad effects A collection of behaviors that appear to be highly related and specific to cannabinoid receptor activity. These effects are primarily suppression of locomotor activity, catalepsy, hypothermia, and analgesia.

Tolerance The ability of a tissue or organism to adapt or attenuate its effects in response to a certain stimuli.

Cannabinoid Signaling in Glioma Cells and Therapeutic implications

A. Ellert-Miklaszewska, I. A. Ciechomska, B. Kaminska

Laboratory of Molecular Neurobiology, Neurobiology Center, Nencki Institute of Experimental Biology, Warsaw, Poland

SUMMARY POINTS

- CB2 receptor is overexpressed in gliomas, and the expression correlates with tumor malignancy grade.
- Ceramide accumulation plays a central role in cannabinoid-induced cell death.
- Inhibition of prosurvival pathways, ER-stress, and autophagy contribute to apoptosis induction in cannabinoid-treated glioma cells.
- Antitumoral activity of cannabinoids in vivo results from inhibition of tumor cell proliferation, blocking of cell invasiveness and angiogenesis, as well as induction of cancer stem cells differentiation.
- Antitumor effectiveness of cannabinoids reported in preclinical studies, and the good safety profile observed in a pilot clinical trial, in patients with malignant human glioblastoma (GBM), encourage to further evaluation of the therapeutic potential of cannabinoids in cancer treatment.

KEY FACTS OF GLIOMA

- Gliomas are the most common primary brain tumors.
- Derived from glial cells or their precursors. Can grossly be divided into astrocytomas (accounting for 60–70% of all gliomas), oligodendrogliomas, and ependymomas, depending which glial cell phenotype they most closely resemble.
- According to the WHO, gliomas are classified from grade I—least aggressive, to grade IV—most aggressive glioblastomas. High-grade gliomas, WHO grade III and IV, account for approximately 70% of all gliomas.
- Tumor cell invasiveness into normal brain tissue is a defined hallmark of gliomas, and accounts for their poor prognosis.
- Difficult to treat—crossing the blood–brain barrier is an important limitation to available drugs.
- The median survival of patients with the malignant glioblastoma is 18 months since diagnosis.

LIST OF ABBREVIATIONS

Δ^9-THC	(−)-*trans*-Δ^9-Tetrahydrocannabinol
2-AG	2-Arachidonoylglycerol
AEA	Anandamide, arachidonoylethanolamide
Akt	Protein kinase B/Akt
ATF4	Activating transcription factor 4
cAMP	Cylic adenosine monophosphate
CB1	Cannabinoid receptor type 1
CB2	Cannabinoid receptor type 2
CHOP	C/EBP-homologous protein
DAG	Diacylglycerol
eIF2α	Eukaryotic translation initiation factor 2α
ER	Endoplasmic reticulum
ERK1/2	Extracellular signal-regulated kinase 1/2
FAAH	Fatty acid amide hydrolase
GBM	Malignant human glioblastoma
IP_3	Inositol 1,4,5-trisphosphate
LPS	Lipopolysacharide

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00076-4

MAPK	Mitogen-activated protein kinase
MEK	MAP kinase-ERK kinase
MGL	Monoacylglycerol lipase
mTORC1	Mammalian target of rapamycin, complex 1
NAPE	N-arachidonylphosphatidylethanolamide
PI3K	Phosphatidylinositol 3-kinase
PIP_2	Phosphatidylinositol 4,5-bisphosphate
PKA	Protein kinase A
PKC	Protein kinase C
PLC	Phospholipase C
TRB3	Pseudo-kinase tribbles homolog 3
TRPV1	Transient receptor potential cation channel subfamily V member 1, capsaicin or vanilloid receptor
WIN55,212-2	Synthetic cannabinoid

INTRODUCTION

Along with our expanding knowledge on the mechanisms of cannabinoids action, the endocannabinoid system, and the development of synthetic cannabinoids, targeting cannabinoid signaling for therapeutic purposes has inevitably emerged as an interesting area of scientific and clinical investigations. One of the most extensively studied applications of cannabinoids is their potential use as anticancer agents. The pioneer study to show that cannabinoids had antitumor effect was reported by Munson, Harris, Friedman, Dewey, and Carchman (1975). Administration of Δ^9-THC, Δ^8-THC, and cannabinol retarded tumor growth, and prolonged the life of mice bearing Lewis lung adenocarcinoma. Further research in this area was not performed until late 1990s, when an interest in the role of cannabinoids in cancer therapy was renewed. Since then, plant-derived, synthetic, and endogenous cannabinoids have been successfully used to block proliferation and invasive potential of various cancer types (glioma, lymphoma, lung, thyroid, skin, pancreas, breast, and prostate carcinoma) in both in vitro and in vivo models (Guzman, 2003; Pisanti et al., 2009). The research on therapeutic potential of cannabinoids in cancer treatment is the most advanced in gliomas, the most common primary brain tumors.

Signaling pathways and intracellular processes underlying cannabinoid action on glioma cells are reviewed here. A brief overview of the alterations in endocannabinoid system in glial tumors, other pharmacological effects of cannabinoid action in glial tumors, beyond blocking of tumor cells proliferation, and current scientific data relevant to the use of cannabinoids in treatments of glioblastomas are also included.

ENDOCANNABINOID SYSTEM IN HUMAN GLIOMAS

A growing array of data suggest that significant alterations of a balance in the cannabinoid system between the levels of endogenous ligands and their receptors occur along with the malignant transformation in various types of cancer, including brain tumors (Table e11.1). Cannabinoid receptor 1 (CB1) is the predominant receptor for endogenous and exogenous cannabinoids in the central nervous system, expressed on neurons and astrocytes—the major glial cells in the brain. The CB2 receptor is believed to be absent in the healthy brain, its expression has been only detected in microglia-brain macrophages (Stella, 2004; Gong et al., 2006), as well as in a small subpopulation of neurons (Van Sickle et al., 2005; Gong et al., 2006). However, both types of functional cannabinoid receptors were found in primary cultures established cell lines derived from malignant human glioblastoma (GBM) (Galve-Roperh et al., 2000; Sanchez et al., 2001; Howlett et al., 2002). CB2 mRNA and protein levels in tumor tissue extracts were elevated in low-grade gliomas, and even greater in high grade gliomas, in comparison with nontumor tissue controls (Wu et al., 2012). Immunohistochemical analysis of human glioma surgical specimens revealed increased CB2 receptor expression in tumor cells, invading microglia/macrophages and endothelial cells of the tumor blood vessels, as compared to nontumor brain samples (Sanchez et al., 2001; Ellert-Miklaszewska, Grajkowska, Gabrusiewicz, Kaminska, & Konarska, 2007; Schley et al., 2009). An example of CB2 detection in human glioblastoma is presented in (Fig. e11.1) Moreover, CB2 receptor immunoreactivity markedly prevailed over detected CB1 receptor levels in grade IV astrocytomas (Sanchez et al., 2001; Schley et al., 2009). The discrepancies in CB1 receptor expression in glial tumors versus normal tissues were observed by different groups. According to the majority of authors, the levels of CB1 receptor expression in tumor and tumor-associated endothelial cells were not significantly different from the control tissue (Sanchez et al., 2001; Held-Feindt, Dorner, Sahan, Mehdorn, & Mentlein, 2006; Schley et al., 2009).

Increased levels of CB2 are reported in tissues during development, inflammation, injury, and cancer, revealing a critical role for the CB2 receptor in regulating these processes (Howlett et al., 2002). In examined glial tumors, CB2 receptors were usually located in the areas of intense tissue proliferation and invading cells. The enhancement of cannabinoid receptor expression in malignant versus healthy tissues might suggest a possible role of the endocannabinoid system in the tonic suppression of cell divisions and cancer growth. In support of this hypothesis, inhibitors of endocannabinoid transport or degradation (VDM-11 and AA-5-HT) have been shown to inhibit tumor growth and progression in some

types of cancer, by enhancing the levels of endocannabinoids in the cells (Izzo et al., 2008).

Alterations in the endocannabinoid system in tumors refer also to endogenous ligands, specific enzymes involved in their biosynthesis and degradation, as well as other putative target receptors (Maccarrone et al., 2001; Petersen et al., 2005; Wu et al., 2012). Table e11.1 summarizes the reported levels of the two major endocannabinoids human glioblastoma specimens, compared to nontumor brain tissues. The alterations of the endocannabinoid levels were consistent with the changes in the expressions and activities of the enzymes responsible for their biosynthesis and degradation (Petersen et al., 2005; Wu et al., 2012). Compared to the nontumor tissues, mRNA expression and the enzymatic activity of NAPE-PLD, the enzyme

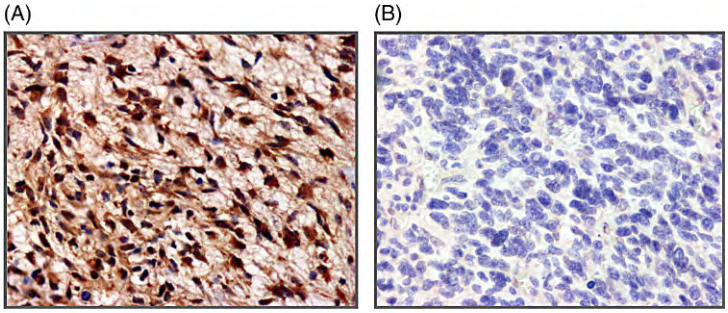

FIGURE e11.1 **Expression of CB2 receptor in human glioblastoma.** (A) Immunohistochemistry was performed using 3,3′-diaminobenzidine (DAB). Cell nuclei were visualized by hematoxylin counterstain. (B) Negative control-specimen incubated with the antibody preabsorbed on the blocking peptide.

responsible for anandamide biosynthesis, decreased in tumor tissues. It was accompanied by the reduction of the anandamide hydrolyzing enzyme FAAH's mRNA expression, and enzymatic activity in low- and high-grade glioma samples (by 30 and 60%, respectively), which might be a result of a negative feedback induced by low levels of the substrate. mRNA expression and activity of MGL, the 2-AG hydrolyzing enzyme, decreased in glioma tissues, compared to that in the nontumor tissues, whereas there was no difference in the expression levels of DGL-a, the 2-AG generating enzyme, between the groups (Wu et al., 2012).

GPR55, an orphan G-protein linked receptor, which can be engaged by cannabinoid-like compounds, appears upregulated in some cancer-derived cell lines, and plays a pivotal role in tumor cells proliferation (Andradas et al., 2011). Higher TRPV1 expression was found in high grade human astrocytomas, as compared to nonneoplastic brains (Stock et al., 2012).

INTRACELLULAR MECHANISMS UNDERLYING ANTIPROLIFERATIVE ACTIVITY OF CANNABINOIDS

Antitumoral Action of Cannabinoids In Vitro

Antiproliferative activity of cannabinoids against glioma cells was first described by Guzman and coworkers (Sanchez, Galve-Roperh, Canova, Brachet, & Guzman, 1998). They showed that Δ^9-THC is able to inhibit growth of rat C6 glioma cells in vitro, and induce programmed cell death with typical features of apoptosis (Sanchez et al., 1998). We reported the induction of apoptosis upon treatment with a mixed CB1/CB2 synthetic agonist WIN 55,212-2 in the same rat glioma cell line (Ellert-Miklaszewska, Kaminska, & Konarska, 2005). Subsequent studies (Gomez del Pulgar, Velasco, Sanchez, Haro, & Guzman, 2002; Salazar et al., 2009) and our own observations show consistently that Δ^9-THC, cannabidiol, endogenous and synthetic cannabinoids, including CB2-selective agonists, effectively decrease cell viability of cultured human glioblastoma cells and tumor-derived primary cultures.

Mechanism of Cannabinoids Proapoptotic Action—Inhibition of Prosurvival Pathways

Several events and signal transduction pathways triggered mostly by stimulation of the CB1 and CB2 receptors have already been described to participate in the cannabinoid-induced apoptosis, a programmed cell death process (Guzman, Sanchez, & Galve-Roperh, 2001; Guzman, 2003). They include inhibition of PKA, superoxide generation, and strong increase in intracellular calcium concentration (Howlett et al., 2002). Sanchez, Velasco, and Guzman (1997) showed that Δ^9-THC was able to partially antagonize the forskolin-induced elevation of intracellular cAMP concentration, but did not affect basal cAMP levels in C6 glioma cells. Glioma C6 cells are characterized by a very low constitutive level of cAMP, and rather increased than decreased concentration of intracellular cAMP may be responsible for inhibition of cell proliferation. It suggest, that cannabinoid receptors may be coupled to inhibition of adenylyl cyclase (AC) in glioma cells, but downregulation of cAMP levels is unlikely to play a role in the induction of apoptosis triggered by cannabinoids in these cells. Involvement of other signaling molecules or adaptor proteins (of still mostly unknown identity) in cannabinoid receptor signaling is a subject of ongoing studies.

The best-characterized mechanism of cannabinoid-induced cell death involves sustained accumulation of proapoptotic sphingolipid ceramide, which modulates signaling pathways crucial in the control of tumor cell growth and survival (Galve-Roperh et al., 2000; Sanchez et al., 2001). Ceramide functions as a physiological signaling molecule, particularly with regard to the control of apoptosis, but also growth arrest, differentiation, cell migration, and adhesion and, as such, has an accepted role in the development of some cancers (Morad & Cabot, 2013). Cannabinoid receptor activation triggers two peaks of ceramide generation in glioma cells (Fig. e11.2) (Galve-Roperh et al., 2000; Sanchez et al., 2001; Gomez del Pulgar et al., 2002). Treatment with Δ^9-THC or another CB1/CB2 receptor agonist produces a rapid release of ceramide via enzymatic hydrolysis of sphingomyelin from the cell membrane. The second ceramide peak is generated within hours or days after receptor activation, and depends on increase of ceramide synthesis de novo via induction of serine palimitoyltransferase, a regulatory enzyme of sphingolipid biosynthesis (Gomez del Pulgar et al., 2002). Selective CB2 receptor agonists, such as JWH133, are supposed to stimulate only the ceramide synthesis process, which is sufficient for turning on the cell death program (Sanchez et al., 2001; Gomez del Pulgar et al., 2002). Thus, enhanced production of ceramide de novo is considered as an important event in cannabinoids-induced apoptosis.

Galve-Roperh et al. (2000) postulated that the increased ceramide levels reported upon cannabinoid challenge led to prolonged activation of Raf-1/MEK/Erk signaling cascade, and thus mediated glioma cell cycle arrest, and cell death. The same authors showed also that pharmacological inhibition of ceramide synthesis de novo prevented the inhibition of protein kinase B (also known as Akt) triggered by cannabinoids (Gomez del Pulgar et al., 2002). Our studies revealed that rather downregulation of Erk activity, together with inhibition of PI3K/Akt pathway, contributed to C6 glioma cell death induced by WIN55,212-2 (Ellert-Miklaszewska

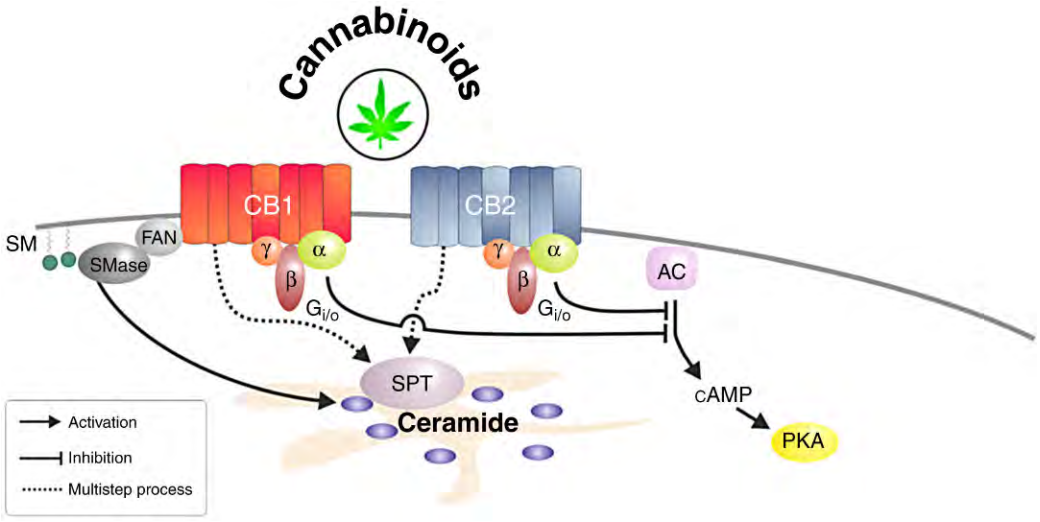

FIGURE e11.2 Ceramide in cannabinoid signaling. Increased ceramide synthesis de novo via induction of serine palmitoyltransferase (SPT) plays a central role in cannabinoid-induced cell death. Signals from CB1 via adaptor protein FAN (factor associated with neutral sphingomyelinase activation) also trigger the ceramide production from sphingomyelin breakdown, catalyzed by neutral sphingomyelinase (SMase). Stimulation of cannabinoids receptors leads to inhibition of adenylyl cyclase, reduction of cAMP levels, and decreased protein kinase A (PKA) activity.

et al., 2005). The serine/threonine protein kinase Akt, activated downstream of phosphoinositide 3-kinase (PI3K), as well as the Ras-activated Raf1/MEK/Erk pathway are widely recognized as key mediators of growth factor-promoted cell survival in gliomas (Kapoor & O'Rourke, 2003). We proposed a mechanism in which the decrease of mitogenic/prosurvival signaling evoked by the synthetic cannabinoid promoted the proapoptotic function of Bad (Fig. e11.3), a proapoptotic member of a Bcl-2 family of proteins. Phosphorylation of Bad by Akt and Erk retains the protein in the cytosol, and directs it for sequestration (Zha, Harada, Yang, Jockel, & Korsmeyer, 1996). Otherwise, Bad forms heterodimers with antiapoptotic proteins, such as Bcl-X_L or Bcl-2, resulting in loss of integrity of the outer mitochondrial membrane. The subsequent release of apoptogenic proteins, including cytochrome c, triggers the executive phase of programmed cell death (Zha et al., 1996). Accordingly, we demonstrated that decreased Bad phosphorylation and collapse of the mitochondrial membrane potential in WIN55,212-2-treated C6 cells preceded activation of apoptotic proteases-caspases (Ellert-Miklaszewska et al., 2005).

Our further studies, as well as some published data, suggest that human glioma cells treated with cannabinoids enter the suicide cell death, using the same mitochondria-dependent (intrinsic) pathway (Carracedo et al., 2006). This mechanism contributes to the induction of apoptosis by cannabinoids in other types of tumor cells (Velasco et al., 2007), as well. However, an involvement of an alternative, death receptor-dependent (extrinsic) pathway in the apoptotic process triggered by these compounds cannot be ruled out.

The Role of ER Stress and Autophagy in Cannabinoid-Induced Cell Death

Proapoptotic and tumor growth-inhibiting activity of cannabinoids relies on the accumulation of de novo–synthesized ceramide, an event that occurs in the ER (endoplasmic reticulum), and eventually leads to execution of cell death via mitochondrial intrinsic pathway. A study by Carracedo et al. (2006) suggested a new link between the two events, alternative to inhibition of prosurvival pathways. They showed that Δ^9-THC treatment of glioma cells leads to upregulation of the stress-regulated protein p8, and ER stress-related downstream targets: ATF-4 (activating transcription factor 4), CHOP (the C/EBP-homologous protein), and TRB3 (tribbles homolog 3) (Fig. e11.4). Selective knockdown of ATF-4 and TRB3 blocked cannabinoid-induced apoptosis in glioma cells. Inhibition of ceramide synthesis de novo prevented Δ^9-THC-induced p8, ATF-4, CHOP, and TRB3 upregulation, as well as ER dilation, indicating that ceramide accumulation is an early event in the cannabinoid-triggered ER stress, and apoptosis in glioma cells (Carracedo et al., 2006). Furthermore, ER stress-evoked stimulation of the p8/TRB3 pathway preceded the inhibition of the Akt/mTOR (mammalian target of rapamycin) axis, considered a key step in the early triggering of autophagy (Fig. e11.4) (Salazar et al., 2009).

Autophagy, is an evolutionarily conserved catabolic process, where a cell self-digests its cytoplasmic contents in newly formed vesicle structures called autophagosomes. Autophagy is activated in response to stress conditions, such as nutrient starvation, the unfolded protein response (ER stress), and hypoxia, both in normal cells

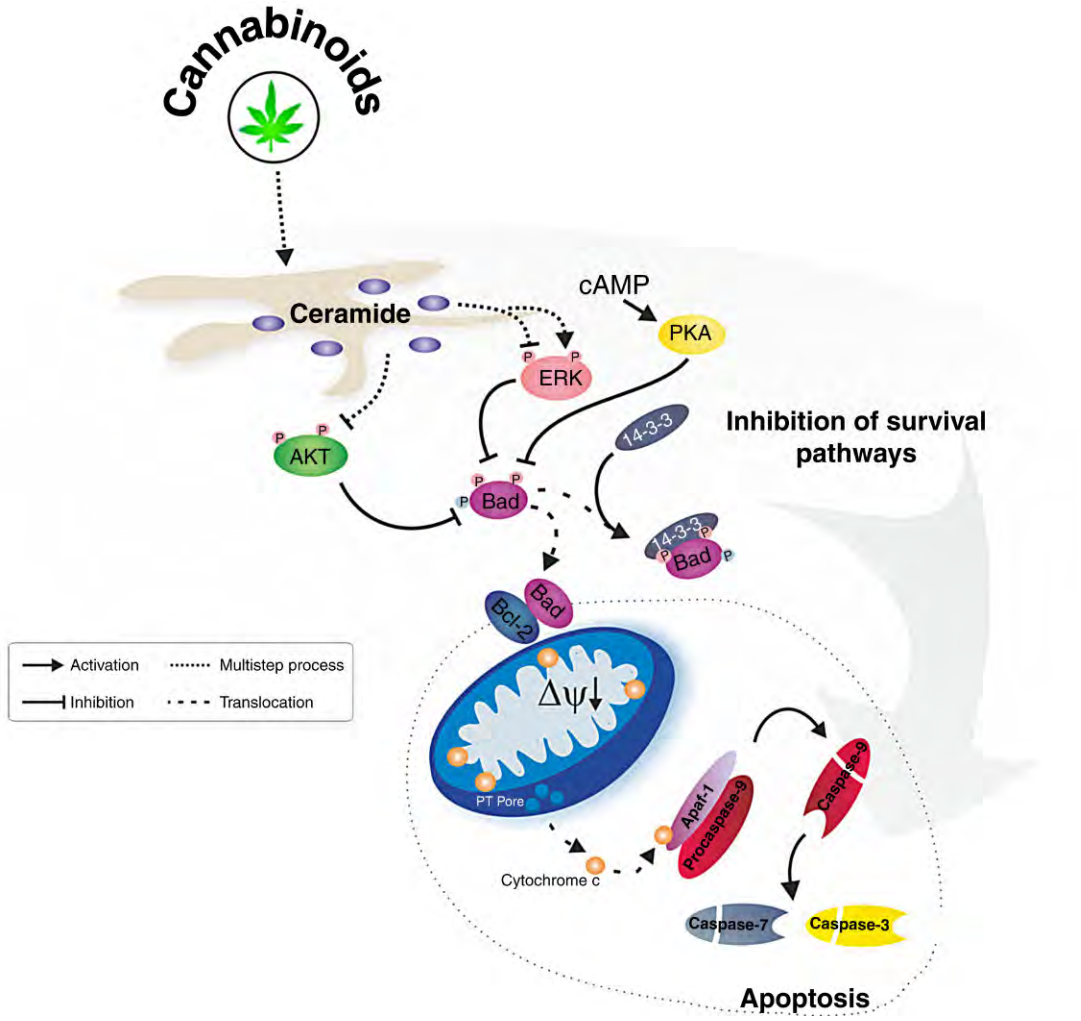

FIGURE e11.3 Inhibition of prosurvival pathways in antitumoral action of cannabinoids. Inhibition Akt and ERK signaling in response to cannabinoids stimulates translocation of Bad to the outer mitochondrial membrane, and its proapoptotic function. Interaction between Bad and Bcl-2 triggers a decrease of the mitochondrial membrane potential (Δψ) and release of proapoptotic factors (such as cytochrome c) to the cytosol, where apoptosis is executed by caspase cascade.

and during cancer progression. Classic autophagy promotes cell survival, but it may also contribute to cell death. Recently it was demonstrated that autophagy, not apoptosis, is induced in glioblastomas by radiation and several chemotherapeutic agents (Aoki et al., 2008).

Δ^9-THC treatment led to formation of autophagosomes in human glioma cells (Salazar et al., 2009). The authors also observed that ER stress occurred earlier than autophagy, which preceded apoptosis in cannabinoid-induced cell death. Administration of Δ^9-THC to mice bearing tumors derived from human astrocytoma cells produced increased TRB3 expression, inhibition of mTOR signaling pathway, occurrence of autophagy markers, and caspase-3 activation. These findings indicate that cannabinoid promotes the autophagy-mediated cell death through stimulation of ER stress, in human glioma cells. The role of autophagy in causing cell death, rather than occurring along with cell death, is still not clear. Pharmacological or genetic inhibition of autophagy, at different levels, prevented Δ^9-THC induced cell death, suggesting that autophagy contributes to cannabinoid antitumoral action in gliomas (Salazar et al., 2009). Of note, cannabinoid treatment also led to autophagy in other type of tumors (Vara et al., 2011).

Actions Beyond CB1/CB2 Receptors

Some cannabinoids activate apoptosis independently of cannabinoid-receptor binding. Cannabidiol antiproliferative action likely involves the induction of oxidative stress through the generation of reactive oxygen species. This effect is inhibited by tocopherol, a potent antioxidant and, interestingly, this was not observed in noncancerous primary glial cells (Massi et al., 2006). Anandamide promotes apoptosis through either the activation of vanilloid receptor (Maccarrone, Lorenzon,

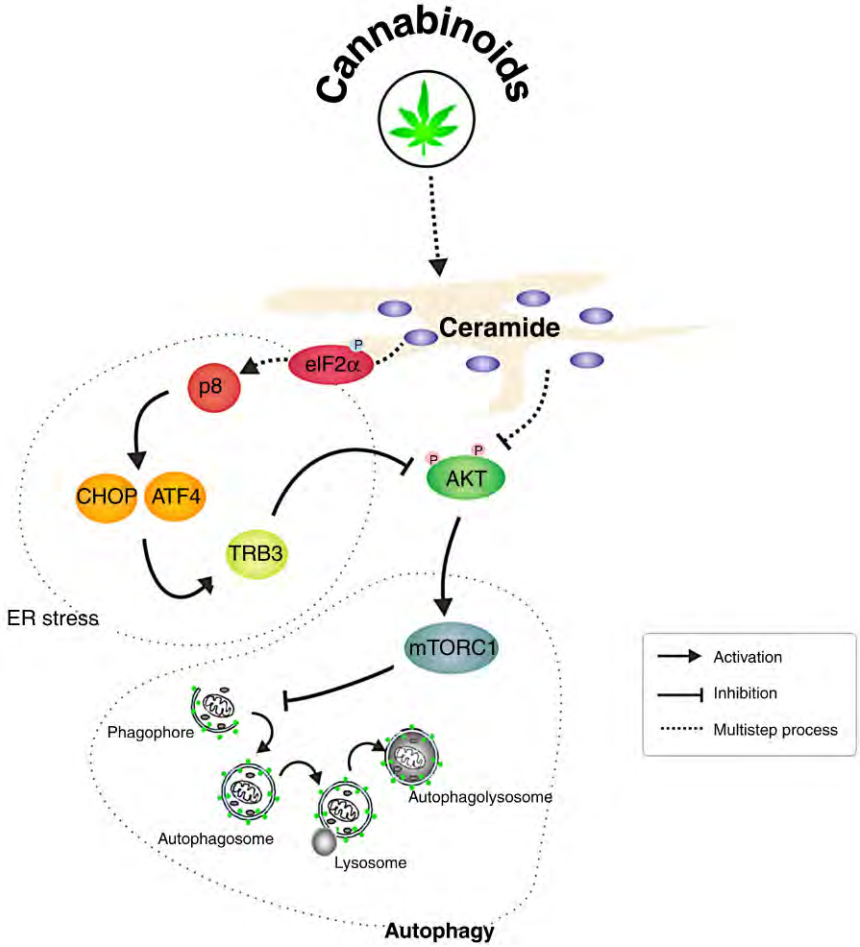

FIGURE e11.4 **Contribution of ER-stress and autophagy to cannabinoids-induced cell death.** Cannabinoid-induced phosphorylation of eIF2α (eukaryotic translation initiation factor 2α) and subsequent upregulation of the stress-regulated protein p8 and ER-stress-related downstream targets: ATF4 (activating transcription factor 4), CHOP (the C/EBP-homologous protein), and TRB3 (tribbles homolog 3) leads to inhibition of Akt, an upstream activator of mTORC1. Decreased activity of Akt/mTORC1 pathway contributes to initiation of autophagy that precedes apoptosis of glioma cell.

Bari, Melino, & Finazzi-Agro, 2000) or the accumulation of the proapoptotic sphingolipid ceramide mediated via CB1 or CB2 receptor activation (Galve-Roperh et al., 2000). All these results suggest that, overall, cannabinoids affect multiple cellular signaling pathways and, thus, have the potential to decrease cancer development. The mechanisms are, however, both cancer- and cannabinoid-specific. The final role of the cannabinoid receptors (CB1 and CB2) versus vanilloid or novel receptors is also likely to be of ongoing importance.

MULTIMODAL ACTION OF CANNABINOIDS AGAINST GLIAL TUMORS

Antitumoral Action of Cannabinoids In Vivo

The antitumor action of cannabinoids, mediated via the CB1 or CB2 cannabinoid receptors, has been also proved in vivo, revealing a significant regression of malignant gliomas in cannabinoid-treated animals (Galve-Roperh et al., 2000; Sanchez et al., 2001; Massi et al., 2004; Duntsch et al., 2006). Local intratumoral administration of Δ^9-THC or WIN55,212-2 (50 μg/day, for 8 days) reduced the size of tumors generated by intracranial inoculation of C6 glioma cells in rats, leading to complete eradication of gliomas, and increased survival in one-third of the treated rats (Galve-Roperh et al., 2000). There has been no recurrence in any of the surviving rats, as monitored periodically by MRI scan. Intratumoral and intraperitoneal administration of cannabidiol (Massi et al., 2004), a CB2-selective agonist such as JWH133 (Sanchez et al., 2001), or a novel cannabinoid such as KM-233 (Duntsch et al., 2006), blocked the proliferation of human astrocytoma cells implanted subcutaneously in the flank of immune-deficient mice. Our preliminary data suggest that systemic cannabinoid administration can effectively hamper intracranial tumor growth in rats (unpublished).

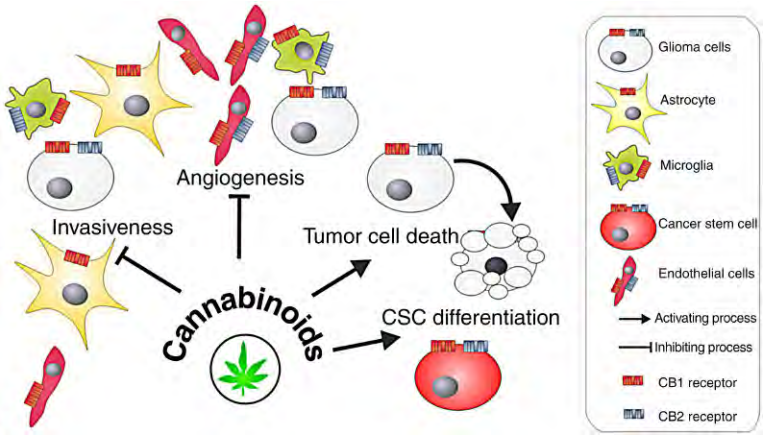

FIGURE e11.5 **Multimodal action of cannabinoids.** Cannabinoids induce tumor cell death, block angiogenesis and invasiveness, crucial for tumor progression, and induce differentiation of cancer stem cells (CSC).

Effects of Cannabinoids on Angiogenesis, Cell Migration, and Invasion

Cannabinoids have displayed a great potency in reducing glioma tumor growth in experimental animal models. Apparently, their effectiveness in vivo is attributed not only to antiproliferative action against tumor cells, but it also points to other cellular targets and additional mechanisms of action. JWH-133 reduced cell viability by 50% in vitro, while in vivo studies showed a 71% decrease in tumor growth after 8 days ($Rag^{-/-}$ mice, 40 μg/day intratumorally). Beyond affecting tumor cell survival, cannabinoids impair tumor angiogenesis, invasiveness, and even gliomagenesis (Fig. e11.5) (Blazquez et al., 2003; Aguado et al., 2007).

Increased demand for oxygen and nutrients supply to proliferating cancer cells makes angiogenesis a critical factor for the progression of solid tumors, and a popular target for oncologic therapies. Local administration of the CB2 selective cannabinoid JWH133 in a mouse flank inoculation model of glioma turned the vascular hyperplasia characteristic of actively growing tumors to a pattern of blood vessels, characterized by small, differentiated, and impermeable capillaries, thus proving antiangiogenic potential of the cannabinoid (Blazquez et al., 2003). In glioma (C6 cells) and astrocytoma xenografts, the overall vascularization of tumors was reduced by 88 and 21%, respectively (50 μg/day intratumorally, 8 or 25 days for gliomas and astrocytomas). This was associated with a reduced expression of proangiogenic factors, such as vascular endothelial growth factor (VEGF), and angiopoietin-2 in cannabinoid treated tumors. Downregulation of the major vascularization factors, including VEGF, was observed following treatment with Δ^9-THC, Met-F-AEA, WIN-55,212-2, and JWH-133, in various types of tumors (Blazquez et al., 2003; Pisanti et al., 2007). More importantly, intratumoral administration of Δ^9-THC to two patients with glioblastoma multiforme (grade IV astrocytoma) decreased VEGF levels and VEGFR-2 activation in the tumors (Blazquez et al., 2004). Antiangiogenic activity of cannabinoids could be partly related to a direct influence of the cannabinoids on endothelial cells migration and survival (Blazquez et al., 2003). Overall, cannabinoids appear to have consistent effects on the vascularization pathway, causing a decrease in tumor vascularization in in vivo models.

Δ^9-THC or JWH133 administration to glioma-bearing mice decreased the activity and expression of matrix metalloproteinase-2 (MMP-2), and tissue inhibitor of metalloproteinase 1 (TIMP-1) (Blazquez et al., 2008a,b). Δ^9-THC inhibited MMP-2 and TIMP-1 expression and cell invasion in cultured glioma cells (Blazquez et al., 2008a,b). MMP-2 is a proteolytic enzyme that allows tissue breakdown and remodeling, during angiogenesis and metastasis, and its upregulation is associated with high progression and poor prognosis of gliomas. Blocking the release of the extracellular matrix degrading enzyme by in vivo administered cannabinoids correlated with decreased tumor volumes (Blazquez et al., 2008a,b). TIMP-1 plays a critical role in the acquisition of migrating and invasive capacities by tumor cells. Decreased TIMP-1 expression was observed in biopsies from patients with recurrent glioblastoma multiforme tumors undergoing a clinical trial of THC efficacy (Blazquez et al., 2008a).

Multiple mechanisms were also suggested for antineoplastic activity of cannabidiol; however, they are unlikely mediated by the cannabinoid receptors. Cannabidiol effectively inhibited glioma cell proliferation, migration, and invasion, and caused a decrease in the expression of a set of proteins specifically involved in growth, invasion, and angiogenesis (Vaccani, Massi, Colombo, Rubino, & Parolaro, 2005; Solinas et al., 2013). Cannabidiol also inhibited HIF-1a, the regulatory subunit of the hypoxia inducible transcription factor, which

is responsible for orchestrating the adaptive transcriptional programs, inducing cell survival, motility, and tumor angiogenesis under hypoxic conditions (Solinas et al., 2013).

Although the identification of the cell of origin of gliomas is still a matter of debate, recent findings support the existence of brain cancer stem cells, responsible for tumor generation and recurrence. Aguado et al. (2007) showed that activation of CB1 and CB2 receptors with HU-210 and JWH133 promoted differentiation of glioma stem-like cells, derived from GBM biopsies and glioma cell lines. Moreover, cannabinoid challenge decreased neurosphere formation and cell proliferation in secondary xenografts, which correlated with the decreased efficiency of cannabinoid-treated glioma stem-like cells to initiate glioma formation in vivo (Aguado et al., 2007). Multimode action of cannabinoids, including inhibition of gliomagenesis, may have important implications for the development of cannabinoid-based therapeutic strategies.

THERAPEUTIC POTENTIAL OF CANNABINOIDS AGAINST HUMAN GLIOMAS

There is emerging evidence that cannabinoids, beyond their application for symptomatic relief, can in fact modify the progression of certain diseases. The efficacy of intratumorally or systemically administered cannabinoids in rat and mouse glioma models (Galve-Roperh et al., 2000; Sanchez et al., 2001; Massi et al., 2004; Duntsch et al., 2006) raised promises of using cannabinoid-based therapies against malignant gliomas in humans.

Safety Profile of Therapeutic Cannabinoids

Based on evidence from in vitro and in vivo studies, cannabinoids appear to have a favorable safety profile, and do not produce the generalized toxic effects as most conventional chemotherapeutic drugs. In contrast to the proapoptotic action of CB1/CB2-activating cannabinoids, such as Δ^9-THC and WIN55,212-2, on transformed cells, treatment of primary cultured astrocytes with these compounds did not trigger ceramide accumulation or induction of ER stress-related genes. Furthermore, cannabinoids promote survival of glial cells and neurons in different models of injury, suggesting that the antiproliferative effect of cannabinoids is selective for brain tumor cells, and viability of normal brain cells remains unaffected, or even favored by cannabinoid challenge (Guzman, 2003).

Apparently negligible expression of CB2 receptor in the brain, and its abundance in high-grade gliomas seems to confer a relative safety of CB2-selective agonists for targeted glioma therapy. Concomitantly, a novel cannabinoid chemotherapeutic exhibiting over 10-times higher affinity for the CB2 versus CB1 receptor produced minimal toxicity to healthy cultured brain slices at micromolar concentrations, required to eradicate U87 glioma cells (Duntsch et al., 2006). Moreover, clinical monitoring of mice with U87-derived subcutaneous tumors proved that intratumoral or systemic administration of the cannabinoid was effective in reducing tumor volume, and produced no general toxic effects. More importantly, animal studies also show a good safety profile of CB1-activating agents. In the studies by Galve-Roperh et al. (2000), Δ^9-THC and WIN55,212-2 were delivered intratumorally for 7 days, leading to partial or complete eradication of the tumors generated by intracranial inoculation of C6 glioma cells. MRI analysis showed no signs of damage related to necrosis, edema, infection, or trauma in tumor-free animals undergoing parallel treatment. Cannabinoid administration to tumor-bearing and control rats induced no substantial modification in behavioral parameters, in food and water intake, or in body weight. No abnormalities in biochemical and hematological parameters, or markers of tissue damage have been revealed during the 7-day delivery period, and for at least 2 months after cannabinoid treatment (Galve-Roperh et al., 2000).

Risks and Constrains

Although the general consensus indicates that cannabinoids have antitumor effects, there are a few studies that have shown contradictory results or duality of cannabinoids effects on tumor cell fate, depending of the dose range used (Guzman, 2003; Pisanti et al., 2009). Some authors questioned whether cannabinoid receptors do constitute relevant molecular targets to treat glioblastoma in humans, as the high concentrations of the currently available cannabinoids required to trigger apoptosis in glioma cells in culture are not pharmacologically relevant (Widmer, Hanemann, & Zajicek, 2008). This emphasizes the need for comprehensive dose-response studies in the future, correlated with analysis of the cannabinoid receptor expression. More importantly, immunosuppressive properties of cannabinoids in vivo, related to CB2 receptor stimulation on immune cells, raise concern about the risk of the antitumor immune response inhibition. Current evidence suggests that the type and stage of the cancer is likely to affect the outcome of cannabinoid exposure.

Results From a Pilot Clinical Study

On the basis of successful preclinical findings, Guzman et al. (2006) conducted a pilot phase I clinical trial, in which nine patients with recurrent glioblastoma

multiforme were administered Δ^9-THC intratumorally, via an infusion catheter placed into the resection cavity (Guzman et al., 2006). The primary endpoint of the study was to determine the safety of intracranial Δ^9-THC administration, in a dose escalation regime from the initial dose of 20–40 µg at day 1, increasing progressively for 2–5 days up to 80–180 µg/day. The cannabinoid treatment did not result in any marked alterations of clinical and laboratory tests in patients. There was no evidence of hemorrhage, edema, or injury over the median treatment duration of 15 days.

The good safety profile observed in this pilot clinical trial, together with remarkable antitumor effects reported in preclinical studies, may set the basis for further evaluation of the therapeutic potential of cannabinoids.

MINI-DICTIONARY

Angiogenesis Formation and maturation of new blood vessels.
Apoptosis A process of programmed cell death, involving specific proteolytic enzymes, called caspases, which leads to fragmentation of cellular content into apoptotic bodies, removed by phagocyting cells.
Autophagy A catabolic process accompanied by the encapsulation of parts of cytoplasm and organelles directed for breakdown and recycling in double-membrane vesicles called autophagosomes, which fuse with lysosomes to trigger degradation.
Cancer stem cell A rare population of cancer generating cells with stem-like properties.
Caspases Cysteine proteases, which play essential roles in apoptosis.
Ceramide A lipid signaling molecule, composed of sphingosine and a long chain fatty acid.
ER stress Cellular stress response related to endoplasmic reticulum.
Immunohistochemistry Imaging technique for detection of proteins in tissue sections.
Signaling pathway A cascade of intracellular events that transforms a signal (ie, growth factor binding to a cell membrane receptor, drug- or UV radiation-induced DNA damage) to cell response (ie, gene expression, cell movement, cell death).
Western blotting Molecular biology technique for detection of proteins bound to nitrocellulose membrane.

CHAPTER

72

The Role of 5-HT$_{1A}$ Receptor, and Nausea and Vomiting Relief by Cannabidiol (CBD), Cannabidiolic Acid (CBDA), and Cannabigerol (CBG)

E.M. Rock, L.A. Parker

Department of Psychology and Collaborative Neuroscience Program, University of Guelph, Guelph, ON, Canada

SUMMARY POINTS

- Cannabidiol and cannabidiolic acid reduce acute vomiting, acute nausea, and anticipatory nausea in animal models.
- Cannabidiol and cannabidiolic acid's effects are mediated by indirect agonism of the 5-HT$_{1A}$ receptor.
- Cannabigerol acts as a 5-HT$_{1A}$ receptor antagonist, as it blocks the antinausea and antiemetic effects of cannabidiol
- Cannabidiol and/or cannabidiolic acid may be potential treatments for chemotherapy-induced nausea and vomiting.
- Human clinical trials need to evaluate the efficacy of cannabidiolic acid to reduce chemotherapy-induced nausea and vomiting, especially for the reduction of anticipatory nausea, because there is currently no selective treatment for this symptom.

KEY FACTS OF CANNABIDOL AND CANNABIDIOLIC ACID'S EFFECTS IN ANIMAL MODELS OF NAUSEA AND EMESIS

- Cannabidiol and cannabidiolic acid reduce acute vomiting, acute nausea, and anticipatory nausea in animal models.
- Cannabidiolic acid is much more potent than cannabidiol in these animal models.
- These effects are mediated via the 5-hydroxytryptamine 1A (5-HT$_{1A}$) receptor, as administration of a 5-HT$_{1A}$ antagonist blocks these effects.
- As these phytocannabinoids do not exert their actions via the cannabinoid 1 receptor, these compounds are nonpsychoactive.
- Cannabidiol and/or cannabidiolic acid may be promising therapeutics for cancer patients undergoing chemotherapy.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00083-1

KEY FACTS OF CANNABIGEROL'S EFFECTS IN ANIMAL MODELS OF NAUSEA AND EMESIS

- Cannabigerol blocks cannabidiol's antiemetic effects, suggesting that cannabigerol acts as a 5-HT_{1A} receptor antagonist.
- Cannabigerol also blocks cannabidiol's antinausea effects, suggesting that cannabigerol acts as a 5-HT_{1A} receptor antagonist.
- These two phytocannabinoids may be acting in opposition at the 5-HT_{1A} receptor to modulate nausea and vomiting
- This finding has important implications for the potential therapeutic effects of various *Cannabis sativa* strains.
- A *C. sativa* strain with higher cannabidiol relative to cannabigerol may be more effective in reducing nausea and vomiting in human patients.

LIST OF ABBREVIATIONS

AN	Anticipatory nausea
CB_1	Cannabinoid receptor 1
CB_2	Cannabinoid receptor 2
CBD	Cannabidiol
CBDA	Cannabidiolic acid
CBG	Cannabigerol
DRN	Dorsal raphe nucleus
5-HIAA	5-Hydroxyindoleacetic acid
5-HT	Serotonin
5-HT_{1A}	5-Hydroxytryptamine 1A
5-HT_3	5-Hydroxytryptamine 3
LiCl	Lithium chloride
MRN	Median raphe nucleus
NK-1	Neurokinin-1
8-OH-DPAT	8-Hydroxy-2-(di-*n*-propylamino) tetralin
THC	Δ^9-Tetrahydrocannabinol

INTRODUCTION

Cannabis sativa has been used for medicinal purposes for more than 5000 years. Although the psychoactive cannabinoid Δ^9-tetrahydrocannabinol (THC) was isolated in 1964, and extensively studied thereafter, only recently have other cannabinoid compounds been investigated. This chapter reviews recent findings on the potential of the phytocannabinoids cannabidiol, cannabidiolic acid, and cannabigerol, to modulate nausea and vomiting via 5-hydroxytryptamine$_{1A}$ (5-HT_{1A}) receptors. First, we describe chemotherapy-induced nausea and vomiting, the preclinical animal models that are used to evaluate these potential treatments, and the involvement of the 5-HT_{1A} receptors in nausea and vomiting.

NAUSEA AND VOMITING

Emesis (vomiting), the act of eliminating poisonous or toxic contents via expulsion through the mouth, can be observed and quantified objectively. In contrast, nausea, a subjective experience, is less easily defined. It has been characterized as "an unpleasant, but not painful, sensation associated with a heightened awareness of the upper gut, cold sweating and the expectation that vomiting is imminent" (Andrews, Rapeport, & Sanger, 1988). Nausea and vomiting are distressing symptoms associated with pharmacological treatments, such as with anticancer drug therapies.

Chemotherapy-Induced Nausea and Vomiting

Cancer patients undergoing chemotherapy treatment often experience the distressing side effects of acute nausea and vomiting, as well as delayed nausea and vomiting (Fiore & Gralla, 1984). If posttreatment nausea and vomiting are not properly managed, anticipatory nausea (AN) and vomiting—a conditioned response elicited by reexposure to the illness-paired context of the clinic—can result (Morrow, 1982). Please refer to Table 72.1 for a description of the three phases of chemotherapy-induced nausea and vomiting. Although acute vomiting has become relatively well managed since the advent of the 5-hydroxytryptamine 3 (5-HT_3) receptor antagonists such as ondansetron, and the neurokinin-1 (NK-1) receptor antagonists, such as aprepitant (Hickok et al., 2003), delayed nausea and AN are still unmanaged (Hickok et al., 2003). Nausea is often identified as one of the most distressing symptoms experienced by cancer patients undergoing chemotherapy treatment (Aapro, Molassiotis,

TABLE 72.1 Three Phases of Chemotherapy-Induced Nausea and Vomiting

Phase	Description
Acute	Occurring within 24 h after treatment (day 1 of the chemotherapy cycle)
Delayed	Occurring 24 h to 7 days after treatment (days 2–7 of the chemotherapy cycle)
Anticipatory	A conditioned response, whereby patients feel ill upon simply returning (or preparing to return) to the clinic where they have received chemotherapy Occurring when acute and delayed phases are not properly managed

This table describes the three phases of chemotherapy-induced nausea and vomiting experienced by cancer patients, as discussed by Bender et al. (2002).

& Olver, 2005). With some 76% of patients reporting nausea, and up to 43% of patients reporting vomiting after their first treatment cycle (Morrow et al., 1998), the need for effective pharmacotherapies is apparent.

ANIMAL MODELS OF NAUSEA

In order to assess the efficacy of novel pharmacotherapies, reliable preclinical animal models are necessary. While the neural mechanisms of the emetic reflex have been well established using animal models, such as the ferret and the shrew (Hornby, 2001), the central mechanisms regulating nausea are not well understood (Andrews & Horn, 2006). In contrast to vomiting, nausea is subjective, making development of an animal model difficult. Further, we summarize the current selective models (for a comprehensive review refer to Sharkey, Darmani, & Parker, 2014) used to determine the nauseating potential of compounds, and to determine the potential of antinausea agents that can block or reduce nausea.

Conditioned Gaping

Conditioned Gaping to a Nausea-Paired Flavor (Acute Nausea)

Recent evidence suggests that conditioned disgust (gaping) reactions elicited by exposure to a flavor that has been previously paired with an illness-inducing agent, such as lithium chloride (LiCl), is a sensitive and selective model of nausea-induced behavior in rats (Parker, Rana, & Limebeer, 2008). Conditioned gaping reactions (see Fig. 72.1) are only produced by drugs capable of producing vomiting (in emetic species), and antiemetic drugs suppress conditioned gaping (see Parker et al., 2008). Using this model, if a rat is pretreated with a compound, resulting in a reduction of nausea-induced conditioned gaping reactions (relative to vehicle-pretreated controls), then this compound may be a potential therapeutic for reducing acute nausea.

FIGURE 72.1 **Conditioned gaping.** Conditioned gaping in rats, described as a wide, triangular opening of the mouth and jaw, exposing the incisors, is the most sensitive and reliable rodent model of nausea.

Conditioned Gaping to a Nausea-Paired Context (Anticipatory Nausea)

Interestingly, in addition to displaying conditioned gaping reactions to a LiCl-paired flavor, rats also display conditioned gaping reactions to a LiCl-paired context (Limebeer et al., 2008; Rock, Limebeer, Mechoulam, Piomelli, & Parker, 2008). Like the chemotherapy patient who feels nauseous upon returning to the clinic (where they have previously experienced nausea-inducing chemotherapy treatments), these contextually elicited conditioned gaping reactions serve as a rodent model of AN. Indeed, once AN develops in human chemotherapy patients, it is refractive to classic antiemetic treatments such as ondansetron (Hickok et al., 2003). Similarly, pretreatment with ondansetron is ineffective in suppressing conditioned gaping responses elicited by a LiCl-paired context, in rats (Limebeer, Hall, & Parker, 2006; Rock et al., 2014).

The conditioned gaping model is a useful tool for assessing the therapeutic potential of a compound, as a reduction in acute nausea (conditioned gaping to a LiCl-paired flavor) or AN (conditioned gaping to a LiCl-paired context) can be assessed. The work reviewed here employs the conditioned gaping model to assess the antinausea properties of the phytocannabinoids that exert their action via 5-hydroxytryptamine 1A (5-HT_{1A}) receptors.

SEROTONIN$_{1A}$ (5-HYDROXYTRYPTAMINE; 5-HT$_{1A}$) RECEPTORS AND NAUSEA AND VOMITING

5-HT_{1A} Receptors

5-HT_{1A} receptors, coupled to $G_{i/o,}$ are distributed throughout the central nervous system (see Hannon & Hoyer, 2008), with high levels expressed in limbic areas such as the raphe nuclei of the brainstem (Verge et al., 1986). 5-HT_{1A} autoreceptors, found on the cell bodies and dendrites of serotonin (5-HT) containing neurons (Riad et al., 2000) in the rat median raphe nucleus (MRN) and dorsal raphe nucleus (DRN), regulate 5-HT release (Verge et al., 1986) to terminal forebrain regions by decreasing the rate of neuronal firing (see Blier, Pineyro, el Mansari, Bergeron, & de Montigny, 1998). Activation of these somatodendritic 5-HT_{1A} autoreceptors leads to a reduction in neuronal firing (Blier & de Montigny, 1987). Local 5-HT release in the raphe nuclei reduces neuronal firing, producing negative feedback regulation of neurotransmitter release (Adell & Artigas, 1991). Indeed, 5-HT receptor agonists inhibited release of 5-HT from in vitro preparations of rodent brain tissue (Chase, Katz, & Kopin, 1969). In addition, in vivo, 5-HT receptor agonists reduced the electrical activity of serotonergic neurons in the DRN (Aghajanian, 1972). Therefore, stimulation of

somatodendritic 5-HT_{1A} autoreceptors results in a decrease of available 5-HT.

Classic 5-HT_{1A} Receptor Agonists and Antagonists

8-hydroxy-2-(di-*n*-propylamino) tetralin (8-OH-DPAT) is a highly selective and centrally active potent ligand (Arvidsson et al., 1981) preferentially binding to the somatodendritic (Hjorth & Magnusson, 1988) 5-HT_{1A} autoreceptor (Middlemiss & Fozard, 1983). 8-OH-DPAT has traditionally been utilized as the standard receptor agonist to evaluate behavioral effects of the 5-HT_{1A} receptor. Indeed, systemically administered 8-OH-DPAT dose-dependently reduces the 5-HT synthesis rate, decreases 5-hydroxyindoleacetic acid (5-HIAA), the main metabolite of 5-HT (Sharp, Bramwell, & Grahame-Smith, 1989), and inhibits 5-HT neuronal firing in the DRN (Blier, Steinberg, Chaput, & de Montigny, 1989), ultimately reducing release of 5-HT in the brain (Hjorth et al., 1982).

WAY100135, a 5-HT_{1A} receptor antagonist, has been used to investigate this receptor, however, WAY100135 has since been shown to act at both presynaptic and postsynaptic 5-HT_{1A} receptors (Fletcher et al., 1993). More recently, the highly selective and potent 5-HT_{1A} receptor antagonist WAY100635 has replaced the use of WAY100135 (Forster et al., 1995). These 5-HT_{1A} receptor antagonists effectively block the effects of 8-OH-DPAT on extracellular levels of 5-HT in the rat hippocampus (Assie & Koek, 1996) and, when given alone, WAY100135 but not WAY100635 decreases 5-HT levels, indicating possible partial agonist properties of WAY100135 at somatodendritic 5-HT_{1A} receptors (Assie & Koek, 1996).

Classic 5-HT_{1A} Receptors, and Nausea and Vomiting in Humans

With the advent of the antiemetic 5-hydroxytryptamine 3 (5-HT_3) receptor antagonists, most nausea and vomiting research has focused on the involvement of this receptor, rather than the 5-HT_{1A} receptor, in mediating these effects. Although a great deal of animal literature supports the involvement of the somatodendritic 5-HT_{1A} autoreceptors in the regulation of emesis and nausea, little human literature exists. Chial et al. (2003) reported that administration of the 5-HT_{1A} receptor partial agonist buspirone selectively suppressed self-report nausea scores in the nutrient drink test (an assessment of gastric functioning).

Classic 5-HT_{1A} Receptors and Nausea and Vomiting in Animals

5-HT_{1A} receptor agonists such as 8-OH-DPAT, buspirone, and LY228729 suppress vomiting in emetic species, such as pigeons (Wolff & Leander, 1994, 1995, 1997), *Suncus murinus* (house musk shrew; Javid & Naylor, 2006; Okada, Torii, Saito, & Matsuki, 1994), cats (Lucot & Crampton, 1987a,b, 1989; Lucot, 1990a,b) and dogs (Gupta & Sharma, 2002). In the rat acute nausea model, 8-OH-DPAT reduces conditioned gaping (Limebeer & Parker, 2003; Limebeer, Litt, & Parker, 2009). Please refer to Table 72.2 for a summary of the involvement of 5-HT_{1A} receptor ligands in nausea and vomiting using animal models. This evidence indicates that agonism of the 5-HT_{1A} receptor via classic 5-HT_{1A} ligands reduces toxin-induced nausea and vomiting. The remainder of this chapter will focus on the constituents of the cannabis plant (phytocannabinoids) that exert their antinausea and antiemetic effects via activation of the 5-HT_{1A} receptor.

PHYTOCANNABINOIDS AND NAUSEA AND VOMITING

C. sativa has been used for centuries as a therapeutic for many ailments (Mechoulam, 2005), such as the alleviation of nausea and vomiting. In fact, in the 19th century, *C. sativa* was used in British medical practice to treat nausea and vomiting (O'Shaughnessy, 1843). In the 1970s, young chemotherapy patients anecdotally reported experiencing less (or none) of their nausea and vomiting when they were "high" from smoking cannabis (Sweet, Miller, Weddington, Senay, & Sushelsky, 1981), prompting early clinical trials demonstrating the efficacy of THC, the psychoactive component in cannabis, to reduce chemotherapy-induced nausea and vomiting (Sweet et al., 1981). Due to the unsuccessful control of chemotherapy-induced nausea and vomiting, oncologists began to investigate cannabinoids for their therapeutic potential. Recently, the mechanisms by which cannabinoids reduce chemotherapy-induced nausea and vomiting have been investigated (see Sharkey et al., 2014 for review) using animal models.

Cannabidiol

A major nonpsychoactive component in cannabis, cannabidiol (CBD), was isolated from Lebanese hashish in 1963 by Mechoulam and coworkers (Mechoulam & Hanus, 2002). CBD has a very low affinity (in the micromolar range) for the cannabinoid 1 (CB_1) and cannabinoid 2 (CB_2) receptors (Pertwee, 2008). Although CBD exerts its therapeutic effects via a number of mechanisms, CBD's antiemetic and antinausea effects seem to be mediated by action at the 5-HT_{1A} receptor. For a summary of the antinausea and antiemetic effects of cannabidiol in animal models, please refer to Table 72.3.

TABLE 72.2 Summary of Classic 5-HT_{1A} Receptor Ligand Modulation of Nausea and Vomiting in Animal Models

Compound	Species	Effect	References
8-OH-DPAT	Pigeon	Eliminated ditolyguanidine-induced emesis	Wolff and Leander (1994)

Gepirone	*S. murinus*	Eliminated motion-induced emesis	Okada et al. (1994)
WAY100635	*S. murinus*	No effect alone on motion-induced emesis Unable to block 8-OH-DPAT-induced attenuation of motion-induced emesis	Javid and Naylor (2006)

This table summarizes the published effects of classic 5-HT_{1A} receptor ligands in animal models of nausea and emesis.

CBD Reduces Nausea and Vomiting in Human Patients

In a phase II clinical trial, when added to the standard therapy, the oromucosally administered cannabis-based medicine Sativex (containing approximately 50/50 THC and CBD) was effective (57% of Sativex patients vs 22% of placebo patients reporting no delayed emesis, and 71% of Sativex patients vs 22% of placebo patients reporting no delayed emesis) in suppressing delayed nausea and vomiting (Duran et al., 2010). To date, there are no published human clinical trials evaluating the ability of CBD alone to reduce chemotherapy-induced nausea and vomiting.

CBD Reduces Vomiting in Animal Models

In *S. murinus*, CBD produces a biphasic effect, at low doses (5 mg/kg) suppressing, and at higher doses (40 mg/kg) potentiating acute cisplatin-induced vomiting (Kwiatkowska et al., 2004). In addition, acute LiCl-induced vomiting has been suppressed by low doses (5–10 mg/kg) of CBD, while higher doses (20–40 mg/kg) of CBD were found to facilitate (rather than reduce) LiCl-induced vomiting (Parker et al., 2004). Interestingly, CBD is ineffective in reducing motion-induced vomiting (Cluny et al., 2008). Consistent with the low binding affinity of CBD to the CB_1 receptor (Pertwee, 2008), the CB_1 receptor antagonist SR141716 did not block the CBD-induced suppression of vomiting (Parker et al., 2004). WAY100135 effectively blocked the CBD- (5 mg/kg) induced suppression of acute nicotine-, LiCl- and cisplatin- (20 mg/kg, but not 40 mg/kg) induced vomiting in *S. murinus*, indicating a 5-HT_{1A} receptor mediated antiemetic effect (Rock et al., 2012).

CBD Reduces Acute Nausea in Animal Models

In rats, CBD (5 mg/kg) has been shown to reduce conditioned gaping to a LiCl-paired flavor, when

TABLE 72.3 Summary of Cannabidiol's Effects in Animal Models of Nausea and Vomiting

Phytocannabinoid	Animal model	Effect	Mechanism of action	References

		Ineffective for motion-induced emesis	Not evaluated	Cluny, Naylor, Whittle, and Javid (2008)
	Acute nausea in rats	Reduced conditioned gaping	5-HT_{1A} receptor	Rock et al. (2012)
		Enhanced 8-OH-DPAT-induced reduction of conditioned gaping	Not evaluated	Rock et al. (2012)
	Anticipatory nausea in rats	Reduced conditioned gaping	Not evaluated	Rock et al. (2008)

This table summarizes the published effects of cannabidiol (CBD) in animal models of nausea and emesis, as well as whether these effects are mediated by the 5-HT_{1A} receptor.

administered systemically (Rock et al., 2012) or centrally to the DRN (Rock et al., 2012). In addition, at a subthreshold dose (0.5 mg/kg), CBD systemically enhances the antinausea effect of a subthreshold dose (0.005 mg/kg) of 8-OH-DPAT (Rock et al., 2012).

The antinausea effect of CBD has been blocked by WAY100635, when it is systemically or centrally (intra-DRN) administered (Rock et al., 2012). In fact, when WAY100635 was infused outside of the DRN, CBD's antinausea effects were not blocked, indicating that the effect was selective to the DRN. Since the DRN is a site of somatodendritic 5-HT_{1A} autoreceptors, activation of which decreases the firing rate of 5-HT afferents projecting to terminal brain regions (Verge et al., 1985), these results suggest that CBD may be exerting its antinausea effects by reducing the firing rate of 5-HT afferents which project to terminal forebrain areas. CBD enhanced the action of 8-OH-DPAT in vitro (% stimulation of [^{35}S]GTPγS binding above basal) and in vivo (conditioned gaping), without acting as a direct agonist at the 5-HT_{1A} receptor in brainstem preparations (Rock et al., 2012). Therefore, CBD may be acting as an indirect agonist, thereby augmenting endogenous 5-HT activation of the 5-HT_{1A} receptor to reduce toxin-induced acute nausea.

CBD Reduces Anticipatory Nausea in Animal Models

CBD (1 and 5, but not 10 mg/kg) reduced conditioned gaping to a LiCl-paired context (Rock et al., 2008); however, CBD's mechanism of action in AN has not yet been evaluated. As there are currently no specific treatments for AN, this nonpsychoactive component in cannabis could be a promising therapeutic option; however, its limited effective dose range may prove difficult.

Conclusions

It is unfortunate that CBD has not yet been investigated in published human clinical trials with chemotherapy patients, despite its efficacy in reducing acute vomiting, acute nausea, and anticipatory nausea in animal models (via indirect 5-HT_{1A} receptor agonism). Indeed, CBD has also been shown to inhibit paclitaxel-induced neuropathic pain (through 5-HT_{1A} receptors), without diminishing chemotherapeutic efficacy (Ward et al., 2014), and has even been shown to have antitumor action itself (De Petrocellis et al., 2013).

Cannabidiolic Acid

Cannabidiolic acid (CBDA) is the nonpsychoactive carboxylic acidic precursor of CBD. It is present in the fresh cannabis plant, and decarboxylates upon heating, such as when cannabis is smoked or dried. In comparison to CBD, much less work has focused on this acidic precursor. Studies in our laboratory indicate that it is a highly potent antiemetic and antinausea agent. For a summary of the antinausea and antiemetic effects of CBDA in animal models, please refer to Table 72.4.

TABLE 72.4 Summary of Cannabidiolic Acid's Effects in Animal Models of Nausea and Vomiting

Phytocannabinoid	Animal model	Effect	Mechanism of action	References
Cannabidiolic acid	Emesis in *Suncus murinus*	Reduced motion-, LiCl-, or cisplatin-induced emesis	Not evaluated	Bolognini et al. (2013)
	Acute nausea in rats	Reduced conditioned gaping	5-HT_{1A} receptor	Bolognini et al. (2013)
		Enhanced ondansetron- or metoclopramide-induced suppression of conditioned gaping	Not evaluated	Rock and Parker (2013a,b)
	Anticipatory nausea in rats	Reduced conditioned gaping	5-HT_{1A} receptor	Bolognini et al. (2013)
		Enhanced tetrahydrocannabinolic acid-induced suppression of conditioned gaping	5-HT_{1A} receptor and CB_1 receptor	Rock et al. (2014)

This table summarizes the published effects of cannabidiolic acid (CBDA) in animal models of nausea and emesis, as well as whether these effects are mediated by the 5-HT_{1A} receptor.

CBDA Reduces Vomiting in Animal Models

Recent evidence indicates that CBDA (0.1 and/or 0.5 mg/kg, i.p.) potently reduces motion-, LiCl-, and cisplatin-induced vomiting in *S. murinus* (Bolognini et al., 2013). Unfortunately, the 5-HT_{1A} receptor mediation of these effects has not yet been investigated.

CBDA Reduces Acute Nausea in Animal Models

CBDA (0.1 mg/kg) also reduced LiCl-induced acute nausea, an effect that was blocked by WAY100635, but not SR141716 (Bolognini et al., 2013). CBDA also increased the ability of the 5-HT_{1A} receptor agonist, 8-OH-DPAT, to potently stimulate [^{35}S]GTPγS binding to rat brainstem membrane, without activating CB_1 receptors in vitro (Bolognini et al., 2013). CBDA, like CBD, seems to inhibit nausea in rats by enhancing the activation of 5-HT_{1A} receptors. More recently, CBDA has been shown to reduce acute nausea at a dose as low as 0.5 μg/kg (Rock & Parker, 2013a). As well, a subthreshold dose of CBDA (0.1 μg/kg) enhanced the ability of a mildly effective dose of ondansetron (1 μg/kg), or a subthreshold dose of metoclopramide (0.3 mg/kg, a dopamine antagonist) to reduce LiCl-induced acute nausea (Rock & Parker, 2013a,b).

CBDA Reduces Anticipatory Nausea in Animal Models

CBDA suppressed contextually elicited conditioned gaping (at doses as low as 0.001 mg/kg) in the rodent model of AN (Rock et al., 2014), and this effect was blocked by the 5-HT_{1A} receptor antagonist, WAY100635 (Bolognini et al., 2013). In addition, coadministration of subthreshold doses of CBDA (0.1 μg/kg) and tetrahydrocannabinolic acid (the acidic precursor of THC, 5 μg/kg) enhanced the suppression of AN, over that of either agent alone (Rock et al., 2014), indicating that these acidic precursors potently reduce AN. Pretreatment with SR141716 (CB_1 receptor antagonist) or WAY100635 blocked the combined effect of CBDA and THCA, indicating the involvement of both receptors in this effect (Rock et al., 2014).

Conclusions

CBDA suppresses nausea and vomiting in rats, in a 5-HT_{1A} receptor dependent manner, suggesting that CBDA could be developed as a treatment for nausea and vomiting because of its potency. CBDA could be a particularly interesting candidate treatment for AN, as there is no current selective therapeutic available, once AN develops. CBDA is also promising for development as a treatment for acute nausea, because, unlike CBD, it does not potentiate nausea and/or vomiting at high doses. In fact, CBDA is active at much lower doses than CBD, but at high doses CBDA is merely ineffective. As well, CBDA does not modify overall activity level of rats (Bologini et al., 2013; Rock et al., 2014). In addition to its antiemetic and antinausea properties, CBDA (5, 10, 25 mM) inhibits its highly aggressive human breast cancer cell migration, a factor crucial in the prevention of cancer metastasis (Takeda et al., 2012). These results highlight the need for clinical trials with cancer patients undergoing chemotherapy, perhaps especially in breast cancer patients, in order to prevent metastasis.

Cannabigerol

Cannabigerol (CBG), a nonpsychoactive component of cannabis (Gaoni & Mechoulam, 1964) has been shown to act as a 5-HT_{1A} receptor antagonist (Cascio, Gauson, Stevenson, Ross, & Pertwee, 2010), and recent work in our laboratory has confirmed a 5-HT_{1A} mediated effect in our animal models. For a summary of CBG's effects in animal models of nausea and vomiting, please refer to Table 72.5.

CBG Blocks CBD-Induced Antiemetic Effects in Animal Models

CBG (5 mg/kg, i.p.) blocked the CBD- (5 mg/kg, i.p.) induced suppression of LiCl-induced acute vomiting in

TABLE 72.5 Summary of Cannabigerol's Effects in Animal Models of Nausea and Vomiting

Phytocannabinoid	Animal model	Effect	Mechanism of action	References
Cannabigerol	Emesis in *Suncus murinus*	Blocked the CBD-induced reduction of LiCl-induced emesis	5-HT_{1A} receptor	Rock et al. (2011)
	Acute nausea in rats	Blocked the CBD- or 8-OH-DPAT-induced reduction of conditioned gaping (5 or 10 mg/kg)	5-HT_{1A} receptor	Rock et al. (2011)
		Reduced conditioned gaping (1 mg/kg)	Not evaluated	Rock et al. (2011)

This table summarizes the published effects of cannabigerol (CBG) in animal models of nausea and emesis, as well as whether these effects are mediated by the 5-HT_{1A} receptor.

S. murinus, suggesting that CBG exerts its action at the 5-HT_{1A} receptor to block the effect of CBD at this receptor (Rock et al., 2011).

CBG Blocks CBD-Induced Antinausea Effects in Animal Models

CBG (5 or 10 mg/kg, i.p.) blocked the CBD- (5 mg/kg, i.p.) and 8-OH-DPAT- (0.01 mg/kg, s.c.) induced suppression of acute nausea (Rock et al., 2011), again suggesting that CBG is acting on the 5-HT_{1A} receptor to block the 5-HT_{1A} mediated effects of CBD and 8-OH-DPAT. Also of interest is the finding that CBG (1 mg/kg, i.p.) actually suppressed acute nausea on its own (Rock et al., 2011). This result is in line with the in vitro concentration specific effects of CBG, such that low concentrations of CBG stimulate GTPγS binding to mouse brain membranes, but this effect disappears at higher concentrations where CBG acts as a 5-HT_{1A} receptor antagonist (Cascio et al., 2010).

Summary

Interestingly, CBG and CBD, two constituents found in the cannabis plant, both target 5-HT_{1A} receptors, although with opposite actions, to modulate the effects of these receptors on nausea and vomiting. Therefore, the concentration of these opposing cannabinoids in a specific strain of cannabis may be important in its efficacy to reduce chemotherapy-induced nausea and vomiting.

CONCLUSIONS

It is only recently that the therapeutic potential of phytocannabinoids (other than THC) has been investigated. Here we provide evidence that several nonpsychoactive phytocannabinoids (CBD, CBDA, CBG), which act at 5-HT_{1A} receptors, are potential treatment options for chemotherapy-induced nausea and vomiting.

MINI-DICTIONARY

Acute nausea Chemotherapy-induced nausea that occurs within 24 h of the initial chemotherapy administration (see Table 72.1). This condition is modeled in rats with conditioned gaping to a lithium chloride-paired flavor.

Anticipatory nausea A classically conditioned response to the hospital context that becomes associated with the chemotherapy-induced illness experienced by patients (see Table 72.1). This condition is modeled in rats with conditioned gaping to a lithium chloride-paired context.

Cannabidiol (CBD) A nonpsychoactive phytocannabinoid exhibiting a low binding affinity for the CB 1 and 2 receptors. Its antinausea and antiemetic effects are mediated by the 5-HT_{1A} receptor, as the CBD-induced effects can be blocked by a 5-HT_{1A} receptor antagonist.

Cannabidiolic acid (CBDA) The acidic precursor to cannabidiol, found in the fresh *Cannabis sativa* plant. CBDA potently reduces nausea and vomiting through a 5-HT_{1A} receptor mediated mechanism, as the CBDA-induced effects can be blocked by a 5-HT_{1A} receptor antagonist.

Cannabigerol (CBG) A nonpsychoactive phytocannabinoid that acts as a 5-HT_{1A} receptor antagonist, in contrast to CBD. In fact, CBG blocks CBD's antiemetic and antinausea effects.

Conditioned gaping Although rats cannot vomit, they exhibit conditioned disgust reactions (gaping), in response to the delivery into their oral cavity of a flavor that has been previously paired with illness (see Fig. 72.1). This is considered a rodent model of acute nausea. Gaping, described as a wide, triangular opening of the mouth and jaw exposing the incisors, is the most sensitive and reliable rodent model of nausea. Indeed, rats also exhibit gaping in response to a context that has been previously paired with illness—a rodent model of anticipatory nausea.

Emesis Also known as vomiting, it is the body's means of rejecting noxious or toxic substances via the oral cavity. Therefore, antiemetic compounds prevent (or reduce) vomiting.

5-Hydroxytryptamine 1A (5-HT_{1A}) receptors A serotonin (5-HT) receptor subtype binding the endogenous 5-HT neurotransmitter, mediating inhibitory neurotransmission. The 5-HT_{1A} receptors located in the dorsal raphe nucleus are largely somatodendritic (located on the soma and dendrites of serotonergic neurons).

Phytocannabinoid Cannabinoids derived from *C. sativa*.

S. murinus Also known as the house musk shrew, these insectivores vomit in response to toxins such as lithium chloride. Therefore, *S. murinus* are an animal model to assess whether certain compounds can reduce (or eliminate) vomiting, indicating an antiemetic effect.

Acknowledgments

We would like to thank NSERC (Grant #92057) and GW Pharmaceuticals for their support of this work, and in particular GW Pharmaceuticals for supply of several compounds that we have evaluated in the experiments reviewed here.

SUMMARY POINTS

- Marijuana and hashish are currently the most frequently self-administered "soft narcotics," worldwide.
- The discovery of specific THC receptors (CB1 and CB2) was a decisive point in the research of the biological activity of their compounds.
- The biological activity of cannabinoids is closely connected with specific receptor-agonist interactions.
- The activity of a "reward system" of CNS, stimulation of dopaminergic pathway of neurotransmission, and receptors response are believed to be crucial for dependence development.
- This mechanism of dependence development is believed to be a universal process for most addictive substances.
- Chronic exposure to THC can influence the stimulation of genetically-related changes connected with stimulation of long-term response genes.
- Addiction is a complex disease that is multifactorial and polygenic, and does not follow a Mendelian pattern of gene expression.
- No single gene has been identified that would predispose individuals to develop addictive behaviors.

KEY FACTS OF THC ADDICTION DEVELOPMENT

- Addiction with THC and other cannabinoids develops according to general mechanisms, similar to the mechanisms typical for other drugs of abuse.
- The dopaminergic system, as well as negative reinforcement, play a critical role in addiction with cannabinoids.
- Molecular mechanisms of addiction are closely connected with cannabinoids receptors expression, signaling cascades, synaptic plasticity, and changes in gene expression.
- In spite of the differences in chemical structure of newly designed synthetic cannabinoids, they act through cannabinoid receptors, but involving different neuronal pathways.

LIST OF ABBREVIATIONS

BDNF	Brain-derived neurotrophic factor
cAMP	Cyclic adenosine monophosphate
CB1	Cannabinoid receptor 1
CB2	Cannabinoid receptor 2
CNR 1	Cannabinoid receptor 1 gene
CNR 2	Cannabinoid receptor 2 gene
CNS	Central nervous system
CREB	c-AMP response element binding protein

[1]Genetic links to dependence, expression, and polymorphism of involved genes, neurotransmission and signaling cascade, brain plasticity, THC chemical structure and CB receptors response.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00084-3
Copyright © 2017 Elsevier Inc. All rights reserved.

DNA	Dezoxyribonucleic acid
ERK	Extracellular signal-regulated kinase
ΔFosB	Δ Fos family protein
GABA	Gamma-aminobutyric acid
LTD	Long-term depression
LTP	Long-term potentiation
MAPK	Mitogen-activated protein kinase
mRNA	Messenger ribonucleic acid
NFκB	Nuclear factor kappa-light-chain-enhancer of activated B cells
NMDA	*N*-methyl-D-aspartate
RNA	Ribonucleic acid
SNP	Single gene polymorphism
TrkB receptor	Neurotrophic tyrosine kinase receptor type 2
THC	Δ^9-Tetrahydrocannabinol

INTRODUCTION

Cannabis sativa derivatives (such as Δ^9-tetrahydrocannabinol, THC) are currently the most frequently self-administered "soft narcotics" worldwide. Despite common opinion, regular use of THC results in complete physical and psychological addiction, and in a number of somatic disorders. THC, like other psychoactive substances, leads to a chronic and recurrent central nervous system (CNS) disease, complex in terms of its etiology, molecular mechanisms, clinical course, and treatment. This phenomenon is thought to be influenced by several concurrently acting genetic, molecular, psychological, and social factors, but the molecular aspects of this process are not fully known yet.

Gene expression and genetic polymorphism may influence the risk of dependence development, the clinical course of the disease, as well as the frequency of intake of the drug of abuse. Therefore, the polymorphism and expression of dopaminergic neurotransmission genes and brain-derived neurotrophic factor become adequate candidates for the examination of the correlation between genetic factors and the development of addiction.

Regardless of genetic component, participation in the development of dependence is variously assessed and continually discussed. We must be aware that CNS disorders, as well as addiction, are polygene qualified and, therefore they are not inherited according to Mendelian pattern. The methodology (heterogeneity of estimated population), techniques, and conclusions regarding molecular examination of addiction were postulated by numerous scientists and practitioners. This could explain the differences and often contradictory results obtained by researchers.

The development of cannabinoid addiction impacts several neurobiological processes. To understand this problem better, it is necessary to analyze how THC acts during an initial exposure, and after repetitive exposure. This problem was described in detail by Nestler (2001). Over the last two decades, cannabinoid investigation has made enormous progress. Recent research has focused on mechanisms by which cannabinoids bring on alterations in brain functioning. The changes caused by cannabinoids in brain neuronal circuits, among which are neurotransmitters receptors, signaling cascades and gene expression are intensively investigated. Owing to the fact that genetic variability may increase the risk of addictive behaviors, exposure to THC may result in neuroadaptation—for example, an addicted state. This adaptation occurs at the cellular, molecular, or genetic level, and is associated with synaptic plasticity and altered gene expression. A significant breakthrough has been the discovery of an endogenous cannabinoid system which plays a major role in neuromodulation.

Currently, apart from natural THC residues, a pivotal problem appears to be brought by a number of newly designed, synthetic THC derivatives. Due to the phenomena of their receptor-related activity, regardless of distinctly different chemical structures, this problem is extensively discussed in the subsequent section of this chapter.

THE ROLE OF THE DOPAMINERGIC SYSTEM IN THE DEVELOPMENT OF THC ADDICTION

There is a variety of drugs of abuse presenting a diverse chemical and pharmacological profile. These substances act on different neurobiological systems, and undergo different metabolic pathways. However, each one of them appears to exert its initial effects on the mesocorticolimbic dopaminergic pathway, despite their chemical diversity and individual molecular targets, a matter that was emphasized by Nestler (2005).

Dopamine is a messenger involved in many functions that are essential for the survival of the organism. Berke and Hyman (2000) conclude in their study that the main behaviors affected by dopamine include movement, cognition, pleasure, and motivation, as well as learning and memorization. Dopamine is an essential element in identifying natural rewards for the organism, and it seems that all substances of abuse increase the release of this neurotransmitter in specific areas of the brain, including cannabinoids. Hyman, Malenka, and Nestler (2005) show that dopamine is directly implicated in the positive reinforcement of drug addiction, and that it plays a major role in motivation. The development of addiction recruits different sources of reinforcement, different neuroadaptive mechanisms, and different neurochemical changes to deregulate the brain reward system. This

problem was a main topic in studies performed by Koob and Le Moal (2001). Several behavioral studies have used different animal models to clarify the consequences of chronic exposure to cannabinoids. There is considerable evidence that an increase in extracellular dopamine concentration in the nucleus accumbens may be observed following acute and chronic administration of THC. It was also demonstrated that THC releases dopamine along the reward pathway, and definitely increases dopamine activity in the ventral tegmental area. The repeated use of psychoactive substances is thought to arise from neurochemical actions causing the positive reinforcing effects of a drug. Nevertheless, the transition from occasional drug use to drug addiction requires an additional source of reinforcement, and the reduction of the negative emotional state resulting from the repeated exposure. Since the majority of drugs of abuse have been found to cause a negative emotional state during acute abstinence, the combination of the positive reinforcing effects of the psychoactive substances with the reduction of the negative emotional states of drug abstinence provides a powerful motivational force for compulsive drug taking, which is characteristic for addiction. Drug discontinuation is accompanied by electrophysiological and biochemical changes resulting from decrease of dopamine function. The increased reward threshold during abstinence from psychoactive substances intake has been observed in the course of the withdrawal from THC. Due to the complex nature of drug addiction, it seems necessary to analyze two different types of brain responses to addictive substances: neuroadaptation, and synaptic plasticity. Neuroadaptation is the brain's response to repeated psychoactive drugs administration, and exhibits as a ground for tolerance, sensitization, and withdrawal syndrome. The following subsequent exposures to the addictive substances can lead to the various adaptations in key neural circuits, and may play a significant role in the development and maintenance of addiction. Studies carried out by Lüscher and Malenka (2011) showed that these long-lasting changes are associated with reward circuitry via a mechanism known as synaptic plasticity, which is the dynamic adjustment of synaptic efficacy occurring in response to environmental or internal stimuli. The best known forms of synaptic plasticity are described as long-term potentiation (LTP) and long-term depression (LTD), and are involved in adaptive learning and memory. The previously mentioned mechanisms of synaptic plasticity could lead to the changes in synaptic strength in several brain regions, and reorganization of neural circuitry by altering gene and protein expression in neurons that receive diverse signals as effect of LTP or LTD. LTP is the enhancement of synaptic strength that results from synchronous firing of connecting neurons, whereas LTD is the weakening of synaptic strength. Synaptic transmission is a dynamic process, and can be modified by several factors, for example, *Cannabis* administration. THC increases mesolimbic dopamine transmission in the nucleus accumbens, probably via a μ-opioid receptor-mediated mechanism because μ-receptor antagonists prevent the THC-induced dopamine increase in the brain mesolimbic area, as proved by Tanda, Pontieri, and Di Chiara (1997). THC also inhibits release of glutamate and GABA in the striatum, and causes long-term forms of synaptic plasticity.

MOLECULAR MECHANISMS OF ADDICTION

A central role of endocannabinoid physiological control system in the regulation of a variety of constitutional processes, as well as in the regulation of the rewarding effects of abused substances, is well evidenced. The endocannabinoid system appears to play a role as a modulator of dopaminergic activity, therefore it participates in the primary rewarding effects of THC, and acts as retrograde messenger to inhibit classical transmitters such dopamine, serotonin, GABA, glutamate, acetylcholine, or norepinephrine, as described by Onaivi (2007). This system comprises endogenous cannabinoids, the metabolic enzymes responsible for the formation and degradation of endocannabinoids, and the cannabinoid receptors. The endocannabinoids are endogenous lipid-signaling molecules, which are generated in the cell membrane from phospholipids precursors, and possess cannabimimetic properties, since they bind and activate cannabinoid receptor subtypes. The best-studied endocannabinoids are anandamide and 2-arachidonylglycerol. These molecules are involved in the action of a variety of addictive substances' mechanisms. Both endogenous and exogenous cannabinoids (like THC) produce their effects through the activation of two different receptors identified as G protein-coupled cannabinoid receptors. The first subtype of cannabinoid receptors was sequenced, cloned, and named CB_1, and is encoded by the *CNR1* gene. These receptors are highly expressed in brain, and mediate most of central effects of THC. The second subtype, abbreviated CB_2, initially was believed to be peripheral, and that it did not mediate any central effect of THC. This cannabinoid receptor is both positively and negatively coupled to MAPK and cAMP pathways, as revealed by Pertwee (2010). CB_2 receptors are encoded by the *CNR2* gene located on chromosome 1p36. CB_2 receptors are also present at low levels in several areas of the brain, and are expressed in the CNS on microglia, astrocytes, and subpopulations of neurons, which was the aim of the study carried out by Roche and Finn (2010). It is important to stress that the activation of metabotropic receptors can produce effects which can

persist for a considerable period. For example, the effect of protein kinase A action is protein phosphorylation (ie, transcription factors) that regulates gene expression. The expression of CB_1 cannabinoid receptors in the brain and peripheral tissues is well studied, but the data connected with brain neuronal expression of CB_2 receptors are controversial. It seems that CB_1 and CB_2 receptors work independently, but also cooperate in different neuronal populations to regulate a number of physiological activities influenced by THC use. MAPK/ERK cascade seems to be crucial for neuronal plasticity, and is activated by cannabinoids. Some experiments performed on animal models reveal that acute administration of THC induces a progressive and transient activation (via phosphorylation) of MAPK/ERK cascade in the dorsal striatum and the nucleus accumbens. It is also shown that ERK inhibition blocks THC-induced rewarding properties. The data strongly support that ERK activation in the striatum is critically involved in long-term neuronal adaptive responses underlying THC-induced long-term behaviors.

Koob, Sanna, and Bloom (1998) suggested that the study of transcriptional mechanisms of addiction is based on the hypothesis that regulation of gene expression is an important mechanism by which chronic exposure to addictive substances causes long-lasting changes in the brain. There are a number of mechanisms by which drugs of abuse are able to regulate gene expression, including activation and suppression of transcription factors, epigenetic mechanisms, and induction of noncoding RNAs. Transcription factors are proteins that bind to specific response elements in the promoter regions of target genes, and regulate those genes' expression. A number of transcription factors have been identified for their potential role in addiction because their expression and activation is regulated in the mesocorticolimbic pathway at the time of exposure to drugs of abuse. Prominent examples include: ΔFosB, CREB, and NFκB. ΔFosB is one such transcription factor that has received particular attention due to its unusual stability; it is a truncated splice variant of the *FosB* gene, and it shares homology with other Fos family members. ΔFosB accumulates in the striatum, following chronic drug administration, and its expression persists for several weeks after the last drug exposure. Due to its ability to increase the incentive motivational properties of drugs of abuse, this transcription factor is called a "molecular switch" which facilitates the transition to addiction. CREB is expressed at a high level in the brain, and is believed to have an effect as a negative modulator of drug reward. NFκB controls transcription of DNA, and belongs to the category of "rapid-acting" primary transcription factors. NFκB seems to be a factor regulating addiction-induced plasticity, and is implicated in processes of memory.

THE MOLECULAR BASIS OF LONG-TERM BRAIN PLASTICITY

The central topic in cellular and molecular biology is the issue of gene expression, and involves studies on the mechanisms of transcription initiation, elongation, and termination. Numerous studies analyzed phenomena of primary transcripts by RNA polymerases, the processing of primary transcripts to produce mature mRNAs, intercompartmental transport of mRNAs to sites of translation, translation of mRNA by polyribosomes, and, finally, the processing and decay of the protein products. There are a number of mechanisms by which drugs of abuse are able to regulate gene expression, including activation and suppression of transcription factors, epigenetic mechanisms, and induction of noncoding RNAs. Some of them were described by Madsen, Brown, and Lawrence (2012).

Regulation of gene expression leads to relatively stable changes within neurons. Repeated exposure to a drug of abuse eventually causes changes in nuclear function, and alters rates of transcription of particular target genes by causing repeated perturbation of intracellular signal transduction pathways. Modified gene expression leads to altered activity of the neurons in which those changes occur. Ultimately, these circumstances can cause changes in the neural circuits in which the neurons operate. Investigations of long-term changes in brain structure and function that accompany chronic exposure to abused drugs suggest that alterations in gene regulation contribute substantially to the addictive phenotype.

Recent findings indicate that there are specific mechanisms which regulate posttranslational modification of gene expression, as well. This enables the control of heritable changes to phenotypes that are not dependent on changes in the genetic code. Epigenetics has a number of definitions, but in neuroscience it is commonly defined as changes in gene expression that occur through modulation of chromatin which are not brought about by changes in the underlying DNA sequence. So-called epigenetic modifications occur beyond remodeling of chromatin structure, incorporating the effect of environmental stimuli. Consequently, enhanced or suppressed transcription of genes to proteins is influenced by the accumulation of posttranslational modifications to histones, or changes to DNA, independent of the DNA sequence. These modifications limit access of transcription factors, and thus result in altered gene expression. Data published by Robison and Nestler (2011) suggested that knowledge regarding the function of epigenetics in addictive behaviors is incomplete, and is focused on alterations in the accessibility of genes within their native chromatin structure induced by histone tail modifications and DNA methylation, and the regulation of gene expression by noncoding RNAs. Methylation in promoter regions inhibits the ability

of transcription factors to interact with the gene. DNA methylation is crucial in synaptic plasticity, learning, and memory formation. Addictive substances induce specific changes to histones which can be heavily influenced by acute and chronic exposure, and histone methylation may play a critical role in the process of neuroadaptation. The regulation of gene expression by noncoding RNAs determines a number of cellular processes by influencing inhibition or activation of gene expression in processes including regulation of the cell cycling, differentiation signal transmission, apoptosis, synaptic plasticity, and response to DNA damage. Heterogeneous morphology of dendritic spines is thought to be the morphological basis for synaptic plasticity associated with learning and memory formation. Indeed, dendritic spines' structure is regulated by molecular mechanisms that are fine-tuned and adjusted according to the level and direction of synaptic activity, development, specific brain region, and different experimental behavioral conditions, as revealed in studies performed by Sala, Cambianica, and Rossi (2008). Drugs of abuse can induce presynaptic and postsynaptic plasticity, and cause alterations in neuronal signaling and synaptic rearrangement resulting from modification in synaptic structures and effecting signal transduction, and in the level of receptor expression. Among the many neuroadaptations, most important are the alterations in cell morphology, including changes in dendritic spines. Changes to the density and morphology of dendritic spines represent a commonly reported neuroadaptation, following exposure to a drug of abuse, or during withdrawal. It appears as a significant increase in the density and branching of dendritic spines of medium spiny neurons. Neurotrophic factors also play an important role in drug-induced neuroadaptative changes. They regulate survival, development, and function of the nervous tissue, and act via appropriate receptors and activation of various signaling pathways in the target cells.

GENETIC LINKS TO DEPENDENCE

Addiction is a complex disease that is multifactorial and polygenic, and does not follow a Mendelian pattern of gene expression. No single gene has been identified which predisposes individuals to develop addictive behaviors. However, genetic background appears to influence addiction development, with mutations in certain genes believed to increase an individual's vulnerability to addictive behaviors. So far, 1500 genes have been linked to an addiction phenotype in humans. Duncan (2012) suggested that the best studied effects in the genetic sequence occur at the level of change to a single nucleotide in a gene (single gene polymorphism—SNP). There is strong evidence that SNPs have the potential to influence addictive behaviors, but the relationship between SNPs and drug addiction is not fully understood. Understanding this relationship is complicated by the possibility of gene splicing. As proteins are not derived from continual sequences in the genes, splicing occurs when different exons of RNA are reconstituted in different ways, thus producing different isoforms of the same protein. Patterns of gene expression are regulated by transcription factors which are transiently expressed to act locally in order to regulate gene expression in the cell in which they were initially produced. Transcription factors are proteins which bind to a specific DNA sequence to regulate the transcription of DNA to mRNA, often acting to enhance or decrease the activity of enzymes such as RNA polymerase, or molecules which regulate the acetylation of histones.

To elucidate the genetic aspects of drug dependence, it is important to note that there is increasingly more evidence that genetics and alterations in gene expression have long-term consequences on addictive behaviors. Changes to gene structure via SNPs may increase an individual's vulnerability to becoming addicted, if they are exposed to psychoactive substances. There is also a greater understanding of the significance of epigenetic mechanisms and the noncoding RNA in mediating addiction, and altering the transcription and translation of DNA and RNA.

SIGNIFICANCE OF RECENT FINDINGS OF MOLECULAR AND GENETIC EFFECTS OF CHRONIC CANNABINOID ADMINISTRATION, AND PROSPECTS OF NEW STRATEGIES TO TREAT CANNABINOID DEPENDENCE

Recent developments in cellular and molecular neurobiology focused on the mechanisms by which cannabinoids produce persistent alterations in brain functioning, and facilitate the development of drug dependence. Neuronal circuits and their elements undergo significant adaptations in response to exposure to cannabinoids. Fratta and Fattore (2013) suggest that THC acts not only via presynaptic CB_1 receptors to inhibit release of GABA and glutamate, but also causes long-term forms of synaptic plasticity by modulation of the number and strength of connections between the neurons. Uncoupling and downregulation of brain CB_1 receptors, due to prolonged THC exposure, result in the development of cannabinoid addiction and tolerance. Neuroadaptive changes in various brain regions are reported in studies on animal models, and in humans. Decreased mRNA expression in limbic area, and a reversible and regionally selective downregulation of cortical CB_1 receptors are observed in the brains of chronic cannabis smokers. Signaling cascades activated by THC are involved in neuronal plasticity, and it is thought that different neuronal circuits

might be involved in the early and late phases of cannabinoid addiction. Chronic THC exposure affects induction of immediate early genes, and also increases the expression of brain-derived neurotrophic factor (BDNF), a key regulator of the mesolimbic dopamine pathway that was described by Ninan (2011). BDNF potentiates dopamine release in the nucleus accumbens through activation of TrkB receptors on dopaminergic nerve terminals. BDNF-TrkB signaling is involved in transcription, translation, and trafficking of proteins during various phases of synaptic development, and has been implicated in several forms of synaptic plasticity. The latest data published by Biskupska et al. (2013) indicate the importance of the relationship between the Val66Met BDNF gene polymorphism, and dependence of psychoactive agent. The expression of BDNF is partially regulated by the transcription factor CREB, a central integrator of signaling from a number of extracellular stimuli that influence neuronal plasticity. A number of gene modifications occur in brain during THC abstinence. They are mostly related to three molecular networks, such as the glutamate/corticoids and CREB/ERK networks, as well as the network involving transcription factor regulating addiction induced plasticity, such as NFκB.

Recently, the growing field of epigenetics highlighted some of the mechanisms by which drugs of abuse regulate the transcriptional potential of cells in order to initiate lasting changes in gene expression. Increasing evidence implicates various mechanisms of gene regulation in the lasting changes that THC induces in the brain. Only through an integrated approach that establishes casual links between the molecular, cellular, and behavioral levels, as well as genetic aspects, it may be possible to understand the complex nature of the phenomenon of cannabis abuse. Nemeroff and Vale (2005) presented their opinion that recent technological advances, including the completion of the sequencing of the human genome, chromosome mapping, and several neurobiological findings, offer the hope of identifying the genetic basis of addiction, and new approaches to addiction therapy.

THE STRUCTURES AND BIOLOGICAL ACTIVITIES OF THC AND ITS ANALOGS—OWN CONSIDERATIONS

The biological activity of cannabinoids is closely connected to specific receptor–agonist interactions. The localization of CB1 and CB2 receptors is known and

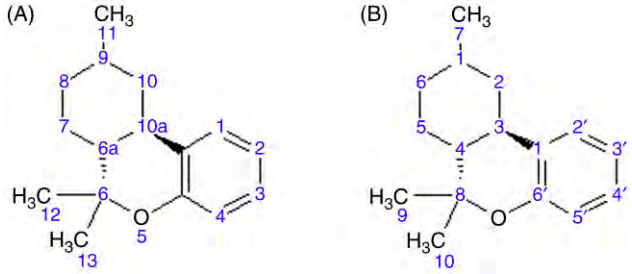

FIGURE 73.1 **Chemical structure of cannabinoles.** (A) Dibenzopyran numbering; (B) monoterpenoid numbering. *Source: The structures prepared in ACD/Labs ChemSketch software.*

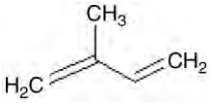

FIGURE 73.2 **The chemical structure of isoterpen.** *Source: The structure prepared in ACD/Labs ChemSketch software.*

widely described in the literature. All the narcotic properties of THC can be easily explained by the fact that CB1 receptors are localized in brain regions responsible for emotions and feelings, among other physiological functions. However, the chemical variety of THC-like compounds has not been fully discussed yet. Newly designed synthetic molecules, revealed nearly every month, indicate that, in spite of their chemical composition being different from natural cannabinomimetics, their internal activity against CB receptors is even better than the original compounds. To understand the chemical variety better, it is necessary to study the chemical structures of these molecules in detail. Cannabinoles belong to a specific class of compounds whose core fragment is dibenzopyran (Fig. 73.1A).

On the other hand, the core moiety can be also classified as monoterpenoid derivate (Fig. 73.1B); however, the first classification seems to better reflect the chemical properties of cannabinoles. In fact, THC is not a typical terpen composed of several five-carbon isoprene units (Fig. 73.2), but it possesses only one isoprene fragment without isolated double bond system, composed of at least two of the same units typically found in terpens (Fig. 73.3).

Moreover, specific benzene coupled double-bond system, included in the molecules, influence the three-dimensional shape of cannabinoles, while electron distribution in terpens is known to form regular

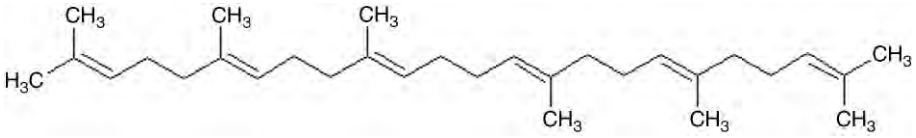

FIGURE 73.3 **Squalene—typical terpen structure.** *Source: The structure prepared in ACD/Labs ChemSketch software.*

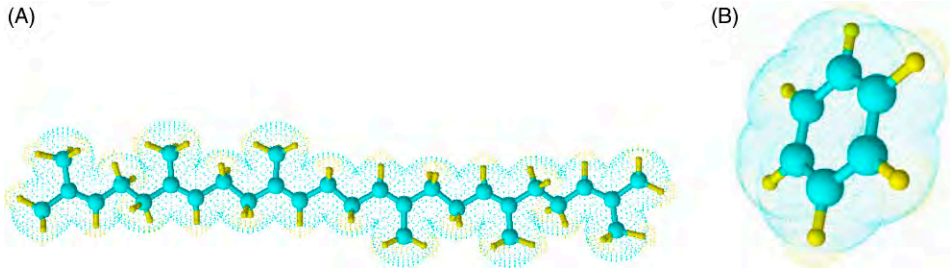

FIGURE 73.4 **The three-dimensional shape of squalene (A) and benzene (B) molecules.** *Source: The structures prepared in ACD/Labs 3D Viewer software.*

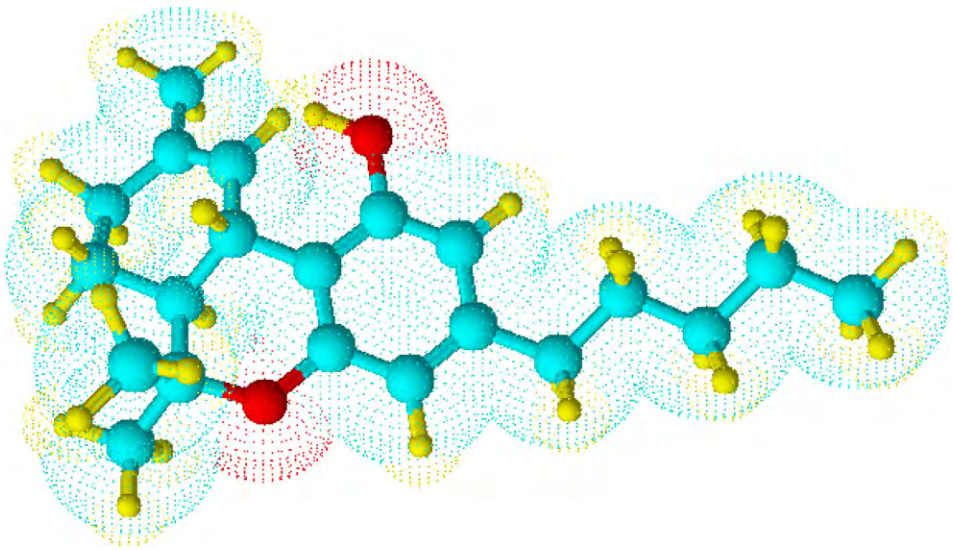

FIGURE 73.5 **The three-dimensional shape of THC structure.** *Source: The structure prepared in ACD/Labs 3D Viewer software.*

round-shaped spaces, whereas substituted benzene structure is nearly flat (Fig. 73.4).

The presence of the benzene ring in cannabinoles results in the specific shape of the molecule, and may have considerable influence on its biological activity, that is, receptor interactions. Another characteristic feature of cannabinoles is the presence of oxygen ether bridges coupling the benzene ring (sp2 hybridization), with carbon (sp3 hybridization) bounding two methyl groups. This connection of flat benzene rings with space-distributed aliphatic chains of nonaromatic properties influences additionally the very characteristic shape and properties of the molecule (Fig. 73.5).

Depending on the name of the core used as the basic cannabinoles' moiety, there are different rules for naming the structures of cannabinoles (Fig. 73.1). Regardless of the core name, cannabinoles include two stereoisomeric carbons (positions 6a, 10a), and thus appear as four optical stereoisomers, all indicating narcotic properties. Apart from their optical activity, cannabinoles form a number of geometrical isomers resulting mainly from the localization of double bond in cyclic hexane (positions 7, 8, 9, 10). The change in localization of this double bond is of key importance for narcotic properties because only when situated in position 9 it forms the most active THC. The localization of the penthyl aliphatic chain is limited only to position 3 in most cannabinoles exhibiting of biological activity, and this fragment of the molecule, besides providing characteristic shape, is responsible for increased lipophilic properties, rather than increased narcotic properties.

While analyzing the molecular composition of cannabinoles, it is clear that all of them are hydrophobic and do not have any heteroatom which may be easily metabolized to more easily water soluble derivatives. Even though there is oxygen present in the ethyl bridge, the ethers used will not undergo biological first phase reactions such as, for example, nitrogen including compounds. Instead, THC is metabolized through oxidization of methyl group (position 11) but the ether bridge remains unchanged (Fig. 73.6). This process incorporates many multistage enzymatic reactions, and it results in long time for THC elimination.

The comparison of psychoactive cannabinoles' molecular properties with other CB receptors agonists provides very interesting findings. The molecular structure of anandamide or 2-arachidonoglycerol, known to be a physiological, endogenous agonist of CB receptors,

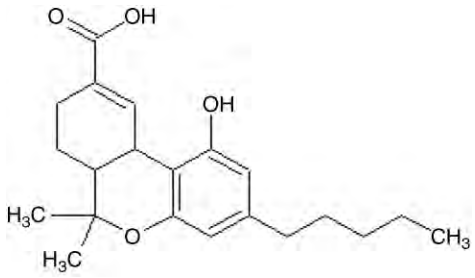

FIGURE 73.6 **The structure of 11-nor-9-carboxy-THC.** *Source: The structure prepared in ACD/Labs ChemSketch software.*

belongs to a completely different chemical group than THC, like many THC functional analogs (Fig. 73.7).

Anandamide is composed of a long aliphatic chain with coupled double-bond system, ending with second order amide bound with aliphatic alcohol, and it forms structures of no optical activity. The core of anandamide is more likely to be similar to isoterpens than THC. The part common to both THC and anandamide is the aliphatic chain of butane that ends anandamide, and is coupled to the benzene ring of THC. Anandamide does not include oxygen, having instead nitrogen; it is of aliphatic structure, without aromatic chemical properties, and it poses aliphatic alcohol hydroxyl group, not phenol, as in the case of THC. All these differences in chemical composition make important differences for these two molecules. It is clear that the key for the narcotic properties of THC is localization of double bond in position 9, since the other natural tetrahydrocannabinol, Δ^8-THC, does not have narcotic action. On the other hand, the presence of aliphatic butane chain being common for CB receptors interacting compounds suggests some hard importance of this substructure, especially compared to newly designed CB agonists belonging to the general cannabinoids group.

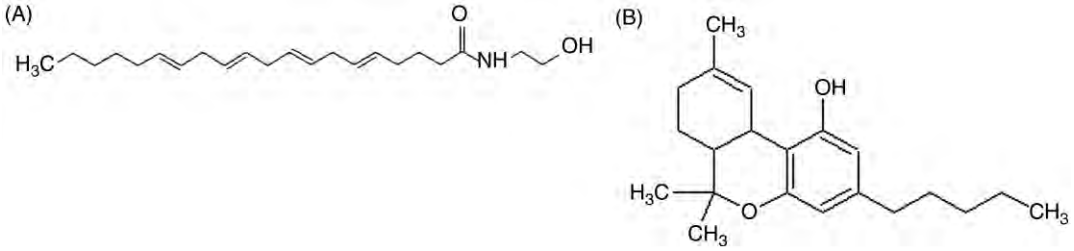

FIGURE 73.7 **The chemical structure of anandamide (A) and THC (B).** *Source: The structures prepared in ACD/Labs ChemSketch software.*

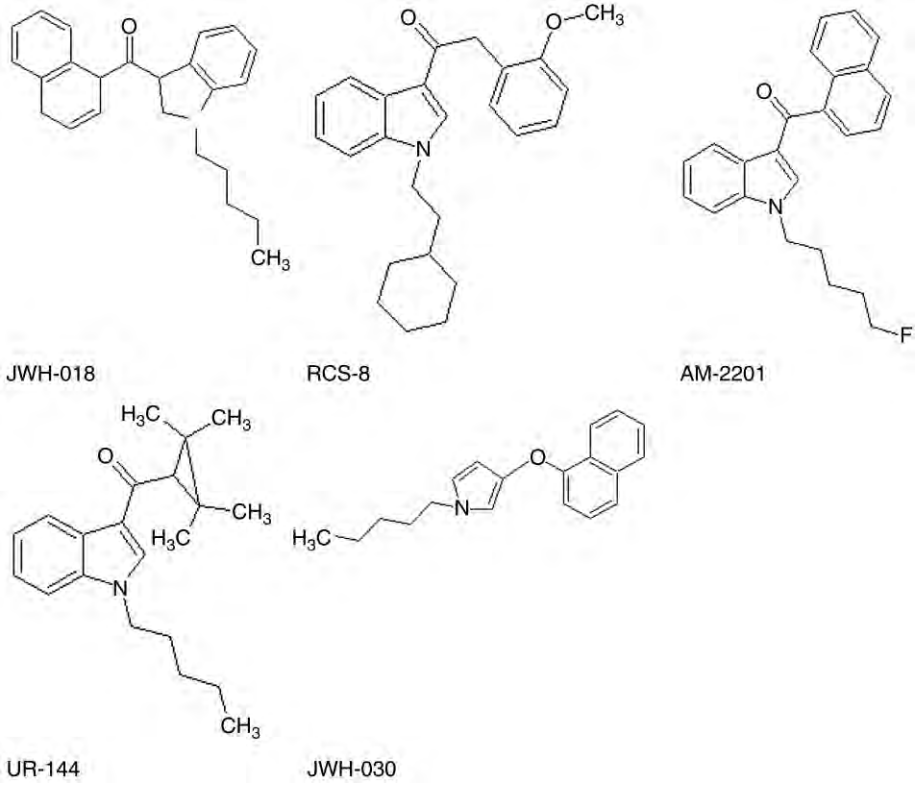

FIGURE 73.8 **Newly designed synthetic cannabinoids classes.** *Source: The structures prepared in ACD/Labs ChemSketch software.*

All the numerous newly designed synthetic cannabinoids indicate more chemical variety, both against anandamide and THC. All the compounds so far known can be classified into five main groups (Fig. 73.8):

- Naphtoylindoles (JWH-018, JWH-073),
- Phenylacethylindoles (RCS-8, JWH-250),
- Benzoylindoles (AM-2201, AM-1241),
- Cyclopropanoylindoles (UR-144, A-834,735),
- Naphthoylpyrroles (JWH-030, JWH-147).

We can easily see indole structure to be common for four of five newly designed cannabinomimetics, and the same is valid for the four carbon aliphatic chains attached to nitrogen, which we pointed out in typical cannabinoles. All the structures of newly designed compounds contain nitrogen, similar to anandamide, but here it is implemented typically into the cyclic system of the indole. The chemical properties of the molecules with an indole system (cyclic third order amine coupled to aromatic ring) are considerably different from amide properties such as anandamide, therefore it is hard to find chemical similarity between these five molecules, tetrahydrocannabinoles, and anandamide. Indole structure is more likely to be found in serotoninergic agents (the base core of serotonin), and its presence may result in nonselective, cannabinomimetic action of these compounds. In fact, the symptoms observed after intake of these substances are not only connected with stimulation of endocannabinoid system, but also to serotoninergic and GABAergic systems. Moreover, narcotic symptoms following their consumption are described as more emphatogenic. It is not clear if increased activity of these compounds results from stronger CB receptors' interaction, or rather multidirectional way of action involving more than one CNS pathway. Other characteristic feature of these newly designed cannabinoids that results from different chemical composition is their water solubility that stands in full contrast with THC, which is completely hydrophobic. This physical property is very important in respect of the way of administration (not only smoking, but could be sniffed or eaten) but it may also have a large influence on biological half-life time, rate of brain blood barrier crossover and, finally, elimination time from the body. The nitrogen present in all these molecules is more easily metabolized and eliminated through the urinary system.

SUMMARY POINTS

- Δ^9-Tetrahydrocannabinol (Δ^9-THC) is currently used medicinally (ie, dronabinol, a synthetic form of Δ^9-THC) as well as recreationally (drug abuse).
- Δ^9-THC is not yet used as an anticancer agent in patients.
- There are conflicting findings regarding the effects of Δ^9-THC on the proliferation of cancer cells (protumor effects); (1) depending on the concentrations, cannabinoids either inhibit or stimulate the proliferation of cancer cells (Bifulco et al., 2006; Velasco et al., 2012), and (2) the large majority of studies published to date have yet to demonstrate that cannabinoids exert anticancer effects on breast, as well as on many other types of cancer (Bifulco et al., 2006; Velasco et al., 2012).
- Concerning the inconsistencies described earlier, our group and other researchers have suggested that Δ^9-THC can stimulate the proliferation of breast cancer cells under conditions in which the expression of cannabinoid receptors is very low or undetectable (McKallip et al., 2005; Takeda et al., 2008a, 2009; Watanabe et al., 2005), although it is currently difficult to directly compare the expression levels of CB receptors.
- The mechanism(s) responsible for Δ^9-THC evoked estrogen receptor (ERα)-positive MCF-7 cell proliferation observed in the absence of cannabinoid (CB) receptors remains unknown; we hypothesized that cyclooxygenase-2 (COX-2)/prostaglandin E_2 (PGE_2) pathways, which are suppressed by CB receptors, are activated under 17β-estradiol (E2)-deprived conditions (E2–) due to the downregulation of the receptors that are positively modulated by E2/ERα, and this results in the Δ^9-THC stimulation of MCF-7 cell growth (Fig. 74.4).
- Under E2-rich conditions (E2+), (1) upregulated CB receptors suppress COX-2 pathways, (2) Δ^9-THC activates CB receptors, and (3) simultaneously increased ERβ inhibits MCF-7 cell growth by suppressing E2/ERα (Figs. 74.5 and 74.6).
- Further studies including in vivo experiments are needed to confirm this hypothesis.

KEY FACTS OF BREAST CANCER AND ESTROGEN RECEPTORS

- The vast majority of human breast cancers originate from epithelial cells.
- Epithelial human breast cancer cell lines such as MCF-7 and MDA-MB-231 cells are frequently used in the experiments to analyze molecular mechanisms of breast cancer growth.
- Approximately 60% of all breast cancer patients have 17β-estradiol (E2)-dependent breast cancer that expresses estrogen receptor α (ERα), and requires E2 for tumor growth. MCF-7 breast cancer cell growth is sensitive to treatments with E2 due to its stimulation (as a ligand) of ERα. On the contrary, MDA-MB-231 cells are known as ERα-negative.
- In addition to ERα, research is now focusing on ERβ, the second type of ER discovered in 1996. The expression levels of ERβ were found to be the highest in normal mammary tissue and decreased with the development of breast tumors.
- Although the physiological role of ERβ in breast cancer cells has not been examined in as much detail as ERα, accumulating evidence suggests that ERβ can act as an inhibitory molecule for ERα activity via the heterodimerization of ERα and ERβ.

LIST OF ABBREVIATIONS

CB	Cannabinoid
CHIP	Chromatin immunoprecipitation
COX-2	Cyclooxygenase-2
E2	17β-Estradiol
ER	Estrogen receptor
ERE	E2-responsive element
FAAH	Fatty acid amide hydrolase
HBCC	Human breast cancer cell
PGE_2	Prostaglandin E_2
Δ^9-THC	Δ^9-Tetrahydrocannabinol

INTRODUCTION

Δ^9-Tetrahydrocannabinol (Δ^9-THC) (Fig. 74.1), a major cannabinoid component of marijuana, is currently used not only recreationally (drug abuse), but also medicinally (ie, dronabinol) for the treatment of pain and nausea in cancer patients undergoing chemotherapy, in the United States and other countries. At least two cannabinoid (CB) receptor subtypes have been discovered and cloned: CB1 and CB2 receptors. Both CB receptor subtypes are members of the G-protein coupled receptor family. Δ^9-THC and anandamide (Fig. 74.2) have been identified as nonselective agonists for CB1 and CB2 receptors (Guindon & Hohmann, 2011; Pertwee, 2008), and Δ^9-THC has been shown to exert a wide variety of biological effects by mimicking the actions of endogenous substances, referred to as endocannabinoids (ie, anandamide) (Guindon & Hohmann, 2011; Pisanti & Bifulco, 2009). The expression of CB1 and CB2 receptors has been detected in many types of cancer cells (Sarfaraz, Adhami, Syed, Afaq, & Mukhtar, 2008; Velasco, Sánchez, & Guzmán, 2012). Previous studies reported that Δ^9-THC exhibited anticancer activities (eg, antiangiogenic, antimetastatic, and antiproliferative effects) in various types of cancers such as breast, glioma, lymphoma, lung, pancreas, prostate, skin, and thyroid cancers, using both in vitro and in vivo systems (Bifulco, Laezza, Pisanti, & Gazzerro, 2006; Velasco et al., 2012); however, Δ^9-THC may also stimulate the proliferation of cancer cells such as breast cancer (MCF-7 cells), glioblastoma (U373-MG), lung carcinoma (NCI-H292), and astrocytomas (Cudaback, Marrs, Moeller, & Stella, 2010; Hart, Fischer, & Ullrich, 2004; Watanabe et al., 2005; Takeda et al., 2008a; Takeda, Yamamoto, & Watanabe, 2009). Furthermore, there have been conflicting findings regarding the roles of endocannabinoids in cancer cell growth (Sánchez, Sánchez, Ruiz-Llorente, & Díaz-Laviada, 2003).

When studies focused on the effects of Δ^9-THC on epithelial human breast cancer cell (HBCC) lines such as MCF-7 and MDA-MB-231 cells, these cells were found to be resistant to Δ^9-THC induced cytotoxicity (McKallip, Nagarkatti, & Nagarkatti, 2005). These findings indicated that the sensitivity of breast cancer cells to Δ^9-THC may be related to the expression levels of CB1 and CB2 receptors, and that exposure to Δ^9-THC may enhance the growth rate of cancer cells with very low to the absent expression of cannabinoid receptors. We also demonstrated that exposure to Δ^9-THC stimulated the proliferation of MCF-7 cells, when CB receptors were not detected at the mRNA level (Watanabe et al., 2005; Takeda et al., 2008a, 2009). A previous study reported that the expression of CB receptors in MCF-7 cells could be influenced by the culture

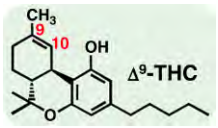

FIGURE 74.1 **Chemical structure of Δ^9-THC.** Numbers in the structure correspond to the dibenzopyran numbering system.

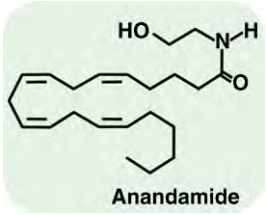

FIGURE 74.2 **Chemical structure of anandamide.**

conditions (Melck et al., 2000). Since Δ^9-THC itself, but not marijuana smoking, was shown to have no carcinogenic properties, as demonstrated by the Ames test (Glatt et al., 1979; Hall & MacPhee, 2002), Δ^9-THC may "accelerate" (possibly as a tumor promoter) the proliferation of cells after they are malignantly transformed. CB receptor expression levels have generally been implicated as a fundamental factor for the growth inhibitory effects by cannabinoids, including endocannabinoids (Guindon & Hohmann, 2011; Pertwee, 2008). Cannabinoids, including Δ^9-THC, can induce cell-cycle arrest and/or apoptosis in different human cancer cell lines, through CB receptors, but are less efficient in their nontransformed cell counterparts, in which the expression of these receptors is very low and/or undetectable (Pisanti & Bifulco, 2009). If this is a general in vivo phenomenon, Δ^9-THC may be able to provide some advantage(s) over currently used antitumor agents. Although Δ^9-THC is not currently used as an anticancer agent in patients, it has been approved for, and is used to reduce the side effects associated with cancer chemotherapy, such as nausea and vomiting (Watson, Benson, & Joy, 1999).

In this chapter, we will summarize the findings of studies that focused on the biological effects of Δ^9-THC on breast cancer, and provide an insight into mechanisms responsible for the modulation of Δ^9-THC sensitivity in breast cancer cells.

INTERPLAY BETWEEN Δ^9-THC AND CANNABINOID RECEPTORS IN BREAST CANCER CELL GROWTH

Studies that investigated the effects of cannabinoids on tumor biology were performed using HBCC lines such as MCF-7 (cell type classification: luminal) and MDA-MB-231 (cell type classification: mesenchymal) cells. MCF-7 cells are an HBCC line that is utilized for the in vitro screening of antiproliferative agents. The majority of studies published to date suggest that Δ^9-THC may abrogate the proliferation of different types of cancer cells and, coupled with the induction of cell death (ie, apoptosis, necrosis, and autophagy) (Velasco et al., 2012), the responsiveness of MCF-7 cells to Δ^9-THC is very complex: (1) sensitive (decrease in the growth rate), (2) resistant, or (3) sensitive (increase in the growth rate) (Ligresti et al., 2006; McKallip et al., 2005; Takeda et al., 2008a, 2009; Watanabe et al., 2005). McKallip et al. (2005) and our group previously reported that Δ^9-THC-mediated stimulating effects on the proliferation of MCF-7 cells were specifically observed when the expression levels of CB1 and CB2 receptors in these cells were very low or undetectable (McKallip et al., 2005; Watanabe et al., 2005; Takeda et al., 2008a, 2009). Details of these inconsistencies have not yet been definitively resolved. Wang et al. (2008) reported that CB1 receptor expression was silenced in human colorectal cancer through DNA methylation of the CB1 promoter, and the loss of CB1 accelerated intestinal tumor growth in vivo (Wang et al., 2008). The estrogenic induction of CB1 in human colon cancer cell lines has been reported, and the CB1 receptor is suggested to be an estrogen (17β-estradiol, E2)-responsive gene in DLD-1, HT-29, and SW620 human colon cancer cells (Notarnicola et al., 2008; Proto et al., 2012). Furthermore, E2 regulated the CB2 receptor by recruiting a putative E2-responsive element (ERE) in CB2 encoding for the gene (Rossi et al., 2013). Thus, since the regulation of the CB1/CB2 receptors by E2 is also true for MCF-7 breast cancer cells, these findings suggest that the biological fate of Δ^9-THC for MCF-7 cell growth can be affected by E2 levels. In support of these findings, (1) Δ^9-THC was able to stimulate the proliferation of MCF-7 cells (Watanabe et al., 2005; Takeda et al., 2008a, 2009) cultured in the phenol-red-free media containing 5% dextran-coated charcoal-treated serum ("E2-deprived medium;" in particular for a long time) (Lewis, Osipo, Meeke, & Jordan, 2005; Martin, Farmer, Johnston, Ali, & Dowsett, 2005; Yue et al., 2002), and (2) although fatty acid amide hydrolase (known as FAAH), which breaks down anandamide, was detected, the expression of the CB1/2 receptors was not detectable at mRNA levels in the cells (Watanabe et al., 2005; Takeda et al., 2008a, 2009). The physiological levels of E2 (10 pM–1 nM)-stimulated proliferation of MCF-7 cells precultured in E2-deprived medium (ie, long-term E2 deprivation) was completely antagonized by Δ^9-THC (Takeda et al., 2009). This interactive phenomenon between E2 and Δ^9-THC, for the proliferation of MCF-7 cells, has been demonstrated previously (von Bueren, Schlumpf, & Lichtensteiger, 2008) (see Section "Interplay Between Δ^9-THC and Estrogen Signaling in Breast Cancer Cell Growth").

By performing a chromatin immunoprecipitation (CHIP) assay, Bifulco and coworkers demonstrated that estrogen receptor α (ERα), but not ERβ, associated with the CB1 promoter region containing one full ERE and two ERE half-sites in human colon cancer SW620 cells treated with 100 nM E2 (Proto et al., 2012). Since colon cancer SW620 cells express high levels of both CB1 and ERα, it may be reasonable to expect the ERα-mediated regulation of CB1 in the presence of E2, a ligand for ERα. In accordance with this, E2 was shown to induce the expression of CB1 in human colon cancer cell lines (Notarnicola et al., 2008). Our preliminary study also demonstrated the E2-mediated regulation of CB receptors in ERα-positive MCF-7 cells (Takeda et al., unpublished observations).

INTERPLAY BETWEEN Δ^9-THC AND ESTROGEN SIGNALING IN BREAST CANCER CELL GROWTH

Approximately 60% of all breast cancer patients have E2-dependent breast cancer that expresses ERα, and requires E2 for tumor growth. MCF-7 breast cancer cell

growth is sensitive to treatments with E2 due to its stimulation of ERα. As described in Section "Interplay Between Δ9-THC and Cannabinoid Receptors in Breast Cancer Cell Growth," an interaction may exist between Δ9-THC and E2 in order to regulate the proliferation of MCF-7 cells. The proliferation of MCF-7 cells precultured under E2-deprived conditions was more likely to be stimulated by the addition of E2 with an EC_{50} value of approximately 10 pM (Fokialakis et al., 2004; Takeda et al., 2009). In these deprived conditions (ie, long-term E2 deprivation), MCF-7 cells endogenously produced very low levels of E2 (pmol concentration; 0.26 pM/10^6 cells) of E2 (Miki et al., 2007), and Δ9-THC could stimulate the proliferation of MCF-7 cells. The stimulating effects of Δ9-THC were further enhanced in a concentration-dependent manner by the addition of two types of aromatase (cytochrome P450 19A1) inhibitors (aminoglutethimide and α-naphthoflavone) (Takeda et al., 2009). Aromatase has been identified as the enzyme that produces intracellular E2 through the metabolism of testosterone, while MCF-7 cells express functional aromatase. In support of the phenomenon described earlier, Δ9-THC-induced proliferation was blocked by a cotreatment with testosterone, although the physiological concentrations of testosterone (1–100 nM), which can be converted into E2, stimulated the MCF-7 cell growth (Takeda et al., 2009). Thus, these findings strongly implied that Δ9-THC may be able to interact with the very low levels of E2 produced by cells, resulting in the abrogation of the E2-stimulated proliferation of MCF-7 cells when simultaneously treated; however, Δ9-THC stimulation was counteracted by E2 in these cells (Fig. 74.3). The mechanism by which Δ9-THC stimulates the proliferation of MCF-7 cells in a low E2 milieu currently remains unknown. We are now investigating this phenomenon; until now, it has been suggested that cyclooxygenase-2 (COX-2) and its metabolite prostaglandin E_2 (PGE_2), which can inhibit apoptosis signals, as well as

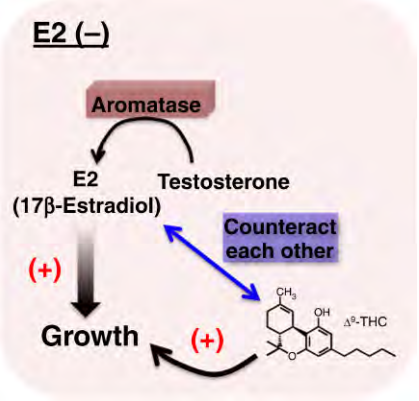

FIGURE 74.3 A model suggesting that 17β-estradiol (E2) or Δ9-THC can stimulate the growth of MCF-7 cells under E2-deprived conditions (Takeda et al., 2009). However, the respective stimulation effects are counteracted when they are administered simultaneously. E2 is produced from testosterone by aromatase (CYP19A1).

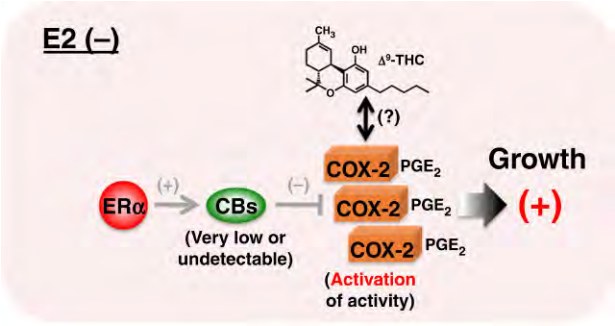

FIGURE 74.4 A hypothetical model for the interaction between Δ9-THC and estrogen signaling pathways in ERα-positive MCF-7 human breast cancer cells. The following hypothetical model was made together with previous findings. Under 17β-estradiol (E2)-deprived conditions (indicated as ER–), CB1/CB2 receptors regulated by ERα are downregulated, which, consequently, activates cyclooxygenase-2 (COX-2)/prostaglandin E_2 (PGE_2) signaling pathways, followed by the Δ9-THC stimulation of breast cancer cell growth (Notarnicola et al., 2008; Proto et al., 2012; Takeda et al., 2009). However, there is currently no evidence to suggest how Δ9-THC utilizes COX-2/PGE_2 to induce cell proliferation (indicated as "?") (see also Fig. 74.6).

positively enhance the tumorigenic potential of cancers (Tsujii & DuBois, 1995), may be involved in Δ9-THC-induced cell proliferation (Takeda et al., 2009) (Fig. 74.3). Because CB2 receptor agonism has been suggested to inhibit the COX-2/PGE_2 axis in breast cancer cells (Qamri et al., 2009), COX-2/PGE_2 signaling pathway(s) may manifest under E2-depleted conditions, and participate in the Δ9-THC stimulation of MCF-7 growth (Fig. 74.4) (see Fig. 74.6). No inhibitory/stimulation effects of Δ9-THC have yet been confirmed on the activity/expression of COX-2 (Takeda et al., 2008b, 2009).

We next investigated the effects of Δ9-THC on the proliferation of MCF-7 cells precultured for 24 h in E2-deprived medium (ie, short-term E2 deprivation). The results obtained revealed that Δ9-THC itself was able to "suppress" the proliferation of MCF-7 cells in a concentration-dependent manner, and that the antiproliferative effects of Δ9-THC were positively enhanced by the exogenous addition of E2 (100 pM) (the IC_{50} values of Δ9-THC alone and Δ9-THC + E2: 34.5 vs 10.4 μM, respectively) (Takeda et al., 2013). Taken together, these findings suggested that the sensitivity of MCF-7 cells to Δ9-THC may be affected by the levels of E2 supplied by breast cancer cells themselves, or by its exogenous addition.

INTERPLAY BETWEEN Δ9-THC AND ESTROGEN SIGNALING IN BREAST CANCER CELL GROWTH: POSSIBLE INVOLVEMENT OF ERβ

To comprehensively understand the mechanisms underlying the proliferation of breast cancer cells, in addition to ERα, research is now focusing on ERβ, the second type of ER, discovered in 1996 (Kuiper, Enmark,

Pelto-Huikko, Nilsson, & Gustafsson, 1996). Previous studies reported that approximately 60–70% of breast tumors express ERβ, and most tumors simultaneously express both ERα and ERβ (Dotzlaw, Leygue, Watson, & Murphy, 1997; Fuqua et al., 2003). Furthermore, the expression levels of ERβ were found to be the highest in normal mammary tissue, and decreased with the development of breast tumors (Roger et al., 2001; Zhao et al., 2003). Although the physiological role of ERβ in breast cancer cells has not been examined in as much detail as ERα, accumulating evidence suggests that ERβ can act as an inhibitory molecule for ERα activity through the heterodimerization of ERα and ERβ (Hall & McDonnell, 1999; Pettersson, Delaunay, & Gustafsson, 2000; Powell & Xu, 2008; Zhao et al., 2007), and that ERβ itself acts as a tumor suppressor with both antiproliferative and antimigration activities (Lazennec, Bresson, Lucas, Chauveau, & Vignon, 2001; Paruthiyil et al., 2004). In addition, the antagonistic effects of ERβ on E2/ERα-mediated transcription have been explained by the altered recruitment of c-Fos/c-Jun transcription factors composed of activator protein 1 (AP-1) to estrogen-positive promoters (Matthews et al., 2006). Thus, ERβ itself, or the expression of ERβ in ERα-positive breast cancer, may be associated with better clinical outcomes in women.

Based on the experimental findings that Δ9-THC abrogated the E2-mediated proliferation of ERα-positive MCF-7 cells (Takeda et al., 2009; von Bueren et al., 2008), we first focused on the effects of Δ9-THC on ERα activity. Accumulating evidence has demonstrated that Δ9-THC exhibits "no" binding/activation potential to ERα (Okey & Bondy, 1978; Ruh, Taylor, Howlett, & Welshons, 1997; Sauer, Rifka, Hawks, Cutler, & Loriaux, 1983), and also that aromatase activity is insensitive to Δ9-THC (Lee, Oh, Lee, & Chung, 2005); however, the antiestrogenic activity/property of Δ9-THC has so far been demonstrated in both in vitro and in vivo experiments (Paria, Kapur, & Dey, 1992; Smith & Asch, 1984; Takeda et al., 2009, 2013; von Bueren et al., 2008). Thus, a definitive answer regarding the Δ9-THC disruption of E2 signaling in ERα-positive breast cancer cells has not yet been obtained. To clarify the properties of Δ9-THC acting as an antiestrogen for E2/ERα-mediated transcription, we performed a DNA microarray analysis of ERα-positive MCF-7 cells cultured under short-term E2-deprived conditions, in the presence of Δ9-THC. The upregulation of ERβ (9.6-fold) was significantly higher than that in vehicle-treated groups, whereas ERα levels were not essentially affected by the cannabinoid, which demonstrated that Δ9-THC disrupted the balanced expression between ERα and ERβ by upregulating ERβ, the basal expression of which was very low due to the DNA methylation of CpG sites on the promoter region in mammary carcinoma and MCF-7 breast cancer cells (Rody et al., 2005; Zhao et al., 2007). The Δ9-THC stimulation

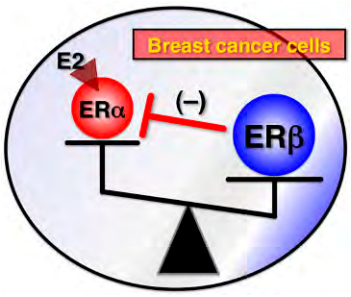

FIGURE 74.5 **A model suggesting that Δ9-THC can abrogate 17β-estradiol (E2)/ERα signaling by upregulating ERβ in MCF-7 human breast cancer cells (see also Takeda et al., 2013).**

of ERβ was also demonstrated by western immunoblot analysis. We next determined whether upregulated ERβ affected the expression of the E2/ERα-regulated target gene (Lin et al., 2007), CDC2, a key player in cell cycle regulation; the expression level of CDC2 was reduced when ERβ was upregulated by the Δ9-THC treatment. We also demonstrated that Ki-67, a general proliferation marker upregulated by E2 in breast cancer, was downregulated by Δ9-THC in a similar manner to that of CDC. Furthermore, the overexpression of ERβ resulted in the further inhibition of E2/ERα-mediated transcription over that with the Δ9-THC alone system, which indicated that ERβ was a likely target of the antiestrogenic actions of Δ9-THC on E2/ERα activity, possibly coupled with Δ9-THC-mediated antiproliferative effects (see Section "Interplay Between Δ9-THC and Estrogen Signaling in Breast Cancer Cell Growth") (Figs. 74.5 and 74.6). It should be noted that Δ9-THC could not bind to the ligand

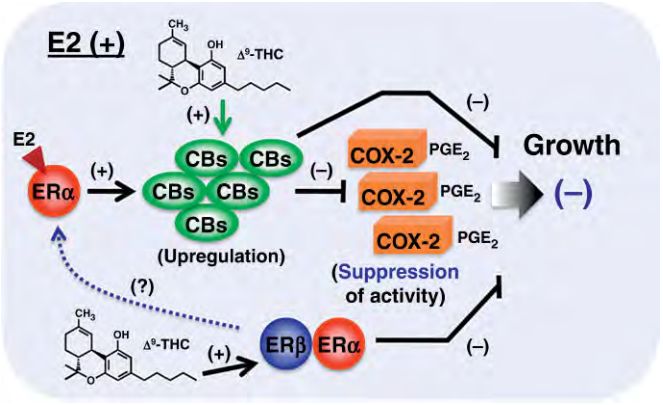

FIGURE 74.6 **A hypothetical model for the interaction between Δ9-THC and estrogen signaling pathways in ERα-positive MCF-7 human breast cancer cells.** Under 17β-estradiol (E2)-rich conditions (indicated as E2+), the basal expression of CB1/CB2 receptors is stimulated by E2/ERα coupled with the suppression of cyclooxygenase-2 (COX-2) activity (Qamri et al., 2009). The activation of CB1/CB2 receptors by Δ9-THC then inhibits breast cancer cell growth. In addition, concomitantly upregulated ERβ inhibits breast cancer cell growth through the abrogation of E2/ERα (Takeda et al., 2013). However, there is currently no evidence for the effects of ERβ on E2/ERα involved in the expression of CB receptors (indicated as "?").

(E2) binding domain of ERβ, as was also the case for ERα (Ruh et al., 1997; Takeda et al., 2013). In ERα-negative MDA-MB-231 cells, Δ^9-THC did not evoke antiproliferative effects on ERα-deficient cells at 48 h, in the presence of E2 (100 pM); however, the expression of ERβ was clearly induced (Takeda et al., 2013). Taken together, these findings suggested that Δ^9-THC may require ERα for its antiproliferative effects on MCF-7 breast cancer cells under short-term E2-rich conditions. We are now investigating the mechanism(s) underlying the Δ^9-THC-mediated upregulation of ERβ by focusing on the effects of Δ^9-THC on the promoter DNA methylation status of ERβ.

MINI-DICTIONARY

Antiestrogens Compounds with the potential to block the production or utilization of E2, or directly (antagonism of E2 for ERα) or indirectly (upregulation of ERβ, eg, Δ^9-THC) inhibit the effects of E2 on ERα.

Aromatase (CYP19A1) An enzyme that converts testosterone (an androgen) into E2 (an estrogen); thus, its inhibitor is used in the treatment of estrogen receptor (ER)-positive breast cancer.

Cannabinoid (CB) receptors Two different cannabinoid receptors (ie, CB1 and CB2) have been identified and cloned; both types are members of the G-protein coupled receptor (GPCR) family.

Cannabinoids Originally defined as a group of C_{21} compounds uniquely produced by *C. sativa*. Approximately 70 different cannabinoids have been identified to date. Δ^9-THC is a naturally occurring "phyto"cannabinoid. (cf. "endo"cannabinoids, produced and released in the body).

Chromatin immunoprecipitation (CHIP) assay Used to determine the relationship between protein(s) with a specific DNA region, including promoter regions in vivo.

Cyclooxygenase-2 (COX-2) Highly expressed in cells with inflammation and in cancer cells; it is known to be involved in the aggressive phenotype of tumors (eg, survival, migration etc.).

17β-Estradiol (E2) Having two hydroxyl groups in its molecular structure, and the most potent form of mammalian estrogenic steroids (see: Estrogen receptor β).

Estrogen receptor β (ERβ) Discovered as a second type of estrogen receptor in 1996; its physiological function has not yet been fully elucidated, but it is being recognized as a tumor suppressor through its own and/or the inhibition of ERα activity. ERβ has weaker transcriptional activity than ERα in response to E2.

MCF-7 cell line A human breast cancer cell line expressing ERα (ER-positive), which was established in 1973 at the Michigan Cancer Foundation [Soule H. D., Vazguez J., Long A., Albert S., & Brennan M. (1973). A human cell line from a pleural effusion derived from a breast carcinoma. *Journal of the National Cancer Institute*, *51*, 1409–1413]. (cf. MDA-MB-231 cell line, a highly aggressive human breast cancer cell line with an ER-negative phenotype).

Δ^9-Tetrahydrocannabinol (Δ^9-THC) A major component of marijuana that is used both recreationally (drug abuse) and medicinally (ie, dronabinol, a synthetic form of Δ^9-THC) (see: cannabinoids)

Acknowledgments

This study was supported in part by a Grant-in-Aid for Scientific Research (C) [25460182, (to S.T.)] from the Japan Society for the Promotion of Science (JSPS) KAKENHI. The author wishes to thank students at the Department of Molecular Biology, Daiichi University of Pharmacy, for their technical contributions.

CHAPTER

75

Δ^9-THC and COX-2 Signaling

J. Zhang, C. Chen

Neuroscience Center of Excellence, School of Medicine, Louisiana State University Health Sciences Center, New Orleans, LA, United States

SUMMARY POINTS

- This chapter briefly describes the role of cyclooxygenase-2 (COX-2) in THC-induced synaptic and cognitive impairments, and other behavioral changes.
- COX-2 is a constitutively expressed and inducible enzyme converting arachidonic acid to prostaglandins.
- THC includes CB1 receptor-dependent increases in activity and expression of COX-2 in the brain.
- THC-increased COX-2 expression is mediated through CB1 receptor-coupled G-protein βγ subunits and downstream NF-κB signaling pathway.
- Pharmacological or genetic inhibition of COX-2 prevents disruptive effects of repeated THC exposure on synaptic structure and function, spatial learning, and memory.
- Medical use of marijuana would be broadened by concurrent COX-2 inhibition, which eliminates the major adverse effects of THC, while retaining cannabinoid beneficial effects.

KEY FACTS OF CANNABIS-INDUCED MAJOR ADVERSE EFFECTS

- Repeated or heavy use of marijuana induces cannabis-related disorders, including adverse physical, mental, emotional, and behavioral changes.
- Major intoxication of cannabis brings impairments in synaptic function, learning, and memory.
- Repeated use of marijuana induces tolerance, dependence, and possibly addiction.
- Abuse of marijuana is often associated with taking other addictive substances.

KEY FACTS OF POTENTIAL MEDICAL CANNABIS USE

- Chronic pain
- Epilepsy
- Inflammatory and neurodegenerative diseases (eg, multiple sclerosis, Alzheimer disease)
- Weight loss and poor appetite
- Nausea
- Cancer
- Sleep disorders
- Traumatic brain injury

LIST OF ABBREVIATIONS

AA	Arachidonic acid
2-AG	2-Arachidonoylglycerol
AMPA	α-Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid
CB1R	Cannabinoid receptor 1
COX-2	Cyclooxygenase-2
CRD	Cannabis-related disorders
ERK	Extracellular signal-regulated kinase
FAAH	Fatty acid amide hydrolase
G-protein	GTP-binding protein
IL-1β	Interleukin-1β
LPS	Lipopolysaccharides
LTP	Long-term potentiation
MGL	Monoacylglycerol lipase
NF-κB	Nuclear factor-kappa B

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00086-7

NMDA	*N*-methyl-D-aspartic acid
NSAIDs	Nonsteroidal antiinflammatory drugs
p38 MAPK	p38 mitogen-activated protein kinase
PGD_2	Prostaglandin D_2
PGE_2	Prostaglandin E_2
$PGF_{2\alpha}$	Prostaglandin $F_{2\alpha}$
PGI_2	Prostacyclin
PLA_2	Phospholipase A_2
PLC	Phospholipase C
PTGS	Prostaglandin-endoperoxide synthase
THC	Δ^9-Tetrahydrocannabinol
TNFα	Tumor necrosis factor α
TXA_2	Thromboxanes

INTRODUCTION

Marijuana, a mixture of the leaves and flowering tops of the *Cannabis sativa* plant, has been used by humans for a few thousand years, as a recreational or medicinal drug. The chemical ingredients of cannabis were unknown until the 1960s, when a research group led by Professor Raphael Mechoulam identified Δ^9-tetrahydrocannabinol (THC) as the major psychoactive ingredient in marijuana (Gaoni & Mechoulam, 1971; Mechoulam & Gaoni, 1965). Even though humans have been using marijuana or cannabis as medical treatments for a wide array of intractable medical conditions (Robson, 2001; Russo, 2007), its neuropsychological adverse effects greatly limit the medicinal use of cannabis (Carlini, 2004). Marijuana is also the most commonly used illicit drug of abuse in the United States. The increasing spread of marijuana use, especially among middle and high school students, has heightened societal awareness of the risks associated with this drug. The use of marijuana is also associated with taking other addictive substances such as alcohol, cocaine, morphine, or nicotine (Maldonado, Valverde, & Berrendero, 2006). Use of marijuana can produce adverse physical, mental, emotional, and cognitive changes, which are termed cannabis-related disorders (CRD). Like other abused drugs, repeated administration of marijuana induces tolerance, dependence, and addiction (Bass & Martin, 2000; Gonzalez, Cebeira, & Fernandez-Ruiz, 2005; Lichtman & Martin, 2005; Lupica, Riegel, & Hoffman, 2004). Neuropsychological and memory deficits induced by short-term or long-term THC exposure are the major effects of intoxication with cannabinoids, confirmed both in humans and laboratory animals (Bolla, Brown, Eldreth, Tate, & Cadet, 2002; Chen et al., 2013; Hampson & Deadwyler, 1999; Han et al., 2012; Heishman, Arasteh, & Stitzer, 1997; Lichtman & Martin, 1996; Messinis, Kyprianidou, Malefaki, & Papathanasopoulos, 2006; Niyuhire, Varvel, Martin, & Lichtman, 2007; Pope, Gruber, Hudson, Huestis, & Yurgelun-Todd, 2002; Puighermanal et al., 2009; Solowij & Battisti, 2008; Solowij et al., 2002). For a long time, it was not clear how cannabinoids induce these unwanted side effects, and what signaling molecules mediate these effects. Given the extent of the use of cannabis in the general population as a recreational drug, and in clinic as medical treatments, it is imperative to understand the molecular mechanisms contributing to the major side effects produced by cannabinoid exposure. In this chapter, we will primarily discuss the recent progress toward our understanding of signaling molecules that mediate the cannabinoid-induced undesirable side effects.

PGE_2 IS A SIGNALING MOLECULE IN THC-INDUCED BEHAVIORAL RESPONSES

Hypomotility, analgesia, hypothermia, and catalepsy are physiological and behavioral responses to cannabinoids, and are termed "tetrad effects." However, little is known about signaling molecules that mediate these responses. Earlier studies show that the cataleptic effect induced by oral or intraperitoneal administration of THC in mice was blocked by aspirin or indomethacin, which are nonsteroidal antiinflammatory drugs (NSAIDs), and was restored by exogenous application of prostaglandin E_2 (PGE_2), but not $PGF_{2\alpha}$ or PGE_1 (Fairbairn & Pickens, 1979). However, aspirin failed to abolish the cataleptic effect of chlorpromazine (CPZ), a dopamine antagonist. This study provides evidence that the THC-elicited cataleptic response is associated with PGE_2, while the CPZ-induced catalepsy is related to different signaling mediator(s). This assumption was supported by another study where immunization of mice with a thyroglobulin-PGE_2 conjugate eliminates the cataleptic response of THC (Burstein, Hull, Hunter, & Shilstone, 1989). In particular, it was observed that plasma levels of PGE_2 and prostacyclin (PGI_2) were significantly elevated after oral administration of THC, and also blocked by indomethacin. Elevation of plasma PGE_2 by THC was confirmed in human subjects who smoked marijuana, and the elevation was also shown to be inhibited by pretreatment with indomethacin (Perez-Reyes, Burstein, White, McDonald, & Hicks, 1991). Importantly, PGE_2 levels are also elevated in the brains of rats and mice exposed to THC, and this elevation can be antagonized by NSAIDs (Bhattacharya, 1986; Hunter, Audette, & Burstein, 1991). In addition, it has been reported that THC-induced neurotoxicity in cultured hippocampal neurons was prevented by indomethacin or aspirin (Chan, Hinds, Impey, & Storm, 1998). These earlier studies provide information that cannabinoids trigger formation of PGE_2, resulting in an elevation of PGE_2 levels in the plasma and brain (Fig. 75.1). Particularly, THC-

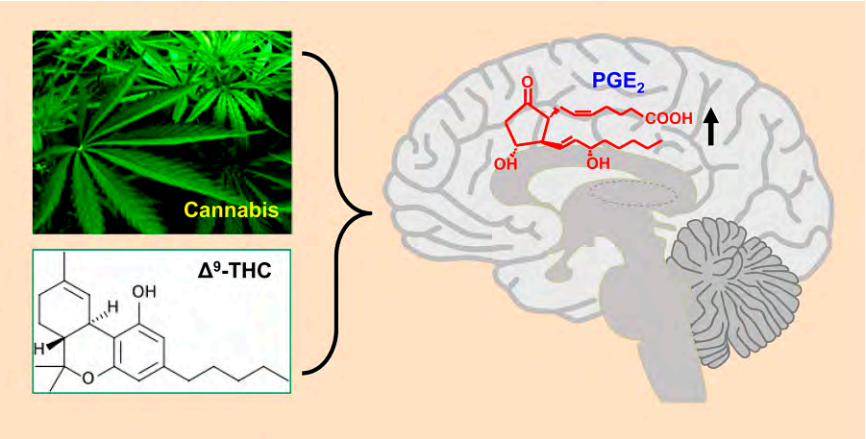

FIGURE 75.1 **Cannabis or Δ^9-tetrahydrocannabinol (THC) exposure increases synthesis of prostaglandin E_2 (PGE_2) in the brain.**

induced cataleptic effects and behavioral suppression in animals, and marijuana smoking-induced "high" and heart rate acceleration in humans are attenuated by NSAIDs (Burstein, Hull, Hunter, & Latham, 1988; Fairbairn & Pickens, 1979; Perez-Reyes et al., 1991; Yamaguchi, Shoyama, Watanabe, & Yamamoto, 2001), suggesting that PGE_2 is likely a signaling mediator for these behavioral responses to cannabinoids.

THC-ELEVATED PGE_2 IS DERIVED FROM THE COX-2 PATHWAY

THC or marijuana elevates the plasma and brain levels of PGE_2 both in animals and humans, and the elevation of PGE_2 is blocked by aspirin or indomethacin. Together, this suggests that cyclooxygenase-1 and -2 (COX-1 and COX-2) are likely involved in cannabinoid-induced responses. As shown in Fig. 75.2, COX-1 and COX-2 are the rate-limiting enzymes that catalyze the first two steps converting arachidonic acid (AA) to prostanoids (Sang & Chen, 2006; Smith, Urade, & Jakobsson, 2011; Vane, Bakhle, & Botting, 1998). While COX-1 is constitutively expressed everywhere in our body, and responsible for the production of prostanoids needed for complex integrative physiological functions, COX-2 is an inducible isoform expressed in all the tissues, and is responsible for injury and inflammation (Sang & Chen, 2006; Vane et al., 1998). Interestingly, COX-2 is also constitutively expressed in only a few organs, including the central nervous system (CNS), the kidney, and the testis, indicating the importance of COX-2 in these tissues. In the CNS, constitutively-expressed COX-2 is restricted to the cortex, hippocampus, hypothalamus, and spinal cord (Vane et al., 1998), suggesting that two forms of COX-2 are present in these regions of the CNS.

Commonly used NSAIDs, such as ibuprofen, aspirin, indomethacin and naproxen are nonselective COX-1 and COX-2 inhibitors. Also, as illustrated in Fig. 75.2, both COX-1 and COX-2 are capable of converting AA into prostanoids, including prostaglandins (PGD_2, PGE_2, $PGF_{2\alpha}$), prostacyclin (PGI_2), and thromboxane (TX_{A2}). This suggests that PGE_2 stimulated by cannabinoids may be derived from COX-1 and/or COX-2. It has been documented that COX-1 and COX-2 exhibit their preference in synthesizing these prostanoids. For instance, COX-1 is primarily responsible for synthesizing PGD_2, $PGF_{2\alpha}$, and TX_{A2}, whereas COX-2 is predominant in making PGE_2 and PGI_2 (Brock, McNish, & Peters-Golden, 1999; Sang, Zhang, Marcheselli, Bazan, & Chen, 2005). Therefore, PGE_2 produced by marijuana or THC is likely derived from the COX-2 pathway. This speculation has been confirmed by a recent study where THC-induced increase in PGE_2 in mouse hippocampal tissue is blocked by Celebrex (Celecoxib), a selective COX-2 inhibitor (Chen et al., 2013). Moreover, THC failed to increase hippocampal PGE_2 in COX-2 knockout animals. These results indicate that THC-triggered release of PGE_2 is through the COX-2 pathway. This conclusion was further supported by the fact that THC induces time- and dose-dependent increase of COX-2 expression, but not COX-1, in the mouse brain (Chen et al., 2013). In addition, this study also reveals that COX-2 expression triggered by THC was more pronounced in an astroglial cell-enriched culture than that in a relatively pure neuronal culture, suggesting that THC-induced released PGE_2 occurs largely from astroglial cells. The results generated from this study provided the compelling evidence that marijuana- or THC-triggered generation of PGE_2 is derived from the COX-2 pathway. This compelling evidence fills a conceptual gap on origination of PGE_2 induced by cannabinoids.

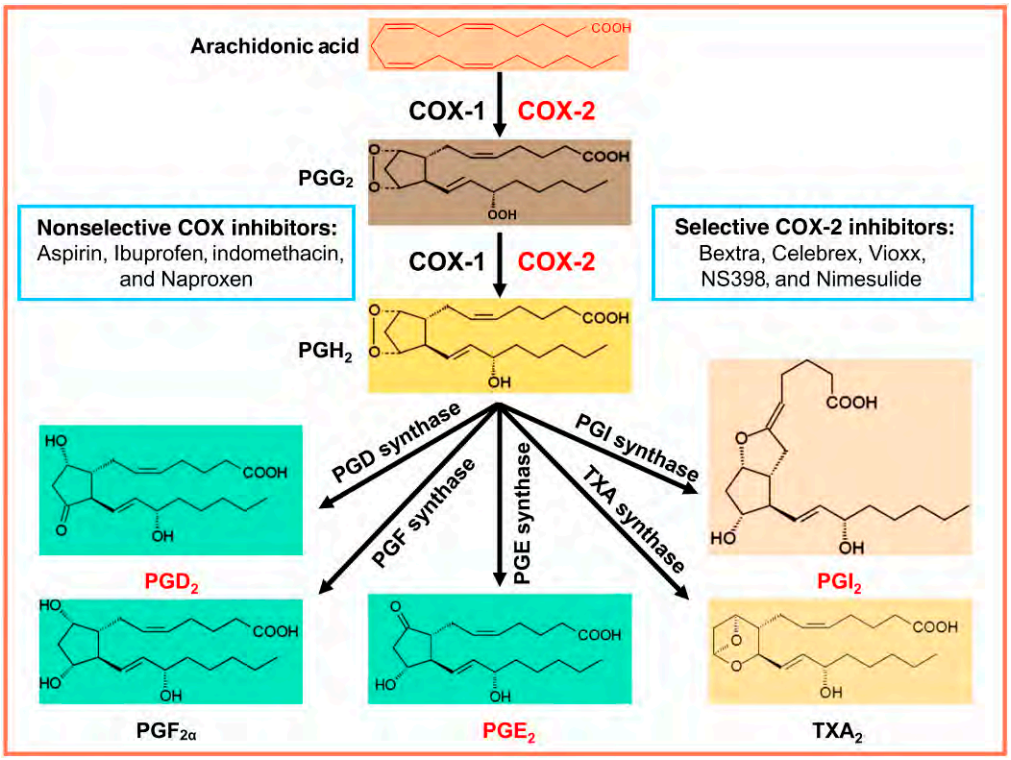

FIGURE 75.2 **Biosynthesis of prostanoids.** Prostanoids consist of prostaglandins (PGD_2, PGE_2, and $PGF_{2\alpha}$), thromboxane (TXA_2), and prostacyclin (PGI_2). Prostanoids are synthesized from the precursor arachidonic acid (AA), derived from membrane phospholipids catalyzed by phospholipase C (PLC) and phospholipase A_2 (PLA_2). AA is converted to intermediate PGG_2, which is rapidly converted to unstable PGH_2 by prostaglandin-endoperoxide synthase (PTGS), also called cyclooxygenases, including COX-1 and COX-2. PGH_2 is then immediately transformed to a series of biologically active PGD_2, PGE_2, $PGF_{2\alpha}$, PGI_2, and TXA_2 through specific isomerases, including PGD, PGE, PGF, PGI, and TXA synthases.

COX-2 INDUCTION BY THC IS MEDIATED VIA THE CB1 RECEPTOR, AND ITS COUPLED Gβγ SUBUNITS

Two types of cannabinoid receptors (CB1R and CB2R) have been cloned and identified. It is clear now that neuropsychological and behavioral responses to cannabinoids are primarily mediated via CB1R, which is predominantly expressed in the CNS. For instance, marijuana- or THC-induced memory impairments, and cannabinoid tolerance and dependence, are mediated by CB1R (Gonzalez et al., 2005; Hampson & Deadwyler, 1999; Han et al., 2012; Lichtman & Martin, 1996; Niyuhire et al., 2007; Puighermanal et al., 2009). As discussed earlier, COX-2 derived PGE_2 is an important signaling mediator in mediating some of the behavioral responses to cannabinoids, suggesting that THC-induced increase in COX-2 expression may be mediated by CB1R. Indeed, Chen et al. (2013) reported that THC-increased expression of COX-2 in the brain is diminished by rimonabant (SR141716), a selective CB1R antagonist, and in mice lacking CB1R (Chen et al., 2013), suggesting that THC-induced increases in COX-2 activity and expression is mediated by CB1R.

It has been reported previously that the endogenous cannabinoid 2-arachidonoylglycerol (2-AG) suppresses COX-2 expression in response to proinflammatory and excitotoxic insults, both in vitro and in vivo, via a CB1R-dependent mechanism (Zhang & Chen, 2008). This brought up a question of why the same CB1R exhibits different, even opposite, effects on COX-2 expression upon binding of the exogenous cannabinoid THC or the endocannabinoid 2-AG to the receptors. CB1R is a pertussis toxin (PTX)-sensitive GTP-binding protein-coupled receptor. Activation of CB1R by agonists results in a dissociation of Gβγ subunits from the GTP-bound Gαi subunit. It is possible that differential regulation of COX-2 expression by CB1R results from the functioning of Gαi or Gβγ. To validate this assumption, Chen et al. (2013) designed elegant experiments in which they used several approaches, including overexpressing, silencing, or rescuing silenced Gαi or Gβγ, and found that COX-2 induction by THC is mediated via Gβγ subunits (Fig. 75.3), while 2-AG suppression of elevated COX-2 expression in response to proinflammatory stimuli is mediated via Gαi subunit (Fig. 75.4). Interestingly, disruption of Gαi does not affect the COX-2 induction effect of THC, while disruption of Gβγ does not change

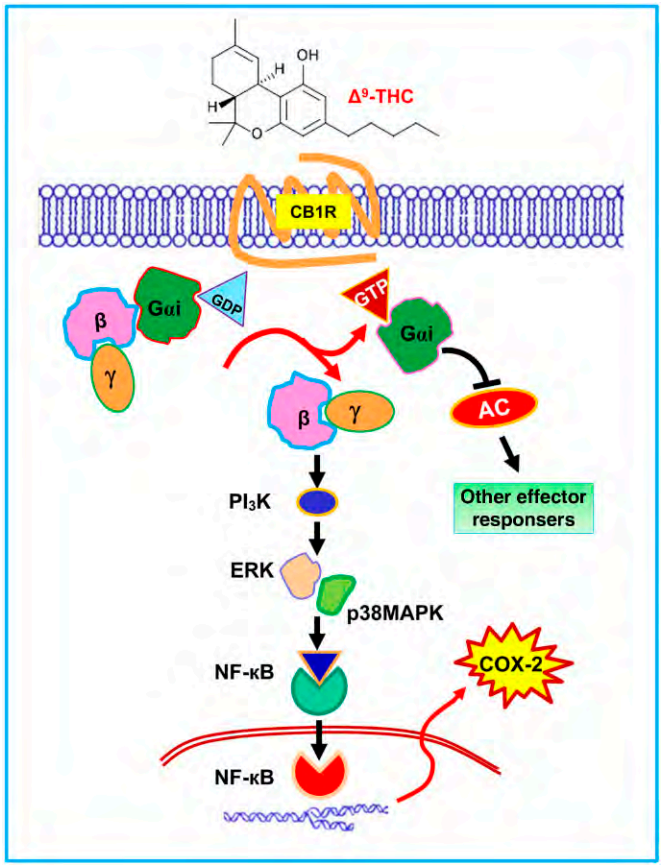

FIGURE 75.3 **Δ⁹-THC stimulates COX-2 induction via CB1R-coupled G-protein βγ subunits.** THC binds to and activates CB1R, which leads to dissociating CB1R-coupled G-protein βγ subunits from the GTP-bound Gαi subunit. Gβγ subunits induce phosphorylation of Akt, ERK/p38MAPK, and NF-κB, resulting in transcription of the COX-2 gene (ptgs2). GTP-bound α subunit may induce other effector responses.

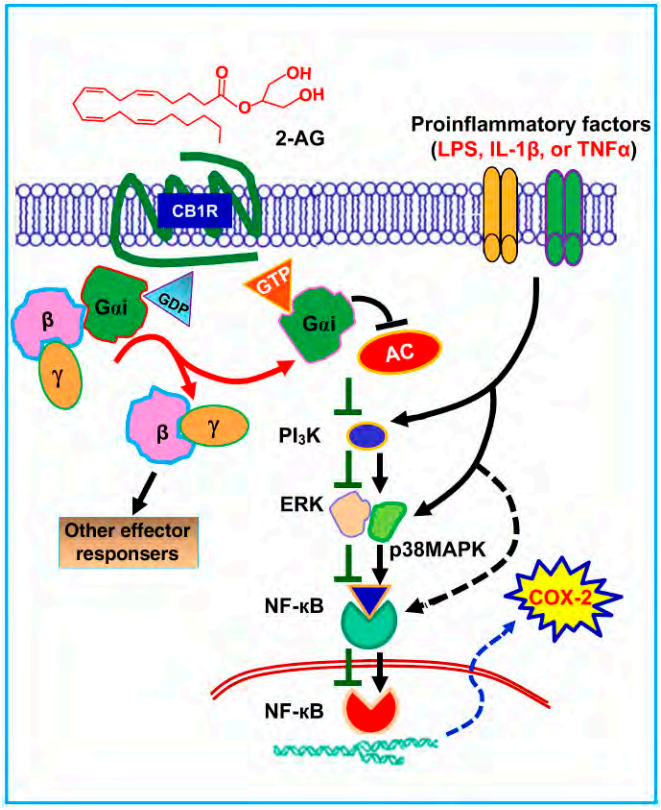

FIGURE 75.4 **The endocannabinoid 2-arachidonoylglycerol (2-AG) suppresses COX-2 overexpression induced by proinflammatory factors via CB1R-coupled G-protein αi subunit.** Proinflammatory factors interleukin-1β (IL-1β), tumor necrosis factor α (TNFα) or lipopolysaccharides (LPS) increase COX-2 expression through phosphorylation of PI_3K, ERK/p38MAPK, and NF-κB. 2-AG binds to and activates G-protein coupled CB1R, resulting in a dissociation of the Gαi subunit from Gβγ subunits. GTP-bound Gαi subunit inhibits proinflammatory stimulus-induced phosphorylation of PI_3K, ERK/p38MAPK, and NF-κB, thereby suppressing COX-2 expression.

the ability of 2-AG to resolve excessive COX-2 expression induced by a proinflammatory assault. Thus, it is evident that THC-induced COX-2 activation and expression are mediated through CB1R-coupled Gβγ subunits (Fig. 75.3).

THC-STIMULATED COX-2 EXPRESSION IS VIA ACTIVATION OF NF-κB

Nuclear factor kappa B (NF-κB) is an important transcription factor that regulates the genes involved in inflammation, including COX-2. It is possible that THC-elevated COX-2 expression is transcriptionally regulated by NF-κB. This speculation is supported by the fact that THC increases phosphorylation of NF-κB, and the binding activity of NF-κB p65 in the promoter region of the COX-2 gene, and that elevation of COX-2 expression induced by THC is reduced by inhibition of NF-κB activity (Chen et al., 2013). The signaling mediators of THC-stimulated COX-2 expression between Gβγ subunits and NF-κB are likely Akt, ERK, and p38MAPK. This is largely due to that fact that THC induces phosphorylation of Akt, ERK, and p38MAPK both in vitro and in vivo. The data from the experiments with silencing and rescuing strategies confirm that this is the case. Knockdown of Gβγ prevents THC-induced phosphorylation of Akt, ERK, p38MAPK, and NF-κB, and the effects of Gβγ loss of function on phosphorylation of these signaling molecules are diminished when Gβγ is rescued from silencing (Chen et al., 2013). Therefore, the COX-2 induction effect by THC is likely mediated through CB1R-coupled Gβγ subunits, and the downstream Akt, ERK, p38MAPK, and NF-κB signaling pathway (Fig. 75.3).

THC RAISES EXTRACELLULAR GLUTAMATE THROUGH COX-2 DERIVED PGE_2

Previous studies demonstrated that the cannabinoid THC and the synthetic cannabinoid WIN55,212-2 (WIN) elevate extracellular glutamate levels both in vitro and in vivo, via a CB1R-dependent mechanism (Ferraro et al., 2001; Tomasini et al., 2002). Prenatal exposure to WIN increases glutamate uptake in the front cerebral cortex of rats (Castaldo et al., 2007), indicating a long-lasting increase in the release of glutamate, after exposure to cannabinoids. The increased basal release probability of glutamatergic synaptic transmission has been observed in the cerebellum, after repeated injections of THC (Tonini et al., 2006). Increased extracellular glutamate levels following cannabinoid exposure are likely associated with the increased release of glutamate from presynaptic terminals and astroglial cells, or reduced uptake of glutamate by glutamate transporters (Chen et al., 2013; Fan, Yang, Zhang, & Chen, 2010; Ferraro et al., 2001; Han et al., 2012; Hoffman, Oz, Yang, Lichtman, & Lupica, 2007; Navarrete & Araque, 2010; Suarez et al., 2004b; Tomasini et al., 2002; Tonini et al., 2006). Expression of glutamate transporters is significantly reduced after repeated exposure to THC (Chen et al., 2013). The reduced expression of glutamate transporters will lead to a decrease in uptake of glutamate, resulting in accumulation of glutamate in an extracellular space. It has also been demonstrated previously that PGE_2 stimulates or facilitates both synaptic and astrocytic release of glutamate (Bezzi et al., 1998; Chen, Magee, & Bazan, 2002; Dave et al., 2010; Chen & Bazan, 2005; Sang et al., 2005; Sanzgiri, Araque, & Haydon, 1999). In particular, astroglial cells may be the primary source for COX-2 derived PGE_2, because THC-induced increase in COX-2 expression is more pronounced in astroglial-enriched culture than in relatively pure neuronal culture (Chen et al., 2013). Therefore, accumulated glutamate in extracellular compartments, after THC exposure, is associated with increased synthesis of PGE_2, which facilitates release of glutamate from synapses, and exocytosis of glutamate from astrocytes.

THC EXPOSURE-IMPAIRED SYNAPTIC PLASTICITY AND COGNITIVE FUNCTION ARE ASSOCIATED WITH REDUCED FUNCTIONAL GLUTAMATE RECEPTOR SUBUNITS, AND DENDRITIC SPINES

Long-term potentiation (LTP) at excitatory synapses is a long-lasting synaptic strength of glutamatergic transmission, and has been long recognized as a cellular model of learning and memory. Repeated THC exposure impairs hippocampal LTP via a CB1R-dependent mechanism (Chen et al., 2013; Fan et al., 2010; Hoffman et al., 2007), which may underlie marijuana- or THC-caused memory impairments. Synaptic and memory impairments by cannabis or THC are apparently associated with alterations in glutamatergic synaptic transmission, and functional expression of glutamate receptor subunits (Fan et al., 2010; Han et al., 2012; Hoffman et al., 2007; Suarez et al., 2004a; Tonini et al., 2006). Recent studies show that cannabinoid exposure leads to downregulation, internalization, and endocytosis of glutamate receptor subunits (Chen et al., 2013; Fan et al., 2010; Han et al., 2012). For instance, pre- and perinatal THC exposure downregulates the AMPA glutamate receptor subunits GluA1 and GluA2/3 in the rat cerebellum (Suarez et al., 2004a). Repeated exposure to THC in young adult mice significantly reduces total and surface expressions of AMPA glutamate receptor subunit GluA1, and NMDA receptor subunits GluN2A and GluN2B in the hippocampus, while the amount of these subunits in intracellular compartment are increased, suggesting that chronic cannabinoid exposure not only reduces expression of glutamate receptor subunits, but also changes receptor trafficking (Chen et al., 2013; Fan et al., 2010). While we still lack clearly defined evidence of how cannabinoid exposure decreases glutamate receptor expression and function, the reduced expression and trafficking of glutamate receptor subunits by THC are likely associated with elevated extracellular glutamate levels stimulated by COX-2 derived PGE_2 (Fig. 75.5). This is supported by the fact that pharmacological or genetic inhibition of COX-2 prevents alterations in expression of glutamate receptor subunits induced by chronic treatment with THC (Chen et al., 2013). Repeated cannabinoid exposure induces persistent elevation of COX-2 expression and PGE_2 formation, which facilitates glutamate release and increases extracellular glutamate accumulation, leading to downregulation and internalization of glutamate receptor subunits. One recent study provides evidence that this is the case by showing that COX-2 expression is steadily elevated in the hippocampus from mice that received THC for 7 days (Chen et al., 2013). This information suggests that reduced functional expression of glutamate receptor subunits, upon repeated THC exposure, is associated with sustained elevation of COX-2, and its derived PGE_2, which stimulates glutamate release. This may be a homeostatic mechanism in response to elevated extracellular glutamate levels.

Dendritic spines, tiny protrusions on dendrites, are a specialized structure where synapses are localized. It is clear now that the density and geometry of dendritic spines are critical for functioning of glutamatergic synaptic transmission and plasticity (Nimchinsky, Sabatini, & Svoboda, 2002). Recent evidence shows that adolescent chronic treatment with THC results in

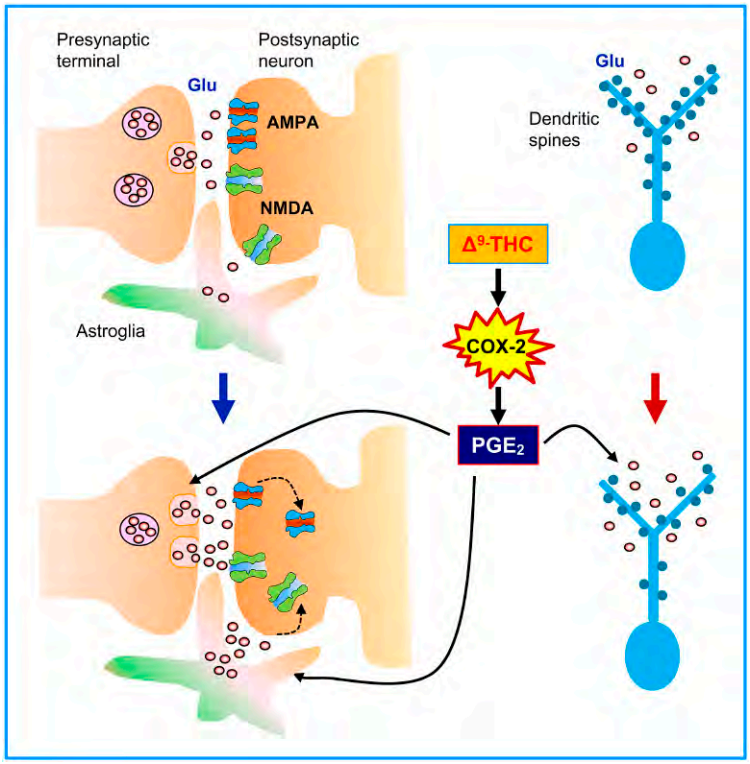

FIGURE 75.5 **Δ^9-THC exposure alters expression and trafficking of glutamate receptor subunits and density of dendritic spines.** COX-2 derived PGE_2 stimulated by THC facilitates release of excitatory neurotransmitter glutamate from presynaptic terminals, and exocytosis of glutamate from astroglial cells. Also, THC-induced suppression of glutamate transporters reduces uptake of glutamate from extracellular space. Accumulated extracellular glutamate causes downregulation, internalization, or endocytosis of AMPA and NMDA glutamate receptor subunits, and decreases density of dendritic spines and PSD-95.

reduced density of dendritic spines, and it lowers the length and number of dendrites in the hippocampus (Rubino et al., 2009). This suggests that changes in dendritic morphology, including size, density, and shape, are important in synaptic and cognitive impairments, following chronic THC exposure. A recent study by Chen et al. (2013) provides convincing evidence that density of dendritic spines is reduced in hippocampal CA1 pyramidal neurons in animals repeatedly exposed to THC. In particular, THC significantly reduces density of mushroom spines, where functional AMPA and NMDA receptors are expressed. Reduced postsynaptic density protein 95 (PSD-95), a postsynaptic marker, in hippocampal neurons of THC-exposed animals further confirms the decreased density of dendritic spines. The changes in dendritic spine density and PSD-95 by THC are blunted in COX-2 inhibitor Celebrex-treated animals, or in COX-2 knockout mice. While reduced expression of functional AMPA and NMDA glutamate receptor subunits, and density of dendritic spines after repeated exposure to THC, may underlie cannabis-caused memory impairments, these deficits in synaptic and cognitive function induced by THC are likely mediated via COX-2 signaling. This assumption is supported by the experimental results showing that impairments in fear memory, spatial learning, and memory induced by chronic THC exposure are prevented by inhibition of COX-2 with selective COX-2 inhibitors, or in mice deficient in COX-2 (Chen et al., 2013). Moreover, it has been demonstrated that a single injection of THC impairs synaptic and cognitive function. For example, a single in vivo exposure to THC has been demonstrated to be sufficient to induce changes in synaptic plasticity, both in the hippocampus and nucleus accumbens, and deficits in working memory (Han et al., 2012; Mato et al., 2004; Puighermanal et al., 2009). This also has been confirmed in a study by Chen et al. (2013), which provides evidence that long-term depression (LTD) of glutamatergic synaptic transmission in the hippocampus is impaired by a single injection of THC, and this effect is blocked by COX-2 inhibition. In addition, cataleptic and locomotion suppressive effects of THC are reduced by COX-2 inhibition. These experimental data suggest that COX-2 is involved in synaptic and memory impairments, as well as behavioral changes induced by both single and repeated exposure to THC. Apparently, marijuana or THC-caused synaptic and memory impairments are likely mediated through CB1R-coupled G protein βγ subunits, and their downstream PI3K, ERK/p38MAPK, NF-κB, and COX-2 signaling pathway (Fig. 75.6).

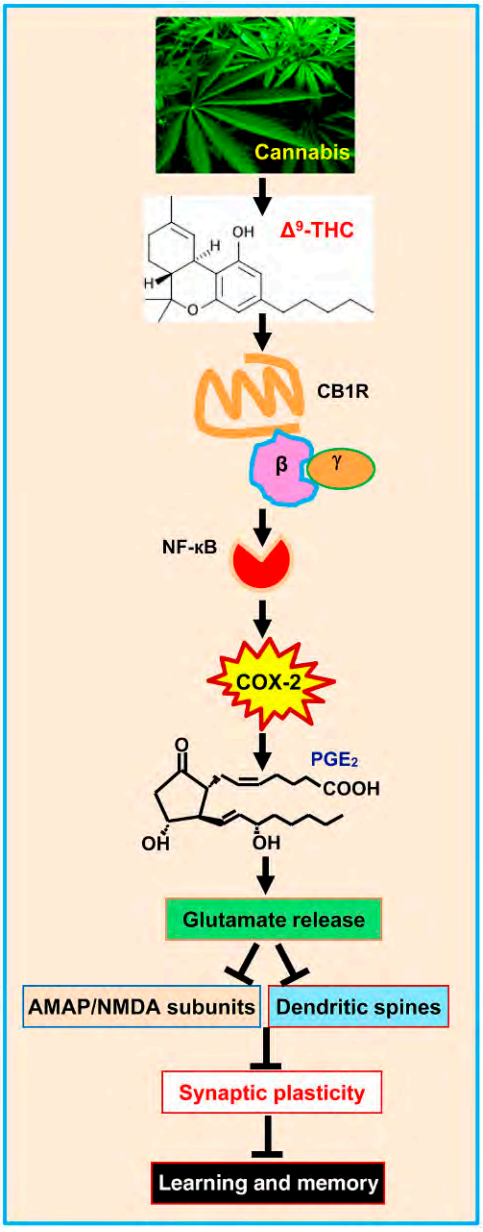

FIGURE 75.6 **Summary of cannabis exposure-impaired synaptic plasticity and memory.** Exposure to THC causes synaptic and cognitive impairments through CB1R-coupled Gβγ, NF-κB, and COX-2 signaling pathway. COX-2 derived PGE_2 increases extracellular glutamate accumulation, which decreases functional glutamate receptors and dendritic spine density. Alterations in structure and function of synapses impair synaptic plasticity, learning, and memory.

CONCLUSIONS

As stated previously, cannabis or marijuana has been used for thousands of years, as a recreational drug and for medical treatments. Heavy use of marijuana is known to induce cannabis-related disorders (CRD), including physical, neuropsychological, and cognitive changes. However, there are no FDA-approved medications available to prevent or treat CRD. Also, undesirable side effects of cannabinoids greatly limit the medical use of cannabis or THC (Marinol/Dronabinol, FDA-approved cannabinoid medicine). If COX-2 is a critical signaling mediator in THC-induced unwanted effects, inhibition of COX-2 with a COX-2 inhibitor may alleviate symptoms of CRD. In addition, concurrent inhibition of COX-2 would broaden the applicability of medical marijuana. In particular, selective COX-2 inhibitors, such as Celebrex, are currently used in clinical applications, and over-the-counter NSAIDs, such as ibuprofen and aspirin, are nonselective COX inhibitors. Thus, a combination of THC with a COX-2 inhibitor may provide a novel therapeutic intervention for preventing or treating some intractable medical conditions. Chen et al. (2013) provides initial evidence that THC is capable of reducing β-amyloid, a neuropathological hallmark of Alzheimer disease (AD), and neurodegeneration in an animal model of AD, showing that these beneficial effects are preserved when COX-2 is concurrently inhibited. This suggests that a cocktail intervention of THC and Celebrex may form a novel therapy for preventing and treating AD, or halting disease progression. Nevertheless, we still have a lot of unknowns about many other beneficial effects or therapeutic applications of cannabis or THC. Therefore, it is imperative to enhance marijuana research, particularly since legalization of marijuana use is currently spreading throughout the United States, and around the world.

MINI-DICTIONARY

Alzheimer disease (AD) A neurodegenerative disease characterized by deposition of β-amyloid, neuroinflammation, synaptic dysfunction, neurodegeneration, loss of memory, and dementia.
CB1 receptor A G-protein coupled cannabinoid type 1 receptor that mediates cannabinoid-induced biological responses.
Cyclooxygenase-2 (COX-2) An inducible enzyme that converts arachidonic acid to prostaglandins.
Long-term potentiation (LTP) A form of long-lasting synaptic strength.
Nonsteroidal antiinflammatory drugs (NSAIDs) Over-the-counter nonselective cyclooxygenase inhibitors.
Synapse A point of contact between nerve cells for transmitting chemical or electrical signals from one cell to another (cell-to-cell communication).
Δ9-Tetrahydrocannabinol (THC) The major psychoactive ingredient of cannabis.

Cannabinoids and the Addictive Effects of Nicotine

L.V. Panlilio, S.R. Goldberg

Preclinical Pharmacology Section, Behavioral Neuroscience Branch, Intramural Research Program, National Institute on Drug Abuse, National Institutes of Health, Baltimore, MD, United States

SUMMARY POINTS

- THC and nicotine (in the forms of cannabis and tobacco, respectively) are commonly used together.
- These drugs affect reward-related brain circuits that partially overlap and interact.
- These interactions could be responsible for promoting addiction in co-users of THC and nicotine.
- Interaction between the endogenous cannabinoid and nicotinic acetylcholine systems might also provide new avenues for the treatment of addiction.
- In animal models of drug abuse, simultaneous administration of THC and nicotine can enhance the rewarding effects of nicotine.
- A history of THC exposure can also increase nicotine reward making rats more likely to start taking nicotine and to become highly persistent in seeking nicotine.
- Cannabinoid antagonists, which bind to cannabinoid receptors but do not produce THC-like effects, decrease nicotine use in humans and animals, but are unsuitable as medications due to adverse side effects.
- Drugs that activate peroxisome proliferator-activated receptors have beneficial effects in animal models of nicotine reward and relapse, and some of these drugs are already in use to treat lipid disorders in humans.
- Drugs that reduce the effects of acetylcholine at alpha-7 nicotinic receptors block THC reward and relapse to THC seeking in nonhuman primates.

KEY FACTS OF BEHAVIORAL MODELS OF NICOTINE REWARD

- Drug self-administration and conditioned place-preference are the main models of nicotine reward.
- Drug self-administration—in which the animal is allowed to take nicotine by pressing a lever—provides the clearest evidence of rewarding effects, has high face validity, and is the most homologous animal model of human drug use.
- Since smoke and the bitter taste of most drugs are aversive to animals, self-administered nicotine is delivered through an intravenous catheter.
- Conditioned place-preference—in which nicotine is given in a distinctive environment, and the animal is later tested to see if it prefers to be in that environment—is a less direct measure of reward, but is widely used because it is easier to perform; usually the drug is injected intraperitoneally or subcutaneously once per day, so catheter implantation and maintenance are not required.
- Conditioned place-preference is well-suited to making comparisons between groups, for example, when irreversible treatments such as genetic manipulations are being studied.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00087-9
2017 Published by Elsevier Inc.

- Drug self-administration is well-suited for making within-subject comparisons, such as varying the dose of the self-administered drug, or a treatment drug.
- With both conditioned place-preference and drug self-administration, relapse can be modeled by discontinuing delivery of the drug until the learned drug-seeking behavior ceases, then presenting triggers that reinstate the behavior. Reinstatement is induced in animals by the same kinds of triggers that induce relapse in humans: reexposure to the drug, reexposure to environmental cues previously associated with the drug, and exposure to stress.

LIST OF ABBREVIATIONS

2-AG	2-Arachidonoylglycerol
CB_1	Type-1 cannabinoid receptor
FAAH	Fatty acid amide hydrolase
OEA	Oleoylethanolamine
PEA	Palmitoylethanolamide
PPARs	Peroxisome proliferator-activated receptors
THC	Δ^9-Tetrahydrocannabinol
URB597	A FAAH inhibitor
WIN55,212-2	A synthetic cannabinoid agonist

INTRODUCTION

Cannabis and tobacco are commonly used together. Besides sharing similar routes of administration, these drugs have certain effects that overlap and interact in the brain, and their simultaneous or sequential use might increase the likelihood of developing addiction. Information about interactions between these drugs comes from two general sources, human research and animal research. Human research (Agrawal, Budney, & Lynskey, 2012; Meier & Hatsukami, 2016) is clearly most relevant to human drug use. However, animal models of drug use also have distinct advantages, such as the ability to maintain a higher level of control over experimental variables, and to use neuroscience techniques that are not feasible in humans. The present article will focus on information obtained with animals, using procedures that model processes relevant to cannabinoid drugs and nicotine addiction in humans.

It is well-known that the main psychoactive constituents of cannabis and tobacco are Δ^9-tetrahydrocannabinol (THC) and nicotine, respectively. The abuse-related effects of THC are mediated by its actions at type-1 cannabinoid receptors (CB_1) in the brain, while nicotine's effects are mediated by its actions at nicotinic acetylcholine receptors. Cannabinoid receptors normally bind endogenous substances, including anandamide and 2-arachidonoylglycerol (2-AG), as part of the endocannabinoid system. Nicotinic receptors normally bind endogenous acetylcholine. Most of the research to be described here has used purified forms of nicotine and THC, or synthetic drugs that act on the same brain systems as these drugs.

Like all addictive drugs, THC and nicotine have rewarding effects in the brain that lead the user to seek out and use the drug again in the future. Rewarding effects are believed to depend largely on increased activity of neurons that release the neurotransmitter dopamine in the nucleus accumbens, part of the reward system of the brain. Most addiction-related studies of how THC and nicotine interact in the brain have involved looking at this reward system by measuring dopamine levels, the density and functionality of cannabinoid and dopamine receptors, and the firing of dopamine cells.

The following sections will describe findings from animal research relevant to tobacco addiction, including evidence that simultaneous use of THC and nicotine enhances the rewarding effects of nicotine, and that THC exposure has lasting effects that increase the rewarding effects of nicotine taken at a later date. On a more positive note, we will also describe findings suggesting that pharmacological manipulations of the endogenous cannabinoid system might have beneficial effects that promote abstinence from tobacco, and vice versa: that pharmacological manipulations of the endogenous nicotinic system might promote abstinence from cannabis.

SIMULTANEOUS THC AND NICOTINE USE

Many simultaneous users report that they combine tobacco and cannabis to enhance the effects of cannabis. In addition, there are probably many simultaneous users who take each drug for its unique effects. While users can become dependent on cannabis (as defined by the *Diagnostic and Statistical Manual, 4th edition*), tobacco is generally considered more addictive, and complications stemming from its use are the eventual cause of death in a substantial percentage of smokers. So, it could be highly beneficial to determine whether (and how) combinations of THC and nicotine interact to increase the likelihood or severity of nicotine addiction.

In an extensive early study in rats, (Pryor, Larsen, Husain, & Braude, 1978) it was found that—unlike cocaine and amphetamine, which reversed the motor depressant effects of THC—a subthreshold dose of nicotine combined with THC essentially abolished spontaneous locomotor activity. This depression was specific to exploratory behavior, since nicotine did not increase the effect of THC on a conditioned avoidance response. The interactive effect was also persistent; the combination of nicotine and THC

continued to suppress spontaneous locomotion, even after tolerance had developed to the effects of THC alone.

More recently, combinations of THC and nicotine have been tested in rodent models of drug reward. In mice, Valjent, Mitchell, Besson, Caboche, and Maldonado (2002) found that combining subthreshold doses of these drugs had a rewarding effect in a conditioned place-preference procedure (Fig. 76.1). Scherma et al. (2012) observed a similar potentiation of conditioned place-preference when they combined subthreshold doses of THC and nicotine in rats, and they found that THC potentiated the motor-depressant effects of a low dose of nicotine. Scherma et al. (2012) also found that THC did not alter the place-preference produced by a higher dose of nicotine, possibly due to a ceiling effect. Valjent et al. (2002) found that the combination of THC and nicotine had a potentiating effect on neuronal activity on several brain areas highly innervated by dopamine inputs, although the combined effect was approximately additive in the nucleus accumbens shell. In the same study, nicotine also potentiated the anxiolytic effect of a low dose of THC in two models of anxiety, and it enhanced three of the classic effects of high doses of THC: hypothermia, antinociception, and hypolocomotion. The fact that most of these effects involve potentiation rather than simple additive effects of THC and nicotine suggests the cannabinoid and cholinergic systems interact in functional, meaningful ways.

Unfortunately, these few studies represent the extent of animal research into the reward-related effects of simultaneous THC and nicotine administration. This is likely due to the fact that, compared to opioids and psychomotor stimulants, the rewarding effects of cannabinoids and nicotine are difficult to study in rodents. In particular, self-administration of THC in rodents is not robust, and conditioned place-preference occurs only within a narrow range of doses. Rodents might be particularly sensitive to aversive effects of THC, such as anxiety, which counteract or mask rewarding effects. Robust models of THC self-administration have been developed in nonhuman primates, but they have yet to be applied in this area.

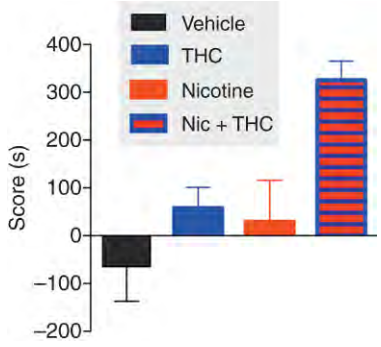

FIGURE 76.1 Rats expressed a preference for a place previously associated with a combination of a low dose of THC and a low dose of nicotine ("Nic + THC"), but not for a place associated with only vehicle, THC, or nicotine. Positive score (mean ± s.e.m.) indicates how much more time rats chose to spend in the treatment-associated compartment, compared to a control compartment. *Source: Adapted from Valjent et al. (2002). Used with permission.*

LASTING EFFECTS OF THC EXPOSURE

It has long been recognized that drug use tends to follow a certain progression over time, with alcohol and cannabis use initiated prior to use of drugs such as cocaine and heroin. This phenomenon is known as the gateway effect. There is also accumulating evidence for a reverse gateway effect, in which cannabis use develops before tobacco use, and increases the likelihood of tobacco addiction.

There has been much debate about the causes of gateway effects and, for many reasons, it is hard to draw strong conclusions about causality in human populations. However, animal models of drug abuse are well-suited for studying at least one factor that might contribute to gateway phenomena: drug exposure, per se. The animal's environment can be carefully controlled, and social influences such as use by conspecifics are not confounded with pharmacologic effects. The animals' drug history can also be precisely manipulated, for example by exposing them to THC during the perinatal or adolescent stage. Due to the difficulty of studying the rewarding effects of THC in rodents, gateway studies in rodents have focused on the ability of prior THC exposure to alter the rewarding effects of other drugs. These studies have primarily involved opioid self-administration, with only a few investigating cocaine, amphetamine, or nicotine self-administration.

The endocannabinoid system modulates dopamine signaling in brain circuits involved in reward, motor control, motivation, emotion, and cognition (Rodriguez de Fonseca et al., 2005). Exposure to THC produces not only immediate effects on the dopamine system, but also longer-lasting changes. In rats, exposure to THC can alter the expression and sensitivity of dopamine receptors after repeated prenatal (DiNieri et al., 2011) or perinatal exposure (Moreno, Trigo, Escuredo, Rodríguez de Fonseca, & Navarro, 2003), and even after a single exposure in adulthood (Gorriti et al., 2005). Perinatal exposure to THC can alter the activity of dopamine cells in reward-related brain areas during adulthood (González et al., 2003; Singh, McGregor, & Mallet, 2006). Subchronic exposure to THC (21 days) induced neurochemical and functional supersensitivity of dopamine receptors in the nucleus accumbens that were present 1 day after THC treatment, and only partially reversed 1 week later (Ginovart et al., 2012). Kolb, Gorny, Limebeer, and Parker

(2006) found that 12 days of exposure to low or moderate doses of THC (0.5–4 mg/kg) increased both the length of dendrites and the number of dendritic branches in the nucleus accumbens shell and medial prefrontal cortex, measured 40 days after THC exposure. After a single exposure to a synthetic CB_1-receptor agonist, adolescent rats showed increased dopamine-receptor density, but adult rats only showed such an effect after 14 days of exposure, suggesting that the adult rat brain has compensatory mechanisms not present in adolescents.

To study the addiction-related behavioral effects of THC exposure, a series of studies has been conducted, using an exposure regimen in which rats are given two intraperitoneal injections of THC per day, for 3 consecutive days, with the dose escalating over days from 2 to 8 mg/kg per injection; the last THC injection is given at least a week before behavioral or neurophysiological tests are begun (Cadoni, Pisanu, Solinas, Acquas, & Di Chiara, 2001; Cadoni, Simola, Espa, Fenu, & Di Chiara, 2013; Cadoni, Valentini, & Di Chiara, 2008; Panlilio, Solinas, Matthews, & Goldberg, 2007; Panlilio, Zanettini, Barnes, Solinas, & Goldberg, 2013; Solinas, Panlilio, & Goldberg, 2004). This treatment models a period of regular cannabis use, with escalating intake to compensate for the development of tolerance. Compared to control rats given only vehicle injections during the exposure period, rats that were exposed to THC under this regimen showed reduced dopamine transmission in the nucleus accumbens shell when they were given morphine (Cadoni et al., 2008), and higher levels of spontaneous locomotor activity when given morphine (Cadoni et al., 2001, 2008) or heroin (Panlilio et al., 2007). When allowed to self-administer heroin starting 1 week after the last THC injection, THC-exposed rats took more heroin than controls when only a single response was required for each injection of heroin (Solinas et al., 2004). However, when the price of heroin was raised by increasing the number of responses required for each injection, THC-exposed rats did not differ from controls suggesting that THC exposure did not increase the reward value of heroin. Rather, the higher rate of intake under the low-price condition might be explained in terms of THC-exposed rats being more active than controls after receiving heroin, allowing them to take heroin more rapidly, with only brief pauses between injections.

Another series of studies has focused on the effects of light, occasional exposure to THC, with rats given intraperitoneal injections of THC every third day during adolescence (postnatal days 28–49), at a dose of 1.5 mg/kg per injection (Ellgren, Spano, & Hurd, 2007; Szutorisz et al., 2014; Tomasiewicz et al., 2012). In these studies, THC exposure produced increases in opioid self-administration similar to those observed by Solinas et al. (2004), and long-lasting changes in the endogenous opioid system were also revealed, such as elevated expression of the precursor gene of the endogenous opioid, enkephalin (Tomasiewicz et al., 2012). It has even been shown that parental exposure can produce addiction-relevant physiological and behavioral changes in offspring conceived after THC was no longer in the system (Szutorisz et al., 2014). There has also been one study of the effects of THC exposure on the later self-administration of amphetamine and the dopamine agonist apomorphine (Cortright, Lorrain, Beeler, Tang, & Vezina, 2011); amphetamine self-administration was unaffected, but apomorphine self-administration was slightly increased, and postsynaptic dopamine receptor signaling was increased in the nucleus accumbens.

Extending the findings that Solinas et al. (2004) obtained with heroin self-administration, Panlilio et al. (2007) studied the effects of 3-day escalating THC exposure on subsequent cocaine self-administration. Rats exposed to THC in young adulthood did not differ from vehicle-exposed control rats when only one response was required for each cocaine injection. However, THC exposed rats responded less than controls when the response requirement was increased, indicating that prior THC exposure actually decreased the reward value of cocaine. Since THC exposure is known to alter the effects of morphine and heroin on spontaneous locomotor activity, THC-exposed rats were also tested to determine whether similar effects would occur with cocaine. Although they did not differ significantly from controls, in the overall level of locomotor activity when given cocaine, THC-exposed rats showed a different spatial pattern of activity, avoiding the center of the open field. This behavior is considered an indication of anxiety, and further testing with another animal model of anxiety also indicated that cocaine induced higher levels of anxiety in THC-exposed rats than in controls. Together, these findings suggest that THC exposure might have exacerbated the anxiety-inducing effect of cocaine, making it less valuable as a reward. THC exposure might have had a similar effect on anxiety induced by yohimbine, in a study by Stopponi et al. (2014) in which stress-induced reinstatement of heroin seeking was increased in THC-exposed rats.

To our knowledge, there has only been one study investigating the effects of previous THC exposure on the reward-related effects of nicotine (Panlilio et al., 2013), and one study investigating effects in the opposite direction, with exposure to nicotine prior to testing with cannabinoid-receptor CB_1 agonists. Werling, Reed, Wade, and Izenwasser (2009) exposed rats to nicotine or vehicle, and later tested their sensitivity to cannabinoids by administering THC or a synthetic CB_1 agonist. Previous exposure to nicotine led to enhanced locomotor-decreasing effects of cannabinoid agonists in adolescent male rats, but not in adult male rats. Cannabinoid-receptor density was increased in the prelimbic prefrontal cortex and

ventral tegmental area of nicotine-exposed adolescent male rats, compared with controls. This suggests that adolescent nicotine self-administration might increase sensitivity to cannabinoids, in line with the traditional gateway effect in which tobacco use seems to promote cannabis use.

Panlilio et al. (2013) examined a reverse gateway hypothesis, that cannabis exposure might facilitate subsequent formation of tobacco addiction. This study extended the series of experiments in which the 3-day escalating THC exposure regimen was given prior to allowing rats to self-administer heroin or cocaine. In the earlier studies, about 80% of rats acquired the heroin or cocaine self-administration response, regardless of whether they were THC-exposed or vehicle-exposed. In contrast, THC exposure increased the percentage of rats that acquired the nicotine self-administration response, from 65% in the vehicle-exposed group to 94% in the THC-exposed group (Fig. 76.2). This finding is consistent with cocaine and heroin generally having more powerful rewarding effects than nicotine, but with the rewarding effects of nicotine being increased by a history of THC exposure. This interpretation was further supported by the finding that, when the price of nicotine was increased, THC-exposed rats placed a higher value on nicotine than control rats did, a phenomenon that did not occur with either heroin (which was equally valued by both groups) or cocaine (which was valued less by THC-exposed groups). These findings suggest that humans who progress from cannabis use to tobacco addiction might do so, at least in part, because of pharmacological effects of THC exposure that specifically enhance the addictive potential of nicotine. This contribution of prior THC exposure to reverse gateway effects would be in addition to any pharmacological enhancement produced by simultaneous use of tobacco and cannabis (which has yet to be modeled with nicotine self-administration in animals), and also in addition to any nonpharmacological factors such as peer pressure, experience with smoking as a route of administration, or individual disposition toward addiction in general.

POSSIBLE AVENUES TO THE DEVELOPMENT OF TREATMENTS FOR ADDICTION

Epidemiological and animal-model studies suggest that co-use of cannabis and tobacco has the potential to lead to or intensify addiction, probably due to interactions between reward-related circuits in the cannabinoid and nicotinic systems of the brain. However, this interactivity might also provide the basis for pharmacological treatments that help induce and maintain abstinence from tobacco.

Some of the strongest evidence for interactions between the cannabinoid and nicotinic systems comes from studies in which cannabinoid receptors are genetically deleted or are blocked with CB_1 antagonist drugs, such as rimonabant. For example, in rats, CB_1-antagonists decrease nicotine self-administration and nicotine-induced dopamine elevations in the nucleus accumbens (Cohen, Perrault, Voltz, Steinberg, & Soubrie, 2002; Shoaib, 2008). Cannabinoid antagonists also have protective effects in reinstatement models of relapse, decreasing the effects of reexposure to nicotine or nicotine-associated cues (Cohen, Perrault, Griebel, & Soubrie, 2005; De Vries, de Vries, Janssen, & Schoffelmeer, 2005; Shoaib, 2008). When given to rats during the acquisition phase, rimonabant prevented the development of preference for a place associated with nicotine, and when given only before a test session, rimonabant prevented the expression of such a preference; however, expression was only blocked when

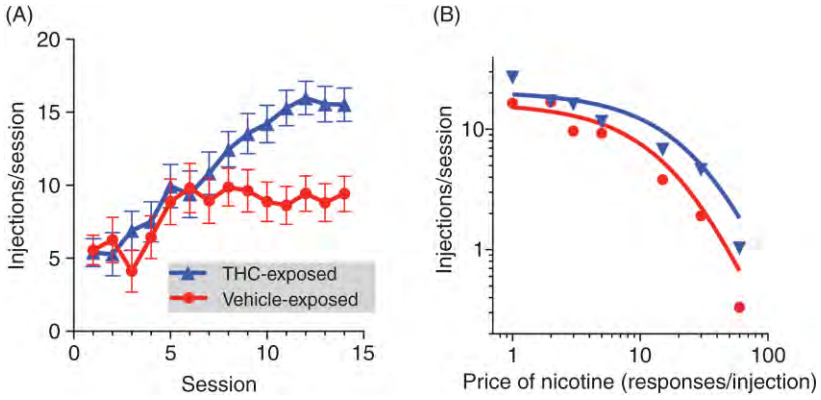

FIGURE 76.2 **Rats were exposed to THC or vehicle for 3 days, 8 days before being allowed to self-administer nicotine.** (A) THC-exposed rats acquired the self-administration response more readily, and took larger amounts of nicotine. (B) When the price of nicotine (responses per injection) was raised, THC-exposed rats took nicotine at higher prices than vehicle-exposed rats, indicating that nicotine was more valued by THC-exposed rats. *Source: Adapted from Panlilio et al. (2013). Used with permission.*

the test was performed 24 h after the last conditioning session, and was ineffective when rats were tested 3 or 12 weeks later (Forget, Hamon, & Thiebot, 2005).

Cossu et al. (2001) found that CB_1-receptor knockout mice would self-administer nicotine, cocaine, or amphetamine, but not morphine. In contrast, CB_1 knockout mice and wild-type mice given rimonabant did not develop nicotine-induced conditioned place-preference (Castane et al., 2002; Merritt, Martin, Walters, Lichtman, & Damaj, 2008). This difference between nicotine self-administration and nicotine-induced conditioned place-preference might be due to the cannabinoid system being more relevant to the rewarding effects of nicotine-associated cues (which provide the basis for conditioned place-preference and cue-induced reinstatement), as opposed to the direct reinforcing effects of nicotine (which are more prominent in self-administration procedures).

When tested in humans, blockade of cannabinoid receptors by rimonabant showed efficacy for the treatment of tobacco smoking, but was also found to produce depression-like side effects, leading to the drug being withdrawn from the market in Europe, and never receiving Food and Drug Administration approval in the United States (Le Foll, Gorelick, & Goldberg, 2009). The adverse effects of rimonabant might be due to the fact that it not only blocks the cannabinoid receptor from being activated by endogenous cannabinoids, such as anandamide and 2-AG, but also has inverse-agonist effects that are opposite to those of the endogenous cannabinoids. It remains to be seen whether cannabinoid antagonists that lack inverse-agonist effects would be better tolerated, and whether they would be useful as a treatment for tobacco addiction. However, there are two other strategies for manipulating the endocannabinoid system that also might provide effective treatment for tobacco addiction, without rimonabant-like side effects: inhibition of fatty acid amide hydrolase (FAAH), and direct activation of peroxisome proliferator-activated receptors (PPARs).

FAAH is the main enzyme responsible for inactivation of the endogenous cannabinoid CB_1 agonist anandamide, and the related fatty acid amides, OEA and PEA, which act at PPARs. Thus, pharmacological inhibition or genetic deletion of FAAH increases endogenous levels of anandamide, OEA, and PEA, enhancing and prolonging their effects when they are naturally released. Despite the abuse potential of CB_1 agonists such as THC, and the fact that FAAH inhibition increases levels of anandamide, at least one FAAH-inhibiting drug, URB597, has been found to be devoid of rewarding effects in animals (Justinova et al., 2008). But, surprisingly, FAAH inhibition counteracts the rewarding effects of nicotine in rats and monkeys. For example, URB597 prevented acquisition and reinstatement of nicotine self-administration and conditioned place-preference in rats (Fig. 76.3), and it reduced nicotine-induced elevations

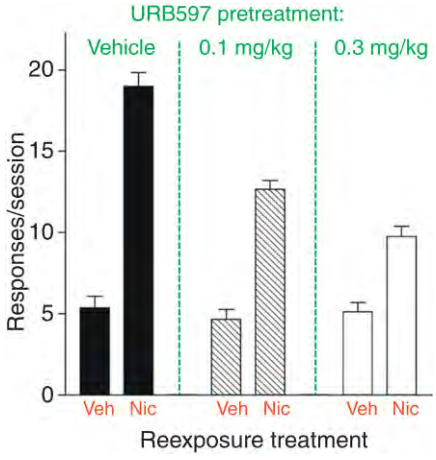

FIGURE 76.3 **In rats that had learned to self-administer intravenous nicotine, abstinence was imposed by discontinuing nicotine delivery.** Then, rats were reexposed to nicotine (or vehicle) by intraperitoneal injection. Nicotine reexposure reinstated the nicotine-seeking response, but pretreatment with the FAAH inhibitor URB597 blocked this relapse-like effect, with a higher dose of URB597 having the strongest blocking effect. *Source: Adapted from Scherma et al. (2008). Used with permission.*

of dopamine in the nucleus accumbens shell (Scherma et al., 2008). However, these effects of FAAH inhibition appear to be species-dependent, with FAAH knockout mice and wild-type mice treated with URB597 showing the opposite effect: enhanced nicotine-induced conditioned place-preference (Merritt et al., 2008).

The potentially beneficial effects of FAAH inhibition on nicotine reward appear to be due to its ability to increase levels of both anandamide and the endogenous PPAR ligands, OEA and PEA. Selectively increasing endogenous anandamide levels blocks the effects of nicotine on nucleus-accumbens dopamine, and also blocks the development and reinstatement of nicotine-induced conditioned place-preference (Scherma et al., 2012). Using electrophysiology techniques, Melis et al. (2008) found that some of the effects of URB597 on nicotine-induced firing of dopamine cells in the ventral tegmental area (which projects to the nucleus accumbens) were mediated by cannabinoid receptors, and others by PPARs. The paradox—in which systemic injection of one CB_1 agonist (THC) enhances nicotine's effects, but increasing endogenous levels of another CB_1 agonist (anandamide) blocks nicotine's effects—might be due to endogenous anandamide affecting CB_1 receptors only in specific brain areas, as opposed to exogenous THC affecting them globally, throughout the brain.

Subsequent experiments with behavioral models of nicotine reward, in vivo microdialysis, and electrophysiology suggest that selective PPAR agonists (with no activity at CB_1 receptors) could be useful for the treatment of tobacco smoking. Mascia et al. (2011) found that the alpha-type PPAR agonist WY14643 decreased: (1) nicotine

self-administration and nicotine-induced reinstatement in rats and monkeys (Fig. 76.4); (2) nicotine-induced excitation of dopamine neurons in the ventral tegmental area of rats; and (3) nicotine-induced dopamine elevations in the nucleus accumbens shell of rats (Fig. 76.5). Similar effects were produced by another PPAR-alpha agonist, clofibrate, a representative of the fibrate class of medications used to treat lipid disorders in humans (Fig. 76.6) (Panlilio et al., 2012). In monkeys, clofibrate not only decreased ongoing nicotine self-administration, but also decreased reinstatement induced by reexposure to either nicotine or nicotine-associated cues; these findings suggest that fibrate medications already approved for other purposes could be useful for both inducing and maintaining abstinence from tobacco.

In comparison with tobacco, cannabis is less addictive, and less of a public health problem. Nonetheless, there are substantial numbers of people who meet DSM criteria for cannabis dependence, many of whom seek treatment, and there are no approved pharmacotherapies for this purpose. However, just as it has led to new approaches to the treatment of tobacco addiction, research on interactivity between the endogenous cannabinoid and nicotinic systems has led to identification of a pharmacological strategy for treating cannabis dependence.

Alpha-7 nicotinic receptors are localized in reward-related brain areas, and control glutamate release, which in turn, controls dopamine release. In rats, Solinas et al. (2007) found that blocking alpha-7 nicotinic receptors with methyllycaconitine decreased self-administration of the cannabinoid-receptor synthetic agonist WIN55,212-2, and that it also completely prevented THC from elevating dopamine in the nucleus accumbens shell. While these findings suggest that manipulation of nicotinic receptors might decrease the abuse-related effects of cannabis, unfortunately, direct agonists of apha-7 receptors such as methyllycaconitine are unsuitable as medications, due to side effects such as cognitive impairment.

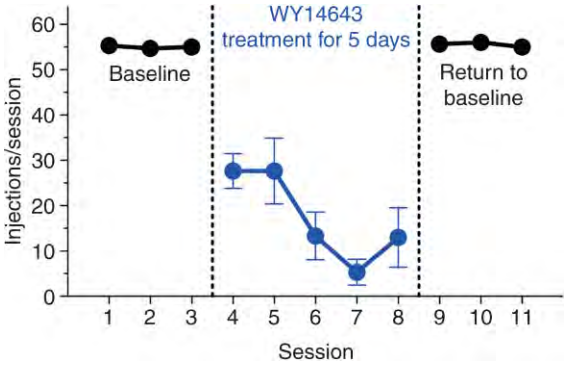

FIGURE 76.4 Monkeys with a long history of nicotine self-administration substantially decreased their nicotine intake when treated for 5 days with the PPAR-alpha agonist WY14643. *Source: Adapted from Mascia et al. (2011). Used with permission.*

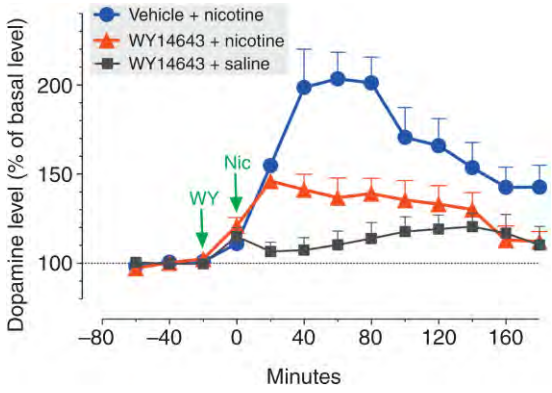

FIGURE 76.5 Intraperitoneal nicotine treatment increased dopamine levels in the nucleus accumbens shell of rats that were pretreated with vehicle ("Vehicle + Nicotine"), but nicotine's effect was substantially reduced by pretreatment with the PPAR-alpha agonist WY14643 ("WY14643 + Nicotine"). WY14643 by itself had little or no effect on dopamine levels ("WY14643 + Saline"). *Green arrows* indicate time of pretreatment ("WY") and treatment ("Nic") injection. *Source: Adapted from Mascia et al. (2011). Used with permission.*

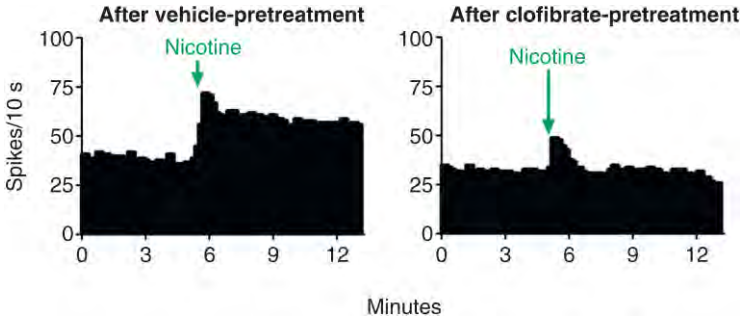

FIGURE 76.6 In anesthetized rats, intravenous nicotine increased the firing of ventral tegmental area dopamine neurons that project to the nucleus accumbens shell (A), but pretreatment with the PPAR-alpha agonist clofibrate blocked this effect (B). Each panel shows the firing rate of a single neuron over time. *Source: Adapted from Panlilio et al. (2012). Used with permission.*

A potentially safer means of blocking alpha-7 receptors in the brain is by enhancing endogenous levels of kynurenic acid, a negative allosteric modulator of alpha-7 receptors. Negative allosteric modulation of alpha-7 receptors does not directly affect neuronal signaling, but diminishes the effects of nicotine or endogenous acetylcholine when they bind to the receptor. Justinova et al. (2013) found that enhancing endogenous levels of kynurenic acid has potentially beneficial effects in rodent and nonhuman-primate models of cannabis reward and reward-related effects, including: (1) preventing THC and WIN55,212-2 from elevating dopamine levels in the nucleus accumbens and ventral tegmental area of rats; (2) decreasing WIN55,212-2 self-administration and WIN55,212-2-induced reinstatement in rats; (3) decreasing THC self-administration in monkeys; and (4) decreasing reinstatement induced by reexposure to THC or THC-associated cues in monkeys. All of these effects were shown to be due to negative allosteric modulation of alpha-7 receptors, since the effects were reversed by coadministration of positive allosteric modulators of alpha-7 receptors. This study also provided some evidence for the safety of this treatment strategy by showing that the same treatments that blocked cannabinoid reward did not induce nonspecific depressant effects or cognitive deficits in working memory. These findings suggest that manipulations of the nicotinic system might eventually be used to treat cannabis dependence and, perhaps, dual cannabis-tobacco dependence.

MINI-DICTIONARY

CB_1 Receptor subtype that binds THC and endogenous cannabinoids (including anandamide), and modulates their psychoactive effects.
CB_1 knockout mice Mice genetically engineered to have no CB_1 receptors.
Conditioned place-preference A model of drug seeking that measures rodents' preference for a place previously associated with a drug effect.
Drug reward Drug reward occurs when a specific behavior that causes a drug to be delivered and this increases the likelihood that the behavior will continue to occur in the future. Environmental cues associated with drugs can also acquire rewarding effects, such as in the conditioned-place preference procedure.
Drug self-administration A model of drug reward that allows animals to take a drug, usually by pressing a lever that produces a small intravenous injection.
Endocannabinoid system The brain circuitry that involves CB_1 and CB_2 receptors, anandamide, and other endogenous chemicals that bind to these receptors, and also anandamide-related chemicals such as OEA and PEA that bind to PPARs.
Fatty acid amide hydrolase The main enzyme responsible for deactivating anandamide, OEA, PEA, and related chemicals.
Nucleus accumbens Brain area considered to be important in the rewarding effects of drugs, natural substances such as food, and events such as sexual activity. One of the main sources of input to this area is dopamine-releasing neurons originating in the ventral tegmental area.
Peroxisome proliferator-activated receptors PPARs have a range of functions, including regulation of feeding and metabolism. Alpha-type PPARs negatively modulate beta-2 nicotinic receptors. Due to their structural and functional properties, endogenous PPAR ligands such as OEA and PEA are considered part of the extended endocannabinoid family.
Reinstatement A model of relapse in which drug seeking is established, then diminished by discontinuing drug availability, and finally tested by exposing the animal to triggers such as stress, reexposure to the drug, or reexposure to drug-associated environmental cues.

Cannabinoid Regulation of Intraocular Pressure: Human and Animal Studies, Cellular and Molecular Targets

A. Aloway, A. Kumar, A.S. Laun, Z.H. Song

Department of Pharmacology and Toxicology, University of Louisville School of Medicine, Louisville, KY, United States

SUMMARY POINTS

- All three classes of cannabinoids, including phytocannabinoids, synthetic cannabinoids, and endocannabinoids, have been demonstrated to lower IOP in human subjects, as well as in animal models.
- The molecular targets mediating the IOP-lowering effects cannabinoids include CB1 and CB2 cannabinoid receptors, non-CB1/CB2 cannabinoid receptors, endocannabinoid metabolizing enzymes, and transporters.
- These molecular targets are found in the regions of the eye that are important for IOP regulation, including ciliary epithelium, trabecular meshwork, and ciliary muscle.
- Cannabinoids exhibit their IOP-lowering effects either through reducing aqueous humor production, or by enhancing aqueous humor outflow through conventional or uveoscleral routes.
- Cannabinoids represent a class of promising therapeutic agents for the treatment of glaucoma.

KEY FACTS INTRAOCULAR PRESSURE

- Intraocular pressure is the pressure within the eye.
- Intraocular pressure is determined by the production and drainage of aqueous humor.
- Aqueous humor is produced by nonpigmented epithelial cells of the ciliary body in the eye, and is drained by either the trabecular meshwork pathway, or the uveoscleral pathway.
- Elevated intraocular pressure is a risk factor for the development of glaucoma.
- Drugs can lead to a change in intraocular pressure by altering aqueous humor production or outflow.

LIST OF ABBREVIATIONS

AEA	Arachidonylethanolamide
2-AG	2-Arachidonylglycerol
CB1, CB2	Cannabinoid receptors type 1 and 2
IOP	Intraocular pressure
PEA	Palmitoylethanolamide
Δ^9-THC	Δ^9-Tetrahydrocannabinol
TM	Trabecular meshwork

GLAUCOMA AND INTRAOCULAR PRESSURE

Glaucoma is the second leading cause of human blindness affecting as many as two million people in the United States (Rocha-Sousa et al., 2013; Toris, 2010; Weinreb, Aung, & Medeiros, 2014). Increased intraocular pressure (IOP) is the primary risk factor for developing glaucoma. Current medical intervention for glaucoma slows the progression of the disease by lowering the IOP (Rocha-Sousa et al., 2013; Toris, 2010; Weinreb et al., 2014).

IOP is determined by the rate of secretion of aqueous humor into the posterior chamber of the eye, and the rate of aqueous humor outflow (Rocha-Sousa et al., 2013; Toris, 2010; Weinreb et al., 2014). Aqueous humor is produced and secreted by nonpigmented epithelium of the ciliary body. Aqueous humor then flows from the posterior to the anterior chamber through the pupil, exiting the anterior chamber by the conventional or nonconventional pathways. In the conventional pathway, aqueous humor passes through the trabecular meshwork (TM) and exits into Schlemm's canal, where it eventually empties into veins under the conjunctiva. The nonconventional, uveoscleral pathway involves the diffusion of aqueous humor through intercellular spaces of the ciliary muscle fibers. All three aspects of aqueous humor dynamics, including secretion, conventional, and nonconventional outflow processes provide potential pharmacological targets for controlling IOP (Rocha-Sousa et al., 2013; Toris, 2010; Weinreb et al., 2014).

CURRENT TREATMENT OF GLAUCOMA

Glaucoma is clinically treated by surgical means or noninvasive pharmacotherapy (Rocha-Sousa et al., 2013; Toris, 2010; Weinreb et al., 2014). Surgical treatments reduce IOP by trabeculectomy which removes a section of the TM to facilitate draining of aqueous humor. Current pharmacotherapy of glaucoma is comprised of five categories of IOP-lowering drugs: β blockers, α agonists, cholinergic agonists, carbonic anhydrase inhibitors, and prostaglandin analogs. These treatments reduce IOP by decreasing the rate of aqueous humor production, or increasing the rate of aqueous humor outflow through the nonconventional, uveoscleral pathway (Rocha-Sousa et al., 2013; Toris, 2010; Weinreb et al., 2014).

The currently available IOP-lowering drugs are able to reduce IOP through varied mechanisms, but shortcomings still remain: suitable drugs that target the conventional, TM pathway to enhance the rate of outflow remain unavailable. In addition, currently available IOP-lowering drugs frequently result in undesirable side effects. This necessitates newer antiglaucoma drugs targeting the TM pathway, and with fewer side effects (Rocha-Sousa et al., 2013; Toris, 2010; Weinreb et al., 2014).

CANNABINOIDS AND INTRAOCULAR PRESSURE

Marijuana smoking was first reported to lower IOP by Hepler and Frank (1971). From then on, the IOP-lowering effects of many cannabinoids, including phytocannabinoids, synthetic cannabinoids, and endocannabinoids, have been explored.

Phytocannabinoids

Δ^9-Tetrahydrocannabinol

The most prominent phytocannabinoid is Δ^9-tetrahydrocannabinol (Δ^9-THC), well known for its psychoactive properties (Howlett et al., 2002; Pertwee, 1999; Pertwee et al., 2010). Δ^9-THC is a heterotricyclic compound found in marijuana that interacts with both CB1 and CB2 cannabinoid receptors. The following studies provide evidence of the abilities of Δ^9-THC to reduce IOP (Table 77.1).

HUMANS

Many human trials have been performed to examine the role of Δ^9-THC in reduction of IOP.

An early study of two humans receiving intravenous (i.v.) administration of Δ^9-THC showed a reduction in IOP (Purnell & Gregg, 1975).

Furthermore, in a study of 8 normotensive individuals, 8 hypotensive patients, and 16 patients diagnosed with open angle glaucoma, IOP was measured after inhalation of Δ^9-THC, and significant reduction of IOP was noted, lasting for 4 h (Crawford & Merritt, 1979).

In another study, nine glaucoma patients receiving current glaucoma treatment added a regimen of inhaled or oral tablet of Δ^9-THC. These patients achieved their goal reduction in IOP (Flach, 2002).

In a more recent study, utilizing six patients with open angle glaucoma, the effect of sublingual administration of Δ^9-THC was compared with that of a placebo. Δ^9-THC was shown to significantly reduce IOP in study participants, from an average of 27.3 to 23.5 mmHg (Tomida et al., 2006).

In another study, after an oral dose of Δ^9-THC, normotensive patients showed significant reductions in IOP, from 13.2 to 11.8 mmHg (Plange et al., 2007).

TABLE 77.1 Effect of Phytocannabinoids on Intraocular Pressure

Drug	Study	Species	Route of administration	Intraocular pressure change
Δ^9-THC	Purnell and Gregg (1975)	Human	Intravenous	Decrease
	Crawford and Merritt (1979)	Human	Inhalation	Decrease
	Flach (2002)	Human	Inhalation/oral	Decrease/decrease
	Tomida et al. (2006)	Human	Sublingual	Decrease
	Plange et al. (2007)	Human	Oral	Decrease
	Colasanti, Powell, and Craig (1984c)	Cat	Topical	Decrease
	Colasanti (1990)	Cat	Topical	Decrease
	Elsohly, Harland, Murphy, Wirth, and Waller (1981)	Rabbit	Intravenous	Decrease
	Green, Symonds, Oliver, and Elijah (1982)	Rabbit	Intravenous	Decrease
	Liu and Dacus (1987)	Rabbit	Cerebral bolus/intravenous	No change/decrease
	Szczesniak, Kelly, Whynot, Shek, and Hung (2006)	Rat	Intratracheal/intraperitoneal	Decrease/no change
	Crandall et al. (2007)	Rat	Intravenous	Decrease
	Fischer, Ward, and Hendrix (2013)	Dog	Topical	Decrease
	Green et al. (1982)	Monkey	Intravenous	No change
CBD	Elsohly et al. (1981)	Rabbit	Intravenous	No change
	Green et al. (1982)	Rabbit	Intravenous	No change
	Tomida et al. (2006)	Human	Sublingual	No change
	Colasanti, Brown, and Craig (1984a)	Cat	Topical	Decrease
Δ^8-THC	Elsohly et al. (1981)	Rabbit	Intravenous	Decrease
	Green et al. (1982)	Rabbit	Intravenous	No change
	Liu and Dacus (1987)	Rabbit	Intravenous	No change
	Muchtar, Almog, Torracca, Saettone, and Benita (1992)	Cat	Topical emulsion	Decrease
CBG	Green et al. (1982)	Rabbit	Intravenous	No change
	Green et al. (1982)	Monkey	Intravenous	No change
	Colasanti et al. (1984a)	Cat	Topical	Decrease
CBN	Elsohly et al. (1981)	Rabbit	Intravenous	Decrease
	Green et al. (1982)	Rabbit	Intravenous	Decrease
	Colasanti et al. (1984a)	Cat	Topical	Decrease

Δ^9-THC, Δ^9-Tetrahydrocannabinol; CBD, cannabidiol; Δ^8-THC, Δ^8-tetrahydrocannabinol; CBG, cannabigerol; CBN, cannabinol.

CATS

In cats, a comparison of acute delivery and chronic delivery of Δ^9-THC provided different outcomes. Acute delivery by ophthalmic drops to cat eyes provided little reduction in IOP, whereas chronic delivery resulted in significant reduction in IOP (Colasanti, 1990; Colasanti et al., 1984c). Δ^9-THC had no effect on the rate of formation of aqueous humor, but produced a two- to three-fold increase in aqueous outflow facility (Colasanti, 1990).

RABBITS

Several studies have shown that i.v. administration of Δ^9-THC reduces IOP in rabbits (Elsohly et al., 1981; Green et al., 1982; Liu & Dacus, 1987). However, direct perfusion of Δ^9-THC to albino rabbit cerebral ventricles did not change IOP, but intravenous injection did decrease IOP (Liu & Dacus, 1987). These data indicate that the IOP-lowering effects of Δ^9-THC do not originate in the central nervous system (CNS).

RATS

An intratracheal (i.t.) administration of a liposome-entrapped Δ^9-THC has been shown to reduce IOP in rats (Szczesniak et al., 2006). In another study, in a rat model of glaucoma, i.v. administration of Δ^9-THC led to a reduction of elevated IOP in operated eye, without affecting the contralateral control eyes (Crandall et al., 2007).

DOGS

Topical application of 2% Δ^9-THC ophthalmic solution resulted in moderate reduction of mean IOP in clinically normal dogs (Fischer et al., 2013).

MONKEYS

Intravenous administration of Δ^9-THC did not change IOP or total outflow facility in the rhesus monkey (Green et al., 1982). This indicates that the IOP-lowering effect of Δ^9-THC is species specific.

In summary, Δ^9-THC has been shown in several species to reduce IOP. However, species differences may account for the wide differences in drug efficacy. In addition, route of administration plays an important role in achieving IOP-lowering effects of Δ^9-THC.

Cannabidiol

Cannabidiol (CBD), a non-CB1/CB2 phytocannabinoid, has been studied for its ability to reduce IOP. Intravenous administration of CBD in normotensive rabbits was unable to reduce IOP (Elsohly et al., 1981; Green et al., 1982). Additionally, a comparison of the effects of CBD and Δ^9-THC sublingual application in humans with open angle glaucoma showed that CBD is unable to reduce IOP (Tomida et al., 2006). However, in another study, CBD delivered topically to cat eye had a hypotensive effect, without ocular toxicity or neurotoxicity (Colasanti et al., 1984a). Thus, CBD is able to reduce IOP in cats, but not in rabbits or humans.

Δ^8-Tetrahydrocannabinol Analog

Natural Δ^8-tetrahydrocannabinol (Δ^8-THC) also has affinities to cannabinoid receptors similar to those of Δ^9-THC, and behaves as partial agonist for CB1 receptors (Howlett et al., 2002; Pertwee, 1999; Pertwee et al., 2010). A study has demonstrated the ability of Δ^8-THC to reduce IOP by i.v. administration to rabbits (Elsohly et al., 1981). Additionally, another study has shown that administration of a submicron emulsion preparation of Δ^8-THC to normotensive rabbit eyes led to a decrease in IOP (Muchtar et al., 1992).

In contrast, two studies have failed to show the IOP-lowering effects of Δ^8-THC. Green et al. (1982) have shown that i.v. administration of Δ^8-THC to normotensive rabbits does not produce a reduction of IOP (Green et al., 1982). In addition, intravenous administration of Δ^8-THC did not reduce IOP (Liu & Dacus, 1987).

Cannabigerol

Cannabigerol (CBG) binds CB1 and CB2, but functions as a competitive antagonist for the CB1. This compound also functions as an agonist for the α2 adrenoceptor (Cascio, Gauson, Stevenson, Ross, & Pertwee, 2010). Green et al. (1982) showed that i.v. administration of CBG to normotensive rabbits or monkeys does not lower IOP. However, in a later study, topical administration of CBG to normotensive cats showed a reduction in IOP by 7 mmHg. This effect was sustained with chronic use, and with minor systemic side effects (Colasanti, Craig, & Allara, 1984b). The CBG-induced reduction of IOP was enhanced when given with Δ^9-THC, with little CNS side effects (Colasanti, 1990).

Cannabinol

Cannabinol (CBN) has greater affinity for CB2 than CB1 (Howlett et al., 2002; Pertwee, 1999; Pertwee et al., 2010). In rabbits, i.v. administration of CBN resulted in a reduction in IOP (Elsohly et al., 1981; Green et al., 1982). Further examination of topical CBN administration to cat eyes has been shown to reduce IOP, and the greatest reduction in pressure was noted with chronic daily administration (Colasanti, Craig, & Allara, 1984b).

Synthetic Cannabinoids

Classical

NABILONE

Oral administration of nabilone to glaucoma patients resulted in a reduction in IOP; in addition, topical administration of nabilone to normotensive rabbits resulted in a reduction in IOP (Newell, Stark, Jay, & Schanzlin, 1979; Table 77.2).

HU-211

HU-211 is the enantiomer of HU-210. HU-211 differs from other cannbinoids since it works through the NMDA receptor, and has low affinity for CB1/CB2 (Howlett et al., 2002; Pertwee, 1999; Pertwee et al., 2010). Topical application of an ophthalmic emulsion of HU-211 resulted in a reduction of IOP in normotensive rabbits, sustained for 6 h (Naveh et al., 2000). In another study, intravenous administration of HU-211 to rabbits resulted in a decrease in IOP without significant changes in blood pressure or heart rate (Beilin et al., 2000).

BW146Y

A final example of classical synthetic cannabinoid agonist is BW146Y. In a pilot study of ocular hypertensive patients, an oral dose of BW146Y was found to lower IOP without affecting the orthostatic blood pressure, or producing neurological side effects (Tiedeman et al., 1981).

TABLE 77.2 Effect of Synthetic Cannabinoids on Intraocular Pressure

Drug	Study	Species	Route of administration	Intraocular pressure change
CLASSICAL				
Nabilone	Newell et al. (1979)	Human	Oral	Decrease
	Newell et al. (1979)	Rabbit	Topical	Decrease
HU-211	Naveh, Weissman, Muchtar, Benita, and Mechoulam (2000)	Rabbit	Topical emulsion	Decrease
	Beilin, Neumann, Belkin, Green, and Bar-Ilan (2000)	Rabbit	Intravenous	Decrease
BW146Y	Tiedeman et al. (1981)	Human	Oral	Decrease
JWH-133	Laine, Jarvinen, and Jarvinen (2003)	Rabbit	Topical	No change
NONCLASSICAL BICYCLIC				
CP-55,940	Laine et al. (2003)	Rabbit	Topical	Decrease
	Pate, Jarvinen, Urtti, Mahadevan, and Jarvinen (1998)	Rabbit	Topical	Decrease
Abn-CBD	Szczesniak, Maor, Robertson, Hung, and Kelly (2011)	Rat	Intraperitoneal/topical	Decrease/decrease
AMINOALKYLINDOLE				
WIN55212-2	Hodges, Reggio, and Green (1997)	Rabbit	Intravenous	No change
	Song and Slowey (2000)	Rabbit	Topical	Decrease
	Porcella, Maxia, Gessa, and Pani (2001)	Human	Topical	Decrease
	Chien, Wang, Mittag, and Podos (2003)	Monkey	Topical	Decrease
	Hosseini et al. (2006)	Rat	Topical	Decrease
	Oltmanns et al. (2008)	Rat	Topical	Decrease

Abn-CBD, Abnormal cannabidiol.

Nonclassical

CP-55,940

Nonclassical, bicyclic cannabinoids are represented by the prototype compound, CP-55,940. This compound behaves as a full agonist for both CB1 and CB2 (Howlett et al., 2002; Pertwee, 1999; Pertwee et al., 2010). Topical application of aqueous solution of CP-55,940 to normotensive rabbits resulted in reduced IOP, in at least two studies (Laine et al., 2003; Pate et al., 1998).

ABNORMAL CANNABIDIOL

Abnormal cannabidiol (abn-CBD) is a synthetic regioisomer of cannabidiol. When abn-CBD was given by intraperitoneal injection or topically in rat, IOP was reduced (Szczesniak et al., 2011).

Aminoalkylindoles

WIN55212-2

RABBITS WIN55212-2 displays high affinity for both CB1 and CB2, with moderate selectivity for CB2, and exhibits high intrinsic activity at both CB1 and CB2 (Howlett et al., 2002; Pertwee, 1999; Pertwee et al., 2010). In an initial study, systemic intravenous administration of WIN55212-2 in normotensive rabbits resulted in no significant change in IOP (Hodges et al., 1997). However, in a later study, topical application of WIN55212-2 to rabbits significantly reduced IOP in treated eyes, in a dose-dependent manner (Song & Slowey, 2000). Thus, the route of administration in rabbit seems to be important for the ability of WIN55212-2 to reduce IOP.

HUMANS Topical application of WIN55212-2 decreased IOP in human glaucoma cases resistant to conventional therapies. This demonstrates the potential for WIN55212-2 for treating glaucoma patients who have exhausted other methods of treatment (Porcella et al., 2001).

MONKEYS Topical administration of WIN55121-2 reduced IOP in both normal and glaucomatous monkey eyes. The reduction in IOP was sustained for 5 days with daily administration of the WIN55212-2 compound (Chien et al., 2003).

RATS Topical application of WIN-55212-2 in rat also led to reduction in IOP. The reduction in IOP was noted without cardiovascular toxic effects (Hosseini et al., 2006; Oltmanns et al., 2008).

TABLE 77.3 Effect of Endocannabinoids, Enzyme Inhibitors, and Transport Inhibitors on Intraocular Pressure

Drug	Study	Species	Route of administration	Intraocular pressure change
ENDOCANNABINOID				
AEA	Pate et al. (1998)	Rabbit	Topical	Decrease
	Mikawa et al. (1997)	Rabbit	Topical	Decrease
	Pate et al. (1996)	Rabbit	Topical	Decrease

AEA, Arachidonylethanolamide; 2-AG, 2-arachidonylglycerol; PEA, palmitoylethanolamide; PMSF, phenylmethylsulfonyl fluoride.

Endocannabinoids

Arachidonylethanolamide

Arachidonylethanolamide (AEA) was the first compound to be identified as an endocannbinoid ligand, and behaves as a partial agonist at both CB1 and CB2 (Howlett et al., 2002; Pertwee, 1999; Pertwee et al., 2010). In several studies, topical administration of AEA in normotensive rabbits caused an IOP reduction in the treated eyes (Laine, Jarvinen, Pate, Urtti, & Jarvinen, 2002b; Mikawa et al., 1997; Pate, Jarvinen, Urtti, Jarho, & Jarvinen, 1995; Pate et al., 1996, 1998) (Table 77.3).

2-Arachidonylglycerol

2-Arachidonylglycerol (2-AG) is an endogenous cannabinoid agonist for both CB1 and CB2 (Howlett et al., 2002; Pertwee, 1999; Pertwee et al., 2010). Topical application of 2-AG in rabbits reduced IOP (Laine, Jarvinen, Mechoulam, Breuer, & Jarvinen, 2002a).

Palmitoylethanolamide

Palmitoylethanolamide (PEA) is an endogenous fatty acid amide related to AEA, and was found to reduce IOP, in recent clinical studies of glaucoma patients. Utilizing 42 glaucoma patients, oral administration of PEA resulted in a 3.2 mmHg drop in IOP. This drop was not accompanied by a change in heart rate or systemic side effects (Gagliano et al., 2011; Pescosolido et al., 2011).

MOLECULAR TARGETS FOR THE IOP-LOWERING EFFECTS OF CANNABINOIDS

To determine the involvements of molecular targets in the IOP-lowering effects of cannabinoids, several approaches have been used. For example, receptor involvement has been examined by using receptor selective antagonists. In addition, partial knockdown (through RNA interference) and total knockout of gene expression have been used to confirm the role of particular molecular targets in mediating the IOP-lowering effects of cannabinoids.

CB1

The expression of CB1 in the eye has been established in several studies. Initially, CB1 mRNA was detected in rat eyes, with the greatest concentration of mRNA found in the ciliary body, retina, and choroid (Porcella, Casellas, Gessa, & Pani, 1998). In a second study, using human eye tissues, immunohistochemistry staining for CB1 showed strong expression in the ciliary body and TM, with moderate signals within the ciliary muscle and vasculature (Straiker, Maguire, Mackie, & Lindsey, 1999). In addition, Stamer et al. (2001) confirmed the expression of both CB1 mRNA and proteins in the ciliary body and TM of human eye tissues.

The involvement of CB1 in the IOP-lowering effects of cannabinoids has been demonstrated using selective CB1 antagonist SR141716A, in combination with a variety of

nonselective CB1 agonists, including phytocannabinoid Δ^9-THC, nonclassical, bicyclic cannabinoid CP-55,940, aminoalkylindole prototypic ligand WIN55212-2, and endocannabinoids AEA and 2-AG.

Intertracheal (i.t.) administration of a liposome-entrapped Δ^9-THC led to a significant decrease in IOP. This decrease in IOP was blocked by pretreatment with CB1 antagonist SR 141716A (Szczesniak et al., 2006).

Topical administration of the nonclassical cannabinoid CP-55,940 caused a dose-dependent reduction in IOP in normotensive rabbits. Further experiments demonstrated that the reduction in IOP caused by CP-55,940 can be blocked by administration of CB1 antagonist SR 141716A (Laine et al., 2003; Pate et al., 1998).

In normotensive rabbits, topical application of WIN55212-2 significantly reduced IOP, and this reduction was partially blocked by SR141716A (Song & Slowey, 2000). In rats, similar findings were observed (Oltmanns et al., 2008).

Normotensive rabbits treated with AEA and 2-AG had reduced IOP, and AEA- or 2-AG-induced IOP reduction was blocked by CB1 antagonists SR141716A or AM251 (Laine et al., 2002a; Pate et al., 1998).

These studies have emphasized the prominent role of CB1 receptors involved in the regulation of IOP.

CB2

Because of low expression levels of CB2 in eye tissues, doubt initially arose regarding the role of CB2 in maintaining IOP (Porcella et al., 1998). However, more recent studies have established the presence of CB2 receptor in the eye. Using porcine eye tissues, immunohistochemistry staining showed the presence of CB2 in the TM. Furthermore, Western blot confirmed the expression of CB2 in cultured porcine TM cells (Zhong, Geng, Njie, Feng, & Song, 2005).

An initial study conducted by the Jarvinen group showed that topical application of the CB2 agonist JWH-133 to normotensive rabbits had no effect on IOP; they concluded that CB2 is not involved in regulating IOP (Laine et al., 2003). However, recent studies conducted in our lab have shown that CB2 plays an important role in regulating aqueous humor outflow. Stimulation of CB2 receptor by JWH015, a selective CB2 agonist, resulted in an enhancement of aqueous humor flow. The increase in aqueous humor flow was completely blocked by the pretreatment of CB2 antagonist, SR144528 (Zhong et al., 2005).

Further studies are needed to establish a clearer role for the CB2 receptor in regulating IOP.

Non-CB1/CB2 Cannabinoid Receptors/Targets

The presence of non-CB1/CB2 receptors/targets that interact with a variety of cannabinoids has been established recently (Pertwee et al., 2010). Additionally, several of these receptors/targets have been shown to be expressed in the eye. For example, using immunohistochemistry, GPR18 protein was detected prominently in the ciliary epithelium, corneal epithelium, and in the TM (Caldwell et al., 2013). In addition, using Western blot analysis, the presence of GPR55 and PPARα has been demonstrated in the porcine TM model (Kumar, Qiao, Kumar, & Song, 2012).

In an initial IOP study, systemic administration of a nonpsychotropic cannabinoid, abnormal cannabidiol (abn-CBD) decreased IOP in the normotensive Brown Norway rat eye, independent of CB1 or CB2 activation (Szczesniak et al., 2011). Further studies showed that topical administration of GPR18 ligands, abn-CBD and *n*-arachidonyl glycine, caused a reduction of IOP in normotensive mice. In addition, the IOP-lowering effects of abn-CBD and *n*-arachidonyl glycine are independent of CB1, CB2, and GPR55, because these two GPR18 ligands were able to lower IOP in mice whose CB1, CB2, or GPR55 were knocked out (Caldwell et al., 2013).

Furthermore, non-CB1/CB2 receptors have been shown to influence aqueous humor outflow in animal models. Treatment with abn-CBD resulted in a dose-dependent increase in aqueous humor outflow through the TM. This increase in outflow was lost with pretreatment of O-1918, a selective non-CB1/CB2 receptor antagonist. Pretreatment with CB1 antagonist SR141716A or the CB2 antagonist SR144528 had no effect on the increase in humoral outflow induced by abn-CBD (Qiao, Kumar, Kumar, & Song, 2012).

Additionally, PEA caused an enhancement of aqueous humor outflow in perfused porcine eye anterior segments. This PEA-induced increase in aqueous humor outflow was partially blocked when PPARα or GPR55 receptors were knocked down by introducing to the perfusion system small hairpin RNA (shRNA) against PPARα or GPR55 (Kumar et al., 2012).

Enzyme Inhibitors

Enzyme inhibition can be used to prolong the effects of endocannabinoids in the reduction of IOP. Enzyme inhibition works indirectly to regulate IOP: by inhibiting degradation enzymes, endocannabinoids are no longer degraded, and free to work on receptors.

Phenylmethylsulfonyl fluoride (PMSF) is a nonspecific inhibitor of fatty acid amide hydrolase (FAAH), which degrades AEA. When rabbits were pretreated with PMSF, researchers noted an immediate reduction in IOP, if AEA was also administered. In contrast, rabbits not treated with the enzyme inhibitor showed a biphasic response of initial increase in IOP, followed by a decrease in IOP (Laine et al., 2002b).

Using porcine TM tissues, studies conducted in our lab have shown that FAAH inhibitor URB597 inhibited the

degradation of AEA. Administration of URB597 in the porcine organ model prolonged the outflow-enhancing effects of AEA (Njie, Qiao, Xiao, Wang, & Song, 2008b).

Additionally, monoacylgylcerol lipase (MGL) inhibitor LY2183240 inhibited the breakdown of 2-AG. The outflow-enhancing effects of 2-AG was prolonged by the coadministration of LY2183240 (Njie, He, Qiao, & Song, 2008a).

Transporter Inhibitors

Transporters work to reuptake endocannabinoids after their release (Pazos, Nunez, Benito, Tolon, & Romero, 2005). By inhibiting the transporters, it is possible to potentiate the IOP-lowering effects of endocannabinoids.

For example, AEA transport inhibitors AM404 and olvanil, administered unilaterally onto rabbit eyes, dramatically reduced IOP in the eyes that received these ligands. Hence, this study demonstrated the role of transporter inhibitors in regulation of IOP (Laine et al., 2001).

Association of CB1 Receptor With β-Adrenergic Receptor

To determine which receptors are essential for IOP reduction, Hudson, Beazley, Szczesniak, Straiker, and Kelly (2011) administered β-adrenergic agonists, β-adrenergic antagonists, and cannabinoid agonists to knockout mice for three receptors: CB1, CB2, and β-adrenergic receptor (βAD). Reduction in IOP was noted in CB2 knockout mice, suggesting that ligand binding to CB2 was not essential for IOP reduction. However, administration of these ligands in either βAD or CB1 deficient mice led to no reduction in IOP. Further examination showed that desensitization of βAD or depletion of catecholamines prevented reduction in IOP. Finally, immunohistochemistry staining revealed colocalization of CB1 with adrenergic neurons. Taken together, these data imply that CB1 receptors associate with β-adrenergic to reduce IOP (Hudson et al., 2011).

CELLULAR MECHANISMS OF CANNABINOID-INDUCED REDUCTION OF IOP

There are three main mechanisms to decrease IOP: to decrease aqueous humor production in the ciliary epithelium, to increase aqueous humor outflow through the conventional, TM pathway, and to increase aqueous humor outflow by the nonconventional, uveoscleral pathway in the ciliary muscle. These three mechanisms are controlled by multiple signaling pathways which can be affected by cannabinoids.

Ciliary Epithelium

Aqueous humor is produced and secreted by the ciliary epithelium. Therefore, interactions between cannabinoids and the ciliary epithelium is a mechanism by which IOP can be controlled. Ciliary epithelium expresses high levels of CB1, as shown by immunohistochemistry (Straiker et al., 1999).

Morphological changes in the ciliary epithelium have been observed after exposure to marijuana. Specifically, monkey ciliary epithelium experienced swelling, followed by a reduction in IOP after intravitreal injection of soluble marijuana extracts (McDonald, Cheeks, Slagle, & Green, 1991).

Further mechanistic studies demonstrated that cannabinoid-induced IOP reduction may involve prostaglandins and metalloproteinase produced by nonpigmented ciliary epithelium. Treatment of human nonpigmented ciliary epithelium with R(+)-methanandamide, a CB1 agonist, resulted an increase in cyclooxygenase-2 (COX-2) mRNA expression. Increased COX-2 expression was followed by increased phosphorylation of p38 and p42/44 mitogen-activated protein kinase (MAPK), two key signaling molecules in metalloproteinase (MMP) regulation. Correspondingly, mRNA and protein expression of MMP-1, MMP-3, MMP-9, and tissue inhibitor of metalloproteinase 1 (TIMP-1) was increased; therefore a potential mechanism contributing to the IOP-lowering effects of cannabinoids may be the stimulation of COX-2 and MMP expression in nonpigmented ciliary epithelium (Rosch, Ramer, Brune, & Hinz, 2006).

Trabecular Meshwork

The TM is located at the base of the cornea, near the ciliary body. This tissue regulates the aqueous humor outflow in the anterior chamber. Within this tissue, there are a variety of receptors/targets for cannabinoid ligands, including the CB1, CB2, as well as non-CB1/CB2 cannabinoid receptors (Caldwell et al., 2013; Kumar et al., 2012; Qiao et al., 2012; Stamer et al., 2001; Straiker et al., 1999; Zhong et al., 2005). This section reviews the signaling pathways of these receptors in the TM, and their relevance to the regulation of aqueous humor outflow.

cAMP

Previously, it has been shown that cAMP is an important regulator of aqueous humor outflow through the TM pathway. Usually, CB1/CB2 receptors are G_i-protein receptors, and there is a decrease in cAMP when these receptors are activated. However, in TM cells, CP-55,940 has been shown to cause a two- to three-fold increase in cAMP, as a result of CB1 activation (Stamer et al., 2001).

Ions and Ion Channels

Relaxation of TM is thought to result in a reduction in IOP. Stimulation of human TM strips with CP-55,940 or WIN55212-2 caused a dose-dependent relaxation of TM that is blocked by AM251. In addition, cannabinoids opened high-conductance Ca(2+)-activated K(+) channels, and this effect may contribute to the relaxation of TM, thus modulating aqueous humor outflow (Stumpff et al., 2005).

Further studies showed the ability of cannabinoids to modulate intracellular calcium in TM. Stimulation of human TM cells with WIN55212-2 or CP-55,940 yielded an increase in intracellular Ca^{2+} release. However, the mechanism of Ca^{2+} release was ligand-dependent. WIN55212-2-induced increase in $[Ca^{2+}]_i$ was insensitive to PTX, and is therefore independent of $G_{i/o}$ coupling. In contrast, the $[Ca^{2+}]_i$ increase mediated by CP-55,940 was PTX-sensitive, indicative of CB1- $G_{i/o}$ coupling (McIntosh, Hudson, Yegorova, Jollimore, & Kelly, 2007).

P42/44 MAP Kinase

P42/44 MAP kinase is an important regulator of aqueous humor outflow through the TM pathway.

Various cannabinoid ligands have been shown to activate P42/44 MAP kinase in the TM. Furthermore, P42/44 MAP kinase has been shown to be important for the outflow-enhancing effects of a variety of cannabinoid agonists, including CB1 selective ligand Noladin ether, CB2 selective agonist JWH015, endocannabinoids AEA and 2-AG, and non-CB1/CB2 cannabinoid ligand abn-CBD and PEA (Kumar et al., 2012; McIntosh et al., 2007; Njie et al., 2008a,b; Qiao et al., 2012; Zhong et al., 2005).

Ciliary Muscle

Nonconventional, uveoscleral outflow pathway represents another mechanism that might mediate the IOP-lowering actions of cannabinoids. Immunohistochemstry experiments have demonstrated the presence of CB1 in the human ciliary muscle (Straiker et al., 1999). To our knowledge, there are no published studies on the effects of cannabinoids on the uveoscleral pathway. However, cannabinoids have been shown to cause ciliary muscle contraction, which may lead to an enhanced aqueous humor outflow through the conventional pathway.

Exposure of bovine ciliary muscle to CP-55,940 and AEA caused a dose-dependent contraction of ciliary muscle that is prevented by SR141716A. Further investigation showed that the CP55,940- and AEA-induced contraction is dependent on the $G_{i/o}$-protein, and phospholipase C (Lograno & Romano, 2004).

Stimulation of ciliary muscle by AEA in presence of muscarinic agonist carbachol increased contractility in a greater manner than AEA alone. This showed a possibility of using muscarinic agonists in concert with cannabinoids to reduce IOP (Romano & Lograno, 2013).

In conclusion, modulation of the ciliary muscle by cannabinoids maybe an important mechanism for the IOP-lowering effects.

PROBLEMS AND FUTURE DIRECTIONS

Problems

Cannabinoids represent a promising way of reducing IOP. However, as with all emerging therapeutics, cannabinoid treatment of ocular hypertension is associated with several problems that must be remedied.

First of all, administration of cannabinoids is associated with systemic side effects, such as psychoactivity and cardiovascular problems (Purnell & Gregg, 1975). These systemic side effects interfere with patient compliance (Flach, 2002). Systemic side effects can be minimized through effective ocular drug delivery.

A second problem is the short duration of action of cannabinoids. The duration of action for topical administration of Δ^9-THC in humans is 2–4 h before a return to hypertensive ocular pressure (Plange et al., 2007). This poses a treatment problem, as hypertensive conditions last for the full day.

Finding new, innovative ways to solve these problems is of utmost importance for treating ocular hypertension with cannabinoids.

Solutions and Future Directions

Non-CB1 Cannabinoid Ligands

Systemic side effects such as psychoactivity and cardiovascular problems can be remedied by utilizing cannabinoids that do not target the CB1. For example, topical administration of HU-211 in rabbit caused a reduction in IOP without the cardiac side effect of increased heart rate (Naveh et al., 2000). Unlike Δ^9-THC and HU-210, which act on the CB1 and CB2, HU-211 blocks the NMDA receptor (Pertwee et al., 2010). Therefore, HU-211 should not have the psychoactive and cardiac side effects mediated by the CB1.

Sustained Drug Delivery

Nanotechnology poses a possible way to overcome the short duration of action problem of cannabinoids. Nanomedicine utilizes particles that are between 1 and 100 nm in size, and exhibit distinct physical properties. Because of these properties, nanoparticles are able to protect and transport complex molecules, and prevent degradation. Nanoparticles can be composed of many types of materials and forms, including liposomes, hydrogels, and dendrimers. These higher order structures

tightly regulate drug delivery, and allow for target delivery of therapy to desired tissues.

Nanotechnology has been illustrated to improve the delivery of glaucoma treatments. For example, a study has been conducted in rabbits using uniform Egg-phosphatidylcholine (EggPC) liposomes loaded with latanoprost for ocular delivery. These liposomes loaded with latanoprost were found to be stable, and a single injection to rabbit eye lowered IOP for at least 90 days. Therefore, nanoparticles can be potentially used to deliver cannabinoids directly to targets, and to not only reduce systemic side effects, but also increase efficacy and durations of actions (Kim et al., 2014).

In summary, future directions for lowering IOP with cannabinoids include non-CB1 ligands, and sustained drug delivery.

MINI-DICTIONARY

Aqueous humor A gelatinous fluid that provides nutrients for avascular tissues in the eye. Secretion and outflow of aqueous humor regulate intraocular pressure.
Ciliary epithelium Located in the posterior chamber of the eye. Generates and secretes aqueous humor.
Ciliary muscle Composed of smooth muscle, it is part of the uveoscleral pathway.
Conventional outflow pathway Aqueous humor flows through the trabecular meshwork, and then empties into Schlemm's canal.
Glaucoma An eye disease begins with peripheral vision loss, and eventually total vision loss. Risk factors include genetic predisposition and elevated intraocular pressure.
Intraocular pressure The pressure within the eye. Many antiglaucoma medications work to lower intraocular pressure.
Nonconventional/uveoscleral outflow pathway Aqueous humor flows through the ciliary muscle and passes over the suprachoroidal space, then exiting through the sclera.
Ocular hypertension A condition in which the intraocular pressure is higher than normal. It is one of the most important risk factors for glaucoma.
Trabecular meshwork Located in the anterior portion of the eye, it is a component of the conventional outflow pathway.

***Department of Pharmaceutics and Drug Delivery, School of Pharmacy, University of Mississippi, Oxford, MS, United States**

****ElSohly Laboratories Inc., Oxford, MS, United States**

SUMMARY POINTS

- This chapter focuses on ocular drug delivery of tetrahydrocannabinol (THC).
- THC is a key constituent of the cannabis plant, and has been shown to have beneficial effects in glaucoma and other ocular disorders.
- Numerous studies have shown that THC reduces intraocular pressure (IOP) in glaucoma, and also has neuroprotective actions.
- Ocular delivery of THC encounters several challenges: those associated with anatomical and physiological barriers of the eye, and also the physicochemical properties of THC such as solubility, lipophilicity, and stability.
- Various approaches to improve the physicochemical characteristics, and hence ocular delivery, are being explored.

KEY FACTS OF GLAUCOMA

- Glaucoma, a leading cause of irreversible blindness worldwide, characterized by damage to the optic nerve leading to blindness, manifests as rise in intraocular pressure (IOP).
- Though the exact cause is not known, elevated IOP for a prolonged period is suggested to be a risk factor behind optic nerve damage and vision loss.
- Glaucoma is categorized into open angle glaucoma and closed angle glaucoma, depending on the iridocorneal angle.
- Open angle glaucoma is mostly asymptomatic, progresses slowly, with gradual damage to the optic nerve, and, if undetected, it leads to irreversible blindness which continues even if the intraocular pressure is normal with conventional glaucoma drugs; meanwhile, closed angle glaucoma develops rapidly and produces symptoms such as eye pain and, if untreated, results in irreversible blindness.
- Current treatment is based on reducing the elevated intraocular pressure by either increasing the aqueous humor outflow, via trabecular and uveoscleral outflow and/or by decreasing the production of aqueous humor.

KEY FACTS OF PRODRUGS

- Prodrugs are inactive, bioreversible derivatives of active drug molecules that, upon enzymatic and/or chemical modifications, release the active parent drug in the body, which exhibits pharmacological effect in the target organ/tissue.
- It is estimated that, currently, about 10% of worldwide marketed drugs can be classified as prodrugs.
- The basic aim of designing a prodrug is to mask the undesirable properties of the parent drugs molecule, such as poor solubility, poor bioavailability, due to poor physical, chemical or biological stability, low target selectivity, undesirable taste, or pain/local irritation on administration, presystemic metabolism, etc.
- Esters are the most commonly employed prodrugs, as numerous catalytic esterases are present in the body,

and actively hydrolyze simple esters to the respective active parent molecules.
- With species variation, there exists a difference in the amounts and types of enzymes (esterases) which results in varied substrate specificities and rates of hydrolysis, which generates a lot of variations in preclinical animal model studies and clinical studies.

LIST OF ABBREVIATIONS

BRB	Blood retinal barrier
CB1	Cannabinoid receptor 1
CB2	Cannabinoid receptor 2
CBD	Cannabidiol
CNS	Central nervous system
EDTA	Ethylenediaminetetraacetic acid
HPMC	Hydroxypropyl methylcellulose
IOP	Intraocular pressure
LMO	Light mineral oil
mm	Millimeter
NMDA	*N*-methyl-D-aspartate receptor
PEG	Polyethylene glycol
RGC	Retinal ganglion cell
Δ^8-THC	Δ^8-Tetrahydrocannabinol
THC	Δ^9-Tetrahydrocannabinol
THC-HS	Δ^9-Tetrahydrocannabinol hemisuccinate
THC-HG	Δ^9-Tetrahydrocannabinol hemiglutarate
VEGF	Vascular endothelial growth factor

INTRODUCTION

Schlicker, Timm, and Gothert (1996) discovered the existence of cannabinoid (CB) receptors in the ocular tissues, stimulating investigations into the role of these receptors in the eye. Straiker, Maguire, Mackie, and Lindsey (1999) observed that CB1 receptors are more prevalent in the human ciliary epithelium, corneal epithelium, and endothelium, trabecular meshwork, Schlemm's canal, ciliary muscle, and ciliary blood vessels. The human retina was also found to express CB1 receptors (Straiker et al., 1999).

Unlike CB1 receptors, CB2 receptor mRNA has been reported to be undetectable in the human retina (Porcella, Maxia, Gessa, & Pani, 2000), although its expression in the rat retina has been demonstrated (Lu, Straiker, & Maguire, 2000). The trabecular meshwork cells have also been shown to have functional CB2 receptors (He and Song, 2007).

The localized distribution of cannabinoid receptors in the eye strongly suggests the influence of endogenous cannabinoids on aqueous humor formation, and trabecular and uveoscleral outflow. CB1 and CB2 receptors are also thought to play an important role in visual function, and in protection against glutamate toxicity in glaucoma (Lu et al., 2000).

THERAPEUTIC POTENTIAL OF THE CANNABINOIDS IN OCULAR DISORDERS

In view of their broad spectrum of biological activity, cannabinoids hold tremendous therapeutic potential in various ocular diseases. The following sections discuss the potential utility of the cannabinoids in the management and treatment of various ocular disorders.

Glaucoma

Lowering of Intraocular Pressure

Glaucoma is defined as an ocular neuropathy with progressive and irreversible loss of vision, and is the second largest cause of blindness worldwide (Cook & Foster, 2012). Elevated IOP has been identified as an important risk factor in the pathogenesis of the disease which leads to degeneration of retinal ganglion cell (RGC) axons. Current therapy targets a reduction in IOP to prevent progression of the disease.

Following the initial observation that marijuana smoking reduced IOP (Hepler & Frank, 1971), multiple studies confirmed the IOP-lowering properties of cannabinoids (Pertwee, 1999). Initially, it was assumed that the effect of the cannabinoids was mediated through the central nervous system (CNS). Several studies, however, presented strong evidence that the IOP lowering is not only via CNS, but could also be associated with CB receptors in the eye (Colasanti, Craig, & Allara, 1984a). In one study it was observed that the IOP lowering effect of the cannabinoids was not related to arterial blood pressure reduction (Green, 1979), a sign of lack of CNS involvement. In another study, Δ^9-tetrahydrocannabinol (THC) reduced ciliary processes, and dilated the ocular blood vessels via adrenergic mechanism (Green & Pederson, 1973). A calcium channel influx inhibition was also observed to reduce norepinephrine release in the ciliary bodies, thus reducing aqueous humor production (Sugrue, 1997). A vasodilatory action of cannabinoids on the ocular blood vessels has also been reported (Porcella, Casellas, Gessa, & Pani, 1998), predominantly in anterior uvea, thus improving the aqueous humor uveoscleral outflow. A prostaglandin-mediated pathway has also been suggested (Green, Kearse, & McIntyre, 2001). Thus, it appears that the cannabinoids can potentially lower IOP through multiple mechanisms which could set it apart from the currently available antiglaucoma medicaments.

Retinal Neuroprotection

RGC cell death as a result of glaucoma-mediated apoptosis is the major implication of elevated IOP for prolonged periods of time (Weinreb & Levin, 1999). *N*-methyl-D-aspartate (NMDA) receptor activation appears to be one of the several pathways that result in apoptotic cell death. Activation of NMDA receptors increases the influx of calcium into the cells, resulting in the generation of free radicals. Recent studies have reported the neuroprotective properties of cannabinoids. THC, the major component of marijuana, inhibits the release of glutamic acid by increasing potassium and decreasing calcium permeability, while HU-211 (a synthetic cannabinoid) inhibits glutamate (NMDA) receptors (Howlett et al., 2002; Jin, Mao, Goldsmith, & Greenberg, 2000) through their action on CB1 presynaptic receptors. In an optic nerve axotomy study, wherein calibrated crush injury was induced in rats, HU-211 administered intraperitoneally showed neuroprotective actions (Yoles, Belkin, & Schwartz, 1996). Cannabinoids such as THC, HU-211, and cannabidiol (CBD), also demonstrated antioxidant properties that are not mediated by CB1 receptors suggesting free radical scavenging activity of the cannabinoids (Marsicano, Moosmann, Hermann, Lutz, & Behl, 2002).

Cannabinoids have also been reported to possess vasorelaxant activity, increasing the blood flow to the ocular tissues. An endogenous cannabinoid, 2-arachidonoylglycerol, was shown to reduce endothalin-1 induced calcium mobilization, thereby preventing vasoconstriction of human brain capillaries or microvessels (Chen et al., 2000). Endothalin-1 synthesized by vascular endothelial cells plays a critical role in the regulation of blood circulation in ocular tissues by inducing vasoconstriction, and this effect is suggested to be involved in RGC death in glaucoma (Gray, Battistini, & Webb, 2000; Haefliger, Meyer, Flammer, & Luscher, 1994). Considering that the cannabinoids act primarily through the CB receptors, and that these receptors are present in various ocular tissues, including the retina (Straiker et al., 1999), the cannabinoids may be very useful in the management of glaucoma and glaucoma-mediated neuropathy.

Ocular Tumors

The use of cannabinoids as a neoplastic agent was reported in 1975 (Munson, Harris, Friedman, Dewey, & Carchman, 1975), wherein oral administration of THC, Δ^8-THC, and cannabinol inhibited the growth of Lewis lung adenocarcinoma cells in vitro and in vivo. Since then, antiproliferative, antimetastatic, antiangiogenic, and proapoptotic effects of the cannabinoinds have been reported in various cancer types (Galve-Roperh et al., 2000).

A nonselective CB receptor agonist, WIN 55,212-2, exhibited antineoplastic activity in several cell lines (Blazquez et al., 2006; Ellert-Miklaszewska, Kaminska, & Konarska, 2005; McAllister et al., 2005; Sarfaraz, Afaq, Adhami, & Mukhtar, 2005). Studies with WIN-55,212-2, HU-210, JWH-133, and THC have also been reported to induce vascular endothelial cell apoptosis, inhibit their migration, and inhibit the expression of the proangiogenic factors VEGF and Ang2 (Casanova et al., 2003). CB1/CB2 receptor activation is also reported to block matrix methalloproteinase-2 (Blazquez et al., 2003). JWH-133 administration to C6 glioma-bearing mice altered the expression of 10 genes, all of which were directly or indirectly related to VEGF pathway (Blazquez et al., 2004). One of the mechanisms by which cannabinoids act as an antiangiogenic agent is through the inhibition of the p21ras pathway (Portella et al., 2003).

Although not yet indicated for the treatment of cancer, pharmacological targeting of the endocannabinoid system is emerging as a promising new approach for slowing the progression of cancer (Pacher & Kunos, 2013). In particular, combination therapy utilizing both traditional chemotherapeutics and molecules targeting the endocannabinoid system may be an excellent next generation treatment for cancer. The potential anticancer activity of the cannabinoids can find wide application in the treatment of retinoblastoma, and other ocular tumors.

Ocular Pain and Inflammation
