Pain management by cannabinoids is through (1) direct action of cannabinoids on cannabinoid receptors, (2) inhibition of enzymes, such as fatty acid amide hydrolase and monoacyl glycerol lipases that degrade endocannabinoids (Di Marzo, 2008), and (3) antinociceptive properties of cannabinoids (Pertwee et al., 2000). The cannabinoid combination containing THC and cannabidiol (CBD) is reported to reduce pain characterized by allodynia, in patients suffering from pain of neurological origin often refractory to other treatments (Nurmikko et al., 2007). Studies with WIN-55,212-2, CP-55,940, and HU-210 have been shown to suppress neuropathic pain in the chronic constriction injury model (partial sciatic ligation model), primarily via CB1 receptor-mediated mechanisms, and produced a reversal of mechanical hyperalgesia upon subcutaneous administration (Fox et al., 2001).

Thus, the cannabinoids present a wealth of untapped potential in the management of ocular pain, such as in glaucoma, corneal and uveal tract infections, inflammation, and the localized management of injury-related pain.

OCULAR DELIVERY OF TETRAHYDROCANNABINOL

In the past, various routes of cannabinoid administration have been explored to study the effect of these agents on IOP. These routes include inhalation (Merritt, Crawford, Alexander, Anduze, & Gelbart, 1980), oral (Merritt, McKinnon, Armstrong, Hatem, & Reid, 1980), and intravenous administration (Green, Symonds, Oliver, & Elijah, 1982). Although some of these studies ratified the IOP lowering properties of the cannabinoids, the systemic side effects observed far outweighed their benefits in the management of ocular conditions. Thus, topical administration of the cannabinoids is the most logical delivery route for ocular diseases.

Challenges in Ocular Delivery of Cannabinoids Through the Topical Route

Topical delivery to the deeper ocular tissues is, however, a very challenging task. The complicated anatomy of the eye poses a major barrier for the topically administered drug/drug candidates, and requires that the therapeutic agent possess favorable physicochemical characteristics for ocular absorption to occur. Some of these challenges are briefly described later in the chapter (Table 78.1).

Physiological Factors

The structure of the eye is illustrated in Fig. 78.1. Physiological barriers include both static, such as different layers of cornea, sclera, and retina, as well as dynamic barriers, such as choroidal and conjunctival blood flow, lymphatic clearance, and tear dilution. Drug absorption into the deeper ocular tissues from the ocular surface may involve corneal or noncorneal pathways.

Cornea is the primary absorption restricting membrane in the corneal pathway. It is composed of a lipophilic epithelium, hydrophilic stroma, and lipophilic endothelium and, thus, poses a major barrier for both lipophilic and hydrophilic molecules. Tight junctions (zonula occludens) seal off the gap between the cells, and block the paracellular penetration of the hydrophilic and lipophilic molecules into the deeper ocular tissues (Majumdar & Srirangam, 2010).

The noncorneal route of absorption mainly involves diffusion across the conjunctiva and sclera (Mizuno et al., 2009). The vascular and lymphatic drainage mechanisms in the conjunctiva, sclera, choroid, and retina, however, rapidly clear the topically administered agents

TABLE 78.1 Physicochemical Properties and Chemical Structures of (A) Tetrahydrocannabinol, (B) Tetrahydrocannabinol Hemisuccinate, and (C) Tetrahydrocannabinol Hemiglutarate

Properties	THC	THC-HS	THC-HG
Polar surface area	29.46	72.83	72.3
Hydrogen bond donor	1	1	1
Hydrogen bond acceptor	2	5	5
Rotatable bonds	4	8	10
$logD_{7.4}$	7.07	2.7	4.66
logP	—	3.3	7.77
pKa	9.6	4.25	4.6
Structure			
THC, Tetrahydrocannabinol; THC-HS, tetrahydrocannabinol hemisuccinate; THC-HG, tetrahydrocannabinol hemiglutarate. The physicochemical properties of THC, THC-HS, and THC-HG are shown in the table (calculated using ACD/I-Lab 2.0, Advanced Chemistry Development, Inc., Toronto, ON, Canada, 2014). Compared to THC, both THC-HS and THC-HG are more hydrophilic (increased polar surface area, and lower $logD_{7.4}$ compared to THC).

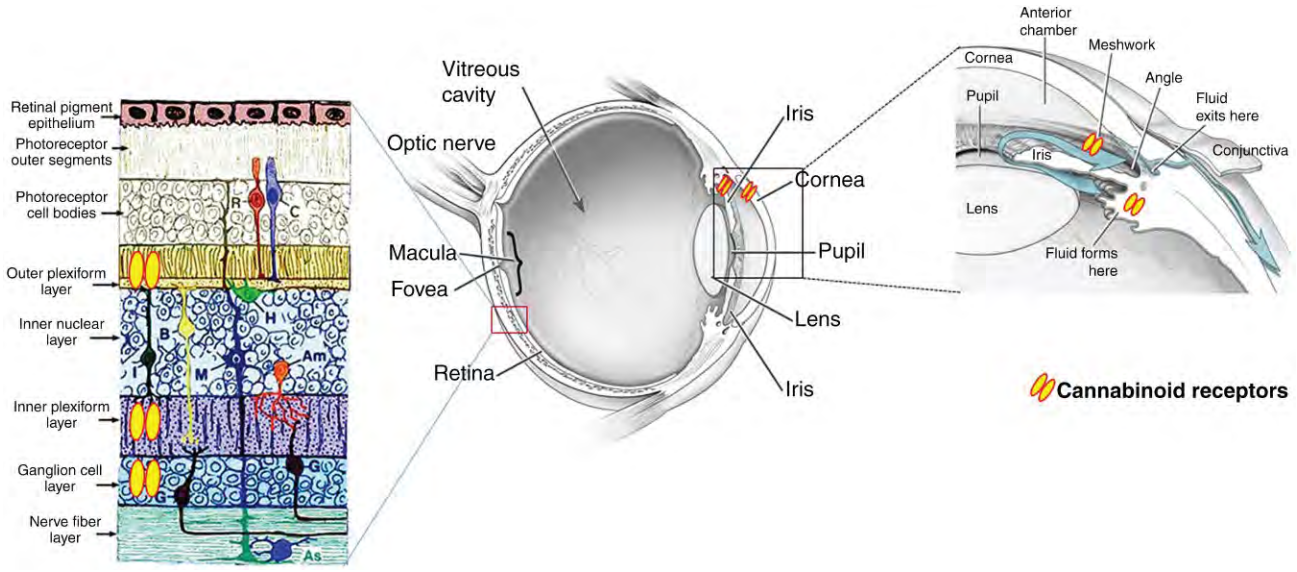

FIGURE 78.1 Structure of the human eye depicting the localization of cannabinoid receptors in various ocular tissues. Anatomical features of the eye, depicting localization of cannabinoid receptor in the cornea, ciliary body, and layers of retina. McDonnell, J. M. (1989). Basic Science and Inherited Retinal Disease. T. E. Ogden. 1, 8. The key target site for tetrahydrocannabinol (THC) action are cannabinoid receptors, localized predominately in the cornea (corneal epithelium and endothelium), ciliary body (ciliary muscle, nonpigmented ciliary epithelium, trabecular meshwork, and ciliary body), and cornea (outer plexiform layer, inner plexiform layer, and ganglionic cell layer). *Source: Straiker et al. (1999). The figure is adapted from NEI/NIH, and modified to show the localization of cannabinoid receptors.*

into the systemic circulation. Furthermore, the outer blood-retinal barrier (BRB)—the retinal pigmented epithelium (RPE)—presents a formidable diffusion barrier in the transscleral pathway, for lipophilic, as well as hydrophilic moieties.

Additionally, various transport systems expressed on biological membranes may modulate ocular absorption. While influx transporters expressed on the corneal, conjunctival, and retinal epithelial cells may aid in the absorption of topically administered substrates, efflux transporters such as P-glycoprotein and multidrug resistance proteins expressed on the corneal, RPE, and conjunctival membranes can restrict transmembrane diffusion of their substrates (Hippalgaonkar, Srirangam, Avula, Khan, & Majumdar, 2010).

Considering the various challenges to ocular absorption of topically administered agents, it is not surprising that, generally, less than 10% of the topically instilled formulation reaches the deeper ocular tissues (Geroski & Edelhauser, 2000). The multiple barriers in the ocular drug absorption pathway from the ocular surface have been illustrated in Fig. 78.2.

Physicochemical Characteristics

Permeation of molecules across biological membranes can take place either through the transcellular or paracellular pathway. Most lipophilic molecules primarily penetrate biological membranes via the transcellular pathway, while the paracellular route is preferred by most hydrophilic molecules (Borchardt, 1990).

There are several factors that affect the permeability of molecules across biological membranes such as the cornea and the conjunctiva. Partition coefficient or logP, aqueous solubility, molecular size, charge and degree of ionization, polar surface area, hydrogen bond acceptors and donors, and stereochemical configuration are some of the critical factors that affect transmembrane passive diffusion (Over et al., 2014).

Effectiveness of Topical THC in Lowering Intraocular Pressure

Green, Bigger, Kim, and Bowman (1977) dissolved 0.1 %w/v THC in four different vehicles: light mineral oil (LMO), mineral oil, sesame oil, and saline (90%)–Tween 80 (10%) combination). Clinically normotensive albino rabbits received 50 µL twice a day, in a 9-day study, and once a week in a 60-day study. The IOP dropped by 20% in all cases. The THC in LMO formulation produced an aqueous humor concentration of 0.05 µg/mL, 1-h post topical application.

Merritt, Olsen, Armstrong, and McKinnon (1981) reported that topical application of 50 µL of THC (0.1 %w/v, 50 µg dose) in mineral oil showed a 5.4 ± 2.6 mm drop in test, and 5.2 ± 2.8 mm drop in contralateral eye, in adult hypertensive human subjects, accompanied by a 12 mm

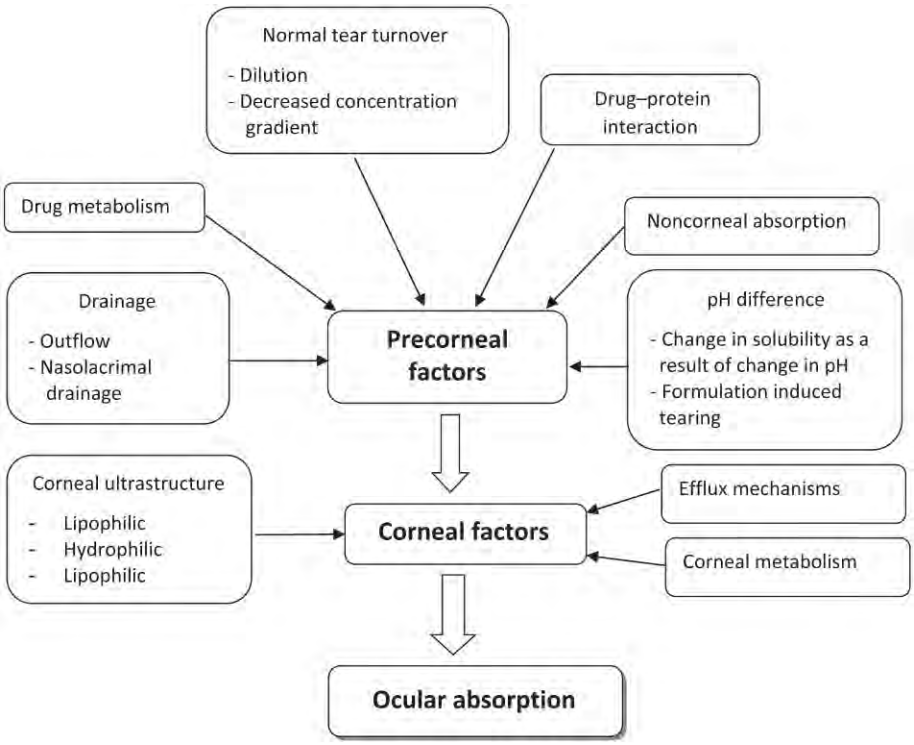

FIGURE 78.2 Illustration depicting the various barriers affecting ocular absorption via the corneal pathway. The illustration depicts the precorneal and corneal barriers that restrict drug availability at the ocular surface, and also limit transcorneal absorption. Considering the multiple barriers involved, less than 10% of the topically administered therapeutic agent generally reaches the deeper ocular tissues (Geroski & Edelhauser, 2000).

drop of systolic blood pressure. With THC in mineral oil (0.05 %w/v), IOP reduced by 4.8 ± 2.8 mm in test eye, and 6.8 ± 2.5 mm in fellow eye from baseline, and did not show any systemic effect. Considering the drop in systolic blood pressure and IOP in the contralateral eye, Merritt et al. (1981) suggested that the IOP lowering effect of THC is through the systemic route, rather than a local mechanism. In yet another study, Green et al. evaluated the IOP lowering efficacy of a single drop of THC in LMO (0.1 %w/v) in normal human volunteers. In this study, a decrease in IOP was not observed (Green & Roth, 1982). In a multidose study, THC in LMO (1 %w/v) was administered four times a day for 1 week, in 28 male human subjects (Jay & Green, 1983). THC did not show any drop in the IOP, compared to the control. A few other reports (Elsohly, Harland, Murphy, Wirth, & Waller, 1981) also reported failure of topical THC to decrease IOP in the rabbit model.

Colasanti, Powell, and Craig (1984b) studied the effect of THC in normotensive cats after a single drop administration, and a chronic study of 9 days. In acute studies, IOP was measured for 6 h after administration of a single drop of THC in light paraffin oil (dose: 1 mg). A minimal drop (approximately 2 mm of Hg) in IOP was observed after a single dose administration (Colasanti et al., 1984b). In the chronic study, a subcutaneous cannula with a mini pump was implanted and delivered 20 µg/h of THC (dissolved in PEG) over a period of 9 days. A drop of 4–7 mm of Hg was observed over a period of 9 days of chronic unilateral delivery of THC.

Some other studies also confirmed the IOP lowering activity of THC. Muchtar, Almog, Torracca, Saettone, and Benita (1992) reported that a Δ^8-THC (0.4 %w/v) in a submicron emulsion formulation produced intense and long lasting reduction in IOP, in an alpha-chymotrypsin induced rabbit model of ocular hypertension. In a more recent randomized longitudinal crossover design study, Fischer, Ward, and Hendrix (2013) reported that 50 µL of THC in olive oil formulation (2 %w/v, dose: 1 mg) showed a drop in ocular pressure in eight clinically normal dogs. Mean IOP drop from baseline in the treated eyes was observed to be 21% in the morning and 15% in the evening sessions.

From the previous discussion, it is apparent that the IOP lowering efficacy of THC from topical ophthalmic formulations is erratic (wide variation in dose-effect) and inconsistent, within and across animal models. In fact, based on the earlier data, a study panel constituted by the National Eye Institute of the National Institutes of Health had concluded that there was insufficient evidence to conclude that THC could be useful in the treatment of glaucoma (NIH, 1981).

Approaches to Improve Ocular Bioavailability of THC Through the Topical Route

Tetrahydrocannabinol has a logP of 6.3, a total number of hydrogen bond donors and acceptors of 3, a polar surface area of 29.46, and a pH independent aqueous solubility of only 1–2 μg/mL. Moreover, stability of THC in aqueous solutions is very low. In view of these unfavorable membrane permeability characteristics, it would be expected that THC would be inefficient in crossing the ocular membranes, and would rather accumulate in the epithelial membranes of the cornea and conjunctiva. In fact, a lipophilic vehicle, as used in most of the earlier pharmacological studies conducted by various researchers, would further hamper partitioning into the ocular tissues. This conclusion is supported by a report from Kearse and Green (2000) wherein in vitro transcorneal permeability of THC from a LMO vehicle was observed to be only 0.18 x 10^{-9} cm/s, which is extremely low.

In vivo ocular tissue distribution of THC using LMO and emulsion-based formulations was investigated in New Zealand white rabbits. At the end of 1-h post topical administration, THC concentrations were found to be below the limit of detection in all ocular tissues tested, except for the cornea and sclera, from both formulations (Hingorani et al., 2013). The data underscores the ocular bioavailability issues encountered with topical THC delivery.

An ophthalmic formulation designed to increase aqueous solubility, retention at the ocular surface, and transcorneal permeability could improve ocular THC concentrations. Based on the in vitro permeability data obtained with various formulations, a THC (0.13 %w/v) formulation containing Cremophor RH 40, ethylenediaminetetraacetic acid (EDTA), benzalkonium chloride, and hydroxypropyl methyl cellulose (HPMC) was tested in vivo (Hingorani et al., 2013). Ocular tissue concentration 1-h post topical administration in rabbits was determined. Except for the cornea and sclera, THC levels were again not observed in any of the ocular tissues (Table 78.2). THC concentrations in the cornea and sclera, however, were much higher in comparison to the LMO and emulsion formulations tested earlier (Hingorani et al., 2013), suggesting that THC partitioned into the ocular tissues from an aqueous formulation better than from an oily vehicle.

Considering that the oil based formulations, used in the earlier studies, were able to deliver very low concentrations of THC to the iris-ciliary bodies and the retina, it is not surprising that in many of these studies topical THC administration did not result in a drop in IOP. Moreover, the high lipophilicity of THC results in its getting trapped in the lipophilic layers of the eye (cornea and sclera). For THC to be successfully employed in the control of IOP, approaches to improve its physicochemical characteristics, so as to improve transmembrane permeability, is needed.

TABLE 78.2 Total Tetrahydrocannabinol Concentrations Observed in Rabbit Ocular Tissues 1-h Post Topical Administration in Light Mineral Oil, Emulsion, or Cremophor Micellar Solutions

Tissue	THC		
	Light mineral oil	Emulsion	0.5% Cremophor RH 40 + 0.1% EDTA + 0.02% BAK + 0.5% HPMC
Drug concentration in terms of THC (% w/v)	0.1	0.37	0.125
Cornea (ng/50 mg tissue)	68.8 ± 14.5	300.6 ± 79.6	553.9 ± 87.4
Aqueous tumor (ng/100 μL)	ND*	ND*	ND*
Iris-ciliary bodies (ng/50 mg tissue)	ND*	ND*	ND*
Vitreous humor (ng/mL)	ND*	ND*	ND*
Retina-choroid (ng/50 mg tissue)	ND*	ND*	ND*
Sclera (ng/250 mg tissue)	104.1 ± 36.1	171.1 ± 66.6	439.3 ± 280.2

ND*, Drug concentration below detection limit. THC levels observed in the cornea and sclera following topical application of all three formulations. However, THC was not detectable in the aqueous humor and the iris-ciliary bodies. The micellar formulations, however, produced significantly higher THC concentrations in the cornea and sclera.
Data are from Hingorani et al. (2013), with permission from the publishers.

Hydrophilic Prodrug Derivatization

Chemical modification of drugs/drug candidates into prodrugs has become an important technique to overcome poor transmembrane permeability of actives. A significant positive aspect of the prodrug approach is that it does not induce any change in the membrane structure, fluidity, or characteristics. The synthesis and development of ganciclovir and acyclovir acyl ester prodrugs to enhance partitioning into the ocular tissues has been previously demonstrated (Hughes & Mitra, 1993; Majumdar, Kansara, & Mitra, 2006). Several other studies have also reported enhanced permeability using a prodrug approach (Majumdar & Mitra, 2006). These reports strongly suggest that a prodrug approach to improve the hydrophilicity of THC can be useful in delivering THC into the deeper ocular tissues.

Two dicarboxylic acid ester prodrugs of THC, THC-hemisuccinate (THC-HS) and THC-hemiglutarate (THC-HG), have been investigated for ocular delivery through the topical route. THC-HS has a logP of 3.3, and pKa of 4.25. However, it demonstrated very poor stability in aqueous solutions. THC-HG ($logD_{7.4}$: 4.66, and polar surface area: 72.3) on the other hand was more stable than THC-HS, and 1.5–2-fold more soluble. To improve the solubility of these prodrugs further, an ion-pair complex formation strategy with L-arginine (ARG) and tromethamine (TRIS), was explored. Solubility of THC-HG increased with increasing concentrations of ARG or TRIS. Surfactants were also tested, and Cremophor RH 40 was observed to be the best solubilizer (Hingorani et al., 2013).

In vitro transcorneal permeability studies revealed that both THC-HS and THC-HG demonstrated pH dependent permeability. At lower pH (5.0), both prodrugs were sixfold more permeable than THC, while at physiological pH (7.4), the permeability of the prodrugs decreased threefold by shielding the negative charge at physiological pH. The counter ions ARG and TRIS significantly improved the transcorneal permeability of the prodrugs (Hingorani, Gul, Elsohly, Repka, & Majumdar, 2011).

Ocular tissue distribution of topical THC-HG was evaluated in vivo in anesthetized rabbits. Surfactant and ion-pair formulations were both tested. THC-HG produced markedly higher total THC concentrations in the ocular tissues compared to THC, 1-h post topical application of the formulations. Among the two formulations tested, the ion-pair formulation appeared to be slightly better than the surfactant formulation (Table 78.3), and maintained significant THC concentrations in the ocular tissues, even after 3-h post topical application. In all cases, THC levels were below detection limits in the vitreous humor and retina-choroid (Hingorani et al., 2011).

Future Directions for Topical THC Delivery for Ocular Diseases

A combination of prodrug design and formulation strategies has significantly improved THC delivery to the anterior segment tissues. This will positively impact therapeutic outcomes in many of the indications associated with the front-of-the eye. THC, however, could still not penetrate into the posterior segment ocular tissues, such as the retina and posterior uvea. Prodrugs with improved solubility, permeability, and chemical and enzymatic stability characteristics could improve THC penetration into the back of the eye. Mono- and di-amino acid conjugated prodrugs may yield compounds with significantly better physicochemical, solubility, and stability characteristics (Elsohly, Gul, Repka, & Majumdar, 2010). Moreover, use of formulation strategies, such as nanoparticulate systems, may help deliver the prodrugs into the deeper ocular tissues. Overall, THC presents itself as a very promising drug candidate for ocular diseases, and needs carefully designed dosage forms to utilize its therapeutic potential.

TABLE 78.3 Total Tetrahydrocannabinol Concentrations Observed in Rabbit Ocular Tissues Post Topical Administration of 50 µL of Tetrahydrocannabinol Hemiglutarate Formulated in Cremophor Micellar Solution (1 h) and Ion Pair Formulations (1- and 3-h Time Points)

	THC-HG		
	0.5% Cremophor RH 40 + 0.1% EDTA + 0.02% BAK + 0.5% HPMC	Ion pair formulation (8 mM tromethamine + 0.5% HPMC)	
Tissue	**1 h**	**1 h**	**3 h**
Drug concentration in terms of THC (% w/v)	0.18	0.16	0.16
Cornea (ng/50 mg tissue)	2451.6 ± 645.6	2245.7 ± 240.2	1382.7 ± 109.8
Aqueous humor (ng/100 µL)	32.1 ± 12.6	52.2 ± 18.7	27.3 ± 11.3
Iris-ciliary bodies (ng/50 mg tissue)	35.6 ± 12.5	93.1 ± 41.4	67.1 ± 55.6
Vitreous humor (ng/mL)	ND*	ND*	ND*
Retina-choroid (ng/50 mg tissue)	ND*	ND*	ND*
Sclera (ng/250 mg tissue)	354.7 ± 86.4	2258.1 ± 1331.1	166.1 ± 49.4

ND*, Drug concentration below detection. The data given in the table shows that hydrophilic derivatization of THC and incorporation into an appropriate formulation markedly improves delivery of tetrahydrocannabinol (THC) to the aqueous humor and the iris-ciliary bodies. The tetrahydrocannabinol hemiglutarate (THC-HG)/tromethamine ion pair formulation delivered significantly higher THC concentrations to the iris-ciliary bodies, compared to the micellar formulations, and significant THC concentrations were still detectable in the aqueous humor and iris-ciliary bodies at the 3-h time point post topical application.
Data are from Hingorani et al. (2013), with permission from the publishers.

MINI-DICTIONARY

Anterior segment of the eye Anterior segment of the eye refers to the anatomical structures between cornea and iris-ciliary bodies, including aqueous humor, pupil, and trabecular meshwork.

Drug delivery Delivery of a drug or drug candidates at therapeutic levels through various approaches, formulations, and technologies, across physiological membranes and to the site of action.

Endocannabinoid system A combination of endocannabinoids (endogenous substances that activate cannabinoid receptors), enzymes involved in their degradation (fatty acid amide hydrolase) and biosynthesis, and cannabinoid receptors (CB1 or CB2).

Neuroprotection A mechanism to protect retinal ganglionic cells from neuronal injury or degeneration due to various ocular disorders (glaucoma, age-related macular degeneration, vitreoretinopathy, and diabetic retinopathy).

Posterior segment of the eye It is also referred to as back-of-the eye segment, and includes the ocular structures such as anterior hyaloid membrane, vitreous humor, retinal pigmented epithelium, choroid, and optic nerve.

Retinal ganglionic cells Retinal ganglionic cells are a type of neurons which help in transmission of the image forming and nonimage forming visual information received by the photoreceptors to the brain.

WIN 55,212-2 WIN 55,212-2 is a synthetic cannabinoid compound which serves as a full agonist at the cannabinoid receptor to produce similar activities as tetrahydrocannabinol.

CHAPTER

79

The Role of γ-Aminobutyric Acid in the Interoceptive Effects of Oral Δ^9-Tetrahydrocannabinol in Humans

J.A. Lile, J.S. Fogel**, T.H. Kelly**

***Departments of Behavioral Science and Psychiatry, University of Kentucky College of Medicine, and Department of Psychology, University of Kentucky College of Arts and Sciences, Lexington, KY, United States**

****Department of Psychology, University of Kentucky College of Arts and Sciences, Lexington, KY, United States**

SUMMARY POINTS

- This chapter focuses on the involvement of γ-aminobutyric acid (ie, GABA) in the interoceptive effects of Δ^9-tetrahydrocannabinol (ie, Δ^9-THC) in humans.
- The interoceptive effects of drugs can be assessed using drug discrimination procedures: a selective means to examine neuropharmacological interactions between neurotransmitter systems.
- Δ^9-THC, the primary active constituent of cannabis, can be trained as a discriminative stimulus in humans.
- The GABA reuptake inhibitor tiagabine substituted for Δ^9-THC, and enhanced the discriminative stimulus effects of Δ^9-THC.
- The $GABA_B$ agonist baclofen, but not the $GABA_A$ positive allosteric modulator diazepam, also substituted for Δ^9-THC, and enhanced the discriminative stimulus effects of Δ^9-THC.
- The results from the clinical drug-discrimination studies differ from preclinical data, suggesting that the neuropharmacological interactions between GABA and CB systems differ between human and nonhuman species.
- The studies reviewed here indicate that GABA, particularly the $GABA_B$ receptor subtype, plays a significant part in the interoceptive effects produced by Δ^9-THC, and by extension cannabis, in humans.

KEY FACTS OF MEDICATIONS DEVELOPMENT FOR CANNABIS-USE DISORDERS

- Cannabis accounts for over half of recently used illicit drugs in the United States.
- The number of Americans who meet diagnostic criteria for cannabis-use disorders is similar to that of other illicit drugs.
- For personal health, social, or legal reasons, a subset of users decide, or are compelled, to quit their use.
- Behavioral interventions are moderately successful, but experts believe that a medication could enhance the efficacy of behavioral interventions, and reduce their cost.
- No medications are approved to treat cannabis-use disorders
- Understanding the neuropharmacological mechanisms of the abuse-related effects of cannabis is necessary

for the development of medications for cannabis-use disorders.

- Some theorists propose that medications that block of the interoceptive effects of cannabis would result in the extinction of drug-seeking and -taking behaviors.
- Other theorists argue that drugs that produce effects that overlap with cannabis would address some of the signs and symptoms of cannabis withdrawal that are reported to make abstinence difficult.

LIST OF ABBREVIATIONS

CB	Cannabinoid
CNS	Central nervous system
GABA	γ-aminobutyric acid
mg	Milligrams
Δ^9-THC	Δ^9-Tetrahydrocannabinol
VDCC	Voltage-dependent calcium channels

CANNABINOID AND GABA NEUROPHARMACOLOGY AND THE GAP IN OUR UNDERSTANDING OF THE INTERACTIONS OF THESE NEUROTRANSMITTER SYSTEMS RELATED TO THE INTEROCEPTIVE EFFECTS OF CANNABIS

The central effects of cannabis (*Cannabis sativa*, *Cannabis indica*) are mediated primarily through endogenous cannabinoid neurotransmitter system receptors, especially the CB_1 receptor subtype (Compton et al., 1993). However, a principal function of CB receptors is the modulation of non-CB neurotransmitter release via retrograde signaling (Szabo & Schlicker, 2005), so it stands to reason that other neurotransmitter systems play a role in the effects of cannabinoids. Neuroanatomical and neurochemical studies support a functional link between CB and GABA systems. CB_1 receptors are co-localized with GABA receptors in regions throughout the brain (Freund, Katona, & Piomelli, 2003; Mailleaux & Vanderhaeghen, 1992), and modulate synaptic GABA levels (Antonelli et al., 2009; Engler, Freiman, Urbanski, & Szabo, 2006). For example, GABAergic transmission is enhanced by reducing GABA reuptake via stimulation of presynaptic cannabinoid receptors in certain GABA neurons (Romero, de Miguel, Ramos, & Fernández-Ruiz, 1998), and also possibly by direct interactions of cannabinoids with the GABA transporter (Coull, Johnston, Pertwee, & Davies, 1997).

Research to determine the in vivo behavioral and physiological consequences of neuroanatomical and neurochemical interactions between the CB and GABA systems is, however, relatively scarce. Information about the overlap between these systems is generally limited to what can be ascertained from the comparisons of the results of individual studies that tested CB and GABA drugs separately (reviewed later in the chapter). Further, the experimental outcomes from those cross-study comparisons generally lack the pharmacological selectivity required for evidence-based inferences about the interaction of these neurotransmitter systems, and have also not focused on the role that GABA might play in the interoceptive effects of cannabinoids. Considering the growing interest in the use of cannabinoid medications for various therapeutic indications, a better understanding of the function of other neurotransmitters in the interoceptive effects produced by centrally acting cannabinoids would be beneficial, as they represent potential side effects (eg, abuse-related effects) that are undesirable to healthcare professionals, regulatory bodies, and some patients. Furthermore, such information would be informative in the development of medications for cannabis dependence (see Key Facts of Medications for Cannabis-Use Disorders).

DRUG DISCRIMINATION AS AN IN VIVO METHOD FOR DETECTING CNS INTERACTIONS BETWEEN NEUROTRANSMITTER SYSTEMS

A valuable method of studying CNS interactions between neurotransmitter systems, especially as it pertains to the interoceptive effects of psychoactive substances, is drug discrimination. Drug discrimination is trained across multiple sessions, using differential conditioning procedures, in which reinforcement is contingent upon correct identification of the specific drug condition (eg, presence vs absence of the training drug) administered under blind conditions. In this way, the interoceptive effects of the training drug come to control behavior, following its administration. Decades of research have demonstrated that these procedures yield data that are concordant with the neuropharmacological actions of a drug at the receptor level (Holtzman & Locke, 1988). An example germane to the present topic is that, in rodents and monkeys trained to discriminate Δ^9-THC, synthetic cannabinoid agonists such as WIN 55212-2 and CP 55-940 generalized to Δ^9-THC (ie, engendered Δ^9-THC-like responding), whereas drugs from a range of other pharmacological classes having functionally distinct receptor-level effects generally do not (Barrett, Wiley, Balster, & Martin, 1995; Browne & Weissman, 1981; Wiley, Barrett, Lowe, Balster, & Martin, 1995; Wiley, Huffman, Balster, & Martin, 1995). Similarly, in studies in which human subjects were trained to discriminate Δ^9-THC, the cannabinoid agonist nabilone, but not methylphenidate,

triazolam, or hydromorphone, occasioned Δ9-THC-like responding, despite the fact that each of the drugs engendered interoceptive stimulus effects, as evidenced by increased ratings on self-reported drug-effect questionnaire items (Lile, Kelly, Pinsky, & Hays, 2009; Lile, Kelly, & Hays, 2010).

In humans, drug discrimination training and testing generally follows a three-phase design. In an initial sampling phase, subjects receive the training dose, identified as the Drug condition, but are not informed of the capsules' contents. A subsequent control phase is then conducted to determine whether subjects can discriminate the training drug from placebo (ie, the Not Drug condition). During the control phase, subjects receive Drug and Not Drug under double-blind and randomized conditions, and accurate drug identification responding following drug administration is reinforced with money. An acquisition criterion (eg, ≥80% correct responding for multiple consecutive sessions that include both Drug and Not Drug conditions) is imposed, and subjects are typically dismissed from the study if they do not meet the criterion within a predetermined number of sessions. A final test phase is then conducted to test additional doses of the training drug, as well as novel drugs alone and/or in combination with the training drug. During test sessions when drugs and/or doses other than the control conditions are administered, responding is reinforced with money, regardless of the option chosen during task performance.

The interoceptive effects of drugs can also be assessed in humans, using subjective effects questionnaires, and is the more typical method. Advantages include being able to examine a wide range of drug effects with minimal eligibility and training requirements. However, self-report and drug discrimination outcomes are not isomorphic and, importantly, drug discrimination procedures have been found to have greater pharmacological selectivity, compared to subjective effects questionnaires (reviewed in Kelly, Stoops, Perry, Prendergast, & Rush, 2003). A potential explanation for the reduced fidelity of self-report measures for examining neuropharmacological mechanisms of drug action is that an appropriate verbal conditioning history is likely not uniform across subjects. For example, the adjective "stimulated" could be interpreted differently, as it could be associated with a variety of different internal states, such as motivation or interest, or physiological cues related to cardiovascular or motor states. In contrast, the relationship between neuropharmacologically-based interoceptive drug cues and drug-identification responding are formally established during drug discrimination training. Thus, drug discrimination serves as an in vivo method to characterize neuropharmacological interactions, and also informs our understanding of how various neurotransmitter systems contribute to the interoceptive effects of drugs.

THE INFLUENCE OF GLOBAL CNS ELEVATION OF GABA ON Δ9-THC DISCRIMINATION

In order to address the gap in our understanding of the function of GABA in the interoceptive effects of cannabinoids, a series of studies using drug-discrimination and drug combination procedures was undertaken. In the first of these studies, the separate and combined effects of the GABA reuptake inhibitor tiagabine (ie, NO-328; Gabitril) and Δ9-THC was determined (Lile, Kelly, & Hays, 2012a). A GABA reuptake inhibitor was chosen because global elevation of GABA levels would permit an initial, albeit nonselective, probe into whether there was an interaction between GABA and cannabinoid systems. Tiagabine was chosen because it is a commercially available GABA reuptake inhibitor that is approved for human use, and elevates extracellular brain concentrations of GABA (Fig. 79.1).

Previous studies have evaluated potential CB–GABA interactions by comparing or combining CB agonists and drugs that elevate central GABA via blockade of the reuptake transporter, and have demonstrated an overlap in some of their central effects. For instance, GABA reuptake inhibition by tiagabine augmented catalepsy produced by Δ9-THC in rodents (Pertwee, Greentree, & Swift, 1988; Pertwee, Browne, Ross, & Stretton, 1991). Likewise, individual studies have shown that, under certain conditions, both CB agonists and GABA transporter blockers are anxiolytic (Moreira & Wotjak, 2010; Schmitt & Hiemke, 1999), induce hypothermia (Frosini,

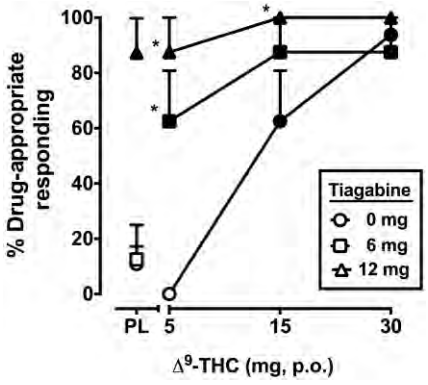

FIGURE 79.1 Global CNS elevation of GABA enhances the discriminative stimulus effects of Δ9-THC. Separate and combined effects of Δ9-THC and tiagabine on Δ9-THC-appropriate responding on the drug-discrimination task. Filled symbols indicate values that are significantly different from placebo. *Asterisks* indicate combinations of Δ9-THC and tiagabine that are significantly different from that dose of Δ9-THC alone. Statistical analyses were conducted using within-subjects ANOVA with $p \leq 0.05$. The *x*-axis represents the Δ9-THC dose in mg; PL denotes placebo. Data points show means of 8 subjects. Unidirectional brackets indicate 1 SEM. *Source: With permission from Lile et al. (2012a).*

Valoti, & Sgaragli, 2004; Wenger & Moldrich, 2002), impair memory processes and motor activity (Castellano, Rossie-Arnaud, Cestari, & Costanzi, 2003; Sañudo-Peña, Romero, Seale, Fernandez-Ruiz, & Walker, 2000; Schmitt & Hiemke, 2002; Suzdak et al., 1992), and produce antinociception (Hohmann, 2002; Laughlin, Tram, Wilcox, & Birnbaum, 2002). In separate clinical studies, CB agonists and tiagabine have each been shown to alleviate pain and anxiety, and promote sleep (Bestard & Toth, 2011; Nakano, Gillespie, & Hollister, 1978; Schwartz & Nihalani, 2006; Steiger, 2007; Todorov, Kolchev, & Todorov, 2005; Ware, Fitzcharles, Joseph, & Shir, 2010).

To further explore these possible CB–GABA interactions within the CNS, tiagabine and Δ^9-THC were administered orally alone and in combination to adult men and women who had been trained to discriminate 30 mg of Δ^9-THC. In addition to the drug discrimination measure, a self-report questionnaire, performance tasks, and physiological assessments were also included to provide a more comprehensive assessment of interactions between tiagabine and Δ^9-THC. The self-report questionnaire consisted of items rated on a Visual Analog Scale (VAS) that assessed positive (eg, Like Drug) and negative (eg, Bad Effects) drug effects, as well as items specific to cannabinoids (eg, Stoned). Performance tasks included a Digit-Symbol-Substitution task and a Repeated Acquisition task to assess impairment in psychomotor function and learning/memory processes. Data were collected immediately prior to drug administration, and at regular intervals after drug administration.

During the test phase of the study, after demonstrating acquisition of the 30 mg Δ^9-THC discrimination, subjects received placebo, 5, 15, and 30 mg Δ^9-THC, and 6 and 12 mg tiagabine, alone and in combination, during separate sessions. For reference, the acute recommended Δ^9-THC dosing range in adults, for appetite stimulation and the prevention of nausea and vomiting is 2.5–20 mg (Marinol Product Information, 2006). The starting dose of tiagabine for epilepsy is 4 mg (Gabitril Product Information, 2009), although acute doses of 12–24 mg tiagabine have been administered without reports of serious adverse events (Zwanzger et al., 2005).

Δ^9-THC dose-dependently functioned as a discriminative stimulus, increased subject ratings on multiple VAS items (eg, High, Stoned, Like Drug), elevated heart rate, and impaired rate and accuracy on psychomotor performance tasks. The higher tiagabine dose substituted for the Δ^9-THC discriminative stimulus, and engendered subjective and performance-impairing effects that overlapped with those of Δ^9-THC, when administered alone. In combination, tiagabine shifted the discriminative stimulus effects of Δ^9-THC leftward/upward, and enhanced Δ^9-THC effects on self-report and performance measures. These results indicated that GABA is involved in the interoceptive and other behavioral effects of Δ^9-THC (ie, a positive nonselective signal was obtained).

The substitution of the higher tiagabine dose, and potentiation of the discriminative stimulus effects of Δ^9-THC by concurrent administration with tiagabine was remarkably similar to what was observed in a previous study in which the CB agonist nabilone was administered alone and in combination with Δ^9-THC (Lile, Kelly, & Hays, 2011). In that study, Δ^9-THC and nabilone shared behavioral and physiological effects, when administered separately. In combination, nabilone significantly shifted the discriminative stimulus effects of Δ^9-THC leftward/upward, and enhanced Δ^9-THC effects on cannabinoid-sensitive measures. It is worth noting that in a previous human study in which 4 and 8 mg of tiagabine were tested in subjects discriminating oral cocaine (Lile et al., 2004), tiagabine did not change the cocaine dose-effect curve. The impact of tiagabine on the discriminative stimulus effects of Δ^9-THC, but not cocaine, suggest a role for GABA in the neuropharmacological effects of cannabinoids, rather than a general impact on all drug effects.

THE INFLUENCE OF $GABA_B$ ACTIVATION ON Δ^9-THC DISCRIMINATION

As described, tiagabine modulates GABA activity by blocking reuptake transporters, thereby producing global elevations in GABA levels, so the contribution of specific GABA receptor subtypes (ie, $GABA_A$ or $GABA_B$) could not be determined in the previous study. With respect to $GABA_B$, some preclinical research has supported its involvement in the effects of cannabinoids. For example, a study found that Δ^9-THC and the $GABA_B$ agonist baclofen (Lioresal) both decreased open field locomotor activity in rodents, and the $GABA_B$ antagonist CGP 35348 reversed the locomotor-decreasing effects of both drugs (Romero, García-Palomero, Fernández-Ruiz & Ramos, 1996). In addition, baclofen augmented the catalepsy produced by Δ^9-THC in rodents (Pertwee et al., 1988). Preclinical studies that have tested cannabinoid and $GABA_B$ agonists separately have demonstrated overlap in their pharmacological profiles; specifically, these drugs are anxiolytic (Moreira & Wotjak, 2010; Pilc & Nowak, 2005), induce hypothermia (Frosini et al., 2004; Wenger & Moldrich, 2002), impair memory processes (Castellano et al., 2003; DeSousa, Beninger, Jhamandas, & Boegman, 1994), and produce peripheral antinociception (Dario, Pisani, Sangiorgi, Pessina, & Tomei, 2007; Hohmann, 2002).

$GABA_B$ participation in the effects of cannabinoids in humans has received less attention. There appears to be only a single clinical research study that has combined

a $GABA_B$ agonist (baclofen) with a cannabinoid, under controlled laboratory conditions (Haney et al., 2010). In that study, daily cannabis users were maintained on 60 and 90 mg/day of baclofen, divided into three 20 or 30 mg doses, and then received active (3.3% Δ^9-THC) and placebo cannabis. Baclofen had minimal impact on the direct effects of active cannabis, except that the low, but not the high, dose of baclofen significantly decreased self-reported ratings of High. In addition, baclofen did not reduce cannabis self-administration, using a laboratory model of relapse in that study. It is worth mentioning, however, that two case report publications described the ability of baclofen treatment to reduce the signs and symptoms of cannabis withdrawal, and facilitate abstinence (Imbert, Labrune, Lancon, & Simon, 2014; Nanjayya, Shivappa, Chand, Murthy, & Benegal, 2010).

A follow-up study was therefore conducted to determine the potential involvement of the $GABA_B$ receptor subtype in the clinical effects of Δ^9-THC by assessing the effects of Δ^9-THC and the $GABA_B$ agonist baclofen, using drug-discrimination procedures (Lile, Kelly, & Hays, 2012b). Baclofen was chosen because it is a $GABA_B$ agonist that is commercially available for use in humans, and has a favorable safety profile. Using procedures similar to those described above, baclofen (25 and 50 mg), Δ^9-THC (5, 15, and 30 mg), and placebo were administered alone and in combination to cannabis users. For reference, the recommended starting dose of baclofen for the treatment of muscle spasticity is 5 mg, taken three times a day, subsequently increased at 3-day intervals by 5 mg, up to an optimum dose range of 30–75 mg daily (Lioresal Product Information, 2008). Single doses of 40 mg and 50 mg have been administered previously in the initial pharmacokinetic and efficacy studies.

As demonstrated previously, Δ^9-THC functioned as a discriminative stimulus, produced subjective effects typically associated with cannabinoids, elevated heart rate, and impaired rate and accuracy on psychomotor performance. The higher dose of baclofen alone substituted for the Δ^9-THC discriminative stimulus, and both baclofen doses shifted the discriminative stimulus effects of Δ^9-THC leftward/upward. Similar results were observed on other cannabinoid-sensitive outcomes, although baclofen generally did not engender Δ^9-THC-like subjective responses, when administered alone. These results suggest that the $GABA_B$ receptor subtype is involved in the interoceptive effects of Δ^9-THC (Fig. 79.2).

The results obtained with baclofen were comparable to tiagabine, suggesting that $GABA_B$ receptors were responsible, at least in part, for the effects of tiagabine-induced elevated GABA on cannabinoid-related behaviors in the previous study. A few differences are worth pointing out, however. With respect to the drug-discrimination data, tiagabine fully (≥80% drug-appropriate responding) substituted for the Δ^9-THC discriminative stimulus, whereas baclofen significantly, but only partially, substituted for Δ^9-THC. Likewise, both doses of tiagabine (6 and 12 mg) significantly increased the discriminative stimulus effects of 5 mg Δ^9-THC, while only the larger dose of baclofen (50 mg) enhanced the low-dose Δ^9-THC discriminative stimulus effects. In addition, 12 mg of tiagabine alone engendered a response on many of the self-reported drug-effect items, but baclofen did not. One possible explanation for these differences is that relative doses of tiagabine were larger than baclofen. However, baclofen, but not tiagabine, augmented Δ^9-THC effects on heart rate, which might not be expected if the differences were simply dose dependent. Another explanation is that activation of the $GABA_A$ receptor is also involved in the effects of cannabinoids in humans, and contributed to the responses observed when GABA was elevated by tiagabine (Fig. 79.3).

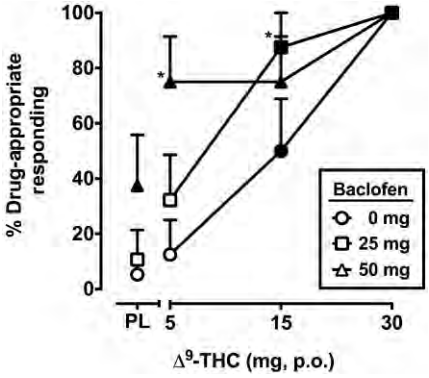

FIGURE 79.2 $GABA_B$ agonism enhances the discriminative stimulus effects of Δ^9-THC. Separate and combined effects of Δ^9-THC and baclofen on Δ^9-THC-appropriate responding on the drug-discrimination task. Other details are as in Fig. 79.1. *Source: With permission from Lile et al. (2012b).*

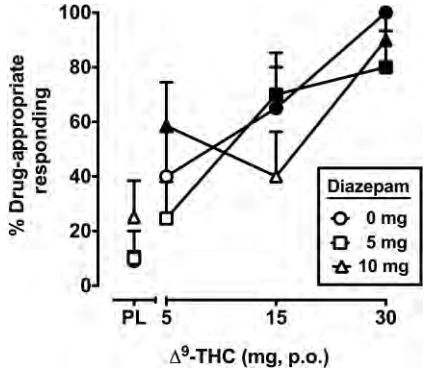

FIGURE 79.3 $GABA_A$ positive allosteric modulation does not influence the discriminative stimulus effects of Δ^9-THC. Separate and combined effects of Δ^9-THC and diazepam on Δ^9-THC-appropriate responding on the drug-discrimination task. Data points show means of 10 subjects. Other details are as in Fig. 79.1. *Source: With permission from Lile et al. (2014).*

THE INFLUENCE OF POSITIVE ALLOSTERIC MODULATION OF $GABA_A$ RECEPTORS ON Δ^9-THC DISCRIMINATION

To address the possibility that the $GABA_A$ receptor subtype is also involved in the effects of cannabinoids in humans, and contributed to the responses observed when GABA was elevated by tiagabine, a third study was conducted to test the interoceptive effects of Δ^9-THC in combination with diazepam (Lile, Kelly, & Hays, 2014). Diazepam, first marketed as Valium, is a benzodiazepine sedative-hypnotic drug that functions as a positive allosteric modulator of $GABA_A$ receptors. A direct $GABA_A$ agonist was not used due to side effects associated with that class of drugs (eg, dissociative hallucinations with muscimol), as well as their limited availability for use in humans. Diazepam was selected over other $GABA_A$ positive allosteric modulators because earlier preclinical work demonstrated that diazepam engendered partial drug-appropriate responding in animals trained to discriminate Δ^9-THC (Barrett et al., 1995; Browne & Weissman, 1981; Mokler, Nelson, Harris, & Rosecrans, 1986; Wiley & Martin, 1999). These Δ^9-THC-like discriminative stimulus effects of diazepam appeared to be mediated by its interaction with $GABA_A$, rather than cannabinoid receptors, because the partial substitution in animals trained to discriminate Δ^9-THC was blocked by the benzodiazepine antagonist flumazenil (Mokler et al., 1986) but not the cannabinoid inverse agonist/antagonist rimonabant (Wiley & Martin, 1999).

Similarities in some of the other behavioral effects of benzodiazepines such as diazepam and cannabinoid agonists have also been documented. For example, diazepam produced a positive signal on three of the four tests included in the "tetrad" traditionally used to assess cannabinoid activity in rodents, specifically catalepsy, locomotor activity, and antinociception (Wiley & Martin, 2003). In addition, impairment of psychomotor performance, as well as learning and memory processes, are well-characterized effects of $GABA_A$ positive allosteric modulators and cannabinoids (Evans, Griffiths, & de Wit, 1996; Kelly, Foltin, & Fischman, 1993). Lastly, cannabinoids promote sleep, and function as anxiolytics under certain conditions and doses, which are therapeutic indication of $GABA_A$ positive allosteric modulators (Nakano et al., 1978; Ware et al., 2010).

In the third study, diazepam (5 and 10 mg), Δ^9-THC (5, 15, and 30 mg), and placebo were administered alone and in combination to cannabis users, using the procedures and outcomes described earlier. For reference, the recommended acute oral dosage of diazepam for the treatment of anxiety is 2–10 mg (Valium Product Information, 2013). Δ^9-THC produced the anticipated effects on the drug-discrimination task, subjective questionnaire, performance measures, and heart rate. Diazepam alone impaired performance on psychomotor performance tasks, and increased ratings on a limited number of self-report questionnaire items (eg, Any Effect, Sedated), but did not substitute for the Δ^9-THC discriminative stimulus or alter the Δ^9-THC discrimination dose-response function, and had little impact on the other behavioral effects of Δ^9-THC. These results suggest that the $GABA_A$ receptor subtype has minimal involvement in the interoceptive effects of Δ^9-THC or cannabis in humans.

This study found no evidence of overlap in the discriminative stimulus effects of diazepam and Δ^9-THC. These results contrast with previous research that demonstrated partial substitution of diazepam for the Δ^9-THC discriminative stimulus in rats and monkeys (Barrett et al., 1995; Browne & Weissman, 1981; Mokler et al., 1986; Wiley & Martin, 1999). However, Δ^9-THC did not occasion drug-appropriate responding in animals trained to discriminate diazepam, demonstrating that the partial cross-generalization was asymmetrical (Wiley & Martin, 1999). In addition, the benzodiazepines chlordiazepoxide and midazolam failed to produce Δ^9-THC-appropriate responding under conditions in which diazepam partially substituted (Barrett et al., 1995). Muscimol, a direct $GABA_A$ agonist, also did not engender drug-appropriate responding in rats trained to discriminate Δ^9-THC (Browne & Weissman, 1981). In humans, triazolam did not occasion Δ^9-THC-like discriminative stimulus effects, up to doses that impaired psychomotor performance (Lile et al., 2009). Together, these results indicate that there is minimal involvement of $GABA_A$ in the interoceptive cue produced by Δ^9-THC in humans, and that shared discriminative stimulus effects between Δ^9-THC and benzodiazepines are limited to diazepam, only under certain training conditions, and in nonhuman species. Also worth noting is that baclofen did not share discriminative stimulus effects with Δ^9-THC in rodents (Browne & Weissman, 1981). Taken in the context of the clinical drug discrimination study with baclofen described above, and the cross-species differences with diazepam, it appears that the neuropharmacological interactions between GABA and CB systems differ between human and nonhuman species.

SUMMARY AND FUTURE CONSIDERATIONS

The studies reviewed here indicate that GABA, particularly the $GABA_B$ receptor subtype, plays a significant part in the interoceptive effects produced by Δ^9-THC in humans, and, by extension, cannabis. Drugs that produce effects that overlap with cannabis have been shown to address some of the signs and symptoms of cannabis withdrawal that are reported to make abstinence

difficult and, as such, could serve as effective pharmacotherapies for cannabis dependence. These results suggest that GABA could be targeted in the development of medications for cannabis dependence. In fact, gabapentin, a GABA analog that is approved for treating neuropathic pain and seizures, has recently emerged as a promising candidate for cannabis-use disorder management (Mason et al., 2012) and, to date, is the only medication that has demonstrated initial pharmacotherapeutic efficacy in clinical trials in adults. In the pilot study by Mason et al. (2012), 1200 mg/day of gabapentin decreased Δ^9-THC metabolite levels in the urine, self-reported cannabis use, craving, and depression, and improved performance on tests of executive function in treatment-seeking cannabis users. Although the therapeutic effects of gabapentin have been linked primarily to VDCCs, there is also evidence that it elevates brain GABA levels (Cai et al., 2012). In addition, the therapeutic effects of gabapentin overlap with those of tiagabine. Specifically, gabapentin and its derivative pregabalin alleviate pain and anxiety, and promote sleep, effects that are also produced by tiagabine (Bestard & Toth, 2011). In a study using drug discrimination procedures similar to those described here, gabapentin substituted for the interoceptive cue produced by Δ^9-THC, and enhanced the discriminative stimulus effects of Δ^9-THC (Lile, Kelly, & Hays, 2016) in a manner similar to what was observed in the studies with tiagabine and baclofen. However, a role for VDCCs in gabapentin's efficacy in cannabis dependence cannot be ruled out. For example, one of the main consequences of CB receptor mediated G-protein activation is the inhibition of VDCCs (Howlett, Blume, & Dalton, 2010). In addition, there is evidence for a CB-receptor-independent modulation of VDCCs by CB ligands, either through interaction with the plasma membrane lipid bilayer, or by direct interaction with a binding site on the ion channel (Lozovaya, Min, Tsintsadze, & Burnashev, 2009). Future research is needed to disentangle the mechanism by which gabapentin reduces cannabis use, and also to determine whether a GABA reuptake inhibitor or $GABA_B$ agonist would be useful for managing cannabis dependence.

MINI-DICTIONARY

Agonist A chemical that activates a receptor.
Allosteric modulator A chemical that binds to a receptor at a site distinct from the primary binding site for the endogenous ligand, and either increases or decreases receptor activity.
Antagonist A chemical that binds to a receptor but does not produce a response, and prevents other chemicals from binding to that receptor.
GABA The major inhibitory neurotransmitter in the CNS.
GABA transporter A protein present in the membrane of GABA neurons that transports recently released GABA back into the neuron.
$GABA_A$ receptor One of the two well-characterized GABA receptors; $GABA_A$ are ionotropic, meaning that binding of an agonist opens a pore formed by the receptor that spans the cell membrane, through which ions may pass; $GABA_A$ receptors permit the influx of negatively charged chloride ions through the channel which hyperpolarizes the neuron, reducing the likelihood of an action potential, and thus having an overall inhibitory effect on neurotransmission.
$GABA_B$ receptor The other of the two well-characterized GABA receptors; $GABA_B$ are metabotropic, meaning they affect cellular communication via intracellular signaling pathways originating with G-proteins. $GABA_B$ activation of G-proteins stimulates the opening of channels that permit the passage of positively charged potassium ions out of the neuron, which hyperpolarizes the cell.
Interoceptive effects Internal stimulus that cannot be directly observed, in this case referring specifically to the perception of drug effects based on specific neuropharmacological mechanisms.
Neurotransmitter An endogenous chemical that transmits signals to and from neurons (nerve cells); typically, these are released by one neuron to travel across the synaptic cleft (space between two neurons) to transmit a chemical signal to another neuron.
Receptor A protein embedded within a cell membrane that binds endogenous (native to the body) or exogenous (foreign to the body) ligand (chemical) to affect cellular communication.
Retrograde signaling In this case, the process by which a neuron sends a chemical message back to a neuron that controls it, in order to provide regulatory feedback of neurotransmission.

CHAPTER

80

The Role of Δ^9-Tetrahydrocannabinol in Diabetes Mellitus

Z.M. Coskun, S. Bolkent***

***Department of Molecular Biology and Genetics, Faculty of Arts and Sciences, Istanbul Bilim University, Istanbul, Turkey**

****Department of Medical Biology, Cerrahpasa Faculty of Medicine, Istanbul University, Istanbul, Turkey**

SUMMARY POINTS

- This chapter focuses on diabetes treated with Δ^9-tetrahydrocannabinol (Δ^9-THC), the main constituent of *Cannabis sativa*.
- Diabetes mellitus is one of the metabolic diseases that are characterized by hyperglycemia due to deficiency in production of insulin by the pancreas.
- In clinical and experimental studies, dyslipidemia, oxidative stress, and inflammation have critically key roles in diabetes and its complications.
- Δ^9-THC demonstrates therapeutic effects by means of cannabinoid receptors.
- Cannabinoid receptors are present in the brain, pancreas, lung, heart, thymus and testicles.
- Hence, Δ^9-THC may be effective against oxidative stress, inflammation, food intake, energy balance, and secretion of endocrine hormones.

KEY FACTS OF DIABETES

- The pancreas consists of the exocrine and endocrine portions.
- The endocrine portion, consists of the pancreatic islets that secrete glucagon and insulin hormones.
- Beta (β) cells produce the insulin hormone in pancreas.
- The degeneration of β cells causes the deficiency of insulin.
- Therefore, the blood glucose levels are elevated in diabetic patients.
- In addition, lipid profile is changed in diabetes.
- Diabetes is a critical medical problem that is dramatically on-the-rise.

KEY FACTS OF Δ^9-THC

- Δ^9-Tetrahydrocannabinol (Δ^9-THC) is the principal cannabinoid of the *Cannabis sativa*.
- Δ^9-THC has pharmaceutical properties.
- The therapeutic features of Δ^9-THC result from the agonist activity of the cannabinoid receptors.
- There are two cannabinoid (CB1 and CB2) receptors in the endocannabinoid system.
- Δ^9-THC accumulates in adipose tissue.
- The excretion of Δ^9-THC is provided via urine.

LIST OF ABBREVIATIONS

α	Alpha
β	Beta
CAT	Catalase
CART	Cocaine- and amphetamine-regulated transcript
CB1 receptor	Cannabinoid 1 receptor

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00091-0
Copyright © 2017 Elsevier Inc. All rights reserved.

CB2 receptor	Cannabinoid 2 receptor
CGRP	Calcitonin gene-related peptide
DM	Diabetes mellitus
δ	Delta
GHRL	Ghrelin
GPx	Glutathione peroxidase
GSH	Glutathione
HDL	High-density lipoprotein
LDL	Low-density lipoprotein
MDA	Malondialdehyde
PP	Pancreatic polypeptide
PPAR-γ	Peroxisome proliferator-activated receptor gamma
PPARs	Peroxisome proliferator-activated receptors
PYY	Peptide YY
SOD	Superoxide dismutase
STZ	Streptozotocin
Δ^9-THC	Δ^9-Tetrahydrocannabinol
VLDL	Very low density lipoprotein

INTRODUCTION

Diabetes mellitus (DM) is a multifactorial disease characterized by high levels of glucose in the blood. Hyperglycemia is caused by reduced insulin secretion and enhanced insulin resistance. It is also due to the disturbances of carbohydrate, protein, and fat metabolisms. A high level of blood glucose is frequently accompanied by hyperlipidemia (Derek, Taylor, & Olefsky, 2000; Kahn et al., 2008; Kim & Caprio, 2011).

Pancreas is a glandular organ responsible for the digestion and homeostasis of glucose. Pancreas is the well-known main source of insulin. Pancreas consists of the exocrine and endocrine portions. The endocrine functions of pancreas are led by the cells in islets of Langerhans. There are classically four types of cells in islets of Langerhans. It has been indicated that in addition to the classical islet hormones, such as insulin (secretion of β cells), glucagon (secretion of α cells), somatostatin (secretion of δ cells), and pancreatic polypeptide (PP) (secretion of PP cells), the islets also express nonclassical islet hormone-like peptides such as islet calcitonin gene-related peptide (CGRP), peptide YY (PYY), ghrelin (GHRL), and cocaine- and amphetamine-regulated transcript (CART) (Yildirim, Sundler, & Bolkent, 2007; Yildirim, Bolkent, & Sundler, 2008). In an adult human, the total islet cells contain ~70–80% β cells, ~15–20% α cells, ~5% δ cells and ~ 1% PP cells, and other cells in the remaining percentage. β cell impairment is due to development and progression of diabetes (Derek et al., 2000; Kahn et al., 2008).

It is known that the islets of Langerhans are regulators of glucose homeostasis. The main hormones in the regulation of glycemia are insulin and glucagon. In diabetes, the number of β cells is decreased in the islets of Langerhans (Fig. 80.1). On the contrary, the number of glucagon-secreting cells is increased in the islets of Langerhans (Fig. 80.2) (Coskun & Bolkent, 2014). The level of plasma glucose is increased, while the level of plasma insulin is decreased in streptozotocin (STZ)-induced diabetes (Bolkent, Bolkent, Yanardag, & Tunali, 2005; Havel et al., 2000). In a study by Sefi et al. (2012), the serum insulin level decreased, and the blood glucose level was elevated in alloxan-induced diabetic rats, as compared to healthy rats. The body weights of rats were decreased in both diabetic animal models (Duarte et al., 2007; Sefi et al., 2012).

Increasing evidence suggests that the development and progression of DM and its complications are derived from increased oxidative stress. Oxidative stress is a lack of balance between the prooxidative and antioxidative stress in an organism (Derek et al., 2000; Kopáni, Celec, Danisovic, Michalka, & Biró, 2006). The clinical and experimental studies have demonstrated that oxidative

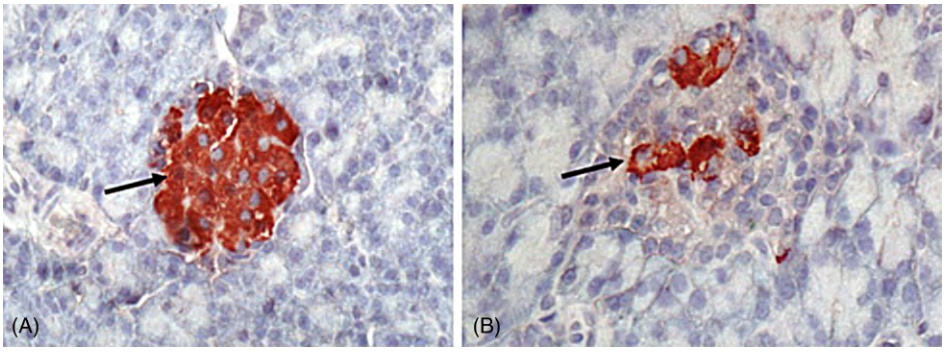

FIGURE 80.1 The expression of insulin reduced due to beta cells dysfunction. The immunopositive cells of insulin *(arrow)* were observed in islets of Langerhans. FIGURE 80.2 **The expression of glucagon increased in the Langerhans islet of diabetic pancreas.** The immunopositive cells of glucagon *(arrow)* were shown in islets of Langerhans. (A) Healthy pancreas, (B) diabetic pancreas of rat by using the Streptavidin–biotin–peroxidase technique, hematoxylin counterstain; magnification ×400 (Coskun & Bolkent, 2014).

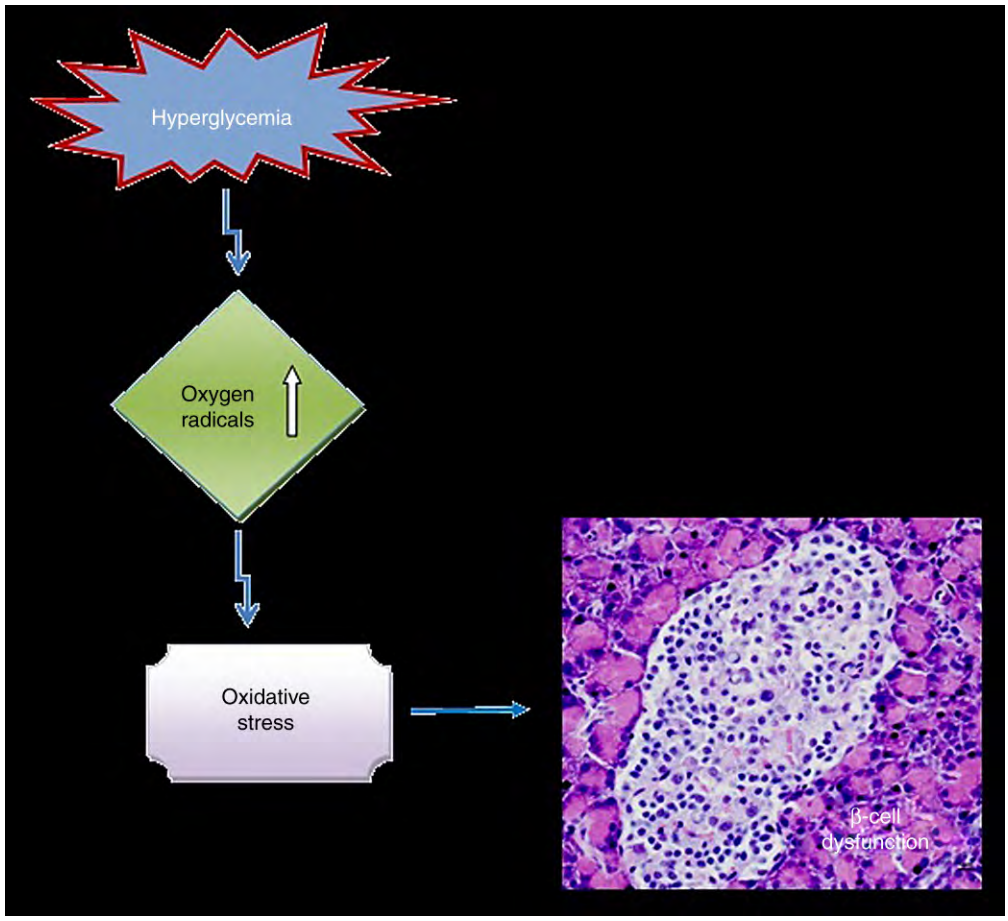

FIGURE 80.3 **Beta cells dysfunction is a consequence of the oxidative stress increased due to hyperglycemia.** The increased oxygen radicals induce oxidative stress and damage in islets of Langerhans (Coskun & Bolkent, 2014).

stress has a central role in the progression of diabetes (Fig. 80.3). The many pathways of diabetic complications include oxidative stress (Ávila de Lima et al., 2013; Baburao Jain & Anand Jain, 2012; Coskun et al., 2013; Giacco & Brownlee, 2010; Kassab & Piwowar, 2012; Li et al., 2011c; Stadler, 2012). Vascular problems such as cardiomyopathy, nephropathy, neuropathy, and retinopathy are among major complications of diabetes (Frostegård, 2013; Tiwari & Ndisang, 2014; Turenkov, Voronkov, & Slietsans, 2013). Diabetic dyslipidemia is one of the major risk factors for vascular problems. Although the precise pathogenesis of diabetic dyslipidemia is not

known, the lipid changes were shown to be associated with DM (Bolkent et al., 2005; Coskun & Bolkent, 2014).

The main constituent of *Cannabis sativa* is known to be Δ^9-tetrahydrocannabinol (Δ^9-THC), a natural phytocannabinoid. It has been known that Δ^9-THC is an agonist of cannabinoid receptors (Waldman et al., 2013). The cannabinoids are mediated by the activation of cannabinoid receptors. The endocannabioid system consists of cannabinoid 1 (CB1) and cannabinoid 2 (CB2) receptors (Li, Jones, & Persaud, 2011b). The CB1 and CB2 receptors are expressed in brain and peripheral organs, including pancreas, lung, heart, thymus, and testicles (Herkenham et al., 1991; Howlett et al., 2002; Li et al., 2011b; Munro, Thomas, & Abu-Shaar, 1993; Pertwee, 1997). Most research studies on the identification of over diabetes have been focused on glucose homeostasis in which cannabinoid receptors agonists or antagonists are useful on glucose homeostasis (Coskun & Bolkent, 2014; Li et al., 2011a; Tharp, Lee, Maple, & Pratley, 2008; Kim et al., 2011; Vilches-Flores, Delgado-Buenrostro, Navarrete-Vázquez, & Villalobos-Molina, 2010).

In this chapter, we will consider the roles of Δ^9-THC in diabetes, and its therapeutic potential of regulation regarding insulin secretion, lipid alterations, and energy homeostasis, as well as its properties as an antioxidant, and immunosuppressive agent.

Δ^9-THC IN OXIDATIVE STRESS IN DIABETES

The antioxidative defense system involves the activities of catalase (CAT), superoxide dismutase (SOD), and glutathione peroxidase (GPx) enzymes. Lenzen, Drinkgern, and Tiedge (1996) have shown that pancreatic islets have a weak antioxidative defense mechanism. Hence, it can easily be affected by overproduction of reactive species. The levels of glutathione (GSH) and the activities of CAT, SOD, and GPx enzymes in the pancreas were decreased in diabetic rats, when compared to healthy rats (Coskun et al., 2013; Perez Gutierrez et al., 2014). The marker of lipid peroxidation index, such as malondialdehyde (MDA) formation, can play a role in tissue damage related with diabetes. The MDA level in pancreas increases during diabetes (Turk, Dagistanli, Sacan, Yanardag, & Bolkent, 2012). In many diseases, Δ^9-THC can provide protection as an antioxidant (Carroll, Zeissler, Hanemann, & Zajicek, 2012; Chen et al., 2005; Hampson, Grilmaldi, Axelrod, & Wink, 1998; Waldman et al., 2013). Δ^9-THC was protective against diabetes-induced by oxidative stress. The decreased GSH level in pancreas showed an increase, when treated with Δ^9-THC in diabetes, which also applied to the activities of CAT and SOD. However, the level of MDA was not changed in diabetic pancreas with Δ^9-THC (unpublished data). In diabetic pancreas treated with Δ^9-THC, the increasing activities of SOD and CAT enzymes, and increased GSH level, demonstrated that Δ^9-THC may protect the cells against reactive species. Δ^9-THC may reduce oxidative damage up to a point, during diabetes.

Δ^9-THC IN DYSLIPIDEMIA IN DIABETES

Diabetic dyslipidemia is characterized by the high plasma triglyceride concentration, reduced high density lipoprotein (HDL) cholesterol concentration, and increased concentration of low density lipoprotein (LDL) cholesterol level, as well as overproduction of very low density lipoprotein (VLDL) (Mooradian, 2009). An increase in total cholesterol, triglyceride, LDL cholesterol, and VLDL cholesterol levels of the blood was observed in STZ-induced diabetic rats (Krishnamurthy, Lakshman, Pruthvi, & Chandrika, 2011). Increased VLDL, LDL, total cholesterol, and triglyceride levels of serum were reduced in diabetes treated with Δ^9-THC (Coskun & Bolkent, 2014).

Peroxisome proliferator-activated receptors (PPARs) are members of the nuclear receptors family, and they play essential roles in regulating gene expression, differentiation, and development of cells, as well as metabolism of lipid, carbohydrate, and protein. There are three subtypes (α, β, and γ) of PPARs (Shearer & Hoekstra, 2003). PPAR-γ is associated with insulin resistance and adipocytes, and it is expressed in the β cells of the islets (Celi & Shuldiner, 2002; Yildirim et al., 2008). Recent evidence indicates that cannabinoids act on PPARs (Burstein, 2005; O'Sullivan, 2007). Thus, an exchange in the lipid profile can be provided by Δ^9-THC-induced activation of PPARs in diabetes.

Δ^9-THC IN THE SECRETION OF INSULIN IN DIABETES

Cannabinoid receptors may play a role in the endocrine secretion by pancreas (Bermúdez-Silva et al., 2008). An increase in insulin secretion was observed in rat insulinoma β-pancreatic cells, islet cells of mice and rats, which was induced by the cannabinoid receptor agonist (Matias et al., 2006; Vilches-Flores et al., 2010; Li, Bowe, Jones, & Persaud, 2010). It may be suggested that Δ^9-THC demonstrates therapeutic effects, which result from cannabinoid receptors. Both receptors are present in the pancreas of rodent species. However, their localization is different in pancreas. While the CB1 receptors are mostly expressed in the islets of Langerhans, the CB2 receptors are expressed in pancreatic ducts (unpublished data) (Figs. 80.4 and 80.5). In diabetes treated with Δ^9-THC, the expressions of insulin and

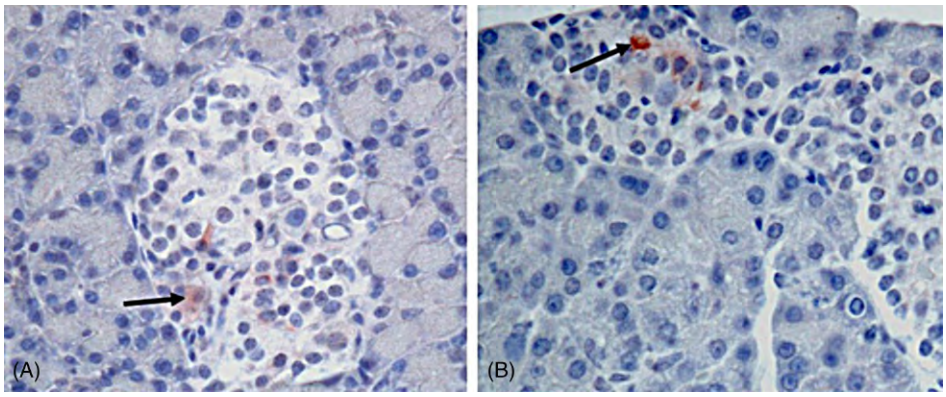

FIGURE 80.4 The localization of CB1 receptor in rat pancreas by Δ^9-THC. CB1 receptor signals *(arrow)* are seen in the Langerhans islets of pancreas immunohistochemically. (A) Nontreated diabetes, (B) diabetes treated with Δ^9-THC. Streptavidin–biotin–peroxidase technique, hematoxylin counterstain; magnification ×400 (Coskun & Bolkent, 2014).

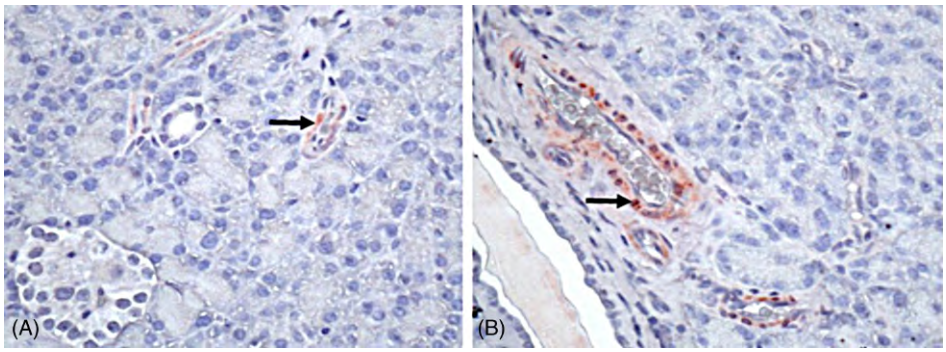

FIGURE 80.5 The localization of CB2 receptor in rat pancreas by Δ^9-THC. CB2 receptor signals *(arrow)* are observed in pancreatic ducts. (A) Nontreated diabetes, (B) diabetes treated with Δ^9-THC. Streptavidin–biotin–peroxidase technique, hematoxylin counterstain; magnification ×400 (Coskun & Bolkent, 2014).

glucagon hormones was changed in pancreas (Coskun & Bolkent, 2014). These observations demonstrate that Δ^9-THC has a potential role in regulating the secretion of pancreatic hormones. Specifically, Δ^9-THC can influence the pancreatic hormone mediated by CB1 receptors in the islets of Langerhans.

Δ^9-THC IN FOOD INTAKE AND ENERGY HOMEOSTASIS IN DIABETES

The CB1 and CB2 receptors may provide control of food intake and regulation of energy homeostasis. Hence, appetite regulation and body weight gain are affected by the endocannabinoid system (Doyle, 2011; Jesudason & Wittert, 2008; Li et al., 2010; Romero-Zerbo et al., 2011). It is suggested that Δ^9-THC reduced weight loss in a rat model of activity-based anorexia (Verty et al., 2011). On the other hand, studies on obesity showed that cannabinoid receptor antagonists could be used to lose weight (Alonso et al., 2012; Verty, Lockie, Stefanidis, & Oldfield, 2013). Body weight was increased in Δ^9-THC-treated diabetic rats (unpublished data). Therefore, Δ^9-THC may aid in controlling weight loss in diabetes.

IMMUNOSUPPRESSIVE EFFECTS OF Δ^9-THC

Studies have demonstrated that Δ^9-THC may be used as a therapeutic agent for the treatment of immune-mediated diseases. Δ^9-THC is capable of reducing inflammation (Lyman, Sonett, Brosnan, Elkin, & Bornstein, 1989; Hegde, Nagarkatti, & Nagarkatti, 2010). β cell damage is caused by STZ-induced diabetes. Moreover, the immune system enhances the destruction of β cells. According to Li, Kaminski, and Fischer (2001), the immunosuppressive influence of Δ^9-THC can attenuate the autoimmune response in the mouse model of autoimmune diabetes. Most probably, the immune suppression effect of Δ^9-THC is capable of ensuring the activation of cannabinoid receptors.

EXCRETION OF Δ9THC METABOLITES IN THE URINE OF DIABETICS

Δ^9-THC is highly lipophilic, and accumulates in adipose tissue from where it is dispersed into the blood stream for long durations (Kreuz & Axelrod, 1973). The metabolic degradation of Δ^9-THC is in the liver (Bland, Haining, Tracy, & Callery, 2005). The Δ^9-THC metabolites can be detected in serum and urine of cannabis consumers (Jung, Kempf, Mahler, & Weinmann, 2007).

Furthermore, in our experimental study, the level of Δ^9-THC metabolites in the urine was elevated in diabetic rats treated with Δ^9-THC, as compared to healthy rats that were given Δ^9-THC (unpublished data). The reduced level of Δ^9-THC metabolites in urine may be induced by weight loss in diabetes (unpublished data). Hence, the accumulation of Δ^9-THC metabolites in adipose tissue can be reduced in diabetic status.

In summary, studies have shown that Δ^9-THC may be effective against diabetes and its complications. Δ^9-THC, a natural cannabinoid receptor agonist, may decrease blood glucose levels, and increase body weight in diabetes. The administration of Δ^9-THC can attenuate the oxidative damage induced by diabetes. The protection provided by Δ^9-THC in diabetes is mediated by cannabinoid receptors and antioxidant properties. Thus, it is suggested that Δ^9-THC can be considered for its pharmaceutical effects against symptoms of diabetes such as regulating food intake, glucose homeostasis, oxidative damage, and attenuation of the severity of the autoimmune response. In the future, Δ^9-THC may be preferred for its protective benefits in diabetes.

MINI-DICTIONARY

Alloxan Alloxan is a toxic chemical. It has been used to induce diabetes in experimental animals by destroying the insulin-secreting cells of Langerhans islet in pancreas.
Antioxidant It provides protection against some of the damage induced by free radicals. It may neutralize free radicals.
Dyslipidemia A disorder of lipoprotein metabolism in the blood that involves lipoprotein overproduction or deficiency.
Enzyme A biomolecule that triggers chemical reactions very quickly. They are made of amino acids.
Hormone A regulator of the functions of tissues and organs that is derived from glands in organisms.
Metabolite A metabolite is the byproduct of a breakdown of any substance in tissues and organs.
Oxidative stress A disturbance in the balance between antioxidant defense system and the production of free radicals and peroxides.
Streptozotocin It is a toxic agent that causes degeneration in β cells of Langerhans islet, and induces the experimental diabetes model.
Δ9-Tetrahydrocannabinol (Δ9-THC) It is the main psychoactive ingredient in the plant *Cannabis*.
Therapeutic effect The beneficial effect that is the consequence of a medical treatment.

Cannabidiol: An Overview of its Antipsychotic Properties

F.F. Peres, V. Almeida, V.C. Abilio

Department of Pharmacology, Federal University of Sao Paulo, Sao Paulo, Brazil; Integrated Laboratory of Clinical Neurosciences (LiNC), Federal University of Sao Paulo, Sao Paulo, Brazil

SUMMARY POINTS

- Schizophrenia presents three categories of symptoms: positive, negative, and cognitive symptoms.
- The available antipsychotic drugs treat mainly the positive symptoms, presenting low efficacy against the negative and cognitive symptoms, and induce significant side effects.
- Alterations in the endocannabinoid system seem to be implicated in the pathophysiology of schizophrenia, suggesting that this system might be a target for therapeutic strategies.
- CBD (cannabidiol), a nonpsychotomimetic compound of cannabis, seems to be able to treat the positive symptoms of schizophrenia, and represents an advance with regard to the existing antipsychotics, since it might be effective also against the negative and cognitive symptoms of schizophrenia.
- CBD treatment does not induce significant side effects.

KEY FACTS OF CANNABIDIOL AS AN ANTIPSYCHOTIC DRUG

- CBD (cannabidiol), when administered prior or simultaneously to Δ^9-tetrahydrocannabinol (THC), prevents THC psychotomimetic effects.
- Cannabis with high CBD content induces less psychotic symptoms and memory impairments than those with low CBD levels.
- In animal models of schizophrenia, CBD attenuates behavioral abnormalities that model the positive, negative, and cognitive symptoms.
- In a case-report, CBD significantly reduced the symptoms of a schizophrenia patient in the brief psychiatric rating scale (BPRS).
- CBD treatment decreases psychotic symptoms of patients with Parkinson disease (PD).
- In a double-blind controlled clinical trial with schizophrenia patients, it was seen that CBD reduces the patients' symptoms in a way similar to the atypical antipsychotic amisulpride.
- Unlike typical and atypical antipsychotics, CBD does not induce significant side effects.

LIST OF ABBREVIATIONS

5-HT$_{1A}$	5-Hydroxytryptamine receptor 1A
AEA	Anandamide
BAD	Bipolar affective disorder
BPRS	Brief psychiatric rating scales
CB$_1$	Cannabinoid-1 receptor
CB$_2$	Cannabinoid-2 receptor
CBD	Cannabidiol
CFS	Cerebrospinal fluid
D$_2$	Dopamine 2 receptor
GPR55	G-protein coupled receptor 55
MK-801	Dizocilpine

TRPV2 Potential vanilloid receptor type 2
YMRS Young mania rating scale

INTRODUCTION

Schizophrenia is a complex and severe psychiatric disorder that affects around 0.7% of the world's population. Its onset occurs between late adolescence and early adulthood. Schizophrenia patients may experience three categories of symptoms: positive, negative, and cognitive symptoms. The positive symptoms, also known as psychotic symptoms, comprise hallucinations, delusions, and thought disorders. It is worth mentioning that psychosis is seen not only in schizophrenia, but also in other psychiatric conditions, such as bipolar affective disorder (BAD) and major depressive disorder, and it may be induced by dopaminergic agonists and glutamatergic antagonists. The negative symptoms of schizophrenia include social withdrawal, anhedonia, and apathy. With respect to the cognitive symptoms, patients present mainly deficits in working and attentional memories, as well as impairments in the sensorimotor gating functioning.

Schizophrenia and psychotic states can be devastating to the patients and their caregivers. In this context, the advent of antipsychotic drugs has brought enormous benefits, and is therefore considered one of the major advances in psychopharmacology. However, the therapeutic effectiveness of the antipsychotics seems to be restricted to the positive symptoms of schizophrenia. Moreover, the drugs available are not able to benefit all patients, and induce significant side effects that impair the quality of life, and are even life-shortening. Consequently, the search for new therapeutic strategies for schizophrenia is required.

In this scenario, cannabidiol (CBD)—a nonpsychotomimetic compound of cannabis—emerges as a potential new therapeutic strategy to schizophrenia and other psychotic states. This chapter will discuss the latest evidence on CBD's antipsychotic profile, focusing on its discovery, and the subsequent studies with animal models, healthy individuals, and psychiatric patients. In addition, we review here the data concerning CBD's possible side effects. Fig. 81.1 summarizes the aim of this chapter.

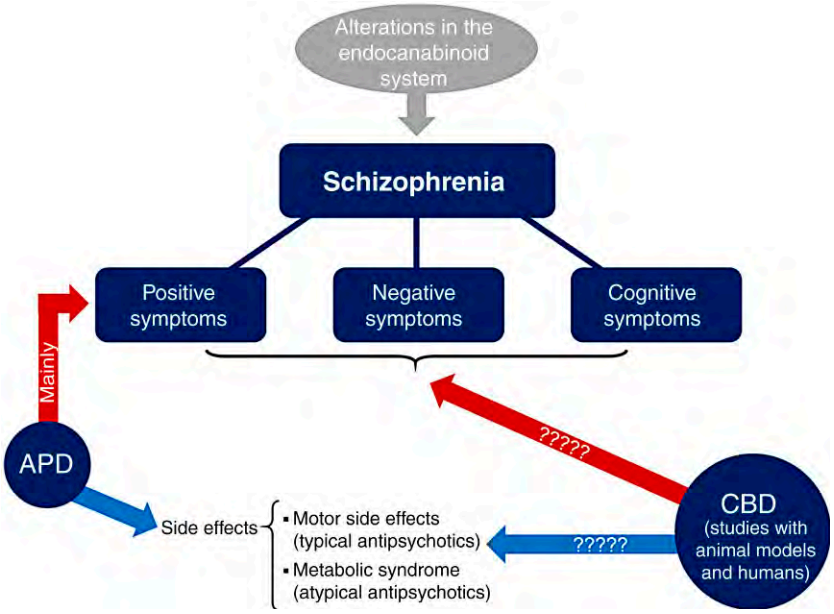

FIGURE 81.1 **Summary of the aims of this chapter.** Schizophrenia presents three categories of symptoms: positive, negative, and cognitive symptoms. The available antipsychotic drugs (APD) treat mainly the positive symptoms, having a low therapeutic efficacy against the negative and cognitive symptoms. In addition, APD induce important motor and metabolic side effects. The motor side effects are promoted primarily by the typical antipsychotics, while the metabolic syndrome is provoked mostly by the atypical antipsychotics. Therefore, the search for new therapeutic strategies is needed. In parallel, alterations in the endocannabinoid system seem to be implicated in the pathophysiology of schizophrenia. In this scenario, cannabidiol (CBD)—a nonpsychotomimetic compound of cannabis—emerges as a potential new therapeutic strategy for schizophrenia. Preclinical and clinical studies are essential to elucidate its therapeutic profile, as well as possible side effects.

ENDOCANNABINOID SYSTEM AND SCHIZOPHRENIA

The endocannabinoid system has recently emerged as an important neurotransmitter system in schizophrenia: both its involvement in the pathophysiology of this disorder, as well as its potential as a therapeutic target have been extensively studied. This interest is based on some compelling facts: first, the exposure to Δ^9-tetrahydrocannabinol (THC), the main psychotropic component of cannabis, may induce transient psychotic states in healthy individuals. Second, cannabis consumption provokes more and earlier psychotic relapses in schizophrenia patients, even under antipsychotic treatment, and cannabis abuse has been shown to be a risk factor for psychotic outcomes. Conversely, the rates of cannabis abuse are higher in schizophrenia patients than in the general population, and its use has been suggested as a self-medication strategy.

In parallel, the endocannabinoid system modulates neurotransmissions related to the pathophysiology of schizophrenia, such as dopaminergic and glutamatergic systems. Neurochemical evaluations point to alterations in the endocannabinoid system in this disorder: (1) the levels of anandamide (AEA), one of the main endocannabinoids, are increased in cerebrospinal fluid (CSF) and peripheral blood of schizophrenia patients. The increase of AEA levels in CSF is also seen in individuals at high risk of developing schizophrenia; (2) in nonmedicated schizophrenia patients, the psychotic symptoms are negatively correlated to CSF AEA levels, and it has been demonstrated that some successful treatments with antipsychotics are accompanied by a decrease of these levels; (3) in vivo studies using positron emission tomography (PET) demonstrate increased density of cannabinoid-1 receptors (CB_1) in both medicated and nonmedicated schizophrenia patients. In addition, the CB_1 density in the nonmedicated group is negatively correlated to negative symptoms; (4) several postmortem studies show increased density of CB_1 in the dorsolateral prefrontal, anterior cingulated, and posterior cingulated cortices of schizophrenia patients; (5) there is an association between schizophrenia phenotype and polymorphisms of the genes that codify the cannabinoid receptors CB_1 and CB_2 [for a broad review of the role of the endocannabinoid system in schizophrenia, see: Fernandez-Espejo, Viveros, Nunez, Ellenbroek, & Rodriguez de Fonseca (2009); Zamberletti, Rubino, and Parolaro (2012)].

CBD AS AN ANTIPSYCHOTIC DRUG

CBD is one of over 60 cannabinoids identified in *Cannabis sativa*, being the most abundant after THC. CBD constitutes up to 40% of the plant's extract, but its proportion in cannabis is highly variable, and depends on the phenotype and the growing conditions of the plant. CBD was first isolated in 1940 by Adams, Hunt, and Clark (1940), and its structure (depicted on Fig. 81.2) was only elucidated 23 years later by Mechoulam and Shvo (1963). Perez-Reyes, Timmons, Davis, and Wall (1973) described that, unlike THC, CBD is not a psychotomimetic compound. Since then, several pharmacological effects in the central nervous system and in the periphery have been described for CBD, including anxiolytic, antiinflammatory, neuroprotective, and antipsychotic actions.

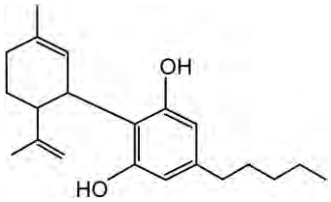

FIGURE 81.2 Chemical structure of cannabidiol. The chemical structure of cannabidiol, first described by Mechoulam and Shvo (1963).

The mechanisms underlying CBD effects are still not precisely known, but it is clear that it presents many molecular targets. CBD can act as an antagonist of CB_1 and CB_2 receptors, and as an inverse agonist of CB_2. CBD also inhibits the reuptake and degradation of AEA, therefore increasing its levels. Furthermore, CBD may interfere on other neurotransmitter systems, besides the endocannabinoid: it has been described, among other actions, that it works as antagonist of the orphan receptor GPR55, as well as agonist of the serotonin receptor 5-HT_{1A}, and of the vanilloid receptors TRPV1 and TRPV2. Only few studies addressed the molecular targets involved in the antipsychotic effects of CBD, but undoubtedly elucidating it is paramount. The main CBD mechanisms of action are summarized in Fig. 81.3 [for a review, see Izzo, Borrelli, Capasso, Di Marzo, and Mechoulam (2009)].

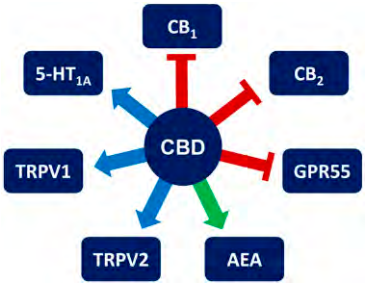

FIGURE 81.3 Proposed mechanisms of action of cannabidiol. Cannabidiol (CBD) activates the 5-hydroxytryptamine receptor 1A (5-HT_{1A}), the potential vanilloid receptor type 1 (TRPV1), and the potential vanilloid receptor type 2 (TRPV2). On the other hand, CBD blocks the cannabinoid-1 receptor (CB_1), the cannabinoid-2 receptor (CB_2) and the G protein-coupled receptor 55 (GPR55). In addition, CBD inhibits the reuptake and degradation of anandamide (AEA), therefore increasing its levels. The *blue arrows* represent agonism, the *red bars* indicate antagonism and the *green arrow* represents inhibition of reuptake and degradation.

Evidence From Healthy Subjects

The first evidence of CBD's antipsychotic profile comes from studies with healthy subjects. Perez-Reyes et al. (1973) demonstrated that, unlike THC and cannabinol, the intravenous administration of CBD does not induce psychological changes in healthy individuals, indicating, therefore that CBD is not a psychotomimetic compound. One year later, Karniol, Shirakawa, Kasinski, Pfeferman, and Carlini (1974) showed that CBD, when administered simultaneously to THC, blocks the THC effects on psychological reactions, pulse rate, and time production tasks. Moreover, the administration of CBD prior or concomitant to THC reduces the psychotomimetic symptoms induced by THC (Bhattacharyya et al., 2010; Zuardi, Shirakawa, Finkelfarb, & Karniol, 1982). These results indicated that not only is CBD devoid of psychotomimetic effects, but it is also able to inhibit the psychotic symptoms induced by other cannabinoids, leading to the suggestion that CBD might act as an antipsychotic. CBD also attenuates the binocular depth inversion—a model of impaired perception during psychotic states—provoked by nabilone, a synthetic analog of THC (Leweke, Schneider, Radwan, Schmidt, & Emrich, 2000), and shows a trend to reduce the depersonalization symptoms induced by ketamine (Hallak et al., 2011). Ketamine is an antagonist of NMDA glutamatergic receptors, and presents a psychotomimetic profile.

In addition, Rottanburg, Robins, Ben-Arie, Teggin, and Elk (1982) described a higher frequency of cannabis-related psychosis in a cohort of patients who used a variety of cannabis virtually devoid of CBD, pointing to the protective effect of CBD against THC's psychotomimetic effects. Reinforcing this suggestion, it was seen that individuals who have only THC in hair present higher levels of schizophrenia-like symptoms than those with CBD and THC, and that the CBD + THC group displays better recognition memory (Morgan & Curran, 2008; Morgan et al., 2012). Likewise, CBD's proportion in cannabis influences its effects: cannabis with high CBD content induces less psychotic symptoms and memory impairments than cannabis with low CBD levels (Morgan, Schafer, Freeman, & Curran, 2010; Schubart et al., 2011).

The evidence of antipsychotic effects of CBD in healthy subjects is summarized in Table 81.1.

TABLE 81.1 Antipsychotic Effects of CBD in Humans

Zuardi et al. (2009)	Chronic CBD treatment (4 weeks) reduced psychotic symptoms in six patients with Parkinson disease, without worsening their motor function
Leweke et al. (2012)	Chronic CBD treatment (4 weeks) reduced psychotic symptoms in 21 schizophrenia patients, in the same way as amisulpride. CBD induced fewer side effects

Summary of the studies indicating the antipsychotic effects of CBD in healthy subjects and in psychiatric patients. CBD, Cannabidiol; THC, Δ^9-tetrahydrocannabinol.

Evidence From Animal Studies

Considering the compelling evidence of CBD antipsychotic profile derived from observations with healthy subjects, the next step was to evaluate effects of CBD on animal models of schizophrenia. These models display some behavioral abnormalities that resemble the symptoms observed in patients, and are reversed by the administration of antipsychotic drugs. It is the case of diminished social interaction—that mimics social withdrawal—and deficits in prepulse inhibition of startle (PPI), a paradigm that evaluates the sensorimotor gating functioning, and that is also impaired in schizophrenia patients. Alongside these, hyperlocomotion and stereotyped behavior are used in animals to model the positive symptoms of the disorder, since they are all related to increased dopaminergic transmission. In addition, animal models of schizophrenia, similar to patients, might present cognitive deficits. The behavioral abnormalities seen in animal models of schizophrenia, and the corresponding symptoms observed in patients, are depicted on Fig. 81.4 [for a review, see Lipska and Weinberger (2000)].

The first study evaluating the effects of CBD administration on an animal model of schizophrenia was performed in 1991. The authors demonstrated that CBD, as the antipsychotic drug haloperidol, is able to reduce the stereotyped behavior induced by apomorphine in rats (Zuardi, Rodrigues, & Cunha, 1991). Later, it was seen that CBD is also capable of inhibiting, in rodents, the hyperlocomotion induced by dopamine agonists or NMDA antagonists (Gururajan, Taylor, & Malone, 2012; Long et al., 2010; Moreira & Guimaraes, 2005). This inhibition is comparable to the one induced by the antipsychotic clozapine. It is noteworthy, however, that CBD was not able to reverse the hyperlocomotion induced by MK-801 (an NMDA antagonist) in another study (Gururajan, Taylor, & Malone, 2011), nor the spontaneous hyperlocomotion presented by the SHR strain (Almeida et al., 2013), suggested as an animal model to study several aspects of schizophrenia (Calzavara et al., 2009, 2011; Levin et al., 2011). Moreover, despite a trend, CBD inhibition of the hyperlocomotion induced by ketamine failed to reach significance (Moreira & Guimaraes, 2005).

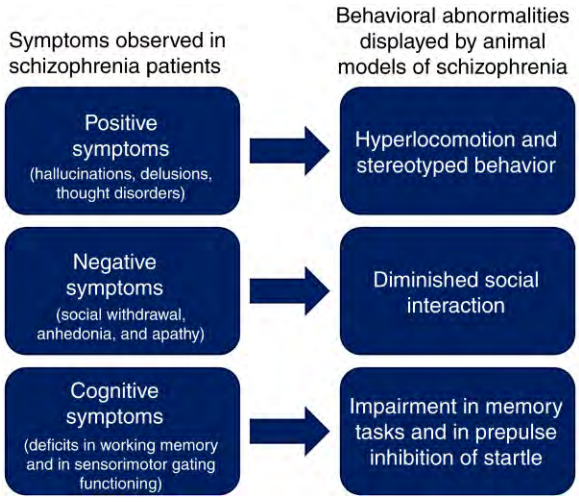

FIGURE 81.4 The relationship between schizophrenia symptomatology and the behavioral abnormalities presented by animal models of schizophrenia. Animal models of schizophrenia display behavioral abnormalities (depicted in the right column) that model its symptoms (the corresponding symptom is listed in the left column).

CBD also reverses the deficits in social interaction induced by THC or MK-801 (Gururajan et al., 2012; Malone, Jongejan, & Taylor, 2009). On the other hand, it failed to restore the spontaneous deficit on social interaction presented by the SHR strain (Almeida et al., 2013). Deficits in PPI, induced by MK-801 or spontaneously presented by the SHR strain, are also attenuated by CBD (Levin et al., 2014; Long, Malone, & Taylor, 2006). Conversely, one study did not see this beneficial effect of CBD on the PPI deficit promoted by MK-801 (Gururajan et al., 2011). Finally, CBD restores the spontaneous impairment in emotional context processing presented by the SHR strain (Levin et al., 2012).

The discrepancies found in the previous studies are probably due to differences in the rodent species, and in the drug regimen. However, even with conflicting results, preclinical data reinforce the CBD antipsychotic profile, suggesting it is effective against several schizophrenia-like behavioral abnormalities. The data concerning the antipsychotic profile of CBD from animal models of schizophrenia are summarized in Table 81.2.

Evidence From Clinical Studies

Taken as a whole, the striking evidence of the antipsychotic profile of CBD described earlier led to studies with patients. The first one was a case-study, and it was only performed in 1995. A 19-year-old female schizophrenia patient who was experiencing serious side effects with the previous antipsychotic treatment was treated with increasing doses of CBD, for 4 weeks. CBD significantly reduced the patient's symptoms in the brief psychiatric rating scale (BPRS), in a way superior to the antipsychotic drug haloperidol (Zuardi et al., 1995).

In 2006, a second study was conducted with three male patients with treatment-resistant schizophrenia. They received CBD for 4 weeks, with the doses increasing throughout the treatment. Only one patient had a mild improvement under CBD treatment, while the others showed no improvement. The authors argue that the lack of CBD effect is probably due to the therapeutic approach, different from the one used in the previous case-study. Another possible explanation is that the patients were resistant to conventional antipsychotic treatments, and CBD might be ineffective on these individuals (Zuardi et al., 2006).

TABLE 81.2 Antipsychotic Effects of CBD in Animal Models

References	Animal	Results
Zuardi et al. (1991)	Rats	CBD attenuates stereotyped behavior induced by apomorphine, as well as the antipsychotic drug haloperidol

Levin et al. (2014)	Rats	CBD attenuates the spontaneous PPI deficit presented by SHR strain

Summary of the studies indicating the antipsychotic effects of CBD in animal models of schizophrenia. CBD, Cannabidiol; MK-801, dizocilpine; PPI, prepulse inhibition of startle; SHR, spontaneously hypertensive rats; THC, Δ^9-tetrahydrocannabinol.

CBD antipsychotic effects were also evaluated in patients with Parkinson disease (PD). An open-label study with six PD patients showed that CBD administration for 4 weeks, in addition to their usual treatment, decreases psychotic symptoms—evaluated by BPRS and by Parkinson Psychosis Questionnaire. It was also seen that CBD treatment does not worsen the motor function of the patients (Zuardi et al., 2009).

Another study performed in 2010 investigated the effects of acute CBD administration on selective attention, in 28 schizophrenia patients. No beneficial effects of CBD were seen, although it cannot be disregarded that chronic CBD administration might have had a different outcome (Hallak et al., 2010). The lack of CBD effectiveness was also observed in a case report with two patients with BAD. The 4-week treatment with CBD showed no improvement on patient's symptomatology—accessed by BPRS and Young mania rating scale (YMRS)—indicating that CBD is probably ineffective against the psychosis associated to BAD (Zuardi et al., 2010).

The first double-blind controlled clinical trial with CBD in schizophrenia patients was performed in 2012. Forty-two patients were randomly assigned to receive CBD or amisulpride (a potent atypical antipsychotic) for 4 weeks. Patients' symptoms, evaluated by BPRS and positive and negative syndrome scale (PANSS), significantly decreased under both treatments, and no difference was seen between them. Nonetheless, CBD induced fewer side effects (weight gain, changes in prolactin levels, and extrapyramidal symptoms) than amisulpride. Furthermore, the treatment with CBD, but not with amisulpride, increased the levels of AEA in serum, and this increase was associated to the decrease of psychotic symptoms (Leweke et al., 2012).

Taken together, these data strengthen the suggestion of CBD as an antipsychotic drug, and point to its use on the treatment of schizophrenia, as well as other psychiatric conditions that present psychotic symptoms. Table 81.1 summarizes the positive results from clinical studies.

SIDE EFFECTS OF CBD

As commented earlier, the available antipsychotic drugs induce significant side effects that impair the patients' quality of life. It is the case of motor disturbances—also known as extrapyramidal symptoms—induced mainly by typical or first generation antipsychotics, and of metabolic syndrome, promoted primarily by atypical antipsychotics. It is important, therefore not only to evaluate the therapeutic profile of potential new antipsychotic drugs, but also to assess their side effects.

Several studies conducted with CBD address its toxicity, and potential side effects. With regard to the motor side effects, studies with rodents show that CBD does not modify motor activity or induce catalepsy (which parallels the acute motor side effects induced by typical antipsychotics), even at high doses. In accordance, CBD treatment in humans does not promote extrapyramidal symptoms. CBD also does not alter some metabolic parameters such as body weight gain and blood levels of glucose, gonadal hormones, or prolactin. Several other blood analyses are also not affected by CBD: in rodents, pH, pO_2, pCO_2, hematocrit, K^+, and Na^+ levels were evaluated after CBD administration, and were not different from control group. The assessment of hematocrit, hemoglobin, leukocyte, and erythrocyte counts, bilirubin and creatinine blood levels in humans treated with CBD also did not yield any significant effect of the cannabinoid. CBD also does not modify urine osmolarity, pH, albumin, leukocyte, and erythrocyte counts, as well as cylinders and crystals levels in humans.

Moreover, some studies investigated the effects of CBD on physiological parameters. CBD does not alter blood pressure or heart rate in rodents; human studies corroborate these findings, and show that CBD does not induce changes in electrocardiogram or electroencephalogram, either. In addition, studies with animals demonstrate that CBD does not affect gastrointestinal motility or rectal temperature. In humans, it was also seen that CBD does not impair psychomotor performance. Finally, some animal studies demonstrate that CBD does not affect the vitality of nontumor cell lines, nor does it alter embryonic development [For a broad review of the side effects of CBD, see: Bergamaschi, Queiroz, Zuardi, and Crippa (2011)].

CONCLUSIONS

Several evidence reinforce the therapeutic potential of CBD in the treatment of schizophrenia's symptomatology. The available data demonstrate that CBD, as the current antipsychotic drugs, is able to treat the positive symptoms of schizophrenia. It is noteworthy that CBD represents an advance with regard to the existing antipsychotics, since it might also be effective against the negative and cognitive symptoms of schizophrenia. Furthermore, significant side effects are not seen with CBD, a common outcome of treatment with antipsychotic drugs.

It is worth mentioning that, although much evidence point to CBD as a safe compound with extensive antipsychotic properties, not all reports are concurring. Therefore, further studies are still necessary to strengthen CBD's antipsychotic profile. Accordingly, it is important to emphasize the relevance of using animal models and translational approaches in the investigation of new therapeutic strategies, such as CBD.

MINI-DICTIONARY

Anandamide (AEA) An endogenous cannabinoid neurotransmitter (endocannabinoid) derived from arachidonic acid.
Antipsychotic drugs Class of drugs used mainly to treat psychotic states, in particular schizophrenia and bipolar disorder. There are two classes of antipsychotic drugs: typical and atypical. The typical antipsychotics are linked to extrapyramidal side effects, while the main side effects of the atypical ones are metabolic disturbances.
Cannabidiol (CBD) One of over 60 cannabinoids identified in cannabis. It is devoid of psychotomimetic actions, but presents several pharmacological effects in the central nervous system and periphery.
Extrapyramidal symptoms Motor dysfunctions that are a common side effect of typical antipsychotic drugs.
Hyperlocomotion Increase in locomotion, evaluated in behavioral tasks, used to model the positive symptoms of schizophrenia in rodents.
Prepulse Inhibition of Startle (PPI) Behavioral paradigm that assess the sensorimotor gating functioning in humans and animals. It is impaired in some psychiatric conditions, including schizophrenia, and is a marker of schizophrenia animal models.
Psychotomimetic drugs Class of drugs that induce psychotic symptoms, such as hallucinations and delusions. It is the case of dopaminergic agonists and glutamatergic antagonists (eg, amphetamine, apomorphine, MK-801, ketamine).
Social interaction A series of behaviors evaluated in rodents, indicating their social performance. Its impairment models the negative symptoms of schizophrenia.
Stereotyped behavior Mechanical repetition of movements or speech, seen in schizophrenia patients. The stereotyped behavior is also observed in animal models of schizophrenia.
Δ^9-Tetrahydrocannabinol (THC) The main psychoactive compound of cannabis. It may be obtained from the plant, or made synthetically, and presents psychotomimetic effects.

SUMMARY POINTS

- This chapter focuses on cannabidiol (CBD), a naturally occurring plant-derived compound.
- CBD is produced by the cannabis plant, which produces several other chemically related compounds, collectively called phytocannabinoids or simply cannabinoids.
- CBD does not produce the psychoactive effects typically produced by Δ^9-tetrhydrocannabinol (THC), the main active compound in cannabis.
- Preclinical and human studies suggest that CBD has unique anticonvulsant effects, and presents good safety and tolerability, producing few side effects.
- Despite its promising anticonvulsant effects, only a small number of placebo-controlled clinical trials testing the antiepileptic potentials of CBD were published.
- Given the good safety profile of CBD and its promising anticonvulsant potentials, there is a clear need to perform new randomized, controlled clinical trials with this phytocannabinoid.

KEY FACTS OF CANNABIDIOL

- Cannabis is a plant original from Central Asia that has been used for ritual and medicinal purposes for thousands of years.
- The cannabis plant is rich in unique chemical compounds called cannabinoids.
- The main cannabinoids are Δ^9-tetradydrocannabinol (THC), responsible for producing most of the subjective effects of cannabis, and cannabidiol (CBD), which lacks the psychoactivity of THC.
- The chemical structure of CBD was elucidated in 1963, while THC, the main active component in cannabis, was isolated in a pure form, and its structure determined, in 1964.
- The antiepileptic/anticonvulsant actions of CBD were first described in the 1970s, and the first clinical trial was published in the 1980s.
- The isolation and structure of anandamide, the brain's first identified endogenous constituent that binds to the cannabinoid receptors, occurred in 1992.

LIST OF ABBREVIATIONS

4-AP	4-Aminopyridine
5-HT$_{1A}$	Serotonergic receptor 1A
CB$_1$	Cannabinoid receptor 1
CB$_2$	Cannabinoid receptor 2
CBD	Cannabidiol
CNS	Central nervous system
COX	Cyclooxygenase
DG	Dentate gyrus
EEG	Electroencephalography
IFN-γ	Interferon γ
LFP	Local field potential
NO	Nitric oxide
PGE2	Prostaglandin E2
THC	Δ^9-Terahydrocannabinol
TNF	Tumor necrosis factor
TRPV$_1$	Transient receptor potential vanilloid 1 (vanilloid receptor 1)
TRPV$_2$	Transient receptor potential vanilloid 2 (vanilloid receptor 2)

INTRODUCTION

Cannabis (*Cannabis sativa*), a plant of the Cannabaceae botanical family, has been used for thousands of years for medicinal, religious, and recreational uses by cultures around the world (Mechoulam & Carlini, 1978; Schultes & Hofmann, 1992; Furst, 1994; Robinson, 1995; Iversen, 2000; Spinella, 2001; Russo et al., 2008; Crippa, Zuardi, & Hallak, 2010; Godlaski, 2012). Nowadays, cannabis is the most consumed illegal recreational drug worldwide (Degenhardt et al., 2013; Greydanus, Hawver, Greydanus, & Merrick, 2013; Hall & Degenhardt, 2014).

Besides terpenoids, flavonoids, steroids, and enzymes, cannabis contains over 100 compounds called cannabinoids, which are unique to the plant (Mechoulam & Carlini, 1978; Mechoulam & Hanus, 2012). Several preclinical and human studies suggest that the main cannabinoid responsible for producing the subjective effects associated with cannabis consumption is Δ^9-tetrahydrocannabinol (THC), while the other main cannabinoid present in cannabis is cannabidiol (CBD), which lacks the psychoactivity of THC (Mechoulam & Carlini, 1978; Iversen, 2000; Spinella, 2001; Zuardi, 2008; Zuurman et al., 2008, 2010; Crippa et al., 2010; Morgan, Freeman, Schafer, & Curran, 2010; Carbuto et al., 2012; Mechoulam & Hanus, 2012; Zhornitsky & Potvin, 2012; Robson, 2014).

In the last decades, a growing number of studies have reported that CBD has a number of therapeutic potentials, including: antiepileptic, sedative, anxiolytic, antipsychotic, antiinflammatory, antioxidative, neuroprotective, antiemetic, anticancer, antidepressant, and mood stabilizer, and with therapeutic action on movement disorders, ischemia, diabetes, and on cannabis withdrawal syndrome (Mechoulam & Carlini, 1978; Ben Amar, 2006; Zuardi, 2008; Crippa et al., 2010; Hazekamp & Grotenhermen, 2010; Mechoulam & Hanus, 2012; Zhornitsky & Potvin, 2012; Robson, 2014). A recent review reported that there are 18 clinical trials involving the administration of CBD to clinical populations, including patients with multiple sclerosis (six studies), schizophrenia and bipolar mania (four studies), social anxiety disorder (two studies), neuropathic and cancer pain (two studies), cancer anorexia (one study), Huntington disease (one study), insomnia (one study), and epilepsy (one study) (Zhornitsky & Potvin, 2012).

Epilepsy is a common neurological disorder characterized by recurrent, unprovoked seizures. Seizures are caused by excessive brain electrical activity, and not all seizures are characterized by convulsions, an abnormal and involuntary contraction of the muscles. There are several types of epilepsy, and available treatments include antiepileptic drugs, steroids, or surgery. Antiepileptic drugs currently available do not benefit all patients, and many produce several side effects, limiting their clinical use. Thus, the present text will introduce an overview of the antiepileptic effects of CBD, both in preclinical and human studies. The text will focus specifically on the antiepileptic effects of CBD because, although this was one of the first pharmacological actions described for this compound in the 1970s, there is only a small number of case reports and placebo-controlled clinical trials testing the antiepileptic potentials of CBD. Therefore, there is a clear necessity to keep investigating the antiepileptic actions of CBD.

CBD'S MECHANISMS OF ACTION

CBD has multiple mechanisms of action, and its pharmacology is not completely understood. In the endocannabinoid system, THC acts as a partial agonist at cannabinoid CB$_1$ receptors, found primarily in the central nervous system (CNS), and CB$_2$ receptors, found primarily on cells of the immune system (Iversen, 2000; Zuurman et al., 2008, 2010; Carbuto et al., 2012). On the other hand, CBD has little affinity to cannabinoids receptors CB$_{1/2}$, although it is capable of antagonizing CB$_{1/2}$ receptor agonists. Moreover, CBD blocks the uptake of the endocannabinoid anandamide, and the inhibition of its enzymatic hydrolysis, and antagonizes the putative novel cannabinoid receptor GPR55 (Zuardi, 2008; Zhornitsky & Potvin, 2012).

Regarding other pharmacological mechanisms that are not directly mediated by the endocannabinoid system, CBD activates 5-HT$_{1A}$ serotonergic and TRPV$_{1\text{-}2}$ vanilloid receptors, antagonizes α_1 adrenergic

and μ-opioid receptors, inhibits the uptake of adenosine, noradrenaline, dopamine, serotonin, and γ-aminobutyric acid, and stimulates the activity of the inhibitory glycine-receptor. Moreover, CBD reduces hydroperoxide-induced oxidative damage, T cell responses, the release of bioactive tumor necrosis factor (TNF), the production of prostaglandin E2 (PGE2), and cytokines interferon γ (IFN-γ) and tumor necrosis factor (TNF), reduces tissue cyclooxygenase (COX) activity and the production of nitric oxide (NO) (Zuardi, 2008; Zhornitsky & Potvin, 2012).

The wide range of pharmacological actions produced by CBD clearly indicates the need for further research to clarify the precise mechanisms that underlie its therapeutic effects, including its antiepileptic potentials.

PRECLINICAL STUDIES SUPPORTING CBD'S ANTICONVULSANT EFFECTS

The antiepileptic effects of CBD were one of the first pharmacological actions described for this compound, still in the 1970s (Carlini, Leite, Tannhauser, & Barardi, 1973; Izquierdo, Orsingher, & Berardi, 1973; Turkanis, Cely, Olsen, & Karler, 1974; Consroe & Wolkin, 1977; Mechoulam & Carlini, 1978; Consroe, Benedito, Leite, Carlini, & Mechoulam, 1982). According to previous studies in rodents, CBD is an effective and relatively potent anticonvulsant (Carlini et al., 1973; Izquierdo et al., 1973; Turkanis et al., 1974; Consroe & Wolkin, 1977; Consroe et al., 1982).

CBD decreased the susceptibility of rat dorsal hippocampus to seizures discharges caused by afferent stimulation (Izquierdo et al., 1973), and significantly protected mice from the convulsant and lethal effects of leptazol (Carlini et al., 1973).

According to Consroe and Wolkin (1977), CBD might be an effective anticonvulsant with specificity more comparable to drugs clinically effective in major (eg, tonic-clonic seizures) than minor seizures. Using the maximal electroshock (a model of partial seizure with secondary generalization) and audiogenic seizures tests, CBD enhanced the anticonvulsant effects of drugs clinically effective in major seizures, and reduced the effects of drugs effective in minor seizures. The anticonvulsant potency of phenytoin was significantly increased when combined with phenobarbital, CBD, and phenobarbital plus CBD, but CBD reduced the anticonvulsant potencies of chlordiazepoxide, clonazepam, trimethadione, and ethosuximide (Consroe & Wolkin, 1977). It is uncertain whether the interactions of CBD with other antiepileptic drugs results from pharmacokinetic or pharmacodynamic mechanisms, but since CBD is a potent inhibitor of multiple cytochrome P450 enzymes including CYP1A2, CYP2B6, CYP2C9, CYP2D6, and CYP3A4 (Zhornitsky & Potvin, 2012), it is possible that pharmacokinetic mechanisms are involved.

Another study in rodents, using transcorneal electroshock current or proconvulsant drugs to induce seizures, reported that CBD selectively prevented tonic, but not clonic, convulsions (Consroe et al., 1982).

More recently, a study reported that CBD caused concentration-related and region-dependent attenuation of chemically induced epileptiform activity in hippocampal brain slices, using in vitro electrophysiological recordings (Jones et al., 2010). This study used extracellular multielectrode array recordings to show that CBD decreased epileptiform activity in the Mg^{2+}-free and 4-aminopyridine (4-AP) in vitro models of epilepsy in the mammalian hippocampus, which is a key epileptogenic brain region. Specifically, in the Mg^{2+}-free model, CBD decreased epileptiform local field potential (LFP) in CA1 and dentate gyrus (DG) regions, while in the 4-AP model CBD decreased LFP in CA1, CA3, and DG regions. Overall, CBD induced more prominent effects in the Mg^{2+}-free than in 4-AP model, which could reflect inherent differences between the two models, which affect NMDA glutamate receptors and K^+ channels, respectively (Jones et al., 2010). Furthermore, this study also examined the effects of CBD in vivo, using the pentylenetetrazole (PTZ) model of generalized seizures, and reported that CBD reduced the incidence of severe seizures and mortality in rodents. Moreover, the antiepileptic effects associated with CBD were suggested to be produced by a potentially CB_1-independent mechanism, since CBD acted with only low affinity at CB_1 receptors (Jones et al., 2010).

In another study (Jones et al., 2012), the same research group examined the anticonvulsant potential of CBD in rodents, using the acute pilocarpine model of temporal lobe seizure, and the penicillin model of partial seizure. In the pilocarpine model, CBD showed modest anticonvulsant effects, reducing the incidence of the most severe seizures, but failing to reduce mortality. On the other hand, CDB produced strong anticonvulsant effects in the penicillin model, with significant reductions in the lethality of seizures, and in the proportions of animals developing the most severe (tonic-clonic) seizure types. Furthermore, CBD had very little effect on motor function tests, suggesting that CBD may present a better safety profile, when compared to currently available antiepileptic drugs, which cause significant and strong motor side effects. Taken together, the studies by Jones et al. (2010, 2012) suggest that CBD appears to hold the greatest potential for the treatment of partial and generalized seizures, rather than temporal lobe seizures.

A recent rodent study using the maximal electroshock and the PTZ seizure models reported anticonvulsant effects of CBD, in both seizure models (Shirazi-zand,

Ahmad-Molaei, Motamedi, & Naderi, 2013). Moreover, this study also evaluated the possible interactions between CBD and the potassium BK channel blocker paxilline. Paxilline did not produce significant change in the PTZ model, but co-administration of CBD and paxilline attenuated the antiseizure effect of CBD in PTZ-induced tonic seizures. In the MES model, both CBD and paxilline produced anticonvulsant effect, but there was no interaction between both substances. According to the authors, these results suggest a BK channel-mediated anticonvulsant action of CBD in the PTZ model of seizure, where CBD could act by decreasing intracellular calcium levels.

Table 82.1 shows that preclinical evidence clearly attests the protective effect of CBD in respect to seizures induced by a number of agents in laboratory animals.

HUMAN STUDIES SUPPORTING CBD'S ANTICONVULSANT EFFECTS

Only a small number of placebo-controlled clinical trials testing the antiepileptic potentials of CBD were published (Mechoulam & Carlini, 1978; Cunha et al., 1980; Ben Amar, 2006; Zuardi, 2008; Hazekamp & Grotenhermen, 2010; Gloss & Vickrey, 2014; Zhornitsky & Potvin, 2012; Robson, 2014). All these trials used CBD as an add-on medication at doses ranging from 200 to 300 mg/day, over treatment periods ranging from 4 weeks to 12 months. Most trials reported reduction in seizures and few side effects after CBD administration (Mechoulam & Carlini, 1978; Cunha et al., 1980; Ben Amar, 2006; Zuardi, 2008; Hazekamp & Grotenhermen, 2010; Gloss & Vickrey, 2014; Zhornitsky & Potvin, 2012; Robson, 2014).

TABLE 82.1 Antiepileptic Effects of CBD in Animal Models

Model	Animals	Results (symbol)[a]		Dose with significant results	References
Convulsant hippocampal discharges	Rats	Reduced susceptibility	(+)	5 mg/kg	Izquierdo et al. (1973)
Leptazol-induced seizures	Mice	Seizure and mortality reduction	(+)	200 mg/kg	Carlini et al. (1973)
Electroshock-induced seizure	Mice	Seizure reduction	(+)	ED_{50}[b] = 120 mg/kg	Turkanis et al. (1974)
Electroshock-induced seizure	Rats	Seizure reduction	(+)	Oral (?)	Consroe and Wolkin (1977)
Electroshock-induced seizure transcorneal	Mice	Reduction of tonic seizures	(+)	ED_{50} = 267 mg/kg	Consroe et al. (1982)
Seizures induced by strychnine sulfate	Mice	No protection against seizures or death	(−)	—	Consroe et al. (1982)
Picrotoxin-induced seizures	Mice	Reduction of tonic seizures	(+)	ED_{50} = 194.4 mg/kg	Consroe et al. (1982)
Seizures induced by 3-mercaptopropionic acid	Mice	Reduction of tonic seizures	(+)	ED_{50} = 122.5 mg/kg	Consroe et al. (1982)
Pentylenetetrazol-induced seizures	Mice	Reduction of tonic seizures	(+)	ED_{50} = 304.8 mg/kg	Consroe et al. (1982)
Seizures induced by isonicotinic acid hydrazide	Mice	Reduction of tonic seizures	(+)	ED_{50} = 266.1 mg/kg	Consroe et al. (1982)
Bicuculline-induced seizures	Mice	Reduction of tonic seizures	(+)	ED_{50} = 379.9 mg/kg	Consroe et al. (1982)
Epileptiform activity in hippocampal tissue	In vitro (rats)	Protection	(+)	1–100 μM	Jones et al. (2010)
Pentylenetetrazol-induced seizures	Rats	Seizure and mortality reduction	(+)	100 mg/kg	Jones et al. (2010)
Pilocarpine-induced seizures	Rats	Seizure reduction	(+)	1–100 mg/kg	Jones et al. (2012)
Partial seizures induced by intraventricular penicillin	Rats	Seizure reduction	(+)	10–100 mg/kg	Jones et al. (2012)
Electroshock-induced seizure	Mice	Increased threshold	(+)	20–200 ng (intraventricular)	Shirazi-zand et al. (2013)
Pentylenetetrazol-induced seizures	Mice	Increased threshold	(+)	200 ng (intraventricular)	Shirazi-zand et al. (2013)

The antiepileptic effects of cannabidiol (CBD) were demonstrated in several animal models.
[a] *(+), Anticonvulsant action; (−), no anticonvulsant action.*
[b] *Median effective doses.*

According to several reviews (Ben Amar, 2006; Hazekamp & Grotenhermen, 2010; Gloss & Vickrey, 2014; Zhornitsky & Potvin, 2012; Robson, 2014), the study by Cunha et al. (1980) seems to be the only double-blind, placebo-controlled clinical trial on the antiepileptic effects of CBD that was fully published in a peer-reviewed journal. There are other studies cited by Zuardi (2008), Robson (2014), and by Gloss and Vickrey (2014). However, one of these studies was published as a one-page letter to the editor, while another study was published as a one-page abstract from a conference. In both reports, few methodological details are given, and the overall quality of the reports is low (for details, see Zuardi, 2008; Robson, 2014; Gloss & Vickrey, 2014). Another study seems to be a preliminary report from nine volunteers from the study by Cunha et al. (1980) (See paragraph below). Thus, only the study by Cunha et al. (1980) will be further discussed.

Cunha et al. (1980) evaluated 15 patients (11 women/4 men; aged 14–49 years; average 24 years) suffering from secondary generalized epilepsy with temporal lobe focus that was unresponsive to prescribed antiepileptic drugs. Patients continued to take their regular antiepileptic drugs throughout the study period. Patients participated in a double-blind, placebo-controlled study, where eight patients received 200–300 mg/day oral CBD for 8–18 weeks, and the other seven individuals received placebo. In this study, four out of eight CBD-treated patients evidenced significant improvement in their condition, remaining virtually convulsion-free for the duration of the study. The other three CBD-treated subjects exhibited partial improvement in their clinical condition. Therefore, only one of the eight patients getting CBD showed no improvement. Moreover, three CDB-treated patients showed improvements in electroencephalographic (EEG) measures. Among the patients who received placebo, only one improved, while seven remained unchanged. CBD was well tolerated by all participants. No further clinical trials investigating the antiepileptic effects of CBD have been published since then.

More recently, a study explored the use of CBD-enriched cannabis in children with treatment-resistant epilepsy (Porter & Jacobson, 2013). The researchers presented a survey to parents belonging to a Facebook group dedicated to sharing information about the use of CBD-enriched cannabis to treat their child's seizures. Nineteen responses met the following inclusion criteria for the study: a diagnosis of epilepsy, and current use of CBD-enriched cannabis. Thirteen children had Dravet syndrome, four had Doose syndrome, one had Lennox–Gastaut syndrome, and one had idiopathic epilepsy. Before using CBD-enriched cannabis, the average number of antiepileptic drugs tried was 12 (range 4–17), and seizure frequency ranged from 2 per week to 250 per day. The children experienced a variety of seizure types, including focal, tonic-clonic, myoclonic, atonic, and infantile spasms. In most cases, the children experienced treatment-resistant epilepsy for more than 3 years before trying CBD-enriched cannabis. The treatment period with CBD-enriched cannabis ranged from 2 weeks to over 1 year. Sixteen (84%) of the 19 parents reported a reduction in their child's seizure frequency. Of these, two (11%) reported complete seizure freedom, eight (42%) reported reduction greater than 80% in seizure frequency, and six (32%) reported a 25–60% seizure reduction. Other beneficial effects included increased alertness, better mood, and improved sleep. Side effects were mild, and included drowsiness and fatigue.

Clinical studies with CBD focusing on children with intractable epileptic syndromes, such as Dravet and Lennox–Gastaut syndromes, are currently underway (ClinicalTrials.gov Identifier: NCT02091206, NCT02091375, NCT02224560, NCT02224573, NCT02224690, and NCT02224703).

The clinical trials available on the effectiveness of CBD in epilepsy are shown in Table 82.2.

CONCLUSIONS

CBD definitely has anticonvulsant effects, as reported by several preclinical studies. In humans, case reports, and at least one randomized controlled study, suggest that CBD is well tolerated, and has substantial therapeutic potentials to be further explored. Moreover, CBD has a good safety and tolerability profile, as reported by several preclinical and human studies. The small number of clinical trials suggests that no reliable conclusions can be drawn at present regarding the efficacy of CBD as a treatment for epilepsy.

CBD has a polypharmacological profile, resulting in multiple mechanisms of action possibly responsible for its anticonvulsant effects. CBD's anticonvulsant effects may result from numerous cannabinoid receptor-independent mechanisms. CBD may potentially modulate neuronal hyperexcitability via a number of different mechanisms, which include regulation of Ca^{2+} homeostasis, agonistic properties at 5-HT_{1A} receptors, and reduction in adenosine reuptake (Zuardi, 2008; Jones et al., 2010, 2012; Zhornitsky & Potvin, 2012; Shirazi-zand et al., 2013). Investigating CBD's mechanisms of action may improve its efficacy and safety profile, and may stimulate research with new antiepileptic agents with fewer side effects than current available antiepileptic drugs.

Given the good safety profile of CBD, and its promising anticonvulsant potentials, there is a clear need to perform new randomized, controlled clinical trials with this phytocannabinoid. Research should focus on determining safety, optimal dosing, tolerability, and possible interactions with other antiepileptic drugs. Moreover, clinical trials

TABLE 82.2 Clinical Trials with CBD in Epilepsy

Study design	Sample	Results (symbol)[a]		Dose with significant results	References
Double blind, placebo-controlled trial	15 patients with treatment-resistant epilepsy	7 of 8 patients improved with CBD; 1 of 7 improved with placebo	(+)	200–300 mg/day (add-on) for 8–18 weeks	Cunha et al. (1980)
Placebo-controlled trial (*letter* with few details)	12 patients with mental retardation and seizures	No differences between groups (6 and 6?)	(−)	300 mg/day for 4 weeks	Ames and Cridland (1986), cited in Gloss and Vickrey (2014)
Double blind trial (unpublished congress abstract)	12 patients with epilepsy	No statistical analysis (does preliminary analysis suggests any reduction?)	(+/−)	300 mg/day for 12 months (6 on drug and 6 on placebo)	Trembly and Sherman (1990), cited in Gloss and Vickrey (2014)
Retrospective assessment with questionnaires completed by parents of children treated with CBD	19 children with treatment-resistant seizures[b]	84% reported seizure reduction	(+)	*Cannabis* extract rich in CBD	Porter and Jacobson (2013)
Open label trial	27 treatment-resistant children or young adults (up to 18 years), predominantly with Dravet syndrome ($n = 9$)	Compared with baseline: 15%—no seizures; 22%—90% reduction, 41%—70% reduction; 48%—50% reduction	(+)	5–20 mg/kg per day for 12 weeks	GW Pharmaceuticals (2014)[c]

Few studies assessed the antiepileptic effects of cannabidiol (CBD) in patients, and many of these studies have important methodological limitations, such as small sample size. Thus, it is difficult to have a definitive opinion regarding the clinical efficacy of CBD in epileptic patients.

[a] *(+), Anticonvulsant action; (−), no anticonvulsant action.*

[b] *12 children with Dravet syndrome, 4 with Doose syndrome, 1 with Lennox–Gastaut syndrome, 1 with mental retardation, and 1 with early-onset idiopathic epilepsy.*

should be conducted among different populations of patients, such as children with treatment-resistant epilepsy.

MINI-DICTIONARY

Anandamide *N*-arachidonoylethanolamine. From the Sanskrit word "ananda": bliss, delight. Endogenous cannabinoid neurotransmitter.

Antiepileptic/anticonvulsant drugs Drugs used for the treatment of epilepsy. These drugs control the occurrence of seizures in epileptic patients.

Cannabidiol (CBD) One of the main phytocannabinoids. It lacks the psychoactive characteristics of Δ^9-tetradydrocannbinol (THC) and has several therapeutic potentials.

Cannabinoid receptors G-protein-coupled receptors present in the endocannabinoid system.

Cannabinoids Chemical compounds present exclusively in the cannabis plant. More than 100 cannabinoids have been identified. Cannabinoids are also called phytocannabinoids, in opposition to endocannabinoids.

Cannabis A plant of the Cannabaceae botanical family, with three different species: *Cannabis sativa*, *C. indica*, and *C. ruderalis*.

CB_1 cannabinoid receptor Cannabinoid receptors mainly distributed in the central nervous system. CB_1 receptors are densely distributed in the frontal cerebral cortex, basal ganglia, cerebellum, hippocampus, hypothalamus, and anterior cingulate cortex, but rarely in the brainstem nuclei.

CB_2 cannabinoid receptor Cannabinoid receptors mainly distributed in immune cells. CB_2 receptors are also expressed in microglia, spinal cord, and sparsely in several brain regions, such as the cerebellum, cortex, and brainstem.

Convulsion An abnormal and involuntary contraction of the muscles. The term is often used interchangeably with "seizure," which is an abnormal electrical activity in the brain, but not all seizures are characterized by convulsions.

Endocannabinoids Endogenous cannabinoid neurotransmitters. Endocannabinoids are chemically and pharmacologically related to phytocannabinoids, both groups of substances acting at the endocannabinoid system, which is basically composed by endocannabinoids, cannabinoid receptors, and the enzymes responsible for endocannabinoid synthesis and degradation.

Epilepsy A group of neurological diseases characterized by the presentation of several types of seizures.

Δ^9-Tetrahydrocannabinol (THC) The main chemical in the cannabis plant responsible for producing the typical subjective effects reported for cannabis consumption.

SUMMARY POINTS

- This chapter focuses on the potential use of cannabidiol (CBD), one of the chemical compounds found in *Cannabis sativa*, as a neuroprotective agent, for the treatment of neurodegenerative disorders.
- Evidence from preclinical studies indicates that CBD displays antioxidant, antiinflammatory, and antiapoptotic properties.
- CBD was also shown to hinder excitotoxicity, and protect mitochondria against mitochondrial toxins.
- Evidence supports the view that CBD may increase progenitor cell proliferation and neurogenesis.
- CBD was shown to improve and ameliorate damage observed in animal models of neurodegeneration associated to hypoxic-ischemic brain injury, multiple sclerosis, brain iron overload, Alzheimer's, Parkinson's, and Huntington's disease.
- Since neurodegeneration is considered a multifactorial process, and CBD acts on multiple pharmacological targets implicated on neurodegeneration, CBD may constitute a promising therapeutic agent for the prevention/treatment of neurodegenerative disorders.

KEY FACTS OF HYPOXIA-ISCHEMIA

- Hypoxia-ischemia (HI) encephalopathy results from stroke, which is a focal disruption of blood supply to a part of the brain, or from global ischemia, which can affect the entire brain.
- HI encephalopathy may also result from perinatal asphyxia in neonates, and may cause long-term neurologic sequelae or death.
- Physiopathology of HI includes energy failure due to reductions in cerebral blood flow and oxygen.
- Energy failure may lead to excitotoxic damage.
- Oxidative stress, mitochondrial failure, and apoptotic cell death are also associated to HI.

KEY FACTS OF ALZHEIMER'S DISEASE

- Alzheimer's disease (AD) is the most prevalent neurodegenerative disorder, affecting 7–10% of individuals over 65 years of age, and 50–60% of people over 85 years of age.
- Features include memory loss, followed by a progressive deterioration of other domains of cognitive functioning.
- Degeneration affects primarily the hippocampus and the neocortex.
- Neuropathological hallmarks of AD are neuritic plaques and neurofibrilary tangles.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00095-8
Copyright © 2017 Elsevier Inc. All rights reserved.

- Neurofibrillary tangles are filamentous inclusions, formed of hyperphosphorylated tau.
- Neuritic plaques are extracellular deposits of aggregated amyloid-β peptide, which results from aberrant cleavage of amyloid precursor protein.

KEY FACTS OF IRON INVOLVEMENT IN NEURODEGENERATIVE DISORDERS

- Iron is the most abundant metal in the human brain.
- It progressively accumulates in selective brain regions affected by neurodegenerative disorders (NDD) such as PD, AD, among others.
- Due to its redox states, iron can catalyze free radical formation, leading to oxidative stress.
- Iron accumulation in the hippocampus and the basal ganglia has been related to impairments in spatial, aversive, and recognition memory in rodents.
- In humans, performance in cognitive tests negatively correlates with iron deposition, assessed by resonance magnetic imaging, in brain regions such as the hippocampus, cortical areas, and basal ganglia.

LIST OF ABBREVIATIONS

AD	Alzheimer's disease
AMPA	α-Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid
APP	Amyloid precursor protein
BV2	Immortalized murine microglial cell line
CA1	Cornu ammonis area 1
CB1	Cannabinoid receptor type 1
CB2	Cannabinoid receptor type 2
CBD	Cannabidiol
COX2	Cyclooxygenase-2
Cu,Zn SOD	Copper and zinc superoxide dismutase
CX3CR1	Chemokine (C-X3-C motif) receptor 1
DNA	Deoxyribonucleic acid
DNM1L	Dynamin-1-like protein
FCCP	Carbonyl cyanide-*p*-trifluoromethoxyphenylhydrazone
GABA	γ-Aminobutyric acid
GSK3β	Glycogen synthase kinase 3 beta
HD	Huntington's disease
HI	Hypoxic-ischemic
5HT1A	5-Hydroxytryptamine (serotonin) receptor 1A
iNOS	Inducible oxide nitric synthase
mRNA	Messenger ribonucleic acid
MS	Multiple sclerosis
NDD	Neurodegenerative disorders
NMDA	*N*-Methyl-D-aspartate
3NP	3-Nitropropionic acid
NO	Nitric oxide
6-OHDA	6-Hydroxydopamine
PC12	Pheocromocytoma cells
PD	Parkinson's disease
PPARγ	Peroxisome proliferator-activated receptor-γ
PS1	Presenilin-1
ROS	Reactive oxygen species
S100B	S100 calcium binding protein B
SHSY5Y	Human neuroblastoma cells type
SOD	Superoxide dismutase
THC	Δ^9-Tetrahydrocannabinol
TNFα	Tumor necrosis factor alpha

INTRODUCTION

There are two main neuroactive components in *Cannabis sativa*: the psychoactive Δ^9-Tetrahydrocannabinol (THC), and the nonpsychoactive Cannabidiol (CBD). CBD was firstly isolated during late 1930s, but its structure was only elucidated by Mechoulam and Shvo (1963). Nowadays, many researchers are studying this compound, and some of its pharmacological effects are already reported, including antiinflammatory, antioxidative, anxiolytic, antipsychotic, and neuroprotective effects, although its mechanisms of action are not completely elucidated (Zuardi, 2008). In view of these effects, CBD has been considered as an interesting compound with potential therapeutic application in a number of neurological and neuropsychiatric disorders. Studies have been conducted to verify the effects of CBD in nervous system pathologies. In recent years, preclinical in vitro and in vivo studies have investigated the potential of CBD in experimental models, focusing mainly on neurodegeneration associated to hypoxic-ischemic (HI) injury and Alzheimer's disease (AD). The purpose of this chapter is to provide a comprehensive overview on the main studies reporting the effects of CBD in the context of HI injury and AD, as well as other relevant experimental models of neurodegeneration, and to discuss its putative mechanisms. Studies in which CBD was used in combination with other cannabinoid compounds were not included in this chapter.

EXCITOTOXICITY AND HYPOXIC-ISCHEMIC BRAIN INJURY

Hampson, Grimaldi, Axelrod, and Wink (1998) analyzed the effects of CBD in rat cortical neuron cultures exposed to glutamatergic excitotoxicity. CBD was able to block *N*-methyl-D-aspartate receptor (NMDAR) and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)/kainate receptor-mediated neurotoxicity, and to protect neurons against reactive oxygen species (ROS)-

induced cell death. The results also indicated that the effects of CBD were independent of cannabinoid receptors. From these results, the authors proposed that CBD could be a useful therapeutic agent for the treatment of neurological disorders associated to excitotoxicity and oxidative stress, such as cerebral ischemia. Therapeutic options to treating HI brain injury are very limited, and in vitro and in vivo preclinical studies indicate that CBD would be a candidate to be tested to treat this condition. Accordingly, Castillo, Tolón, Fernández-Ruiz, Romero, and Martinez-Orgado (2010) investigated the effects of CBD in HI immature brain of newborn mice, as a model of neonatal HI. Forebrain slices from newborn mice underwent glucose and oxygen deprivation, and the effects of CBD on acute and apoptotic cell death, excitotoxicity, inflammatory markers, and inducible oxide nitric synthase (iNOS) expression were evaluated. By using selective antagonists, they also analyzed cannabinoid receptors CB1 and CB2, and adenosine A_{1A} and A_{2A} receptors in mediating these effects. They observed that CBD was able to reduce acute and apoptotic damage in immature brain slices by reducing glutamate and interleukin-6 concentration, and tumor necrosis factor-α (TNF-α), cyclooxygenase-2 (COX-2), and iNOS expression. These effects were reversed by CB2 and A_{2A} antagonists, suggesting that CBD-induced neuroprotection in HI cell death was mediated by CB2 and adenosine receptors.

Hayakawa et al. (2007) examined the neuroprotective effects of CBD, using a 4 h middle cerebral artery occlusion model of ischemia in mice. Results indicated that both pre- and postischemic treatment with CBD decreased infarct volume, reversed the reduction in cerebral blood flow, and increases in myeloperoxidase activity and number of myeloperoxidase positive cells, which are markers of neutrophil response, induced by ischemia. Thus, this study provided evidence that CBD conferred long-lasting neuroprotection, through an antiinflammatory mechanism against ischemic brain damage. The effect of CBD on behavioral end-point of neuroprotection was assessed in the rota-rod test for motor coordination, showing that CBD was able to significantly improve motor coordination in mice submitted to ischemia.

The effects of CBD were also verified in newborn piglets submitted to acute HI (Lafuente et al., 2011). In this study, the authors found that CBD recovered brain activity, assessed by amplitude-integrated electroencephalography, reduced neuronal damage and astrocytosis in the cortex, decreased the percentage of TNF-α positive cells, and normalized general neurobehavioral changes induced by ischemia. CBD administration displayed a neuroprotective effect, which included both neurons and astrocytes, possibly mediated by an antiinflammatory effect in the newborn brain. Pazos et al. (2013) have also analyzed the effects of CBD on HI brain injury using a HI model in newborn pigs. CBD was able to prevent all the alterations induced by HI, increasing the number of viable neurons, recovering brain activity, reducing excitotoxicity assessed by glutamate/*N*-acetylaspartate ratio, oxidative stress assessed by glutathione/creatine ratio and protein carbonylation, and inflammation assessed by brain levels of interleukin-10. The effects of CBD were reversed by CB2 and $5HT_{1A}$ antagonists, suggesting that these receptors are implicated in CBD's neuroprotective profile.

The same group has also analyzed the effects of CBD on neurobehavioral parameters in rats, 30 days after HI injury. Once again, neuroprotective effects of CBD were associated to reductions in excitotoxicity, oxidative stress, and inflammation. Neuroprotection was further confirmed by magnetic resonance imaging and histological evaluation to measure the extension of brain damage. At the functional level, results showed that CBD improved motor and coordination deficits tested in the rota-rod, and short-term object recognition memory (Pazos et al., 2012).

Neuroprotection against excitotoxic insult was also investigated using a diverse model of glutamatergic excitotoxicity in retinal neurons (El-Remessy et al., 2003). Intravitreal injection of NMDA in rats induced a dose- and time-dependent accumulation of nitrite/nitrate, lipid peroxidation, and nitrotyrosine (mark of peroxynitrite), and a dose-dependent apoptosis and loss of inner retinal neurons. CBD injected immediately before the intravitreal injection of NMDA significantly attenuated NMDA-induced tyrosine nitration and apoptosis. Given the involvement of excitotoxicity in retinal cell death observed in glaucoma, CBD has been proposed as a candidate therapy for its treatment.

NEURODEGENERATIVE DISORDERS

Neurodegenerative disorders (NDD) are characterized by progressive loss of neurons in selected areas of the nervous system, which determine their clinical presentation. Although the etiology of NDD is not completely elucidated, there is a general consensus that they are multifactorial diseases that involve oxidative stress, iron accumulation, mitochondrial dysfunction leading to energetic and subsequent synaptic failure, protein misfolding, and formation of protein aggregates, neuroinflammation, excitotoxicity, and apoptosis (Duncan, 2011; Li, O, Li, Jiang, & Ghanbari, 2013).

In spite of tremendous effort put into the investigation of therapeutic agents to treat NDD, no effective disease-modifying drugs that can interrupt the progressive course of the disease are currently available. Thus, due to the already characterized pharmacological properties of CBD, this compound may be promising for the treatment of NDD.

Alzheimer's Disease

In order to investigate cellular and molecular alterations related to AD, many in vitro studies, in which cells are exposed to amyloid-β peptide, have been performed. Iuvone et al. (2004) investigated the effects of CBD in reversing amyloid-β peptide-induced cell death in cultured rat pheocromocytoma PC12 cells. Pretreatment with CBD significantly increased cell survival, and decreased ROS production, lipid peroxidation, as well as the active form of caspase 3 (a key enzyme in the effector phase of apoptosis) appearance, DNA fragmentation, and reversed increases in intracellular calcium induced by amyloid-β exposure. Those results suggested that antioxidant and antiapoptotic properties may underlie CBD-mediated neuroprotection against amyloid-β toxicity. Another study using PC12 neuronal cells reported that CBD inhibits hyperphosphorylation of tau in amyloid-β-stimulated cells. CBD dose-dependently reversed amyloid-β-induced glicogen synthase kinase 3β (GSK-3β) phosphorylation, and reduction in the expression of β-catenin, suggesting that the effects of CBD in rescuing amyloid-β-challenged PC12 cells are mediated through the Wnt/β-catenin pathway (Esposito, De Filippis, Carnuccio, Izzo, & Iuvone, 2006). In the same line, recently, Janefjord, Måag, Harvey, and Smid (2014) have shown that CBD was able to protect SH-SY5Y cells against amyloid-β_{1-42} neurotoxicity.

Esposito et al. (2011) investigated the effects of CBD on the release of inflammatory mediators induced by amyloid-β challenge in rat primary astroglial cultures. CBD antagonized the enhanced release of the proinflammatory molecules, nitric oxide (NO), interleukin-1β, TNFα, and S100B (S100 calcium binding protein B), and the blockade of peroxisome proliferator-activated receptor-γ (PPARγ) reversed this effect. In the same study, the authors stereotaxically inoculated human amyloid-β into the hippocampus of adult rats that were subsequently treated with chronic CBD. CBD rescued CA1 pyramidal neurons integrity, and downregulated reactive gliosis, as shown by a significant decrease of glial fibrillary acidic protein immunostaining. PPARγ antagonism completely abolished CBD neuroprotective effects. Remarkably, CBD restored neurogenesis in dentate gyrus of amyloid-β injected rat hippocampi through PPARγ activation. These findings provide evidence that the neuroprotective effects of CBD against AD neuroinflammation may be related to PPARγ activation. Along this line, the effects of CBD in a cellular model of AD were investigated using $SHSY5Y^{APP+}$ cells (Scuderi, Steardo, & Esposito, 2013). CBD induced the ubiquitination of amyloid precursor protein (APP), with subsequent reduction of amyloid-β production. In addition, CBD was able to reduce apoptosis, increasing survival of $SHSY5Y^{APP+}$ neurons. Results also indicated that these effects were related to selective activation of PPARγ. PPARs have been recently related to AD (Kitamura et al., 1999), and studies have proposed that CBD translocates into the nucleus, thereby interacting with PPARs (O'Sullivan, Sun, Bennett, Randall, & Kendall, 2009).

Martín-Moreno et al. (2011) investigated the effects of CBD in primary rat microglial cultures. CBD promoted microglial cell migration, and decreased NO generation in the culture media of lipopolysaccharides-stimulated microglia. Migration of microglial cells that may subserve a beneficial function as a requisite for phagocytosing aggregated amyloid-β. They also demonstrated that CBD could rescue spatial memory deficits, tested in the Morris water maze, in amyloid-β-injected mice, and to significantly reduce interleukin-6 mRNA expression, which was markedly increased by amyloid-β injection.

Cheng, Low, Logge, Garner, and Karl (2014) analyzed the effects of chronic CBD in a transgenic mouse model of AD. They used APP/PS1 mutant mice and these animals underwent a behavioral test battery. CBD reversed deficits in social recognition and object recognition displayed by APP/PS1 mice, without affecting fear-associated memory and anxiety-related behavior.

While in vitro and ex vivo studies are useful in the search of cellular and molecular mechanisms associated to CBD's neuroprotective actions, in vivo behavioral studies are essential to identify the potential of this drug in reversing neurofunctional deficits associated with the disease. Table 83.1 summarizes findings from the main behavioral studies investigating the effects of CBD in the context of preclinical models of NDD.

Parkinson's Disease

Parkinson's disease (PD) is the second most common neurodegenerative disease, characterized by a selective degeneration of dopaminergic neurons of the substantia nigra pars compacta, that leads to motor deficits, including tremor, rigidity, bradykinesia, and postural instability (Kim, Ko, Dawson, & Dawson, 2005). The effects of CBD were investigated in the 6-hydroxy-dopamine (6-OHDA) rat model of PD (García-Arencibia et al., 2007). Results showed that CBD administration immediately after the lesion, but not 1 week later, was able to recover 6-OHDA-induced dopamine depletion, and upregulate mRNA levels for Cu,Zn-superoxide dismutase (SOD), a key enzyme in endogenous defenses against oxidative stress, and a representative parameter of the degree of neuronal injury caused by oxidative stress in PD.

Although only a few studies investigated the effects of CBD in preclinical models, CBD was already tested in patients suffering from PD. Zuardi et al. (2009) investigated safety, tolerability, and efficacy of CBD on PD patients. In this study they observed that CBD was able to decrease psychotic symptoms scores evaluated

TABLE 83.1 Summary of Studies Testing the Effects of Cannabidiol (CBD) on Behavioral Parameters

Experimental Model	Regimen of Treatment	Effects	Receptor(s) Involved	References
Ischemic mouse	Pre/postischemia, 1 or 3 mg/kg, intraperitoneally	Improved motor coordination	Not investigated	Hayakawa et al. (2007)
Neonatal hypoxic-ischemic rat	Acute (10 min after ischemia), 1 mg/kg, subcutaneous	Improved motor coordination deficits and short-term recognition memory	Not investigated	Pazos et al. (2012)
Mouse model of Alzheimer's disease (hippocampal amyloid-β injection)	Chronic, 24 h after procedure (first week: daily injection, second and third weeks: 3 days/week), 20 mg/kg, intraperitoneally	Rescued spatial memory deficits	Not investigated	Martín-Moreno et al. (2011)
Mouse model of Alzheimer's disease (APP/PS1 mutant mice)	Chronic (daily/3 weeks prior behavioral tests and 8 weeks in total duration), 20 mg/kg, intraperitoneally	Reversed social recognition and object recognition deficits	Not investigated	Cheng et al. (2014)
Mouse model of multiple sclerosis	Chronic, after infection (daily/10 days), 5 mg/kg, intraperitoneally	Improved motor deficits	Not investigated	Mecha et al. (2013)
Rat model of cognitive impairment induced by iron overload	Acute and chronic, in adult age (daily/2 weeks), 5 or 10 mg/kg, intraperitoneally	Rescued recognition memory deficits	Not investigated	Fagherazzi et al. (2012)

CBD improved motor or cognitive parameters when administered acute or chronically to rodent models of neurodegenerative disorders or hypoxic-ischemia. APP/PS1, amyloid precursor protein/presenilin-1.

by questionnaires in PD patients, but this compound did not affect any cognitive or motor function. Given these positive results, further studies investigating the neuroprotective effects of CBD in PD are warranted.

Huntington's Disease

Huntington's disease (HD) is an inherited NDD characterized by loss of striatal projection neurons, characterized by chorea, cognitive, and psychiatric disturbances involving the basal ganglia and cerebral cortex. HD has been modeled in rodents by lesioning the striatum with the inhibitor of the mitochondrial complex II, 3-nitropropionic acid (3NP) (Kumar, Kalonia, & Kumar, 2010). Administration of CBD completely reversed 3NP-induced reductions in γ-aminobutyric acid (GABA) contents and mRNA levels for substance P, markers of striatal GABAergic projection neurons, neuronal-specific enolase, and SOD-2. This study demonstrated that CBD provided neuroprotection, mediated by cannabinoid receptor-independent antioxidant properties, against 3NP-induced striatal damage, which may be relevant for HD (Sagredo, Ramos, Decio, Mechoulam, & Fernández-Ruiz, 2007).

Multiple Sclerosis

Multiple sclerosis (MS) is an inflammatory and degenerative disease affecting the central nervous system, characterized by demyelination and axonal degeneration (Messina & Patti, 2014). Mecha et al. (2013) investigated the effects of CBD using a viral model of MS. It was observed that CBD reduced the expression of inflammatory molecules, such as vascular cell adhesion molecule-1, chemokines, and the proinflammatory cytokine interleukin-1β, and attenuated microglia activation. CBD has also improved motor deficits. Some of the anti-inflammatory effects were blocked by an A_{2A} adenosine receptor antagonist. This study highlights the potential of CBD for the treatment of neuropathologies with an inflammatory component, such as MS.

OTHER MODELS OF NEURODEGENERATION

Cognitive Impairment Associated to Brain Iron Overload

Rats and mice treated with iron show severe memory impairment, and our research group has been using this animal model to investigate the involvement of iron in NDD-related cognitive impairment, as well as a tool for the search of compounds with therapeutic potential (for a review, see Schröder, Figueiredo, & de Lima, 2013). We have tested the effects of CBD in reversing cognitive dysfunction associated with brain iron overload (Fagherazzi et al., 2012). Male adult rats, treated with iron, received acute or chronic injections of CBD in adulthood, and were tested in the object recognition task. We showed

that CBD rescued recognition memory deficits in iron-overloaded animals (Fig. 83.1).

Subsequently, we decided to investigate the cellular and molecular mechanisms associated with CBD's ability in restoring the damage caused by iron loading in rats, using the same dose previously shown to ameliorate memory deficits associated with iron loading (da Silva et al., 2014). We analyzed proteins involved in mitochondrial fusion and fission mechanisms, which are crucial processes for mitochondrial recycling and survival of healthy mitochondria, synaptophysin, a transmembrane protein of synaptic vesicles, often regarded as a synaptic marker, and caspase 3, an apoptosis-related protein. Iron overload resulted in mitochondrial dynamics imbalance,

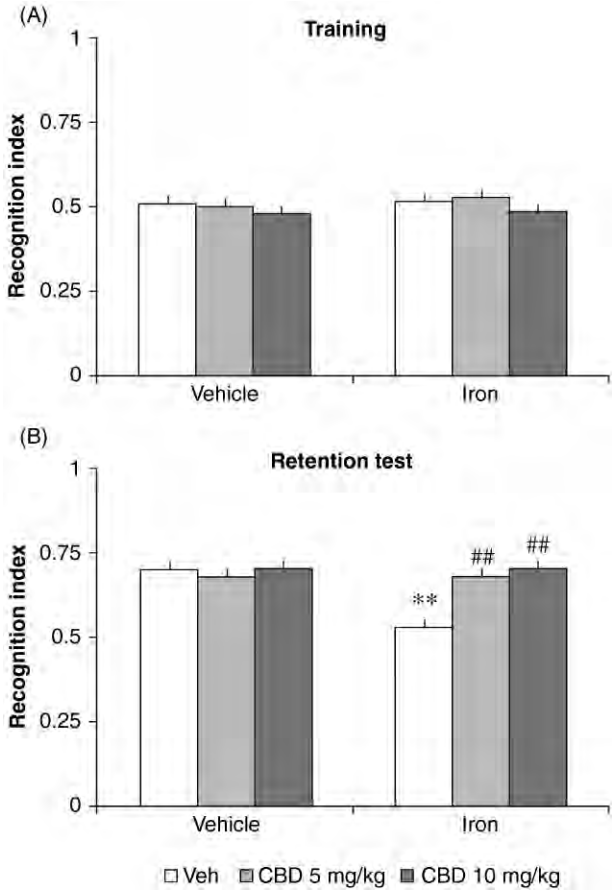

FIGURE 83.1 Effects of chronic CBD on iron-induced recognition memory deficits. Effects of chronic cannabidiol *(CBD)* on iron-induced recognition memory deficits. Recognition indexes in (A) training and (B) retention test session are expressed as mean ± SEM. A daily single injection of vehicle or CBD (5.0 or 10.0 mg/kg) was administered for 14 days. Animals were trained in the object recognition task 24 h after the last injection. N = 12–15 per group. Differences between vehicle–vehicle versus other groups are indicated as $^{**}p < 0.001$; difference between iron–vehicle versus iron–CBD is indicated as $\#\#p < 0.001$. *Adapted from* Springer and Psychopharmacology *(Berlin)*, 219*(4)*, *2012, 1133–1140, "Memory-rescuing effects of cannabidiol in an animal model of cognitive impairment relevant to neurodegenerative disorders." (Fagherazzi et al., 2012, Fig. 3). With kind permission from Springer Science and Business Media.*

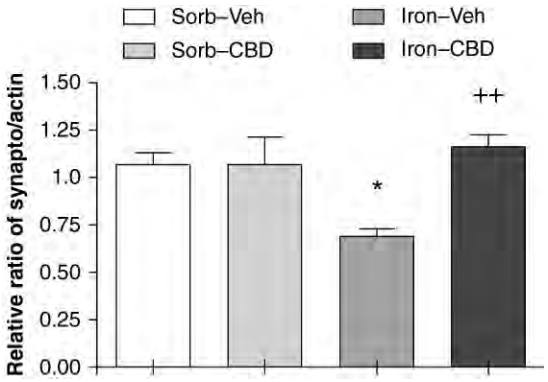

FIGURE 83.2 Effects of chronic CBD on Synaptophysin expression in hippocampus of iron-treated rats. Western blot of synaptophysin in the hippocampus of 3-month-old rats treated with sorbitol *(Sorb)* or iron neonatally, and treated with vehicle *(Veh)* or cannabidiol *(CBD)* chronically; 25 μg of protein, normalized to β-actin, were separated on SDS–PAGE and probed with antisynaptophysin. Statistical analysis was performed using one-way ANOVA followed by Tukey's HSD posthoc. Data expressed as mean ± SEM. N = 4–6/group. $^{*}p < 0.05$, differences between Sorb–Veh versus iron–Veh; $^{++}p < 0.01$, difference between iron–Veh versus iron–CBD. *Adapted from* Springer and Molecular Neurobiology, 49*(1)*, *2014, 222–233, Cannabidiol normalizes caspase 3, synaptophysin, and mitochondrial fission protein DNM1L expression levels in rats with brain iron overload: implications for neuroprotection (da Silva et al., 2014, Fig. 5a). With kind permission from Springer Science and Business Media.*

possibly triggering synaptic loss, expressed as a reduction of synaptophysin levels, and apoptotic cell death, related to increased caspase 3 levels. We found that CBD rescued iron-induced effects, bringing hippocampal synaptophysin levels (Fig. 83.2) and caspase 3 (Fig. 83.3) back to values comparable to the control group. We also showed that CBD was able to restore hippocampal levels of mitochondrial fusion protein, dynamin 1-like (DNM1L) in iron-treated rats. Altogether, our results suggest that CBD should be considered as a potential molecule with memory-rescuing and neuroprotective properties to be used in the treatment of cognitive deficits observed in NDD.

The neuroprotective potential of CBD was evaluated in an animal model of sciatic nerve transection in neonatal rats (Perez et al., 2013). In neonatal rats, transection of a peripheral nerve leads to an intense retrograde degeneration of both motor and sensory neurons, which is prominently related to neuronal loss resulting of apoptotic processes. Neuronal counting revealed both motor and sensory neuron rescue following treatment with CBD. Administration of CBD decreased the astroglial and microglial reaction, and number of apoptotic cells, mostly located in the spinal cord intermediate zone. CBD also induced synaptic preservation within the spinal cord, revealed by synaptophysin staining.

Recently, the effects of transdermal delivery CBD against alcohol-induced neurodegeneration were studied in a rodent model of alcohol use disorder

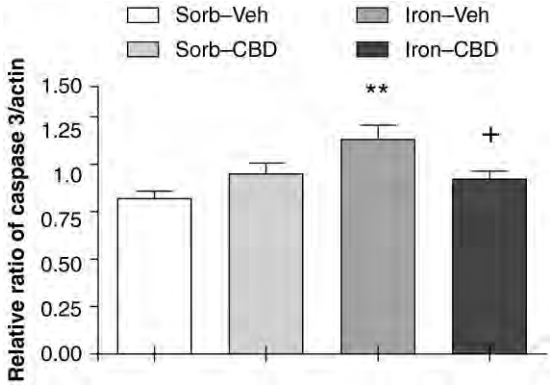

FIGURE 83.3 Effects of chronic CBD on caspase 3 expression in hippocampus of iron-treated rats. Western blot of caspase 3 in the hippocampus of 3-month-old rats treated with sorbitol *(Sorb)* or iron neonatally, and treated with vehicle *(Veh)* or cannabidiol *(CBD)* chronically; 25 μg of protein, normalized to β-actin, were separated on SDS–PAGE and probed with anticaspase 3. Statistical analysis was performed using one-way ANOVA followed by Tukey's HSD posthoc. Data expressed as mean ± SEM. $N = 4–6$/group. $^{**}p < 0.01$, differences between Sorb–Veh versus other groups; $+p < 0.05$, difference between Iron–Veh versus Iron–CBD. *Adapted from* Springer and Molecular Neurobiology, *49(1), 2014, 222–233, Cannabidiol normalizes caspase 3, synaptophysin, and mitochondrial fission protein DNM1L expression levels in rats with brain iron overload: implications for neuroprotection (da Silva et al., 2014; Fig. 7a). (Liput, Hammell, Stinchcomb, & Nixon, 2013). Ethanol exposure resulted in neurodegeneration as indicated by the presence of Fluoro-Jade B positive cells along the entorhinal cortex. Treatment with CBD by either intraperitoneal injection or a second generation transdermal CBD gel resulted in a reduction in Fluoro-Jade B positive cells in the entorhinal cortex following binge ethanol treatment. Although the mechanisms involved in protection against alcohol-induced neurodegeneration are not clear, previous studies had indicated that impairment in mitochondrial function, and subsequent oxidative stress, are likely causal factors contributing to alcohol-induced neurodegeneration. It is possible that CBD attenuates oxidative stress caused by impairments in the mitochondrial electron transport chain.

SUMMARY OF THE MECHANISMS OF ACTION OF CBD

Using in vitro and ex vivo models, it is possible to investigate the molecular and cellular pathways targeted by CBD that mediate its neuroprotective effects. Some studies aimed to elucidate whether CBD's effects were related to its interaction with membrane receptors. Thus, the possibility of blocking CBD's effects by using cannabinoid receptor, adenosine receptor, and serotonin receptor antagonists was investigated. Remarkably, many studies have reported effects of CBD in specific intracellular pathways, which are probably receptor-independent effects. Table 83.2 presents a summary of the in vivo studies investigating the neuroprotective effects of CBD, indicating doses and regimen of treatment, and dependence on membrane receptors, when applicable.

Many studies report the antioxidant properties of CBD in brain tissue or neural cell cultures, using different molecular markers of oxidative stress, such as glutathione/creatine ratio, reduction of oxidative damage to proteins and lipids, assessed by levels of protein carbonylation and lipid peroxidation, respectively, ROS production, and upregulation of enzymatic antioxidant defense, such as SOD. The chemical structure of CBD, including a resorcinol, confers potent antioxidant effects (Mechoulan, Peters, Murillo-Rodriguez, & Hanus, 2007). CBD is also well known for its antiinflammatory actions. In vitro and in vivo studies have shown that CBD reduces numerous inflammatory markers, including cytokines, such as interleukin-6, TNF-α, and interleukin-1β, chemokines, and vascular cell adhesion molecule-1. Reductions in enzymes related to the inflammatory pathway, such as COX-2, and NOS, as well as attenuation of microglia activation were also demonstrated. Excitotoxicity and apoptotic cell death were also demonstrated to be hindered by CBD.

To characterize the transcriptional effects of CBD, Juknat et al. (2012) treated BV-2 microglial cells with CBD, and performed microarray analysis. They identified 1204 differentially expressed genes in response to CBD treatment, which were associated with many different functions, including stress, inflammatory response, membrane transport, adhesion and migration, cell cycle, and proliferation. CBD repressed the expression of an important subset of proinflammatory genes, especially the chemokine ligands, and the chemokine receptor CX-3CR1.

Intracellularly CBD was shown to interact with the GSK-3β pathway, thereby inhibiting hyperphosphorylation of tau, and also to activate nuclear receptors of the PPAR family. Increasing evidence also supports the view that CBD may have protective effects against mitochondrial damage. CBD restored hippocampal levels of a mitochondrial fusion protein, DNM1L, in iron-loaded rats, and increased the activity of mitochondrial complexes (I, II, II–III, and IV) in the rat brain, raising the possibility that CBD modulates brain energy production (Valvassori et al., 2013). CBD was shown to protect SH-SY5Y or cultured hippocampal neurons against the mitochondrial toxin FCCP (carbonyl cyanide-*p*-trifluoromethoxyphenylhydrazone) (Ryan, Drysdale, Lafourcade, Pertwee, & Platt, 2009).

Interestingly, Campos et al. (2013) have shown that CBD was able to significantly increase hippocampal progenitor proliferation and neurogenesis, in mice submitted to chronic unpredictable stress. Experiments

TABLE 83.2 Summary of In Vivo/Ex Vivo Studies Testing Cellular and Molecular Effects of CBD.

Experimental Model	Regimen of Treatment (Effective Dose)	Effects	Receptor(s) Involved	References
Ischemic mouse	Doses injection pre/postischemia, 1 or 3 mg/kg, intraperitoneally	⇩ Infarct volume, ⇧ myeloperoxidase activity	Cannabinoid receptor type 1 and 2-independent	Hayakawa et al. (2007)
Neonatal hypoxic-ischemic pig	Two doses (15/240 min after ischemia), 0.1 mg/kg, intravenous	⇧ Brain activity, ⇩ neuronal damage/astrocytosis in the cortex, ⇩ tumor necrosis factor α positive cells	Not investigated	Lafuente et al. (2011)
Neonatal hypoxic-ischemic pig	Acute (30 min after ischemia), 1 mg/kg, intravenous	⇧ Number of viable neurons, ⇧ brain activity, ⇩ excitotoxicity, ⇩ Oxidative stress, ⇩ Inflammation	Effects dependent on cannabinoid receptor type 2 and serotonin receptor 1A	Pazos et al. (2013)
Neonatal hypoxic-ischemic rat	Acute (10 min after ischemia), 1 mg/kg, subcutaneous	⇩ Excitotoxicity, ⇩ oxidative stress, ⇩ inflammation, ⇩ brain damage	Not investigated	Pazos et al. (2012)
Retinal neurotoxicity in rat	Acute before induced excitotoxicity, 2 mg/kg, intravenous	⇩ Nitrotyrosine formation, ⇩ apoptosis	Not investigated	El-Remessy et al. (2003)
Rat model of Alzheimer's disease (hippocampal amyloid-β injection)	Chronic, after surgery (daily/15 days), 10 mg/kg, intraperitoneally	⇧ Neurons integrity, ⇩ reactive gliosis, ⇧ neurogenesis	Not investigated	Esposito et al. (2011)
Mouse model of Alzheimer's disease (hippocampal amyloid-β injection)	Chronic, 24 h after procedure (first week: daily injection, second and third weeks: 3 days/week), 20 mg/kg, intraperitoneally	⇩ Interleukin 6 expression	Not investigated	Martín-Moreno et al. (2011)
Rat model of Parkinson's disease (6-OHDA)	Chronic, 16 h after procedure (daily/2 weeks) 3 mg/kg, intraperitoneally	⇧ Dopamine, ⇧ levels of Cu,Zn-superoxide dismutase	Cannabinoid receptor-independent	García-Arencibia et al. (2007)
Rat model of Huntington's disease	Chronic, 4 h after first procedure (daily/5 days), 5 mg/kg, intraperitoneally	⇩ Striatal degeneration	Effects dependent on cannabinoid receptor type 1/transient receptor potential vanilloid 1/ adenosine A_{2A}-receptor-independent	Sagredo et al. (2007)
Mouse model of multiple sclerosis	Chronic, after infection (daily/10 days), 5 mg/kg, intraperitonealy	⇩ Expression of inflammatory molecules, ⇩ microglia activation	Effects dependent on A_{2A} adenosine receptor	Mecha et al. (2013)
Rat model of cognitive impairment induced by iron overload	Chronic in adult age (daily/2 weeks), 10 mg/kg, intraperitoneally	⇩ Hippocampal caspase 3, ⇧ hippocampal synaptophysin, ⇧ hippocampal dynamin-1-like protein	Not investigated	da Silva et al. (2014)
Rat model of sciatic nerve transection	Chronic, after transection (daily/5 days), 15 or 30 mg/kg, intraperitoneally	⇧ Motor and sensory neuron intregality, ⇩ astrogliosis and microgliois, ⇩ apoptotic cells, ⇧ synaptic preservation	Not investigated	Perez et al. (2013)
Rat model of alcoholism	Chronic, after 3rd ethanol dose (transdermal: daily/3 days; intraperitoneally: twice a day/3 days), 2.5 or 5%, transdermal gel; 20 mg/kg, intraperitoneally	⇩ Fluoro-Jade B positive cells in the entorhinal cortex	Not investigated	Liput et al. (2013)
Energetic metabolism in rat	Acute and chronic (daily/2 weeks), 15, 30, or 60 mg/kg, intraperitoneally	⇧ Activity of mitochondrial complexes (I, II, II–III and IV), ⇧ creatine kinase	Not investigated	Valvassori et al. (2013)
Mouse model of chronic unpredictable stress	Chronic, 2 h after daily stress (daily/2 weeks), 30 mg/kg, intraperitoneally	⇧ Neurogenesis	Not investigated	Campos et al. (2013)

Summary of studies designed to investigate cellular and molecular aspects of neuroprotective effects of CBD. CBD displays antiapoptotic, antiinflammatory, and antioxidant properties. CBD also reduces excitotoxicity, reactive astrocytosis, and improves brain activity and neuronal survival, synaptic and mitochondrial parameters, and neurogenesis. (6-OHDA: 6-hydroxydopamine; CBD, cannabidiol.)

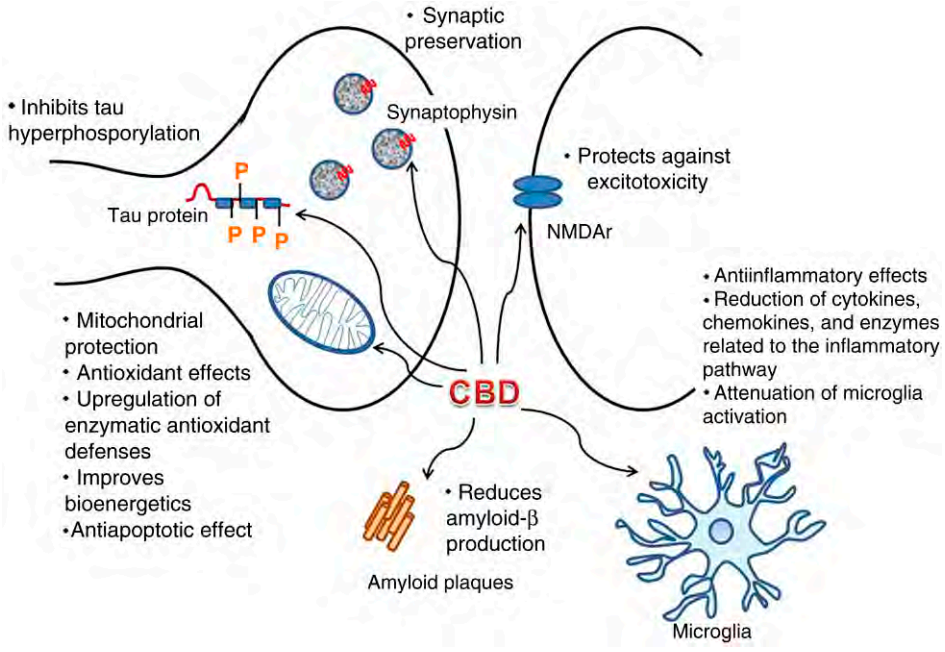

FIGURE 83.4 Summary of the main mechanisms of action of CBD. Using in vitro and ex vivo approaches, studies have shown that cannabidiol *(CBD)* exhibits antioxidant, antiinflammatory, and antiapoptotic effects. CBD was also demonstrated to exert a protective action on mitochondria, thus preserving energy production. CBD prevents synaptic loss, demonstrated by the maintenance of the synaptic marker, synaptophysin. CBD also prevents hyperphosphorylation of tau and amyloid-β production, and protects against excitotoxic cell death. *NMDAr*, NMDA receptor.

conducted with hippocampal progenitor cells in culture showed that CBD promoted progenitor proliferation and cell cycle progression, and mimicked the proliferative effect of CB1 and CB2 cannabinoid receptor activation, supporting the view that CBD may promote neurogenesis in the hippocampus.

Fig. 83.4 summarizes the putative mechanisms of action of CBD.

CONCLUSIONS

Despite the fact that the mechanisms of action of CBD are not fully understood, a great deal of evidence suggests that, by protecting against oxidative damage and neuroinflammation, and possibly by protecting the mitochondria, thereby maintaining energy supply, CBD may provide resistance against synaptic loss, and subsequent cell death. Neurodegeneration is considered a multifactorial process, involving oxidative stress, energetic failure, and synaptic dysfunction that may ultimately culminate in cell death. CBD combines multitarget pharmacological properties that might make it a promising candidate compound for the prevention/treatment of NDD.

Since CBD has been already tested in humans (Consroe et al., 1991; Zuardi et al., 2009) showing safety, with no toxic side effects, and while preclinical tests continue, in order to provide a better understanding of mechanisms, clinical tests with CBD should proceed, perhaps as a multitarget drug for the treatment of NDD.

MINI-DICTIONARY

Excitotoxic damage Damage resulting from excessive glutamate release and membrane depolarization associated to stimulation of NMDA receptors, which mediate an increase in intracellular calcium levels. Calcium activates enzymes involved in the catabolism of proteins, phospholipids, and nucleic acids.

Oxidative stress Imbalance between ROS production and a biological system's ability to remove or repair damage caused by ROS.

Apoptotic cell death A type of programmed cell death, characterized by ordered cellular destruction without inflammatory response, having an important role in development and tissue homeostasis; however, deregulation in this process results in pathological conditions.

Rota-rod Equipment used to evaluate motor behavior, including balance, coordination, and motor learning in rodents, particularly to test experimental drugs' effects, analyze brain damage, and diseases. In this performance test, rodents are placed on a rotating rod with a controlled speed.

Astrocytosis An abnormal increase in the number of astrocytes, in response to all forms of central nervous system injury and disease.

Object recognition Behavioral test used to evaluate the recognition memory in rodents, based on the proportion of time that the animal explores a novel object, when presented together with a familiar object.

PPARs Ligand-activated transcription factors belonging to the nuclear receptor superfamily. They play an essential role in energy homeostasis and other important biological processes, such as inflammation, cell proliferation, and differentiation.

APP/PS1 mutant mice Mice carrying mutations in amyloid precursor protein (APP) and presenilin-1 (PS1) genes, known as a double transgenic AD model.
6-OHDA model of PD 6-hydroxydopamine is a neurotoxic synthetic compound involved in massive destruction of nigrostriatal dopaminergic neurons, widely used to induce parkinsonism in laboratory animals.
Fluoro-Jade B positive cells Fluoro-Jade staining, an anion derived from fluorescein and highly acidic, is a specific marker for neurons that are in the process of degeneration.

SUMMARY POINTS

- Three major phytocannabinoids, Δ^9-Tetrahydrocannabinol (Δ^9-THC), cannabidiol (CBD), and cannabinol (CBN), inhibit the catalytic activities of CYP1 enzymes.
- CBD is a potent CYP1A1 inhibitor.
- CBN is a potent inhibitor of CYP1A2 and CYP1B1.
- CBD is a potent mechanism-based inhibitor of CYP1A1.
- The torsionable structure and two phenolic hydroxyl groups have important roles in the interaction between CBD and CYP1A1.
- Two phenyl rings are important for the interactions between CBN and CYP1A2 and CYP1B1.
- CBD may be a promising lead candidate for anticancer drugs, due to its inhibition of CYP1 enzymes.

KEY FACTS FOR THE INHIBITION OF CYP1 ENZYMES BY PHYTOCANNABINOIDS

- Three major phytocannabinoids (Δ^9-THC, CBD, and CBN) inhibit the catalytic activities of CYP1 enzymes.
- CBD is a potent inhibitor of CYP1A1, and its inhibitory potency is similar to those of 2,4,3′,5′-tetramethylstilbene and rhapontigenin.
- CBN is a potent inhibitor of CYP1A2 and CYP1B1. The inhibitory potency of CBN for CYP1A2 is similar to that of fluvoxamine, while that for CYP1B1 is markedly higher than those of *trans*-resveratrol and flutamide.
- CBD is a potent mechanism-based inhibitor of CYP1 enzymes, and its K_{inact}/K_I value for CYP1A1 is similar to that of rhapontigenin.

THC Tetrahydrocannabinol

INTRODUCTION

The three major phytocannabinoids, Δ^9-tetrahydrocannabinol (Δ^9-THC), cannabidiol (CBD), and cannabinol (CBN), are highly lipophilic compounds that are distributed in the membrane fractions of animal tissues in vivo. Thus, these cannabinoids are efficiently metabolized by drug-metabolizing enzymes involving cytochrome P450 (CYP) (Agurell et al., 1986; Harvey, 1984; Huestis, 2005; Yamamoto, Watanabe, Narimatsu, & Yoshimura, 1995). Hundreds of metabolites have been identified for these cannabinoids, some of which are known to be active metabolites that contribute to their biological effects, particularly in the case of Δ^9-THC. CYP2C9, CYP2C19, and CYP3A4 were found to be mainly involved in the metabolism of the three major phytocannabinoids in the human liver (Jiang, Yamaori, Okamoto, Yamamoto, & Watanabe, 2013; Watanabe, Matsunaga, Yamamoto, & Yoshimura, 2005; Watanabe, Yamaori, Funahashi, Kimura, & Yamamoto, 2006; Watanabe, Yamaori, Funahashi, Kimura, & Yamamoto, 2007). A high-affinity substrate of CYPs could be a strong inhibitor of the corresponding CYP enzymes (Hollenberg, 2002). These major cannabinoids were previously shown to inhibit CYP-mediated drug metabolism in experimental animals, both in vitro and in vivo (Hamajima et al., 1983; Paton & Pertwee, 1972; Siemens, Kalant, Khanna, Marshman, & Ho, 1974; Watanabe, Hamajima, Narimatsu, Yamamoto, & Yoshimura, 1986; Watanabe, Arai, Narimatsu, Yamamoto, & Yoshimura, 1987; Watanabe, Narimatsu, Gohda, Yamamoto, & Yoshimura, 1988). These findings suggested that these cannabinoids in marijuana may cause pharmacokinetic alterations to other coadministered drugs, and also that more attention should be paid to marijuana (or cannabinoid)-drug interactions, in some cases. The drug interactions that can potentially occur between cannabinoids (or cannabis) and other drugs have been attributed to changes in pharmacokinetics (Benowitz, Nguyen, Jones, Herning, & Bachman, 1980; Chetty, Miller, & Moodley, 1994; Jusko, Schentag, Clark, Gardner, & Yurchak, 1978; Roth et al., 2001). Our research group more recently systematically evaluated the inhibitory potencies of the major phytocannabinoids on human CYP enzymes (Yamaori, Kushihara, Yamamoto, & Watanabe, 2010; Yamaori, Maeda, Yamamoto, & Watanabe, 2011; Yamaori, Ebisawa, Okushima, Yamamoto, & Watanabe, 2011a; Yamaori, Okamoto, Yamamoto, & Watanabe, 2011c; Yamaori et al., 2012, 2013; Yamaori, Okushima, Yamamoto, & Watanabe, 2014; Jiang et al., 2013).

The human CYP 1 family consists of three members: CYP1A1, CYP1A2, and CYP1B1. CYP1A2 is almost exclusively expressed in the liver, while CYP1A1 and CYP1B1 are expressed in extrahepatic tissues (Shimada et al., 1996). CYP1A2 has been shown to play an important role in the metabolism of caffeine and melatonin, as well as many marketed drugs (Agundez, 2004; Ding & Kaminsky, 2003). CYP1A1 and CYP1B1 are responsible for the metabolic activation of polycyclic aromatic hydrocarbons, heterocyclic amines, and estradiol to carcinogenic intermediates (Shimada & Fujii-Kuriyama, 2004; Sissung, Price, Sparreboom, & Figg, 2006). The 4-hydroxylation of estradiol by CYP1 enzymes is known to be critical for estrogen-related carcinogenesis, such as breast cancer (Badawi, Cavalieri, & Rogan, 2001; Chun & Kim, 2003). A growing body of research has indicated that the overexpression of CYP1 enzymes, in particular CYP1B1, in several tumor cells may be used as a novel target for anticancer chemotherapy (Purnapatre, Khattar, & Saini, 2008; Androutsopoulos et al., 2013).

Human CYP1 enzymes are able to metabolize cannabinoids, while these were not the main enzymes responsible for cannabinoid metabolism in the human liver (Watanabe et al., 2007; Jiang, Yamaori, Takeda, Yamamoto, & Watanabe, 2011). In this review, we summarized the inhibitory potencies of Δ^9-THC, CBD, and CBN on human CYP1 enzymes, with a focus on drug interactions caused by marijuana, as well as the implications of the potent inhibition of CYP1 enzymes by the major phytocannabinoids.

INHIBITION OF CYP1 ENZYMES BY MAJOR PHYTOCANNABINOIDS

CYP1 enzymes are not the main enzymes responsible for metabolizing cannabinoids in mammalian species. Therefore, a limited amount of research has been undertaken to evaluate the ability of cannabinoids to induce or inhibit CYP1 enzymes. In an earlier study, Witschi and Saint-Francois (1972) reported that the oral administration of Δ^9-THC to rats caused a threefold increase in the activity of arylhydrocarbon hydroxylase, which is a marker of CYP1 activity, in lung homogenates. Roth et al. (2001) demonstrated that marijuana tar and Δ^9-THC induced CYP1A1 mRNA in murine Hepa-1 cells, while the 7-ethoxyresorfin *O*-deethylase (EROD) assay, a typical marker of CYP1 activity, revealed that Δ^9-THC competitively inhibited CYP activity. However, the interactions between cannabinoids and human CYP1 enzymes have not yet been examined in detail. We recently demonstrated that

the three major phytocannabinoids, Δ^9-THC, CBD, and CBN, could inhibit recombinant human CYP enzymes (Yamaori et al., 2010, 2011a, 2011b, 2011c, 2012, 2013, 2014; Jiang et al., 2013), in particular CYP1 enzymes (Table 84.1). Among the three cannabinoids, CBD showed the highest inhibitory effect on CYP1A1 (K_i = 0.155 μM), whereas CBN showed the highest inhibitory effect on CYP1A2 (K_i = 0.0790 μM), and CYP1B1 (K_i = 0.148 μM). Table 84.2 summarizes the K_i values of known CYP1A1 inhibitors (Chang, Chen, & Lee, 2001; Chang, Chen, & Yeung, 2006; Chun, Ryu, Jeong, & Kim, 2001b; Pastrakuljic, Tang, Roberts, & Kalow, 1997; Rochat, Morsman, Murray, Figg, & McLeod, 2001) with those of the three phytocannabinoids. When compared to known inhibitors of CYP1 enzymes, the inhibitory potency of CBD toward human CYP1A1 was similar to those of 2,4,3′,5′-tetramethylstilbene (Chun, Kim, Kim, Lee, & Guengerich, 2001a) and rhapontigenin (Pastrakuljic et al., 1997), which are known to be potent CYP1A1 inhibitors with K_i values of 0.130 and 0.210 μM, respectively. The inhibitory potency of CBN was markedly higher than that of *trans*-resveratrol. The K_i value of Δ^9-THC was markedly lower than those of isosafrole and fluvoxamine, which are typical CYP1A1 inhibitors. Table 84.3 summarizes the K_i values of known CYP1A2 inhibitors (Chang et al., 2001, 2006; Langouet et al., 2000; Pastrakuljic et al., 1997; Rochat et al., 2001; Yao, Chang, Lan, & Yeh, 2008) with those of the three phytocannabinoids. The inhibitory potency of CBN toward human CYP1A2 was similar to that of fluvoxamine (Pastrakuljic et al., 1997), which is a potent CYP1A2 inhibitor, and more effective than kaempferol (K_i = 0.109 μM) and isorhamnetin (K_i = 0.137 μM) (Chang et al., 2006). The inhibitory potencies of Δ^9-THC and CBD were lower than those of isosafrole, quercetin, and flutamide. Table 84.4 summarizes the K_i values of known CYP1B1 inhibitors (Chang et al., 2001, 2006; Roberts et al., 2004; Rochat et al., 2001; Sparfel, Van Grevenynghe, Le Vee, Aninat, & Fardel, 2006) with those of the three phytocannabinoids. The K_i value of CBN for the inhibition of CYP1B1

TABLE 84.4 Comparison of K_i Values for Inhibition of the EROD Activity of Human CYP1B1 by the Major Phytocannabinoids and Other CYP1B1 Inhibitors

Inhibitors	K_i (nM)	References
Isorhamnetin	3	Chang et al. (2006)
2,4,3′,5′-Tetramethoxystilbene	3	Chun et al. (2001a)
Pifithrinα	4	Sparfel et al. (2006)
Kampferol	14	Chang et al. (2006)

Paclitaxel	31,600	Rochat et al. (2001)

was markedly lower than those of *trans*-resveratrol (K_i = 0.8 μM) (Chang et al., 2001) and flutamide (K_i = 1 μM) (Rochat et al., 2001), but higher than those of isorhamnetin, 2,4,3′,5′-tetramethoxystilbene, kampferol, and quercetin. The K_i values of Δ^9-THC and CBD were similar to those of doxorubicin and daidzein, respectively, but lower than those of tamoxifen and paclitaxel.

However, the inhibitory potencies of these cannabinoids toward human CYP1 enzymes were markedly less potent than that of α-naphthoflavone (K_i = 2 nM), the most potent inhibitor of CYP1 enzymes (Shimada et al., 1998; Pastrakuljic et al., 1997; Liu, Sridhar, & Foroozesh, 2013) (Tables 84.2 and 84.3).

MECHANISM-BASED INHIBITION OF CYP1 ENZYMES BY MAJOR PHYTOCANNABINOIDS

Earlier studies suggested that the inhibitory effects of CBD on liver microsomal drug-metabolizing enzymes may be attributed to the formation of inhibitory metabolites (Bornheim & Grillo, 1998; Karler, Sangdee, Turkanis, & Borys, 1979; Narimatsu et al., 1990; Watanabe et al., 1987, 1988). CBD is known to decrease mouse liver CYPs in a metabolism-dependent manner, while active species of CBD metabolites have not yet been specified (Watanabe et al., 1987, 1988). Δ^9-THC, CBD, and CBN are

TABLE 84.5 Kinetic Parameters for the Mechanism-Based Inhibition of Human CYP1 Enzymes by the Major Phytocannabinoids

Cannabinoids	Enzymes	K_{inact} (min^{-1})	K_i (μM)	K_{inact}/K_i (L/mmol/min)
Δ^9-THC	CYP1A1	0.0239	1.22	19.6
CBD	CYP1A1	0.316	0.585	540
	CYP1A2	0.109	3.09	35.3
	CYP1B1	0.0267	2.12	12.6
CBN	CYP1A1	0.0191	0.0856	223

able to inhibit recombinant human CYP1 enzymes in a metabolism-dependent manner (Table 84.5) (Yamaori et al., 2010). CBD inhibited EROD activities by the three CYP1 enzymes, in preincubation time- and concentration-dependent manners, whereas Δ^9-THC and CBN only inhibited EROD activity by CYP1A1, in a metabolism-dependent manner. The K_i values of CBD for the inactivation of CYP1A1, CYP1A2, and CYP1B1 were 0.585, 3.09, and 2.12 μM, respectively. CBD showed the highest K_{inact} value for the inactivation of CYP1A1 (0.316 min^{-1}), among the CYP enzymes and phytocannabinoids investigated. The K_{inact} values of Δ^9-THC and CBN for CYP1A1 were 13- and 17-fold lower, respectively, than that of CBD. CBD for the inactivation of CYP1A1 showed the highest ratio of K_{inact} to K_i (540 L/mmol/min), followed by CBN (223 L/mmol/min). The alkyl resorcinol structure of CBD was previously shown to be important for the inactivation of CYP1A1 by the cannabinoid (Yamaori et al., 2014). Thus, CBD is a potent mechanism-based inhibitor of CYP1 enzymes, and its K_{inact}/K_i value for CYP1A1 was shown to be similar to that of rhapontigenin (K_{inact}/K_i value = 667 L/mmol/min) (Shimada et al., 2007).

INTERACTIONS BETWEEN MAJOR PHYTOCANNABINOIDS AND CYP1 ENZYMES

The structures of CYP1A2 and CYP1B1 could be constructed using the crystallographic data of the complex between α-naphthoflavone and CYP1 enzymes (Sansen et al., 2007; Wang, Savas, Stout, & Johnson, 2011). The conformations of the three cannabinoids have been constructed using the Insight II/Search-Compare module on a SGI Indigo 2 workstation. The amino acid residues at the catalytic sites of the CYP1 enzymes were drawn using RasMol version 2.6-ucb-1.0, as reported previously (Masuda et al., 2005). Possible interactions between the three major phytocannabinoids and CYP1 enzymes could be searched for using this model (Fig. 84.1). In the case of CYP1A1, the phenyl ring of the three cannabinoids could form a stacking interaction with

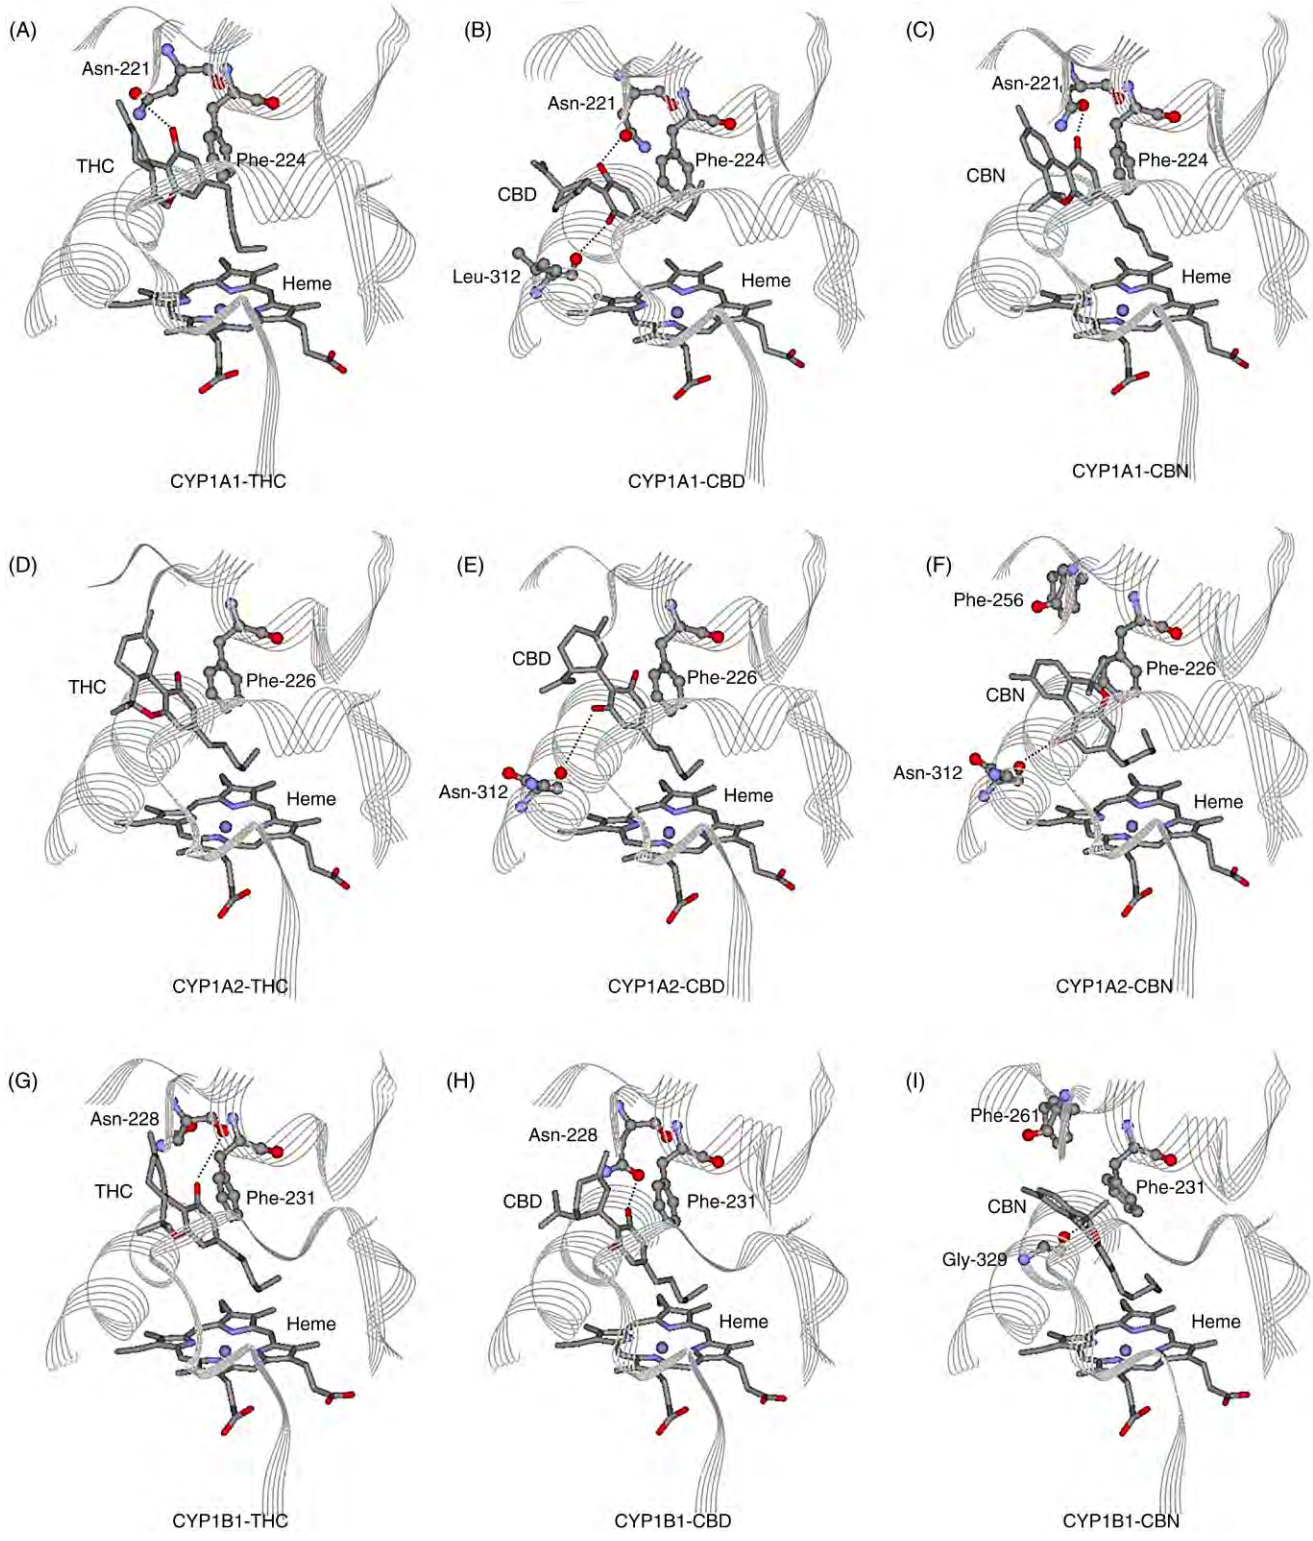

FIGURE 84.1 Proposed models for the interactions between the major phytocannabinoids and amino acid residues in the active-site cavity of humanCYP1 enzymes. (A) CYP1A1-Δ^9-THC, (B) CYP1A1-CBD, (C) CYP1A1-CBN, (D) CYP1A2-Δ^9-THC, (E) CYP1A2-CBD, (F) CYP1A2-CBN, (G) CYP1B1-Δ^9-THC, (H) CYP1B1-CBD, (I) CYP1B1-CBN.

Phe-224, and a hydrogen bond with Asn-221 (the calculated distances for hydrogen bonding were 2.53–3.57 Å) (Fig. 84.1A–C). CBD had two phenolic hydroxyl groups, one of which was able to form an additional hydrogen bond with the carbonyl group of Leu-312 (the calculated distance for hydrogen bonding was 3.72 Å) (Fig. 84.1B). In the case of CYP1A2, the phenyl ring of the three cannabinoids may form a stacking interaction with Phe-226 (Fig. 84.1D–F). In addition, another phenyl ring of CBN could make a stacking interaction with Phe-256, in the catalytic site of CYP1A2 (Fig. 84.1F). In the same manner as CYP1A2, the phenyl ring of the three cannabinoids formed a stacking interaction with Phe-231, and their phenolic hydroxyl groups formed a hydrogen bond with Asn-228 for Δ^9-THC and CBD (Fig. 84.1G and H), or Gly-329 for CBN (Fig. 84.1I) (the calculated distances for hydrogen bonding were 2.70–3.72 Å) in the active site of CYP1B1 (Fig. 84.1G–I). In addition, another phenyl ring of CBN could provide additional stabilization by a stacking interaction with Phe-261, in the active site of CYP1B1 (Fig. 84.1I). These multiple stabilizations of CBD (CYP1A1) and CBN (CYP1A2 and CYP1B1) within the catalytic site of CYP enzymes suggest that these cannabinoids act as strong inhibitors of particular CYP1 enzymes.

SIGNIFICANCE OF CYP1 INHIBITION BY MAJOR PHYTOCANNABINOIDS

The potent inhibition of CYP1 enzymes by these cannabinoids indicated that cannabinoid-mediated drug interactions may occur. The peak plasma levels of the three major cannabinoids were previously reported to be from 84.3 ng/mL (268 nM) to 126 ng/mL (406 nM) after smoke inhalation from a marijuana cigarette containing these cannabinoids (15.8–20 mg) (Huestis, Henningfield, & Cone, 1992; Johansson et al., 1987; Ohlsson et al., 1984). In clinical settings using treatments with Marinol or Sativex (http://www.marinol.com/; http://www.bayer.ca/), the C_{max} values of Δ^9-THC and CBD were shown to be from 3.02 ng/mL (9.62 nM) to 7.88 ng/mL (25.1 nM) in healthy humans. Δ^9-THC may not cause a significant drug interaction through CYP1 enzymes because the K_i values of Δ^9-THC were found to be markedly higher than the blood concentrations of the cannabinoid, as reported in previous studies. The K_i values of CBD for CYP1A1, and those of CBN for CYP1A2 and CYP1B1, were markedly lower than the blood levels of these cannabinoids, after smoking marijuana, but were slightly higher than the blood concentrations of CBD in the clinical settings described previously. These cannabinoids have high lipid solubility, and are known to be selectively distributed in various tissues, in particular the membrane fractions. Thus, the local tissue concentrations of these cannabinoids may be markedly higher than the blood concentrations in particular cases. These findings suggested that the inhibition of CYP1 enzymes by CBD and CBN may exert a cannabinoid-drug interaction through CYP1 enzymes.

CYP1 enzymes are able to activate procarcinogens, such as polycyclic aromatic hydrocarbons, heterocyclic amines, aromatic amines, and nitropolycyclic hydrocarbons, in metabolic reactions, resulting in the formation of highly mutagenic compounds. CYP1A1 and CYP1B1 have also been shown to be expressed in certain cancer cells, and are known to be involved in the regulation of tumor development (Androutsopoulos et al., 2013). CYP1B1 also plays an important role in the metabolism of estradiol to 4-hydroxyestradiol, which is a reactive metabolite that plays a critical role in estrogen-mediated carcinogenesis (Liehr & Ricci, 1996; Guengerich, Chun, Kim, Gillam, & Shimada, 2003). In addition, CYP1B1 was suggested to be involved in angiotensin-induced hypertension, and the resulting renal failure (Jennings et al., 2012), as well as in the pathogenesis of glaucoma, and other anterior segment dysgenesis disorders (Vasiliou & Gonzalez, 2007). These findings suggested that the inactivation of CYP1A1 and CYP1B1 may be a potential target of chemopreventive agents (Badal & Delgoda, 2013; Purnapatre et al., 2008; Sissung et al., 2006). Previous studies reported that resveratrol exhibited anticancer properties (Chang et al., 2001; Jang et al., 1997), whereas its inhibitory potency for CYP1A1 and CYP1B1 was less effective than those of CBD and/or CBN, respectively. Therefore, potent and selective inhibitors of CYP1 enzymes, such as CBD and CBN, may represent a new class of anticancer agents. CBD, in particular, which is a potent mechanism-based inhibitor of CYP1A1, may be a promising candidate as a lead compound of chemopreventive drugs.

MINI-DICTIONARY

CYP1A1 A member of the CYP1 family, which is expressed in extrahepatic tissues, and catalyzes the oxidation of granisetron and dacarbazine as well as the bioactivation of carcinogenic polycyclic aromatic hydrocarbons and heterocyclic amines.
CYP1A2 A member of the CYP1 family that is principally expressed in the human liver, and contributes to the bioactivation of carcinogenic aromatic and heterocyclic amines, as well as the metabolism of caffeine, flutamide, lidocaine, melatonin, phenacetin, and theophylline.
CYP1B1 A member of the CYP1 family that is expressed in extrahepatic tissues, and overexpressed in many cancer cells. It is involved in the metabolic activation of carcinogens, such as polycyclic aromatic hydrocarbons, and heterocyclic amines.
Insight II A graphical modeling program developed by Accelrys, Inc. In conjunction with the use of Discover, a dynamic manipulation of a molecular system can be achieved.
K_{inact} The maximal rate of enzyme inactivation at the saturating concentration of an inhibitor.
K_i value The concentration of an inhibitor that achieved half the

maximal rate of inhibition.

Mechanism-based inhibition Irreversible or quasi-irreversible loss of enzyme function when a substrate binds to an enzyme by irreversible or stable complex formation during the catalytic reaction of the enzyme.

α-Naphthoflavone A typical and strong inhibitor of CYP1 enzymes and CYP19, also known as 7,8-benzoflavone.

Phytocannabinoids A series of lipophilic compounds composed solely of carbon, hydrogen, and oxygen, which are the constituents of *cannabis*, and biosynthesized by corresponding synthases in the plant.

****Division on Substance Abuse, New York State Psychiatric Institute and Department of Psychiatry, College of Physicians and Surgeons of Columbia University, New York, NY, United States**

SUMMARY POINTS

- Nabilone (Cesamet), a synthetic analog of Δ^9-tetrahydrocannabinol (Δ^9-THC) developed in the early 1970s, is approved for the treatment of nausea and vomiting suffered by cancer patients undergoing chemotherapy.
- Nabilone is a potent cannabinoid receptor agonist with high oral bioavailability, and a long duration of action suitable for once or twice daily dosing (1–2 mg).
- At higher doses (3–8 mg), nabilone can produce moderate cognitive impairment, and feelings of "high"and "drug effect" similar to that of THC.
- In individuals with cannabis use disorder, laboratory studies suggest nabilone may have utility as a treatment for cannabis withdrawal and relapse.
- Nabilone is effective in treating pain and insomnia in some patients with chronic pain conditions though it has not been shown effective as an analgesic for acute pain.
- Nabilone has also shown promise for the treatment of dyskinesia resulting from Huntington disease, spinal cord injury, and levodopa treatment in patients with Parkinson disease.
- Finally, nabilone may have utility for long-term management of anxiety, but not for the treatment of acute anxiety.

KEY FACTS

- Nabilone is an orally available, synthetic analog of THC with better potency, bioavailability, and a longer duration of action than dronabinol (perhaps due to an active metabolite).
- Although nabilone produces some subjective intoxication and increased heart rate, its slow rate of onset relative to smoked cannabis results in low abuse liability.
- Placebo-controlled studies demonstrate nabilone can be used in the treatment of chronic and neuropathic pain.
- Placebo-controlled research are needed to demonstrate nabilone's potential efficacy for the treatment of cannabis use disorder, posttraumatic stress disorder, insomnia, and dyskinesias.

ABBREVIATIONS

cAMP	Cyclic adenosine monophosphate
CB1 and CB2	Cannabinoid receptor 1 and 2
GABA	Gamma-aminobutyric acid
GTPγS	Guanosine 5′-O-[gamma-thio] triphosphate
POMS	Profile of mood states
PTSD	Posttraumatic stress disorder
Δ9-THC	Δ9-Tetrahydrocannabinol

INTRODUCTION

Medical uses of cannabis and cannabinoids, the primary psychoactive chemicals in the *Cannabis sativa* plant, are a topic of great interest and continued debate. Although the arc of science points toward the potential benefits of this class of compounds, controlled clinical studies are clearly needed. Currently, there are two oral cannabinoids available for medical use and research: dronabinol, a synthetic Δ9-tetrahydrocannabinol (Δ9-THC), and nabilone, a synthetic analog of THC. In 1985, the United States Food and Drug Administration (FDA) approved nabilone, marketed as Cesamet, for the treatment of nausea and vomiting suffered by cancer patients undergoing chemotherapy. The Medicines and Healthcare Products Regulatory Agency (MHRA) in the United Kingdom licensed nabilone in 1995. Compared to dronabinol, nabilone has a higher bioavailability and a longer duration of action (Ben Amar, 2006; Glass, Uhlenhuth, & Hartel, 1979; Lemberger et al., 1982; Matsuda, Lolait, Brownstein, Young, & Bonner, 1990; McGilveray, 2005). Nabilone's most common adverse effects, such as drowsiness, dry mouth, intoxication, vertigo, and tachycardia, are generally mild enough, so as to not prevent continued use. Beyond extensive research of nabilone's use as an antiemetic, it has been evaluated for use in a number of other medical and psychiatric conditions. The objective of this chapter is to describe the potential utility of nabilone for a range of disorders: cannabis use disorder, analgesia, motor disorders, and anxiety.

PHARMACOLOGY

Nabilone was developed in the early 1970s by Lilly Research Laboratories, and its synthesis is described by Archer et al. (1977). Nabilone's structure is quite similar to that of THC (Fig. 85.1). Both compounds are dibenzopyrans, with a dimethyl at the 6 position, and a hydroxyl at the 1 position. Unlike THC, nabilone has a dimethylheptyl side chain at the 3 position, a saturated ring with no double bond in the 9–10 position, and a ketone group rather than a methyl group in the 9 position. Because of these structural differences, nabilone is not converted into THC or vice versa (Stark, 1982). Further, nabilone administration does not produce a positive urine toxicology result for THC (Fraser & Meatherall, 1989).

Nabilone is a potent cannabinoid agonist and binds with high affinity to both the CB1 and CB2 cannabinoid receptors, with dissociation constants of 2.2 and 1.8 nM, respectively (Gareau et al., 1996). Across most measures, 1 mg of nabilone is equivalent to approximately 7 mg of dronabinol (Johnson & Jasinski, 1983). In addition to high binding affinity, nabilone is more efficacious than THC, producing greater cAMP inhibition and [^{35}S]GTPγS binding than THC, in mouse brain tissue (Matsuda et al., 1990; Baillie, Ross, & Pertwee, 2010).

Lemberger and Rowe (1975) provide the first description of nabilone administration to healthy human subjects, showing that the onset of behavioral effects begin at about 1 h after dosing, and last for 8–9 h. Five milligram of nabilone produced dry mouth, euphoria, tachycardia, and postural hypotension. These effects were minimal at 2.5 mg, and absent at 1 mg. All doses produced relaxation and sedative effects. Tolerance to side effects developed following 3 days of dosing. The findings from this early study are fairly consistent with the results from later work, although side effects have been reported at 1 and 2 mg doses, in some studies (Ware, Daeninck, & Maida, 2008). However, side effects generally do not seem to deter patients from continuing to take nabilone.

Following oral administration, nabilone is readily absorbed, and has a short plasma half-life of approximately 2 h (Rubin et al., 1977). However, the metabolites of

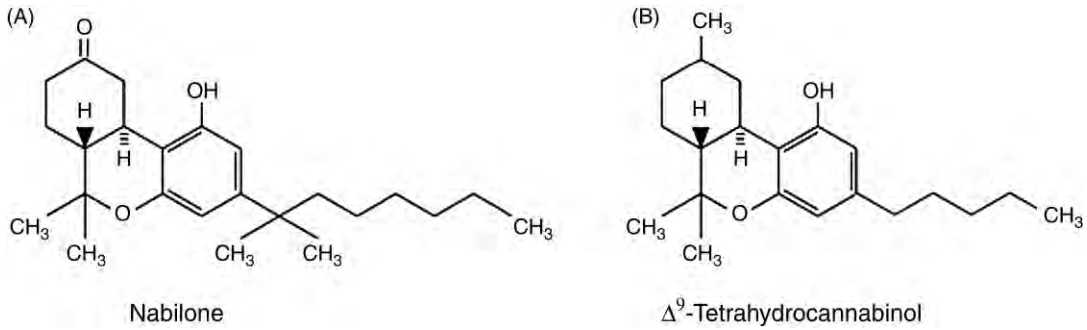

FIGURE 85.1 Nabilone and Δ9-tetrahydrocannabinol (THC). Chemical structures for nabilone (left) and THC (right).

nabilone, including isomeric carbinols, persist in plasma with a half-life of over 20 h. The long duration of action of nabilone, despite rapid metabolism, suggests that at least one or more of these metabolites are pharmacologically active (Rubin et al., 1977).

COGNITIVE AND SUBJECTIVE EFFECTS

A series of studies has also sought to better understand the cognitive and subjective effects of nabilone. Wesnes et al. (2010) found that high (3 mg) but not lower (1 or 2 mg) nabilone doses produced significant changes in measures of attention, working memory, and episodic memory, at 4 h after drug administration in healthy, drug-naïve participants, as compared to placebo capsules. Participants also reported feelings of "high" and "drug effect" following all doses, but did not report a desire to consume more of the drug.

These results are consistent with the findings from a study by Bedi, Cooper, and Haney (2013) comparing the acute effects of nabilone (2, 4, 6, 8 mg) to dronabinol (10, 20 mg) in current cannabis smokers. Note: because of cross tolerance, a higher nabilone dose range was tested relative to those used for drug-naïve participants in earlier studies. The highest doses of nabilone (6 and 8 mg) produced modest decreases in psychomotor speed, and 4, 6, and 8 mg doses increased ratings of "good drug effect," and "high." Nabilone also increased heart rate dose dependently. Interestingly, in comparison to dronabinol, the subjective effects of nabilone had a slower onset to peak effect (180–240 vs 90 min), a longer duration of action (6 vs 4 h), and were more dose-related, supportive of nabilone's better bioavailability.

In a drug discrimination study, the interoceptive effects of 3 and 5 mg of nabilone substituted for 25 mg of dronabinol in regular cannabis users, again demonstrating nabilone's higher potency relative to dronabinol (Lile, Kelly, & Hays, 2010). A follow-up study replicated these results, and also showed that low dose nabilone in combination with low dose THC could substitute for higher training doses of THC (Lile, Kelly, & Hays, 2011). The additive nature of the interoceptive effects suggests a shared mechanism of action, that is, the CB1 receptor.

CANNABIS USE DISORDER

Given the shared pharmacology and subjective effects of nabilone and THC, nabilone has been tested as an agonist substitution treatment for cannabis use disorder. In one promising study, Haney et al. (2013) found that nabilone (6 or 8 mg/day) significantly reversed cannabis withdrawal-induced irritability, sleep disruption, and anorexia in nontreatment seeking cannabis smokers. Nabilone also attenuated a laboratory measure of cannabis relapse, defined as cannabis self-administration after several days of abstinence. This is particularly significant because few medications, including dronabinol, have been shown to disrupt cannabis self-administration in a comparable manner.

Adding to the appeal of nabilone as a treatment option is the fact that, unlike dronabinol, nabilone produces urinary metabolites that are distinct from those of cannabis (Fraser & Meatherall, 1989), which would allow clinicians to distinguish medication compliance from ongoing cannabis use in a clinical setting. There is always a risk that a CB1 agonist would have abuse liability that, if substantial, would lessen enthusiasm for its use to treat cannabis use disorder. However, in a comprehensive review of scientific literature as well as popular press and interviews with medical professionals and law enforcement officials suggest this is unlikely: Ware and St Arnaud-Trempe (2010) found that there is little evidence for nabilone abuse—it has no known street value and there are almost no instances of diversion, most likely due to its slow rate of onset relative to smoked cannabis.

ANALGESIA

Beyond the treatment of nausea, analgesia is one of the most commonly proposed indications for cannabinoids (Russo, 2008). Yet, in a placebo-controlled clinical trial of nabilone (1–2 mg every 8 h) for acute postoperative pain, patients reported higher pain scores, compared to placebo-treated patients, suggesting an enhancement rather than attenuation of pain (Beaulieu, 2006). This is consistent with laboratory studies showing that nabilone failed to attenuate thermal or capsaicin-induced acute pain (Redmond, Goffaux, Potvin, & Marchand, 2008; Kalliomaki et al., 2012). These results are somewhat surprising, as both smoked cannabis and oral THC (dronabinol) have shown moderate analgesia following acute experimenter-induced pain (Cooper, Comer, & Haney, 2013).

In contrast to acute pain studies, nabilone has shown more promise for the treatment of chronic pain. Pinsger et al. (2006) published a placebo-controlled crossover design study of nabilone (up to 4 mg/day) as an add-on treatment for patients with chronic musculoskeletal pain ($n = 30$). Over the 4-week treatment period, patients taking nabilone reported significantly less pain as compared to those receiving placebo. A 6-week crossover design study in patients with neuropathic pain ($n = 96$) showed that nabilone (2 mg/day) reduced pain ratings relative to baseline. However, dihydrocodeine (240 mg), a relatively weak opioid medication, was able to produce greater reductions in pain ratings than nabilone (Frank, Serpell,

Hughes, Matthews, & Kapur, 2008). A longer 6-month open label study reported that nabilone was comparable to gabapentin for management of neuropathic pain (Bestard & Toth, 2011). Nabilone (up to 2 mg twice per day) was also well tolerated and effective in an open label study showing that 26 of 37 patients had reduced neuropathic pain associated with diabetes (Toth et al., 2012). During a 5-week, double-blind, placebo-controlled phase, following the initial 4-week trial, patients maintained on nabilone continued to report analgesic effects, while patients switched to placebo reported increases in pain scores. The longest treatment durations are reported in a chart review from Berlach, Shir, and Ware (2006), in which nabilone was used as an off-label analgesic for up to 4 years (average 1.5 years). Fifteen of 20 patients reported subjective overall improvement with nabilone, and 9 reported reduced pain intensity; however, patients were not blinded to the medication.

Nabilone (1 mg) has also been shown to be more effective than ibuprofen in treating medication overuse for rebound headaches, which result from long-term use of therapeutic agents in patients with frequent migraines (Pini et al., 2012), and more effective than placebo as an adjunct therapy for pain management in advanced cancer patients (Maida, Ennis, Irani, Corbo, & Dolzhykov, 2008).

Finally, nabilone (1–2 mg/day) was assessed in a 4-week, placebo-controlled, randomized trial for the treatment of fibromyalgia. Patients treated with nabilone reported significant decreases in pain severity as well as anxiety, while no changes were seen in placebo-treated patients (Skrabek, Galimova, Ethans, & Perry, 2008). Ware, Fitzcharles, Joseph, and Shir (2010) studied nabilone's effects on sleep in fibromyalgia patients. They found that low dose nabilone (0.5–1 mg) prior to bedtime significantly improved sleep quality, compared to baseline, as well as compared to amitriptyline, a common treatment for insomnia. However, no effect on pain was observed in this study. Improved sleep in fibromyalgia patients is consistent with the results of multiple other studies reporting that nabilone improved sleep quality for other chronic pain patients (Bestard & Toth, 2011; Toth et al., 2012).

Limited research has also been done on the effectiveness of nabilone in treating spasticity-associated pain. This line of research began with a case report of a 45-year-old man with relapsing-remitting multiple sclerosis (Martyn, Illis, & Thom, 1995). Both pain from muscle spasms and nocturia decreased during a 4-week treatment with nabilone (1 mg), compared to alternating placebo treatment periods. Nabilone has not been further assessed as a treatment for nocturia in humans, though the result may be consistent with the findings of Pertwee and Fernando (1996) that nabilone dose-dependently attenuated electrically-evoked contractions of isolated mouse urinary bladder tissue. A chart review from Notcutt, Price, Blossfeldt, and Chapman (1999) reported that only 6 out of 16 patients experienced significant analgesic effects from nabilone for multiple sclerosis-associated pain. However, in a placebo-controlled crossover design in patients (n = 13) with spasticity-associated pain, nabilone (1 mg/day) significantly decreased pain following 4 weeks of active treatment compared to placebo (Wissel et al., 2006).

Overall, these limited studies show that nabilone can reduce chronic pain and improve quality of life by its effects on sleep or perhaps nocturia, for example, in a variety of pain conditions.

MOTOR DISORDERS

Although spasticity in patients with multiple sclerosis was not significantly decreased by nabilone (1 mg/day; Wissel et al., 2006), there is evidence that it may show promise as a treatment for other types of motor disorders. In patients with spasticity resulting from spinal cord injury, 4 weeks of treatment with nabilone (0.5–1 mg/day) produced significant improvements in the Ashworth scale for spasticity, as compared to placebo (Pooyania, Ethans, Szturm, Casey, & Perry, 2010). Dyskinesia, involuntary movements that are a common side effect of levodopa, results from dopaminergic hyperactivity and is often treated with medications that upregulate GABA. Sieradzan et al. (2001) found in an in vivo study that nabilone dose-dependently decreased GABA reuptake, possibly through activation of CB1 receptors expressed on GABAergic neurons. They went on to conduct a small placebo-controlled study demonstrating that nabilone (0.03 mg/kg) significantly reduced levodopa-induced dyskinesia in patients with Parkinson disease. Importantly, a study in a nonhuman primate model of Parkinson disease showed that nabilone treatment for dyskinesia did not disrupt the antiparkinsonian effects of levodopa (Fox, Henry, Hill, Crossman, & Brotchie, 2002). In a randomized, placebo-controlled trial of patients with Huntington disease, 5 weeks of treatment with nabilone (1 or 2 mg/day) produced modest but significant decreases in the severity of dyskinesia (Curtis, Mitchell, Patel, Ives, & Rickards, 2009). Thus, results with nabilone on dyskinesias are promising, suggesting that further research is warranted in this area.

ANXIETY

Three small studies failed to show significant effects of nabilone on measures of acute anxiety, following experimentally induced anxiety in healthy (2 mg; Nakano,

Gillespie, & Hollister, 1978), as well as in anxious research volunteers (1–5 mg; Glass, Uhlenhuth, Hartel, Schuster, & Fischman, 1980; Glass, Uhlenhuth, Hartel, Schuster, & Fischman, 1981). At the highest doses (4–5 mg) tested in the studies by Glass and coworkers, significant effects on heart rate and sedation were observed, but no change in anxiety was observed.

However, nabilone may have utility in the treatment of chronic anxiety. One study found that participants with general anxiety disorder ($n = 25$) treated with nabilone (1 mg TID) over 1 month had significant reductions in multiple measures of anxiety, compared to both baseline ratings and a placebo-treated group (Fabre & McLendon, 1981). Side effects, such as dry mouth and drowsiness were reported, but there were no reports of euphoria or feelings of a drug "high." In another study, nabilone-treated patients with advanced cancer reported significant improvements in overall distress and anxiety compared to untreated controls (Maida et al., 2008).

In addition to general anxiety, a chart review report found that nabilone (0.2–4 mg) provided relief from PTSD-associated nightmares in 34 out of 47 (72%) patients, none of whom had responded to conventional therapies (Fraser, 2009). The effect of nabilone lasted for the duration of treatment (4–12 months), but nightmares returned following the cessation of drug. Research to date suggests that nabilone is not appropriate for the treatment of acute anxiety, but may have utility for long-term management of anxiety, although again, large placebo-controlled clinical trials are needed.

CONCLUSIONS

The body of literature from the past 40 years provides clear evidence for nabilone's efficacy as an antiemetic, particularly for patients who do not respond to other treatments. In addition, there is evidence that nabilone has moderate efficacy in the treatment of chronic pain, pain-associated insomnia, PTSD-induced nightmares, dyskinesia, chronic anxiety, and cannabis use disorder. For all of these conditions, more research, especially large, placebo-controlled, clinical trials, is warranted. It is worth noting that medications exist to address many of these conditions; however, nabilone can have utility as either an adjunct treatment or as an alternative for patients who are unresponsive to other therapies. Additionally, in some cases, nabilone can address multiple symptoms thus reducing the number of medications required (Cameron, Watson, & Robinson, 2014).

The potential therapeutic uses for nabilone are comparable to the other FDA-approved oral cannabinoid, dronabinol. However, nabilone seems to be superior to dronabinol as a medication due to its high bioavailability and long duration of action. In addition, although nabilone can produce euphoric effects at therapeutic doses, it seems to have very minimal abuse liability or potential for diversion (Lemberger et al., 1982; Ware & St Arnaud-Trempe, 2010). Looking to the future, new uses for nabilone may emerge as our understanding of the cannabinoid system expands.

MINI-DICTIONARY

Analgesic A drug used for pain relief.
Antiemetic A drug that is effective against nausea and vomiting. Often used to treat chemotherapy-associated nausea and vomiting.
Cannabinoids A class of diverse chemicals that act on the cannabinoid receptors, CB1 and CB2. Phytocannabinoids, such as Δ^9-tetrahydrocannabinol (Δ^9-THC), are produced by the cannabis plant.
Dronabinol A pharmaceutical formulation of Δ^9-tetrahydrocannabinol (Δ^9-THC), the primary psychoactive cannabinoid produced by the cannabis plant. Marketed as Marinol, it is FDA approved to treat chemotherapy-associated nausea and vomiting, as well as loss of appetite in people with AIDS.
Drug discrimination study An experimental paradigm used to identify drugs with similar interoceptive effects. Humans or animals are trained to discriminate between a drug and placebo. Subjects then respond to indicate whether a new test drug "feels" more like the first drug or placebo.
Dyskinesia A category of movement disorders that are characterized by involuntary muscle movements, such as those seen in patients with Parkinson disease, Huntington disease, or following certain spinal cord injuries.
Fibromyalgia A syndrome characterized by a chronic, widespread pain in joints, muscles, tendons, and other soft tissue.
Multiple sclerosis An autoimmune disease that leads to demyelination and death of the neurons in the brain and spinal cord. The disease is associated with a wide range of symptoms, including spasticity.
Nabilone A synthetic analog of Δ^9-tetrahydrocannabinol (Δ^9-THC). Marketed as Cesamet, it is FDA approved to treat chemotherapy-associate nausea and vomiting.
Nocturia Waking often during the night to urinate. This can be a symptom of multiple sclerosis.

SUMMARY POINTS

1. The burden of dementia and its complications is largely still unaffected by the current therapeutic modalities.
2. Cannabinoids exert a number of mechanisms of action that could positively affect neuronal resilience.
3. That positive effect may cover the different types of dementing illnesses.
4. The scientific community should endeavor to bridge the gap in the evidence base supporting the use of cannabinoids in dementia.

KEY FACTS

- Dementia is a severe, irreversible, and very expensive disease with rising prevalence rates globally.
- There is no effective strategy to effectively slow down or stop the progress of the illness while maintaining quality of life.
- Cannabinoids have been used for centuries, and can also be synthesized in the laboratory to ensure standardization. Used in various medical conditions, cannabinoids have a positive role in dementia with agitation.
- Current treatment strategies are largely unsatisfactory.
- Cannabinoids seem to be a potential helpful adjunctive treatment.
- Side effects with current interventions include an increased risk of cardiovascular events.
- The reported side effects of synthetic cannabinoids, as noted by the authors, have been restricted to an increased appetite and sedation.

AREAS OF INTEREST

1. Cannabinoids and cognitive functioning.
2. Their effect on various neurotransmitter systems, as well as neuronal homeostatic mechanisms.
3. Effect of these agents on different brain pathologies, including dementias.
4. Potential for affecting phenotypic presentation of dementia, including its complications, using both synthetic and natural cannabinoids.

TNFα	Tumor necrosis factor alpha
TVRP1	Transient receptor potential vanilloid type 1

INTRODUCTION

In the field of medicine, the use of synthetic cannabinoids have been studied (Ben Amar, 2006) by way of its constituent cannabidiol (CBD) and Δ^9-tetrahydrocannabinol (THC). Cannabinoids have increasingly been reported to be of benefit in a number of conditions such as Parkinson's (FD), frontotemporal dementia (FTD), Huntington disease (HD) dementia (Amanullah, MacDougall, Sweeney, Coffin, & Cole, 2013; Campbell & Gowran, 2007; Robson, 2001). Evidence for routine use is limited, however, and this chapter will hopefully educate the reader on the current understanding and role of synthetic cannabinoids in dementia.

BACKGROUND

Dementia includes all neurocognitive disorders that are characterized by a decline in memory, other cognitive skills, and independent functioning, estimated to affect 14% (35 million) of people aged 71 and older in more developed countries. The number is expected to reach 70 million in 2030 (Plassman et al., 2007).

Various mechanisms and theories of dementia include cholinergic theories, apoptosis, oxidative stress, neuroendocrine alterations, shortening of telomere, damage to mitochondria, and autoimmune changes (Wilson & Nicoll, 2002).

The oldest among such theories is the cholinergic theory. It states that there is a reduction of about 40–70% in cholinergic neurons in the basal forebrain region (Kanof, Greenwald, Mohs, & Davis, 1985). Continued use of medications that inhibit cholinesterases can increase phosphorylation of tau protein (Chalmers et al., 2009), a process that can affect the long term effectiveness of cholinesterase inhibitors. Clinical presentation occurs only after significant neuronal loss, highlighting the importance of early detection.

The process seen in Alzheimer's dementia (AD) is due to the neurodegenerative process that is different from normal age related changes. Different species of Aβ (fibrillar β amyloid) produced by the cleavage of Aβ precursor proteins by β and γ secretases enzymes are a feature of AD (Aso & Ferrer, 2014).

Agonists cause an inhibition of GABA, and glutamate release is modulated (Walther & Halpern, 2010). Studies have shown lower anandamide (AEA) and 2-arachidonoylglycerol (2-AG) levels in Alzheimer's versus normal subjects (Koppel et al., 2009), but the lower levels of AEA in mid-frontal and temporal cortex of patients with AD in post mortem studies suggests a contribution of Aβ 42 dependent AEA impairment by the inverse correlation with Aβ 42 neurotoxic levels (Jung et al., 2012).

MECHANISMS OF ACTION OF CANNABINOIDS IN DEMENTIA

Much of our scientific data is derived from experimental animal models that mimic several traits of the neurodegenerative processes that lead to dementia. These animal models have provided some information about the mechanism of action and the therapeutic properties of cannabis derivatives.

The improvements observed were mainly in cognition and behavior.(Aso et al., 2012; Aso, Juvés, Maldonado, & Ferrer, 2013; Aso & Ferrer, 2014; Fakhfouri et al., 2012; Haghani, Shabani, Javan, Motamedi, & Janahmadi, 2012; Ramírez, Blázquez, Gómez del Pulgar, Guzmán, & de Ceballos, 2005).

Location of Cannabinoid Receptors in the Brain

It can be hypothesized that the potential role of cannabinoids in dementia relies on their capacity to concomitantly mitigate the pathological mechanisms seen in most types of dementia. These include toxicity, oxidative stress, excitotoxicity, mitochondrial dysfunction, abnormal protein folding, and inflammation at the neuronal level. It is reported that this can occur with 20 times the potency of aspirin (Aso & Ferrer, 2014; Fagan & Campbell, 2014; Russo, 2011).

Table 86.1 summarizes the main mechanisms, as currently understood, modulated by cannabinoids that are involved in AD pathology, which can be extrapolated to other pathological conditions (but, as one would expect, clinical trials are needed with larger sample sizes).

Toxicity Secondary to Abnormalities in Protein Folding

Several in vitro and in vivo studies demonstrate that certain cannabinoid compounds, including CB_1 and CB_2 receptor synthetic agonists, endocannabinoids, and natural cannabinoids such as Δ^9-THC and CBD, confer neuroprotection against Aβ. A peptide derived from aberrant

TABLE 86.1 Anatomical Localization and Associated Central Functions of Cannabinoid Receptors in the Mammalian Brain

Receptor class	Intensity	Localization	Functions
CB_1	Dense	Hippocampus, caudate, putamen, nucleus accumbens (ventral striatum), globus pallidus, substantia nigra pars reticulata, horizontal limb of the diagonal band, periaqueductal gray, dorsal horn of spinal cord, some olfactory regions	Cognition, pain modulation, regulation of food intake, motor coordination, mood, autonomic function, memory, sensation, lipid and glucose metabolism
	Moderate	Neocortex, basal amygdala, medial hypothalamus, solitary nucleus	
	Low	Human cerebellum, thalamus, brain stem	
CB_2	Dense	Anterior olfactory nucleus, neurons of layers III and V of the piriform, orbital, visual, motor, and auditory cortex, pyramidal neurons of the hippocampal allocortex, reticular thalamic nucleus, Purkinje cell bodies	Involved in immune function and inflammatory responses, including modulation of cytokine release and control of proliferation, differentiation and survival of neuronal and nonneuronal cells
	Moderate	Periaqueductal gray, substantia nigra pars reticulata, other nuclear structures of brain stem, dendrites of Purkinje cells in the molecular layer	
	Low	Ventromedial and arcuate hypothalamic nuclei	

Cannabinoid receptors CB_1 and CB_2 in the mammalian brain each have unique regional distributions, with receptor densities in brain areas found to be high, moderate, or low. These anatomical localizations play a role in the differing set of functions of each receptor type.
Note. Data compiled from Svíženská, Dubový, and Šulcová (2009).

processing of amyloid precursor protein (APP)—one of the hallmarks of AD (Aso et al., 2012; Harvey, Ohlsson, Mååg, Musgrave, & Smid, 2012; Iuvone et al., 2004).

Protective actions of cannabinoids:

1. Indirectly reducing the Aβ harmful effects on inflammation, oxidative stress, excitotoxicity, and cellular signaling.
2. Directly affecting Aβ processing by stimulating Aβ removal (Bachmeier, Beaulieu-Abdelahad, Mullen, & Paris, 2013; Martín-Moreno et al., 2012; Tolón et al., 2009; Wu et al., 2013).
3. Reducing Aβ levels (Aso et al., 2012; Aso & Ferrer, 2014).

A role for cannabinoids has also been reported in:

1. Tau hyperphosphorylation (Aso et al., 2012, 2013; Casarejos et al., 2013; Esposito et al., 2011).
2. Inhibition of formation of mutant huntingtin-aggregates that accumulate, leading on to neuronal cell death in HD (Blázquez et al., 2011; Scotter, Goodfellow, Graham, Dragunow, & Glass, 2010).

Preclinical studies also suggests the disease-modifying effects of cannabinoid-based medicines in HD (Fernandez-Ruiz et al., 2012).

Modulation of Neurotransmission

Certain cannabinoids may act on the same target receptors as current medications for cognitive impairment; eg, Δ^9-THC competitively inhibits acetylhydrolase (AChE), thus increasing acetylcholine (ACh) levels in the brain (Eubanks et al., 2006). Synthetic cannabinoid HU-211 acts as a stereoselective inhibitor of NMDA receptors and protects cells from NMDA-induced neurotoxicity (Eshhar, Streim, & Biegon, 1993; Feigenbaum et al., 1989; Nadler, Mechoulam, & Sokolovsky, 1993).

Cannabinoids mediate neuroprotection against excitotoxicity by:

1. Inhibiting the presynaptic glutamate release (Marsicano et al., 2003).
2. Blocking the voltage dependent calcium channels (Mackie & Hille, 1992).
3. Inhibiting the calcium release from ryanodine sensitive stores (Zhuang et al., 2005), mechanisms in which CB_1 receptors play a prominent role.
4. Promotion of neurogenesis (Esposito et al., 2011; Tanveer et al., 2012).
5. Facilitation of cerebral blood flow may also contribute to the therapeutic effects of cannabinoids in dementia, although their contribution remains to be fully elucidated. (Ellis, Moore & Willoughby, 1995; Iring et al., 2013).
6. Control of apoptosis pathways through neuroprotection (Noonan et al., 2010).

Mechanism of Action of CB_1 and CB_2 (Table 86.2)

Limitations:

1. Complexity of the human cognitive functions makes it irreproducible in animal models.

TABLE 86.2 Summary of the Basic Mechanism of Actions of CB_1 and CB_2 Receptors

Shared mechanism of action	CB_1 mechanism of action	CB_2 mechanism of action
Coupled to G proteins G_i or G_o Coupled positively to mitogen-activated protein Coupled negatively to adenylyl cyclase Net result: decreased production of cAMP and subsequent inhibition of cAMP-dependent protein kinase (PKA)	Coupled to ion channels via G_i/G_o mechanism • Positively: A type, and inwardly rectifying potassium channels • Negatively: N type, and P/Q type calcium channels, D type potassium channels Net result of PKA inhibition: reduction to ion channel protein phosphorylation • Inhibition of calcium channels on CB_1 containing presynaptic terminals likely reduces neurotransmitter release, including glutamate, acetylcholine, and noradrenaline	PKA inhibition results in decreased phosphorylation of cAMP response element-binding protein cAMP response element binding protein is a transcription factor that regulates a variety of cellular responses including survival, proliferation and differentiation of immune cells Net result: immune inhibition

Cannabinoid receptors CB_1 and CB_2 belong to the same superfamily of receptors that couple to guanine-nucleotide binding proteins (G proteins). Some of the basic mechanism of action for CB_1 receptors is the same as that of CB_2 receptors. Cannabinoids have been suggested to play a role in the regulation of neurotransmitter release, including glutamate, acetylcholine, and noradrenaline. This has been suggested to occur through CB_1 receptors on presynaptic terminals coupled to ion channels.

Note. Data for shared mechanism for action and CB_1 mechanism of action from Sviženská et al. (2009), and data for CB_2 mechanism of action from Malfitano, Basu, Maresz, Bifulco, and Dittel (2014).

2. Mammalian models have limitations due to highly advanced language skills in humans.
3. Moreover, the efficacy of cannabinoids in curbing the cognitive impairment was inversely proportional to the stage of disease at the onset of treatment in the animal models (Aso et al., 2012; Aso & Ferrer, 2014). This will have important ramifications in human studies and interventions.

Early detection and intervention in dementia in patients is critical, in order to take advantage of cannabinoids as potential therapeutic agents.

A series of studies (Solowij, Grenyer, Chesher, & Lewis, 1995), revealed relevant and replicable evidence linking the duration of cannabis use and sensitive measures of brain function; event-related potentials during a complex selective attention task. The results showed impairments in the ability to focus attention, and also abnormalities in filtering out relevant from irrelevant information.

Neuroinflammation

Neuroinflammation is a major contributor to progressive neuronal damage, leading on to dementia. Ongoing research on neuroinflammation focuses on compounds that act on CB_2 receptors, such as THC and THCV (tetrahydrocannabivarin) (Cabral & Griffin-Thomas, 2009), mainly due to expression in the immune system, and activation leading to:

1. Reduced microglial response and proinflammatory molecule production, including cytokines and TNF-α.
2. Attenuation of nitric oxide oversynthesis (Aso et al., 2013; Esposito et al., 2007; Fakhfouri et al., 2012; Martín-Moreno et al., 2012; Ramírez et al., 2005; Russo, 2011; van der Stelt et al., 2006; Wu et al., 2013).

Several CB_1 receptors agonists and natural CBD have shown antiinflammatory properties in certain neurodegenerative models (Aso et al., 2012; Casarejos et al., 2013; Esposito, De Filippis, Carnuccio, Izzo, & Iuvone, 2006a; Martín-Moreno et al., 2011).

Oxidative Stress and Dysfunction of Mitochondria

Mitochondrial dysfunction is one of the earliest events in neurodegenerative processes. Mitochondrial dysfunction leads to energy deficiency and increased production of oxidants that compromise neuronal cell function (Burchell et al., 2010; Ferrer, 2009). The cannabinoid derivatives, mainly CBD, have shown antioxidant properties in cell cultures exposed to toxic proteins like Aβ (Esposito et al., 2006b, 2011; Hampson, Grimaldi, Axelrod, & Wink, 1998; Hampson et al., 2000; Iuvone et al., 2004).

Similar findings were also observed in tauopathy animal models (Casarejos et al., 2013) that were treated with CB_2 agonist or a combination of Δ^9-THC and CBD.

TAUOPATHIES AND CANNABINOIDS

Tauopathy is a term that encompasses all neurodegenerative diseases associated with the pathological modification of tau protein by hyperphosphorylation, leading to tau protein aggregation, and neurotoxicity.

Different types of tauopathies can develop, based on the specific tau modifications, brain areas affected, and the existence of other pathological traits:

1. AD, Down's syndrome (which are also beta-amyloidopathies).
2. Dementia with only tangles—Pick's disease, dementia pugilistica, frontotemporal lobe degeneration associated with MAPT mutations, progressive supranuclear palsy, corticobasal degeneration, argyrophilic grain disease, myotonic dystrophy, and other rarer tauopathies.
3. Studies on animal models have shown potential benefits in taupathies, however no specific information is available about the effects of cannabinoids in patients affected by tauopathies different from AD.

Prolonged exposure to a combination of Δ^9-THC and CBD (natural extracts) have shown a significant reduction in neurofibrillary tangles in murine models that had parkinsonism, complex frontotemporal dementia, and lower motor neuron disease (Casarejos et al., 2013). Reduction in the deposition of tau and amyloid proteins in the hippocampus and the cerebral cortex was also observed in this study. This is of clinical significance, given the paucity of conventional interventions. However, one would also need to look at the prolonged exposure in relation to those who use cannabinoids culturally for protracted periods, to see if there is a reduction in the formation of tangles (Fig. 86.1).

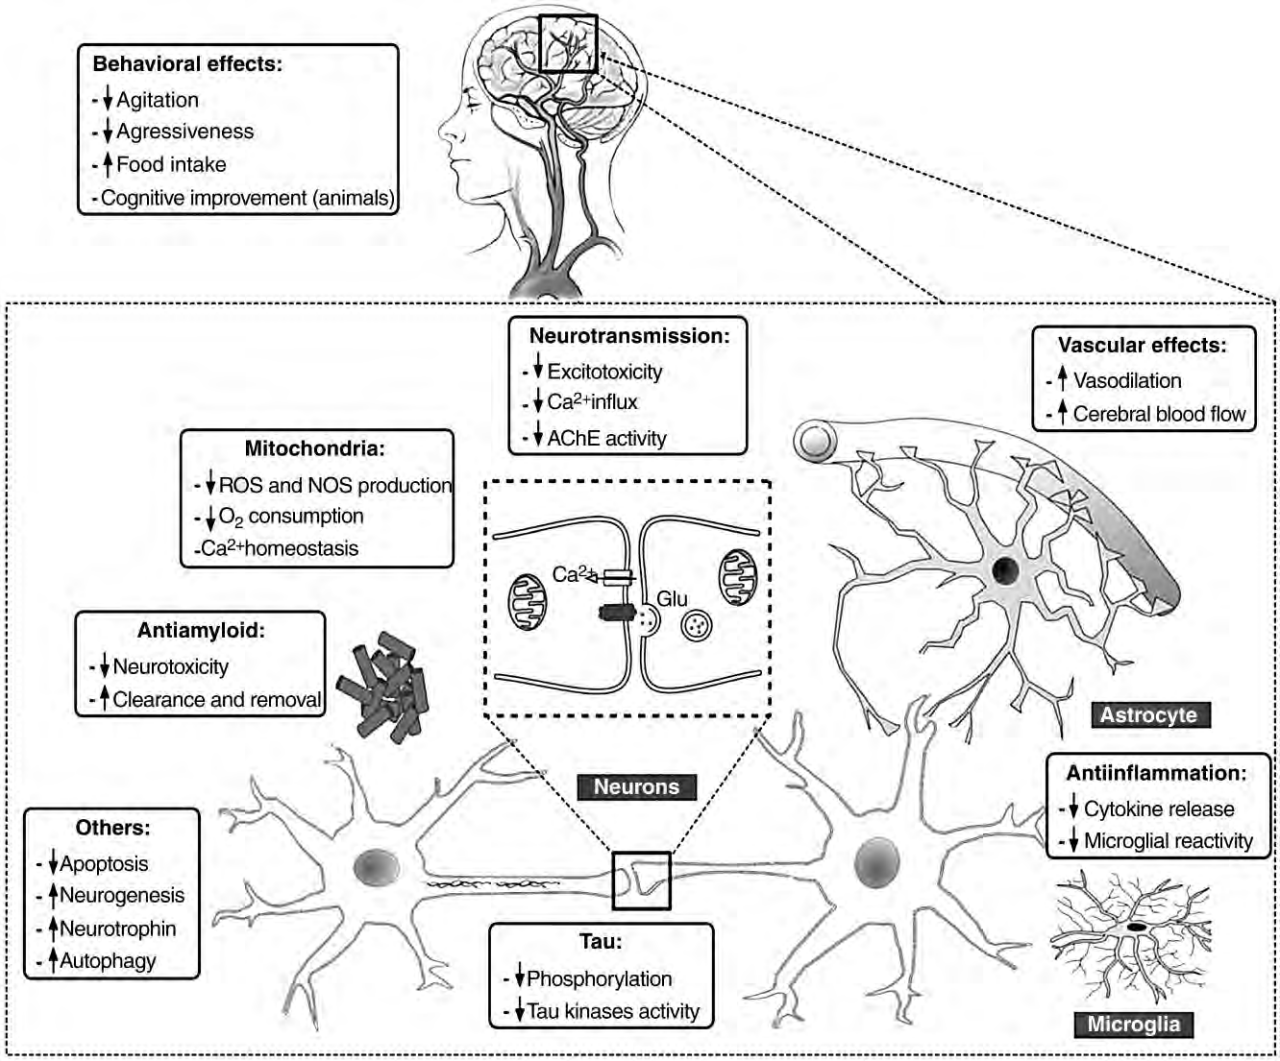

FIGURE 86.1 **Summary of the main findings demonstrating beneficial effects of cannabinoid compounds in AD models.** Cannabinoids may target in parallel several processes that play key roles in AD, including Aβ and tau aberrant processing, chronic inflammatory responses, excitotoxicity, mitochondrial dysfunction, and oxidative stress, among others. Clinical data also reveal an improvement in behavioral in patients with AD, after treatment with cannabinoids. *Source: Reproduced with permission from Aso and Ferrer (2014).*

TABLE 86.3 Cortical and Subcortical Dementia Types

Cortical dementias	Subcortical dementias
Alzheimer disease	***Vascular dementia***
Most common type of dementia Neuropathic process: intracellular neurofibrillary tangles, extracellular β-amyloid plaques Early disease: hippocampus and temporal lobe affected—memory impairment Later disease: tangles and plaques progress to frontal and parietal regions—impairment of: judgment, word finding, temporal orientation, route navigation Eventually, patients may exhibit agitated behavior and/or personality change Typical disease course is 6 to 9 years from symptom onset to death	Second most common type of dementia Cognitive impairment varies depending on location and degree of tissue damage Pathogenesis: ischemia to large or small vessels Large vessel ischemia: abrupt symptom onset; results in stroke Small vessel ischemia: gradual symptom onset as lesions accumulate; often misdiagnosed as cortical dementia Risk factors: smoking, atherosclerosis, hypertension, hypercholesterolemia, and diabetes mellitus
Dementia with lewy bodies	***Parkinson disease dementia***
Neuropathic process: Lewy body protein deposits throughout the cortex, paralimbic areas, substantia nigra Prominent impairment in: attention, visuospatial and executive functioning Other signs and symptoms: sleep disturbance, extrapyramidal symptoms, visual hallucinations, fluctuations in attention and alertness More rapid progression than AD	Slowly progressing dementia that can develop in individuals with Parkinson disease Typically presents 10 years after onset of disease Occurs in approximately 30% of patients with Parkinson's disease; more common in those with greater physical impairment Impairment to: executive functioning, attention, visuospatial functioning, memory
Frontotemporal dementia	
Group of heterogenous disorders Neuropathic process: frontal cortical atrophy, temporal cortical atrophy First symptom: personality change Two subtypes: Behavioral—impaired insight; distinct patterns of behavioral dysfunction Language—distinct patterns of language dysfunction Rapid progression over 5–10 year course	

Cortical dementias result from disease causing diffuse cortical neuronal atrophy, and are typically progressive and degenerative. Subcortical dementias result from diseases involving subcortical structures, including vasculature, the thalamus, and the basal ganglia, and may be progressive, static, or reversible.
Note. Data from Buffington, Lipski, and Westfall (2013).

CANNABINOIDS IN SUBCORTICAL DEMENTIAS AND PARKINSON DISEASE

Although a controversial term, the term subcortical dementia is useful for the clinician in diagnostics and, to some extent, management. The evidence is primarily in AD and HD (Table 86.3).

The role of the cannabinoid system in movement warrants special attention. This encompasses both types of CB receptors, and the related vanilloid TRPV1 receptor. These are all densely located in the output nuclei of the basal ganglia (Mackie, 2005). The various positive effects of cannabinoids on the basal ganglia support their potential therapeutic effects in hyperkinetic movement disorders such as HD, hypokinetic disorders such as PD, and also other disorders of different etiologies, such as primary dystonias, dykinesias, and Tourette syndrome.

Cannabinoids increase GABAergic transmission, inhibit glutamate release, and positively affect dopaminergic uptake.

Tables 86.4 and 86.5 show the available evidence for its use in diseases associated with it.

CONCLUSIONS

The incidence of dementia is expected to quadruple by 2050, with an incidence rate of BPSD of over 90% in sufferers (Steinberg et al., 2008).

Agitation, which presents as a major management challenge, occurs in 60% of patients with dementia, and is associated with the severity of the disease (Senanarong et al., 2004). The lack of satisfactory and enduring results with current mainstream treatments has forced clinicians to look for less studied alternatives, such as

TABLE 86.4 Cannabinoids Suggested for Use in Alzheimer Disease (AD), Vascular Dementia (VD), Huntington Disease (HD) and Parkinson Disease (PD) Using Clinical Trial Findings

Neurodegenerative disease	Cannabinoids suggested for use	Mechanism of action	Suggested benefits	Possible side effects	Number of subjects	References
AD	Dronabinol (THC)	$CB_{1/2}$ agonism	↓ Agitation	Seizure, infection, ↑ body weight, anxiety/nervousness, tiredness, emotional liability, somnolence, euphoria, balance disorder, GI disorder, blurred vision, muscle weakness	15	Volicier, Stelly, Morris, McLaughlin, and Volicier (1997)
	Dronabinol (THC)	$CB_{1/2}$ agonism	↓ Nocturnal motor activity, strengthened circadian rhythms	Not assessed; however, found a slight ↓ in mini mental state exam (MMSE)	2	Walther, Schupbach, Seifritz, Homan, and Strik (2011)
VD	No clinical trials conducted					
HD	Nabilone (mimics THC)	$CB_{1/2}$ agonism	Positive effects on cognition, behavior, and chorea symptoms	Suicidal ideation, drowsiness and forgetfulness, severe sedation	44	Curtis, Mitchell, Patel, Ives, and Rickards (2009)
PD	Nabilone (mimics THC)	$CB_{1/2}$ agonism	Reduced levodopa-induced dyskinesia	Well tolerated	7	Sieradzan et al. (2001)
	Oral cannabis extract (THC: Cannabidiol)	$CB_{1/2}$ agonism and unknown cannabidiol mechanism	Hopeful for reduced levodopa-induced dyskinesia, but no effect found	Drowsiness/lethargy, detachment, dry mouth	19	Carroll et al. (2004)

All studies ($N = 5$) were conducted using randomized double-blind placebo controlled crossover trials; however, study sample sizes were small, and treatment dosages varied. Limited evidence is available on the medicinal use of cannabinoids in dementia and, as a result, there is little guidance available to practitioners regarding its use.
Note. Data from Walther et al. (2011) and van den Elsen et al. (2014).

TABLE 86.5 Cannabinoids Suggested for Potential Use in Neurodegenerative Diseases Using Preclinical Findings

Neurodegenerative disease	Intervention	Possible benefits	Mechanism of action if known
AD	CB_1 agonists	1. Prevention and protection against excitotoxicity 2. Prevention of Aβ-induced neurotoxicity	Inhibition of the presynaptic release of glutamate via G-protein mechanisms 1. Reduction of tau protein hyperphosphorylation via reduction of nitric oxide production 2. Brain-derived neurotrophic factor mediation of CB_1 agonist neuroprotective effects
	N-methyl-D-aspartate	Protection mechanism against neurotoxicity	Increase of endogenous cannabinoid anandamide
	Δ^9-THC or AEA	1. Reduction to neuronal damage 2. Prevention to Aβ-aggregation	CB_1 receptor mediated effects Inhibition of acetylcholine esterase
	CB_2 agonists	1. Suppression to the neuroinflammatory process	1. Reduction of CD40 expression 2. Reduction of nitric oxide and tumor necrosis factor α production in activated microglia
		2. β-amyloid removal	1. Stimulation of human macrophages 2. Suppression of CD40-mediated inhibition of microglial phagocytosis

TABLE 86.5 Cannabinoids Suggested for Potential Use in Neurodegenerative Diseases Using Preclinical Findings (*cont.*)

Neurodegenerative disease	Intervention	Possible benefits	Mechanism of action if known
	CB_1/CB_2 agonists WIN55212-2 and HU-210	1. Prevention of microglial activation 2. Improvement to memory performance	
	Cannabidiol	Antioxidant effects including protection against Aβ-induced neurotoxicity	Mechanism remains unclear
VD	Inconsistent findings	Presently no potential cannabinoid-based intervention for cerebral ischemia	
HD	CB_2 agonists	Possible reduction to neuroinflammation, but still unclear	
PD	CB_1/CB_2 agonist CP55,940	Protection against paraquat toxicity which induces parkinsonism	Inactivation of the oxidative stress response Jun-*N*-terminal kinase signaling
	CB_1 agonist Δ^9-THC, cannabidiol, and endocannabinoid inactivation inhibitor AM404	Amelioration of nigrostriatal lesion effects	Likely the result of antioxidant properties
	CB_2 receptor agonist HU-308	Small recovery to nigrostriatal lesion effects	Contribution to neuroprotection via activation of CB_2 receptors
	CB_1/CB_2 agonist WIN55, 212-2	Amelioration of nigrostriatal lesion effects independent of CB_1 receptor activation	
	CB_1/CB_2 agonist WIN55, 212-2 and CB_2 agonist JWH015	Reduction to lesion-induced microglial activation	
	Coinjection of D_2 receptor agonist quinpirole and CB_1/CB_2 agonist WIN 55, 212-2	Alleviation of akinesia	
	CB_1 antagonists	Alleviation of motor dysfunction	Augmentation of levodopa
	Coadministration of D2 agonist quinpirole and CB_1 receptor antagonist SR141716A	Restoration of locomotion	SR141716A augmentation of quinpirole effects
	Δ^9-THC	Improvement to motor deficits in mild PD	
	Coadministration of CB agonists HU-210 and nabilone with levodopa	Reduction to dyskinesia	CB agonists prevent the reduction of extracellular glutamate caused by levodopa; extracellular glutamate is inversely correlated with dyskinesia
	Anandamide membrane transporter inhibitors, fatty acid amide hydrolase inhibitors, or CB_1 agonists	Decrease to elevated glutamatergic transmission; CB_1 agonists only—decrease to glutamate release from afferent terminals in the striatum	

Endocannabinoids have been suggested as interventions for neurodegenerative diseases including Alzheimer disease (AD), Vascular dementia (VD), Huntington disease (HD), and Parkinson disease (PD), due to their impact on neurotransmission via retrograde signaling. Despite an increase in preclinical data suggesting the potential benefits of cannabinoids in neurodegenerative diseases, treatment plans for those with AD, VD, HD, and PD do not currently incorporate these findings.
Note. Data from Walther and Halpern (2010).

cannabinoids and electroconvulsive therapy (ECT); although a randomized controlled trial in 2011 assessing the latter yielded satisfactory results.

Cannabinoids can potentially alter the progression of the underlying pathology in dementia by different mechanisms. Moreover, they should spur serious randomized controlled trials in assessing their efficacy in clinical populations with dementia.

MINI-DICTIONARY

Alzheimer disease A chronic progressive condition characterized by cognitive decline not in keeping with age, changes in personality, loss of visuospatial skills, language dysfunction, disturbances in planning, judgment, and planning.
Dementia A condition characterized by cognitive dysfunction, changes in personality, loss of visuospatial skills, language dysfunction, disturbances in planning, judgment, and planning. They may occur in isolation, or in varying combinations based on the type of dementia.
Subcortical dementia A controversial term that refers to dementia involving the subcortical regions and presenting with significant slowing of cognition, affective, and motor symptoms.
Synthetic cannabinoids Synthetic cannabinoids are strictly defined as any designer drug that can mimic the effects of cannabis and can be often found as "spice products."
Tauopathies Tauopathy is a general term that encompasses all the neurodegenerative diseases associated with the pathological modification of tau protein by hyperphosphorylation that leads to tau protein aggregation and neurotoxicity.
Vascular dementia This term generally refers to dementia in which vascular causation is seen as the primary etiology

Synthetic Cannabinoid Receptor Agonists (Spice) as New Recreational Psychoactive Substances

A. Helander

Department of Laboratory Medicine, Karolinska Institutet, and Karolinska University Laboratory, Stockholm, Sweden

SUMMARY POINTS

- "Spice" is a generic name for herbal smoking blends containing highly potent synthetic cannabinoid receptor agonists.
- Because many synthetic cannabinoids are not classified, they can be sold openly without risk of legal consequences (legal highs).
- A large number of Spice products are easily available over the internet from online retailers of new psychoactive substances (NPS).
- Spice products are increasingly being used, especially by teenagers and young adults.
- When new synthetic cannabinoids are introduced, little is usually known about their potency (ie, receptor affinity), pharmacology, toxicology, and metabolism, implying risks for overdose and serious adverse effects.
- Synthetic cannabinoids are not detected by standard urine drug testing procedures.
- Because many synthetic cannabinoids are not banned, they can be marketed over the internet, in herbal smoking blends as "legal marijuana substitutes."
- Compared with Δ^9-tetrahydrocannabinol (THC), the principal psychoactive constituent of the cannabis plant, which is a partial cannabinoid receptor agonist, many synthetic cannabinoids are highly potent receptor full agonists, increasing the risk for overdose and adverse health consequences.
- Spice products are increasingly being abused, especially by teenagers and young adults.
- When new synthetic cannabinoids are introduced, little is usually known about their pharmacology, toxicology, and metabolism, implying a risk for serious adverse effects.
- Synthetic cannabinoids are not detected by standard urine drug testing procedures.
- The key facts include the cannabinoid receptors, their endogenous and exogenous ligands, and clinical and bioanalytical consequences when synthetic cannabinoids are being used as new recreational drugs in herbal smoking blends ("Spice" products).

KEY FACTS ON SYNTHETIC CANNABINOIDS

- Synthetic cannabinoids are cannabinoid receptor agonists originally developed as research tools or therapeutic drug candidates.
- Today, synthetic cannabinoids are added to herbal smoking blends ("Spice" products), and used as "recreational" drugs.

LIST OF ABBREVIATIONS

CB	Cannabinoid receptor
EMCDDA	European monitoring centre for drugs and drug addiction
NPS	New psychoactive substances
SC	Synthetic cannabinoid
THC	Δ^9-Tetrahydrocannabinol

INTRODUCTION

The *Cannabis* plant has an ancient history of medicinal and "recreational" use for its physiological and psychoactive effects. Modern use of cannabis preparations (eg, marijuana and hashish) is primarily as a recreational drug, although occasionally also used for treatment and management of chronic pain (Lucas, 2012). Among the large number of chemical compounds isolated from the cannabis plant (phytocannabinoids) (Russo, 2011), Δ^9-tetrahydrocannabinol (THC) was identified in 1964 as the principal psychoactive constituent (Gaoni & Mechoulam, 1964). Subsequent identification of the cannabinoid type 1 receptor (CB_1; mainly centrally located and associated with psychoactive effects) (Devane, Dysarz, Johnson, Melvin, & Howlett, 1988) and type 2 receptor (CB_2; mainly peripheral and associated with immunomodulatory effects) (Munro, Thomas, & Abu-Shaar, 1993) around 1990, and, in the following years, identification of endogenous cannabinoid receptor agonists (endocannabinoids) such as anandamide (arachidonoylethanolamide) (Devane et al., 1992) and 2-arachidonoylglycerol (Mechoulam et al., 1995; Sugiura et al., 1995), led to an intensive research to exploit the endocannabinoid system for treatment of a broad range of diseases (Di Marzo, Bifulco, & De Petrocellis, 2004; Bahr, Karanian, Makanji, & Makriyannis, 2006; Karanian & Bahr, 2006; Vemuri, Janero, & Makriyannis, 2008; Pacher & Kunos, 2013).

Since the discovery of the human endocannabinoid system, hundreds of cannabinoid receptor agonists (synthetic cannabinoids) with variable binding affinities for the CB_1 and CB_2 receptors have been synthesized as research tools, and patented as therapeutic drug candidates by researchers and pharmaceutical companies (Huffman & Padgett, 2005). However, only few have eventually become available as prescription drugs, one example being nabilone that was approved to treat chemotherapy-induced nausea (Davis, 2008). A main reason is that the therapeutic use of synthetic cannabinoids is limited by the psychoactive effects associated with central CB_1 receptor agonism. Accordingly, there has been a search for selective agonists that enhance CB_2 receptor analgesic and antiemetic effects over CB_1 psychoactive effects (Pertwee, 2006).

HERBAL SMOKING MIXTURES

In mid-2006, discussions were started on internet chat forums for psychoactive substances regarding a herbal smoking mixture sold under the brand name "Spice" (Fig. 87.1) that had been available for some years as a "recreational" drug. Smoking Spice was reported to generate a cannabis-like relaxing effect, despite apparently not containing cannabis. Although labeled with the warning text "not for human consumption," the intended use was obvious and the product was generally considered a "legal" alternative to cannabis. Furthermore, use of Spice was reported not to be detected by standard urine drug testing.

FIGURE 87.1 Spice, the brand name of one of the first herbal smoking blends. A bag of Spice Diamond, one of the early herbal smoking mixtures introduced as natural highs. The "Spice" products were eventually demonstrated to consist of plant materials sprayed with synthetic cannabinoids.

Several of the listed plant-based ingredients, such as bay bean (*Canavalia sp.*), blue lotus (*Nymphaea sp.*), honeyweed (*Leonurus sibiricus*), Indian warrior (*Pedicularis densiflora*), lion's tail (*Leonotis leonurus*), and maconha brava (*Zornia latifolia*), had traditionally been used as "marijuana substitutes" in different parts of the world (EMCDDA, 2009), and were thus proposed to be accountable for the psychoactive effects of Spice. Although not indicated on the label, others rather suggested that the dried plant material in Spice had been spiked with synthetic cannabinoids; one tentative substance mentioned was HU-210, an analgesic drug candidate synthesized by Raphael Mechoulam at the Hebrew University (hence named "HU") that is structurally similar to THC (Fig. 87.2) but considerably (100-fold) more potent, and with an extended duration of action (Mechoulam, Lander, Breuer, & Zahalka, 1990). However, it is uncertain whether Spice and alternative herbal smoking blends ("Spice" has become a generic name for this type of products) actually contained all or any of the listed plants (Ogata, Uchiyama, Kikura-Hanajiri, & Goda, 2013), or if they were listed because of the alleged psychoactive effects, simply in order to confuse and mask the real content, and to present the product as "natural" (Cornara et al., 2013).

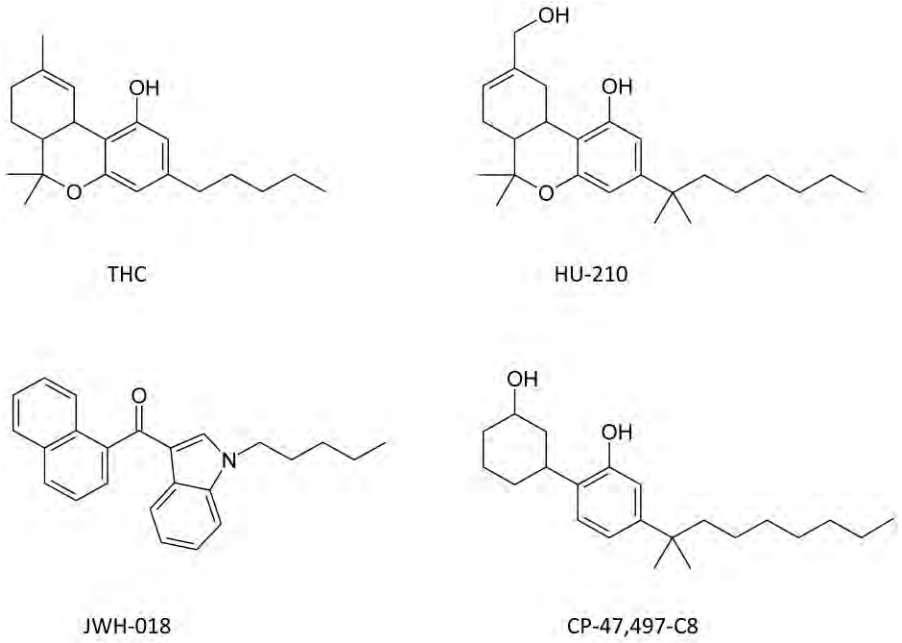

FIGURE 87.2 Chemical structures of THC and the first synthetic cannabinoids used in Spice products. Chemical structure relationships of THC, the principal psychoactive constituent of cannabis, and some "first generation" synthetic cannabinoid receptor agonists (synthetic cannabinoids) added in herbal smoking blends collectively referred to as "Spice" products.

FIRST IDENTIFICATION OF THE PSYCHOACTIVE COMPONENTS IN "SPICE"

The suggestion that the herbal smoking blends had actually been supplemented with synthetic cannabinoids was further supported when new and seemingly stronger Spice variants (ie, Spice Gold and Spice Diamond) (Fig. 87.1) were introduced on the recreational drugs market, despite no apparent change of plant ingredients. Following an increased awareness and associated rapid rise in the popularity of Spice and similar products in many European countries, in 2007–2008, it was eventually reported by Austrian and German national focal points at the end of 2008 that the synthetic cannabinoid receptor agonist JWH-018 (Fig. 87.2) had been identified as the true psychoactive component (EMCDDA, 2009). JWH-018 is one among several hundred analgesic drug candidates synthesized by John W. Huffman (ie,"JWH") at Clemson University, USA (Huffman, 2000). The identification of the naphthoylindole JWH-018, and of the CP-47,497 C8 homolog (Fig. 87.2), a cyclohexylphenol (CP) synthetic cannabinoid developed at Pfizer (Weissman, Milne, & Melvin, 1982), in different Spice products, was soon confirmed in scientific publications (Auwarter et al., 2009; Uchiyama, Kikura-Hanajiri, Kawahara, Haishima, & Goda, 2009).

EFFECT OF LEGISLATION OF SYNTHETIC CANNABINOIDS

Already by the end of Jan. 2009, JWH-018 and CP-47,497-C8 were banned in Germany, due to reports of intoxication, abuse, and health problems associated with chronic use of Spice (Zimmermann et al., 2009). Nevertheless, already a few months later, it was demonstrated that JWH-018 had been replaced in Spice products by one of its "legal" structural analogs, JWH-073 (Lindigkeit et al., 2009).

This represented the start of an ongoing "cat-and-mouse game," where the psychoactive additives in herbal smoking mixtures made illegal are rapidly removed and replaced with novel, similar synthetic cannabinoids (ie, "designer drugs") that are ready in the pipeline, to maintain the legal standing of the products (ie, "legal highs") (Helander, Bäckberg, Hultén, Al-Saffar, & Beck, 2014). Consequently, partly due to legislative actions undertaken in the European countries, the number of "new psychoactive substances" (NPS) noted by the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA) has increased dramatically in the last years (EMCDDA, 2014). Of all NPS identified, synthetic cannabinoids make up an essential part (ie, 27–47% each year since 2009), totally counting to more than 100 during the period 2008–2013 (Fig. 87.3).

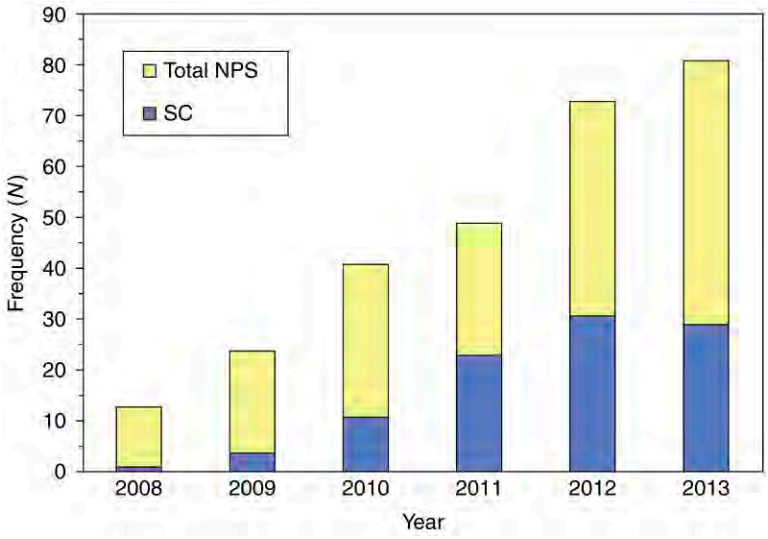

FIGURE 87.3 **NPS reported to the EMCDDA in 2008–2013.** Total number of NPS and the proportion of synthetic cannabinoids (SC) reported to the EMCDDA per year, between 2008–2013 (EMCDDA, 2014).

Since this Spice drug phenomenon first attracted a more widespread attention in the period 2008–2009, different "generations" of synthetic cannabinoids have been used in the herbal smoking products (Table 87.1). JWH-018, JWH-073, JWH-200, CP-47,497, and HU-210 are among the substances usually referred to as the "first generation" Spice substances (Fig. 87.2). Subsequent Spice products have contained a wide variety of synthetic cannabinoids with variable structural design and variable potency, that is, affinity for the CB_1 and CB_2 receptors (Wiley, Marusich, & Huffman, 2014). These include several other JWH variants, fluorinated substances such as AM-694 and AM-2201 (the latter being the fluorinated analog of JWH-018), two in a large series of substances examined by Alexandros Makriyannis (AM) at Northeastern University, USA (Moosmann et al., 2012), RCS-4 and RCS-8 (Kavanagh, Grigoryev, Melnik, & Simonov, 2012), and UR-144 and XLR-11 (ie, the fluorinated analog of UR-144) (Fig. 87.4). AKB48 (also known as APINACA), AB-FUBINACA, AB-CHMINACA, JWH-071, MN-18, and NM-2201 are among the more recently introduced synthetic cannabinoids (Fig. 87.4). In addition, even compounds binding allosterically to the CB1 receptor and thereby eliciting a conformational change that increases agonist affinity (eg, Org 27569) have also become used in Spice products (Price et al., 2005). A list of the synthetic cannabinoids or related substances with CB receptor activity that have been reported to the EMCDDA, by year, until Sep. 2014 are presented in Table 87.1 (EMCDDA-Europol, 2009–2014).

Over the years, a multitude of Spice product and alternative herbal smoking blends with different brand names (eg, Spice Gold/Silver/Diamond, K2, K3, Bonzai, Kronic, Krypton) have been introduced on the recreational drugs market at a rising speed (Fig. 87.5). They have contained variable amounts and/or combinations of synthetic cannabinoids (Table 87.1), to hinder or avoid legal consequences. The Spice products are easily obtainable, initially in "head shops," but since 2009 mainly over the internet from the many online retailers specialized in this and other types of NPS (Vardakou, Pistos, & Spiliopoulou, 2010; Spaderna, Addy, & D'Souza, 2013). They are also sold directly on the illicit drug market.

CLINICAL CONSEQUENCES OF SYNTHETIC CANNABINOIDS

Like smoking cannabis (THC), the desired psychoactive effects of products containing synthetic cannabinoids include euphoria, calmness, relaxation, and a feeling of wellbeing. However, there is limited objective information on possible short-term and long-term effects and health consequences of using Spice products. Because they are marketed as "not for human consumption," this issue is obviously not recognized on the NPS websites. Instead most of the information is anecdotal and obtained from internet chat forums. When novel synthetic cannabinoids are introduced, little is usually known initially about their pharmacology, toxicology, and metabolism, and if so mostly only from studies on laboratory animals (Lewis et al., 2012). Some may actually have been rejected as potential therapeutic drugs due to adverse effects, but the information generated is now used to develop these compounds for illicit use as "marijuana substitutes." As for other types of NPS, synthetic cannabinoids are typically manufactured in unregulated laboratories, implying risks for toxic contaminants, then diluted in a solvent

A list of all synthetic cannabinoid receptor agonists and related substances (eg, cannabinoid receptor allosteric modulators) reported to the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA) per year, from 2008 until Sep. 2014 (EMCDDA-Europol, 2009–2014).

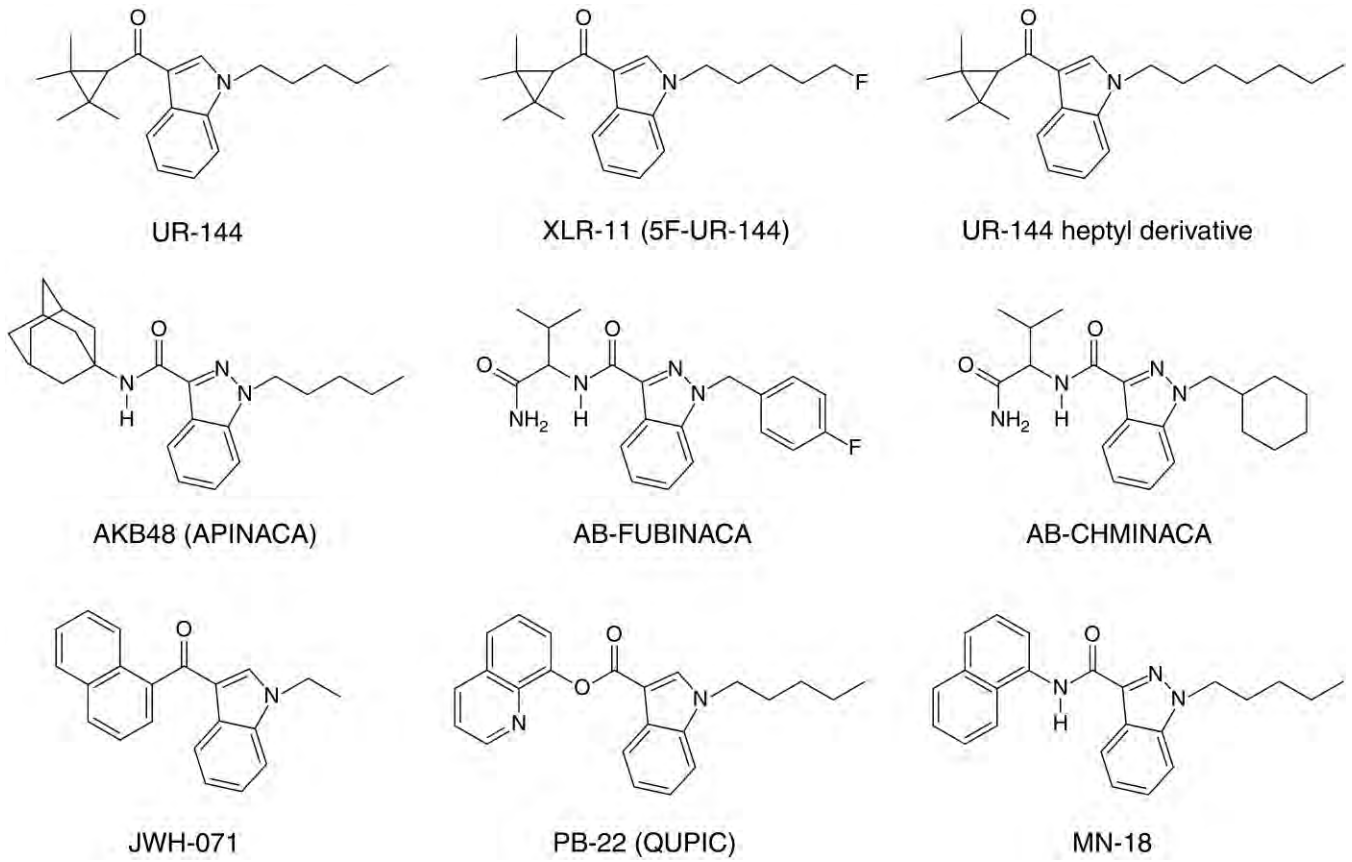

FIGURE 87.4 Chemical structures of a number of novel synthetic cannabinoids appearing in recent Spice products. Chemical structures of several synthetic cannabinoids included in herbal smoking blends ("Spice" products) in 2012–2014 (EMCDDA, 2014).

FIGURE 87.5 Examples of Spice products, and other types of NPS available online as recreational drugs. Over the years, a multitude of products containing synthetic cannabinoids and other types of NPS have been available over the internet from online retailers specialized in this and other types of products.

(eg, acetone), and finally sprayed onto dried plant materials (eg, tobacco, knaster). Hence, in addition to the variability in composition and amounts of synthetic cannabinoids between Spice products, there may also be significant variation between different batches.

Because most synthetic cannabinoids used in Spice products have never been tested for human consumption, and many are considerably more potent CB receptor full agonists, compared with the partial agonist THC, this makes dosing difficult, and increases the risk of accidental overdose and health problems. Furthermore, due to the high lipid-solubility of cannabinoids, they likely persist in the body for long periods of time. As a result, adverse events necessitating contact with poison information centers and treatment at hospital emergency departments are increasing (Centers for Disease, Control, & Prevention, 2013b; Helander et al., 2014), as are the number of published case reports describing serious adverse neurologic and sympathomimetic effects associated with both acute and chronic use of Spice products (Fattore & Fratta, 2011; Seely, Lapoint, Moran, & Fattore, 2012; Freeman et al., 2013; Hopkins & Gilchrist, 2013; Patton et al., 2013; Behonick et al., 2014; Gugelmann et al., 2014; Ibrahim, Al-Saffar, & Wannenburg, 2014; Mckeever et al., 2014). Notably, one specific synthetic cannabinoid,

XLR-11, which is the fluorinated analog of UR-144 (Fig. 87.4), has recently been implicated in several cases of acute kidney injury requiring dialysis (Centers for Disease, Control, & Prevention, 2013a; Thornton, Wood, Friesen, & Gerona, 2013; Buser et al., 2014).

DRUG TESTING FOR SYNTHETIC CANNABINOIDS

In addition to the desired psychoactive effects of synthetic cannabinoids associated with CB_1 receptor agonism, a common reason for using Spice products over cannabis (marijuana) is to avoid detection of drug use, as synthetic cannabinoids are not detected by standard urine drug testing procedures (Gunderson, Haughey, Ait-Daoud, Joshi, & Hart, 2014). For example, apart from some THC analogs (eg, HU-210) (Fig. 87.2), most of these substances will not be detected in the immunoassays used for cannabis screening, due to the marked differences in drug structure (Fig. 87.4). Recently, specific immunoassays targeting synthetic cannabinoids have been introduced, but a main limitation is that they only cover a small part of all these substances (Barnes et al., 2014; Spinelli et al., 2014). Furthermore, due to the rapid turnover of NPS and the constantly changing composition of Spice products (EMCDDA, 2014), these methods risk soon becoming obsolete. Consequently, using flexible methods based on sensitive and selective liquid chromatography-mass spectrometry has become a standard analytical principle for detection of synthetic cannabinoids and their metabolites, in various biological specimens (urine, blood, saliva, and hair) (Salomone, Gerace, D'urso, Di Corcia, & Vincenti, 2012; Kneisel, Auwärter, & Kempf, 2013; Huppertz, Kneisel, Auwärter, & Kempf, 2014; Scheidweiler & Huestis, 2014). Even so, detecting all novel synthetic cannabinoids appearing in Spice products and including them in analytical methods requires frequent updating, and will thus represent a continuing challenge for the clinical and forensic toxicology laboratories (Meyer & Peters, 2012), and also for the implementation of control measures by public health authorities.

Other problems with drug testing for NPS relate to the identification of suitable target compounds for analysis (eg, major metabolites), and an initial lack of certified reference materials. For synthetic cannabinoids, the parent drugs are typically detectable in blood but not, or only rarely, in urine samples (Helander, Beck, Hägerkvist, & Hulten, 2013). A limitation with analysis of blood is that it will cover only recent drug intake. Accordingly, to obtain a longer detection window, analysis of drug metabolites excreted in urine, or even hair, is a common strategy. However, because little is often known about the metabolic pattern of the new drugs, this possibility is also limited until the optimal target metabolites for drug testing have been identified (Grigoryev et al., 2011; Hutter, Broecker, Kneisel, & Auwärter, 2012; Scheidweiler & Huestis, 2014). It should also be considered that because many synthetic cannabinoids are considerably more potent than THC, they need to be administered in much lower doses, resulting in lower drug concentrations and are, thereby, harder to detect. In addition, because many synthetic cannabinoids are structurally closely related and undergo similar biotransformation, they sometimes share common metabolites, making it difficult to identify the specific parent compound (legal or illegal) involved (Hutter, Moosmann, Kneisel, & Auwärter, 2013).

CONCLUSIONS

The Spice phenomenon represents a new trend in substance abuse, and use of Spice products is increasing, especially among teenagers and young adults (Wood, 2013; Helander et al., 2014). A wide variety of herbal smoking blends spiked with highly potent synthetic cannabinoid receptor agonist are continuously introduced by online sale to the recreational drugs market. Banned substances in the Spice products are rapidly replaced by other, structurally similar psychoactive variants, in order to stay ahead of legislation (legal highs). Many synthetic cannabinoids are highly potent CB receptor full agonists, some showing 100-fold higher affinity than the partial agonist THC, and they have not undergone the standard human safety testing required for pharmaceuticals. This may cause problems with drug dosing, and poses a risk for severe medical and psychiatric complications. Due to lack of reference materials, and because little is known initially about the metabolic patterns of novel synthetic cannabinoids, including them in analytical methods for routine drug testing represents an ongoing challenge for the clinical and forensic toxicology laboratories. Furthermore, the rapid turnover and variability in product composition of synthetic cannabinoids also brings major challenges to the control of new drugs. It can be assumed that further structural analogs with CB receptor agonism activity from different chemical groups will continue to appear in Spice products, and that this new drug phenomenon will be a problem to continue. In addition, synthetic cannabinoids are also being distributed in new formulations, such as in liquid form to be consumed using vaporizers and e-cigarettes.

MINI-DICTIONARY

Cannabinoid receptors (CB) Receptor targets for endocannabinoids, phytocannabinoids, and synthetic cannabinoids, of which type 1 (CB1) is mainly centrally located and associated with psychoactive effects, and type 2 (CB2) is mainly peripheral and associated with immunomodulatory effects.

Designer drugs Synthetic variants of classical illicit drugs that have been structurally modified (designed) to circumvent legislative control.

Endocannabinoids Endogenous cannabinoid receptor agonists such as anandamide (arachidonoylethanolamide) and 2-arachidonoylglycerol.

Legal highs Psychoactive substances that are not controlled as illicit drugs, and hence can be sold openly, for example, over the internet.

New psychoactive substances (NPS) Synthetic substances that have the same biological targets as classical illicit drugs, acting on neurotransmitter receptors and transporter, but the chemical structure differences mean legislative control can be circumvented, and products sold openly.

Phytocannabinoids Chemical compounds isolated from the cannabis plant (Cannabis sativa), of which Δ9-tetrahydrocannabinol (THC) is the principal psychoactive constituent.

Spice A common name for herbal smoking blend products containing synthetic cannabinoids that are sold over the internet as "legal marijuana substitutes."

Synthetic cannabinoids Cannabinoid receptor agonists with variable binding affinity for the CB1 and CB2 receptors that have been synthesized as research tools, or patented as therapeutic drug candidates.

Accidents and Synthetic Cannabinoids in Blood of Drivers

S.S. Tuv, V. Auwärter**, V. Vindenes**

***Department of Drug Abuse Research, Division of Forensic Sciences, Norwegian Institute of Public Health, Oslo, Norway**

****Forensic Toxicology Department, Medical Center, University of Freiburg, Institute of Forensic Medicine, Freiburg, Germany**

SUMMARY POINTS

- Synthetic cannabinoids are potent drugs that produce cannabis-like effects.
- The prevalence of synthetic cannabinoids among drivers in normal traffic and accidents is not known.
- Analyzing these substances is challenging due to low concentrations and different variants emerging on the drug market.
- Impairment recognized by clinical tests for impairment can reveal the use of synthetic cannabinoids, and should be used as a guideline in cases of driving under the influence.
- Concentrations of synthetic cannabinoids in the concentration range below 1 ng/mL may cause impairment significant for operating a vehicle.

KEY FACTS OF CANNABINOID RECEPTORS

- There are currently two known subtypes of cannabinoid receptors: the cannabinoid CB-1 receptor, and the cannabinoid CB-2 receptor.
- The CB-1 receptor is mainly located in the brain, and the CB-2 receptor is mainly expressed in the immune system.
- Cannabinoid receptors are transmembrane receptors in the G protein-coupled receptor superfamily.
- The CB-1 receptor is thought to be one of the most widely expressed G-protein coupled receptors in the brain, and is believed to play a significant role in the modulation of GABA and glutamate neurotransmission.
- Agonists to the cannabinoid receptors include cannabinoids naturally occurring in the human body (endocannabinoids), cannabinoids from plants, and synthetic cannabinoids.

KEY FACTS OF CLINICAL TEST OF IMPAIRMENT

- Drivers suspected of driving under the influence (DUI) of drugs in Norway are usually examined by a physician to assess drug impairment.
- The test battery consists of 25 tests and observations related to common signs of impairment.
- It includes testing of specific psychomotor and cognitive tasks.
- The physician makes a conclusion regarding the overall degree of impairment using a four-step scale: not impaired, mildly impaired, moderately impaired, or greatly impaired.
- The clinical test of impairment (CTI) was originally designed to assess traffic related impairment due to alcohol, but has been revised to reveal impairment due to other substances as well.

LIST OF ABBREVIATIONS

CB-1R/CB-2R	Cannabinoid receptors 1 and 2
CTI	Clinical test of impairment
DUI	Driving under the influence
DRE	Drug recognition expert
THC	Δ^9-Tetrahydrocannabinol

INTRODUCTION

Driving under the influence (DUI) of drugs is an issue of growing concern, particularly since it is an important cause of road traffic accidents (Blomberg, Peck, Moskowitz, Burns, & Fiorentino, 2009; Gonzalez-Wilhelm, 2007). Among young adults, road injuries have been found to be the number one risk factor for disease in Western Europe (Lim et al., 2012). Worldwide, around 1.24 million people die every year in road traffic deaths (WHO, 2013), and drugs are involved in a large number of these fatal accidents. The most prevalent illicit drug found in DUI cases in the European Union is Δ^9-Tetrahydrocannabinol (THC) (EU, 2005).

Synthetic cannabinoids have been on the illicit drug market since early 2000, also known as "Spice" in Europe and "K2" in the United States. Initially, these products were believed to be herbal blends producing cannabis-like effects, but synthetic cannabinoids were detected for the first time in 2008 from these blends (Auwärter et al., 2009). Today, more than 50 different synthetic cannabinoids were identified in such products, and new variants appear monthly. The availability through the Internet, legal aspects, the low price, and poor detectability in rapid drug tests have been important factors contributing to the popularity among specific subgroups of drug users.

The main psychoactive component of the plant *Cannabis sativa* is THC. Synthetic cannabinoid products do not usually contain THC. Synthetic cannabinoids are a chemically diverse group, but they all bind to and activate the same receptors as THC (CB-1 and CB-2 receptors), and produce cannabis-like effects when consumed in moderate doses. CB-1 receptors are widely distributed throughout the nervous system, and agonist binding to CB-1 receptors can lead to altered mood and perception, reduced motor-function, impaired memory, altered visual and auditory impressions, severe anxiety, and panic attacks. These effects lead to reduced driving skills. Synthetic cannabinoids have higher binding affinities to CB-1 receptors than THC, and many of them are full agonists at the CB-1 receptor, while THC acts as a partial agonist. Both these conditions contribute to the unfavorable risk profile of the synthetic cannabinoids, and enhance the risk of strong adverse effects. Potent metabolites holding agonistic activity at CB-1 receptors have been described for some of the compounds, further complicating the pharmacodynamic properties.

The effects on driving ability related to recreational use of cannabis are well known, and epidemiologic studies have shown an increased risk of being involved in car accidents after consumption of cannabis (Drummer et al., 2004; Mura et al., 2003). There are no such studies investigating the risk of traffic accidents caused by synthetic cannabinoids, but given the pharmacological activity with binding to the same receptors as THC, and a higher potency and efficacy, it is reasonable to assume similar or even stronger impairing effects on driving ability.

PUBLISHED CASES OF DRIVING UNDER THE INFLUENCE OF SYNTHETIC CANNABINOIDS

Five studies have reported detection of synthetic cannabinoids among impaired drivers. Only 11 different synthetic cannabinoids have been proven in samples from these 84 drivers. The whole blood/serum concentrations are low, and the median concentrations for the different drugs vary between 0.17 and 0.69 ng/mL (Table 88.1).

Yeakel and Logan (2013) describe twelve cases of suspected impaired driving testing positive for synthetic cannabinoids. The concentrations in whole blood ranged from 0.1 to 9.9 ng/mL (LOQ 0.1 ng/mL), and more than one synthetic cannabinoid was found in half of the cases. The detected synthetic cannabinoids included JWH-018, JWH-081, JWH-122, JWH-210, JWH-250, and AM-2201. Drivers with positive findings for alcohol or other drugs were excluded from the study, and results from psychophysical assessment were attributed to the use of synthetic cannabinoids. The subjects were evaluated applying the drug recognition expert (DRE) protocol, and the impairment was categorized in terms of the observed signs. Cannabis was suspected to be the drug responsible for impairment in all cases evaluated by the DRE. Common observations were poor coordination, slow and slurred speech, injected conjunctivae, lack of convergence, and muscle tremors. The pupil size varied, and nystagmus was not observed, pulse rate and systolic blood pressure were generally elevated. Yeakel and Logan found no correlation between the blood concentrations of the synthetic cannabinoids and the degree of impairment. Information regarding the accidents was obtained from seven cases, and four of these had been involved in a car accident. All were considered as the culpable driver. The mean age was 22.4 (range 18–31) years.

Musshoff et al. present six DUI cases, and one 14 year-old girl cycling in a wavy way. Analyses confirmed synthetic cannabinoids where impairment was observed by the police or by a physician (Musshoff et al., 2014).

TABLE 88.1 Blood/Serum Concentrations of Synthetic Cannabinoids Detected in Cases of Driving Under the Influence

Synthetic cannabinoid	Number of DUI cases	Involvement in traffic accident	Blood or serum concentrations in ng/mL, median (range)	References
AM-2201	18	4	0.69 (<0.05–5.5)	Dziadosz, Klintschar, and Teske (2014); Musshoff et al. (2014); Tuv et al. (2014); Yeakel and Logan (2013)
JWH-122	16	3	0.33 (<0.05–28)	Dziadosz et al. (2014); Musshoff et al. (2014); Tuv et al. (2014); Yeakel and Logan (2013)
JWH-210	15	2	0.38 (<0.05–6.2)	Dziadosz et al. (2014); Musshoff et al. (2014); Yeakel and Logan (2013)
JWH-018	17	1	0.17 (<0.05–9.9)	Musshoff et al. (2014); Tuv et al. (2014); Yeakel and Logan (2013)
Other (7 different variants)	12	3		
Unknown	6	5		Chase et al. (2013)

Four of the drivers were checked during general road traffic controls, one had driven his car into a ditch, and the police apprehended another after witness observation. In all cases, more than one synthetic cannabinoid were detected, and serum concentrations ranged from <0.1 ng/mL to 28 ng/mL. Drugs detected included JWH-018, AM-2201, JWH-210, and JWH-122. The impairment registered in these cases was similar to the findings of Yeakel and Logan, and the centrally sedating effects and reduction in fine motor skills were assumed to be of great importance. The authors concluded that the consumption of synthetic cannabinoids could lead to impairment similar to typical performance deficits caused by cannabis use, which are not compatible with safe driving. The mean age of the apprehended drivers was 20.7 (range 14–29) years.

Chase et al. (2013) retrospectively compared drivers suspected of DUI of synthetic cannabinoids ($n = 13$) with a similar group suspected of impairment due to marijuana use ($n = 25$). Thirty-eight percent of the synthetic cannabinoid suspects were involved in a car accident, while only 4% of the marijuana suspects were involved in a car accident. Based on the experiences from the DREs, they concluded that intake of synthetic cannabinoids leads to more pronounced confusion and disorientation, and more frequent involvement in car accidents than intake of marijuana. Blood samples were only provided in seven of the synthetic cannabinoid cases, six of these proved positive for synthetic cannabinoids. No further information is available regarding these findings, nor are blood concentrations given.

Tuv et al. (2014) found a prevalence of synthetic cannabinoids in DUI suspects in Norway of 2.2% (16 out of 726 cases). Four of the cases were collected from drivers involved in a traffic accident; eleven of the cases were due to suspicion of DUI by the police and one after suspicion of drug use. AM-2201 and JWH-018 were the most frequently detected synthetic cannabinoids. Concentrations varied between 0.07 and 1.67 µg/L. All of the cases had concomitant findings of other potent psychoactive drugs, and it was not possible to find a correlation between the concentrations of the detected synthetic cannabinoids and the degree of impairment judged by a physician. Only one synthetic cannabinoid was found in each case. In 15 out of the 16 cases, the drivers were males, and the mean age was 29.6 (range 17–49) years.

Dziadosz et al. present a study where DUI cases with THC or THC metabolites in serum were further analyzed for a selection of synthetic cannabinoids. The results revealed a 0.5% prevalence of synthetic cannabinoids among the THC-positive drivers. There is no information regarding the prevalence of cannabis among the DUI drivers, and the prevalence of the synthetic cannabinoids can thus not be estimated. A total of 12 cases were positive with respect to synthetic cannabinoids, and the repertoire tested included JWH-018, JWH-122, JWH-210, and AM-2201. Almost half of the cases revealed more than one synthetic cannabinoid in combination with THC. Serum concentrations ranged from <0.05 to 0.75 ng/mL, and most of the cases were in the lower concentration area.

CLINICAL PRESENTATION OF INTOXICATION DUE TO SYNTHETIC CANNABINOIDS

The recreational use of synthetic cannabinoids has led to numerous intoxications, and also at least three deaths (Gay, 2012; Saito et al., 2013) in the last few years. Physiological effects of synthetic cannabinoids can be wide-ranging, from mild to serious symptoms which require

TABLE 88.2 Effects of Synthetic Cannabinoids That Might Interfere With Safe Driving

Type of effect	Symptom
Cognitive	Memory impairment
	Reduced concentration
	Attention deficit
	Disorientation, confusion
Neurological	Agitation/panic
	Loss of consciousness/coma
	Anxiety/paranoia
	Psychosis/hallucination
	Changes in mood and perception
	Seizures
	Reduced fine motor skills
Cardiovascular	Chest pain/myocardial infarction
	Arrhythmia
Gastrointestinal	Nausea/emesis

TABLE 88.3 Findings Among Apprehended Drivers

Findings among apprehended drivers
Poor coordination
Slow and slurred speech
Injected conjunctivae
Lack of convergence
Lack of nystagmus
Pupil size varied
Muscle tremors
Increased pulse rate
Elevated systolic blood pressure
Reduction in fine motor skills
Confusion
Disorientation

Some common findings among suspects of driving under the influence due to synthetic cannabinoids.

treatment in an intensive care unit. A review of the literature from 2010 to mid-2013 suggests that synthetic cannabinoids can have more severe side effects than marijuana (Gurney, Scott, Kacinko, Presley, & Logan, 2014; Hermanns-Clausen, Kneisel, Szabo, & Auwärter, 2013), and it is reasonable to assume that effects of synthetic cannabinoids might be of importance regarding skills needed to drive safely. Several of the symptoms are similar to cannabis intoxication, but more severe symptoms not usually associated with the use of cannabis have also been noted. An increasing number of papers describes the clinical presentation of intoxication due to synthetic cannabinoids, and the most common symptoms include severe agitation, hallucinations, vomiting, drowsiness, and altered mood and perception (Forrester, Kleinschmidt, Schwarz, & Young, 2011; Rosenbaum, Carreiro, & Babu, 2012). Effects on cognitive function and the nervous system might be of great concern with respect to driving ability, but also cardiovascular and gastrointestinal effects which are commonly observed might be incompatible with safe driving. Table 88.2 gives an overview of effects of synthetic cannabinoids that may be of importance with regard to driving-related skills.

FINDINGS AMONG APPREHENDED DRIVERS

In several of the DUI cases described in the literature, a DRE evaluation, an examination by a physician or a clinical test of impairment (CTI) has been performed (Bramness, Skurtveit, & Morland, 2003). All these examinations are performed by trained personnel looking for specific signs of drug impairment. Some observations or failures of tests seem to recur often, and Table 88.3 shows some common findings among suspects of DUI due to synthetic cannabinoid use.

CONCENTRATIONS OF SYNTHETIC CANNABINOIDS IN BLOOD FROM SUSPECTED DRIVERS

Concentrations ranged from as low as <0.05 to as high as 28 ng/mL for all the synthetic cannabinoids detected, but the mean concentrations from all the studies were 0.69 ng/mL or below. The highest concentration was seen in a DUI case where six additionally different synthetic cannabinoids were detected. The police noted that the suspect showed retarded movements, was apathetic, nervous, and inert, and had delayed reaction of pupils to light (Musshoff et al., 2014). A majority of the cases was in the lower concentration range, but also high concentrations were present in some cases. Several of the suspects with small amounts of synthetic cannabinoids in blood were described as impaired. In one case, the concentration of JWH-018 in whole blood was only 0.24 ng/mL, however, observations of the driver included raised arms and improper turn during walk-and-turn (WAT) test, raised arms during one-leg stand (OLS) test, and eye flutters during Romberg's test (Yeakel & Logan, 2013). In this study, it could not be excluded that other drugs not included in the analytical repertoire were present in the samples; and since there might be drugs with high potency, low concentrations could thus cause heavy impairment.

No direct link between the degree of impairment and blood or serum concentrations of synthetic cannabinoids has been established, as seen for THC, where higher concentrations of THC are associated with increasing impairment and increased risk of traffic accidents (Ramaekers, Berghaus, van Laar, & Drummer, 2004). From the perspective of these findings, it seems plausible, however, that concentrations of synthetic cannabinoids in the range below 1 ng/mL may cause significant impairment.

VARIANTS OF SYNTHETIC CANNABINOIDS DETECTED AMONG APPREHENDED DRIVERS

Despite the enormous number of available synthetic cannabinoids, the different variants of synthetic cannabinoids detected in published DUI cases are relatively limited. This could be due to analytical limitations (you only find what you are looking for), and the fact that the presented cases fall into a narrow time frame (the spectrum of analytes that is present in the samples will changes over time). The most frequently detected synthetic cannabinoids in the presented DUI cases so far include JWH-122, JWH-018, AM-2201, and JWH-210. The different variants detected may also mirror different trends of abuse in different countries and regions, given that different laboratories have the same repertoire of synthetic cannabinoids. In DUI cases referred to in this paper, JWH-122 was one of the most frequently detected synthetic cannabinoids in Germany and the United States, but this variant was not at all detected in the Norwegian material, although included in the analytical method. AM-2201 was the most frequently detected synthetic cannabinoid among apprehended drivers involved in a traffic accident. One-third of all published DUI cases with detection of AM-2201 were involved in traffic accidents. Few of the drivers who tested positive for the other most popular variants were involved in accidents. The different variants detected in the available literature are given in Table 88.4. However, it must be kept in mind that the synthetic cannabinoids available in "herbal mixtures" change rapidly over time.

THE PREVALENCE OF SYNTHETIC CANNABINOIDS IN TRAFFIC ACCIDENTS

The reasons for a traffic accident might be complex, and it is often difficult to distinguish the different contributing factors. Various types of studies are available for studying the effects of drugs on driving ability. For

well-studied substances, the risk for traffic accidents have been estimated, but the small number of traffic accidents involving analytically confirmed synthetic cannabinoid use sets up limitations. Also, culpability does not exist in all these cases, making it even more difficult to estimate the risk of traffic accidents.

We do not have information about the circumstances in each of the published DUI cases, and only nine traffic accidents are featured in detail in the literature. Other DUI cases with analytically confirmed synthetic cannabinoid use were typically captured in police routine controls. In several of the cases, other psychoactive drugs were detected concomitantly, making it more difficult to assess the contribution of the detected synthetic cannabinoid.

Chase et al. (2013) additionally described five more accidents related to the intake of synthetic cannabinoids, but the different synthetic cannabinoids are not disclosed. From the small number of observations by Chase et al. (2013), it was estimated that among the "Spice" suspects, 38% of the drivers were involved in motor vehicle crashes. However, blood was only available from 7 of the 13 drivers. Nevertheless, the results indicate that DREs in a large part of the cases were able to recognize impairment caused by synthetic cannabinoids.

Dziadosz et al. analyzed samples collected during police traffic control that tested positive for THC and/or metabolites for synthetic cannabinoids. Among these samples, they reported 0.5% to be positive for at least one synthetic cannabinoid in addition. The number of participants in this study is not known. In the Norwegian study, among drugged drivers the prevalence of synthetic cannabinoids was 2.2%.

Table 88.4 gives an overview of DUI cases published, and the different synthetic cannabinoids involved. The prevalence of synthetic cannabinoids in traffic accidents is difficult to estimate from these sparse data. The number of traffic accidents in Table 88.4 exceeds the total number of published accidents because in several of the cases more than one synthetic cannabinoid was detected. In one case, as much as seven different synthetic cannabinoids were analytically confirmed (Musshoff et al., 2014).

It is important to note that the synthetic cannabinoids have been measured in whole blood in some studies, and serum in others. The ratio between concentrations of synthetic cannabinoids in serum and whole blood is not known, and this must be kept in mind when concentrations from different studies are compared. Since the synthetic cannabinoids might have similar properties as THC, it seems likely that the concentrations measured in serum is significantly higher compared to whole blood concentrations. For THC, the ratio between serum and whole blood is around 1.8–2 (Baselt, 2009).

ANALYTICAL CHALLENGES

Only in the last few years analytical methods have been available to detect these substances in blood or serum, and many of the methods are not "up to date" due to quick changes in the composition of synthetic cannabinoid containing products. Knowledge of driving under the influence of these substances is therefore scarce. Many of the synthetic cannabinoids are highly potent substances, and doses in the low or even submilligram range produce the typical effects. This leads to low concentrations in blood or serum samples which are challenging for analytical method development.

Due to the frequent appearance of new variants of synthetic cannabinoids on the drug market, it is a major challenge for analytical laboratories to keep track of the substances to look for. Seizures in the different countries provide some important information. For urine analysis, information regarding metabolism of new substances must be obtained before an analytical method is developed because for most of the synthetic cannabinoids no parent compound is excreted renally. As several of these metabolites act as potent CB-1 agonists, it may be reasonable to include them into methods for blood analyses. However, most forensic laboratories only search for the parent compounds in blood so far (Fantegrossi, Moran, Radominska-Pandya, & Prather, 2014).

The detection rate of synthetic cannabinoids using immunoassays seems to be limited due to the quick structural changes over time (Hutter, Ippisch, Schultis, & Auwärter, 2012).

Most laboratories analyze forensic samples using a standard repertoire where the most common drugs of abuse are included. If there is a suspicion of drug impairment without any findings in the standard drug panel, further analyses are performed. Concomitant consumption of other psychoactive drugs can thus cover the use of synthetic cannabinoids, leading to an underestimation of these drugs in DUI cases. A mixed consumption of synthetic cannabinoids and cannabis has been detected in DUI cases as reported by Dziadosz et al. (2014).

TOLERANCE

Little is known regarding tolerance to the effects of synthetic cannabinoids. From Internet fora, users have described the phenomenon of tolerance after using synthetic cannabinoids. The findings among regular users where high concentrations of synthetic cannabinoids in serum do often not produce signs of intoxication support these statements. Reduced activation of the CB-1 receptor has been observed in rats that had been given HU-201 for a longer period of time (Dalton & Zavitsanou, 2010). In another study, it was shown that synthetic cannabinoids

lead to rapid and robust internalization of CB-1 receptors (Atwood, Huffman, Straiker, & Mackie, 2010; Atwood, Lee, Straiker, Widlanski, & Mackie, 2011). Based on these findings, it is reasonable to assume capacity to produce tolerance to at least some of the effects of synthetic cannabinoids. Regarding well-studied substances, such as the benzodiazepines, it is known that development of tolerance is mostly linked to subjective effects of the drugs, and does not so much affect reduced skills needed to be a safe driver. Users have also described crosstolerance between THC and synthetic cannabinoids with reduced effects of THC after the intake of synthetic cannabinoids, and vice versa. The effect of regular use of synthetic cannabinoids on driving skills is unknown so far.

LEGISLATION

Different countries have different approaches concerning driving under the influence. Two main principles are used: per se law—with fixed concentration limits defining the threshold for punishability (limits of detection (LOD) can be used, but also higher cut-off levels); or impairment-based laws where an individual evaluation of impairment is done in each case, and more severe sanctions are provided with increasing impairment.

Although sometimes referred to as "legal highs," an increasing number of countries have introduced legislation to control synthetic cannabinoids. Due to a constantly changing market of synthetic cannabinoids, different approaches were tried to allow for a rapid and dynamic update of drugs scheduled. Scheduling these substances timely may support prevention work of traffic accidents, as noncontrolled products may mislead users to believe that driving after consumption is legal and safe.

DISCUSSION AND CONCLUSIONS

The prevalence of DUI of synthetic cannabinoids is not known, and neither the prevalence of such drugs in traffic injuries nor in fatal car crashes. Synthetic cannabinoids are not detected using regular rapid tests. Even with chromatographic methods, only a limited number of the available substances can be revealed, and not all laboratories provide analytical methods for the detection of these drugs. Impairment recognized by clinical tests for impairment by physicians, the police, or drug recognition experts can reveal such use, however, and the awareness of such drugs among these people is thus of major importance. The legal approach concerning driving under the influence of synthetic drugs vary between different countries, and, as the name "legal highs" indicates, in some countries there is no legislation effectively regulating these substances. From studies describing the clinical effects of synthetic cannabinoids, and also the reports from apprehended drivers where these drugs have been detected, synthetic cannabinoid use is not compatible with safe driving, and should therefore be regulated in the driving legislation. It is thus of major importance to increase the general knowledge in society of the risk of driving under the influence of synthetic cannabinoids, and further to provide comprehensive analytical methods to be able to reveal such use, and also appropriate legislation.

MINI-DICTIONARY

Spice/K2 Brands of synthetic cannabinoid products often used as an umbrella term for herbal products containing synthetic cannabinoids.

Synthetic cannabinoids A chemically diverse group of substances functionally similar to THC in binding to the same receptors, resulting in a cannabis-like high.

Clinical test of impairment (CTI) A test battery consisting of 25 tests and observations related to common signs of drug impairment.

Drug recognition expert (DRE) A drug recognition expert is a police officer trained to recognize impairment in drivers due to drugs other than alcohol.

Chromatographic analysis Technique for separating the components, or solutes, of a mixture on the basis of the relative amounts of each solute distributed between a moving fluid stream, called the mobile phase, and a stationary phase.

Cannabidiol as an Antioxidant

*R.S. Borges**, *A.B.F. da Silva***

***Faculty of Pharmacy, Institute of Health Sciences, Federal University of Pará, Belém, Para, Brazil**
****Institute of Chemistry of São Carlos, University of São Paulo, São Carlos, Sao Paulo, Brazil**

SUMMARY POINTS

- This chapter focuses on the theoretical antioxidant capacity of cannabidiol (CBD), using density functional theory calculations.
- Structural properties of CBD are compared with related derivatives.
- Antioxidant properties are compared with trolox, a simplified model of α-tocopherol.
- Theoretical properties of CBD and derivatives are associated to electron or hydrogen transfer.
- The antioxidant property of CBD may be related to its electron and hydrogen abstraction at the phenol position.
- Phenol and alkyl moieties increase the highest occupied molecular orbital (HOMO) energies, and decrease the ionization potential (IP) values.
- The lowest O—H bond dissociation energies (BDE_{OH}) are related to the phenol position.
- The limonene moiety has a slight higher relevance than phenyl-pentane.
- Antioxidant mechanisms in biological system and their applications are discussed.

KEY FACTS OF ANTIOXIDANT CAPACITY

- The antioxidant capacity can be determined using experimental and theoretical methods.
- Quantum mechanical methods can provide descriptors to be related with the antioxidant capacity of molecules.
- Density functional theory calculations have been employed to evaluate electron or hydrogen transfer of antioxidant compounds.
- Antioxidant mechanisms can be determined using structure–activity relationship.
- In general, the electron transfer is related to the ionization potential, and the bond dissociation energy to the hydrogen transfer.
- A high antioxidant capacity depends on the number and position of hydroxyl groups or electron donating groups.
- The antioxidant capacity of any molecule can be compared to every structural fragment of parent molecule.

LIST OF ABBREVIATIONS

6–311++G(2d,2p)	Largest basis sets
ArO$^{\bullet}$	Phenoxyl free radical
ArO^{-}	Phenoxyl anion radical
ArOH$^{\bullet+}$	Phenol cation free radical
ArOH	Neutral phenol
B3LYP	Hybrid functional Becke and three-parameter Lee–Yang–Parr
CBD	Cannabidiol
CBD-O$^{\bullet}$	Cannabidiol semiquinone radical
CBD-OH	Neutral cannabidiol
CBD-OH$^{\bullet+}$	Cannabidiol cation free radical
DFT	Density functional theory
E	Energy
E_{GAP}	Energy gap or bandgap
ΔEiso	Stabilization energy

Eq.	Equation
FES$^{\bullet}$	Free radical species
FESH	Free radical species
HOMO	Highest occupied molecular orbital
IP	Ionization potential
LUMO	Lowest unoccupied molecular orbital
P450	Cytochrome P450
PPARγ	Peroxisome proliferator-activated receptor gamma
R$^{\bullet}$	Alkyl free radical
R^{-}	Alkyl anion radical
RH	Alkyl radical
SAR	Structure–activity relationship
TLX	Trolox
THC	(−)Δ^9-Tetrahydrocannabinol

INTRODUCTION

The use of cannabidiol (CBD) or 2-[(1R,6R)-6-isopropenyl-3-methylcyclohex-2-en-1-yl]-5-pentylbenzene-1,3-diol (Fig. e12.1) as an antioxidant and neuroprotective agent is well known in the literature (Moldzio et al., 2012; Hayakawa et al., 2007; Di Marzo, Bifulco, & de Petrocellis, 2004). The CBD is a very low endogenous ligand of cannabinoid receptors CB1 and CB2, however, its metabolism by fatty acid amide hydrolase and monoacylglycerol lipase induces antinociceptive effects (Hohmann & Suplita, 2006; Walker & Huang, 2002).

Currently, its clinical recommendation as analgesic is growing (Fox & Bevan, 2005; Meng, Manning, Martin, & Fields, 1998). In fact, this compound has several biological effects and potential uses, such as antiinflammatory (Naftali, Mechulam, Lev, & Konikoff, 2014), anticancer (Murase et al., 2014), ischemia (Gonca & Darıcı, 2014), antimicrobial (Appendino et al., 2008), and anxiolytic (Almeida et al., 2013). Nevertheless, it has poor solubility in water, and good solubility in organic solvents (Mannila, Järvinen, Järvinen, & Jarho, 2007).

Unlike other cannabinoids, CBD contains two phenolic groups. It has antioxidant activity sufficient to protect the liver against binge alcohol-induced steatosis, by a mechanism including inhibition of oxidative stress (Yang et al., 2014). It has a cardioprotective effect in rats exposed to doxorubicin toxicity by free radical scavenging (Fouad, Albuali, Al-Mulhim, & Jresat, 2013). Actually, tests in mouse during hepatic microsomal metabolism indicate that CBD prevents the generation of reactive oxygen species (Usami, Yamamoto, & Watanabe, 2008). Some CBD properties were observed in previews in an in vivo study, where this compound attenuates cisplatin-induced nephrotoxicity by decreasing oxidative stress through oxygen or nitrogen free radical species, inflammation, and cell death (Pan et al., 2009). Other studies using colon cancer lines showed that CBD has a chemopreventive effect (Aviello et al., 2012).

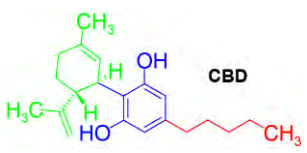

FIGURE e12.1 **Chemical structure of CBD.** Molecular structure of CBD has three different chemical moieties: limonene *(green)*, phenol *(blue)*, and aliphatic group *(red)*.

An experimental study showed that cannabinoids can prevent Alzheimer disease in an animal model by preventing the inflammation caused by microglia cells which are activated by the binding of amyloid protein (Steffens et al., 2005). Nevertheless, the evaluation of the neuroprotective effect of cannabinoids in a rat model of Parkinson disease has confirmed the importance of the antioxidant mechanism, and the cannabinoid receptor-independent properties (García-Arencibia et al., 2007).

In addition, pain and inflammation are other major clinical signs that can be triggered by a free radical mechanism. Nonetheless, CBD exerts an orally effective therapeutic agent in rat models of chronic inflammatory and neuropathic pain (Costa, Trovato, Comelli, Giagnoni, & Colleoni, 2007). CBD has been shown to be extensively metabolized by experimental animals and humans, in the liver, predominantly by cytochrome P450 enzymes from oxidation reactions (Stout & Cimino, 2014). The hydroxylation reactions on limonene and *n*-pentyl moieties were the main metabolites (Jiang, Yamaori, Takeda, Yamamoto, & Watanabe, 2011; Yamaori, Ebisawa, Okushima, Yamamoto, & Watanabe, 2011). In fact, cytochrome P450 enzymes catalyze a variety of reactions (mainly oxidation), converting chemicals to potentially reactive products, as well as producing less toxic compounds. The majority of these reactions can be intermediated by electron or hydrogen abstraction mechanisms (Guengerich, 2001).

In accordance with the literature, two main mechanisms are proposed to explain the protective role for antioxidants for phenol derivatives (Leopoldini, Chiodo, Russo, & Toscano, 2011a; Galano, Macías-Ruvalcaba, Campos, & Pedraza-Chaverri, 2010; Galano, 2011; Iuga, Alvarez-Idaboy, & Russo, 2012; Chiodo, Leopoldini, Russo, & Toscano, 2010; Leopoldini, Marino, Russo, & Toscano, 2004; Leopoldini, Russo, & Toscano, 2006; Leopoldini, Russo, & Toscano, 2007; Leopoldini, Russo, & Toscano, 2011b). One is the H-atom transfer mechanism, in which a free radical R$^{\bullet}$ removes a hydrogen atom from the antioxidant (ArOH) (Eq. e12.1), and the other one is the one-electron transfer mechanism, where the antioxidant compound can give an electron to the radical (Eqs. e12.2 and e12.3). In addition to these mechanisms, the radicals arising from both reactions (ArO$^{\bullet}$ and ArOH$^{\bullet+}$) must be stable, in order to prevent chain radical reactions.

$$R^{\bullet} + ArOH \rightarrow RH + ArO^{\bullet} \quad \text{(e12.1)}$$

$$R^{\bullet} + ArOH \rightarrow R^{-} + ArOH^{\bullet +} \quad \text{(e12.2)}$$

$$R^{\bullet} + ArO^{-} \rightarrow R^{-} + ArO^{\bullet} \quad \text{(e12.3)}$$

An understanding about its mechanism and the role played by the different structural features of CBD, defining how these functional moieties are responsible for its antioxidant properties, can be elucidated using molecular modeling (Borges et al., 2013). Thus, the relationship among electronic properties, antioxidant capacity of CBD, and its possible antioxidant mechanism can be determined using theoretical methods.

Here, a systematic study of the influence of the phenol, limonene, and *n*-pentyl-benzene groups on the antioxidant properties of CBD is reviewed (Borges et al., 2013) (Fig. e12.2). In addition, the properties of CBD and related derivatives were compared with a simplified model of α-tocopherol (trolox, (±)-6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxilic acid) (Huang, Ou, & Prior, 2005). The structural and electronic characteristics of CBD obtained using the Density Functional Theory (DFT) methodology (Frisch et al., 2004) is reviewed with the objective of shedding light on the possible oxidation mechanism of CBD, and its relationship with its putative antioxidant properties. The studies performed here assessed the energies of the highest occupied molecular orbital (HOMO), and the lowest unoccupied molecular orbital (LUMO), ionization potential (IP), stabilization energy (ΔEiso), and hydroxyl bond dissociation energy (BDE_{OH}) (Queiroz, Gomes, Moraes, & Borges, 2009).

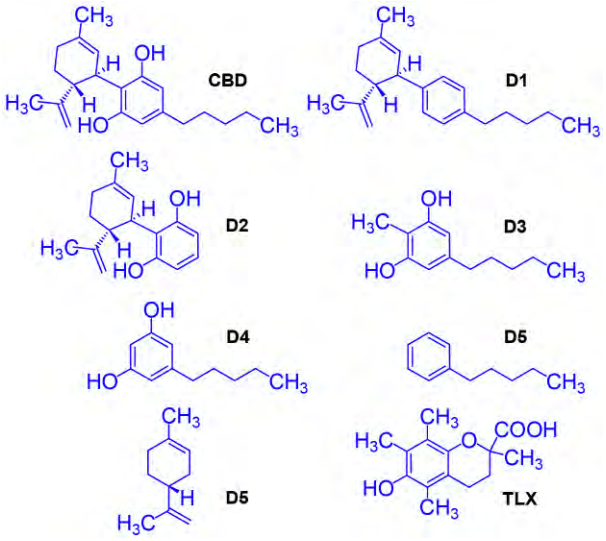

FIGURE e12.2 The structure of CBD and related derivatives. Molecular fragmentation of chemical structure of CBD.

The adiabatic IP were calculated as the energy difference between the neutral molecule and its respective cation free radical (Eq. e12.4). On the other hand, the semiquinone radical stability is usually calculated by the hydroxyl bond dissociation energies (BDE_{OH}). The BDE_{OH} values were calculated as the energy difference between the neutral molecule and its respective semiquinone, plus the hydrogen radical (Eq. e12.5).

$$IP = [E ArOH_{+}] - [E ArOH] \quad \text{(e12.4)}$$

$$BDE_{OH} = [E ArO^{\bullet} + E H^{\bullet}] - [E ArOH] \quad \text{(e12.5)}$$

CONFORMATIONAL STUDIES

The final molecular geometry of CBD and related derivatives (Fig. e12.3) can be obtained by using the DFT methods and B3LYP functional (Kohn, Becke, & Parr, 1996; Parr & Pearson, 1983) with the 6–311++G(2d,2p) basis sets (Parr, Szentpaly, & Liu, 1999).

From the optimized geometries, it was possible to observe that the structure of CBD does not have intermolecular hydrogen bond from the oxygen atom of both phenolic moieties. In this case, the hydrogen of two phenolic groups have a great electronic repulsion with the 3-methyl-cyclohexene and 6-isopropene-cyclohexene rings, due to the difference of polarity (Borges et al., 2013; Borges, 2015).

The geometry of CBD is not planar, having strong repulsion between hydroxyl groups and the limonene ring. The CBD has two rings (phenol and cyclohexene) and five radicals (*n*-penthyl, two hydroxyl phenolic, methyl, and isopropene). In fact, the transverse positions between resorcionol and limonene rings are responsible for the semirigid characteristic of CBD. Thus, when hydroxyl groups are removed (D1), there is a decrease in the molecular rigidity.

FRONTIER MOLECULAR ORBITALS ON ANTIOXIDANT CAPACITY OF CANNABIDIOL

The final geometries were used for the calculations of the antioxidant properties for CBD and related derivatives. Table e12.1 presents the frontier orbital energies, IP, and the O—H bond dissociation energies of the molecules studied (Borges, 2015).

Comparing the HOMO properties from CBD and other hydroxylated derivatives (D2, D3, and D4) with TLX, a more similar value with the nonphenolic derivatives (D1, D5, and D6) was observed. The TLX and CBD molecules showed HOMO values of –5.42 and –6.02 eV, respectively. This indicates that the phenol moiety increases the HOMO values. In fact, the hydroxyl group has great influence on the HOMO contributions, as shown in Fig. e12.4.

The electronic effect in the phenolic compound is mainly influenced by other functional groups, such as

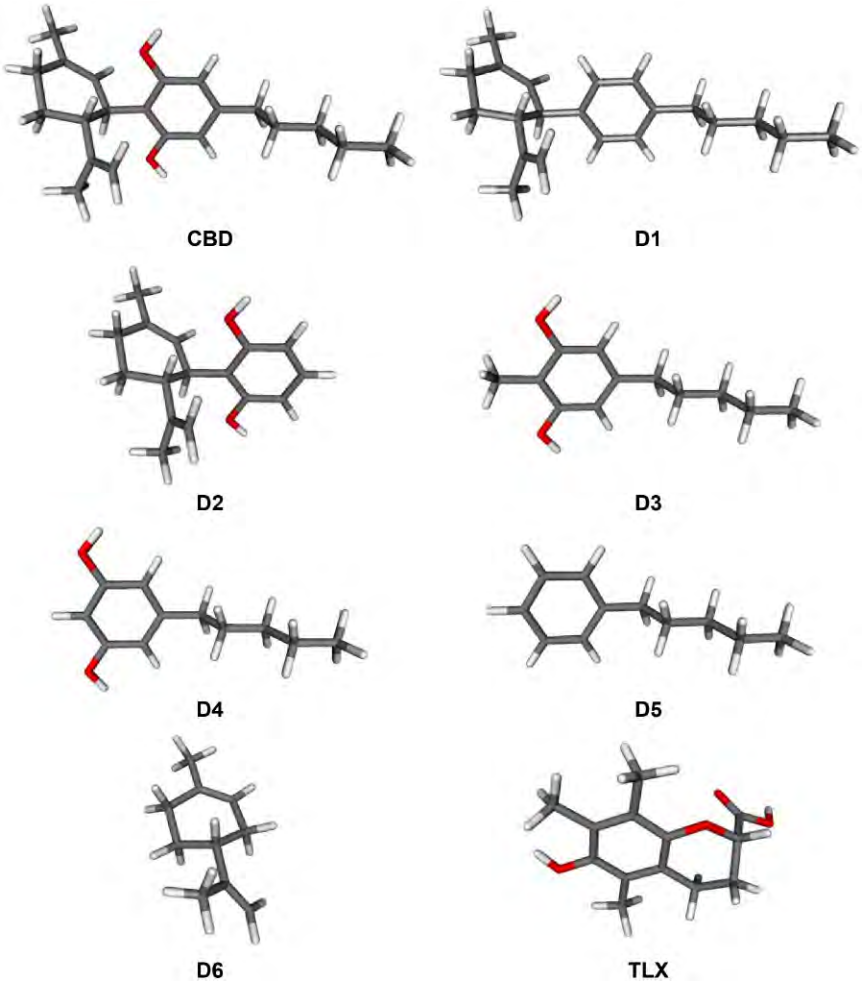

FIGURE e12.3 **The optimized structures of the neutral molecules studied.** The molecular structures of CBD and related derivatives 1-(6-isopropenyl-3-methyl-cyclohex-2-enyl)-4-pentyl-benzene (D1), 2-(6-isopropenyl-3-methyl-cyclohex-2-enyl)-benzene-1,3-diol (D2), 2-methyl-5-pentyl-benzene-1,3-diol (D3), 5-pentyl-benzene-1,3-diol (D4), pentyl-benzene (D5), limonene (D6), and trolox (TLX), show three different atoms: carbon *(gray)*, hydrogen *(white)*, and oxygen *(red)*.

the limonene ring and the *n*-penthyl moiety that have a participation in the inductive or resonance effects, and can indicate a reactive point of scavenging free radicals due to the H-abstraction after electron transfer. The number of resonance structures or electron donating groups, such as alkyl groups (limonene ring and *n*-penthyl moiety) linked to the *ortho*- or *meta*-positions of the phenol moiety, can be related to the highest nucleophilicity of CBD and its hydroxylated derivatives.

The HOMO energy is an important electronic parameter for describing the antioxidant ability of a molecule, since this property can be related to electron transfer reactions. Nevertheless, sometimes its application is very limited. In fact, a molecule with low values of HOMO energy has a weak electron donating ability. On the contrary, a higher HOMO energy implies that the molecule is a good electron donor (Queiroz et al., 2009; Borges et al., 2013). However, it is interesting to note that CBD and its hydroxylated derivatives (D2, D3, and D4) had the lowest values of GAP energy, indicating their low electron transition energy between HOMO and LUMO, when compared with the highest GAP values of nonphenolic derivatives (D1, D5, and D6).

In Fig. e12.4, the most nucleophilic positions were determined by the main HOMO contributions of the phenol moieties. Additional contributions from the alkyl groups (limonene ring and *n*-penthyl moiety) linked to the phenol moieties can be also observed. However, the most important electron donating groups for TLX are ether and methyl moieties.

ANTIOXIDANT CAPACITY BY ELECTRON TRANSFER USING IONIZATION POTENTIAL

The nucleophilicity of CBD and its related derivatives can be expressed by the ionization potential (IP) value, calculated as the necessary energy for the abstraction of an electron of a molecule. The IP value is another

TABLE e12.1 Calculated Electronic Properties for CBD and Related Derivatives (Borges, 2015)

Compound	HOMO (eV)	LUMO (eV)	GAP (eV)	IP (kcal mol^{-1})	ΔEiso (kcal mol^{-1})	BDE_{OH} (kcal mol^{-1})
CBD	−6.02	−0.46	5.56	168.34	3.65	100.83
D1	−6.24	−0.35	5.89	174.35	9.66	—
D2	−6.12	−0.46	5.66	176.11	11.42	
D3	−6.06	−0.45	5.61	178.01	13.31	
D4	−6.14	−0.46	5.68	185.88	21.19	—
D5	−6.71	−0.39	6.32	193.62	28.93	—
D6	−6.42	−0.29	6.12	186.73	22.03	—
TLX	−5.42	−0.56	4.85	164.69	0	92.11

Orbital energies (HOMO, LUMO, and GAP), ionization potential (IP), stabilization energy (ΔEiso), and bond dissociation energy of hydroxyl groups (BDE_{OH}) for cannabidiol (CBD) and related derivatives 1-(6-isopropenyl-3-methyl-cyclohex-2-enyl)-4-pentyl-benzene (D1), 2-(6-isopropenyl-3-methyl-cyclohex-2-enyl)-benzene-1,3-diol (D2), 2-methyl-5-pentyl-benzene-1,3-diol (D3), 5-pentyl-benzene-1,3-diol (D4), pentyl-benzene (D5), limonene (D6), and trolox (TLX).

important electronic parameter used to evaluate the antioxidant ability of molecules. In fact, IP value represents the ease of an electron transfer, and it is the first studied antioxidant mechanism that represents the electron donation capacity (Queiroz et al., 2009).

Thus, a molecule with a low IP value can easily suffer an oxidation process, such as CBD and TLX that have IP values of 168.34 and 164.69 kcal mol^{-1}, respectively. CBD and TLX have an IP value of 168.34 and 164.69 kcal mol^{-1}, respectively. This difference indicates that the number of

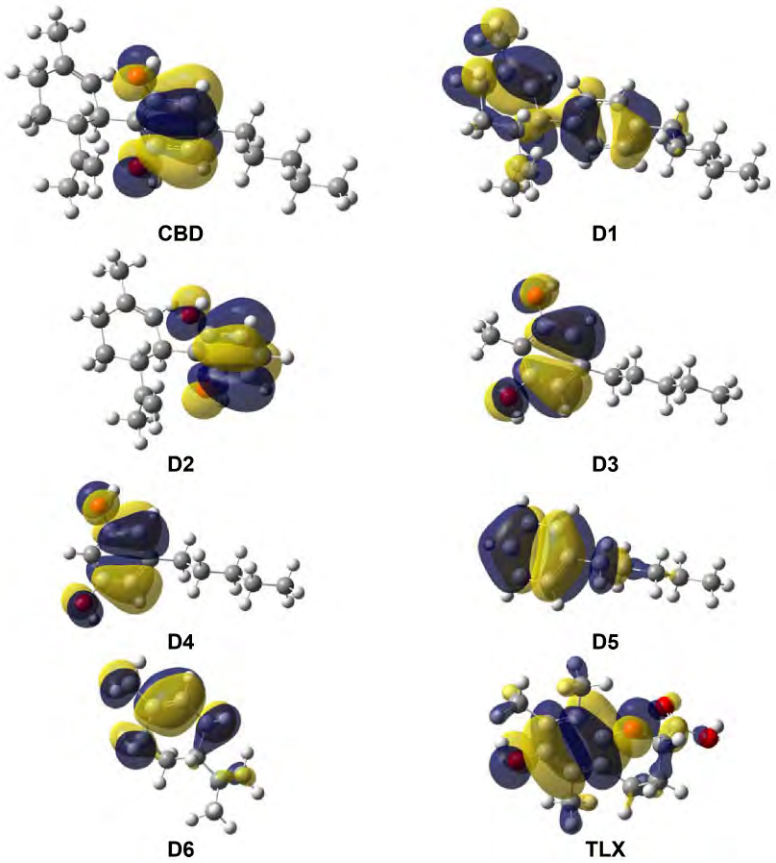

FIGURE e12.4 The HOMO for CBD and its related derivatives. HOMO superficies *(blue and yellow)* show all groups involved in inductive or resonance effects for molecular stabilization, after an electron or hydrogen transfer for CBD and related derivatives 1-(6-isopropenyl-3-methyl-cyclohex-2-enyl)-4-pentyl-benzene (D1), 2-(6-isopropenyl-3-methyl-cyclohex-2-enyl)-benzene-1,3-diol (D2), 2-methyl-5-pentyl-benzene-1,3-diol (D3), 5-pentyl-benzene-1,3-diol (D4), pentyl-benzene (D5), limonene (D6), and trolox (TLX) (Borges, 2015).

alkyl and ether groups at *ortho*- and *para*-position of the phenol ring in the TLX decreases its IP value, and also increases the electron-donating capacity.

Actually, the lowest IP values for the hydroxylated derivatives (D2, D3, and D4), when compared with the highest IP values for the nonphenolic derivatives (D1, D5, and D6), show that the TLX and CBD molecules have a more electron donation capacity due to their electron donating groups.

The stabilization energy (ΔEiso) of CBD and related derivatives is compared with TLX. The determination of ΔEiso is frequently used as a simple method to predict the antioxidant ability to trap free radicals or scavenging effects of molecules. Here, it is related with the experimental method trolox equivalent antioxidant capacity (TEAC). These results show that the lowest ΔEiso values are for CBD and its hydroxylated derivatives (D2, D3, and D4). The electronic capacity for the cation free radical stabilization of these compounds can be considered high, when compared with the nonphenolic derivatives (D1, D5, and D6) (Borges, 2015).

ANTIOXIDANT CAPACITY BY HYDROGEN TRANSFER USING BOND DISSOCIATION ENERGY

In addition, the hydroxyl bond dissociation energies (BDE_{OH}) for the molecules represent the ease of hydrogen donation presented by the CBD and TLX to give semiquinone derivatives. The BDE_{OH} represents the ease of the hydrogen transfer, and it is the second antioxidant mechanism. The BDE_{OH} values for CBD and TLX are 100.83 and 92.11 kcal mol^{-1}, respectively. These properties indicate a great influence of the ether and alkyl moieties on the *ortho*- and *para*- positions, than the limonene ring and the *n*-penthyl moiety of CBD on the BDE_{OH} values. The energy difference between these two molecules is 8.72 kcal mol^{-1} (Borges, 2015).

In fact, a good agreement between HOMO and IP values was observed (Borges, 2015). However, the antioxidant capacity of CBD can be determined by free radical stability generated after the electron or hydrogen abstractions, where the highest energy may be found after a hydrogen abstraction due to the π-delocalized system between the phenol, cyclohexene, and *n*-penthyl moieties (Borges et al., 2013).

These theoretical properties are important in several oxidation processes by electron or hydrogen transfer. Thus, the oxidation in biological system can be inhibited by diverse molecules, in accordance to their antioxidant capacity, which can act on different pathways (Leopoldini et al., 2011a,b; Galano et al., 2010; Galano, 2011; Iuga et al., 2012; Chiodo et al., 2010; Leopoldini et al., 2004, 2006, 2007; Borges et al., 2013). Hence, the elimination of free radical species ($FES^{\bullet}$) using CBD as an antioxidant can occur through two reactions, that is, electron (Eq. e12.6) or hydrogen (Eq. e12.7) transfer, converting them in long-lived and less reactive radicals, mainly at the propagation and termination steps.

$$FES^{\bullet} + \text{CBD-OH} \rightarrow FES^{-} + \text{CBD-OH}^{\bullet+} \quad \text{(e12.6)}$$

$$FES^{\bullet} + \text{CBD-OH} \rightarrow \text{FESH} + \text{CBD-O}^{\bullet} \quad \text{(e12.7)}$$

Therefore, the electron or hydrogen transfer of CBD is all from the phenolic group. In fact, when compared to the TLX molecule, CBD has a good antioxidant activity, and none of their derivatives is more active than itself.

ANTIOXIDANT MECHANISMS IN BIOLOGICAL SYSTEM, AND THEIR APPLICATIONS

A neuroprotective effect was observed for CBD and (−)Δ^9-tetrahydrocannabinol (THC), independent of the cannabinoid receptor. These compounds demonstrated their antioxidant potential by cyclic voltammetry. They have also prevented hydroperoxide-induced oxidative damage much better than other antioxidant compounds. CBD has more protective effect against glutamate neurotoxicity than either ascorbic acid (ASC) or α-tocopherol (TOC), indicating that it is a potent antioxidant compound (Hampson, Grimaldi, Axelrod, & Wink, 1998) (see Fig. e12.5). Among the molecular mechanisms of neuroprotection presented by THC and CBD, one can highlight the attenuation of peroxynitrite on retinal neurotoxicity induced by *N*-methyl-D-aspartate (El-Remessy et al., 2003). Other antioxidant mechanism of CBD is observed by the reduction of neuroinflammation and promotion of hippocampal neurogenesis through PPARγ involvement (Esposito et al., 2011). In addition, the neuroprotective effects might be due to the antioxidant properties of cannabinoids (Lastres-Becker, Molina-Holgado, Ramos, Mechoulam, & Fernández-Ruiz, 2005).

CBD has an excellent safety and tolerability profile in humans, and a great therapeutic potential for the treatment of diabetic complications and cardiovascular

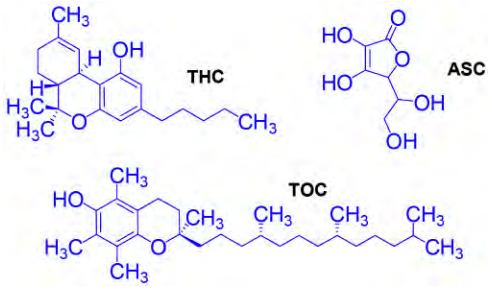

FIGURE e12.5 Structure of THC and vitamins C and E. Molecular structure of THC, ASC, and TOC.

disorders, by attenuating oxidative/nitrative stress, inflammation, cell death, and fibrosis (Rajesh et al., 2010). In fact, the treatment with CBD decreases doxorubicin toxicity by reducing cardiac dysfunction, oxidative/nitrative stress, and cell death. It reduces damage on cardiac mitochondrial function and biogenesis (Fouad et al., 2013; Hao et al., 2015), and has also protected mouse liver from acute alcohol-induced steatosis through multiple mechanisms, including attenuation of alcohol-mediated oxidative stress (Yang et al., 2014). Its efficacy in vivo as a neuroprotective agent, preventing binge ethanol-induced brain injury, can be understood due to its lipophilic properties (Hamelink, Hampson, Wink, Eiden, & Eskay, 2005). CBD also presented a stronger antioxidative power than THC in an in vitro study using the 1,1-diphenyl-2-picryhydrazyl (DPPH) radical (Hayakawa et al., 2007). In fact, the scavenging activity using DPPH assay showed that cannabinoid derivatives exhibited in vitro antioxidative action ranging from 669 ± 11.1 (THC) to 356 ± 29.5 (CBD) μg trolox (a vitamin E derivative)/mg (Moldzio et al., 2012).

CONCLUSIONS

The antioxidant mechanism of CBD was reviewed by a Quantum Chemical approach. Its antioxidant potential can be related to electron and hydrogen abstraction. The limonene ring and the *n*-penthyl moiety are responsible for the stabilization of the cation free radical, or its semiquinone forms. Several resonance structures are attributed for these alkyl groups. These groups contribute to increase the HOMO value, and to decrease the IP and the BDE_{OH} values. The calculated properties showed that the CBD molecule has a good antioxidant profile. None of the CBD derivatives was more antioxidant than the CBD. The CBD antioxidant mechanisms in biological system, and their applications as neuroprotective, cardioprotective, and cytoprotective effects were related with other antioxidant molecules.

MINI-DICTIONARY

Antioxidant Antioxidants are natural or synthetic derivatives that prevent free radical reactions, inhibiting the formation of these radicals, scavenging them, or by promoting their decomposition and then reducing tissue damages.
Antioxidant and cancer Free radicals are highly reactive, and have the potential to cause damage to cells, mainly of DNA and proteins, including damage that may lead to cancer. In general, many antioxidants are used as chemopreventive effects on carcinogenesis.
Antioxidant and inflammation In general, antioxidant molecules have potent antiinflammatory properties, and exert chemopreventive effects on carcinogenesis.
Antioxidant and neuroprotection Antioxidant decreases the lipid peroxidation of membrane, and oxidative damage of proteins; these biological properties are associated with a variety of chronic pathological problems, such as the neurodegenerative diseases.
Antioxidant capacity A powerful antioxidant molecule delays or prevents oxidation of a substrate significantly, by chemical or physical quenching. Its antioxidant capacity is only related to other similar analogs or parents.
Antioxidant mechanisms The antioxidant mechanisms are related to balance concentrations between free radicals and antioxidant defense systems.
Antioxidant theoretical parameters The main physicochemical parameters related to antioxidant properties are the ionization potential and the bond-dissociation energy that involves electron or hydrogen atom transfer.
Density functional theory (DFT) A quantum mechanical and computational method used in physics, chemistry, and materials science. It investigates the electronic and conformational structure of atoms and molecules.
Free radical species Reactive oxygen, nitrogen, or carbon species have high chemical reactivity, when compared with sugar, proteins, nucleic acids, and lipids. They are responsible for cellular aging, mutagenesis, carcinogenesis, inflammation, coronary heart and neurodegenerative diseases.
Molecular modeling Molecular modeling is a method developed by the association between theoretical methods and computational techniques. It can be used as an artificial model of molecular behavior. It is used in computational chemistry, drug design, computational biology, and materials science for studying molecular structures, or theoretical predictions.
Structure–activity relationship Orbital energies and electron or hydrogen abstraction energies are the main quantum chemical descriptors that can be considered in structure–antioxidant activity relationship. They can also be related with chemical stability and nucleophilicity. These values are correlated with the experimental antioxidant activity obtained by using physical, chemical, or biological methods.

SUMMARY POINTS

- The present chapter focused on evidences related to the antianxiety effects of cannabidiol (CBD).
- CBD anxiolytic effects are dose-dependent, in a bell shaped dose–response curves manner.
- CBD antianxiety effects were demonstrated and replicated in several animal models of anxiety.
- CBD also promotes antianxiety effects in humans.
- CBD may affect the function of brain structures related to the control of anxiety-like states in laboratory animals and humans.
- The specific pharmacological mechanism that would explain CBD antianxiety effects remains to be determined, but may involve the modulation of CB1 and 5HT1A receptors functions.

KEY FACTS OF CANNABIDIOL ANTIANXIETY PROPERTIES

- Cannabidiol was isolated from *Cannabis sativa* in 1940, but its chemical structure was elucidated in 1963.
- Cannabidiol can be obtained as extract from the plant, by standard chemical techniques, or as a pure synthetic compound.
- In the early 1980s, the first evidence of CBD's anxiolytic effect in laboratory animals emerged, and independent groups replicated this effect several times.
- Elevated plus maze is based on the innate avoidance of rodents to unprotected and elevated places.
- Social anxiety disorder is characterized by the intense anxiety and fear of humiliation or embarrassment in social situations.

INTRODUCTION

The literature on the relationship between *Cannabis* and anxiety is contradictory. While users report decreased anxiety as motivation for their use, the most common adverse effect of acute cannabis use is the reaction of intense anxiety or panic (Crippa et al., 2009). The dose-dependent biphasic effect of THC on anxiety (Viveros, Marco, & File, 2005) could partially justify this observation, but another possibility is the effect of other cannabinoids present in the plant. In the early 1970s, a Brazilian group gave the first evidences that other cannabinoids interfere with the effects of Δ^9-tetrahydrocannabinol (THC) in animals (Karniol & Carlini, 1972), particularly cannabidiol (CBD), a compound until them considered inactive (Karniol & Carlini, 1973).

These results led to studies of interaction between THC and CBD, in humans. In the first of these studies, healthy volunteers were submitted to cognitive tests, physiologic measures, and interview. Strong feelings of anxiety were reported after the ingestion of 30 mg of THC, while the subjects that received this THC dose with 60 mg of CBD showed less anxiety (Karniol, Shirakawa, Kasinski, Pfeferman, & Carlini, 1974). Confirming this result, a study with appropriate rating scales detected a statistically significant reduction in the elevation of anxiety scores induced by THC (0.5 mg/kg), when associated with CBD (1 mg/kg) (Zuardi, Shirakawa, Finkelfarb, & Karniol, 1982). A possible anxiolytic effect of CBD, suggested by these interaction studies, started a line of research in animals and humans.

CBD EFFECTS IN ANIMAL MODELS OF ANXIETY

The antianxiety properties of CBD have been extensively studied in the last 3 decades. However, the initial studies in animal models found controversial results. In the early 1980s, Silveira Filho and Tufik (1981), using a model based on conflict responses, failed to demonstrate any anxiolytic-like effect of CBD, at a dose of 100 mg/kg i.p. On the other hand, lower doses of CBD (10 mg/kg) were able to attenuate conditioned emotional responses in rats (Zuardi & Karniol, 1983).

Guimarães, Chiaretti, Graeff, and Zuardi (1990), subsequently explained these apparent contradictory results. Using the elevated plus maze (EPM), an ethologically based animal model of anxiety, and testing a large range of CBD doses (2.5–20 mg/kg), they showed that CBD does produce antianxiety effects in laboratory animals in a dose-depend manner, but with an inverted U-shaped dose–response curve (Guimarães et al., 1990). These findings were later replicated by Guimarães and coworkers, as well as other groups, not only in ethologically based tests, but also in conflict and aversive conditioning models of anxiety (Table e13.1).

More recently, the investigation of the antianxiety properties of CBD were extended to animal models related to specific types of anxiety disorders. For instance, some studies suggest that CBD may be useful in trauma-related anxiety disorders (Bitencourt et al., 2008; Campos et al., 2013a; Stern et al., 2012). CBD repeated treatment attenuated the long-lasting behavioral consequences evoked by predator threats, in a proposed animal model of posttraumatic stress disorder (PTSD; Campos et al., 2013a). Moreover, CBD accelerates extinction, and impairs fear memory reconsolidation, two processes that have been associated with PTSD. Recently, a putative antipanic action of CBD was also described. CBD acute and chronic treatment reduce the defensive responses in two different models of panic disorder, the elevated T-maze (ETM) and the electrical stimulation of the dorsal portions of the periaqueductal gray matter (Campos et al., 2013b; Soares et al., 2010). Chronic treatment with a low dose of CBD (5 mg/kg) decreases the escape latency in the ETM, similar to the antidepressant Fluoxetine (Campos et al., 2013b). In addition, CBD reduces marble-burying behaviors, suggesting that this compound could be effective in obsessive-compulsive disorder (OCD; Casarotto et al., 2010; Nardo et al., 2014).

Considering the close relationship between stressful experiences and the precipitation of anxiety disorders symptoms, the effects of CBD during stress responses have also been studied. CBD prevents the autonomic and behavioral consequences of inescapable stress (Resstel et al., 2006). Moreover, Campos et al. (2013a) showed that chronic administration of CBD (30 mg/kg/daily for 14 days) prevented the anxiogenic effect of chronic unpredictable stress in mice tested in the elevated plus maze, and novelty suppressed feeding tests.

ANXIOLYTIC EFFECTS OF CBD IN HUMANS

The first study evaluating the anxiolytic effect of CBD in humans was conducted on healthy volunteers submitted to a simulation of the public speaking test (SPST) (Zuardi et al., 1993). In a double-blind protocol, CBD (300 mg), ipsapirone (5 mg), diazepam (10 mg), or placebo were administered per os, 1 h and 30 min before the SPST. CBD, ipsapirone, and diazepam reduced significantly the anxiety induced by SPST.

Another double-blind, crossover trial study with healthy volunteers investigated CBD effects on regional blood flow (rCBF), using single-photon emission computed tomography (SPECT). It was observed that CBD (400 mg per os) attenuated the anxiety induced by the procedure related to the exam (insertion of the venous cannula, tracer injection, and scanning procedure) (Crippa et al., 2004). Using a similar protocol to study the effect of CBD on rCBF of patients with social anxiety disorder (SAD), the same reductions of anxiety induced by the protocol was observed (Crippa et al., 2011).

The effects of one dose of CBD was studied in patients with SAD submitted on SPST, since the fear of speaking in public is one of the most prevalent symptoms of this disorder. As expected, the SAD group presented significantly higher anxiety level than health volunteers, during the SPST. Previous administration of CBD (600 mg, per os) reduced significantly the anxiety level of SAD group, during the public speaking (Bergamaschi et al., 2011).

These studies suggest that the acute administration of CBD in humans has an anxiolytic action in normal volunteers and patients with SAD. Studies of chronic administration of CBD in anxiety disorder are needed.

MECHANISMS OF CBD EFFECTS

Human Studies

In a study in which we investigated the central effects of CBD on rCBF in healthy volunteers, using SPECT, the anxiety induced by the experiment was reduced in the subjects who received CBD (Crippa et al., 2004). The volunteers received either CBD (400 mg) or placebo, in a crossed double-blind design, in two experimental sessions, one week apart. CBD significantly decreased subjective anxiety, as measured by rating scales (VAMS), while brain activity was changed in limbic and paralimbic areas, specifically increased in the left parahippocampal gyrus, and decreased in the left amygdala-hippocampus complex, including the fusiform gyrus (Fig. e13.1A). Interestingly, the pattern of SPECT results of this study was consistent with an anxiolytic action, as observed in other functional imaging studies using classical anxiolytic drugs such as benzodiazepines. The SPECT neuroimaging technique was also used later to investigate the neural anxiolytic correlates of CBD in a sample of drug-naïve patients with SAD (Crippa et al., 2011). A single dose of CBD 400 mg was able to reduce subjective anxiety measures, and SPECT showed changes in the same regions previously identified in healthy volunteers, but mainly in the opposite direction of activation (Fig. e13.1B). fMRI (functional magnetic resonance imaging), a neuroimaging method that allows the acquisition of larger series of images with a much better temporal and spatial resolution, was used to investigate the neural correlates of the anxiolytic effects of CBD in 15 healthy volunteers (Fusar-Poli et al., 2009). This study showed that 600 mg of CBD attenuated fMRI responses during the recognition of fearful facial expressions, in the amygdala and the anterior cingulate, which are brain areas related to anxiety and emotion. Moreover, the authors found that this attenuation pattern correlated with skin conductance responses to the stimuli. The same group further reported that the antianxiety action of CBD is mediated by altering the subcortical prefrontal connectivity via amygdala and anterior cingulated (Fusar-Poli et al., 2010).

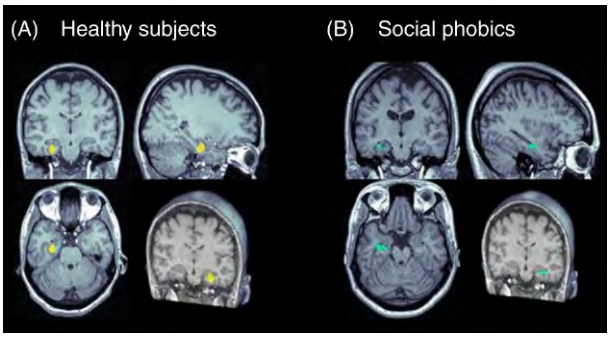

FIGURE e13.1 (A) The brain focus (yellow) of significantly increased rCBF in healthy subjects (n = 10) during CBD (400 mg) versus placebo on sagittal, coronal, axial sections (left side), and coronal sections (right side) located in the left hippocampal area; (B) the brain focus (blue) of significantly decreased rCBF in social anxiety disorder subjects (n = 10) during CBD (400 mg) versus placebo on sagittal, coronal, axial sections (left side) and coronal sections (right side) located in the left hippocampal area. *Part A, adapted from Crippa et al. (2004); part B, adapted from Crippa et al. (2011).*

Animal Studies (Intracerebral Injection)

Although the anxiolytic effects of systemically administered CBD have been extensively reported since the beginning of the 1980s, the neurobiological substrates involved in behavioral actions of this phytocannabinoid only began to be investigated in the last decade (Table e13.1). In 2008, Campos and Guimarães showed for the first time that direct brain administration of CBD into the dorsal portions of the periaqueductal gray (DPAG) promotes anxiolytic-like effects in the EPM, and in Vogel's conflict test (Campos & Guimarães, 2008, 2009). These findings were later replicated by Soares et al. (2010), using two other different models of anxiety-like behaviors, the ETM and the electrical stimulation of the DPAG.

Investigating the effects of systemic administration of CBD (10 mg/kg) in animals exposed to a fear-conditioned environment, Lemos et al. (2010) showed that this drug decreases cFos expression, a marker of neuronal activation, in brain areas related to conditioned fear responses, the ventral medial prefrontal cortex and bed nucleus stria terminalis (BNST). Following these results, we showed that CBD direct injection into BNST produces antianxiety effect in rats tested in EPM, in Vogel's conflict, and contextual fear conditioning (CFC) models (Gomes et al., 2011, 2012). A more complex panorama, however, was found in the ventral medial prefrontal cortex. Whereas direct injections of CBD (30 nmol) into the prelimbic frontal cortex (PL) decreased freezing response in the contextual fear conditioning model (an antianxiety effect), it facilitated these responses when injected into the infralimbic cortex (IL) (Lemos et al., 2010). Recently, Fogaça et al. (2014) confirmed the anxiolytic-like effect of intra-PL administration of CBD. However, the same treatment was anxiogenic in animals tested in the EPM. To explain these contradictory results, the authors suggested that in the PL region of the prefrontal cortex the antianxiety effects of CBD depend on the level of previous stressful experiences. Corroborating this possibility, CBD produces anxiolytic effects in the EPM when

injected into the PL of animals that have been previously (24 h) exposed to a stressful event (2 h restraint) (Fogaça et al., 2014). Intracerebral ventricular administration of CBD also facilitated extinction in a contextual aversive conditioning model (Bitencourt et al., 2008). Moreover, repeated microinjections of CBD into the IL subregion of the prefrontal cortex also facilitated fear extinction (Do Monte et al., 2013). In the amygdala, a brain structure similarly related to the control of anxiety-like behaviors, inconsistent effects have been found in the basolateral as well as in the medial amygdala nuclei (Campos et al., and Lisboa and Guimarães, unpublished results). There is a report, however, of anxiolytic-like effects of CBD after injection into the central nucleus in rats tested in the EPM and open field (Hsiao et al., 2012).

PHARMACOLOGICAL MECHANISMS OF THE ANXIOLYTIC EFFECTS OF CBD

While several pieces of the evidence reviewed earlier indicate that CBD could be a promising new anti-anxiety treatment, its specific mechanism of action remains to be fully determined. CBD seems to exert its anxiolytic effects by interacting with several systems in a wide range of drug concentrations (Campos, Ferreira, & Guimarães, 2012a; Izzo, Borrelli, Capasso, Di Marzo, & Mechoulam, 2009). Moreover, the common bell-shaped dose–response curves produced by this compound further complicate the elucidation of its mechanisms (Campos and Guimarães, 2008, 2013a; Guimarães et al., 1990; Izzo et al., 2009).

CBD is proposed to directly interact with several receptors, including CB_1, CB_2, GPR55, TRPV1, and 5-HT1A (Bisogno et al., 2001; Campos et al., 2008; Russo, Burnett, Hall, & Parker, 2005; Ryberg et al., 2007; Thomas et al., 2007). It also interferes with the uptake and degradation system of endocannabinoids signaling (Bisogno et al., 2001; Campos et al., 2013b). However, the relevance of each of these mechanisms for the anti-anxiety effects of CBD still remains unclear.

Of particular importance, several studies have now established that the complex interaction between CBD and 5-HT1A receptors may explain some of its anxiolytic actions. Russo et al. (2005) published the first report that proposed this interaction. Using Chinese hamster ovary cultured cells overexpressing 5-HT1A, they observed that CBD, at micromolar range, displaces OH-DPAT, a selective 5-HT1A receptor agonist (Russo et al., 2005). In the same year, Mishima et al. (2005) suggested that the pharmacological mechanism of CBD-induced neuroprotection during cerebral infarction in rats involved 5-HT1A receptors activation. Regarding CBD's antianxiety effects, Campos and Guimarães (2008) were the first to demonstrate that the anxiolytic effects of CBD injected into the DPAG depends on facilitation of 5-HT1A receptor signaling, rather than CB_1 receptors activation. The ability of systemically injected CBD in attenuating acute autonomic responses evoked by restraint stress is also mediated by 5-HT1A receptors. Moreover, the 5-HT1A receptor antagonist WAY-100635 also prevented the panicolytic-like effects of intra-DPAG injections of CBD, in rats tested in the DPAG-electrically induced escape responses (Campos & Guimarães, 2008; Soares et al., 2010). Activation of 5-HT1A receptors by CBD in other brain structures related to the control of anxiety-like behaviors, such as the BNST and PL, also decreases anxiety-related behaviors (Gomes et al., 2011, 2012; Fogaça et al., 2014). Although the involvement of 5-HT1A receptors in the clinical effects of CBD has not been directly tested, the study by Zuardi et al. (1993) showed that CBD induces anxiolytic effects in a simulated public speaking model that closely resemble those induced by the 5-HT1A receptor partial agonist ipsapirone.

Despite these pieces of evidence associating acute CBD anxiolytic effects with facilitation of 5-HT1A-mediated neurotransmission, the molecular mechanism of this interaction is still unclear. It does not seem to involve blockade of 5-HT reuptake, as recently demonstrated, after acute and repeated CBD treatment, by Campos et al. (2013b). This same study failed to show any changes in 5-HT1A mRNA expression in the DPAG, after chronic CBD administration. It was recently shown, however, that CBD, although failing to displace the binding of 8-OH-DPAT, even at high concentrations, could enhance the ability of this 5-HT1A agonist to stimulate [^{35}S] GTPγS binding at relatively low concentrations (100 nM) (Rock et al., 2012). Although these results have not been fully explained, they suggest that CBD modulation of 5-HT1A receptors is complex, and could involve allosteric interactions.

Not all CBD effects in anxiety-related behaviors, however, can be explained by interaction with 5-HT1A receptors. Another important mechanism that might contribute to CBD anxiolytic effects involves a complex action of this cannabinoid on the endocannabinoid (eCB) system. CBD could facilitate eCB signaling by blocking the metabolism and uptake of anandamide (Bisogno et al., 2001; Campos et al., 2013b). Although, in the DPAG, AM251 (a CB1 receptor antagonist) failed to interfere in the anxiolytic effects of locally injected CBD, this drug was able to prevent CBD effects on processes related to aversive memories, such as extinction and reconsolidation (Bitencourt et al., 2008; Do Monte et al., 2013; Stern et al., 2012). In addition, AM251, but not a 5-HT1A-receptor antagonist, prevented CBD effects in the marble-burying model (Casarotto et al., 2010). Endocannabinoids can reduce the release of several neurotransmitters, including glutamate, a neurotransmitter closely involved in anxiety responses (Guimarães, Carobrez, De Aguiar, &

Graeff, 1991). An indirect antiglutamatergic action via increased eCB neurotransmission could contribute to the antianxiety effects of CBD.

Another effect of CBD that seems to involve the eCB system is its ability to increase hippocampal adult neurogenesis. Impairment in adult hippocampal neurogenesis has been associated to the pathogenesis of anxiety disorders and depression, and at least some of the behavior effects of antidepressant drugs, such as fluoxetine, depend on facilitation of this process (Samuels & Hen, 2011). CBD facilitation of adult hippocampus has been demonstrated by at least three independent works (Campos et al., 2013b; Esposito et al., 2011; Wolf et al., 2010). Wolf et al. (2010) showed that the proneurogenic effect of CBD was absent in CB_1-knockout mice. CBD has very low affinity for CB_1-receptor, thus this result might be reflecting its ability to inhibit anandamide metabolism/uptake (Bisogno et al., 2001). Corroborating this latter possibility, our group has recently shown that CBD increases in vivo and in vitro cell proliferation by activation of CB_1 and CB_2 receptors (Campos et al., 2013b). In this study, CBD effects were prevented by the overexpression of the fatty acid amide hydrolase, the enzyme responsible for anandamide degradation. Moreover, the anxiolytic effect of repeated administered CBD (30 mg/daily for 14 days) in mice submitted to a chronic unpredictable stress model was abolished in the absence of hippocampal neurogenesis. This behavior profile and neurogenic is similar to that observed with classic antidepressant drugs, and suggests a causal link between the proneurogenic and anxiolytic CBD effects.

Other mechanisms could also be involved in CBD effects on adult hippocampal neurogenesis, for instance the activation of peroxisome proliferator-activated receptors. This particular mechanism seems to be important during neuroinflammation and neurodegenerative processes related to β-amyloid protein deposits in the central nervous system (Esposito et al., 2011).

CBD can also act as an agonist of transient receptor potential (TRP) channels. These channels include over 50 members, and are present in different species, including yeast, worms, insects, fish, and mammals. The vanilloid receptor 1 or TRPV1 is one of the first identified members of the family, and are expressed in the brain, where anandamide has been proposed as an endogenous agonist, or endovanilloid. These receptors facilitate the release of glutamate, a neurotransmitter that, as described earlier, facilitates anxiety-like behaviors (Guimarães et al., 1991). Campos and Guimarães (2009) suggested that TRPV1 activation could explain, at least partially, the inverted U-shaped dose–response curves commonly observed in experiments conducted with CBD. They showed that intra-DPAG injections of an ineffective dose of the TRPV1 antagonist capsazepine turned a higher, ineffective dose (60 nmol) of CBD, into an anxiolytic one (Campos & Guimarães, 2009). TRPV1 blocked is also involved in the bell-shaped dose–responses curves produced by anandamide analogues (Casarotto et al., 2012).

In addition to TRPV1, CBD could also interfere with other members of the TR family, activating TRPV2 and ankyrin type 1 (TRPA1) channels, and antagonizing melastatin type 8 (TRPM8) channels (Qin et al., 2008). The contribution of these mechanisms to CBD's anxiolytic effects has not been tested yet.

In addition to the activation of a classic pharmacological receptor, CBD pharmacological mechanisms could also involve intracellular pathways. The role played by these mechanisms on CBD antianxiety effects also remains to be further investigated.

CONCLUSIONS

Taken together, the results from laboratory animals, healthy volunteers, and patients with anxiety disorders support the idea that CBD clearly presents antianxiety properties. This cannabinoid does not present psychoactive effects, does not affect cognition, has an adequate safety profile (Bergamaschi et al., 2011), good tolerability, positive results in trials with humans, and a broad spectrum of pharmacological actions. Moreover, since this compound does not induce dependence, tolerance, and abstinence symptoms, it may be a good alternative to the benzodiazepinics. Therefore, CBD appears to be the cannabinoid compound that is closer to have its preliminary findings in anxiety translated into clinical practice. However, future double-blind controlled studies should test this possibility in clinical trials, including patients with the diverse anxiety disorders, especially panic, obsessive-compulsive, social anxiety, and posttraumatic stress disorder. Additionally, as the actions of CBD usually present a bell-shaped pattern, the adequate therapeutic dose window for each anxiety disorder should be determined. In respect to the mechanism underlying its antianxiety effects, the most consistent evidence points to the involvement of the serotonergic system, probably through direct action on 5-HT1A receptors, although other systems, such as the eCB itself, may also be involved. Thus, further investigation is necessary to clarify these issues, especially if we consider that CBD is a drug with a wide spectrum of effects in the nervous system.

MINI-DICTIONARY

Bell-shape dose–response-curve Drug-response curve produced by drugs that have the ability of promoting different or opposite responses at low or high concentrations.

Cannabinoids A term that refers a heterogeneous group of compounds that modulates cannabinoid receptors functions, classified into three main groups: endogenous, synthetic, and phytocannabinoids.

Chronic unpredictable stress A model applied to produce sustained stress response in rodents that aims to simulate the variability of stressful stimulus to which humans are exposed in daily life.

Elevated plus maze A wide applied animal model of anxiety, composed by two open arms opposed to two enclosed arms elevated to the floor.

Fear conditioning Behavioral paradigm where animals exposed to an aversive stimulus (eg, foot shocks) learn to predict an unpleasant event.

Functional magnetic resonance imaging A noninvasive technique largely used to detect brain activity by detecting changes in blood flow, and oxygen consumption in the brain tissue.

Intracerebral injection Technique that involves stereotaxic surgery to inject a drug directly into a specific brain structure, in laboratory animals.

Simulated public speaking A model with clinical validity that induces anxiety by exposing healthy volunteers to a simulation of a public speech.

Single photon emission computed tomography A clinical image technique that uses gamma rays emission, and a radioactive material as a tracer, to analyze blood flow in target tissues and organs.

Vogel's conflict test A model used for the screening of antianxiety drugs in which water-deprived rodents are exposed to a conflict: decide to drink water from the spout of a bottle that is connected to a shock generator.

SUMMARY POINTS

- This chapter focuses on the antiaversive effects of cannabidiol (CBD).
- The putative antiaversive effect of CBD was studied in threatened rodents.
- We discuss the viability of a new ethological model of panic attacks to address the panicolytic-like effect of CBD.
- The treatment of the ventral midbrain with CBD caused CB1-receptor-signaled antipanic-like effect.
- The neocortico-neostriatal disinhibitory pathway and the nigro-tectal GABAergic inhibitory connections are discussed as new morphological targets for the panicolytic effect of CBD.

KEY FACTS FOR CANNABIDIOL TREATMENT OF MIDBRAIN STRUCTURES

- The stimulation of dorsal midbrain in humans elicited fear (Nashold, Wilson, & Slaughter, 1969).
- The neostriatum-nigral disinhibitory pathway, and the nigro-tectal GABAergic inhibitory connections modulate the activity of dorsal midbrain structures (Coimbra & Brandão, 1993).
- CBD is a *Cannabis sativa* plant compound with psychoactive medicinal effects.
- The brain produces endogenous agonists that bind to the same receptors than CBD.
- The panicolytic-like effect of CBD, microinjected in the ventral midbrain, depends on CB1-cannabinoid receptor activation.

LIST OF ABBREVIATIONS

AC	Amygdaloid complex
AEA	Anandamide
2-AG	2-Arachidonoylglycerol
CB1	Cannabinoid receptor type 1
CB2	Cannabinoid receptor type 2
CBD	Cannabidiol
dlSC	Deep layers of the superior colliculus
DM	Dorsal midbrain
DPAG	Dorsal columns of the periaqueductal gray matter
EAS	Encephalic aversion system
GABA	γ-aminobutyric acid
5-HT$_{1A}$	5-Hydroxytryptamine (serotonin) 5-HT$_{1A}$ receptor
IC	Inferior colliculus
ilSC	Intermediate layers of the superior colliculus

MT	Midbrain tectum
PAG	Periaqueductal gray matter
SNpr	Substantia nigra, pars reticulata
Δ^9-THC	Δ^9-Tetrahydrocannabinol
TRPV1	Transient receptor potential cation channel subfamily V member 1
VM	Ventral midbrain

INTRODUCTION

Cannabinoid is a term that designates compounds of the *Cannabis sativa* plant. The main psychoactive compounds are Δ^9-tetrahydrocannabinol (Δ^9-THC) and cannabidiol (CBD), which may produce opposite effects on human brain function (Bhattacharyya et al., 2010). Cannabinoids may produce their effects via CB1 and CB2 receptors (Devane et al., 1992). Generally, the CB1 receptor is found in cerebellum, hippocampus, striatum, cortex, substantia nigra, and hypothalamus (Herkenham et al., 1991; Tsou, Brown, Sanudo-Pena, Mackie, & Walker, 1998). CB2 receptors are primarily found in cells and immune system tissue (Pertwee, 1997).

After the discovery of CB1 and CB2 receptors, studies demonstrated that mammals produce endogenous agonists, which are endocannabinoids binding to these receptors (Di Marzo, Melck, Bisogno, & De Petrocellis, 1998; Mechoulam, Fride, & Di Marzo, 1998). The main identified endocannabinoids are N-arachidonoyl ethanolamide, known as anandamide (AEA), 2-arachidonoylglycerol (2-AG), and O-arachidonoylethanolamine (Devane et al., 1992; Sugiura et al., 1995).

Schlicker and Kathmann (2001) and Alger (2002) reported that many axon terminals of the central nervous system express CB1 receptors, but its functions seem to inhibit the release of inhibitory neurotransmitters, such as γ-aminobutyric acid (GABA) (Freund, Katona, & Piomelli, 2003). However, CBD has a low affinity for CB1 and CB2 receptors. CBD may enhance endocannabinoid neurotransmission through an indirect mechanism, such as blockade of AEA uptake and inhibition of its enzymatic hydrolysis (Bisogno et al., 2001). In vitro assays also demonstrated some antagonistic actions of CBD at CB1 and CB2 receptors, which illustrates the complex actions of CBD on the endocannabinoid system (Thomas et al., 2007). CBD may also act as an agonist on other receptors, such as 5-HT_{1A} receptors, according to in vitro (Russo, Burnett, Hall, & Parker, 2005) and in vivo (Campos & Guimarães, 2008; Twardowschy et al., 2013) studies, and transient receptor potential cation channel subfamily V member 1 (TRPV1) (De Petrocellis et al., 2008).

The use and therapeutic efficacy of CBD is controversial, but the literature describes a wide range of possible therapeutic effects of CBD on several medical conditions, including cerebral ischemia, diabetes, rheumatoid arthritis, and other inflammatory diseases, nausea, cancer, motor diseases, schizophrenia, Parkinson's disease, Alzheimer's disease, epilepsy, depression, and anxiety disorders (for a review, see Zuardi, 2008). Notably, CBD promoted anxiolytic-like effects in rats exposed to the elevated plus maze (Campos & Guimarães, 2008; Onaivi, Green, & Martin, 1990), the social interaction test (Almeida et al., 2013), and the Vogel conflict test (Campos & Guimarães, 2008). Anxiolytic properties of CBD were also described in humans (Bergamaschi et al., 2011). CBD also promotes an antiaversive-like effect in rats exposed to the elevated T-maze, or in cases of dPAG electrical stimulation (Soares et al., 2010). However, some results are contradictory because low doses of CBD (10 mg/kg) decrease conditioned emotional responses in rats (Zuardi & Karniol, 1983), and high doses fail to produce anxiolytic-like effects in a conflict paradigm-based model (Silveira Filho & Tufik, 1981). Guimarães, Chiaretti, Graeff, & Zuardi (1990) showed that these opposite results likely occurred because CBD produces an inverted U-shaped dose–response curve, also recruiting noncannabinoid receptors.

The use of animal models to study human behaviors is based on Charles Darwin's studies that support that human beings share basic emotions with other animals, in an evolutionary perspective. Therefore, the root of anxiety and fear may be defensive reactions, expressed by animals submitted to a stimulus that elicits fear or a threat to the survival, well-being, and physical integrity. Notable, these emotions play an important role in our survival, but they are pathological and not useful when they disturb a person's normal activities. Reactions in this situation are classified as anxiety disorders, which are the consequence of dysfunctions in the brain systems that modulate defensive reactions (Zangrossi & Graeff, 2004).

Notably, fear and anxiety are distinct emotions, but they are correlated. The differentiation can be characterized by the stimuli or the situations that trigger them. Fear may be trigged by evident situations of threat and danger, whereas anxiety may be experienced in situations where the dangers are potential, vague, and uncertain (Blanchard, Yudko, Rodgers, & Blanchard, 1993). Gray and McNaughton (2000) suggest that fear can be contrasted with anxiety, because the tendency to avoid (based on fear) in the latter case is combined with a tendency to approach.

Some authors suggest that defensive responses are organized by encephalic structures that are responsible for the integration of aversive states, such as the hypothalamus, amygdaloid complex (AC), periaqueductal gray matter (PAG), deep layers of the superior colliculus (dlSC), and the inferior colliculus (IC) (Castellan-Baldan et al., 2006; Graeff, 1990), which comprise the encephalic aversion system (EAS), that contains potential sites of action for the therapeutic effects of CBD.

NEW ETHOLOGICAL MODELS FOR THE STUDY OF ANTIPANIC-LIKE EFFECTS OF CANNABIDIOL

Polygonal arenas without burrows (Lobão-Soares et al., 2008; Maurin, 2008) or enriched with shelters and escalators with escape platforms (Almada, Roncon, Elias-Filho, & Coimbra, 2014; Twardowschy et al., 2013; Uribe-Mariño et al., 2012) and complex labyrinths (Guimarães-Costa et al., 2007) were used as new experimental models for the study of the panic attack-like behaviors displayed by small rodents confronted with wild venomous Viperidae snakes (Fig. e14.1) or wild constrictor Boidae serpents (Fig. e14.2).

The polygonal arena consists of a semitransparent acrylic quadrangular enclosure (154 cm × 72 cm × 64 cm) with the inner wall surface covered with a light-reflector film that provides 80% light reflection to minimize the visual contact of the predator with the surrounding experimental area, and focus its attention toward the prey. The floor of the quadrangular arena was made of a transparent acrylic platform placed on a rectangular stainless steel plaque below the arena, which was divided into 20 equal rectangles using a green fluorescent line (4.2 mm width; Pritt mark-it). The entire apparatus was placed on a granite rock surface (170 cm × 85 cm × 2 cm) elevated 83 cm above the floor of the laboratory to minimize vibratory stimuli. In one corner of the arena, a shelter in the form of box (36 cm × 26 cm × 12.5 cm) with black acrylic walls was provided.

The complex labyrinth consisted of a transparent acrylic enclosure that was partially a quadrangular arena (small "open-field") contiguous to a complex maze composed of black acrylic walls. The arena totaled 0.42 m^2, and the remaining labyrinth measured 15 cm in height and 6.92 m in length. The entire apparatus containing the complex labyrinth and arena measured 140 × 70 × 15 cm. The top of the labyrinth and the arena contained 84 circular holes (1.5 cm in diameter). The floor of the complex labyrinth, made of a transparent crystal acrylic plaque (140 × 70 cm), was placed on another metallic plaque of the same dimensions. The

FIGURE e14.1 Behavior of threatened rodents in the polygonal arena. Innate fear-induced defensive responses evoked in Swiss mice confronted with *Crotalus durissus terrificus* (A–C) and *Bothrops alternatus* (D–F) for 5 min in a polygonal arena with shelter. Anxiety-related responses: alertness (a1); and flat back approach (E). Panic attack-like responses: freezing (b1); oriented escape behavior (C); and explosive escape behavior (F). An interaction between prey and predator is shown in D.

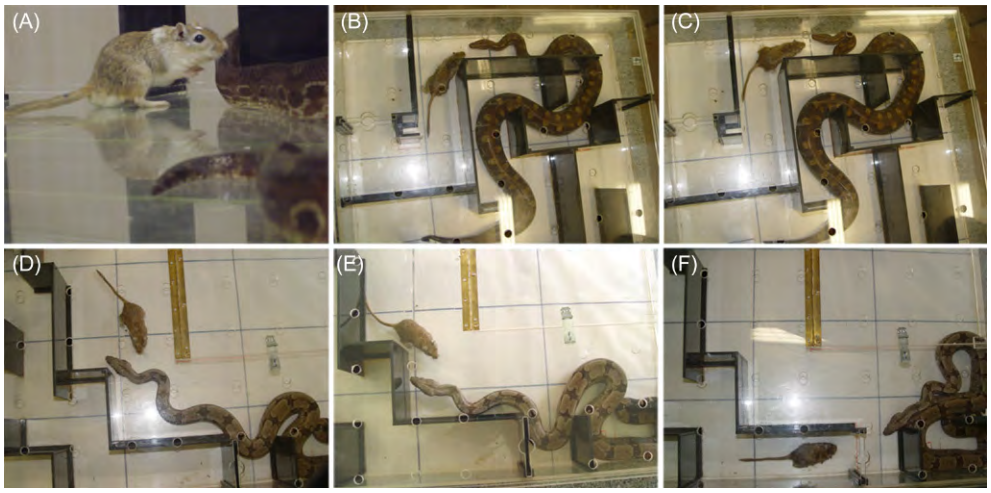

FIGURE e14.2 Behavior of threatened rodents in the complex labyrinth. Innate fear-induced defensive responses evoked in Mongolian gerbils confronted with *Epicrates cenchria crassus* (A–C) and *Boa constrictor amarali* (D–F) for 15 min in Coimbra's complex labyrinth. Anxiety-related responses: alertness (A); and flat back approach inside galleries (B), and in the arena (D). Panic attack-like responses: freezing inside galleries (C) and in the arena (E); inhibitory avoidance and freezing inside galleries (F).

metallic plaque was made of 1-mm-wide stainless steel lamina, divided by 0.4 cm green fluorescent lines in 20 equal rectangles (27.7 cm × 17.2 cm each).

Associations between defensive reactions and predatory attacks were proposed to study the neural bases of innate fear and panic attack (Blanchard et al., 1993). These associations were based on experimental models involving prey and their predators. They include observations of defense strategies, which differ according to some variables, such as the characteristics in which the stimulus is presented, the proximity of the aversive stimulus, previous experiences of the animal, and the social position occupied by the animal in its social group (Blanchard et al., 1993). Other studies (Guimarães-Costa et al., 2007; Uribe-Mariño et al., 2012; Weltson et al., 2002) used experimental models of prey–predator interactions to evaluate the effects of human anxiety-modulating drugs, and drugs that interfere with the endocannabinoid and serotonergic systems (which we believe underlie the action of CBD) in a series of anxiety/defense and fear/defense batteries. These models were also used to evaluate activation of the central nervous system in dangerous situations (Maurin, 2008), which validates the model proposed in these experiments, and presents interesting results of defensive responses evoked in the presence of predators.

The previously cited experiments allowed correlations of defensive responses with integrated functions of encephalic structures (Maurin, 2008; Weltson et al., 2002). The main structures involved in the antipredatory defensive repertoire in the prey versus predator paradigm are the dorsomedial division of the ventromedial hypothalamic nucleus, the anterior hypothalamus, and the premammillary hypothalamic nucleus (Canteras, 2002).

Panicolytic-like effects of CBD were demonstrated in mice submitted to the prey versus predator paradigm using polygonal areas for snakes (Twardowschy et al., 2013; Uribe-Mariño et al., 2012). Notably, Uribe-Mariño et al. (2012) demonstrated that CBD caused a significant decrease in panic-attack-related responses, such as the behavioral index and the duration of defensive immobility (freezing) and explosive escape behavior. However, no significant action on anxiety-related responses, such as defensive attention and risk assessment (flat back approach), or oriented escape behavior, were observed during confrontations with rainbow Boidae snake in a polygonal arena for snakes and rodents. These antipanic-like effects decreased after WAY100635 pretreatment in mice, which suggests that cannabidiol recruited 5-HT_{1A} receptors to exert at least part of its panicolytic effects (Twardowschy et al., 2013).

ANATOMICAL TARGETS FOR THE ANTIPANIC-LIKE EFFECTS OF CANNABIDIOL

Several studies showed that midbrain tectum (MT) structures, such the dPAG, dlSC, and IC are important in the organization of nonoriented/explosive panic-like defensive reactions (Almada et al., 2015; Borelli, Nobre, Brandão, & Coimbra, 2004; Coimbra & Brandão, 1993; Castellan-Baldan et al., 2006; Nashold et al., 1969). There is also evidence that the medial hypothalamus (Biagioni, Silva, & Coimbra, 2012) elaborates more oriented escape reactions when stimulated. Chronic GABAergic input dysfunction of this diencephalic structure is used as a model of panic syndrome in laboratory animals (Shekhar, Keim, Simon, & McBride, 1996). Evidence also

suggests that GABA receptors in the medial and posterior hypothalamic nuclei regulate anxiety (Shekhar, Hingtgen, & DiMicco, 1990) and panic-related responses (Biagioni et al., 2012).

The substantia nigra pars reticulata (SNpr) is a crucial structure in the modulation of instinctive fear-related behaviors elicited by electrical and chemical stimulation of the midbrain tectum (Castellan-Baldan et al., 2006; Coimbra & Brandão, 1993). Coimbra and Brandão (1993) demonstrated that microinjections of the $GABA_A$ receptor selective agonist muscimol into the SNpr increase the sensitivity of the dlSC and dPAG to electrical and chemical stimulation, similar to the effect of neurochemical lesions of the nigro-collicular GABAergic pathways. Microinjections of bicuculline into the continuum comprised of dlSC and dlPAG, following the same procedure in the SNpr, produced the opposite effect (Coimbra & Brandão, 1993). These results highlight the relevance of GABAergic inputs to the SNpr and dorsal midbrain in the modulation of instinctive fear-induced responses produced by dorsal mesencephalic structures.

GABAergic neurons from the reticulate division of the substantia nigra send inputs to the intermediate layers of the superior colliculus (ilSC) and dlSC, and the dorsomedial and dorsolateral columns of the PAG (Di Chiara, Porceddu, Morelli, Mulas, & Gessa, 1979; Eichenberger et al., 2002; Faull & Mehler, 1978; Grofová, Ottersen, & Rinvik, 1978), and exert a strong inhibitory influence on the MT in cranial (Coimbra et al., 2006; Coimbra & Brandão, 1993) and more caudal (Castellan-Baldan et al., 2006) midbrain levels. This GABAergic pathway is under an inhibitory influence exerted by another GABAergic pathway stemming from the neostriatum and pallidum (neostriatum-pallidum-nigral disinhibitory pathway) (Castellan-Baldan et al., 2006; Faull & Mehler, 1978), which modulates the activity of nigrotectal inhibitory projecting neurons also utilizing GABA as a neurotransmitter (Castellan-Baldan et al., 2006; Coimbra & Brandão, 1993). The projections sent by the SNpr to the ilSC and dlSC/dPAG act as a sensorial channel of MT neurons, which organizes defensive reactions (Eichenberger et al., 2002; Redgrave, Marrow, & Dean, 1992). These connections are critical to the modulation of innate fear, and they may be under pre- and postsynaptic endogenous opioid peptide-mediated control (Castellan-Baldan et al., 2006; Eichenberger et al., 2002).

The modulatory mechanisms of aversive states elaborated by the MT are widely associated with GABAergic control (Di Scala, Schmitt, & Karli, 1983). Dorsal midbrain tectum electrical stimulation and intramesencephalic microinjections of the $GABA_A$ receptor selective antagonist bicuculline elicit a clear panic attack-like response (Coimbra & Brandão, 1993; Coimbra et al., 2006; Di Scala et al., 1983) that is expressed by defensive immobility, explosive escape behavior, and neurovegetative responses, such as increased heart rate and frequency (Brandão, Coimbra, & Leão Borges, 1990), defecation, urination, and exophthalmos. This set of responses are similar to innate fear characteristics that are provoked by threatening situations (Twardowschy et al., 2013; Uribe-Mariño et al., 2012).

Electrical (Bovier, Broekkamp, & Lloyd, 1982) and chemical (Coimbra et al., 2006; Eichenberger et al., 2002) stimulation of the MT are used as a model of instinctive fear in rodents. However, more ethological models of innate fear, based on the interaction between prey and predator, are also used as a noninvasive approach to investigate emotional reaction related to innate fear (Guimarães-Costa et al., 2007; McNaughton & Corr, 2004; Twardowschy et al., 2013; Uribe-Mariño et al., 2012). The panic attack model based on the confrontation between prey and predator using small rodents and venomous snakes was validated ethologically, pharmacologically, and morphologically in our laboratory beginning in 2002 (Maurin, 2008; Uribe-Mariño et al., 2012; Weltson et al., 2002). These experimental models of generalized anxiety and panic attacks are used to investigate intense fear-related emotions in rodents submitted to the presence of wild snakes (Lobão-Soares et al., 2008; Uribe-Mariño et al., 2012), with or without artificial burrows and platforms.

The endogenous opioid system and endocannabinoid signaling mechanisms during neuromodulation also play important roles in intramesencephalic GABAergic connections, and the organization of instinctive fear and panic (Castellan-Baldan et al., 2006; Eichenberger et al., 2002). Investigations using morphological techniques demonstrated the presence of μ- and κ-opioid receptors and CB1- and CB2-cannabinoid receptors in the SNpr (Gong, 2006; Herkenham et al., 1991; Mansour, Khachaturian, Lewis, Akil, & Watson, 1988). The presence of μ-opioid receptors and moderate concentrations of δ- and κ-opioid receptors were demonstrated in the SNpr (Mansour et al., 1988). Several axosomatic and axodendritic synapses of tecto-nigral opioid pathways likely use these opioid receptors to exert their modulatory influence on nigro-tectal GABAergic pathways. CB1 cannabinoid receptors are widely distributed in the SNpr (Fig. e14.3), in pre- and postsynaptic membranes (Herkenham et al., 1991). These findings suggest that endogenous cannabinoids act as neuromodulators of opioid inputs and GABAergic outputs in the ventral mesencephalon. Therefore, the role of these receptors during the control of panic attacks deserves attention for the development of new drugs with putative effects on this neural substrate. Pharmacological evidence demonstrated interactions between the endogenous opioid peptide-mediated system and endocannabinoid-signaled mechanisms (López-Moreno, López-Jiménez, Gorriti, & De Fonseca, 2010; Manzanares et al., 1999) in

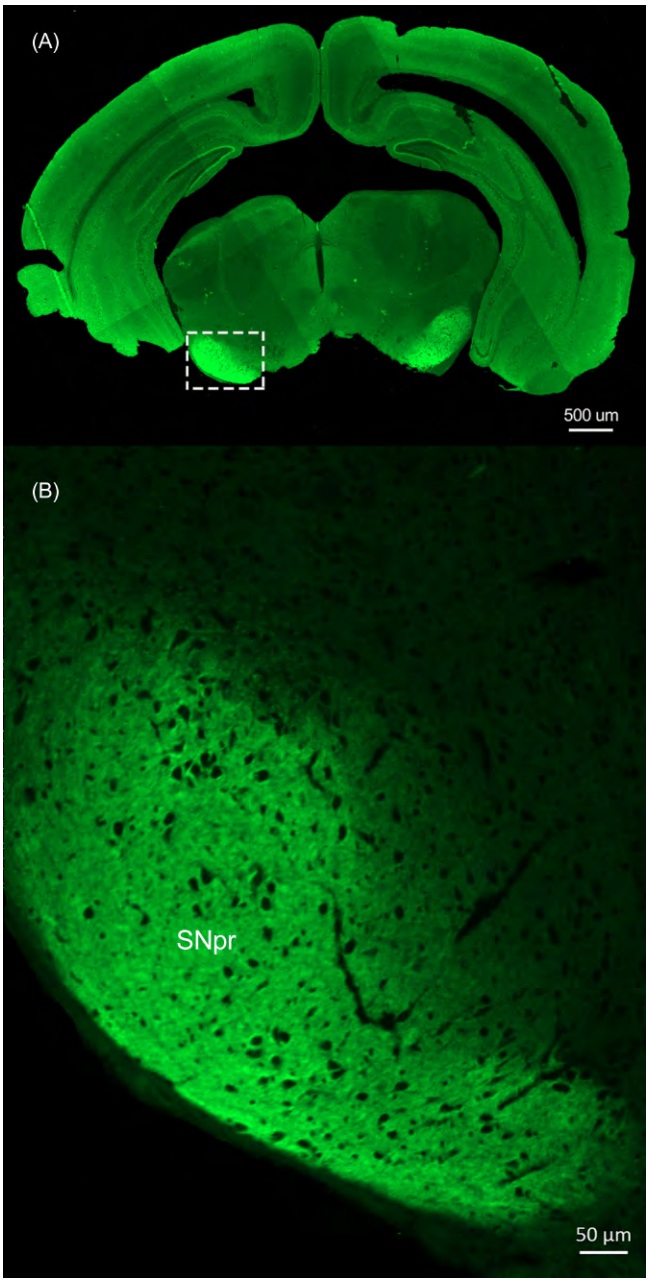

FIGURE e14.3 Morphological localization of CB1 receptors in the ventral mesencephalon. Photomicrographs of transverse sections of *Mus musculus* midbrain showing a panoramic view of the substantia nigra in which CB1-cannabinoid receptors were immunolabeled using monoclonal antibodies labeled with Alexa Fluor-488. The *dashed square* in (A) was amplified in (B). Images were obtained under black-field photomicroscopy (AxioImager Z1with APOTOME, Zeiss, Germany). Calibration bar: 500 µm in A; 50 µm in B.

the brain. Exogenous cannabinoids and endocannabinoids also exert an inhibitory influence on GABA release in the central nervous system, and this effect is mediated by CB1- and CB2-cannabinoid receptor-mediated neurochemical mechanisms (Andó, Bíró, Csölle, Ledent, & Sperlágh, 2012). Cannabinoids also decrease the activity of neostriatum-nigral GABAergic pathways in rodents (da Silva et al., 2015; Wallmichrath & Szabo, 2002).

These findings motivated us to investigate the role of GABAergic mechanisms of the striatum-nigral inputs on nigro-tectal pathway activity during the elaboration of defensive behaviors elicited by microinjections of the $GABA_A$ receptor selective antagonist bicuculline into the MT of mice confronted with the Brazilian *urutu cruzeiro* venomous snake (*Bothrops alternatus*; Reptilia; Viperidae). The decrease in neostriatum-nigral input activity was investigated using SNpr pretreatment with the synaptic blocker cobalt chloride, followed by bicuculline microinjection into the MT of mice confronted with a venomous snake. The decrease in activity of the nigro-tectal GABAergic pathway was studied using lidocaine microinjections into the SNpr. Lidocaine and cobalt chloride are widely used in several brain regions to produce functional and reversible inactivation of neural activity (Kretz, 1984; Sandkühler, Maisch, & Zimmermann, 1987). Pretreatment of the SNpr with physiological saline, followed by $GABA_A$ receptor blockade in the MT in a threatening situation, elicited a clear defensive behavior that was expressed by increased panic attack-like behaviors, such as increased duration of defensive immobility, and increased frequency and duration of nonoriented (explosive) escape behaviors during the venomous snake confrontation. Pretreatment of mouse SNpr with cobalt chloride followed by bicuculline microinjections in the MT decreased the panic attack-like responses elicited by the presence of the wild snake. In contrast, lidocaine microinjections in the SNpr increased panic-like responses. Finally, intranigral injections of AEA produced a clear antiaversive effect in mice exposed to a wild snake in a polygonal arena with burrows (Almada et al., 2014, 2015). These findings suggest that a decrease in striatum-nigral pathway activity causes panicolytic-like effects, and that the inactivation of the nigro-tectal pathway produces panic attack facilitation in threatening situations. This neural substrate of the cranial mesencephalon, including ventral and dorsal midbrain structures, should be explored as a pharmacological target for novel medicines, such as CBD. Da Silva (2011) investigated the effects of cannabidiol microinjections into the SNpr of Wistar rats submitted to bicuculline microinjections in the dorsal midbrain (Fig. e14.4A). $GABA_A$ receptor blockade in the MT increased the frequency [$F_{(7,56)} = 69.23$; $p < 0.001$] and duration [$F_{(7,56)} = 17.39$; $p < 0.001$] of panic attack-like explosive escape reactions. Pretreatment of the SNpr with CBD decreased the frequency and duration ($p < 0.001$ in both cases) of panic attack-like escape behaviors elicited by MT microinjections of bicuculline (Fig. e14.4B and C). The effect of CBD on the frequency of escape was reversed by SNpr pretreatment with the CB1-cannabinoid receptor antagonist AM251, but not after intranigral microinjections of the $5\text{-}HT_{1A}$ receptor selective antagonist

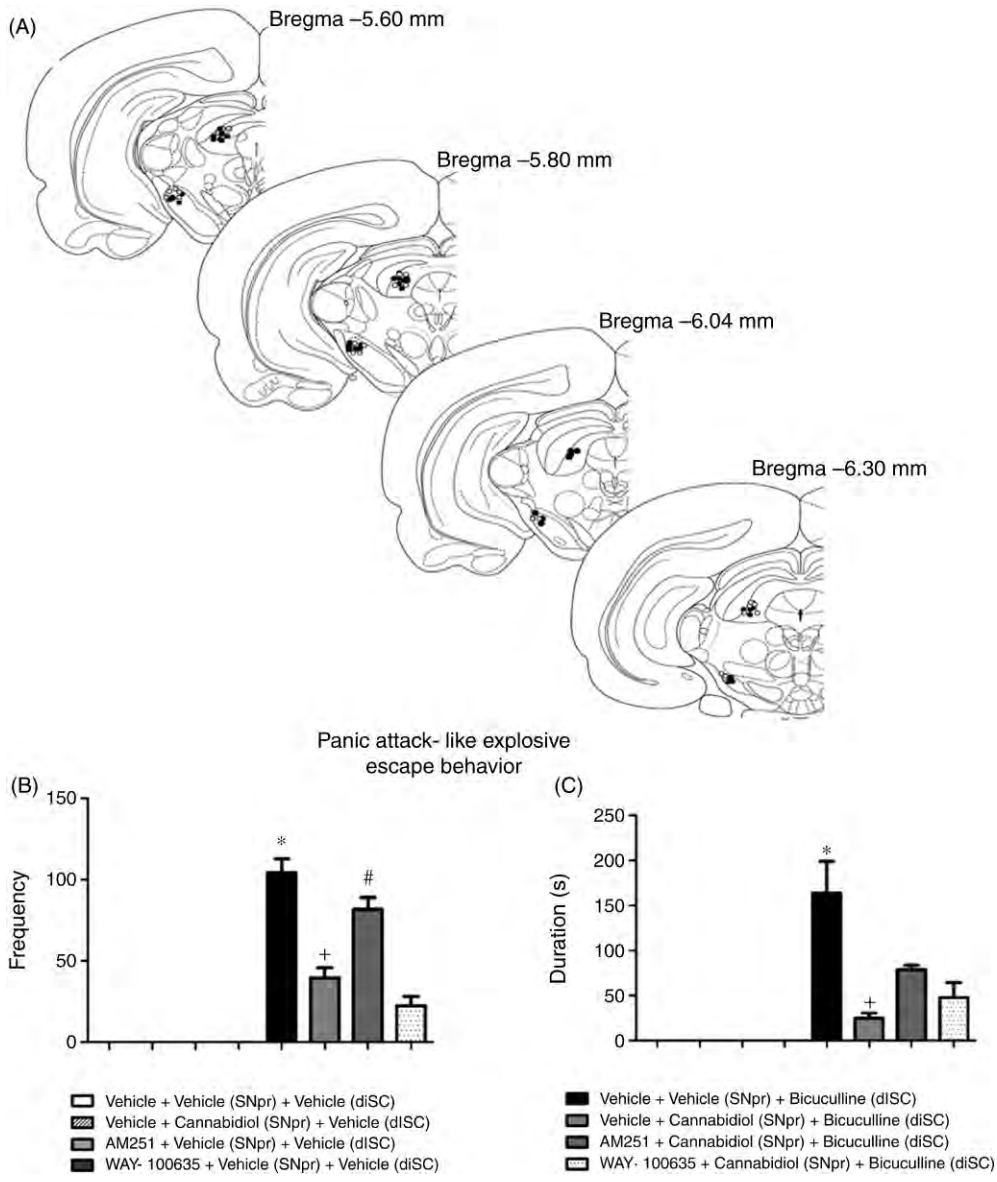

FIGURE e14.4 Panicolytic effects of cannabidiol. Effects of central administration of vehicle, CBD, AM251, or WAY100135 (n = 8 per group) into the substantia nigra pars reticulata (SNpr) on panic attack-like explosive escape behaviors elicited by GABA receptor blockade in the dorsal midbrain (DM), using microinjections of bicuculline (40 ng/200 nL) into the deep layers of the superior colliculus (dlSC). (A): hemitransverse section of the rat midbrain showing histologically confirmed sites of drug microinjections in the SNpr and DM, depicted in modified diagrams of rat brain stereotaxic atlas by Paxinos and Watson (2007). The columns represent the means, and the bars represent the standard errors of the means. $^{*}p < 0.001$, compared to vehicle + vehicle (SNpr) + vehicle (dlSC)-treated group; $^{+}p < 0.001$, compared to vehicle + vehicle (SNpr) + bicuculline (dlSC)-treated group; $^{\#}p < 0.001$, compared to vehicle + CBD (SNpr) + bicuculline (dlSC)-treated group, according to one-way ANOVA followed by Tukey's posthoc test.

WAY100135. These results suggest the involvement of SNpr CB1-cannabinoid receptors, but not serotonergic 5-HT_{1A} receptors, in the panicolytic-effects of intranigral microinjections of CBD (Da Silva et al., 2015).

A summary of the cortico-neostriatum-nigral disinhibitory GABAergic pathways and the nigro-tectal inhibitory GABAergic connections as possible morphological targets to partially explain the panicolytic effects of CBD is provided in Fig. e14.5.

CONCLUSIONS

In conclusion, the prey versus wild snake paradigm is a novel neuropsychobiological tool to investigate new drugs with potential anxiolytic and panicolytic effects. Peripheral CBD treatment of mice confronted with rainbow Boidae snakes in a polygonal arena produced a clear antipanic effect mediated by 5-HT_{1A} receptors. Dorsal and ventral mesencephalic neurons are the putative

pharmacological targets for these antiaversive drugs. The neostriatum-nigral disinhibitory and nigro-tectal inhibitory GABAergic pathways are possible neural substrates for the antipanic-like effect of CBD microinjections in the reticulate division of the substantia nigra. Microinjections of CBD into the SNpr produced a clear panicolytic effect. The GABAergic inputs to ventral mesencephalic structures are likely the central neural substrate of the panic attack attenuation effects of CBD in threatening situations.

MINI-DICTIONARY

γ-Aminobutyric acid (GABA) Inhibitory neurotransmitter widely distributed in the brain.
Amygdaloid complex Prosencephalic (cerebral) limbic structure.
Cannabidiol One of the main compounds of the *Cannabis sativa* plant with medicinal properties.
Endocannabinoids Neuromodulators released on demand in the brain.
Hypothalamus Caudal division of the diencephalon.
Inferior colliculus Caudal division of the mesencephalic tectum.
Midbrain Also known as the mesencephalon, the midbrain consists as an anatomical division of the brainstem situated between the pons and medulla oblongata.
Neostriatum More phylogenetically recent part of the corpus striatum (basal nuclei).
Periaqueductal gray matter Set of neuronal nuclei surrounding the aquaeductus mesencephali (aqueduct of Sylvius).
Serotonin Neurotransmitter involved in several brain functions, found in some brainstem structures.
Substantia nigra A ventral mesencephalic structure divided into lateral, compacta, and reticulata regions.
Superior colliculus Rostral division of the mesencephalic tectum.

Spice Use Among United States Military Personnel

H.A. Morris, J.M. Stogner

Department of Criminal Justice and Criminology, University of North Carolina at Charlotte, Charlotte, NC, United States

SUMMARY POINTS

- Because of its "legal" state, synthetic cannabinoids were introduced to the military for those who would otherwise use illegal drugs.
- In addition to its legal status, synthetic cannabinoids are perceived as safer than other psychoactive drugs; hence, why many more individuals, including service members, are abusing synthetic cannabinoids.
- Use of synthetic cannabinoids is likely higher among military personnel than comparable populations, due to the frequency of drug testing for marijuana.
- According to the Navy.mil website, synthetic marijuana (or synthetic cannabinoids) is being added to the current drug test screening for naval officers.
- Because of the rigors and stresses that being on active duty produce, military personnel feel the need to alleviate their stress through the use of drugs, more recently synthetic cannabinoids.
- Policy that allows service members to seek alternative ways to deal with the stress of being active, such as psychiatric help, needs to be implemented.

KEY FACTS ABOUT SYNTHETIC CANNABINOIDS AND DRUG USE IN THE MILITARY

- There is a long history of substance use among active duty and former military personnel.
- Military personnel are tested for use of illicit substances more frequently than individuals in other careers, suggesting that marijuana use is more risky for military personnel.
- Synthetic cannabinoids are more commonly referred to as synthetic cannabis or synthetic marijuana, and their effects are similar to that of cannabis.
- Synthetic cannabinoids have been used as an alternative for marijuana for over a decade, but use became increasingly prevalent starting around 2008.
- Only limited information exists about synthetic cannabinoid use in the military.

INTRODUCTION

Psychoactive drugs are often used as a means of "escaping" from dreadful moments and stressful life events. Many of those who abuse drugs recreationally are not content with their lifestyle and/or seek alternative mental states to alleviate stress, establish a sense of control, or avoid thinking about problematic issues. Active-duty military personnel experience great deals of stress as a result of their commitment to the armed forces, both due to the rigors of the job and the threat of bodily harm (Ballweg & Li, 1991; Berry-Cabán, Kleinschmidt, Rao, & Jenkins, 2012). These men and women are oftentimes placed in situations where they cannot afford to show any signs of weakness to their peers or superiors. In fact, training may emphasize the need to reduce or eliminate weakness, doubt, and fear. For some, this task becomes one of internalization and compartmentalization. Others confront their emotions and deal with them successfully either by addressing and accepting their situation independently, or with the aid of family and peers. For others, a less healthy approach may be selected—one that involves coping through drug and alcohol use. Alcohol, tobacco, and illicit drug use are all prominent among the United States military (Ballweg & Li, 1991; Berry-Cabán et al., 2012). This is partially due to substances' short-term effects, which may alleviate stress (or the awareness of it).

In the past, the US military provided drugs and cigarettes to their soldiers to help them with their duties and maintain morale. Amphetamines were used to keep soldiers awake for long missions, while cigarettes and alcohol were available to help them relax after the missions were completed (Bray, Kroutil, & Marsden, 1995; Ballweg & Li, 1991; Bray et al., 1986; Bachman, Freedman-Doan, O'Malley, Johnston, & Segal, 1999). This provision of drugs and tobacco to soldiers led to dependences (Bachman et al., 1999), and accidents due to intoxication (Berry-Cabán et al., 2012), which subsequently led the military to cease providing drugs and create drug-testing policies (Borack, 1998). However, even rigorous testing policies are not uniformly successful, particularly within a population predisposed to substance use (young males) and under a great deal of stress. Soldiers developed a "clean urine" black market in which urine from nonusers was sold to other soldiers so that urinalyses would yield negative results. This initial loophole was eventually combated by stricter guidelines in testing (ie, medical personnel watched the personnel provide urine). However, this did not diminish the desire to use psychoactive substances, and only led potential substance users to adapt and become more creative. The soldiers, who would otherwise abuse well-understood drugs, and likely those with limited health consequences (eg, marijuana), but had to pass urinalysis testing, sought alternative substances that were "legal highs," not included in standard drug screens. Synthetic cannabinoids and synthetic cathinones, also known as "designer drugs," are "produced clandestinely and contain modified molecular structures of illegal or controlled substances" (Loeffler, Hurst, Penn, & Yung, 2012, p. 1041). These designer drugs are chemically structured in a way which allows users to experience a high similar to that of the analogous street drug (eg, marijuana for synthetic cannabinoids, methamphetamine or cocaine for synthetic cathinones), but that does not result in failed drug tests. The US military was proactive in dealing with these so-called "legal highs," establishing bans, requiring testing, and developing educational materials. The potential use of designer drugs among military personnel has led to extensive research involving these (formerly) legal highs by military medical services. While this line of inquiry and policy development is critical and efficient, we also stress that the armed forces may similarly reduce substance use by improving the resources available to soldiers for dealing with psychological issues (ie, counseling, psychiatric help, etc.). The current chapter focuses on drug abuse trends among US military personnel, more specifically designer drug use among US active-duty soldiers.

HISTORY

Drug abuse has been common among soldiers in the US military, and in other armies, throughout history. Substance use was commonly viewed as acceptable, and even as recommended due to the harsh realities of combat and combat preparation (Bray et al., 1986, 1995; Ballweg & Li, 1991; Bachman et al., 1999). From morphine and opiate use by American Civil War soldiers to designer drug use today, drugs have continually been utilized as a means of coping "with the challenges of conflict in a setting of dislocation and devastation" (Golub & Bennett, 2013, p. 2). Alcohol, cigarettes, and common illicit drugs such as marijuana were the most prevalent in the preceding decades (Bray, Marsden, Herbold, & Peterson, 1992), but new synthetic drugs may be gaining a foothold.

Today, the Department of Defense (DoD) focuses on maintaining a healthy and combat-ready military through attempting to minimize alcohol, tobacco, and illicit drug use among the soldiers. This has not always been the case—it was once considered the norm for an American soldier to abuse alcohol, tobacco, and other drugs while on serving their country. Alcohol rations and other drugs were given to soldiers by their authorities as "rewards for extra service" (Ballweg & Li, 1991, p. 601). Bray et al. (1995) noted "that within the predominantly male military population, heavy drinking and being able to 'hold one's liquor' have served as tests 'of

suitability for the demanding masculine military role' (pp. 271–272). The perceived need to hypermasculinize one's self is considered a reason that drug use of many sorts is prevalent within the military. Ballweg and Li (1991) note that there are three main motivations of alcohol consumption by soldiers: "relief of boredom, relaxation from tension and anxieties, and reinforcement of the masculine mystique" (pp. 601–602).

Not only was alcohol use acceptable and encouraged within the US military, but other substances, now illicit street drugs, have been provided to soldiers by the United States and other countries. Amphetamine and other stimulants were provided to soldiers in order to help them work harder and longer hours (Kuzmarov, 2009a; Golub & Bennett, 2013). The military would circulate synthetic derivatives of amphetamine, known as "pep pills" to soldiers during the Vietnam War, in order to stay awake while on long missions. Stimulants were also the most prevalent during the period before and during WWII (1935–45); soldiers would oftentimes become dependent, continuing abuse when they left the service (Golub & Bennett, 2013). During the Vietnam War (1955–75), heroin was also popular, and the United States saw the highest documented prevalence of military drug use (Kuzmarov, 2009a). In addition to pep pills, and other amphetamines, soldiers would take drugs to help them sleep in order to "come down" from and relax (Golub & Bennett, 2013). Because marijuana was so readily available, grew naturally, had high potency, and was very cheap for the soldiers, estimates of the prevalence of recreational marijuana use among US soldiers were as high as 90% during that time (Kuzmarov, 2009a).

The government generally took a relatively relaxed position on drug abuse within the military (Kuzmarov, 2009a). From drinking alcohol and caffeinated drinks, such as coffee, in the American Revolution, to amphetamine provisions during WWII (Golub & Bennett, 2013), there has always been a close, oft ignored, relationship between military service and substance abuse. The historical amphetamine provision, recreational drug abuse among the soldiers, and the prevalence of self-medication within the US military today should draw attention to the issue of military substance use and testing. Some scholars have identified inconsistencies in the military's treatment of drug use among US soldiers (Donovan, 2010; Bray et al., 1992; Bray et al., 2010). Drug use was encouraged and very prevalent historically, but is now frowned upon. In fact, pharmaceutical scientists made efforts to extract the THC and "synthesize cannabinoid receptor agonists" for soldiers to reduce symptoms such as nausea and pain, in 1964 (Loeffler et al., 2012, p. 1041). The recent punitive treatment of substance use and/or possession has done little to deter substance use today (Heath, 1992; Berry-Cabán et al., 2012), but more research is needed.

Because the views of drug use of key military leaders have changed—moving from pushing and providing them to extensive drug screening—aspects of soldier lifestyles have also changed. During WWII, soldiers were actively abusing various types of amphetamines, often provided by the military, and becoming dependent (Bachman et al., 1999). Many eventually took larger doses to get quicker and more enhanced effects, some returned to the United States as a dependent user, and several accidents while on duty were attributed to intoxication (Kuzmarov, 2009a). Once again, these issues raised concerns and led the US military to change its views on drug use and begin wide scale drug testing on the soldiers. Policies were developed to force users to desist, and deter potential users from administering illicit substances. Intense drug testing began in the early 1970s, when accidents from intoxication of amphetamines and heroin were becoming more regular (Kuzmarov, 2009a). According to Dr Jerome H. Jaffe, the physician in charge of the urinalysis testing at this time, low numbers of heroin-positive tests were reported: "[of departing soldiers] 3.6 percent were found to have heroin in their urine, and 5.5 percent were thought to have previously used the drug. Only 1 percent of 13,190 US Air Force personnel tested positive, and 0.3 percent of the 5,754 from the US Navy, Coast Guard, and Marine Corps" (Kuzmarov, 2009a, p. 19). This system did have unintended consequences. A "black market" for "clean urine" developed among the soldiers. Dr Jaffe jokingly claimed the soldiers were using anything, from "beer to their grandmother's urine," in order to have a clean test (p. 19). There were no apparent measures for ensuring to the military that the soldiers were in fact giving their own urine. After recognition of this loophole, military personnel were forced to watch each soldier urinate into a collection cup to ensure accurate urinalysis results (*DOD Urinalysis Program, 2014*). Additionally, the US military provides a "chain-of-custody" document for every specimen which records everyone involved in the collection or transportation of that sample. For example, "the observer who watched the person collect the sample, the person who puts it into the box, or the person who takes it out of the box" can be identified (*DOD Urinalysis Program, 2014,* para. 3). Regulations on drug testing such as this has aided the US military in collecting accurate samples, but new policies have failed to fully resolve the issue of substance use within the military.

Although urinalysis testing for known drugs of abuse has become more rigorous, drug use is still prevalent among US soldiers and other military personnel today. However, as remaining active-duty requires passing these tests, and sidestepping analytic techniques is challenging, soldiers sought new ways to alter their mental state without violating military policy. They sought alternatives of illegal drugs (for which they were being

screened) that would not affect their test results. Soldiers would use these novel synthetic substances to experience the same euphoria, stimulation, or relaxation as their illicit counterparts, while still avoiding positive drug tests (Kuzmarov, 2009a; Loeffler et al., 2012). This form of replacement would eventually lead to essentially the same problems that led to the development of the rigorous testing protocols in the first place: accidents, overdoses, dependency, and unhealthy and irrational soldiers (Kuzmarov, 2009a; Khey, Stogner, & Miller, 2014). Many of these alternative "legal highs" were eventually banned by most of branches of the US military in 2010, ahead of federal regulation (Vardakou, Pistos, & Spiliopoulou, 2010). Of these novel synthetic substances, the most commonly used forms fall under the umbrella of "synthetic cannabinoids," colloquially referred to as "spice" after one of the more popular brand names, and mimic the effect of cannabis.

TABLE e15.1 Known Brand Names of Synthetic Cannabinoids

Aroma	Hard Core	Spark
Blaze	Highdi's Almadrohner	Spice Arctic Synergy
Blue Lotus	K2	Spice Diamond
ChillX	Magma	Spice Egypt
Deliverance	Moon Rocks	Spice Gold
Dream	PEP Spice	Spice Gold Spirit
Earth Impact	PEPpourri	Spice Silver
Ex-ses	Scope	Spice Tropical Synergy
Fusion	Sence	Spike 99
Galaxy Gold	Skunk	Truckin
Genie	Smoke	Yucatan Fire
Gorillaz	Solar Flare	

SYNTHETIC CANNABINOIDS OR "SPICE"

Legal drugs that produce a similar euphoric state to cannabis are considered "synthetic cannabinoids," a form of "designer drugs" or "novel highs," by pharmaceutical companies and other various drug administrations. Designer drugs are those "that are produced clandestinely and contain modified molecular structures of illegal or controlled substances" (Loeffler et al., 2012, p. 1041). Synthetic cannabinoids are one of the broader categories of new designer drugs, and initially allowed users to achieve a level of euphoria similar to that of cannabis, without violating the law, thus the term, "legal high." Synthetic cannabinoids can come in many various forms, but the most common brands were "Spice" and "K2," and included the chemicals such as JWH-200 and JWH-018. The JWH chemical compounds, the largest label of synthetic cannabinoids, are named after an organic chemist at Clemson University, John W. Huffman, credited for their initial synthesis (Loeffler et al., 2012). Other synthetic cannabinoids are often preceded by CP, AM, or HU [standing for Charles Pfizer, Alexandros Makriyannis, and Hebrew University (Raphael Mechoulam), respectively]. CP-47,497 was often found in "spice," as was HU-210, which is noted to be anywhere between 100 and 800 times stronger than THC (Loeffler et al., 2012). Though initially a brand name of one specific synthetic cannabinoid product, spice may now refer to any substance that can be smoked or inhaled, and that reacts on the body similarly to that of cannabis. It can be thought of as the street label for all synthetic cannabinoids (much like how "Band-Aid" brand is used to describe any type of simple bandage). "Bath salts" refers to synthetic cathinone-like chemicals sold as novel highs, but are very different in terms of effect and user profile from synthetic cannabinoids (Berry-Cabán et al., 2012).

As mentioned previously, synthetic cannabinoids come in various forms; many are packaged in small foil packets with colorful cartoon logos. They may carry a label of potpourri or other suggested function, but the packaging, name, and price all allude to its intended recreational purpose. Synthetic cannabinoids consisting "of psycho-actively inert dry plant material sprayed with synthetic cannabinoid receptor agonists" were first introduced in Europe in 2004 under the product names "Spice," "Arctic Spice," "Dream," and "K2" (Loeffler et al., 2012, p. 1041). Other products marketed as spice include Spike 99, Blaze, Genie, and Spice Diamond (Flor, 2010; Sedefov et al., 2009). For a lengthier list of synthetic product names, see Table e15.1.

Spice may create a euphoric state for the user, much like cannabis, although it can be between 4 and 100 times stronger than regular THC (Berry-Cabán et al., 2012). The Controlled Substances Act of 1970 controlled substances that could potentially be abused, and gave many substances "abuse liability" profiles, which placed them within certain classes or "schedules" of drugs (Khey et al., 2014), but synthetic cannabinoids were not assigned a schedule until recently. In order to sidestep the CSA and the Controlled Substances Analogue Enforcement Act of 1986 in the United States, spice products are typically labeled with the "not for human consumption." This regulation only bans sale or possession of analogues of illicit substances if they are intended for human use. This made spice technically legal, so long as it was labeled, advertised, and sold as a product with another purpose (potpourri). The Synthetic Drug Abuse Prevention Act (2012) eventually scheduled several cannabinoids, allowed for the

TABLE e15.2 Drugs on the Navy Drug Screen

Marijuana
Cocaine
Amphetamine/methamphetamine
Designer amphetamines (MDMA, MDA)
Heroin
Opiates (codeine, morphine, oxycodone, oxymorphone, hydrocodone, hydromorphone)
Benzodiazepines (α-OH-alprazolam, lorazepam, nordiazepam, oxazepam, temazepam)

federal government to more easily place substances on an emergency scheduling list, in which the Attorney General feels the substance has an "imminent hazard to public safety" and must take into concern: "(i) the history of the drug or substance and its current pattern of abuse; (ii) the scope, duration, and significance of the drug or substance's abuse; (iii) the risk to public health; (iv) diversion of the drug or substance from legitimate channels; and (v) the drug or substance's 'clandestine importation, manufacture, or distribution' (quoted in Khey et al., 2014). This new act made it much easier for the government to quickly place synthetic cannabinoids into a scheduled tier, once discovered and extended the amount of time that a substance may be "emergently scheduled" prior to reevaluation.

Additionally, spice was not initially detected on routine drug tests, making it easier for soldiers or other individuals undergoing routine drug testing to be able to use a drug while remaining "legal." Drug testing by urinalysis assessments began in 1981 with the Navy's "zero-tolerance" policy on drug use (Borack, 1998), but the Navy is not yet uniformly testing for synthetic cannabinoids (Navy Drug Screening Labs, 2015). For a list of all drugs for which the Navy screens, see Table e15.2. Sweeps of the soldiers' bunks were completed, in addition to soldiers being required to provide urine, however, once soldiers learned how and what they were being tested for, analogues were used to regulations. Thus, synthetic cannabinoids were particularly appealing to enlisted personnel between their introduction and their eventual inclusion on urine screens.

MEDIA COVERAGE OF MILITARY SUBSTANCE USE

Popular media and political rhetoric in the past several decades has painted drug abuse as a substantial problem. As a result, the United States government authorized a "War on Drugs" and enacted legislation that harshly punished drug users. Since the Nixon and Reagan administrations, punitive responses have intensified, even for minor drug offenses that may have otherwise resulted in a citation or fine (Kuzmarov, 2009b). The "War on Drugs" is largely responsible for the substantial increase in prison population, but that does not seem to be a major issue in the eyes of the media. The issue of drug dependence is a substantial one, and needs to be addressed increasingly through intervention and rehabilitation, and less by lengthy mandatory sentences. This, unfortunately, has not been the way the mass media portrays this issue, or the overwhelming public sentiment. A national poll in Sep. 1989 indicated that almost 65% of the nation agreed that drug use is "the major issue facing this country" after President Bush Sr proclaimed the country needed to take a "tough on crime" stance (Heath, 1992, p. 270). Around the early 2000s, drug abuse was still considered a major issue in our society, and costs were increasing at an exponential rate, costing US citizens around $484 billion (National Institute of Health, National Institute on Drug Abuse, 2001). Today, fewer US citizens are using and abusing drugs. According to the National Crime Justice Reference Service, America's drug abuse profile was indicating less drug abuse. Around 12.8 million Americans aged 12 and older abuse illicit drugs—a massive 50% decrease of illicit drug use from earlier extremes.

Not only was the issue of drug use considered a substantial issue in the United States, but drug use among the US military was a specific issue of emphasis. While drug use has been and remains prevalent among military personnel, the media may have sensationalized the relationship between military service and substance use in several instances. Regardless of media coverage, drug use among the military should be, and is, an issue that needs to be addressed, but the "war on drugs" and "tough on crime" philosophies prevalent within today's polity may themselves be dangerous, as would be inaccurate and sensationalized coverage. According to Kuzmarov (2009b), media rumors in the 1960s and 1970s "created the perception that drug use was endemic in Vietnam and linked to a breakdown in military discipline and fighting efficiency," as well as "promoted widespread fear that addicted soldiers returning to the United States would exacerbate domestic crime rates and disorder" (p. 189). These perceptions by the media fueled a nationwide panic that drug use was rampant within the US military.

To further provoke the moral panic of drug use among US military personnel, General Barry R. McCaffrey made an inflammatory statement while under President Clinton's administration:

> The US Army that I was a part of and so loved was almost destroyed by illegal drugs in the 1970s. Up to two thirds of our battalion was using drugs all the time or some of the time, and the impact on our discipline, on rape, violence, spiritual loss of focus, physical health was just atrocious. (*as cited in* Kuzmarov, 2009b, p. 191)

Recently, federal court cases involving military drug use have been on the rise. Many are related to newly emergent substances such as synthetic cannabinoids. In *United States* v. *Larry* (2010) a defendant was convicted of possession and intent to distribute spice, and given a 6-month sentence (Flor, 2010). This case was appealed because there were questions addressing if "possession with intent to distribute the substance is a violation of Article 134," but the original conviction remained (Flor, 2010, p. 24). Although Article 134 did not include language specific to synthetic cannabinoids, the court ruled, someone may still be convicted under Article 134, given its military language, for possession with intent to distribute spice products. The ruling confirmed that unspecified behaviors "such as introduction or simple possession of Spice, may qualify as chargeable offenses under Article 134 if the Government can prove that the conduct was prejudicial to good order and discipline in the Armed Forces" (Flor, 2010, p. 25). Nevertheless, the majority of reports are on *illicit* drug use, leaving questions regarding the extent of the misuse of synthetic cannabinoids and cathinones in the military.

With credible statements such as the one by Gen. McCaffrey (Kuzmarov, 2009b), the general population, as well as the media, has had reason to believe drug abuse among the military was a substantial problem. Continuing the "war on drugs" and "zero-tolerance" approaches, President George W. Bush wanted to ensure the public that our troops are not, by any means, abusing illegal drugs while on duty. He maintained the policies from the original drug abuse acts of the late 20th century, such as the Anti-Drug Abuse Act of 1986, Drug Abuse Prevention and Control Act of 1970, the Controlled Substances Act (CSA) of 1970, as well as funding military troops to travel to Colombia for combating drug traffickers (Khey et al., 2014; Geffray, 2001), and pushed to ensure that illegal drugs were not making their way into the US military. His policies and those already in existence may have led military personnel to seek alternative means of achieving a high, facilitating the development of a black market for "legal highs" among the troops.

Due to the media's emphasis on drug abuse within the US military, our society tends to believe that our military forces might be frequently "high" while active on duty. The resulting moral panic has in turn led politicians to enforce strict "zero-tolerance" policies and restrictions on active US military personnel. Research has shown that this has decreased the use of *illegal* drug use substantially (Kuzmarov, 2009a). However, active duty soldiers are continuing to achieve the "highs" they desire without disobeying the new policies. How? With the introduction of "legal highs" or synthetic cannabinoids as an alternative to illegal drug use, soldiers are sidestepping the system. New policies that address the use of Spice and other synthetic cannabinoids within the US military have been adopted in order to continue the "tough" approaches to keeping our troops sober. However, a major issue with acknowledging synthetic cannabinoids as a scheduled drug is the complications with detecting them (Khey et al., 2014). Further, as new drugs are added to drug screens, still newer variants replace them which may not be specifically regulated or lead to a positive test.

POLICY

The Controlled Substances Act (CSA), enacted in 1970, categorized substances according to "schedules" linked to a certain levels of regulation (Khey et al., 2014). For example, drugs such as marijuana, cocaine, and heroin were categorized as Schedule I drugs, but legal highs often remain unscheduled for some time after their initial introduction. The list of scheduled drugs did not include Spice or similar synthetic cannabinoids until recently, even though the option to place a substance as "temporary" or "emergency" was put in place in 1984. The Federal Analogue Act does not provide clear definitions of similarly designed drugs, and is sometimes challenged in court for vagueness (Khey et al., 2014). This analogue provision does ban compounds chemically similar to specifically scheduled substances, but the legislation is easily rendered ineffective so long as analogues are labeled "not for human consumption." Consequently, the government passed the "Synthetic Drug Abuse Prevention Act" in 2012. This Act clarified the process for temporary or emergency scheduling, and further banned several synthetic cannabinoids.

Drug testing can also be useful in reducing the amount of drug use in any given environment by two ways: (1) terminating the careers of those who do not pass their drug screening, and (2) deterring individuals from taking illicit drugs initially in order to pass their drug tests. This can directly be applied to the abuse of legal highs within the military. In a study to evaluate the deterrence potential of drug use policy among Navy service members in 1998, Jules I. Borack compared the impact of drug testing in the Navy with drug testing among nonactive duty civilians. This allowed Borack to assess whether the "threat" of drug testing does have its intended deterrent qualities within the Navy. Findings of the study indicate that utilizing regular monthly drug tests deters approximately 60% of potential users. Additionally, positive drug urinalysis fell in the 15 years preceding the study, despite increases in nonmilitary drug use (Borack, 1998). Moreover, self-reported data of drug use in the Navy have mirrored these results as well.

We support the need for drug testing, but stress that harm reduction should be prioritized above punitive and restrictive measures. Military personnel need to educate soldiers on the health issues and health disparities among drug abusers and nonabusers, in order to help them understand that, although being active service member on duty is difficult, consuming drugs or alcohol as a dulling agent is not the best option. Campaigns should stress that abusing drugs is related to other negative outcomes, and on-job accidents due to intoxication may be lethal. By educating all levels and sectors of the military, and implementing policy that covers *every* abused and potentially abused drug (even those unregulated/yet to be regulated substances), personnel can better understand the repercussions of their actions, make informed decisions, and continue to be healthy, functioning soldiers (Bray et al., 1992).

The military has engaged in several sensationalized campaigns in recent years, some of which focus on emerging drugs. Antidrug campaigns such as "Not in My Corps" include antispice and antibath salt messages. They stress health repercussions, and the strict guidelines and regulations on the use of spice and its analogues (Loeffler et al., 2012). "Not in My Corps" and other awareness campaigns "targeting active duty service members are increasingly promulgating the dangers and consequences of designer drug use, and screening for designer drugs is rapidly being integrated into command urinalyses throughout the service branches" (Loeffler et al., 2012, p. 1046). According to Loeffler and coworkers, these campaigns were somewhat effective. Prior to the study, 15% of those tested were positive for designer drug use, but after the campaigning, only 5% were positive (2012).

In conclusion, synthetic cannabinoid use among US military soldiers has likely been higher than in other demographics. Intoxication from these drugs may have led to accidents, damaged the health of military personnel, and facilitated drug dependence among US soldiers. This is particularly of concern because the men and women who are defending their country already face a number of risks. Designer drugs and their effects, whether they be direct or the indirect consequences of a fellow soldier's intoxication, should not threaten the men and women of the armed forces. By understanding legal highs, educating our soldiers on their adverse effects, and providing alternative methods to deal with stress and other anxieties, the military can avoid using psychoactive drugs, and defend their country in the best possible way.

MINI-DICTIONARY

Bath salts Synthetic cathinone-like chemicals sold as novel highs, but are very different in terms of effect and user profile from synthetic cannabinoids.

Designer drug A substance that is a synthetic analogue of a particular illegal, or prohibited drug that is created or formulated to avoid drug laws.

Spice Novel synthetic cannabinoid brand that is also used to refer to other brands of similar substance.

Synthetic cannabinoids A type of designer drug that is designed to mimic the psychoactive effects of cannabis.

Tetrahydrocannabinol (THC) Psychoactive compound in marijuana.

CHAPTER

89

Cannabis and Synthetic Cannabinoids for Cancer Patients: Multiple Palliative Indications Together With Promising Laboratory Antineoplastic Effects

D. Zalman, G. Bar-Sela

Division of Oncology, Rambam Health Care Campus and Faculty of Medicine, Technion—Israel Institute of Technology, Haifa, Israel

SUMMARY POINTS

- Cannabinoids are reported to exert various palliative effects in cancer patients.
- Dronabinol and Cesamet were the first approved cannabinoids to relieve chemotherapy-induced nausea and vomiting in cancer patients.
- Cannabinoids may be helpful for appetite stimulation, pain control, mainly of the neuropathic type, and possibly for mood and psychological symptoms relief.
- In laboratory and animal models, cannabinoids were found to have antitumor activity.
- Cannabinoids might have a future role in cancer therapy through their ability to modulate important signaling pathways in the cell cycle, to induce cell arrest and apoptosis, and to inhibit angiogenesis.
- Cannabinoids are psychoactive drugs, and nearly half the patient dropout during trials is due to central nervous system effects, such as dizziness, confusion, hallucinations, etc.
- The newer oromucosal cannabinoid, Sativex THC/CBD 1:1, tries to maintain efficacy with less central side effects, by adding the nonpsychoactive derivative cannabidiol.
- The medical use of cannabinoids is increasing, but still without proven efficacy or safety according to medical standards.

KEY FACTS OF THE USE OF CANNABINOIDS IN CANCER

- The longevity of metastatic cancer patients has nearly doubled in recent decades.
- A major problem for metastatic cancer patients is maintaining a reasonable quality of life, due to chronic multisystem and undertreated symptoms.
- In 2003, ESMO (European Society for Medical Oncology) designated an accreditation program for medical centers which integrates Oncology and Palliative Care at high selected standards.
- Although cannabinoids are prescribed for many medical conditions and symptoms, only chemotherapy-induced nausea and vomiting, and cancer pain are formally indicated and supported by evidence in cancer patients.
- The activity of medically synthetic tetrahydrocannabinol extracts may be limited by central nervous system side effects, mostly hallucinations, confusion, and dysphoria.
- Balancing the activities of the central cannabinoid receptors type 1 with the peripheral cannabinoid receptors type 2 seems to exert the maximal clinical effect with fewer complications.
- The basic data on cannabinoids is large. Nevertheless, only a selected number of medications have been tested in clinical trials, and few have been approved for clinical indications.

LIST OF ABBREVIATIONS

AEA	Anandamide
2-AG	2-Arachidonoylglycerol
CB1 and CB2	Cannabinoid receptors type 1 and 2
CBD	Cannabidiol
CINV	Chemotherapy-induced nausea and vomiting
CTZ	Chemoreceptor trigger zone
DA	Dopamine
ERK1 and 2	Extracellular regulating kinases
GBM	Glioblastoma multiforme
IL1	Interleukin 1
MAPK	Mitogen activated protein kinase
NTS	Nucleus of the solitary tract
THC	Δ^9-Tetrahydrocannabinol
TNF	Tumor necrosis alpha

INTRODUCTION

During the last decade, medications and technologies in oncology treatment have been greatly improved, leading to prolonged survival of cancer patients. Nevertheless, the symptoms of incurable disease last for long periods. Early palliative intervention has improved quality of life, as well as prolonging survival (Temel et al., 2010). The World Health Organization's definition for palliative care indicates that it should relieve all types of suffering in multidisciplinary ways, without influencing life longevity (Becker, 2009).

The patient with advanced cancer can suffer from multiple symptoms, usually in clusters, either physical and/or psychological. The most commonly described symptoms are: pain, fatigue/lack of energy, anorexia/early satiety, nausea/vomiting, dry mouth, constipation, and dyspnea (Shoemaker, Estfan, Induru, & Walsh, 2011).

Cannabis sativa, one of the most ancient psychotropic drugs known to man, gained new medicinal interest in the last 10 years and was approved by many western countries for symptom control, either in cancer or in nonmalignant illnesses, based on its highly unique and diverse pathophysiology.

Endocannabinoids are retrograde transmitters, meaning that they are released from postsynaptic cells, and act on receptors in the axonal terminals of presynaptic cells to release substantial neurotransmitters, such as glutamate, GABA, and also NE, 5HT, etc. Cannabinoids may exert their diverse effects through direct stimulation of both central and peripheral receptors (CB1, CB2), and also through indirect interaction with different neurotransmitters (Manzanares & Carrascosa, 2006).

Table 89.1 summarizes the pharmacokinetic and pharmacodynamic of cannabis and of the synthetic cannabinoid drugs. These unique mechanisms, which activate different organs, systems, and neurotransmitters simultaneously, increase interest in the efficacy of the cannabis extract to relieve symptoms in complicated palliative cancer patients, such as intractable pain, decreased appetite, nausea, and vomiting, and also to improve psychological symptoms, by ameliorating mood, insomnia, and depression. These positive effects should be considered along with the possible side effects of cannabis use. Fig. 89.1 demonstrates the possible effects of cannabinoids in relation to the dispersion of anatomic CB1 receptors in the brain.

TABLE 89.1 Pharmacokinetics and Pharmacodynamics: Values in Commonly Used Cannabinoids

Smoking cannabis	2–56%	10–25 min	2 h
Dronabinol–Marinol	5–20%	1–5 h	24–36 h
Cesamet–Nabilone	20%	2 h	2 h (35 h metabolites)
Levonantradol–IM	Variable	1–2 h	2 h
Ajulemic acid	Unknown	1–2 h (up to 5 h)	Several days
Nabidiolex–Sativex	>90%	2–4 h	24–36 h

Table 89.2 summarizes the possible biochemical pathways of cannabinoids in moderating clinical symptoms. Preclinical data suggest that cannabis may possess antineoplastic mechanisms which merit exploration.

In a prospective observational study published recently (Bar-Sela et al., 2013), cancer patients were evaluated for the supportive and/or palliative benefits which medicinal licensed cannabis might offer. Patients were interviewed and completed questionnaires regarding symptom control and side effects. Nearly half of the 211 patients included in the study dropped out for various reasons, including 12% who dropped out early due to cannabinoid side effects. The remaining 106 patients showed significant symptomatic improvement in cancer and therapy-related symptoms, such as chemotherapy-induced nausea and vomiting (CINV), fatigue, mood disorder, pain, sleep disorder, and anorexia ($p < 0.001$). Memory loss was noted in patients with prolonged cannabis use ($p = 0.002$), and the study had limitations of small size, heterogeneity, subjectivity of symptom scaling, and bias of the results, as those who dropped out were not included.

Only a very small number of synthetic cannabinoids have been approved by the regulatory authorities for symptom relief in cancer patients (Table 89.3).

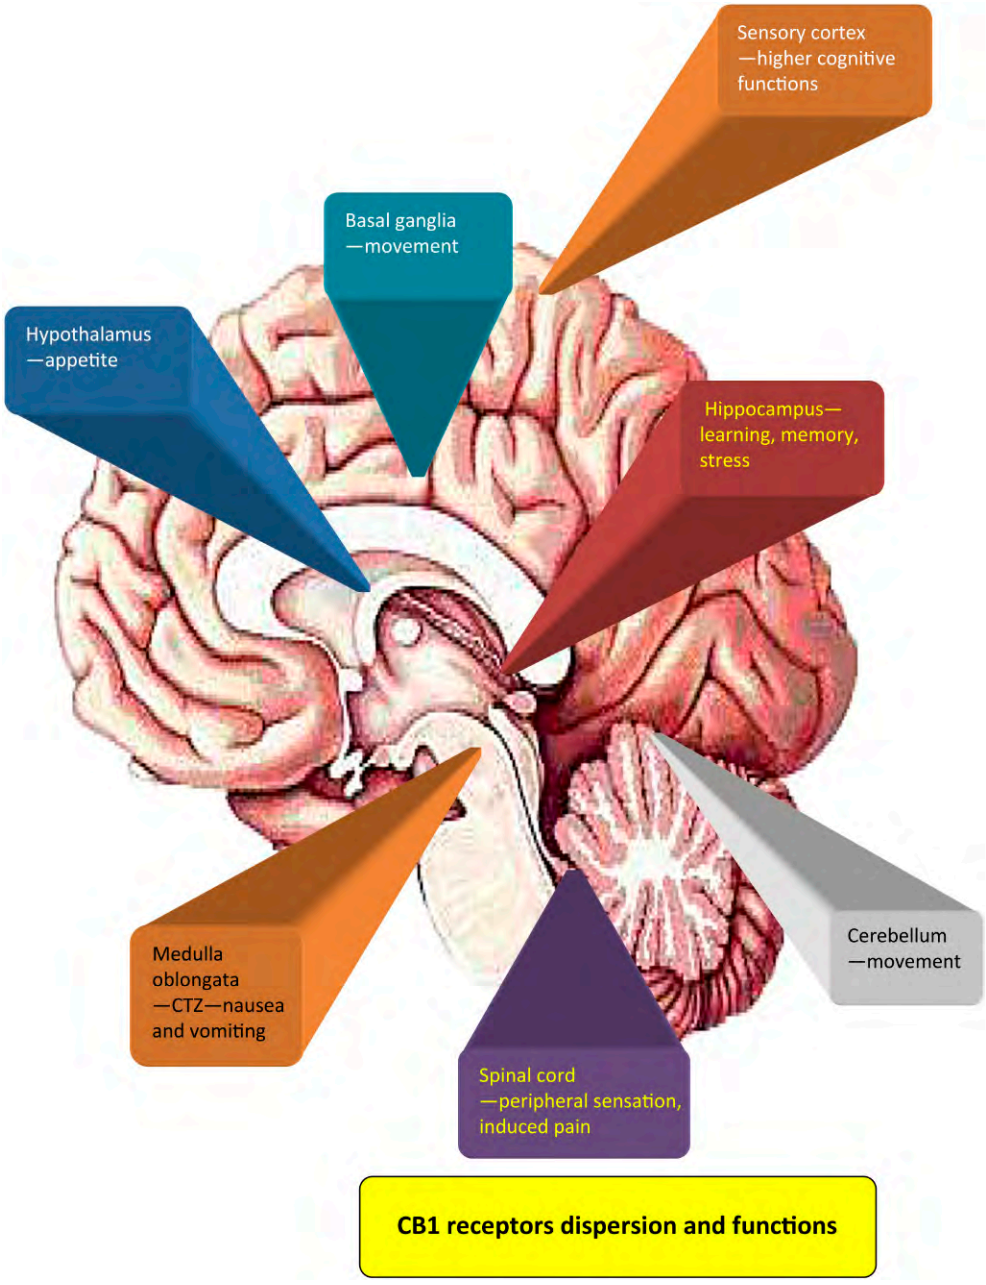

FIGURE 89.1 **CB1 receptors, dispersion in brain and related functions.**

TABLE 89.2 Commonly Treated Symptoms With Cannabinoids and Suggested Mechanisms

Symptoms	Anatomy	Neurotransmitter
CINV	Vagus nerve	Muscarine, CB2
	CTZ	Dopamine, 5HT, CB1
	Vestibular cerebellum	Histamine, muscarine
	Limbic region	CB1
	NTS	5HT, muscarine, histamine, CB1
	Upper GI	5HT, dopamine, CB2
Cancer pain	Neuropathic pain—CB1 activation	Inhibition of GABA, L-glutamate, serotonine, NA, Ach, and DA
Anorexia–cachexia	Hypothalamus	Leptin
	Anabolic factors decrease	IGF, GH, thyroid hormone
	Catabolic factors increase	Cortisol, glucagon, TNF-alpha, IL1, IL6, IFN-gamma
Depression	Cortex	5HT1/2/3, NA
	Hypothalamus-pituitary-axis	5HT, NA
	CBD	5HT1-anxiolytic

The table summarizes the main cannabinoids responsive symptoms and the possible anatomical and pathophysiological mechanisms (Kotler, 2000; Slatkin, 2007; Crippa et al., 2009).

TABLE 89.3 Currently Approved Cannabinoids for Palliative Cancer Symptoms Relief

Symptom	Approved drug	Chemical compound	Approval	References
CINV—chemotherapy-induced nausea and vomiting	Dronabinol–Marinol	Synthetic THC extract (tabs.)	USA (1985), Canada (1998)	Plasse et al. (1991)
	Cesamet–Nabilone	Synthetic THC-alike extract (caps.)	United Kingdom, Canada, Mexico, Australia, USA	Einhorn, Nagy, Furnas, and Williams (1981), Herman et al. (1979)
PAIN—persistent cancer pain	Nabidiolex–Sativex	Combined 1:1 THC/CBD submucosal extract (spray)	USA (2011)	Portenoy et al. (2012)

CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING

The pathogenesis of nausea and vomiting is highly complicated (Grunberg & Hesketh, 1993). It involves the central and peripheral nervous systems, and is mediated by the vagus nerve. Other parts of the nervous system that play a role in the mechanism of nausea and vomiting include the chemoreceptor trigger zone (CTZ) located in the medulla oblongata, the vestibular cerebellum, and the peripheral nerves in the upper GI tract.

It is assumed that the center substantially eliciting nausea and vomiting lies at the medullary nucleus of the solitary tract (NTS), which may represent the site where different inputs from the vagal nerve, the vestibular cerebellum, the postrema area, and the limbic lobe area converge (Miller, 1998).

CINV pathogenesis involves a variety of neurotransmitters, such as dopamine, histamine, muscarine, and serotonin, each responding to a variety of stimuli that may improve or deteriorate nausea and vomiting status. It is not surprising that drug combinations act better than a single medication to overcome CINV.

It is assumed that most of the antiemetic effect of cannabinoids is derived from direct activity on CB1 receptors in the brain, especially in the NTS. Nevertheless, activity in higher cortical regions and in the limbic lobe was also reported to have some antiemetic effects. The NTS nucleus receives information regarding emetogenic substances in two different ways: through the blood stream in the brain stem and CTZ, and neurologically through the vagus nerve. At the limbic system, cannabinoids may have an antianxiety effect which might contribute to reducing anticipatory emesis, and delayed emesis. Through peripheral stimulation of CB2 receptors, cannabinoids are thought to stabilize enterochromaffin cells in the intestine and to reduce vagal stimulation. Also, the indirect effect of cannabinoids on emesis mechanism has been recognized through its effect on dopamine and serotonin receptors (Slatkin, 2007).

Only two trials have been published in which cannabis was given by smoking for CINV. The first trial included 15 patients diagnosed with osteogenic sarcoma, and was published in 1979 (Chang et al., 1979). Patients were treated with high-dose methotrexate, and randomized to smoked marijuana, oral synthetic cannabinoid, or placebo. The patients served as their own controls. Correlation between cannabinoid blood levels and response to treatment was evaluated, as well. Cannabinoid treatment by smoking marijuana or synthetic cannabinoids reduced the level of nausea and vomiting. Efficacy was correlated to blood levels as follows: only 6% suffered from CINV when blood levels of THC were >10 ng/mL, 21% for 5–10 ng/mL, and 44% for <5 ng/mL, compared to 72% in the placebo group.

The second trial published by the same authors in 1981 (Chang et al., 1981) included only eight sarcoma patients who received the adriamycin/cyclophosphamide combination. Only three of eight patients had fair symptom relief. However, only two of eight patients reached what seems to be the therapeutic blood levels of THC > 5 ng/mL.

In 2001, a systematic review was published (Tramèr et al., 2001) which included 30 trials with a total of 1366 patients. The review included studies with the common cannabinoid drugs available at that time: oral medications—Marinol (Dronabinol, Unimed Pharmaceutical by Banner), Nabilone (Cesamet, Valent Pharmaceuticals by MEDA), and a parenteral drug—Levonantradol IM (by Pfizer). These cannabinoids were compared to common antiemesis medications available at that time, for example, metochlopramide, haloperidol, chlorpromazine, and domeperidone, in a variety of malignancies and chemotherapy medications. The antiemetic effect was measured only during the first 24 h after chemotherapy. Therapy with cannabinoids significantly reduced CINV in the low-to-moderate emetogenic treatments, compared with regular medications. The nausea rate was reduced from 59% to 43%, and vomiting from 57% to 45%. In 2008, a metaanalysis was published regarding the therapeutic use of cannabinoids in CINV (Machado Rocha, Stéfano, De Cássia Haiek, Rosa Oliveira, & Da

Silveira, 2008). Only randomized, double-blind controlled trials with high methodology (13 trials) were included. The same three cannabinoids listed in the 2001 review by Tramèr et al. (2001) were analyzed according to each drug. Only Marinol showed significant advantage as an antiemetic. The main reason for dropping out from cannabinoid therapy according to the systematic reviews was cannabinoid toxicity. The most serious side effects described were: 5% paranoia delusions, 6% hallucinations, 13% dysphoria/depression. Additionally, 20–25% hypotension, and dizziness in nearly half the patients was reported.

It seems that cannabis use may result in some CINV relief. However, these results should be interpreted with caution, as the group size in each trial was small, and the cannabinoids were compared to either placebo (which is unethical nowadays) or to old and unpresentable antiemesis medications. None of the newer medications which are the standard of care for CINV in cancer patients, like 5HT3 antagonist or NK1 antagonist, were tested in cannabinoids trials.

In a small recent trial which included 61 patients, cannabinoids were tested against a newer generation of antiemesis medication, 5HT3 antagonist Ondasetron. Patients were divided into four groups. All received 20 mg of dexamethasone and 2.5 mg of Dronabinol before and after therapy, or 16 mg of Ondasetron IV prior to chemotherapy, or both therapies, or none. Both Dronabinol and Ondasetron were also given orally on days 2–5 for delayed emesis prevention. After 5 days, absence of nausea was demonstrated in 71% of patients in the Dronabinol group, 64% in the Ondasetron group, 53% in the combined group, and 15% in the placebo group. No significant difference was observed between the differently treated groups (Meiri et al., 2007). Although small, this is the only trial that may demonstrate a Dronabinol (THC) noninferiority effect in preventing acute and delayed type CINV in comparison to the new generation of antiemetic medications.

Although evidence on cannabinoids efficacy to relieve CINV is inconclusive, their unique ability to interact with a few key receptors involved in the pathogenesis of emesis support adding cannabinoids to the antiemetic combination offered to cancer patients suffering from intractable CINV.

ANOREXIA–CACHEXIA SYNDROME

Cancer anorexia–cachexia syndrome is a complicated metabolic syndrome of continuous process of skeletal muscle breakdown and wasting, together with caloric intake reduction due to loss of appetite (MacDonald, Easson, Mazurak, Dunn, & Baracos, 2003). The process is attributed to decreased levels of various anabolic factors, such as insulin growth factor, thyroid hormone, or growth hormone, and the elevation of catabolic factors and proinflammatory factors, such as cortisol, glucagon, and mainly cytokines, especially TNFα, IL1, IL6, and INF-γ (Kotler, 2000).

Cannabinoids, like many other therapies in this syndrome, may relieve the anorexia part, but they do not have any impact on muscle wasting. To influence the muscle breakdown, an anabolic medication must be provided. Cannabinoids may have some influence on a few cytokines (IL10, IL12) (Smith, Terminelli, & Denhardt, 2000). However, these cytokines do not belong to the major proinflammatory cytokines which play the most important role in the anorexia–cachexia syndrome, for example, IL1, IL6, and TNF.

The exact mechanism by which cannabinoids exert their effect on the anorexia–cachexia syndrome has yet to be found. A study of an animal model (Di Marzo et al., 2001) succeeded to provide evidence of the relationship between the leptin (hormone regulating food intake and body weight) regulation system, the CB1 receptors at the hypothalamus, and cannabinoids. Activation of endocannabinoids in that area may activate the CB1 receptors to maintain food intake through the regulatory leptin system (Cota et al., 2003).

In the early 1990s, a small phase II trial tested the use of oral cannabinoid to improve appetite in advanced cancer patients. The trial included 18 patients, and the cannabinoid therapy improved appetite in nearly two-thirds (Nelson, Walsh, Deeter, & Sheehan, 1994). Based on the positive results supporting the use of cannabinoids for cachexia–anorexia symptoms in HIV patients and the early phase II study, a randomized double-blind trial with more than 460 patients was published in 2002, describing the effect of 2.5 mg Dronabinol b.i.d. and/or 800 mg Megestrol acetate daily to cause weight gain in patients with advanced malignancies suffering from anorexia–cachexia syndrome. The primary end-point was a weight gain of ≥10% from baseline. Treatment with Dronabinol failed to show the anticipated results, but appetite improvement was seen in 75% of the Megesterol group versus 49% in the Dronabinol group, weight gain 11% versus 3%. Quality of life was also better with the megesterol acetate therapy. A combination of both drugs showed no advantage (Jatoi et al., 2002).

A randomized, phase III, double-blind study was published in 2006, comparing two types of cannabinoids (THC alone ± CBD) to placebo. A total of 289 patients were included in the study (Strasser et al., 2006). Increase in appetite was observed in 73% of THC/CBD, 58% of THC alone, and 68% in the placebo arm (these results were insignificant). No significant differences were seen in other symptoms, such as mood distress or nausea. It is worthwhile to note the high percentage of clinical improvement attributed to the placebo effect.

The literature today does not support specific activity of cannabinoids in the cancer anorexia–cachexia syndrome. A theory was suggested that cannabinoids might have a clinical effect through the stimulation of chemoreceptors related to the olfactory zone. Many cancer patients describe not only reduced appetite, but also changes in perception of tastes and odors, which complicates the task of feeding, and reduces the enjoyment from eating. In a small study (Brisbois et al., 2011), 46 patients were randomized to THC tablets or placebo. Adding THC significantly improved chemosensory perception that translated to 73% greater appreciation of food in the THC group, compared to only 30% in the placebo group.

PAIN

During the last decade, awareness and knowledge about pain management increased tremendously. Nevertheless, in advanced cancer patients, pain is still a common problem, causing suffering, disability, and anxiety, and reducing quality of life. In animal models, cannabinoids have been shown to have useful analgesic properties (Pertwee, 2001). However, in humans, the limiting factor is related to dose, as most of the action is transmitted through CB1 receptors in the central nervous system (Staquet, Gantt, & Machin, 1978).

According to studies, the analgesic effect of cannabinoids is presumed to be mild to moderate, at best. The estimated equal analgesic dose of 10 mg of THC is comparable to only 60 mg of codeine (Noyes, Brunk, Avery, & Canter, 1975). However, effective therapy is limited due to dose-related side effects, especially dizziness, somnolence, ataxia, and blurred vision, which are more common when the dose increases to 20 mg (Noyes et al., 1975).

The rationale of giving cannabinoids for intractable pain relates to the increasing data of synergistic effects between opioids and cannabinoids (Cichewicz & McCarthy, 2003). In a phase II study, vaporized THC was given to patients with chronic pain who were treated with long-acting opioids. Pain levels were measured along with opioid blood levels. Adding THC resulted in a temporary reduction of pain levels, without affecting opiate blood levels (Abrams, Couey, Shade, Kelly, & Benowitz, 2011).

A rationale for using cannabinoids in neuropathic pain derives from an animal model which demonstrated mechanical and thermal antihyperalgesia and antiallodynia effects. These effects are probably mediated through the central nervous system, as well as the peripheral nervous system (Fox et al., 2001). Cannabinoids can also relieve neuropathic pain by influencing several neurotransmitters, such as inhibition of noradrenaline, dopamine, serotonin, acetylcholine, GABA, and L-glutamate (Manzanares & Carrascosa, 2006). It is well known that the last two mentioned play an important role in the pathogenesis of neuropathic pain. Unfortunately, clinical data to prove these animal models is still pending. Only several small trials have been completed in cancer patients treated with cannabinoids for pain control.

In a multicenter, double-blind, randomized, placebo-controlled, parallel-group trial (Johnson et al., 2010), 177 patients with advanced cancer and intractable pain despite chronic use of opioids were randomized to three therapy groups—THC/CBD extract, THC alone, or placebo. Treatment was given for 2-week periods. Improvement of pain of more than 30% was significantly better with THC/CBD extract, compared to placebo; however, the results for THC alone did not differ from those of the placebo. A follow-up trial (Johnson et al., 2013) did not limit the length of cannabinoid use. The longest time was nearly 2 years and the shortest less than 2 weeks. Those who achieved pain relief sustained it over time, without a need to elevate opioids dose. Tolerability was acceptable, although more than one-quarter of patients withdrew due to side effects, especially dizziness, somnolence, nausea, and confusion.

Another randomized double-blind study (Portenoy et al., 2012) selectively tested the oromucosal–cannabinoid combination THC/CBD, known as Sativex (GW Pharmaceuticals, United Kingdom), in opioid refractory advanced cancer patients with pain. The spray was given to 260 cancer patients in three escalated doses, low (1–4 sprays/day), moderate (6–10 sprays/day), and high (above 11 sprays/day). Pain improvement was reported, especially with lower doses of Sativex. Failure of the higher dose may be related to side effects which are dose-related and cause high withdrawal due to low tolerance.

MOOD DISORDER AND INSOMNIA

Mood disorders are mainly affected by the serotonergic system. Tryptophan is a major precursor for 5HT, and cannabinoids were found to modulate signaling in the serotonergic system by elevating tryptophan levels (Jenny, Santer, Pirich, Schennach, & Fuchs, 2009).

Only a few studies with cancer patients have been conducted to evaluate cannabinoid effects on anxiety, mood swings, and insomnia. In a small double-blind trial of 25 cancer patients suffering from anxiety, Nabilone was compared to placebo over a 28-day treatment period (Fabre & McLendon, 1981). The study showed significant improvement of anxiety in the Nabilone group compared to placebo. Adverse effects were minimal, mostly dry mouth and drowsiness, with no altered states phenomenon.

TABLE 89.4 Summary of Suggested Antitumor Mechanisms of Cannabinoids in Various Malignancies

	Loss of CdK2 activity and S-phase arrest	Breast cancer	Laezza, Pisanti, Crescenzi, and Bifulco (2006)
Inhibition of angiogenesis and metastases	Inhibition in expression of proangiogenic factors and MMPs	General cancer	Guzmán (2003)
	Inhibition of vascular endothelial cell migration and survival	General cancer	Blázquez et al. (2003)

THC was tested for sleep disorders (Feinberg, Jones, Walker, Cavness, & Floyd, 1976). In normal volunteers, THC caused alterations of the sleep cycle, especially prolongation of stage IV at the expense of the rapid eye movement (REM) sleep length. However, REM rebound, as described with common hypnotics, is rarely seen with cannabinoid withdrawal, unless high doses (more than 70 mg) are given.

The psychological effects of the cannabinoids are highly complicated. In different trials, cannabinoids demonstrated all the possible effects on anxiety: anxiolytic effects, anxiogenic effects, and no effect (Crippa et al., 2009).

Unfortunately, the psychological effects of cannabinoids are still not fully understood. Although some patients experience positive antidepressive, relaxant, euphoric sensations, others may feel exacerbations of their symptoms, from dysthymia to major depression, from restlessness to anxiety, lack of motivation, and withdrawal from society. Negative anxiolytic effects were noticed with THC, and positive or protective ones were more likely to be attributed to CBD (Fusar-Poli et al., 2009).

ANTITUMOR EFFECTS

In cell cultures and mice animal models of lung adenocarcinoma, Munson, Harris, Friedman, Dewey, and Carchman (1975) demonstrated that 10 consecutive days with either Δ^9-THC or Δ^8-THC had a dose-dependent antitumor growth effect, with some survival benefit.

Cannabinoids were found to impact various cellular pathways which are important in cell cycle and survival. For example, by inhibition of c-AMP, they influence Na/K+ channels to cause inhibition of neurotransmitters release (Melck et al., 1999). They also modulate central pathways in apoptosis, like stimulating the MAPKs (mutagen-activated protein kinas) and ERK, the extracellular-signal-regulated kinases that have a role in controlling cell growth and differentiation (Melck et al., 1999). Stimulation of the PIK-AKT survival pathway was reported also (Guzmán, 2003). In a mice model, Blázquez et al. (2003) found two possible mechanisms of cannabinoids' antitumor activity. They demonstrated direct inhibition of vascular endothelial cell migration, and indirect contribution to cell arrest, and apoptosis by activation of cannabinoid receptors in vascular endothelial cells causing inhibition of cell migration and survival. Table 89.4 summarizes the possible mechanisms of antineoplastic activity of cannabis, and a few are illustrated in Fig. 89.2.

Many studies have been done to prove cannabinoids antitumor activity in different malignancies. However, almost all of them were performed in either cell cultures or mice xenograft models. Some of the information from these studies is described briefly regarding several malignancies.

Breast carcinoma is the most common cancer in females. Cell survival in breast cancer is mainly controlled by two pathways: the Ras-Raf/MEK/ERK or the PI3K/AKT. The Src/Ras/Erk pathway is also affected by the hormone system (estrogen, progestin), which is highly important in breast malignancies (Edwards, 2005).

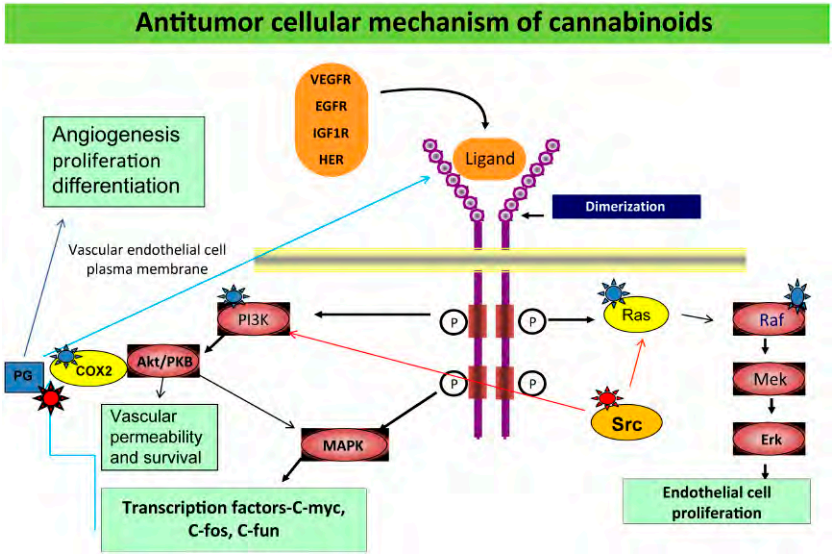

FIGURE 89.2 **Illustration of pathways and connections in a cell which influence proliferation and survival.** The *stars* mark points of possible antitumor cannabinoid effect; *blue star*, stimulatory effect; *red star*, inhibitory effect.

It was shown that cannabinoids prolonged activity of the Raf/Mek/Erk pathway which causes PRL-Rs (prolactin) downregulation in breast cancer cells (Melck et al., 1999).

Qamri et al. (2009) tested CB1 and CB2 agonists on breast cancer cells and in mice models. Mice treated with CB1 and CB2 agonists showed a 40–50% reduction in tumor growth, and a 65–80% reduction in lung metastasis. These effects were reversed by CB1 and CB2 antagonists.

In a mice model, Caffarel et al. (2010) reported that Δ^9-THC can achieve a reduction of tumor growth, and a decrease in the number of lung metastasis. These effects were related to inhibition of cancer cell proliferation, induction of cancer cell apoptosis, and impairment of tumor angiogenesis. It is also worth mentioning that more than 90% of HER2 positive breast tumors express the CB2 receptors, which might open a therapeutic option of combined therapy with anti-HER2 medications.

Prostate carcinoma is the most common cancer in men, and the second leading cause of cancer mortality. Prostate cancer pathogenesis is hormone-dependent, and many tumors, especially in early diagnosis, are androgen-dependent, which means that the tumor may be brought under control by deprivation of androgen. The androgen receptor activity seems to be regulated by the activation of distinct growth factors, such as EGFR, insulin-like growth factor-I (IGF-I), keratinocyte growth factor, IL6 and others (Moschos & Mantzoros, 2002). Some of these growth factors are influenced by the cannabinoid system.

In prostate cancer cell lines, inhibition of CB1/CB2 influences the Erk/PI3k pathways, and causes a decrease of either androgen receptor levels and/or prostatic serum antigen (PSA) levels in androgen-dependent cells (Sanchez et al., 2003).

For brain tumors, Velasco et al. (2004) noticed that, in glioma cell cultures, cannabinoids induce apoptosis and cell death through the accumulation of ceramide, angiogenesis inhibition, and decay of the Akt pathway. Interestingly, cell death is selective to transformed glioma cells only.

Glioblastoma multiforme (GBM) is one of the most devastating malignancies, with a poor prognosis, short survival, and treatments which are mostly palliative in nature (Guzmán et al., 2006). The only clinical trial in humans was conducted in this disease. This phase I trial included nine patients with relapsed or progression of GBM. Cannabinoids were given intracranially directly to the tumor bed, through a specially inserted catheter with a subcutaneous subclavicular reservoir. Median survival was 42 weeks. No correlation was found between CB1/CB2 levels in the tumor tissue and response to THC treatment. Although not statistically significant, the cannabinoids seem to decrease tumor vascularization, demonstrated by CD31 staining. However, this trial is too small to draw real clinical conclusions.

CONCLUSIONS

The results of basic studies regarding the antitumor effects of cannabinoids are complex, and involve different cellular pathways and mechanisms which eventually lead to tumor regression, reduction in blood supply, tumor vascularization, and decreased metastases formation. Still, the clinical application of

the antitumor effects of cannabinoids is unknown and unproven.

MINI-DICTIONARY

Anorexia Loss of appetite.
Anxiolytic An antianxiety medication, a tranquilizer.
Apoptosis A natural genetic determined programmed cell death.
Cachexia Metabolic syndrome of continuous skeletal muscle breakdown and wasting due to unbalanced levels of anabolic and catabolic factors.
Ceramide A combination of fatty acids with sphingosine to form groups of amido-sphingolipids which have a role in cell proliferation and survival.
Chemotherapy Treatment of cancer by using specific chemical agents, or drugs which are selectively destructive to the malignant cells or tissues.
Cytokines A large group of low molecular weight nonantibodies proteins, secreted by various types of cells, which contribute to cell-to-cell communication, intercellular mediators, and immune reactions.
Dysphoria An emotional state marked by anxiety, unhappiness, and/or restlessness.

CHAPTER

90

The Use of Medical Marijuana in the Treatment of Psychiatric Disorders

T. Tellioğlu, Z. Tellioğlu***

***Brown University, Alpert Medical School, Substance Abuse Division, Rhode Island Hospital, Providence, RI, United States**

****Brown University, Alpert Medical School, Rhode Island Hospital, Providence, RI, United States**

SUMMARY POINTS

- Currently, there is no scientific evidence that marijuana is beneficial for the treatment of any psychiatric disorder. Therefore current treatments should not be altered until sufficient clinical evidence supports such changes.
- If the scientific evidence supports the use of marijuana to treat specific conditions, the medication should be subject to the approval process of the Food and Drug Administration (FDA).
- Further research on the use of marijuana as medicine in psychiatric conditions should be encouraged and facilitated by the federal government in collaboration with the appropriate medical societies, such as the American Psychiatric Association (APA) and/or the American Society of Addiction Medicine (ASAM).

KEY FACTS OF MEDICAL MARIJUANA IN PSYCHIATRIC DISORDERS

- This chapter is aimed to investigate the current evidence in the medical literature about the possible use of medical marijuana in the treatment of psychiatric disorders.
- It appears that the majority of anecdotally reported improvements are related to the effects of heightened mood or euphoria, and relaxation, but not to an evidence-based improvement in psychiatric conditions.
- There are some meaningful and promising research data available for anxiety disorders, especially PTSD, which warrants further, higher quality research.
- Current legal regulations ominously limit the research of marijuana and its components.

LIST OF ABBREVIATIONS

CB_1	Cannabinoid type 1 receptors
CBD	Cannabidiol
Delta-9-THC	Delta-9-tetrahydrocannabinol

MEDICAL MARIJUANA

Medical marijuana is one of the most discussed and highly controversial issues in medical treatment. From ordinary people on the streets to high-rating TV news anchormen; from medical practitioners of the various specialties to the legislators of the several States' Senates, the pros and cons of medical marijuana have been debated extensively. Meanwhile, marijuana use rates have risen by 30% from 2006 to 2010, according to a new report from the White House Office of National Drug Control Policy and RAND Drug Policy Research Center (Kilmer

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00105-8
Copyright © 2017 Elsevier Inc. All rights reserved.

et al., 2014). Marijuana is a Schedule 1 chemical—placed in the same classification as heroin—which states that there is no medicinal use or benefit, and there is a high risk of harm. Therefore under federal law, the use, sale, and possession of marijuana in the United States are still illegal. Some states (Colorado and Washington) have created exemptions for the medical use of cannabis, as well as decriminalized nonmedical/recreational marijuana use; however, the decisions were made by legislators but not by the medical authorities. These legislators are under extensive pressure from the public (their voters and also active users), from occluded judicial system which has been struggling to keep chasing, trying or imprisoning the offenders, or from unstable State budgets which hope to create additional income by taxing marijuana sales. On the contrary, medicinal use of marijuana is not supported by the medical authorities (ASAM, 2010; Zaman, Rosenthal, Renner, Kleber, & Milin, 2013) which have major, realistic concerns of allowing a "street drug" to replace (or, at least, to challenge with) the well-supported, established, and controllable medicinal treatments. Medicine, as an evidence-based science, has been approaching the medical marijuana issue very cautiously due to the lack of sufficient, supportive clinical data, and also due to the legal risk of being penalized by using, researching, or recommending a chemical compound which has been declared a crime under federal law.

Medical marijuana simply refers to the use of marijuana, or cannabis derivates as a medical therapy to treat a medical condition, or to relieve its symptoms. (Of note, since cannabis herb or marijuana is much more prominently cultivated and consumed than cannabis resin, hashish, therefore the focus will be more on marijuana in this chapter.) Similar to being treated with prescription medications, which are recommended or prescribed by a clinician/prescriber, individuals who suffer from certain medical conditions have been using the parts of the cannabis plant by smoking, ingesting, or inhaling the vapor. In 2012, the United Nations Office on Drugs and Crime (UNODC) estimated that there were between 119 million and 224 million cannabis users worldwide, ranging from 2.6% to 5% of the adult population (UNODC, 2012). The data are not very reliable as to what portion of these active users consume marijuana for recreational or for medicinal purposes. In both conditions, marijuana users usually experience a heightened mood or euphoria and relaxation soon after the consumption (inhalation faster than ingestion, as expected). Some people report increased enjoyment of food, taste and smell, an enhanced appreciation for music and comedy, and the subjective impression of long elapsed time. At higher doses, altered body image, auditory and/or visual hallucinations, and dissociative states were reported which are most often considered desirable as it has been used in certain religious rituals. All those self-reported experiences and their intensity may differ among people since those are highly subjective.

In laboratory settings, the most common short-term physical effects are observed as (Galanter & Kleber, 2008):

- increased heart rate,
- lowered blood pressure,
- muscle relaxation,
- decreased intraocular pressure,
- reddening of the eyes.

The central nervous system effects of cannabis may be categorized under four major groups (Galanter & Kleber, 2008):

1. mood (euphoria, unreasonable laughing, and in larger doses feelings of paranoia or anxiety),
2. perception (distortions in the perception of time and space),
3. somatic (weakness, lightheadedness, motor coordination difficulties),
4. cognitive (confusion, concentration problems and impairment of short-term and working memory).

Since the beginning of the written history, people have been using several substances to self-administer treatment for often unmanaged, undiagnosed physical, or psychological conditions (Snelders, Kaplan, & Pieters, 2006). Recreational chemicals, psychoactive drugs, alcohol, and other forms of self-medication are used to alleviate symptoms of mental distress, stress, and anxiety, including mental illnesses and/or psychological trauma. Among those, marijuana is often consumed recreationally for its heightened mood or euphoria, and relaxation; however, historic evidence shows that it was also used as a medicine for insomnia, for pain conditions, and to increase appetite in 19th and 20th century. Although its mechanism is not yet understood, several randomized controlled studies suggest that cannabinoids can create analgesia compared to placebo in chronic noncancer pain patients. Severe nausea caused by chemotherapies may respond to marijuana components. Several debilitating conditions, such as acute immune deficiency syndrome (AIDS), anorexia, may benefit from the effect of appetite increasing and antiemetic properties of marijuana. Besides cancer, AIDS and pain conditions, marijuana has been suggested as a potential effective, safe, and low-cost alternative (or adjunct treatment) in other medical conditions, such as multiple sclerosis (MS) and epilepsy. (More detailed discussions about the medical use of marijuana may be found in the other chapters of this book.) All these exciting news has been getting a lot of attention from public, from lawmakers, and from the scientific community.

While the medicinal use of marijuana has been debated for the treatment of medical conditions, patients who are suffering from mental disorders have also reported some benefit (Tellioğlu & Tellioğlu, 2012). Therefore in this chapter, we aimed to investigate the current evidence in the medical literature about the possible use of medical marijuana in the treatment of psychiatric disorders.

MOOD DISORDERS

With the use of marijuana, some patients with depression report improvement in their mood symptoms: living and enjoying life again, taking walks, riding bicycles, maintaining regular sleep and appetite schedules, and doing things that they would not even consider/or be able to do while they were depressed. Carter, Gieringer and Rosenthal (2008) mentioned in their *Marijuana Medical Handbook* that marijuana has potential to manage and improve depressive conditions. In an Internet survey over 4400 adult Internet users it was reported that those who were using marijuana once per week had less depressed mood, more positive affect, and fewer somatic complaints than nonusers (Denson & Earleywine, 2006).

Several clinical studies have also indirectly observed some improvement in depression with the use of marijuana. Prentiss, Power, Balmas, Tzuang, and Israelski (2004) reported perceived benefit of smoked marijuana on 252 HIV-positive patients in terms of relief of anxiety and/or depression (57%), improved appetite (53%), increased pleasure (33%), and relief of pain (28%). Although the study used subjective experience of improvement assessed with a Likert scale (from "1 = not helpful" to "5 = very helpful"), these results may be encouraging to help patients' compliance with treatment and overall improvement. Similarly, patients with MS report symptomatic improvements from marijuana (either self medicated or cannabinoid treated). While the main improvements in MS are observed particularly for muscle stiffness and spasms, anecdotal improvements were reported in the mood symptoms. However, these improvements were not supported by clinical research. A study in 630 MS patients who were treated with oral THC showed evidence of a small treatment effect on muscle spasticity energy level, and tiredness, but unfortunately not on depression rating scales (Zajicek et al., 2005).

An interesting piece of information came from a recent study (Anderson, Rees, & Sabia, 2014) reporting that suicide rates among men aged 20–39 years fell after medical marijuana legalization compared with those in States that did not legalize. The negative relationship between legalization and suicides among young men was interpreted that marijuana may be used to cope with stressful life events.

On the contrary, acute interruption of heavy use of marijuana (multiple times daily) was reported to cause depression along with other symptoms, including mood swings, irritability, anxiety, aggression, nervousness, restlessness, and a loss of concentration (Budney, Hughes, Moore, & Novy, 2001). Compared to withdrawal symptoms associated with quitting alcohol or other drugs, marijuana withdrawal symptoms are relatively mild, but they are uncomfortable enough to cause many individuals to relapse to relieve those symptoms (Levin et al., 2010). Typically, these symptoms begin to diminish after 2–3 weeks, but can remain longer. Interestingly, studies showed that blockade of cannabinoid receptors are also linked to depressive thoughts and suicidal behavior. In 2008, marketing of rimonabant, a promising, breakthrough weight loss agent which blocks the cannabinoid type 1 receptors (CB_1) receptor, was halted because of psychiatric concerns and ongoing clinical trials were stopped after the observation of serious psychiatric side effects and four suicides in the rimonabant arm, while one patient taking the placebo committed suicide (Topol et al., 2010).

Psychiatric side effects caused by either acute interruption of marijuana use or blockade of cannabis receptors suggest that these receptors may actively play a role in mood regulation. However, current data lack of sufficient evidence to support a medical use of marijuana or its derivates in the treatment of depressive disorders. Anecdotal reports of potential benefits of marijuana is likely a result of the euphoria and relaxation experienced by individuals; well-designed randomized clinical trials have not demonstrated any role of marijuana in the treatment of mood disorders, it would be premature to discuss its therapeutic value.

Marijuana use disorders commonly cooccur in bipolar disorder, too; however, the effects of marijuana abuse on outcome have not been well researched. Case histories indicate that a number of patients find marijuana useful in the treatment of their bipolar disorder (Ashton, Moore, Gallagher, & Young, 2005). A report implied that marijuana may actually be mood stabilizing in patients with bipolar disorder, or as an adjunct to lithium (allowing reduced dose or relief of lithium's side effects) (Grinspoon & Bakalar, 1998). However, this suggestion lacks research support. A clinical trial of CBD in two patients with bipolar I disorder failed to show any substantial improvement for the manic episode of these patients (Zuardi et al., 2010). Another study (Strakowski et al., 2007), which followed 144 patients with bipolar I disorder (manic or mixed) for up to 5 years found that marijuana use was associated with longer affective episodes and with rapid cycling. Therefore aggressive drug abuse treatment might decrease

the rate of recurrence and readmission in the course of bipolar disorder.

ANXIETY DISORDERS

Marijuana is commonly known for its relaxing effect which is the most common reason cited for its use. However, patients with panic and anxiety were found to be particularly likely to experience increased anxiety while smoking marijuana (Szuster, Pontius, & Campos, 1988). As a result, continued marijuana smoking in these individuals was found to be infrequent. Panic attacks may occur during the first use of marijuana, and they may even persist in the absence of continued use of marijuana (Yanık, 2002).

These opposing effects of marijuana are considered to be related to the location and CB_1 receptors which are on either presynaptic glutamatergic or GABAergic neurons, resulting in a respective decrease in either glutamate or GABA release. As a result, limiting glutamate release causes reduced excitation, while limiting GABA release suppresses inhibition (Elphick & Egertova, 2001). Researchers from Vanderbilt University identified recently CB receptors in the central amygdala (CeA) which is a key structure at the limbic-motor interface regulating stress responses (Ramikie et al., 2014). Since activation of the CB_1 receptor suppresses glutamate release in this region, it may help explain why marijuana users say they take the drug mainly to reduce anxiety. On the other hand, animal and humans studies suggest that the two main constituents of the marijuana plant delta-9-tetrahydrocannabinol (THC) and cannabidiol (CBD) have quite different acute effects. A functional magnetic resonance imaging study demonstrated that THC and CBD differentially modulate prefrontal, striatal, and hippocampal function during attentional salience processing (Bhattacharyya et al., 2010). In a different study (Martin-Santos et al., 2012), individuals were administered oral THC 10 mg or CBD 600 mg or placebo in a randomized, double-blind, cross-over, placebo-controlled trial. While administration of THC was associated with anxiety, dysphoria, positive psychotic symptoms, physical and mental sedation, subjective intoxication, and an increase in heart rate, there were no differences between CBD and placebo on any symptomatic or physiological variable, suggesting that CBD is better tolerated. Therefore it may not be surprising to hear that individuals who use marijuana actively state that either the suppliers do recommend specific marijuana mixtures to be used for certain conditions, (such as for sleep, pain, or relaxation, etc.) mostly due to THC and CBD content in the mixture.

People with posttraumatic stress disorder (PTSD) who use marijuana often report more relief from their symptoms (anxiety, flashbacks, nightmares, and emotional instability) than they do from antidepressants and other psychiatric medications. However, there has been no controlled trial to test how (or, if) marijuana attenuates any symptoms. In 2013, NYU researchers discovered a connection between the quantities of cannabinoid CB_1 receptors in the human brain by demonstrating that PTSD patients had higher levels of CB_1 receptors in the parts of the brain associated with fear and anxiety (Neumeister et al., 2013). They also have markedly lower concentrations of anandamide, an endocannabinoid, which suggested that trauma-related low levels of anandamide may lead to the brain compensation by increasing the number of CB_1 receptors, which eventually cause clinical symptoms. Abnormal CB_1 receptor-mediated anandamide signaling could provide a promising target to develop novel pharmacotherapies for this disorder. Since blockade of CB_1 receptors could lead to depression and suicide (Topol et al., 2010), a chemical treatment that would restore or provide a normal balance of the endocannabinoids in the brains of people with PTSD by activating CB receptors. Recently, the US Department of Health and Human Services approved that researchers at the University of Arizona could move forward with a study which will measure the effects of 5 different potencies of smoked or vaporized marijuana in treating symptoms of PTSD in 50 veterans (Klimas, 2014) which may be a pioneering step for further studies.

A possible anxiolytic action of CBD led to the hypothesis that this cannabinoid could be effective to treat social anxiety disorder (SAD). In a study of 24 patients with SAD who were given CBD 600 mg, the patients performed similarly in terms of the levels of anxiety, somatic symptoms, and negative self-assessment to controls and to the SAD patients who received placebo (Bergamaschi et al., 2011). In another study, a single dose of CBD 400 mg in a sample of patients with SAD was able to reduce subjective anxiety measures and regional changes detected by SPECT, supporting the neural correlates of CBD's anxiolytic effects (Crippa et al., 2011).

CBD appears to be the main marijuana compound that is closer to have its preliminary findings in anxiety translated into clinical practice. Future studies should test this possibility in clinical trials involving patients with different anxiety disorders, especially panic disorder, SAD, and PTSD.

SLEEP DISORDERS

Mental health clinicians are aware that many psychiatric patients use marijuana for sleep. It also appears that many patients suffering from insomnia also use it.

Many swear by its ability to help them relax and fall into a deep, restful sleep. Studies showed that acute administration of marijuana decreases the sleep latency, and appears to facilitate falling asleep (Schierenbeck, Riemann, Berger, & Hornyak, 2008). Researchers conducting clinical trials of marijuana for other chronic pain disorders and MS have reported improved sleep as secondary outcomes (Russo, Guy, & Robson, 2007). A study reported that nabilone, a synthetic marijuana, improved sleep disturbance in fibromyalgia (FM) (Ware, Fitzcharles, Joseph, & Shir, 2010). Its effect was found to be superior to amitriptyline, suggesting that nabilone is effective in improving sleep in patients with FM, and is well tolerated, and was suggested as an alternative to amitriptyline in FM patients.

Improvement in sleep quality in chronic pain syndromes was considered to be due to analgesic, and spasmolytic effects resulting in nocturnal symptom relief, in addition to the hypnotic properties of marijuana. Some tolerance may occur to the sleep-inducing effect in the chronic marijuana administration. On the contrary, abrupt discontinuation of heavy marijuana use is associated with self-reports of sleep difficulty (Budney et al., 2001), and resumption of the marijuana use attenuates sleep disturbances. Disturbed sleep is clinically important because marijuana users experiencing sleep problems may relapse to marijuana use to improve their sleep quality (Bolla et al., 2010). Despite these promising observations of sleep improvement as secondary outcomes on certain populations, current literature lacks the long-term safety and efficacy of marijuana and its derivates to be safely used in sleep disorders. Further studies on the effects of marijuana on sleep architecture and long-term safety and efficacy are warranted.

PSYCHOSIS

Marijuana can produce a full range of transient schizophrenia-like positive, negative, and cognitive symptoms in some healthy individuals. In patients with an established psychotic disorder, marijuana can exacerbate symptoms, trigger relapse, and have negative consequences on the course of the illness. Furthermore, exposure to heavy use of marijuana was considered a premorbid precipitant and a stressor eliciting relapse in patients with schizophrenia and related disorders (Burns, 2013; Linszen, Dingemans, & Lenior, 1994). Despite these negative consequences, marijuana use was observed in every fourth schizophrenia patient which is 2 times more frequent than in the general population (Koskinen, Lohonen, Koponen, Isohanni, & Miettunen, 2010). One common theory is that patients with psychosis use marijuana for the same reasons the general population does, to "get high", relax, and have fun. There is also the "self-medication" hypothesis, which explains the high rates of abuse by an "alleviation of dysphoria" model (Kolliakou, Joseph, Ismail, Atakan, & Murray, 2011). While cannabis use has been reported to increase positive symptoms in schizophrenia, the findings regarding negative symptoms have been contradictory. In a study, patients with a history of marijuana use were found to have better performance on tests of visual and working memory, and executive functioning (Yucel et al., 2012) which suggested a short-term stimulation of prefrontal neurotransmission to enhance cognitive functions (Verrico, Jentsch, & Roth, 2003). However, in the long-term, repeated administration is shown unfavorable (D'Souza et al., 2005). Another important data suggest that CBD was able to prevent psychotic-like symptoms induced by high doses of THC (Zuardi et al., 2012), suggesting antipsychotic-like properties of CBD. In addition, a preliminary report of a controlled clinical trial comparing CBD with an atypical antipsychotic drug (amisulpride) has suggested that CBD may be an alternative treatment for schizophrenia (Zuardi, Crippa, Hallak, Moreira, & Guimaraes, 2006).

SUBSTANCE USE DISORDERS

Marijuana is commonly used in combination with heroin, cocaine, alcohol, and benzodiazepines in individuals with addiction disorders. In a community-based dispensary, many individuals report using marijuana as a substitute for other potentially more dangerous substances, such as alcohol, or illicit drugs, and for pharmaceuticals due to side effects, and better symptom management (Reiman, 2009).

Historical evidence shows that *Cannabis indica* (a type of marijuana plant which has a higher ratio of CBD:THC compared to *Cannabis sativa*) was used by doctors for conditions, such as agitation and delirium tremens, related to drug dependence and withdrawals (Snelders et al., 2006). This beneficial effect may be explained by a protective effect of CB system against the hyperexcitability of the neurons. During an alcohol withdrawal, excitotoxic damages cause neuronal death. In an in vitro experiment, a CB agonist HU-210 was shown to decrease *N*-methyl-D-aspartate (NMDA)-induced neuronal death exclusively in alcohol-withdrawn neurons (Rubio et al., 2011). By contrast, it was shown that the inhibition of the CB_1 receptor by rimonabant during alcohol withdrawal increased death of alcohol-withdrawn neurons. These results suggest that cannabinoids may have neuroprotectant effect which may potentially be beneficial in the prevention of neuron damage in alcohol withdrawal.

On the other side, THC was suggested that it could reduce opioid withdrawal symptoms. The increment of activity of endogenous cannabinoids (via inhibition of the hydrolytic enzymes) was shown to reduce naloxone-precipitated morphine withdrawal symptoms in in vivo and in vitro models of opioid dependence (Ramesh et al., 2011). A clinical study reported that increased marijuana use was found to be associated with lower severity of withdrawal during methadone induction, suggesting a potential role for marijuana in the reduction of withdrawal severity (Scavone, Sterling, Weinstein, & Van Bockstaele, 2013). Similarly, in patients with cocaine dependence and comorbid attention deficit hyperactivity disorder, marijuana users were more successful than other patients in abstaining from cocaine use (Aharonovich et al., 2006). Furthermore, animal studies showed that CB_1 receptor plays an important role in the mechanisms underlying relapse to heroin-seeking behavior, and CB_1 antagonists could be possible therapeutic agents in the prevention of relapse to heroin abuse (Spano et al., 2004).

Despite these promising preclinical and pilot data and the availability of medical marijuana, it was reported that it increased the number of binge drank days in adults by 6–9% suggesting that by legalizing marijuana, alcohol consumption and binge drinking have increased (Wen, Hockenberry, & Cummings, 2014). Also, marijuana use was reportedly not associated with treatment retention, opiate/cocaine use, or any measure of treatment outcome in methadone maintenance treatment (Scavone et al., 2013).

COGNITIVE DISORDERS AND DEMENTIA

Marijuana use among healthy users has been associated with cognitive impairments, including residual deficits in memory and attention on tests measuring memory, executive functioning, psychomotor speed, and manual dexterity (Pope, Gruber, Hudson, Huestis, & Yurgelun-Todd, 2002). It was reported that heavy users had more difficulty than light users in sustaining and shifting attention and, hence, in registering, organizing, and using information (Bolla, Brown, Eldreth, Tate, & Cadet, 2002). In controlled trials, it was demonstrated that acute administration of THC impairs cognitive performance not only in healthy controls but also in patients with schizophrenia (D'Souza et al., 2005).

Furthermore, in individuals with no medical or psychiatric history it was shown that long-term marijuana use is associated with structural brain abnormalities in a dose-dependent manner (Yucel et al., 2008).

In patients with dementia, night time agitation occurs frequently and creates a major burden on caregivers. An open study of THC for the treatment of agitated behavior at night in severe dementia revealed a 59% decrease in nocturnal motor activity without any adverse effects after single and repeated administrations of THC (Walther, Mahlberg, Eichmann, & Kunz, 2006). Since treatment options are limited (antipsychotics have a black box warning of cardiovascular deaths and benzodiazepines are not recommended), alternative treatments are desperately warranted in this quickly growing group of patients. Randomized controlled trials with larger sample sizes and longer treatment periods needed to corroborate these preliminary findings.

CONCLUSIONS

While the functions of the endocannabinoid system is still under investigation, anecdotally reported improvements in psychiatric conditions invite researchers to explore the possible use of medical marijuana and its derivates in the treatment of psychiatric disorders. Although mostly anecdotal, there are several conditions reported for which the active ingredients of the marijuana plant might have showed some therapeutic effect. In 2014, the website of *clinicaltrials.gov* (reached on 5/1/14) showed that there were 395 current studies for the search word "marijuana"(National Institutes of Health, 2014). Despite this high interest, available clinical data are extremely limited, which confine clinicians to suggest marijuana use for any psychiatric disorders currently. It appears like majority of the reported improvements of symptoms are related to the effects of heightened mood or euphoria, and relaxation, but not an evidence-based improvement in psychiatric conditions. While marijuana may be initially used as a self-therapy for certain conditions, the prolonged exposure to this substance in vulnerable individuals may in turn alter or aggravate depressive or anxious manifestations, and may cause patients refractory to standard treatments (Tambaro & Bortolato, 2012). Further, these chemicals have the risk of causing serious detriment to physical and mental health due to the risk of the addiction syndrome (ASAM, 2010). Nevertheless, pharmacologically, there are 483 known compounds present in the marijuana plant, including 85 cannabinoids, such as CBD and THC (Russo, 2013). As discussed in this chapter, some of these chemicals (such as CBD) are shown that they may have potential beneficial effects on anxiety, neuroprotection, and sleep, which warrant further, good quality clinical research under close monitoring of the federal agencies in collaboration with the medical/psychiatric authorities (Table 90.1).

TABLE 90.1 Comparison of Some Effects of Delta-9-THC (Delta-9-Tetrahydrocannabinol) and CBD (Cannabidiol)

Actions	THC	CBD
Agonist action on CB_1 receptors	+	–
Inhibition of anandamide reuptake and hydrolysis	–	+
Anxiolytic	+[a]	+
Psychotropic	+	–
Antipsychotic	–	+[b]
Anticonvulsant	–	+
Antidepressant	(+)[c]	–
Sedative/hypnotic	+	+
Antinociceptive	+	+
Neuroprotective (inhibition of glutamate release)	+	+
Antiemetic	+	–
Appetite stimulant	+	No data
Cardiovascular effects[d]	+	+

[a]*THC is anxiolytic in some doses, but can be anxiogenic in higher doses or in drug-naïve individuals.*
[b]*CBD also antagonizes some psychotropic effects of THC.*
[c]*Shown in one study in cancer patients.*
[d]*THC causes tachycardia and hypotension; CBD can cause bradycardia and hypotension.*

CHAPTER

91

Beneficial Effects of Cannabis and Related Compounds on Sleep

*I.M.P. Linares**, J.A.S. Crippa**, M.H.N. Chagas**,****

***Department of Neuroscience and Behavior, Faculty of Medicine, Ribeirão Preto, University of São Paulo, Ribeirao Preto, Brazil**

****Barretos School of Health Sciences, Dr. Paulo Prata, Barretos, São Paulo, Brazil**

SUMMARY POINTS

- This chapter described the effects of cannabis and its components on the sleep-wake cycle.
- The action of cannabis and their compounds on the sleep-wake cycle appears to depend on several factors such as dose, route and time of administration.
- CBD seems to be associated with an increased total sleep time and less frequent arousals.
- Lower doses of THC between 10 and 30 mg in healthy volunteers appear to increase sleep latency without other significant effects on the sleep-wake cycle.
- There is a link between the endocannabinoid system and the sleep-wake cycle. However, not enough studies have been conducted to properly explore this association.

KEY FACTS OF CANNABIS

Cannabis consists of more than 60 cannabinoids, which may have different effects, including effects on sleep-wake cycle. These studies suggested that these effects can change various sleep aspects, such as architecture and subjective quality.

KEY FACTS OF CANNABIDIOL

The effects of cannabidiol (CBD) at different doses and routes of administration are still unclear, with contradictory reports ranging from increased wakefulness to sedative and hypnotic effects.

KEY FACTS OF Δ^9-TETRAHYDROCANNABINOL

The action of Δ^9-tetrahydrocannabinol (THC) on the sleep-wake cycle appears to depend on several factors such as dose and time of administration. There has been a lack of basic research studies on this subject.

LIST OF ABBREVIATIONS

CB_1 and CB_2	Cannabinoid receptors type 1 and 2
CBD	Cannabidiol
REM	Rapid eye movement
SWS	Slow wave sleep
THC	Δ^9-Tetrahydrocannabinol
TRPV1	Vanilloid-1 receptor

INTRODUCTION

The plant *Cannabis sativa* has historically been used for medicinal purposes in multiple cultures despite its adverse effects (Zuardi, 2006). For example, there are

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00106-X

indications that in China, before the Christian era, cannabis was used to treat several medical conditions, such as constipation, pain, malaria, epilepsy, and tuberculosis, among others (Adams, 1940).

In addition, the use of cannabis for psychiatric symptoms has been described in historical data. In the early 20th century, cannabis extracts were marketed for the treatment of mental disorders to obtain sedative and hypnotic effects (Russo & Guy, 2006). However, there was a decline in its medical use (Zuardi, 2006) for several reasons, including (1) its active compounds had not been identified, (2) restrictions were imposed due to its illegal classification and (3) there was variation in the composition of its extracts.

In the late 1980s and early 1990s, there was renewed interest in the study of cannabis after the description and cloning of cannabinoid-specific receptors in the nervous system and identification of endogenous ligands for these receptors (see Fig. 91.1). Thus, there was a notable increase in research into cannabis and its components (Zuardi, 2008; Zuardi, Crippa, & Hallak, 2010).

Cannabis consists of more than 60 cannabinoids, which may have different effects (Zuardi, 2008). The two main components of the plant are Δ^9-tetrahydrocannabinol (THC), responsible for the psychoactive effects, and cannabidiol (CBD). Other substances present in cannabis are cannabinol, which has an effect somewhat less potent than THC, cannabigerol, which, similarly to CBD, is not psychoactive, and β-caryophyllene.

The aim of this chapter is to describe the effects of cannabis and its components on the sleep-wake cycle.

Endocannabinoid System and Sleep

The endocannabinoid system is composed of receptors, endogenous agonists, and biochemical apparatus responsible for synthesis of endocannabinoid substances. The main receptors are CB_1 and CB_2, and the endogenous agonists of these receptors are derived from arachidonic acid. The arachidonoyl ethanolamine, also known as anandamide, was the first endocannabinoid identified (Howlett et al., 2002). Subsequently, 2-arachidonoylglycerol and *N*-arachidonoyl-dopamine were also identified. Endocannabinoids can bind to other receptors, that is, vanilloid-1 receptor (TRPV1), in addition to CB_1 and CB_2. Within the central nervous system, TRPV1 is expressed in postsynaptic nerve terminals and may be intracellularly activated by anandamide (Saito, Wotjak, & Moreira, 2010).

After the study of endocannabinoid system neurobiology, it was speculated that this system may contribute to various functions, including sleep modulation. Thus, research has been conducted to understand the physiological role of endocannabinoids in sleep (Murillo-Rodriguez, Blanco-Centurion, Sanchez, Piomelli, & Shiromani, 2003; Murillo-Rodriguez, Cabeza, Mendez-Diaz, Navarro, & Prospero-Garcia, 2001; Murillo-Rodriguez et al., 1998; Santucci, Storme, Soubrie, & Le Fur, 1996). One of the earliest studies was conducted by Santucci et al. (1996). Different doses of SR141716A (CB1 antagonist) were injected in mice, and a dose-dependent increase in time awake and a decrease in the slow wave sleep (SWS) and rapid eye movement (REM) phases were verified. Therefore, wakefulness induction by SR141716A may be due to CB1 receptor blockage.

An additional study demonstrated that the endocannabinoid anandamide may contribute to sleep modulation (Murillo-Rodriguez et al., 1998), when administered to rats exposed to light. This exposure induced a significant decrease in the time awake and an increase in SWS and REM.

It is also hypothesized by some researchers that the administration of SR141716A, before injection of anandamide, could block sleep effects (Murillo-Rodriguez et al., 2001). This hypothesis was confirmed when SR141716A administration blocked sleep disorders induced by anandamide.

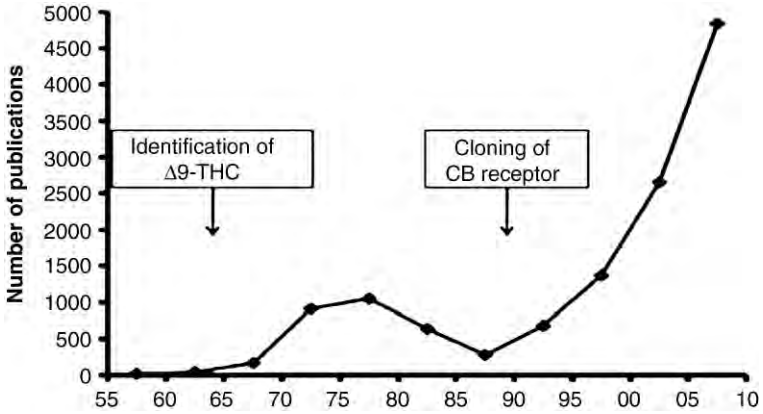

FIGURE 91.1 **Distribution of publication related to *Cannabis sativa*.**

Researchers suggest that anandamide induces sleep by activating a sleep-inducing molecule, such as adenosine. Microdialysis samples were collected in the basal forebrain of rats to measure extracellular levels of adenosine after anandamide injection. Systemic anandamide administration increased extracellular levels of adenosine. Furthermore, it was determined that anandamide injection provoked a decrease in wakefulness, and a significant increase in the SWS phase. Moreover, SR141716A administration significantly reduced adenosine levels. These data support the hypothesis that adenosine is involved in sleep modulation (Murillo-Rodriguez et al., 2003).

Cannabis Sativa

Early research into cannabis and sleep was performed in the 1970s (Mechoulam, 1986). These studies suggested that cannabis can have an effect on various sleep aspects, such as architecture and subjective quality (Babor, Mendelson, & Kuehnle, 1976; Barratt, Beaver, & White, 1974; Chait, 1990; Chait & Perry, 1994; Chait & Zacny, 1992; Ware, Fitzcharles, Joseph, & Shir, 2010). The first study investigated the effect of cannabis administered over 10 days. The researchers noted body movement reduction after 8 days of drug administration. During the same time frame, there was a noted increase in the S2 phase, followed by a reduction after 8 days of drug administration (Barratt et al., 1974). There was no effect on total sleep time and REM.

Subsequently, Karacan et al. (1976) compared the effect of cannabis administered for 8 days between substance users and nonusers. It was noted that the first group had increased sleep latency due to S1 and REM and a reduced number of awakenings during sleep. Another study determined that after 21 days of cannabis use, sleep time was higher in cannabis users when compared with alcohol users (Babor et al., 1976).

Recently, it was demonstrated that there was a decrease in sleep latency for cannabis users when compared with a control group (Chait, 1990; Chait & Perry, 1994). In both studies, cannabis was administered for two nights. Ware et al. (2010) also noted a latency decrease and sleep quality increase in subjects who received higher doses of the drug compared with the control group.

It should be emphasized that methodological aspects of most existing data preclude any definitive conclusions. One example concerns SWS: its time increased in one study (Barratt et al., 1974), whereas it did not change in another study (Karacan et al., 1976).

Although the effects of cannabis on sleep are evident, it is still necessary to understand whether these effects are caused by a specific compound. The effects observed in the sleep-wake cycle following the administration of certain *Cannabis sativa* compounds are described later in the chapter.

THC

Few studies have been performed to evaluate specifically the effects of THC on the sleep-wake cycle.

The first study examining THC was performed by Cousens and DiMascio (1973). In this study, doses of 10, 20, and 30 mg were administered and compared with a placebo. All three doses of THC increased the onset of sleep and had no effect on the amount and duration of awakenings during the night. In the same year, Hosko, Kochar, and Wang (1973) conducted a double-blind placebo controlled trial with higher doses of THC and determined that more than 25% of participants had an increase in SWS and approximately 60% had increased REM sleep in the beginning, followed by a decrease in REM sleep. The total sleep time was similar in both groups.

More recently, Chait and Zacny (1992) observed no difference when compared with the placebo in latency, quality and nocturnal awakenings at doses of 2.5–10 mg/day of THC. Subsequently, Nicholson, Turner, Stone, and Robson (2004) reported increased time awake, increased sleep latency and drowsiness the next day at doses of 15 mg/day, although no differences in sleep efficiency and number of awakenings were reported [see review by Gates, Albertella, and Copeland, 2014].

There has been a lack of basic research studies on this subject, and only one basic research study was found in literature searches. In this study, chronic intraperitoneal administration of THC doses at 5 and 10 mg/kg appears to suppress REM sleep in rats (Moreton & Davis, 1973).

It can be concluded that the action of THC on the sleep-wake cycle appears to depend on several factors such as dose and time of administration. Lower doses between 10 and 30 mg in healthy volunteers appear to increase sleep latency without other significant effects on the sleep-wake cycle.

Cannabidiol

CBD has previously been demonstrated to affect the sleep-wake cycle. Its effects at different doses and routes of administration are still unclear, with contradictory reports ranging from increased wakefulness to sedative and hypnotic effects (Nicholson et al., 2004; Zuardi, 2008).

In healthy volunteers with at least 6 h of sleep, CBD (600 mg) induced sedative effects (Zuardi, Guimaraes, & Moreira, 1993). In volunteers with complaints of insomnia, CBD was associated with an increased total sleep time and less frequent arousals at 160 mg/day (Carlini & Cunha, 1981). This study also reported that CBD reduced dream retrieval and caused no "hangover" at 40,

80, and 160 mg/day (Carlini & Cunha, 1981). However, at low doses (15 mg/day), when coadministered with delta-9-THC (15 mg/day), CBD increased wakefulness (Nicholson et al., 2004).

Similar to CBD sleep clinical trials, studies in animal models are also scarce. The first investigation assessing the effects of systemic CBD administration on sleep demonstrated a decreased SWS latency at 20 mg CBD per kg and increased duration of SWS and decreased wakefulness at 40 mg CBD per kg, with no significant changes in the REM sleep phase (Monti, 1977). During this study, the effects of CBD were recorded for 5 h after CBD administration. Chagas et al. (2013) evaluated the effects of acute CBD administration in rats and demonstrated that CBD appears to increase total sleep time, sleep latency and the percentage of SWS during the light period.

Recently, two studies used intraventricular administration and lateral hypothalamus infusion (Murillo-Rodriguez, Millan-Aldaco, Palomero-Rivero, Mechoulam, & Drucker-Colin, 2006; Murillo-Rodriguez, Millan-Aldaco, Palomero-Rivero, Mechoulam, & Drucker-Colin, 2008) and observed contrasting effects compared with Monti (1977). Intracerebroventricular CBD administration (10 μg/μL) increased wake time 1 and 4 h after CBD administration, and reduced the duration of REM sleep with no changes in SWS (Murillo-Rodriguez et al., 2006). The injection of CBD or placebo in the lateral hypothalamus also increased wake time, reduced REM sleep time, and significantly decreased the SWS (Murillo-Rodriguez et al., 2008). These data suggest that the effects of CBD vary according to the route and dose of administration.

Other Cannabis Compounds

Currently, several cannabinoid substances are known, those present in cannabis and those that are produced synthetically (Table 91.1). Cannabis has two main components: THC, responsible for the psychoactive effects, and CBD, the main component of the plant, accounting for approximately 40% of the total. Other substances present in marijuana are: (1) cannabinol, which has an effect less potent than THC; (2) β-caryophyllene, which acts as an antiinflammatory; and (3) cannabigerol, a nonpsychoactive substance that may be useful for the treatment of glaucoma.

TABLE 91.1 Main Cannabinoid Substances Extracted From Cannabis or Synthetic Compounds

Δ^9-Tetrahydrocannabinol	Sativex (THC + CBD)
Cannabidiol	Canasol
Cannabinol	Nabilone (Cesamet)
β-Caryophyllene	Dronabinol (Marinol)
Cannabigerol	Rimonabant

Nabilone and dronabinol are synthetic CB_1 receptor agonists that have similar characteristics to THC, and their effects on the sleep-wake cycle have been evaluated and will be the subjects of this section.

The studies that evaluated the effects of nabilone on the sleep-wake cycle used volunteers with medical conditions; furthermore, data related to sleep are commonly secondary. The conditions studied were pain, fibromyalgia disorder, and posttraumatic stress (Gates et al., 2014).

At doses ranging from 0.25 to 6 mg daily, two studies observed no changes in sleep patterns in patients with pain (Beaulieu, 2006; Frank, Serpell, Hughes, Matthews, & Kapur, 2008). Moreover, Toth et al. (2012) demonstrated an improved overall quality of sleep, and Bestard and Toth (2011) reported a decrease in pain interference and in sleep disturbances in the sleep-wake cycle.

In a study that evaluated patients with comorbid posttraumatic stress disorder, 72% of patients reported decreased nightmares (Fraser, 2009). In another study that evaluated patients with fibromyalgia and chronic insomnia, the use of 0.5–1 mg of nabilone was associated with decreased insomnia severity and decreased difficulty awakening during sleep, with no effect on the number of awakenings and sleep latency (Ware et al., 2010).

Regarding dronabinol, only four studies have assessed the sleep-wake cycle as secondary outcomes. Haney et al. (2007) observed no effect on objective sleep time. Conversely, Bedi et al. (2010) observed an increase in sleep efficiency during the first week due to the increased time of the S1–S4 stages and decreased time awake. Subjective measures such as sleep satisfaction, "slept well" and "awoke less often" were also improved. These studies were conducted in a small sample, and all participants were HIV positive.

In another sample of patients suffering pain, Narang et al. (2008) observed a decrease in disorders and sleep-related problems; specifically, there was a decrease in the pain interference of sleep at doses between 5 and 60 mg/day. Finally, a study that evaluated patients with amyotrophic lateral sclerosis observed no effect on insomnia symptoms at a dose of 10 mg/day.

Other components or combinations of cannabinoid substances have also been tested, mostly as secondary outcomes and in samples with clinical comorbidities. This fact hampers a specific and detailed assessment of the effects of cannabinoids on the sleep-wake cycle (Fig. 91.2).

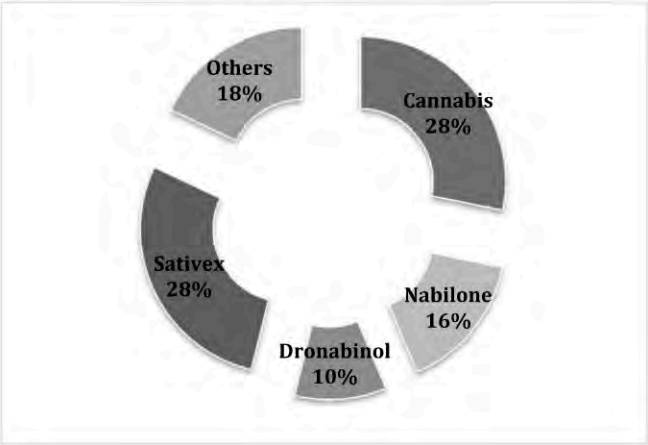

FIGURE 91.2 Percentage distribution of articles relating to the effects of cannabis-based medicine administration on sleep in human protocols. Each point represents the percentage of publications related to *Cannabis sativa* in 5-year periods between 1995 and 2010. *Source: The data were obtained from a search performed on the ISI Web of Science online database using the keywords* cannabis, cannabinoids, marihuana, *and* marijuana. *Adapted from figure published in Zuardi, A. W., Crippa, J. A., & Hallak, J. E. (2010).* Cannabis sativa*: the plant that can induce unwanted effects and also treat them.* Revista Brasileira de Psiquiatria, 32*(Suppl. 1), S1–S2.*

CONCLUSIONS

It can be concluded that there is a link between the endocannabinoid system and the sleep-wake cycle. However, not enough studies have been conducted to properly explore the effects of each cannabinoid compound, and more studies are necessary.

MINI-DICTIONARY

REM Rapid eye movement sleep. Characterized by the active brain waves, flitting motions of the eyes, and weakness of the muscles.

S1 phase A stage of nonrapid eye movement (NREM) sleep occurring after wake. Its criteria consist of a low-voltage EEG with slowing to theta frequencies, alpha activity less than 50%.

S2 phase A stage of NREM sleep characterized by sleep spindles and K complexes against a relatively low-voltage, mixed-frequency EEG background.

Sleep-wake cycle Biological pattern of alternating sleep and wakefulness.

SWS It is represented by slower brain waves called delta activity on EEG. It is a type of NREM sleep: stages 3 and 4.

Cannabinoid-Based Medicines for the Treatment of Gilles de la Tourette Syndrome

A.S. Kanaan[*,**], *K.R. Müller-Vahl*[*]

*Clinic of Psychiatry, Social-Psychiatry and Psychotherapy, Hannover Medical School, Hannover, Germany

**Nuclear Magnetic Resonance Unit, Max Planck Institute for Human Cognitive and Brain Sciences, Leipzig, Germany

SUMMARY POINTS

- Gilles de la Tourette syndrome (GTS) is a childhood-onset neuropsychiatric movement disorder characterized by motor and vocal tics.
- There is an urgent need in identifying new treatment therapeutic strategies as current forms of treatment are unsatisfactory.
- A substantial number of patients with GTS and other chronic tic disorders use cannabis illegally to reduce their symptoms.
- To date, a limited number of controlled trials have been conducted to explore the utility of cannabinoid based medicines (CBMs) in GTS.
- These studies suggested that cannabinoids, such as Δ^9-tetrahydrocannabinol (THC), are effective and safe in the treatment of tics.
- There is some evidence that CBMs may ameliorate tics, as well as psychiatric comorbidities that include attention deficit/hyperactivity disorder (ADHD), obsessive compulsive disorder (OCD), impulsivity, depression, anxiety, and self-injurious behavior.
- According to European and North American guidelines for the treatment of tics, CBMs should be taken into consideration for the treatment of adult patients with GTS that cannot be treated by standard means.
- Clinical trials with larger sample sizes are necessary to further investigate the effects of cannabinoids in this group of patients.

KEY FACTS OF GILLES DE LA TOURETTE SYNDROME

- GTS is a childhood-onset, neuropsychiatric movement disorder characterized by motor and vocal tics.
- The majority of patients also present with psychiatric comorbidities that most commonly include attention deficit/hyperactivity disorder (ADHD) and obsessive compulsive disorder (OCD).
- Different treatment strategies are currently being used to manage GTS symptoms, including behavioral therapy, pharmacological therapy, deep brain stimulation, and alternative medicine.
- In many cases, treatment options are unsatisfactory due to inefficacy or serious adverse effects.
- Currently, there is no accepted pathophysiological model of GTS; though the relevance of the dopaminergic system and cortico-striato-thalamo-cortical (CSTC) circuitry have been consistently highlighted in the literature.

KEY FACTS OF CANNABINOID USE IN GILLES DE LA TOURETTE SYNDROME

- Today, many patients with GTS use cannabis as a kind of a self-medication to reduce their tics and improve psychiatric comorbidities.
- A limited number of case reports and small-scale clinical trials have suggested that cannabinoids such as Δ^9-tetrahydrocannabinol (THC) are effective in the treatment of tics without causing significant adverse effects.
- As a result, it has been speculated that the endogenous cannabinoid system is involved in the pathogenesis of GTS.
- According to various national and international treatment guidelines, cannabinoids should be taken into consideration for the treatment of GTS in adult and otherwise treatment resistant patients.
- Large-scale clinical trials using cannabinoids and other agents that stimulate the endogenous cannabinoid system are needed to corroborate the efficacy of these substances in patients with GTS.

LIST OF ABBREVIATIONS

ADHD	Attention deficit/hyperactivity disorder
ANOVA	analysis of variance
CAMs	complementary and alternative medicines
CB1	Cannabinoid receptor type 1
CB2	Cannabinoid receptor type 2
CBD	Cannabidiol
CBMs	Cannabinoid based medicines
CSTC	Cortico-striato-thalamo-cortical circuitry
FAAH	Fatty acid amide hydrolase
GABA	gamma-aminobutyric acid
GTS	Gilles de la Tourette syndrome
GTS-CGI	Tourette's syndrome clinical global impression scale
OCB	Obsessive-compulsive behavior
OCD	obsessive compulsive disorder
SSRIs	selective serotonin-reuptake inhibitors
STSS	Shapiro Tourette-syndrome severity scale
THC	Tetrahydrocannabinol
TSGS	Tourette syndrome global scale
YGTSS	The Yale global tic severity scale

GILLES DE LA TOURETTE SYNDROME

In popular culture, Tourette syndrome is regarded frequently as a disorder in which individuals utter obscene, socially inappropriate, or derogatory statements without any volitional control. This is partly true, as only a minority of patients suffering from Tourette syndrome exhibit this involuntary swearing condition known as coprolalia. In essence, Tourette syndrome—or more appropriately named as Gilles de la Tourette syndrome (GTS)—is a complex genetic, neurodevelopmental disorder that exhibits a varied symptomatology that spans the fields of psychiatry and neurology. GTS is not rare as current estimates have yielded prevalence rates of approximately 0.7–1% of the general population, thus rendering it as one of the most common movement disorders (Knight et al., 2012).

The cardinal features of GTS are the presence of motor and vocal tics, which are defined as rapid, nonrhythmic involuntary movements that are misplaced in context or time (Jankovic, 1997). While most patients report that their tics are temporarily suppressible, tics are often preceded by unpleasant sensory sensations (premonitory urges) which are usually relieved by the tic.

In the clinical setting, GTS is diagnosed if an individual exhibits: (1) multiple motor tics and one or more vocal tics; (2) a waxing and waning course of tic intensity, frequency, and severity; (3) the persistence of tics for at least 1 year following first onset; (4) tic onset before the age of 18; and (5) tics that are not caused by another medical condition or substance (DSM-5, 307.23, ICD-10 F95.2). The typical age of onset of tics is between 6 and 8 years of age, where peak severity is usually reached between ages 10 and 14. While the majority of patients exhibit significant improvements over the course of their adolescent period, a small number of patients do not improve and in most of these cases, the patients take on a negative course of illness in which other comorbid psychiatric conditions surface. In fact, more than 80% of patients with GTS exhibit the presence of comorbid conditions that most commonly include attention deficit/hyperactivity disorder (ADHD) (~50%) and obsessive compulsive behavior (OCB) (40–80%), in addition to self-injurious behavior, depression, anxiety, impulsivity, rage attacks, sleep problems, and learning disorders (Robertson, 2000). Such associated conditions often impair patients' qualify of life more than tics and are usually the main reason why patients seek treatment.

Etiology and Pathophysiology of GTS

Most of the available evidence points to the hypothesis that GTS is a complex genetic disorder that is likely caused by the effect of multiple genetic susceptibility factors (Caspi & Moffitt, 2006; Paschou, 2013). This nonclassical Mendelian pattern of inheritance tied to increasing evidence that environmental factors play a role in the onset and natural course of the disorder, deem its study very difficult.

Pathophysiologically, the abnormality that has been most consistently highlighted in the literature is tied to

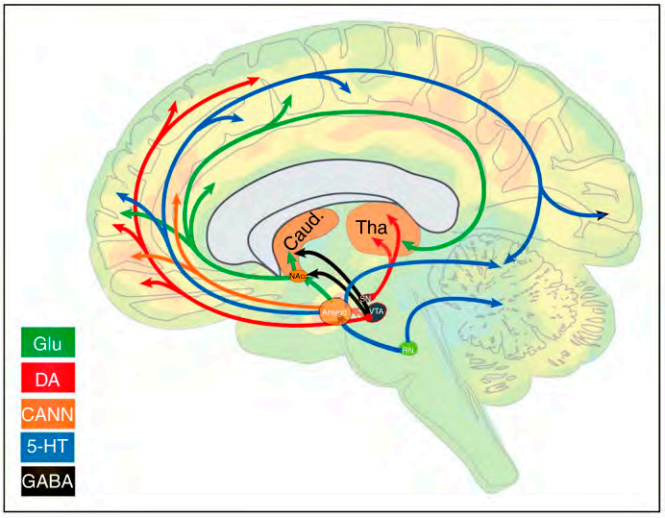

FIGURE 92.1 Schematic illustrating the extent of interaction between the endocannabinoid system and neurotransmitter pathways reported and hypothesized to be involved in Gilles de la Tourette syndrome pathophysiology. The translucent heatmap in the background illustrates the distribution of CB1 receptors. Regions with a high distribution of CB1 receptors *(red/orange)* include the caudate, thalamus, amygdala, prefrontal cortex, and parietal cortex. *Glu*, Glutamatergic; *5-Ht*, seretonergic; *DA*, dopaminergic; *GABA*, gamma-aminobutyric acid; *CANN*, endocannabinoid system. *Source: The figure was adapted based on information from Schumann et al. (2010) and Terry et al. (2010).*

imbalances in the dopaminergic (DA) system within key regions of the cortico-striato-thalamo-cortical (CSTC) circuitry. Nonetheless, given the heterogeneity of clinical phenotypes exhibited by patients with GTS, it is highly likely that more than one neurotransmitter system is affected as the glutamatergic, GABAergic, histaminergic, and cannabinoid receptor systems exhibit various interactions with the dopaminergic system to play a role in the normal mechanics of the CSTC circuitry (Fig. 92.1).

TREATMENT STRATEGIES

Currently, there are different therapeutic strategies that are being used to manage the symptomatology of GTS including: (1) behavioral therapy, (2) pharmacological therapy, (3) deep brain stimulation (DBS), and (4) alternative medicine. The presence of comorbid conditions usually complicates treatment as there are no known treatments to be effective for both tics and associated disorders.

In patients that exhibit tics that interfere with normal functioning, behavioral strategies (eg, habit reversal training or exposure and response prevention training) and pharmacological agents are usually recommended as the first line of treatment (Roessner et al., 2011; Verdellen, Van de Griendt, Hartmann, Murphy, & ESSTS Guidelines Group, 2011). Although a variety of psychotropic drugs have been used to treat tics, only haloperidol and (in some countries) pimozide have been officially licensed for GTS. Nonetheless, due to the severe associated side effects that include sedation, cognitive dulling, dyskinesias and weight gain, haloperidol and pimozide are no longer recommended as first line treatment. Instead newer antipsychotics such as aripiprazole, risperidone as well as tiapride and sulpiride are recommended, although they are also often associated with significant adverse effects (Roessner et al., 2011).

For the treatment of associated obsessive-compulsive disorder (OCD), either behavioral therapy and/or selective serotonin-reuptake inhibitors (SSRIs) are recommended. Psychostimulants such as methylphenidate are the treatment of choice in patients suffering from comorbid ADHD. Treatment of other comorbidities such as depression and anxiety disorders does not differ from recommendations given in patients exhibiting these disorders without GTS. In patients with severe and complex symptoms, combined treatment with several drugs is often inevitable.

Alternative Forms of Treatments

Given the wide range of symptoms and associated conditions that GTS patients might exhibit, many patients are unsatisfied with their treatment strategy. This is possibly due to (1) the low efficacy of the used strategy, (2) complete resistance to treatment, or (3) the emergence of significant adverse effects. Therefore, many patients deem it fit to explore other forms of treatment that have yet to be established scientifically. In fact, two published studies have revealed that an alarming number of GTS patients (64 and 87%, respectively) use at least one other form of complementary or alternative medicine (CAMs) (Kompoliti, Fan, & Leurgans, 2009; Mantel, Meyers, Tran, Rogers, & Jacobson, 2004). For treating physicians, it is important to realize that up 80% of these patients do not inform their doctor that they are pursuing the treatment. Additionally, it is well known that some patients revert to legal and illegal substances such as nicotine, alcohol, and marijuana in bid to assuage their symptoms (Müller-Vahl, Kolbe, & Dengler, 1997b; Müller-Vahl, Kolbe, & Dengler, 1997a).

A RATIONALE FOR THE TREATMENT OF GTS WITH CANNABINOIDS

Despite the fact that the range of treatments for patients with GTS has expanded over the last decade, there remains a need in identifying new substances that might be more effective. With the determination of the chemical structure of the principal psychoactive constituent of the cannabis plant, Δ^9-tetrahydrocannabinol (THC), a new era of cannabinoid based medicines (CBMs) was ushered (Tables 92.1 and 92.2). This discovery was followed by the

TABLE 92.1 Dosage of Cannabinoids in the Treatment of Gilles de la Tourette Syndrome

Substance	Start dose	Increase	Number of doses per day	Usual therapeutic dosages	Maximum dose
THC/dronabinol	2.5 mg	2.5 mg every 3–5 days	Individually	10–20 mg/day	30 mg/day (higher if tolerated and necessary)
Nabiximols	1 spray dose	1 spray dose every 3–5 days	Individually	6–10 spray doses/day	12 spray doses/day (maximum licensed daily dosage)

delineation of the endocannabinoid system in the brain, which is a set of endogenous neuromodulatory ligands (eg, anandamide, 2-AG) and their receptors (eg, CB1, CB2) that are understood to have a functional role in movement and behavior. Various studies have demonstrated that (1) endocannabinoid ligands and their receptors are significantly more abundant in basal ganglia nuclei compared to other brain regions (Fig. 92.1) (Herkenham et al., 1990); (2) the endo cannabinoid system plays a major role in the mechanics of the CSTC circuits, both in health and disease; and (3) the manipulation of the endo cannabinoid system is associated with important motor and behavioral responses (Fernandez-Ruiz, 2009).

TREATMENT WITH *CANNABIS SATIVA* L.

Case Reports

There are only two case studies available reporting on the effects of cannabis in patients with GTS. Sandyk and Awerbuch (1988) explored the effect of cannabis on three patients: (1) a 15-year-old male with a tendency for self-injurious behavior exhibited a 50% reduction in motor tics, a reduction in premonitory urge sensations, improvement in self-injurious behavior tendencies, and a generalized feeling of relaxation; (2) a 17-year-old male with severe motor and vocal tics exhibited a 60–70% tic

reduction, and improvement of attention when smoking cannabis; and (3) a 39-year-old male exhibited a reduction of motor tics and hypersexual behavior. In the second report, Hemming and Yellowlees (1993) explored the effects of cannabis on a retired 36-year-old patient with motor and vocal tics that included coprolalia. By taking a constant dose of marijuana via a water pipe, the authors report that the patient was "completely symptom free."

Prospective Surveys

A few years later, Müller-Vahl et al. (1997b) conducted a survey using a standardized questionnaire to further explore the frequency and effect of marijuana use with afflicted patients. 64 patients (55 males and 9 females, mean age 30.3 years, range 15–64 years) were interviewed about marijuana use. Unsurprisingly, 27% of this group reported the use of marijuana with 82% reporting that they felt marijuana improved their symptoms. More specifically, of the 17 patients that reported marijuana use, 9 patients reported moderate or marked reduction of tics, 4 patients felt a complete remission of motor and vocal tics, 4 patients felt an amelioration of premonitory urges, 1 patient reported a remission of their OCB symptoms, and 1 reported improvement of his ADHD symptoms.

Controlled Trials

A very small number of open and controlled studies investigating the effects of CBMs in GTS are available. In all these studies, however, only pure THC has been used. Just recently, a pilot study has been initiated at Yale University investigating the effect of a fatty acid amide hydrolase (FAAH) inhibitor in patients with GTS (personal communication). Additionally, a multicenter clinical trial in Germany has just been granted funding to investigate efficacy and safety of the cannabis extract nabiximols, a plant extract from *C. sativa* L. containing THC and cannabidiol (CBD) at a 1:1 ratio.

TREATMENT WITH THC

Uncontrolled Single Case Studies

There are a few case studies that have explored the effects of THC on the symptomatology of GTS. The first was published by our group showing that a single dose of orally ingested THC drastically improved the symptomatology of a 25-year-old patient with tic onset at age 6 (Müller-Vahl et al., 1999). In this case, the patient suffered from a number of comorbidities that included ADHD, OCB, anxiety disorder, impulsivity, and self-injurious behavior. The patient reported that by smoking 2–3 g of marijuana a day, his tics and associated behavioral conditions markedly improved. This narrative was addressed clinically using established methods after a single 10 mg dose of THC following 3 days of cessation from all forms of treatment. The patient reported improvements in attention, impulse control, OCB, and reductions in premonitory urges. On the Tourette Syndrome global scale (TSGS) (Harcherik, Leckman, Detlor, & Cohen, 1984), the patient's total tic severity score improved by 80%, while neuropsychological tests revealed improvements in signal detection, sustained attention, and reaction time. No adverse effects were encountered in the patient.

In another study, we highlighted the utility of THC in combination with other pharmacological agents for the treatment of a 24-year-old female. The patient's symptoms had been markedly deteriorating culminating in extreme vocal tics at the age of 23. At this point, risperidone, amisulpride, and THC were administered alone or in different combinations leading to the conclusion that the combination of amisulpride and THC is more effective in tic reduction than monotherapy with THC or amisulpride. The authors suggested that THC may augment the positive effects of dopamine receptor blocking drugs such as amisulpride. This hypothesis is in line with findings in animal studies that demonstrated that haloperidol-induced hypokinesia significantly increases after coadministration with THC (Moss, Montgomery, Salo, & Steger, 1984).

More recently, Brunnauer et al. (2011) described various unsuccessful attempts in treating a 42-year-old patient who suffered from multiple motor and vocal tics (including coprolalia) and ruminating obsessive thoughts using different pharmacological agents. Treatment with a 15 mg daily maximal dose of THC resulted in a 75% tic reduction. Given his occupation as a truck driver, his driving ability was investigated using computerized tests that satisfy the German guidelines for road and traffic safety. Interestingly, the patient's concentration and visual abilities where more pronounced in the on-medication state (with THC) than the off-medication state, thus leading the authors to suggest that treatment with cannabinoids may have a beneficial effect on psychomotor functions related to driving performance. Along the same line, another group reported that treatment with cannabinoids had "atypical and even performance-enhancing effects" on a patient with pure ADHD (Strohbeck-Kuhner, Skopp, & Mattern, 2007).

To the best of our knowledge, there is only a single case report in a minor describing the positive effects of THC on the symptomatology of a treatment resistant 15-year-old adolescent with GTS (Hasan et al., 2010). This study echoed previous studies that concluded an

enhanced effect in tic reduction with di-therapeutic strategy using an antipsychotic agent and THC. The patient's symptoms included severe motor and vocal tics including self-injurious behavior, ADHD, and OCB. Treatment with a maximal daily dose of 15 mg of THC was attempted—after the patient reported that his tics and inner tensions were drastically reduced after smoking marijuana—and resulted in a significant improvement of tics (50%) and quality of life. More interestingly, this was the first report indicating that a daily dose of 30 mg of methylphenidate was tolerated without exacerbating his tics. Combining the clinical evidence with the results of a transcranial magnetic stimulation experiment—which demonstrated increased intracortical inhibition in the on-THC state—suggested that THC might counteract deficits of intracortical inhibition in patients with GTS and comorbid ADHD by modulating the release of several neurotransmitters including dopamine and F-aminobutyric acid.

Randomized Controlled Trials

Currently, only two preliminary controlled trials have been conducted to investigate the efficacy and safety of orally administered THC on patients with GTS. In the first study, a randomized double-blind placebo controlled crossover trial was conducted on 12 adult patients who were treated with a single dose of 5, 7.5, or 10 mg of THC (Müller-Vahl et al., 2002). The choice of dosage used was dependent on the patients' weight, gender and prior use of marijuana. Eleven men and one woman participated in the study (mean age = 34 ± 11 years) and were randomly assigned to a THC treatment group or a placebo group, which were then interchanged following a 4 week washout period. The patients in the THC group exhibited a significant improvement when compared to the placebo group using the Tourette Syndrome Symptom List (TSSL) (Leckman, Towbin, Ort, & Cohen, 1988) and the TSGS scales. Results also suggested that higher doses were more effective in improving the symptoms of patients in the THC group. Overall, 83% of patients in the THC group experienced a global improvement, compared to only 25% of patients in the placebo group. There were no detrimental effects detected on short-term verbal and visual memory, recognition, verbal learning, intelligence, information processing, vigilance, reaction time, sustained attention, and divided attention. Nevertheless, it must be noted that five patients in the THC group experienced transient and mild adverse effects (headache, nausea, dizziness, hot flashes, fatigue, concentration difficulties, dry mouth, ataxia) that did not require specific treatments. In clinical practice, treatment with THC is usually up-titrated from 2.5 to 5 mg/day with an incremental increase in dosage until effective values are reached. In this case, the patients might have experienced these side effects since dosages were not up-titrated.

In a second and more elaborate study, a randomized double-blind parallel group procedure was used to investigate the efficacy of THC on 24 adult patients with GTS (19 men, 5 women, mean age = 33 + 11 (SD) years, range, 18–68 years) (Müller-Vahl et al., 2003b). In this study, patients commenced treatment using a daily dose of 2.5 mg which was incrementally increased to a maximum daily dose of 10 mg, unless the dosage was not tolerated. The study consisted of six visits (visit 1 = baseline, visits 2–4 = treatment, visits 5 = immediately after treatment, visit 6 = follow-up 6 weeks after withdrawal) to assess the progress of each patient's treatment. Overall, results demonstrated the efficacy of THC treatment, which was far superior to the placebo (Figs. 92.2–92.4). Specifically, the Tourette's syndrome clinical global impression scale (GTS-CGI) (Leckman et al., 1988) scale revealed a significant difference between the two groups on the third visit (20–22 treatment days). On fourth visit (30–31 treatment days), the significant difference was observed via several rating scales that included the: (1) GTS-CGI; (2) Shapiro Tourette syndrome severity scale (STSS) (Shapiro, 1988); (3) The Yale global tic severity scale (YGTSS) for the subscore "motor global scale" (Leckman et al., 1989); and (4) Rush videotape-based rating scale (Goetz et al., 1999). Moreover, analysis of variance (ANOVA) demonstrated a trend toward an overall significant difference. The TSSL demonstrated a significant difference between the placebo and THC group on 10 different treatment days (between day 16 and 41). Using ANOVA there was an overall significant difference between the two groups. Seven patients dropped out of the study or had to be excluded but only one due to adverse effects. Five patients in the THC group reported mild adverse effects (tiredness, dry mouth, dizziness, and muzziness) and three patients in the placebo group (tiredness, dizziness, anxiety, and depression). One patient in the THC group stopped medication at day 4 (first day at dose 5 mg) due to adverse effects (anxiety, restlessness). All adverse events resolved spontaneously without specific treatment. No serious adverse events occurred.

In parallel, neuropsychological performance and cognitive function were investigated before, during and after the 6-week treatment period with THC using the following tests: (1) German version of the auditory verbal learning test (VLMT) (Helmstaedter, Lendt, & Lux, 2001), (2) Benton-visual-retention-test (BVRT) (Benton, 1945), (3) Divided attention (TAP) (Zimmermann & Fimm, 1989), and (4) multiple choice vocabulary test (Mehrfachwahl-Wortschatztest, MWT-B) (Merz, Lehrl, Galster, & Erzigkeit, 1975). There were no detrimental effects of THC seen on any of these measurements including learning curve, interference, recall and recognition of word lists, immediate visual memory

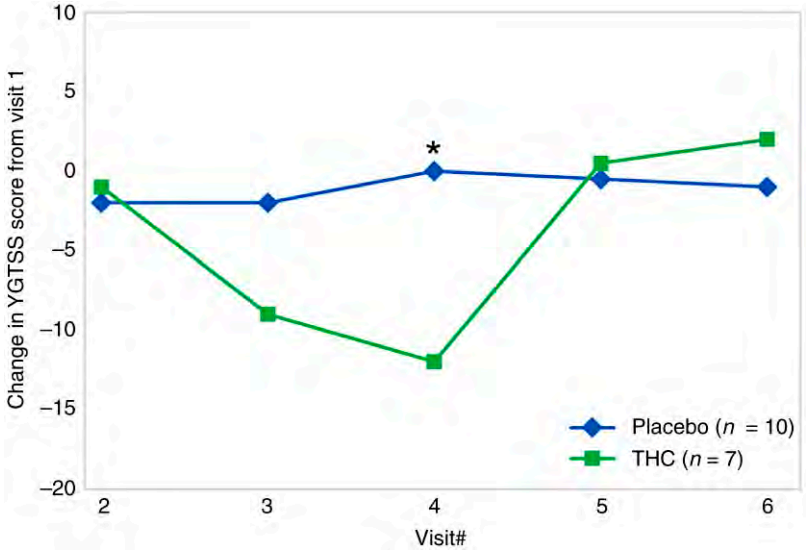

FIGURE 92.2 Changes in YGTSS from visit 1 to visits 2–6 in patients treated with THC, compared with placebo (Müller-Vahl et al., 2003b). Visit 1 = baseline, visit 2 = treatment day 9, visit 3 = treatment days 20–22, visit 4 = treatment days 30–31, visit 5 = 1 day after medication stopped, visit 6 = 5 weeks after medication stopped. ANOVA: $p = 0.077$. *$p < 0.10$. *THC*, Tetrahydrocannabinol; *YGTSS*, Yale Global Tic Severity Scale.

span, and divided attention. Measuring immediate verbal memory span, there was a trend toward a significant improvement during and after treatment. Furthermore, no significant influence on OCB, anxiety, depression and "the current emotional state" was found (Müller-Vahl et al., 2003a).

ADVERSE EFFECTS

From our clinical experience and currently published data, we speculate that the psychological and physiological adverse effects encountered by patients with GTS following CBM use are similar to those encountered by other patient groups. There is limited evidence to support any major side effects or negative effects on neuropsychological performance (Müller-Vahl et al., 2001, 2003a). Some work has suggested that in GTS treatment with THC may improve patient's concentration, visual abilities, and psychomotor functions related to driving performance (Brunnauer et al., 2011). However, since it is known that adolescent-onset heavy cannabis use may cause persistent cognitive decline in healthy cannabis users (Meier et al., 2012), it is of seminal importance to carefully consider treating any adolescent patients with CBMs. Nevertheless, these effects need to be further investigated in patients with GTS, since it is not clear whether the same conclusions can be drawn in a population that exhibits putative malfunctions in the dopaminergic, serotonergic, endocannabinoid, and glutamatergic systems. In our view, treatment resistant minors with significant impairment in quality of life, CBMs should be taken into consideration before reverting to DBS as last resort.

PRACTICAL ASPECTS FOR TREATMENT

Despite the limited number of available studies and the lack of well-powered longitudinal studies on the effects of CBMs, cannabinoids have been used by a substantial number of patients—either as a kind of a self-medication or prescribed by the treating clinician—leading to their recommendation as a form of treatment by the European and Canadian Societies for the study of Tourette syndrome (Pringsheim et al., 2012; Roessner et al., 2011). According to these guidelines, CBMs are recommended for the treatment of patients with GTS in cases where the first-line of treatments fail to improve the patient's symptomatology or if the patient exhibits complete resistance to all forms of standard treatments. Different countries have different laws with respect to the use of cannabinoids for the treatment of disorders. For example, synthetic preparations of THC such as dronabinol or nabilone or cannabis extracts such as nabiximols, can be prescribed in several countries. Additionally, some national authorities allow the use of herbal cannabis in medically supervised treatment regimens.

Extrapolating information from the published literature, the recommended strategy for dealing with patients who are either treatment resistant or exhibit marked adverse effects to first-line treatments is to use

an up-titration procedure with slow and incremental increase from 2.5 mg THC per day to a dose between 10 and 20 mg/day while gauging the efficacy and tolerability of the cannabinoid agent at each step. In some patients, however, much higher doses are needed for symptom control. Depending on the route of intake, the individual duration of effect, and patients' desire for treatment, CBMs should be used once or several times daily.

From our experience, most clinical effects caused by *C. sativa* L. seem to be related to THC. Therefore, one might expect similar effects after treatment of GTS patients with *C. sativa* L. extracts (eg, nabiximols) and pure THC. However, our experience is that patients experience stronger and less adverse effects when using marijuana compared to pure THC. This clinical experience is in accordance with reports from other groups of patients (Hazekamp, Ware, Müller-Vahl, Abrams, & Grotenhermen, 2013). We also note that some patients prefer a combined treatment with longer acting orally taken pure THC and immediate but shorter acting inhaled cannabis.

Longer trials including a larger number of patients are urgently needed to further investigate efficacy and safety of CBMs in GTS. As in other groups of patients, it would be of interest to compare the effect of pure THC to drugs containing different cannabinoids. Finally, it can be speculated that substances that bind more selectively to CB1 receptors or inhibit the uptake or the degradation of endogenous cannabinoids might be even more effective and better tolerated than currently available substances.

CONCLUSIONS

Available data from a limited number of case reports and small-scale controlled clinical trials have provided evidence that cannabinoid based medicine do have a beneficial effect on the treatment of tics in patients with GTS. There is also some evidence that cannabinoids help improve conditions associated with GTS including OCB, ADHD, impulsivity, depression, and self-injurious behavior.

Neuropsychological tests demonstrate that THC has no detrimental effects on memory, reaction time, concentration, and attention in patients with GTS. Interestingly, evidence points to improvements in memory, concentration, and visual perception. It can be assumed that beneficial effects of CBMs in GTS are caused by modulations of the CB1 receptor system, rather than unspecific effects such as sedation or decreased general activity. There is some evidence that THC might augment the anti-tic effect of antipsychotics. Although larger-scale clinical trials are urgently needed to further investigate the effect of cannabinoids in the treatment of GTS, available evidence encourages the consideration of CBMs as a form of pharmacological treatment when other substances fail to improve motor or nonmotor symptoms of GTS.

MINI-DICTIONARY

Attention deficit/hyperactivity disorder (ADHD) A common neurodevelopmental psychiatric disorder characterized by inattention, hyperactivity, and impulsivity.

Cannabinoid based medicines (CBMs) A medical therapy consisting of cannabis or its derivatives that is used to treat disease or alleviate symptoms.

Cortico-striato-thalamo-cortical circuitry (CSTC) A set of parallel and segregated cortico-subcortical loops that play a role in the integration of information related to emotional, cognitive, and motor functions.

Fatty acid amide hydrolase (FAAH) An enzyme that serves as the major metabolic regulator of many of the endogenous fatty acid amides.

Gilles de la Tourette syndrome (GTS) A hereditary, childhood-onset and neuropsychiatric movement disorder that is characterized by multiple motor tics and one or more vocal tics.

Obsessive-compulsive behavior (OCB) This term is used, when a person suffers from obsessions (intrusive thoughts) and/or compulsions (repetitive behaviors), but does not fulfill diagnostic criteria for the diagnosis of obsessive-compulsive disorder (OCD) according to DSM-5.

Tetrahydrocannabinol (THC) The principal psychoactive constituent of the cannabis plant.

Yale global tic severity scale (YGTSS) A clinical rating instrument used for the assessment of patients with Tourette's syndrome and other tic disorders. The YGTSS provides an evaluation of the number, frequency, intensity, complexity, and interference of motor and vocal symptoms.

Cannabidiol and Multiple Sclerosis

M. Mecha, A. Feliú, F.J. Carrillo-Salinas, C. Guaza

Neurobiology and Functional Systems Department, Cajal Institute, CSIC, Madrid, Spain

SUMMARY POINTS

- Multiple sclerosis (MS) is the most frequent chronic neurological disease among young and middle-aged people in the northern industrialized countries.
- MS is pathologically characterized by multifocal inflammation, demyelination and neuronal injury in the central nervous system (CNS).
- The first-line disease modifying therapies for MS patients include immunomodulatory and immunosuppressive medications.
- Cannabidiol (CBD), which constitutes up to 40% of *Cannabis sativa* extract, may represent a promising agent for human therapeutic use due to the lack of psychoactive actions.
- Up to date, there is no evidence about the full binding of CBD to any known receptor site, and the molecular pharmacology of CBD has not been well defined.
- Experimental autoimmune encephalomyelitis (EAE) and Theiler's murine encephalomyelitis virus-induced demyelinating disease (TMEV-IDD) are two experimental models of MS that include classical MS hallmarks like inflammation, neuronal damage, and demyelination.
- CBD has been shown to ameliorate EAE and TMEV-IDD model symptomatology by diminishing inflammation, microglial activity, and leukocyte homing.
- Sativex is used for the treatment of symptoms of MS, particularly spasticity and neuropathic pain.

KEY FACTS OF NEUROLOGY

- Multiple sclerosis is a complex heterogeneous demyelinating autoimmune disease that primarily affects the myelin in the central nervous system (CNS).
- CNS demyelination, the pathological process in which myelin sheaths are lost, is the consequence of a direct insult targeted at the oligodendrocyte.
- Axonal degeneration is accepted as the major cause of irreversible neurological disability in multiple sclerosis (MS) patients.
- Autoantigen-specific Th17 and Th1, B cells and monocytes/macrophages have major pathological roles.
- Pharmacological treatment options approved for MS aim at limiting inflammation and decreasing relapse rate, but, no current therapies can cure the disease.

KEY FACTS OF CNS REPAIR

- Remyelination is the process in which myelin sheaths are restored to demyelinated axons restoring functional deficits.
- Remyelination involves the generation of new mature oligodendrocytes from oligodendrocyte progenitors.
- A key function of remyelination in multiple sclerosis is axon survival.
- The efficiency of remyelination is affected by age, sex, and genetic background regardless of the disease process.
- The most significant approach to enhance remyelination is to target the endogenous regenerative process.

KEY FACTS ON THE CANNABINOID SYSTEM

- The cannabinoid system is a regulatory system identified following the study of *Cannabis sativa* derivatives involved in the homeostasis control.
- The endocannabinoid signaling system is composed of cannabinoid receptors, their endogenous ligands and the enzymes that produce and inactivate these ligands.
- There are >60 cannabinoid compounds present in extracts of *C. sativa*, and Δ^9-tetrahydrocannabinol (Δ^9-THC) is responsible for the psychoactive effects of cannabis, and for many of the potential medicinal effects.
- The nonpsychoactive cannabidiol (CBD)is the other cannabinoid derived from *C. sativa* of current medical interest in MS.
- Sativex is an oromucosal spray, constituted by an equimolecular combination of Δ^9-THC and CBD-enriched botanical extracts approved for the treatment of spasticity and pain associated to MS.

LIST OF ABBREVIATIONS

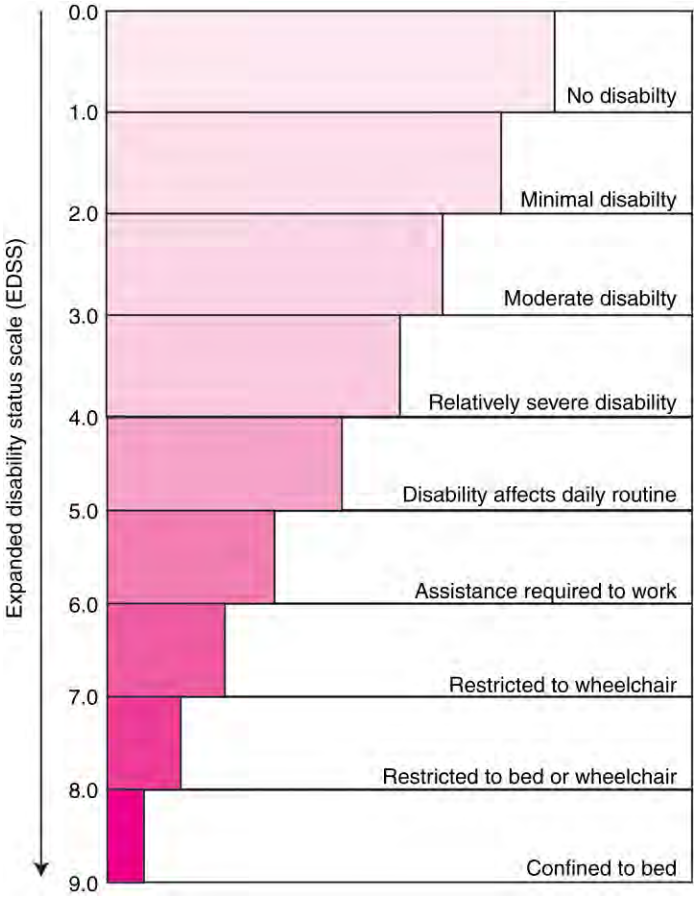
AD	Alzheimer disease
CBD	Cannabidiol
CNS	Central nervous system
EAE	Experimental autoimmune encephalomyelitis
EDSS	Expanded disability status scale
FAAH	Fatty acid amide hydrolase
GPCR	G-protein coupled receptor
IFN-β	Interferon-beta
MCA	Middle-cerebral-artery
MHC	Major histocompatibility complex
MRI	Magnetic resonance image
MS	Multiple sclerosis
PPAR	Peroxisome proliferator activated receptors
PPMS	Primary progressive multiple sclerosis
RRMS	Remittent recurrent multiple sclerosis
SPMS	Secondary progressive multiple sclerosis
THC	Tetrahydrocannabinol
TMEV-IDD	Theiler´s murine encephalomyelitis virus - induced demyelinating disease
TPVR-1	Transient potential vanilloid receptor-1

INTRODUCTION

Multiple sclerosis (MS) is the most frequent chronic neurological disease among young adults in the northern industrialized countries. MS is pathologically characterized by multifocal inflammation, demyelination, and neuronal injury in the optic nerves, brain and spinal cord, and is considered to be an autoimmune disease with a complex pathophysiology (Compston & Coles, 2002). The pathological hallmarks of the disease result in an affectation of white matter tracts and injury to the cortical and deep gray matter, generating neurologic symptoms and disability in patients with MS (Table 93.1).

MS occurs in a female–male ratio of 3 to 1, and has an estimated prevalence of more than 2.1 million people worldwide (Niedziela, Adamczyk-Sowa, & Pierzchala, 2014). It is widely accepted that MS cause is multifactorial, including multiple genetic and environmental risk factors like risk alleles in genes for major histocompatibility complex (MHC), and interleukin-2 and 7 receptors among others (Beecham et al., 2013). Moreover, the geographic location of residence before adolescence may also be predictive of MS risk, as it has been found

TABLE 93.1 Expanded Disability Status Scale (EDSS) in Patients With MS



The Kurtzke's EDSS scores 8 functional systems and the person's ability to walk. From 0.0 to 4.0, people are able to walk without assistance. From 4.0 to 7.5, people can walk but with assistance. Mainly, point 6 on the scale represents walking with a cane, and this point is often used as an endpoint of the progression of disability. From 7.5 to 10, the main determinant of EDSS is the person's ability to transfer from wheelchair to bed and self-care. An EDSS of 10 is not included in this table because it means death of the patient due to MS.

increased rates of the disease in northern and southern latitudes compared with equatorial countries, probably linked to a vitamin D deficiency (Van der Mei et al., 2003). Additionally, the risk to MS may be influenced by the exposure to particular infectious like Epstein–Barr virus (Lassmann, Niedobitek, Aloisi, & Middeldorp, 2011) and Herpesvirus 6 (Tait & Straus, 2008).

The first-line disease modifying therapies for MS patients include immunomodulatory and immunosuppressive medications like interferon-β (IFN-β) or glatiramer acetate among others (Table 93.2), which has been shown to reduce both risk of relapse and new lesion formation on MRI scans. Paradoxically, antiinflammatory treatment might contribute to the failure of repair, as results from studies of patients with MS indicate that the inflammation blockade might trigger counter-regulatory inflammatory mechanisms used to heal the injured tissue (Martino et al., 2002), and suggesting that tissue integrity is restored by the conversion of the inflammatory response from a damaging to a repairing one (Nathan, 2002).

Evidence suggest that neuroinflammation, demyelination, and neurodegeneration may occur in parallel, the combination of antiinflammatory, oligoprotective and neuroprotective strategies arise as an emerging therapy for the symptomatic and therapeutic treatment of MS. In this line, *C. sativa* derivatives have attracted special interest regarding putative therapeutic properties, despite the fact that these compounds have always raised both ethical and practical problems for their potential abuse and unavoidable psychotropic effects. Among marijuana compounds, cannabidiol (CBD), which constitutes up to 40% of cannabis extract, may represent a promising agent for human therapeutic use as it lacks any cognitive and psychoactive actions, and has an excellent tolerability profile in humans (Mechoulam & Hanus, 2002).

A large number of clinical trials have been performed to assess the clinical efficacy of CBD in different pathologies. Most of them has been focused on Sativex compounds (GW Pharmaceuticals; Salisbury, United Kingdom), a commercially available preparation containing CBD and Δ^9-THC under four different formulations that differs in the concentration of CBD and Δ^9-THC (tetrahydrocannabinol). The oromucosal spray administration of Sativex has been agreed in 2005 for the treatment of pain and spasticity in MS (Perras, 2005). In the central nervous system (CNS), CBD has been reported to act as an antiinflammatory compound, thus being useful for neuroinflammatory disorders but also as a neuroprotective agent by normalizing glutamate homeostasis, reducing oxidative stress, and attenuating glial activation and the occurrence of local inflammatory events (reviewed by Fernandez-Ruiz et al., 2013). All these properties point out CBD as a promising therapeutic agent for the treatment of neuroinflammatory disorders like MS.

CBD PHARMACOLOGY AND MECHANISMS OF ACTION

Isolated in across the 1930s and 1940s from *C. sativa*, the structure and configuration of CBD was fully elucidated by Mechoulam et al. in the 1960s (Mechoulam & Shvo, 1963; Mechoulam, Shani, Edery, & Grunfeld, 1970). The first study focusing on CBD pharmacology was published in 1981, regarding hypnotic and anticonvulsant properties (Carlini & Cunha, 1981). Along this time, several studies have been done to identify the mechanisms through which CBD exerts its actions. Up to date, there is no evidence about the full binding of CBD to any known receptor site. The molecular pharmacology of CBD has not been well defined yet, and little is known about a possible CBD-receptor-mediated signaling pathway. It is known that many of the CBD effects are associated with both central and peripheral actions, and numerous studies has been reported trying to elucidate some of its mechanisms of action (Table 93.3), that are detailed later in the chapter.

CBD is a Potent Antioxidant

Pioneer works by Hampson, Grimaldi, Axelrod, and Wink (1998) showed that CBD has antioxidant properties that have been confirmed along several publications. The plant cannabinoids, being monophenols, monophenolic esthers (like THC), or resorcinols (like CBD) are likewise potent antioxidants. Hampson et al. (1998) demonstrated that CBD exerted a potent antioxidant activity that resulted more protective than either ascorbate (vitamin C) or α-tocopherol (vitamin E) against glutamate-mediated neurotoxicity. These observations suggest that CBD may be a potential therapeutic agent for the treatment of oxidative neurological disorders like cerebral ischemia, and for diseases that course with oxidative damage.

CBD Potentiates the Endocannabinoid Signaling System

In the immature damaged brain, CBD has shown direct activity binding to the CB2 receptor, and an indirect activity through an inhibitory effect on the mechanisms of inactivation of endocannabinoids (transporter, FAAH enzyme) (Bisogno et al., 2001; De Filippis et al., 2008). In this line, the enhancement of the endocannabinoid tone may mediate some of the antiinflammatory and neuroprotective effects of CBD.

CBD Binds With Low Affinity to Both CB1 and CB2 Cannabinoid Receptors

At concentrations in the micromolar range, CBD shows weak ability to remove ^{3}[H]CP55940, a not selective ligand for CB receptors from both CB1 and

TABLE 93.2 Currently Available MS Treatments

	Treatment	Year of FDA approval	Type	Route of administration	Implications	Mechanism of action	Side effects
Acute	Methylprednisolone (Solu-Medrol)	1959	Glucocorticoid	Intravenous (3–5 days)	Acute relapse	Stabilizing the BBB, decreasing proinflammatory cytokines, and inducing T cell apoptosis	Disturbance of taste, facial flushing, insomnia, psychiatric disturbance, exacerbation of acne, transient hyperglycemia, and hypertension
	ACTH (H.P. Acthar)	1978	Hormone	Intramuscular or subcutaneous (5–15 days)	Acute relapse	Stimulates the adrenal cortex gland to secrete cortisol, corticosterone, and aldosterone	Vomiting, change in appetite, diarrhea, constipation, restlessness, difficulty sleeping, sweating
	Plasma exchange	/	/	Intravenous	Acute relapse	Exchange of immunoglobulins	Hypocalcemia, hypovolemia, and anaphylactoid reactions
Chronic	IFNβ-1a (Avon ex)	1996	Cytokine (low dose)	Intramuscular injection	RRMS first line	Suppresses the proliferation of myelin-basic protein-specific T cells. Reduces the production of proinflammatory cytokines, and induces antiinflammatory cytokines. Effects on the endothelial cells of the BBB	Production of NAb (IFNβ1A less than IFNβ1B) Influenza-like symptoms. Headache, injection site reaction, asthenia, lymphopenia, depression, hepatic injury, congestive heart failure, anaphylactic shock, and pain
	IFNβ-1a (Rebif)	2002	Cytokine (high dose)	Subcutaneous injection			
	IFNβ-1b (Betaseron)	1993	Cytokine (high dose)	Subcutaneous injection			
	Glatiramer acetate (Copaxone)	1996	Synthetic polymer of random sequences of 4 aa (L-tyr, L-glut L-Ala, L-Lys)	Subcutaneous injection	RRMS first line	Unknown, possible binding to the major MHC-II competing with the other MS putative Ag	Injection site reactions, tightness, anxiety, dyspnea, palpitation, vasodilation
	Mitoxantrone (Novantrone)	2000	Antineoplastic drug	Intravenous infusion	RRMS SPMS	Inhibit B cell, T cell, macrophage proliferation. Impair antigen presentation, and the secretion of IFN-γ, TNFα, and IL-2	Cardiotoxicity, myelogenous leukemia, gonadal dysfunction
	Natalizumab (Tysabri)	2006	Humanized anti-VLA-4 monoclonal antibody	Intravenous infusion	RRMS first line	Targets the α4-chain of α4β1 integrin decreasing the accumulation of activated leukocytes within the CNS	Headache, fatigue, arthralgia, urinary tract infection, lower respiratory infections, gastroenteritis, vaginitis, diarrhea, hypersensitivity reactions, hepatotoxicity, PML
	Dalfampridine (Ampyra)	2010	4-aminopyridine (4-AP)	Oral capsule	Chronic progressive	Potassium channel blocker, potent calcium activator	Dizziness, nervousness, nausea urinary tract infection
	Fingolimod (Gilenya)	2010	Sphingosine-1-phosphate (SIP) receptor modulator	Oral capsule	RRMS second line	SIP receptor antagonist in lymphocytes. It blocks the ability of lymphocytes to leave lymph nodes	Headache, infections, bradycardia bradyarrhythmias, macular edema
	Teriflunomide (Aubagio)	2012	Drug	Oral capsule	RRMS	Binds to DHODH protein inhibiting pyrimidine synthesis in proliferating cells such as T and B lymphocytes (immunomodulatory)	Dyspnea, diarrhea, nausea, alopecia, hepatotoxicity, acute renal failure, hypertension, leukopenia
	Dimethyl fumarate (Tecfidera, BG12)	2013	α,β-unsaturated ester	Oral capsule	RRMS first line	Reduce transendothelial migration of activated leukocytes through the BBB. Neuroprotective effects via activation of antioxidative pathways	Gastrointestinal disorders, lymphopenia, flushing, pruritus, rash, erythema

Acute and chronic treatments available for MS patients (reviewed in Damal, Stoker, & Foley, 2013; Kantarci, Pirko, & Rodriguez, 2014). PML, progressive multifocal leukoencephalopathy; ACTH, adrenocorticotropic hormone; DHODH, dihydroorotate dehydrogenase BBB, blood–brain barrier. Intravenous immunoglobulins (IVIG) and cyclophosphamide for acute relapses are not covered in this table.

TABLE 93.3 CBD Molecular Mechanism of Actions and Effects

Targets	Mechanisms	Affinity/dose	Effect
Receptors and channels			
CB1/CB2	Antagonist	KB 79 nM (CB1); 138 nM (CB2)	Antagonizes cannabinoid induce antispasmodic effect
CB2	Inverse agonist	EC50: 503 nM	Antiinflammatory effect
GPR55	Antagonist	IC50: 350 nM	Antagonistic activity in human osteoclasts
5-HT3A ligand-gated channel	Allosteric inhibition	IC50: 0.6 μM	Modulation of nociception and emesis
TRPM8 cation channel	Antagonist	EC50: 80–140 nM; IC50: 60 nM	Analgesic effects
TRPA1 cation channel	Agonist	EC50: 110 nM; IC50: 160 nM	Analgesic effects
PPARγ nuclear receptor	Agonist	IC50: ±5 μM	Vasorelaxation antiinflammatory effect
T-type Ca^{2+} channel	Inhibitor	IC50: ±1 μM	Nociceptive and antiepileptic effects, sleep regulation
TRPV1 cation channel	Agonist	EC50: 1 μM; IC50: 0.6 μM	Antipsychotic and analgesic effects
TRPV2 cation channel	Agonist	EC50: 1.25 μM; IC50: 4.5 μM	Antiinflammatory/analgesic/antinociceptive effect
5-HT1A receptor	Agonist	80% displacement at 16 μM	Antiischemic and anxiolitic properties. Neuroprotective
μ and δ opioid receptors	Allosteric modulation	EC50 4.38 (μ); 4.10 (δ)	Potentially enhance the effects of opiates
α1 and α1β glycine ligand-gated channels	Positive allosteric modulation	EC50: 12.3 μM (α1); 18.1 (α1β)	Role in chronic pain after inflammation or nerve injury
Abnormal-CBD receptor	Antagonist	Effect at 1 μM	Attenuates the vasodilator response to anandamide
Targets	**Mechanisms**	**Affinity/dose**	**Effect**
Enzymes			
CYP1A1	Competitive inhibitor	IC50: 0.41 μM	Might lead to interaction of drugs or toxicants metabolized by CYP enzymes. Possible adverse effects or intoxication
CYP1A2 and CYP1B1	Competitive inhibitor	IC50: 3.8 μM (A2); 5.96 μM (B1)	
CYP2B6	Inhibitor	K_i: 0.694 μM	
CYP2D6	Competitive inhibitor	IC50: 6.65 μM	
CYP3A5	Inhibitor	IC50: 1.65 μM	
CYP2A6	Inhibitor	K_i: 55 μM	
CYP3A4 and CYP3A7	Inhibitor	IC50: 11.7 μM (A4)23–31 μM (A7)	
FAAH	Inhibitor	IC50: 15.2 μM	Increment of AEA tone. Analgesic, antiinflammatory effects
Mg^{2+} -ATPase	Inhibitor	Effect at 50 μM	Anticonvulsant effect
AANAT	Inhibitor	65% reduction at 10 μM	Reduces melatonin biosynthesis
5-Lipoxygenase	Inhibitor	IC50: 73.73 μM	Antimitotic effect in glioma cells
15-Lipoxygenase	Inhibitor	IC50: 2.56 μM	Involved in atherosclerosis
Phospholipase A2	Activator/inhibitor	EC50: 6.4 μM(+)134 μM(−)	Antiinflammatory effects
Indoleamine-2,3-dioxygenase	Inhibitor	IC50: 2.8 μM/mL	Enhance of tryptophan and therefore serotonin. Improvement of mood disturbances

(*Continued*)

TABLE 93.3 CBD Molecular Mechanism of Actions and Effects (*cont.*)

Targets	Mechanisms	Affinity/dose	Effect
Glutathione peroxidase	Activator	Effect at 10 and 25 μM	ROS production and caspase activation in tumor cells
Glutathion reductase	Activator		
Superoxide dismutase	Inhibitor	Effect at 100 μM	Generates ROS and induces cell toxicity in tumor cells
Catalase	Inhibitor		
NAD(P)H-quinone reductase	Inhibitor		
Progesterone 17α-hydrolase	Inhibitor	Effect at 1 M	Interaction with steroid metabolism. Inhibits the testosterone synthesis in rat testis
Testosterone 6β-hydrolase	Inhibitor		
Testosterone 16α-hydrolase	Inhibitor		
Targets	**Mechanisms**	**Affinity/dose**	**Effect**
Transporters and cellular uptake			
Adenosine uptake	Competitive inhibitor	IC50: 120 nM	Increment of adenosine tone antiinflammatory effect
Intracellular Ca^{2+} uptake	Inhibition	Effect at 1 μM	Neuroprotective and antiepileptic properties
Anandamide reuptake	Inhibitor	IC50: 28 μM	Increment of AEA tone
Choline uptake	Inhibitor	EC50: 1.6 pM	Increment of Ach tone
P-glycoprotein (drug efflux transporter)	Inhibitor	IC50: 39.6 μM	Potentially influence the absorption and disposition of compounds that are P-gp substrates

Molecular targets of CBD, including cannabinoid and noncannabinoid receptors, enzymes, transporters, and cellular uptake proteins (reviewed in Izzo, Borrelli, Capasso, Di Marzo, & Mechoulam, 2009; Mechoulam, Petersa, Murillo-Rodriguez, & Hanus, 2007; Hill, Williams, Whalley, & Stephens, 2012). CYP, Cytochrome P450 enzymes; AANAT, arylalkylamine *N*-acetyltransferase; FAAH, fatty acid amide hydrolase; AEA, *N*-arachidonoylethanolamide; Ach, acetylcholine; ROS, reactive oxygen species.

CB2 receptor sites (Thomas, Gilliam, Burch, Roche, & Seltzman, 1998).

CBD Antagonizes CB1 and CB2 Receptor Agonists, and Can Act as an Inverse Agonist of CB2 Receptor

CBD attenuates the effects of WIN55212 and CP55940 (CB1 agonists) at prejunctional sites in mouse vas deferens (Pertwee, Ross, Craib, & Thomas, 2002). Moreover, at concentration values in low nanomolar range, CBD could work as an inverse agonist of CB2 receptor, as it has been demonstrated in whole-brain membranes and membranes from CHO cells transfected with human CB2 receptors (Thomas et al., 2007). This mechanism may explain some of the pharmacological effects of CBD such as its antiinflammatory properties.

CBD Enhances Adenosine Signaling

CBD binds to the equilibrative nucleoside-transporter-1 with a K_i value below 250 nM, which in turn led to the increase of extracellular adenosine (Carrier, Auchampach, & Hillard, 2006). Neuroprotective effects of CBD in hypoxic–ischemic brain damage also involve adenosine A_2 receptors (Castillo, Tolon, Fernandez-Ruiz, Romero, & Martinez-Orgado, 2010). Moreover, CBD diminishes inflammation in acute models of injury (Ribeiro et al., 2012) and in a viral model of MS through adenosine A_2 receptors (Mecha et al., 2013b).

CBD Interacts With the Transient Potential Vanilloid Receptor Type-1 (TPVR-1), and With 5-HT1$_A$ Serotonin Receptor

Both CBD and its (+) enantiomer interact (EC50 estimated between 3.2 and 3.5 μM) with TPVR-1 receptor, with a maximal effect that is similar to the natural agonist capsaicin. These effects have been confirmed both in vitro (Bisogno et al., 2001) and in a model of acute inflammation in rats (Costa, Giagnoni, Franke, Trovato, & Colleoni, 2004).

In relation to 5HT1$_A$ serotonin receptors, Russo, Burnett, Hall, and Parker (2005) demonstrated that CBD displaces the agonist ([^{3}H]-8-OH-DPAT) from the human cloned receptor in a concentration/dependent manner, and that it increases [^{35}S]GTPgS binding in this G-protein-coupled receptor (GPCR) system decreasing cAMP concentration at similar apparent levels of receptor occupancy. In addition, CBD significantly reduces the infarct

volume induced by middle-cerebral-artery (MCA) occlusion (Mishima et al., 2005), exerting a neuroprotective effect that was inhibited by the serotonin 5-HT1$_A$ receptor antagonist WAY100135, but not by capsazepine, a vanilloid-receptor antagonist.

CBD Allosterically Modulates μ and δ Opioid Receptors

Data from Kathmann, Flau, Redmer, Tränkle, and Schlicker (2006) show that, on rat cerebral cortex membrane homogenates, CBD accelerated the dissociation of both the μ opioid receptor agonist [^{3}H]DAMGO induced by naloxone, and the δ opioid receptor agonist [^{3}H] naltrindole induced by naltrindole. Interestingly, this property was shared by THC, but not by the CB1 cannabinoid-receptor antagonist rimonabant. As this modulation of opioid receptors occurs at very high levels of CBD, it cannot be expected to contribute markedly to the phytocannabinoid actions in vivo.

CBD Affects Nuclear Receptors of the Peroxisome Proliferator-Activated Receptors (PPAR-g), and Antagonizes the Orphan Receptor GPR55

Recently, it has been discovered the ability of different endocannabinoids and phytocannabiniods, including CBD, to display an extra-cannabinoid receptor binding activity by the interaction with peroxisome proliferator-activated receptors (PPARs) (O'Sullivan & Kendall, 2010). PPARs belong to the family of nuclear hormone receptors, and have been reported to control the expression of genes related to inflammatory responses. Esposito et al. (2011) reported that the blockade of PPARγ in a rat model of Alzheimer disease (AD), blunted CBD effects on reactive gliosis and subsequently on β-amyloid-induced neurotoxicity. Moreover, and due to the interaction of CBD with PPARγ, this cannabinoid was observed to stimulate hippocampal neurogenesis.

Additionally, CBD displays GPR55 antagonistic activity in human osteoclasts (Whyte et al., 2009), and has no GPR55 agonistic activity when assayed in β-arrestin recruitment and calcium mobilization assays (Yin et al., 2009; Kapur et al., 2009), demonstrating that CBD can act as an antagonist of the orphan receptor GPR55.

CBD TOXICITY AND PHARMACOKINETIC

In view of the potential therapeutic use of CBD, and encouraged by the lack of its undesired psychotropic effects, several studies have been performed to determine the toxicological profile of this phytocannabinoid.

Very low toxicity of CBD has been found both in human and in other species, with an LD50 of 212 mg/kg when intravenously injected into rhesus monkey (Rosenkrantz, Fleischman, & Grant, 1981). The oral toxicity of CBD had not been clearly established, but Rosenkrantz et al. (1981) showed that an oral dose of 20–50 times larger than the intravenous route of CBD is required to initiate severe intoxication. Additionally, CBD does not cause relevant CNS alterations, and does not display mutagenic or teratogenic activities (Dalterio, Steger, Mayfield, & Bartke, 1984; Matsuyama & Fu, 1981).

In regards of the pharmacokinetic of CBD, reviewed by Grotenhermen (2003), once orally given and due to a marked first-pass effect, CBD bioavailability ranges between values of 13% and 19%, while the systemic bioavailability of inhaled CBD has a range of 11–45% making for this reason the intravenously administration route preferable. With plasma pattern similar to that of THC, after its administration CBD is rapidly distributed, and due to its lipophilic nature can easily pass the blood–brain barrier. The biotransformation routes for CBD are those typically observed for phytocannabinoids, with multiple hydroxilations, oxidations to carboxylic acids, β-oxidation, conjugation and epoxidation (Harvey & Mechoulam, 1990; Samara, Bialer, & Harvey, 1990a). This turns into a prolonged elimination of CBD, with a terminal half-life of about 9 h, being preferentially excreted in the urine as free and its glucuronide compound (Samara, Bialer, & Harvey, 1990b).

CBD AND ANIMAL MODELS OF MS

The use of animal models to study a complex disease like MS has allowed not only to a better understanding about the pathophysiology of the human disease, but also to the development of preclinical testing of disease therapies. There are two main animal models to study MS: experimental autoimmune encephalomyelitis (EAE), induced by immunization against myelin, and experimental viral infection like the one induced with Theiler's murine encephalomyelitis virus (TMEV) in susceptible mice (reviewed in Mecha, Carrillo-Salinas, Mestre, Feliu, & Guaza, 2013a). Both animal models include classical MS hallmarks like inflammation, neuronal damage and demyelination, and it has been described the ability of cannabinoids to exhibit therapeutic potential using these two models.

The enhanced leukocyte trafficking is a key feature in MS, and there are available therapies designed to target CNS inflammation in its early events, such as natalizumab (Tysabri), which interferes with the homing of immune cells to the CNS and is currently prescribed for the treatment of relapsing remitting MS (Krumbholz, Derfuss, Hohlfeld, & Meinl, 2012). In this line, the treatment with cannabinoid agonists has been shown to be effective in the leukocyte rolling and adhesion to endothelial cells in

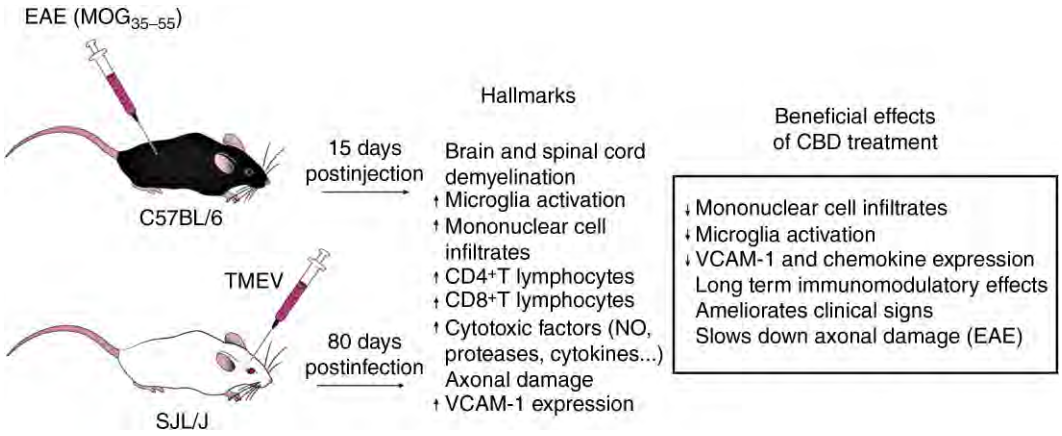


FIGURE 93.1 **CBD and animal models of MS.** Principal hallmarks of the two mouse models of MS, and beneficial effects of CBD (dpi, days postimmunization in the case of EAE; and days postinfection in TMEV-induced demyelinating disease).

EAE (Ni et al., 2004), as well as in the progression of the disease in TMEV infected mice through the regulation of adhesion molecules both in vivo (Mestre et al., 2009) and in vitro (Mestre et al., 2011). The immunoregulatory capacity of cannabinoids in EAE has also been reported (Cabranes et al., 2005; Maresz et al., 2007).

Regarding the effects of CBD in the animal models of MS (Fig. 93.1), only two studies have been published showing the promising therapeutic effect of this *C. sativa* derivative compound. In this line, CBD has been shown to ameliorate EAE symptomatology by diminishing inflammation, microglial activity and leukocyte homing in the spinal cord of immunized animals (Kozela et al., 2011). Lately, Mecha et al. showed in 2013 that CBD also exerts beneficial effects in TMEV-IDD induced demyelinating disease by decreasing the expression of adhesion molecules, the homing of leukocytes to the CNS, and the neuroinflammation in the acute phase of the TMEV-IDD model with long lasting-effects on the clinical course of the disease.

CBD AND MS: PERSPECTIVES

MS, one of the most common autoimmune neurodegenerative diseases, remains with an unclear trigger and still missing therapeutic solutions. Difficulties in clinical trials in patients with MS are due to the diverse and heterogeneous population varying in terms of disease type, severity, variable progression/time course, and with regard to the wide range of presenting symptoms. Beside the currently available MS treatments described in the introduction, there are other potential compounds in clinical phase that involves the immune system as a therapeutic approach (Table 93.4).

Extensive preclinical findings have reinforced the notion deduced from the anecdotal observations that cannabis derivatives may have a role in relieving symptoms in MS patients. The clinical trials focused in Sativex efficacy in the treatment of symptoms of MS, particularly spasticity and neuropathic pain. Beneficial results in placebo-controlled trials were obtained when Sativex was administered as an add-on therapy in these indications, supporting the view that Sativex is efficacious and well tolerated for the treatment of these symptoms (Collin, Davies, Mutiboko, & Ratcliffe, 2007; Wade, Collin, Stott, & Duncombe, 2010; Novotna et al., 2011). Additional trials confirmed that the CBD/THC combination reduce sleep disturbance in patients with MS-related neuropathic pain and that this treatment is mostly well tolerated (Iskedjian, Bereza, Gordon, Piwko, & Einarson, 2007; Rog, Nurmikko, & Young, 2007). Current THC analogs or Sativex trials in MS for symptomatology control have, so far, failed to demonstrate a relevant reduction of relapse, indicative of immunosupressive properties in humans (Zajicek et al., 2005). Evidence from preclinical observations underlines the interest of cannabinoids as neuroprotective agents besides their abilities as immunomodulators. However, there is a lack of preclinical and clinical studies evaluating the Sativex use in progressive MS (primary or secondary) disease as a disease modifying drug. In addition, there is a lack of clinical trials relating the administration of oral CBD alone in MS patients, besides the suggestive profile of CBD as immunomodulator, antioxidant, neuroprotective, and oligoprotective agent as we described above.

Because of the interest of CBD alone as therapeutic agent in other neurodegenerative pathologies (Table 93.5) such as Huntington disease as well as in very diverse CNS pathologies that include epilepsy, schizophrenia or even affective disorders, there are studies administering CBD-alone at different doses to healthy volunteers by oral or IV route (Zhornitsky & Potvin, 2012). On the basis of CBD effects on experimental models of MS and on CNS cell types (Fig. 93.2) future studies should investigate clinical applications of oral CBD for MS, RRMS, and PPMS/SPMS, and should also administer CBD to

TABLE 93.4 MS Therapy Pipeline

Name	Type	Route of administration	Pending indications	Phase	Mechanism of action
Laquinimod	Derivative of linomide	Oral	RRMS	III	Induces antiinflammatory cytokine profile in humans. Inhibits Th1 and Th2 leukocyte migration into de CNS.
Rituximab (Zituxam)	Chimeric human/mouse anti-CD20 monoclonal antibody	Intravenous	RRMS (approved by FDA for lymphoma and arthritis rheumatoid)	III	Depletes $CD20^+$B lymphocytes via cell-mediated and complement-dependent cytotoxic effects, and promotes apoptosis of these cells in the peripheral circulation
Daclizumab (Zenapax)	Humanized anti-CD25 monoclonal antibody	Subcutaneous	RRMS	III	Targets the α subunit of IL2R CD25 on activated T lymphocytes. Blocking the CD25 downregulates the proliferation of B and T lymphocytes via reduction the secretion of proinflammatory cytokines. Production of CD56 positive natural killer cells with regulatory function
Alemtuzumab (Campath-1H)	Humanized anti-CD52 monoclonal antibody	Intravenous	RRMS (approved by FDA for leukemia; better than Rebif)	III	Targets the molecule CD52, expressed on the surface of mature lymphocytes, monocytes, and macrophages. It depletes these cells via complement-mediated lysis antibody-dependent cell toxicity and apoptosis. Induces the production of neurotrophic factors by the reconstituted autoreactive T lymphocytes
Ocrelizumab	Humanized anti-CD20 monoclonal antibody	Intravenous	RRMS	II	Depletes $CD20^+$B lymphocytes

Perspectives for new treatments for MS patients, including the phase of the clinical trial and the expected mechanism of action (reviewed in Minagar, 2013).

Amyotrophic lateral sclerosis

Different diseases in which the treatment with CBD can be therapeutic based on the effects on mouse models (reviewed in Fernandez-Ruiz et al., 2013 and Pertwee, 2012).

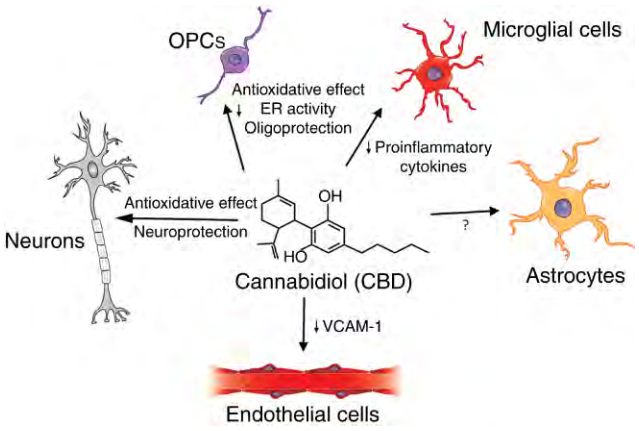

FIGURE 93.2 **Cellular targets of CBD.** Neurons, oligodendrocytes, microglial and endothelial cells can be targets of the effects of CBD in the CNS. The actions on astrocyte cells have not yet been determined.

patients for prolonged period of time in order to simulate the chronic condition of this disease. Among *C. sativa* derived compounds, CBD which lacks any unwanted psychotropic effect may represent a promising agent with the highest prospect for therapeutic use but this hypothesis needs to be proved.

MINI-DICTIONARY

Autoimmune disease An abnormal immune response of the body to tissues and molecules normally present in the body. It compromises the production of autoantibodies from the B-cells of the immune system. The treatment of autoimmunity includes immunosuppresion, to decrease the immune "self" response.
Cannabidiol One of at least 60 active cannabinoids identified in *Cannabis sativa,* counting for up to 40% of the plant's extract, considered to have a wider scope of medical applications than THC with no psychoactive effects.
Demyelination Damage to the myelin sheath that covers nerve fibers in brain and spinal cord. This provokes that nerve impulses slow or even stop, causing neurological alterations.
EAE model An animal model of CNS autoimmune inflammation that courses with inflammation and demyelination, and is used as an experimental model for the human inflammatory demyelinating disease MS. Mainly induced by inoculation with spinal cord homogenates or myelin proteins or peptides, that results in distinct models of disease course depending of the genetic background of mice.
Endocannabinoid system Lipid system of intercellular communication constituted by endogenous ligands, receptors, and the machinery of synthesis and degradation enzymes. It´s involved in a variety of physiological processes including memory, mood, pain-sensation, and appetite. Cannabinoids extracted from *C. sativa* use this endogenous system to exert their central and peripheral actions.
Multiple Sclerosis Chronic neurological disease that is pathologically characterized by multifocal inflammation, demyelination, and neuronal injury in optic nerves, brain, and spinal cord. Mainly considered as an autoimmune disease.
Neurodegeneration A condition that result in progressive loss of neuronal structure and function with neuronal death. Some neurodegenerative disorders include Parkinson, Alzheimer, and Huntington disease.
Neuroinflammation Inflammation of the central or peripheral nervous system. It can be initiated in response to infection, autoimmunity, traumatic brain injury or toxic metabolites among others. Neuroinflammation compromises microglial cells, the resident innate immune cells of the CNS, and circulating peripheral immune cells that infiltrate through the blood brain barrier.
Oligodendrocyte Myelinating cell of the CNS. Myelin acts as an insulator of axonal segments and is a prerequisite for the high velocity of nerve conduction.
Sativex Cannabinoid medicine for the treatment of spasticity due to MS which is also in development for cancer pain and neuropathic pain. Commercialized by GW Pharmaceuticals, the preparation containing CBD and Δ^9-THC is available under four different formulations that differ in the concentration of CBD and Δ^9-THC.
TMEV-IDD model An animal model of primary chronic-progressive disease that courses with inflammation, demyelination, and neurodegeneration in both brain and spinal cord, used as an experimental model for the human disease MS. Induced by the intracerebral inoculation of different strains of the Theiler's virus in susceptible mice.

SUMMARY POINTS

- Chronic neuropathic pain is a common and poorly managed condition.
- This chapter focuses on the effects of cannabinoids on neuropathic pain.
- There is considerable anecdotal and preclinical trial evidence supporting a possible beneficial role for cannabinoids.
- However, there have only been a limited range of short-term clinical trials with largely disappointing outcomes. The long term efficacy of cannabinoids have also not been established.
- By far the largest numbers of clinical trials conducted to date have examined the use of cannabinoids in central neuropathic pain caused by multiple sclerosis.
- There is a restricted role for cannabinoids in certain patient groups with severe painful neuropathy who are inadequately treated on currently available treatments
- Further adequately powered clinical trials are required to fully examine the long term safety and efficacy on pain and functional measures of these compounds.

KEY FACTS OF PAINFUL NEUROPATHY

- Neuropathic pain is a chronic painful condition that results from damage or dysfunction to the nervous system.
- Patients often report a number of typical painful symptoms which includes burning, sharp shooting pain, electric shocks, pins, and needles or tingling.
- Chronic neuropathic pain often results in considerable distress and disability leading to significant morbidity and reduction in quality of life.
- There is often accompanying mood disorders and sleep disturbance.
- Chronic neuropathic pain can be a challenge to manage. Unfortunately, pharmacological therapies are often ineffective and their use is limited by intolerable side effects.
- Patients are often managed by a multi-disciplinary team of specialists with a combination of pharmacotherapy, psychological treatment, physiotherapy, and neuromodulation.

INTRODUCTION

Neuropathic pain is defined as "pain initiated or caused by a primary lesion or dysfunction in the peripheral or central nervous system" (Treede et al., 2008), and is estimated to affect up to 7–8% of the general population in Europe (Torrance, Smith, Bennett, & Lee, 2006). A number of different pathological processes that cause neuronal dysfunction can lead to neuropathic pain (Table 94.1). Common examples include diabetic polyneuropathies, postherpetic neuralgia, trigeminal neuralgia, spinal cord injury, and postsurgical/traumatic neuropathies. Regardless of etiology, chronic neuropathic pain often results in considerable distress and disability leading to significant comorbidity and an overall reduction in an individual's quality of life (Meyer-Rosberg et al., 2001). This leads to mood disorders, pathological sleep states (Gore et al., 2005), and social isolation (McCarberg & Billington, 2006). The management of patients with neuropathic pain is challenging, as current pharmacological treatments are often ineffective and use limited by intolerable side effects (Finnerup, Sindrup, & Jensen, 2010; Attal et al., 2010; Dworkin et al., 2007).

TABLE 94.1 Common Causes of Neuropathic Pain

Metabolic/nutritional	Diabetes mellitus, uremia, vitamin B12 and folate deficiencies, paraneoplastic, hypothyroidism
Toxic/drug related	Alcohol, antiretroviral drugs, antituberculosis drugs, chemotherapy (vincristine, cisplatinum, paclitaxel), fluoroquinolones
Viral	Human immunodeficiency virus, herpes zoster, and postherpetic neuralgia
Structural/pressure/trauma	Postsurgical/traumatic neuropathies, entrapment syndromes, neuropathic lower back pain, phantom limb pain, nerve root syndromes/radiculopathies, radiotherapy
Inflammatory	Vasculitis, Sjogren's syndrome, systemic lupus erythematosus
Others	Complex regional pain syndrome, ischemic neuropathies, neuromas, multiple-sclerosis vascular brain/spinal cord lesions (brainstem/thalamic)

The discovery of cannabinoid receptors and their endogenous ligands has resulted in a number of clinical trials involving cannabinoids in neuropathic pain. Presently, in the United Kingdom, the only approved indication for cannabinoids is for neuropathic pain and muscle spasticity in multiple sclerosis (MS) (Guindon & Hohmann, 2008). Uncertainties remain for its use in other neuropathic pain conditions. This chapter will examine the pathophysiology and mechanisms of neuropathic pain and review the existing literature on cannabinoid use in painful neuropathy.

NEUROPATHIC PAIN MECHANISMS

Despite the broad spectrum of etiologies, the clinical manifestations of neuropathic pain are similar across the different syndromes. This is because the symptoms and signs of neuropathic pain are caused by a combination of abnormal nerve activity (ectopic activity and central sensitization) and lesion-induced reduced sensations (Table 94.2) (Baron, Binder, & Wasner, 2010). Detailed history and clinical examination aimed at identifying these characteristic symptoms and sensory abnormalities are important for the accurate diagnosis of neuropathic pain and to distinguish this from other pain types.

PATHOPHYSIOLOGY OF NEUROPATHIC PAIN

Over the past decade, pain research has made considerable progress to uncover the pathophysiology of neuropathic pain (Fig. 94.1) (Baron et al., 2010). Although this has led to a better mechanistic understanding into human pain pathology, there is still a lack of effective mechanism-based treatment approaches and more efficient analgesia. According to data from basic research and human pain experiments a lesion to the afferent pathway is necessary for the development of neuropathic pain (Baron, 2006). This triggers a cascade of several different mechanisms leading to neuropathic pain. Different mechanisms can be involved in the same disease or in the same individual which could in turn lead to the same symptom (Baron et al., 2010). For example, on-going spontaneous pain and paroxysmal

TABLE 94.2 Symptoms and Signs of Neuropathic Pain

Positive symptoms and signs:
- Spontaneous: burning pain, paresthesia, sharp shooting pain, electric shocks
- Evoked pain: allodynia, hyperalgesia

Negative symptoms and signs:
- Hypoalgesia and hypoesthesia

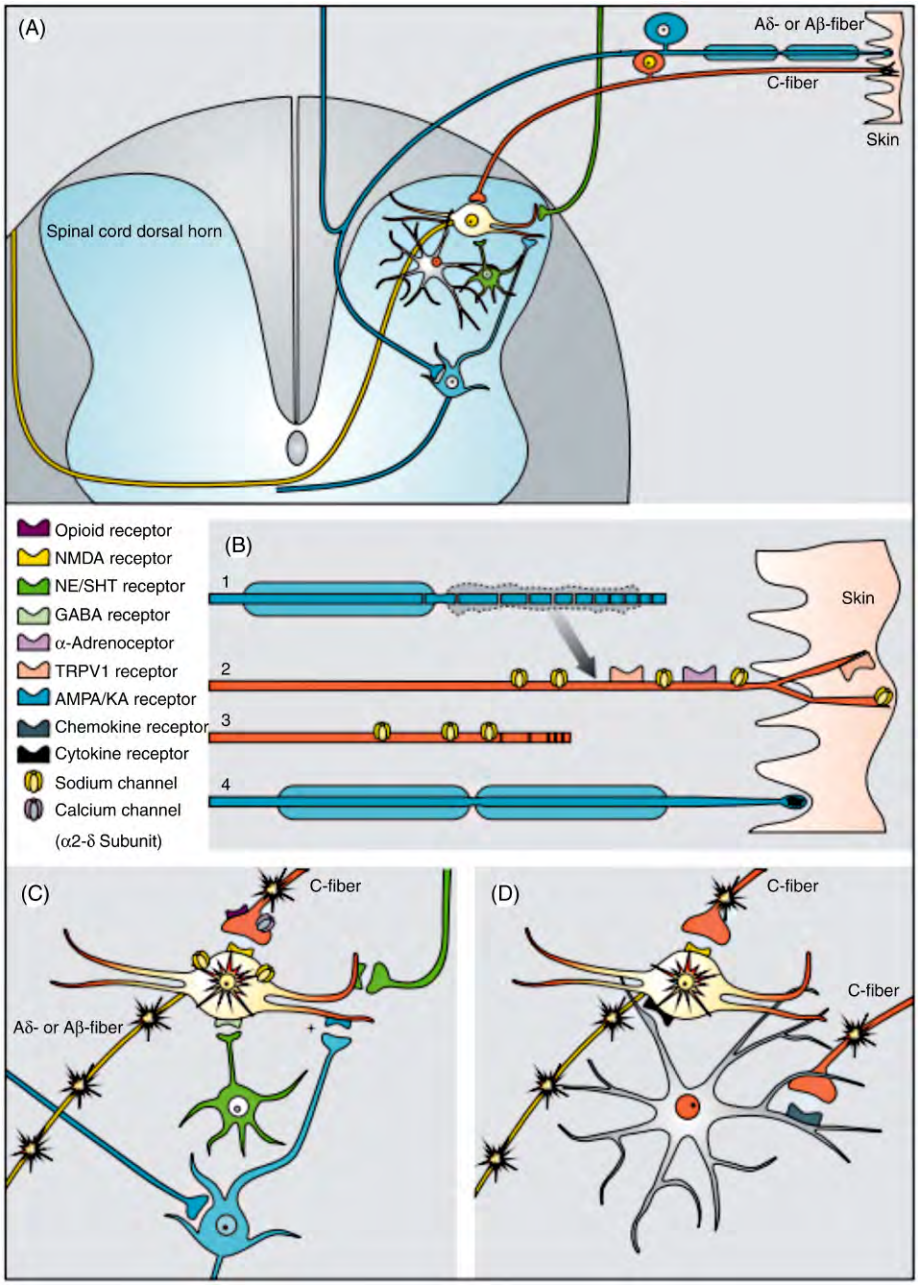

FIGURE 94.1 **Pathophysiological mechanisms of neuropathic pain.** (A) Primary afferent pathways and their connections in the spinal cord dorsal horn. Nociceptive C-fibers *(red)* terminate at spinothalamic projection neurons in the upper laminae (*yellow* neuron). Nonnociceptive myelinated A-fibers project to deeper laminae. The second-order projection neuron receives direct synaptic input from nociceptive terminals and also multisynaptic input from myelinated A-fibers (nonnoxious information, *blue* neuron system). Interaction with microglial (*gray* cell) facilitates synaptic transmission. GABAergic interneurons (*green* neuron) normally exert inhibitory synaptic input on second order neuronal projections. (B) Peripheral changes at primary afferent neurons after a partial nerve lesion, leading to peripheral sensitization. Note that some axons are damaged and degenerate (axons 1 and 3) and some are still intact and connect to the peripheral end organ (skin; axons 2 and 4). Expression of sodium channels is increased on damaged neurons (axon 3), triggered has a consequence of the lesion. Furthermore, products such as nerve growth factor, associated with Wallerian degeneration and release in the vicinity of spared fibers *(arrow)*, trigger expression of channels and receptors (eg, sodium channels, TRPV1 receptors, adrenoreceptors) on uninjured fibers. (C) Spontaneous activity in C-nociceptors induces secondary changes in central sensory processing, leading to spinal cord hyperexcitability (central sensitization of second-order nociceptive neurons, star in yellow neuron) that causes input from mechanoreceptors A-fibers (*blue* neuron system, light touching and punctuate stimuli) to be perceived as pain (dynamic and punctate mechanical allodynia, + indicates gating at synapse). Several presynaptic (opioid receptors, calcium channels) and postsynaptic molecular structures (glutamate receptors, AMPA/kainite receptors, sodium/5HT receptors, GABA receptors, sodium channels) are involved in central sensitization. Inhibitory interneurons and descending modulatory control systems (*green* neurons) are dysfunctional after nerve lesions, leading to disinhibition or facilitation of spinal cord dorsal horn neurons and to further central sensitization. (D) Peripheral nerve injury activates spinal cord glial cells (*gray* cell) via chemokines, such as CCL2 acting on chemokine receptors. Activated microglia further enhance excitability in second order neuronal projections by releasing chemokines and growth factors (eg, tumor necrosis factor, bone-derived nerve factor) and increasing glutamate concentrations. *Source: Adapted from Baron et al. (2010).*

shooting pain is the result of abnormal ectopic nociceptive nerve activity. Under normal physiologic conditions these unmyelinated c-fiber and thinly myelinated Aδ afferent nociceptive fibers usually have a high threshold for activation to indicate potential tissue damage. In neuropathic pain states, this threshold is lowered and results in spontaneous activity (Ørstavik et al., 2006; Ørstavik & Jørum, 2010; Nyström & Hagbarth, 1981). Changes in the voltage gated sodium channels, potassium channels, and upregulation of receptor proteins (eg, TRPV1) have all been shown to correlate with increased spontaneous nerve activity (Caterina & Julius, 2001; Fischer & Reeh, 2007; Ma, Zhang, Bantel, & Eisenach, 2005). Secondary allodynia and hyperalgesia on the other hand occurs as a result of involvement of the central nervous system (CNS) (Baron et al., 2010). In a process called central sensitization, lesions within first order afferent neurons induce postsynaptic changes within second-order nociceptive neurons that lowers the mechanosensitivity threshold of Aβ and Aδ afferent fibers (Hains, Saab, Klein, Craner, & Waxman, 2004; Ultenius, Linderoth, Meyerson, & Wallin, 2006). As a result, nonpainful tactile stimulation (light brushing) becomes painful. These mechanisms are thought to occur at both spinal and supraspinal levels of the CNS. These processes highlight clearly the complexity of neuropathic pain and the challenges posed to develop therapeutic regimens that are effective at treating and preventing this condition. Further research is needed to identify the mechanisms involved for an individual patient as this could lead to targeted treatment regimens for the different pain mechanisms.

One of the earliest documented uses of cannabis was in pain management. It was used for surgical anesthesia in ancient China and for pain relief in early Egyptian, Roman, and Indian civilizations (Peters & Nahas, 1999). More recent experimental studies in animal models of pain have demonstrated beneficial antinociceptive effects and provide substantial preclinical evidence (Guindon & Hohmann, 2009; Hohmann & Suplita, 2006). In a wide range of animal models of neuropathic pain, various studies have demonstrated that cannabinoid agonists reverse the common symptoms of neuropathic pain, including allodynia and hyperalgesia. In these studies, the analgesic properties of cannabinoids depend on a number of factors including administration route, assay conditions and the preparation of the drug (Harris, 1971). Of these factors, route of administration plays a critical role; when given intravenously, THS exhibits high degree of potency and efficacy comparable to morphine. In contract the efficacy of THC is considerably reduced when administered subcutaneously or intraperitoneally. Administration of cannabinoids to animals also elicits a number of significant adverse effects including sedation, motor, and cognitive impairments (Little, Compton, Johnson, Melvin, & Martin, 1988). Such side effects could potentially confound the interpretation of antinociceptive measurements in animal studies which generally rely on paw/tail withdrawal from a noxious stimulus. Thus, it remains to be determined if cannabinoids can produce pain relief at doses below the side effect threshold.

The analgesic properties of cannabinoids occur through a complex range of mechanisms at different levels of the nervous system. This is consistent with the presence of CB1 and CB2 receptors in three key areas involved in pain control (peripheral, spinal, and brain) (Agarwal et al., 2007; Herkenham, 1995; Van Sickle et al., 2005; Jhaveri, Sagar, Elmes, Kendall, & Chapman, 2007). These include the periaqueductal gray, spinal dorsal horn and dorsal root ganglion and are target sites of major endocannabinoids, such as *N*-arachidonoyl ethanolamide (anandamide) and 2-arachidonoyl glycerol (2-AG). They may also modulate analgesic responses via noncannabinoid receptor targets (eg, anandamide is also a ligand for the TRPV-1 receptor) (Cristino et al., 2006; Ahluwalia, Urban, Capogna, Bevan, & Nagy, 2000) and by working synergistically with the endogenous opioid system (Pertwee, 2001). Both endogenous cannabinoid and opioid systems display similarities in receptor structure and signal transduction (Fig. 94.2). Stimulation of these receptors blocks the conversion of noxious stimuli into electrochemical signals by inhibiting voltage-gated Ca^{2+} channels, stimulating K^+ inward channels, and subsequently inhibiting the Ca^{2+} dependent release of pronociceptive effectors such as substance P, calcitonin gene-related peptide, and bradykinin (Roques, Fournié-Zaluski, & Wurm, 2012).

PHARMACOLOGICAL TREATMENT OF NEUROPATHIC PAIN

Treatment of chronic neuropathic pain can be one of the most challenging areas of modern medical practice. In addition to suffering longstanding disabling pain, patients often have complex biological, psychological, and social problems. Their pain has often been diagnosed incorrectly and managed poorly. Pharmocotherapy remains the main pillar of pain management and can be divided into two broad classes, membrane stabilizing agents (antiepileptic drugs and anesthetics) and medications that enhance dorsal horn inhibitory mechanisms (Table 94.3) (Attal et al., 2010). Most agents, however, have multiple mechanisms of action and their effects often may overlap. Despite being the mainstay in the management of neuropathic pain, there are significant limitations to currently available pharmacological treatments. Lack of perceived efficacy,

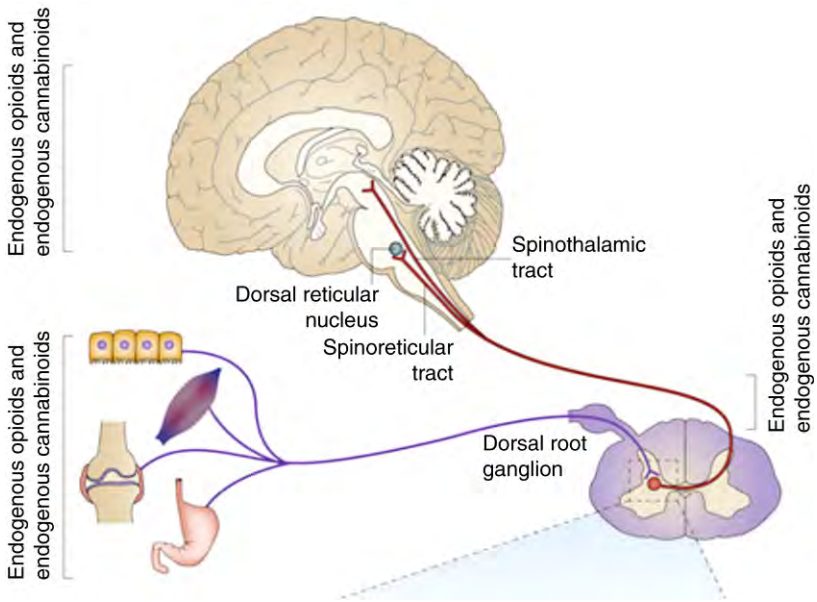

FIGURE 94.2 **Endogenous cannabinoids and opioids are present at all three levels of pain control.** Endogenous opioids and endogenous cannabinoids are distributed widely in the CNS, spinal cord, and peripheral organs. At the periphery, endogenous opioids, and endogenous cannabinoids are present in epithelial cells of the intestine and kidney, in the joints, lung, testis, and skin, as well as on various types of immune cells, including oligodendrocytes and Schwann cells surrounding nerve fibers. Cannabinoid receptors are found at the nociceptor level, and in immune cells, where inhibitors can block the noxious inputs. Noxiously stimulated cutaneous fibers converge to the dorsal horn, sometimes along with nonstimulated fibers from distant cutaneous, muscular or visceral areas. μ-opioid receptors (MORs) and δ-opioid receptors (DORs) are mainly located at the presynaptic end of afferent fibers in the spinal dorsal horn. The brain distribution of MORs and DORs are in structures involved in the control of pain and emotions, such as the periaqueductal gray, thalamus, cortex, and limbic system. Brain neurons enriched in cannabinoid receptor 1 (CB1R), includes structures involved in fear and emotions. *Source: Adapted from Roques et al. (2012).*

TABLE 94.3 Pharmacological Treatments for Neuropathic Pain

Anticonvulsants	Gabapentin, pregabalin, carbamazepine, oxcarbazepine, topiramate, lamotrigine
Antidepressants	
• Selective serotonin and noradrenaline reuptake inhibitor	Duloxetine, venlafaxine
• Tricyclic antidepressants	Amitriptyline, imipramine, nortriptyline
Opioids	Tramadol, morphine, oxycodone

unpleasant side effect profiles, drug interactions, and costs are some of the factors that limit the use of these agents. As a result patients with intractable neuropathic pain are often managed in a patient focused multidisciplinary approach which include attempts to treat the underlying disease (eg, diabetes), a rational titrated approach to medications, neuromodulation (eg, ablation therapy, or spinal cord stimulation), psychological, and physical therapies (Fig. 94.3) (Turk & Melzack, 2011).

CANNABINOIDS AND NEUROPATHIC PAIN

Cannabinoids have been evaluated in a number of different clinical pain studies for their effectiveness on acute postoperative and chronic neuropathic pain. These studies indicate that cannabinoids exhibit their greatest efficacy when employed in the management of neuropathic pain (Dyer, 2013). A number of different preparations and delivery methods (oral-mucosal spray and rectal suppositories—benefit of rapid action) have been examined in these clinical trials. This makes any direct comparisons difficult. For example, there are 460 known chemical constituents in cannabis and as a result the pharmacological properties of smoking cannabis are different from oral preparations of Δ^9-THC or different combinations of Δ^9-THC and cannabidiol (Huesis, 1999).

MULTIPLE SCLEROSIS CENTRAL PAINFUL NEUROPATHY

By far, the largest numbers of disease-related clinical studies conducted to date assessing the effects of cannabinoids have been in central neuropathic pain caused

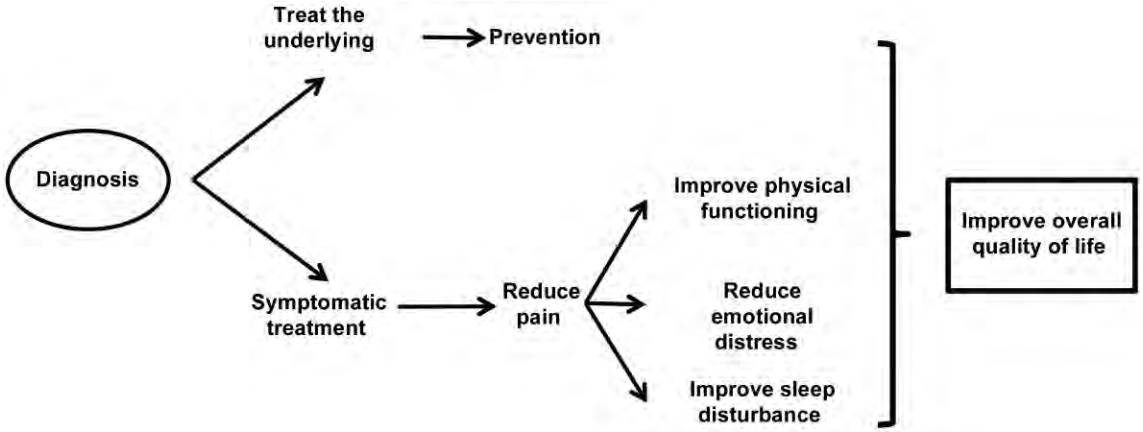

FIGURE 94.3 **Approach to the management of neuropathic pain.** The management of neuropathic pain should follow a two-pronged approach. Following diagnosis of chronic neuropathic pain, efforts should focus on treating (if possible) the underlying condition to prevent further progression of disease. At the same time, appropriate symptomatic treatment should be offered to reduce pain. The aim of symptomatic treatment should not only focus on pain relief but also improve an individual's physical functioning, reduce any emotional distress, and improve sleep duration and quality. This will ultimately result in an overall improvement in an individual's quality of life. *Source: Adapted from Turk and Melzack (2011).*

by multiple sclerosis. Most of these studies, however, focused on the treatment of spasticity. Altogether, there are three Class I, two Class II and four Class III studies of cannabinoids which also included treating central neuropathic pain (either as a secondary end-point or incorporated as part of a composite score) between 1970 and Sep. 2013 (Yadav et al., 2014).

These studies were included in a systematic review by the Guideline Development Subcommittee of the American Academy of Neurology which concluded that for patients with MS with central neuropathic pain or painful spasms, oral cannabinoid extract is effective for reducing central pain. Tetrahydrocannabinol and nabiximols were probably effective in treating MS-related pain or painful spasms. Standard medical therapy was continued in these studies, so no comment was made as to comparative effectiveness. This restricts the use of cannabinoids in multiple sclerosis (Level A) only if other treatments fail. It is difficult to tease out the clinical effectiveness of cannabinoids on the neuropathic pain components in many of these trials in the presence of both painful spasticity and dysesthesia. Some authors view spasm-related pain in multiple sclerosis as being neuropathic whereas others do not. Post-hoc attempts to examine the efficacy of cannabinoids on the different pain manifestation in multiple sclerosis have suggested that both components respond similarly to treatment (Rog, Nurmikko, Friede, & Young, 2005). Hence, from a patients' perspective such comparisons may be unnecessary. Two notable Class 1 studies have evaluated the efficacy of cannabinoids on central neuropathic pain in multiple sclerosis.

Rog et al. (2005) reported a single-center 4-week treatment randomized, double-blind, placebo-controlled trial in 66 patients with MS and central pain states (based on pain description and clinical examination, painless spasms excluded) of nabiximols (2.7 mg THC: 2.5 mg CBD, cannabis based medicinal extract, CBME) oromucosal spray as adjunctive analgesia. They demonstrated that treatment with nabiximols resulted in significant reduction in mean pain intensity [11-point numeric rating scale (NRS-11); nabiximols mean change –2.7, 95% CI: –3.4 to –2.0 vs placebo –1.4 (–2.0:–0.8); $p = 0.005$] and sleep disturbance [–2.5 (–3.4:–1.7) vs –0.8 (–1.5:–0.1); $p = 0.003$], when compared to placebo. Overall, nabiximol treatment was generally well tolerated, although more patients on active treatment reported dizziness, dry mouth, and somnolence compared with placebo. Patients in this study were taking on average, two other medications, with limited efficacy given baseline NRS-11 pain scores of 6.5. This would suggest as adjunctive treatment nabiximol treatment resulted in a significant treatment effect of –1.3 in the NRS-11 pain scores.

Svendsen, Jensen, and Bach (2004) reported a randomized, placebo-controlled crossover study to evaluate the effect of oral synthetic Δ^9-THC dronabinol on central neuropathic pain. In total, 24 patients with MS and central pain (based on clinical examination or quantitative sensory testing) received dronabinol (10 mg OD max) or placebo for 3-weeks separated by a 3-week wash-out period. Dronabinol treatment resulted in significantly lower spontaneous pain intensity compared to placebo treatment [4.0 (25th–75th CI: 2.3–6.0) vs 5.0 (4.0:6.4); $p = 0.02$]. The estimated difference between dronabinol and placebo treatments was –0.6 (95% CI: –1.9 to 0). Lower median radiating pain intensity and higher pain relief score was obtained during the last week of dronabinol treatment compared to placebo. Interestingly, there was a significantly higher pressure

pain threshold during dronabinol treatment (secondary outcome which was not subjected to correction for multiple comparisons) but no differences between treatments in cold sensibility, warm sensibility, tactile detection, tactile pain detection, vibration sense, temporal summation, or mechanical and cold allodynia. Adverse events were more common in the dronabinol treatment (96%) than during placebo treatment (46%). The most common adverse events during active treatment were dizziness, headaches, tiredness, myalgia, and muscle weakness. Overall, dronabinol has a modest analgesic effect on central pain in multiple sclerosis patients. Although the effect size is less than the nabiximol used by Rog et al. (2005) this should be interpreted with caution given the different study designs. Both treatments result in modest improvements in pain which arguably are a clinical relevant analgesic effect in MS patients with central pain. Although, it is suggested that a 30% or 2-point NRC score reduction in pain as being clinically significant, both studies included patients whose pain was controlled poorly on existing medications and even a relatively small reduction in pain intensity are often very appreciated by the patients. Both effect sizes are comparable to other treatment options available with numbers needed to treat to obtain one patient with more than 50% pain relief of 3.45 and 3.7 for dronabinol and CBME respectively (Sindrup & Jensen, 1999).

Systematic reviews of trials of cannabinoids in participants with other types of neuropathic pain have reported mixed results.

HIV PAINFUL NEUROPATHY

Distal symmetrical painful peripheral neuropathy is a frequent complication of HIV infection. Its prevalence is increasing despite (or because of) the introduction of otherwise successful antiretroviral therapy (Evans et al., 2011). The accompanying pain has a major impact on quality of life in otherwise largely healthy individuals. There are at least two etiologies that often coexist and are clinically indistinguishable (Pardo, McArthur, & Griffin, 2001). One associated with HIV disease itself and the other which complicates antiretroviral treatments. Both etiologies cause a distal symmetrical axonal sensory polyneuropathy that affects the feet and less frequently the hands. Often only a temporal association between the onset of symptoms and the starting of a particular antiretroviral agent will provide clues to the possible etiology. A recent systematic review and metaanalysis of randomized control trials was performed to evaluate the clinical effectiveness of analgesics for the treatment of painful HIV painful neuropathy (HIV-PN) (Phillips, Cherry, Cox, Marshall, & Rice, 2010). Of 44 studies identified only 14 met the inclusion criteria for metaanalysis. Authors reported evidence of efficacy only exists for smoked cannabis, capsaicin 8% topical cream, and recombinant human growth factor (clinically unavailable). The evidence for effectiveness of cannabis was based on two randomized clinical trials:

Ellis et al. (2008) reported on the double-blind, placebo-controlled, crossover trial of analgesia with smoked cannabis on neuropathic pain in HIV infection. Patients (n = 34) had intractable painful neuropathic symptoms refractory to at least two previous analgesic classes and consumed between 1% and 8% Δ^9-THC, 4 times daily for 5 consecutive days during a 2-week treatment phase. Active and placebo treatment was separated by a 2-week washout. Pain relief as assessed by the descriptor differential scale was greater in with cannabis than placebo (median difference DDS pain score change, 3.3 points, p = 0.02) among the completers [28 out of 34 subjects randomized (21.4% dropout)]. Proportion of subjects achieving at least 30% reduction in pain intensity with cannabis versus placebo were 0.46 (95% CI: 0.28–0.65) and 0.18 (0.03:0.32) respectively. Sensitivity analysis was performed to examine if blinding was preserved over the course of the study. When subjects were on placebo, accuracy of treatment guesses was no different from random guessing (50%), however, the majority of subjects (93%) were able to guess correctly during the cannabis treatment period. Hence, there was a high risk of performance and detection bias.

Abrams et al. (2007) compared smoked cannabis (3.56% Δ^9-THC tds) to placebo cigarettes in a parallel group RCT design. Only subjects with previous exposure to cannabis were included in this study (n = 27). Those who were current users were asked to discontinue prior to study. Again there was a significant reduction in overall pain intensity from baseline in the cannabis treated group at the end of Day 5 of treatment. A greater proportion of subjects in the cannabis treated group (13/27) reported at least a 30% reduction in VAS pain intensity compared to placebo (6/27). Sensitivity analysis was not performed to assess the robustness of placebo control. It is possible given subjects had a history of previous exposure to cannabis that unintentional unblinding may have occurred during the course of the study. Based on these two studies, the NNT for smoked cannabis was calculated as 3.38 (95% CI: 2.19–7.5). Smoking cannabis should not be clinically advocated. Further well designed clinical trials using alternative routes of administration should be assessed. Both these studies are also limited by small sample sizes, short duration, and restricted subject selection which limits the generalizability of reported findings. They do, however, suggest a "proof of concept" that cannabinoid therapy may be an effective option for pain relief in HIV-PN patients, which needs further investigation.

DIABETIC DISTAL SYMMETRICAL SENSORIMOTOR POLYNEUROPATHY

Diabetes affects approximately 415 million people worldwide (http://www.idf.org/worlddiabetesday/toolkit/gp/facts-figures). This is expected to rise considerably within the next 10 years. Complications of diabetes cause great distress, premature death, and disability to subjects, and is a major burden on national health services. Diabetic neuropathy is one of the commonest long-term complications of diabetes with a prevalence rate of up to 50% after 15–20 years of the disease (Dyck et al., 1993). Painful neuropathy (painful DN) will affect 10% of all subjects with diabetes and causes great distress and disability to sufferers and affects quality of life immensely (Galer, Gianas, & Jensen, 2000). Usually, if the pain persists for longer than 12 months it does not resolve and may thus last for many years. Apart from strict glycemic control there are no pharmacological therapies that have been proven to halt or reverse the neuropathic process. Unfortunately, additional drug treatments used to alleviate painful symptoms are often ineffective and complicated by side effects. A recent metaanalysis of randomized controlled trials for the treatment of painful DN has reported that at best less than a third of patients achieve at least a 30% reduction in pain intensity (Snedecor et al., 2014). Occasionally, in subjects who do not respond to drug treatment electrical spinal cord stimulation has been used. Two small studies have examined the use of cannabinoids in painful DN.

Selvarajah, Gandhi, Emery, and Tesfaye (2010) conducted a randomized, placebo-controlled, double-blind, controlled trial to assess the efficacy of Sativex, a cannabis based medicinal extract, as adjunctive treatment in painful DN. In this small study, 30 subjects were randomized to receive daily sativex or placebo. There was significant improvement in pain scores in both groups, but mean change between groups was not significant. In addition to a large placebo response, post-hoc analysis revealed that subjects with greater depressive symptoms reported higher pain scores at baseline and they improved regardless of intervention. In this first-ever trial assessing the efficacy of cannabis in painful DN showed it to be no more efficacious than placebo. The main limitations of this study were the small sample size and the use of concomitant medications which may have attenuated the analgesic response to sativex. In a subsequent study adopting a different trial design, Toth et al. (2012) reported evaluated add-on treatment of oral cannabinoid, nabilone, for refractory painful DN. They conducted a single center, enriched enrolment, placebo controlled, randomized withdrawal study. 37 subjects with pain scores greater than 4 (0–10 scale) received, single blinded adjuvant nabilone for 4 weeks. Subjects achieving greater than 30% pain relief (responders) were then randomized to either continue on going nabilone treatment or switch to placebo. Although, the study failed to randomize the number of subjects estimated by initial sample size calculation, it reported significant reduction in pain intensity with nabilone treatment compared to placebo in "responders." The number of subjects with more than 30% reduction in pain from baseline to endpoint was 11/13 (85%) in the nabilone group compared to 5/13 (38%) in the placebo group ($p < 0.05$). There were also improvements in anxiety scores, well-being, and sleep disturbance with nabilone treatment. Demonstration of improvement in these multiple measures adds veracity to study findings. However, the overall effect size was small (0.67) for nabilone compared to placebo despite the enriched study design, which also limits the generalizability of study findings. Both studies are limited by the relatively small sample sizes, short duration of follow-up, and risk of inadvertent unmasking with the enriched trial design. Once again, larger, well designed, adequately powered studies are required to truly examine the analgesic effects of cannabinoids in painful DN.

SPINAL CORD INJURY

A systematic review and metaanalysis of drugs for neuropathic pain associated with spinal cord injury examined nine placebo control trials which included one small crossover trial which evaluated dronabinol ($n = 7$) (Snedecor et al., 2013; Rintala, Fiess, Tan, Holmes, & Bruel, 2010). In this pilot study, the effects of dronabinol were comparable to an active placebo diphenhydramine (an antihistamine which does not possess analgesic properties but mimics some of the possible side effects of cannabinoids). On average, dronabinol was no more effective than diphenhydramine for relieving chronic neuropathic pain below the level of injury.

There have been very few head-to-head studies of cannabinoids with other analgesic treatments in neuropathic pain. One notable study compared dihydrocodeine and nabilone in a randomized, double blind, crossover trial of 14 weeks duration (Frank, Serpell, Hughes, Matthews, & Kapur, 2008). Ninety six subjects with neuropathic pain (confirmed on clinical examination) of mixed etiologies (majority 42/96 were nerve injury postsurgery) were randomized. There was a high drop-out rate which can be explained partially by the crossover design. The weak opioid dihydrocodeine was found to provide better pain relief than the cannabinoid in the treatment of chronic neuropathic pain [mean difference in 10.0 cm VAS between nabilone and dihydrocodeine was in favor of the latter: 0.6 cm (95% CI: 1.4–10.5), $p = 0.01$]. Dihydrocodeine use was also accompanied by fewer side effects, although no major adverse events occurred for either drug. Overall, there is a lack of clinical studies as well as a dearth

of comparative data with different pharmacologic therapies. As such, the effectiveness of cannabinoids in the treatment of other neuropathic pain remains unproven.

SIDE EFFECTS

Side effects were reported in all studies in a proportion of patients receiving cannabinoids. In the recent systematic review of cannabinoids in chronic noncancer pain, of the 18 trials examined there were no serious adverse events (Lynch & Campbell, 2011). Drug-related adverse events were generally described as well tolerated, transient or mild to moderate. Most frequently reported side effects were dizziness, loss of balance, feelings of intoxication, dry mouth, gastrointestinal effects, sedation, and hunger. In the longest extension study (up to three years) to date these side effects were reported by 90% of patients and no tolerance was observed (Wade, Makela, House, Bateman, & Robson, 2006). Most clinical studies however treated patients for less than 6 months and report a greater proportion of patients discontinuing medications because of adverse events in the active treatment group compared to placebo. Data on the symptoms that cause withdrawal of medications are often incomplete. Among patients treated with cannabinoids, this could either be a direct result of adverse events related to the drug or an indirect effect caused by interactions with other medications being taken, especially opiates for pain or a combination of both (Sutin & Nahas, 1999). Hence, adverse events are a significant concern with cannabinoid use especially in high risk populations with multiple medical comorbidities and polypharmacy. Hence, individual circumstances (medical and social) should be carefully considered when selecting potential patients for treatment. If medical use is likely to be long-term, patients should be warned that the adverse effects of long-term use are unclear, including the risk of dependence and cognitive impairment. It may be sensible to refer patients to specialist management of the condition, where trial of cannabinoids might be undertaken (Farrell, Buchbinder, & Hall, 2014).

FUTURE CLINICAL STUDIES

As highlighted earlier, there is a need for more robust, well-powered, randomized controlled clinical trials of cannabinoids (either vs placebo or head-to-head studies against established neuropathic pain treatments) in different models of neuropathic pain. Based on the currently available published literature, cannabinoids have at best only a modest effect on neuropathic pain, comparable to other established pharmacological therapies. One possible reason for this may be related to the fact that in most studies a summative pain score is used as the primary outcome. This does not sufficiently consider the heterogeneity of neuropathic pain syndromes. Hence, a comprehensive assessment of symptoms and signs of pain could be a more sensitive way than an overall assessment of pain in demonstrating and characterizing the effects of a given pharmacological treatment (Attal et al., 2011; Baron, Förster, & Binder, 2012). For example, studies have demonstrated that morphine and lidocaine act differently on different neuropathic pain symptoms and signs as captured using quantitative sensory testing and/or neuropathic pain questionnaires that better quantify the heterogeneity of neuropathic pain syndromes (Attal et al., 2002, 2000). A post-hoc analysis performed in the Combination versus monotherapy of pregabalin and duloxetine in diabetic neuropathy study (COMBO-DN) showed that adding pregabalin to existing duloxetine treatment seemed to have benefited those with pressing pain and evoked pain; whereas increasing the dose of duloxetine appeared more beneficial for parethesic/dysesthesic symptoms (Bouhassira et al., 2014). In the context of cannabinoids, this hypothesis is best supported by the recent demonstration that these agents show greater reduction in mechanical/thermal hyperalgesia and tactile allodynia than placebo. Future studies should explore these hypotheses as this might lead to more stratified treatment and potentially to personalized pain therapy where cannabinoids are most effective.

Finally, most studies in neuropathic pain conducted to date have assessed the efficacy of cannabinoids over a relatively short duration. The key question, therefore, is the long-term safety and efficacy of these agents. Large scale, long-term observational outcome studies or record linkage studies based on the use of cannabinoids for medically approved indications such as multiple sclerosis may quantify the risks and benefits of long term use (Farrell et al., 2014). In a recent opinion piece, Farrell et al. (2014) searched key clinical trials registers including US ClinicalTrials.gov, EU Clinical Trials Registry, and Australian and New Zealand Clinical trials Register and found 10 prospective studies of cannabinoids but was unable to identify key studies that would provide important information on the long-term safety and efficacy of these agents in the near future.

CONCLUSIONS

Chronic neuropathic pain is a common and poorly managed condition. Currently available treatments are often ineffective with side effect profiles that limit their use. This leads to significant morbidity and poor quality of life. In this context, patients with chronic neuropathic pain require access to better therapeutic care and additional treatment options. Although there is considerable anecdotal and preclinical trial evidence supporting

an antinociceptive role for cannabinoids, outcomes in the limited range of clinical trials that have been performed thus far have been largely disappointing. Most clinical studies have focused on narrow clinical indications with modest effect sizes not dissimilar to many of the currently used neuropathic pain treatments. As a result, the use of cannabinoids is restricted to specialist use for only a limited range of conditions. Adequately powered, placebo-controlled or head-to-head, multicenter, clinical studies in neuropathy pain models according to predetermined FDA/EMEA guidelines are required in order to fully examine the safety and efficacy on pain and functional measures of these compounds.

MINI-DICTIONARY

Adverse events These are predetermined recorded events that occur to subjects during participation in a clinical trial. Example of such events include hospital admission, injury or harm and death.
Allodynia This is a description of a type of painful symptom that can accompany nerve damage. It occurs when pain is evoked during nonpainful stimulus (eg, soft touch).
Electrical spinal cord stimulation This is a treatment of very severe neuropathic pain in the lower limbs. Low voltage current is delivered by electrodes are placed near the spinal cord. The duration and intensity of the current can be controlled using a portable, remote-control, radio-receiver unit.
Hyperalgesia This is a description of a type of painful symptom that can accompany nerve damage. It occurs when a normally painful stimulus (pressure pain) is report as very painful.
Myalgia Symptom of muscle aches and pains.
Neuromodulation Nonpharmacological treatment of neuropathic pain which can include nerve ablation or electrical spinal cord stimulation.
Neuropathic pain Chronic pain that results from nerve damage. This results in a particular description of either spontaneous or evoked painful symptoms, such as, burning, sharp shooting, or deep aching pain.
Paresthesia This is a description of a type of painful symptom that can accompany nerve damage. It is a description of symptoms of pins and needles or tingling.
Postherpetic neuralgia Nerve damage that follow herpes viral infection.
Post-hoc analysis Secondary or follow-up analysis performed on clinical trial data. This type of analysis of often not planned at the start of the study but informed by its outcome.
Randomized controlled trials These are clinical trials which are often conducted to investigate the effectiveness of a drug. Subjects are randomized to two (sometimes more) treatment arms to compare the effects of the drug under investigation against either placebo or current treatment.
Trigeminal neuralgia Neuropathic pain/symptoms that occurs as a result of damage to the trigeminal nerve.

CHAPTER

95

Cannabis for Basal Ganglia Disorders (Parkinson Disease and Huntington Disease)

O.M.E. Abdel-Salam

Department of Toxicology and Narcotics, National Research Centre, Dokki, Greater Cairo, Egypt

SUMMARY POINTS

- This chapter summarizes the current clinical and experimental data related to the effect of cannabis and/or cannabinoids on motor dysfunction in basal ganglia movement disorders.
- In patients with Parkinson disease (PD), there are data to suggest some benefit for cannabis or cannabis-based medicines on motor symptoms and L-dopa-induced dyskinesia.
- Rodent models of PD suggest a modulatory effect for cannabinoid receptor agonists on L-dopa-induced dyskinesia
- Limited data in Huntington disease (HD) patients suggest a benefit from cannabidiol, herbal cannabis, nabilone, or Sativex.
- Cannabinoids showed mostly a neuroprotective effect in animal models of PD or HD.
- There is evidence for cannabinoid receptor 2 in decreasing activation of microglia cells and neuroinflammation.

KEY FACTS OF PARKINSON DISEASE

- The disease was first described by James Parkinson in 1817.
- It mainly occurs in old age but, in 5% of cases, young persons can be also affected.
- The patients have difficulty and slowness in initiating movement, muscle stiffness, and hand tremor.
- It is due to a gradual and progressive loss of brain cells that synthesize and release dopamine.
- Treatment thus is based on levodopa, a precursor of dopamine and other drugs that increase dopamine brain availability.
- With advancing disease, more cells are lost and the response to L-dopa frequently decreases.

KEY FACTS OF HUNTINGTON DISEASE

- It was described in 1872 by George Huntington.
- This is a rare disease which is genetically transmitted.
- It begins in midlife and progresses over 15–20 years.
- Patients may experience involuntary and unpredictable irregular jerky movements of the limbs and/or body.
- Patients deteriorate over time and emotional and personality changes occur along with the motor dysfunction.
- There is no cure but there are medications which help to lessen the manifestations of the disease.

LIST OF ABBREVIATIONS

2-AG	2-Arachidonoylglycerol
ACEA	Arachidonyl-2-chloroethylamide

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00110-1

AEA	*N*-arachidonoylethanolamine (anandamide)
AIMs	Abnormal involuntary movements
CB1	Cannabinoid receptor subtype 1
CB2	Cannabinoid receptor subtype 2
FAAH	Fatty acid amide hydrolase
GABA	Gamma aminobutyric acid
GPe	Globus pallidus external
GPi	Globus pallidus internal
HD	Huntington disease
iNOS	Inducible nitric oxide synthase
JNK	c-Jun-NH2-terminal kinase
L-dopa	Levodopa
MPP+	1-Methyl-4-phenylpyridinium
MPTP	1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine
3NP	3-Nitropropionic acid
PD	Parkinson disease
PI3K	Phosphatidylinositol 3-kinase
PRARγ	Peroxisome proliferator activated receptor gamma
SNc	Substantia nigra pars compacta
SNr	Substantia nigra pars reticulata
STN	Subthalamic nucleus
TH-ir	Tyrosine hydroxylase immunoreactive
Δ^9-THC	**Δ^9**-Tetrahydrocannabinol
THC	Tetrahydrocannabinol
Δ^9-THCA	Δ^9-Tetrahydrocannabinolic acid
Δ^9-THCV	Δ^9-Tetrahydrocannabivarin
TNF-α	Tumor necrosis factor-alpha
TRPV1	Transient receptor potential vanilloid type-1

INTRODUCTION

The basal ganglia are a group of related subcortical nuclei. These are the striatum (caudate nucleus and putamen), the internal and external segments of the globus pallidus (GPi and GPe), the substantia nigra pars reticulata (SNr), and pars compacta (SNc), and the subthalamic nucleus (STN). These structures are components of circuits involving portions of the cerebral cortex, thalamus, and brain stem. The basal ganglia have significant influence on motor function in that it controls and smoothens the execution of movements (Wichmann & DeLong, 2006). Parkinson disease (PD) is a progressive neurodegenerative disorder, the prevalence of which increases with age, with a peak age of onset around 60 years. There is a selective and progressive loss of dopamine-producing neurons of the SNc. The loss of these neurons produces a marked deficit of dopamine content in the striatum, and a consequent disruption of the basal ganglia circuits (Fig. 95.1). This leads to the characteristic motor abnormalities, namely rigidity, bradykinesia, tremor, and postural instability (Gunzler, Schoenberg, Riley, Walter, & Maciunas, 2011). Huntington disease (HD) is a relatively rare neurodegenerative disease with prevalence 10 per 100,000. It is genetically transmitted as an autosomal dominant trait. The disorder occurs typically in middle to late age, is characterized by insidious progression of motor dysfunction, cognitive, emotional, and behavioral deficits, and results in death within 15–20 years after the onset of symptoms. Motor dysfunction; initially include chorea and other hyperkinetic movements (myoclonic jerks and dystonia). Later bradykinesia, incoordination, and rigidity become more evident. The core pathology is the loss of medium-sized spiny GABAergic projection neurons in the striatum. Striatal degeneration is the first and most obvious neuropathology in the early stages of the disease. Later, there is profound loss of neurons in other brain regions, particularly the neocortex (Walker, 2007).

Cannabinoid CB1 receptors are expressed at high levels in the basal ganglia structures (striatum, GP, SNc). In these regions, CB1 receptors are primarily located on GABAergic and glutamaregic striatal nerve terminals, and their stimulation with Δ^9-THC or synthetic agonists inhibited synaptic release of GABA and glutamate in the striatum (Gerdeman & Fernández-Ruiz, 2008). Anandamide, and 2-arachidonoylglycerol (2-AG), the endogenous ligands for the CB1 receptor are present in the GP and SN, which suggests a role for endocannabinoids in control of motor activity (Di Marzo, Hill, Bisogno, Crossman, & Brotchie, 2000).

The present chapter aims to review the current available evidence pertaining to the effect of cannabis and/or cannabinoids in basal ganglia movement disorders namely PD and HD.

THE ENDOCANNABINOID SYSTEM IN PARKINSON DISEASE

There is evidence that the endocannabinoid system is altered in PD. In caudate nucleus and putamen from patients with PD postmortem and in MPTP-lesioned marmosets, CB1 receptor binding increased and this was amenable to L-dopa treatment (Lastres-Becker et al., 2001). Hurley, Mash, and Jenner (2003) found decreased CB1 receptor mRNA expression in the caudate nucleus, anterior dorsal putamen and GPe in PD brain post-mortem. Van Laere et al. (2012), however, using positron emission tomography (PET) with the CB1-selective radioligand [(18)F] MK-9470 and magnetic resonance imaging, found an absolute decrease in CB1 availability in SN, but a relative increase in nigrostriatal, mesolimbic, and mesocortical dopaminergic projection areas in PD patients.

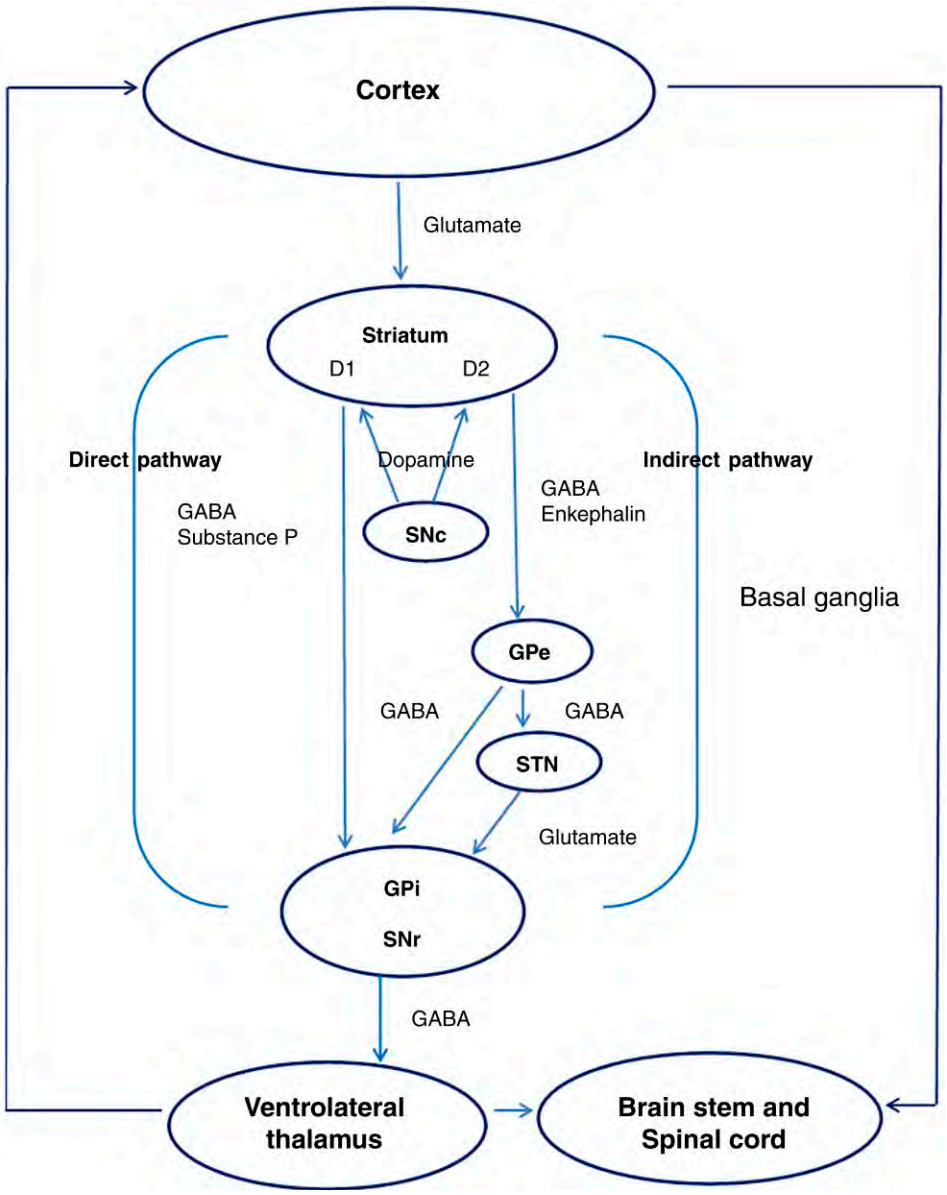

FIGURE 95.1 Schematic representation of the organization of basal ganglia–thalamocortical circuits. By means of direct and indirect pathways that run from the input structure (striatum) to the output nuclei (GPi, GPe, and SNr) the basal ganglia act to disinhibit or facilitate related thalamocortical neurons, and ultimately facilitate or inhibit movements initiated in the cortex. Neurotransmitters involved in each pathway are shown. *GABA*, Gamma aminobutyric acid; *GPe*, globus pallidus external; *GPi*, globus pallidus internal; *SNc*, substantia nigra pars compacta; *SNr*, substantia nigra pars reticulata; *STN*, subthalamic nucleus.

EFFECT OF CANNABINOIDS IN PARKINSON DISEASE

Human Studies

Venderová, Růzicka, Vorísek, and Visnovský (2004) found that PD subjects who used cannabis to alleviate symptoms reported mild or substantial alleviation of their symptoms in general (45%), improvement of resting tremor (30.6%), bradykinesia (44.7%), and of muscular rigidity (37.7%). Cannabis, however, worsened symptoms in 4–7% of patients. Most patients consumed a half teaspoon of fresh or dried leaves orally, usually with meals and mostly once a day (Venderová et al., 2004).

6-HYDROXYDOPAMINE MODEL OF PARKINSON DISEASE

In 6-hydroxydopamine-lesioned rats, the daily administration of Δ^9-THC or cannabidiol (a nonpsychotropic cannabinoid) for 2 weeks conferred significant protection against the toxin-induced decreases in dopamine, and TH-ir in the lesioned striatum. These effects were ascribed to an antioxidant properties or glial modulating effects (Lastres-Becker, Molina-Holgado, Ramos, Mechoulam, & Fernández-Ruiz, 2005). Other authors observed a small recovery in the dopamine depletion in the lesioned side after treatment with HU-308, a CB2 receptor agonist, but not after the CB1 receptor agonist ACEA or the nonselective agonist WIN55,212-2 (García-Arencibia et al., 2007). *N*-(4-hydroxyphenyl)-arachidonamide (AM404), an inhibitor of endocannabinoid uptake (which enhances anandamide availability) was found to have antiparkinsonian effects, possibly through stimulation of striatal 5-HT(1B) serotonin receptor function (Fernandez-Espejo et al., 2004) or possibly due to an antioxidant properties being derived from the phenolic group in its structure (García-Arencibia et al., 2007). In rats, adrenal phaeochromocytoma PC12 cells, the endocannabinoid anandamide inhibited 6-hydroxydopamine-induced apoptosis (caspase-3 activity), independently of cannabinoid receptors or TRPV1. This antiapoptotic effect of anandamide involved activation of phosphatidylinositol 3-kinase and inhibition of JNK signaling (Mnich, Finn, Dowd, & Gorman, 2010).

Motor inhibition due to 6-hydroxydopamine in rats was also alleviated following the acute administration of Δ^9-THCV, a phytocannabinoid with very weak or no psychotropic effects. Moreover, the loss of TH-ir neurons decreased by its chronic administration. These effects of Δ^9-THCV involved changes in glutamatergic transmission and an antioxidant effect (García et al., 2011).

Rimonabant, a selective antagonist of CB1 receptors, displayed antihypokinetic activity at dose of 0.1 mg/kg in 6-hydroxydopamine-lesioned rats. Rimonabant, however, had no effect on the dopamine deficit or on GABA or glutamate transmission in the caudate-putamen (González et al., 2006). In the same model, rimonabant (0.1 and 1 mg/kg) caused marked striatal glutamate release. Rimonabant (1 mg/kg) caused a slight increase in striatal glutamate release in control rats (García-Arencibia, Ferraro, Tanganelli, & Fernández-Ruiz, 2008). Rimonabant was also found to augment the therapeutic effect of a moderate, but not a high, dyskinetic dose of L-dopa (Kelsey, Harris, & Cassin, 2009).

In cultures of mouse cerebellar granule cells exposed to 6-hydroxydopamine, treatment with the nonselective cannabinoid agonist HU-210 increased cell survival by regulating glial influence to neurons (Lastres-Becker et al., 2005). Interestingly, the cannabinoid HU 210 and Δ^9-THC increased TH expression and dopamine content in the striatum of normal rats (Bosier et al., 2012).

1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE MODEL OF PARKINSON DISEASE

It was found that lack of both CB1 and CB2 receptors did not alter the susceptibility to the neurotoxic effect of MPTP in mice (Simkins et al., 2012). Genetic ablation of CB2 receptors, however, exacerbated MPTP toxicity (Price et al., 2009). The cannabinoid agonist WIN55,212-2 protected against nigrostriatal cell loss induced by MPTP. This effect was independent of CB1 cannabinoid receptor activation, but involved reduced MPTP-induced microglial activation (via CB2 cannabinoid receptor activation) (Price et al., 2009). In CB1 knockout mice, WIN55,212-2 was also neuroprotective against MPTP toxicity (Chung et al., 2011). WIN55,212-2 and HU210 increased survival of dopaminergic SN neurons and improved motor function. This effect appears to involve CB1 receptor-mediated inhibition of NADPH oxidase reactive oxygen species production and reduced expression of proinflammatory cytokines from activated microglia (Chung et al., 2011). Suppression of microglia-mediated inflammation might therefore underlie some of the neuroprotective effects ascribed for cannabinoids.

In SH-SY5Y neuroblastoma cells exposed to MPP+ (a complex I inhibitor), lactacystin and paraquat, Δ^9-THC and also WIN55,212-2 protected against toxin-induced cell death (though not α-tocopherol and butylhydroxytoluene, nabilone, and cannabidiol). The effect of Δ^9-THC depended on CB1 receptors and involved increased activation of PRARγ (Carroll, Zeissler, Hanemann, & Zajicek, 2012). In murine mesencephalic culture exposed to MPP+, Δ^9-THCA, Δ^9-THC and cannabidiol showed antioxidant effect and protected dopaminergic neurons in culture against MPP(+)-induced cell death. THC increased dopaminergic cell count. Cannabidiol, however, decreased cell count viability, and decreased TH-ir neurons (Moldzio et al., 2012).

ROTENONE MODEL OF PARKINSON DISEASE

In mouse, mesencephalic cultures and neuroblastoma cells, Δ^9-THC or cannabidiol decreased the rotenone-induced degeneration of dopaminergic cells along with significant restoration of glutathione levels. Either cannabinoid failed to scavenge superoxide radicals in neuroblastoma cells exposed to rotenone (Pöhn et al., 2012). In vivo, cannabis extract (20 mg/kg, expressed as Δ^9-THC, subcutaneously daily) given for 2 weeks in mice,

failed to reduce nigrostriatal damage due to rotenone, lipopolysaccharide or both (Abdel-Salam, Omara, El-Shamarka, & Hussein, 2013) (Tables 95.1 and 95.2).

PRIMATE MODELS OF PARKINSON DISEASE

In cynomolgus monkeys, the cannabinoid agonist levonantradol decreased general and locomotor activity and increased bradykinesia, while tetrahydrocannabinol increased the bradykinesia only. Rimonabant, however, had no significant effects compared with vehicle. Moreover, the authors found that the rimonabant failed to alleviate the motor deficits in an early and advanced stage of MPTP-induced parkinsonism (Meschler, Howlett, & Madras, 2001). In the MPTP-marmoset model, Δ^9-THC (4 mg/kg) improved locomotor activity and hand-eye coordination performance (van Vliet, Vanwersch, Jongsma, Olivier, & Philippens, 2008). In L-DOPA-primed MPTP-treated rhesus monkeys with moderate and severe parkinsonism, selective CB1 antagonism increased the duration responses to L-dopa by 30% (Cao et al., 2007). In the same model, systemic administration

of rimonabant displayed antiparkinsonian actions (71% increase in motor activity) (van der Stelt et al., 2005).

CANNABINOIDS AND L-DOPA-INDUCED DYSKINESIA

The mainstay of PD treatment is L-dopa (the biosynthetic precursor of dopamine). Several years after L-dopa, however, a significant proportion of patients experience motor complications, particularly end-of-dose motor fluctuations and dyskinesias or uncontrolled involuntary hyperkinetic movements which most commonly represent a peak-dose effect (Table 95.3). In L-dopa-induced dyskinesia, there is overactivity of the direct striatal output pathway (Fabbrini, Brotchie, Grandas, Nomoto, & Goetz, 2007).

Human Studies

Improvement of L-dopa-induced dyskinesia has been reported in 14.1% of PD subjects taking fresh or dried cannabis leaves orally (Venderová et al., 2004). In another study, oral cannabis extract given for 4 weeks had no effect on L-dopa induced dyskinesia in PD patients (Carroll et al., 2004). In a randomized, double-blind, placebo-controlled, crossover trial in seven PD patients, L-dopa-induced dyskinesia was significantly reduced by the cannabinoid receptor agonist nabilone (Sieradzan et al., 2001).

Studies in Nonhuman Primates

In the MPTP-lesioned marmoset model of PD, nabilone (0.1 mg/kg) decreased levodopa-induced dyskinesia. Nabilone (0.03 mg/kg) also increased the duration of antiparkinsonian action of levodopa by 76% (Fox et al., 2002). L-dopa-primed MPTP-treated marmosets, coadministration of L-dopa and CB1 receptor antagonist rimonabant resulted in significantly less dyskinesia compared with L-dopa alone (van der Stelt et al., 2005). In the same model, a selective cannabinoid CB1 antagonist (CE) had no effect on the L-dopa-induced dyskinesia (Cao et al., 2007).

EXPERIMENTAL DATA

Studies in rodent models of PD suggested that stimulation of CB1 receptors exerts antidyskinetic effects. Thus, the cannabinoid agonist WIN55,212-2 decreased the AIMs in the 6-hydroxydopamine-lesioned rat treated

with L-dopa (reversed by the CB1 antagonist rimonabanat (SR141716A) (Ferrer, Asbrock, Kathuria, Piomelli, & Giuffrida, 2003, Morgese et al., 2007). The antidyskinetic properties of WIN55,212-2 involved changes of dopamine and glutamate outputs across brain hemispheres (Morgese et al., 2009). In the same model, WIN55212-2 ameliorated L-dopa-induced AIMs and reversed the associated elevation in striatal protein kinase A activity via CB1-mediated mechanism (Martinez, Macheda, Morgese, Luigia, & Giuffrida, 2012). WIN55,212-2, however, failed to alter fetal cell graft-induced dyskinesia in response to an amphetamine challenge in the 6-hydroxydopamine lesioned rat (Smith et al., 2012). In 6-hydroxydopamine-lesioned rats made dyskinetic by daily L-dopa injections, the cannabinoid receptor agonist, HU210 reduced AIMs. This however was achieved at a dose which impaired normal motor functioning (Walsh et al., 2010). Morgese et al. (2007) suggested that CB1 and TRPV1 receptors play opposite roles in L-dopa-induced dyskinesias- and that the antidyskinetic effect of FAAH

inhibitors (which increase anandamide concentration in basal ganglia) is masked by the action of anandamide on TRPV1 receptors. In the reserpine-treated rat, the dyskinetic activity of L-dopa decreased following treatment with rimonabant or the CB1 agonist WIN55,212-2 which also exerted antiparkinsonian effect at a higher dose. This suggested that both cannabinoid agonists and antagonists are useful in L-dopa-induced dyskinesia (Segovia et al., 2003). Other researchers, however, found that in the nondyskinetic 6-hydroxydopamine lesioned rats treated with L-dopa injections, rimonabant precipitated certain subtypes of AIMs (Walsh et al., 2010).

CANNABINOID SIGNALING IN HUNTINGTON DISEASE

Studies revealed alterations in cannabinoid receptor density in the basal ganglia in brains from HD patients, and in transgenic and toxic rodent models (Table 95.4). The loss of cannabinoid receptor occurs early in the course of the disease and is largely thought to be involved in the pathogenesis of HD (Lastres-Becker, Gómez, De Miguel, Ramos, & Fernández-Ruiz, 2002a; Dowie et al., 2009). In brains of HD patients there is severe loss (97.5%) of cannabinoid receptor binding on striatonigral terminals in SNr (Glass, Faull, & Dragunow, 1993). Early and widespread profound reduction of CB1 availability throughout the gray matter of the cerebrum, cerebellum, and brain stem in HD patients was also demonstrated in vivo using PET studies with CB1 ligand. Moreover, CB1 availability in the prefrontal and premotor cortex inversely correlated with the number of CAG repeats in the huntingtin gene (Van Laere et al., 2010).

Fatty acid amide hydrolase is the enzyme that degrades the endocannabinoid anandamide. In peripheral lymphocytes from HD patients the activity of this enzyme was found to be decreased by >90% compared to healthy subjects. Accordingly, anandamide levels were elevated (by ~sixfold). Moreover, defective enzyme activity was observed in pre-HD patients and in brains of HD patients (Battista et al., 2007). Studies also indicated alterations in the brain levels of endocannabinoids in genetic mouse models of HD (Dowie et al., 2009; Blázquez et al., 2011).

EFFECT OF CANNABINOIDS IN HUNTINGTON DISEASE

Clinical Data

One study involving three patients with HD reported improvement in choreic movements by orally administered cannabidiol. The cannabinoid was administered initially at 300 mg/day and increased 1 week later to 600 mg/day for the next 3 weeks. Choreic movements improved by 5–15% after the first week and by 20–40% after the second week of cannabidiol, and this remained stable for 2 more weeks (Sandyk, Consroe, Stern, & Snider, 1986). In a double-blind, randomized crossover study in 15 neuroleptic-free patients with HD, cannabidiol given daily for 6 weeks was without effect relative to placebo (sesame oil). Cannabidiol was administered orally at an average daily dose of about 700 mg/day (10 mg/kg per day) (Consroe et al., 1991). In one patient with HD disease patient, improvement in behavior (irritability), and reduction of chorea coincided with smoking cannabis. This was maintained by daily administration of 1 mg/kg of nabilone (an orally active synthetic THC) (Curtis & Rickards, 2006). Nabilone was evaluated in a double-blind, placebo-controlled, crossover study where 44 randomized patients received either nabilone (1 or 2 mg) followed by placebo ($n = 22$), or placebo followed by nabilone ($n = 22$). Nabilone was found of benefit in improving chorea and cognition (Curtis, Mitchell, Patel, Ives, & Rickards, 2009). A double blind, crossover, placebo-controlled, phase II trial of Sativex conducted on 24 patients reported improvement in symptoms (Caldentey et al., 2012).

3-NITROPROPIONIC ACID-INDUCED STRIATAL DAMAGE

Increasing CB1 receptor activity might improve the hyperkinetic manifestations early in the disease. One approach involved augmenting the residual CB1 receptor activity by inhibiting endocannabinoid reuptake or hydrolysis (Lastres-Becker et al., 2002a,b, 2003b). In this respect, AM404, an inhibitor of endocannabinoid uptake, was found to reduce motor disturbances, and improve the deficits in GABA and dopamine observed in basal ganglia in the early phase of hyperactivity in 3-nitropropionic acid (3NP)-injected rats (Lastres-Becker et al., 2002b). These effects of AM404 were reversed by the TRPV1 antagonist capsazepine, while the improvements in neurochemical deficits in the caudate-putamen caused by AM404, were abolished by rimonabant. In contrast, VDM11 or AM374, two selective inhibitors or the endocannabinoid reuptake or hydrolysis, respectively, failed to reduce hyperkinesia in 3NP-lesioned rats, while CB1 receptor stimulation (with CP55,940) was antihyperkinestic. Interestingly, capsaicin, a TRPV1 receptor agonist exerted a strong antihyperkinetic activity and attenuated the reductions in dopamine and GABA transmission provoked by 3NP (Lastres-Becker et al., 2003b). Thus compounds with VR1 stimulant activity would be of more value in treating hyperkinesia in this case (Lastres-Becker et al., 2003b). Consistent with this notion, arvanil

√√√, Neuroprotective; ↑, increase; ↓, decrease.

(*N*-arachidonoyl-vanillyl-amide), an endocannabinoid/vanilloid structural "hybrid," reduced the hyperkinesia (increased ambulation), and also increased the inactivity in 3NP-lesioned rats. Arvanil increased glutamate content in globus pallidus and thus enhanced excitatory transmission at this region (though in control rats, it enhanced pallidal GABA-ergic transmission (de Lago, Urbani, Ramos, Di Marzo, & Fernández-Ruiz, 2005).

On the other hand, it has been observed that neurodegeneration caused by injection of malonate (complex II inhibitor) into the rat striatum decreased after inhibition of striatal 2-AG biosynthesis by an inhibitor of diacylglycerol lipase (the enzyme that catalyze 2-AG biosynthesis). This effect is likely to be mediated by the proneuroinflammatory prostaglandin E2 glyceryl ester formed from COX-2-mediated oxygenation of 2-AG. In contrast, inhibition of 2-AG inactivation by monoacylglycerol lipase exacerbated the malonate-induced striatal damage (Valdeolivas et al., 2013). In the late akinetic phase of 3-NP-treated rats, administering rimonabant had no effect on akinesia (Lastres-Becker et al., 2002a). In 3-NP-treated rats, Δ^9-THC- and cannabidiol-enriched botanical extracts attenuated neuronal loss, GABA deficiency, the neurotrophin IGF-1 expression, and the upregulation of iNOS, while reversing the reduction in superoxide dismutase-1 expression (Sagredo et al., 2011). It was also found that, cannabidiol (though not the CB1 agonist ACEA or the CB2 agonist HU-308) reversed 3NP-induced reductions in mRNA levels substance P, neuronal-specific enolase, and superoxide dismutase-2 (which are markers of striatal GABAergic projection neurons). Cannabidiol effects were independent of CB1, TRPV1 or adenosine A2A receptors (Sagredo et al., 2007). Thus it is possible to assume that the beneficial effects observed with Sativex are due to its cannabidiol content.

MALONATE-INDUCED STRIATAL DAMAGE

In rats, treatment with Δ^9-THC or with SR141716 (rimonabant) increased striatal damage due to malonate (Lastres-Becker et al., 2002a). In mice, CB2 receptor upregulation occurred in response to malonate injection. Mice deficient in CB2 receptors exhibited increased striatal degeneration caused by malonate. Neither the CB1 agonist arachidonyl-2-chloroethylamide nor cannabidiol decreased striatal neurochemical deficits induced by malonate. Striatal damage, however, decreased upon treatment with HU-308 (CB2 receptor agonist), which also lessened the decreases in GABA, dopamine and neuron-specific enolase mRNA. The protective effect of HU-308 appeared to involve decreased TNF-α level in the striatum (Sagredo et al., 2009). In malonate-lesioned rats, treatment with a combination of phytocannabinoids (Δ^9-THC:cannabidiol = 1:1) reduced oedema and neurodegeneration, attenuated glial activation and both iNOS and IGF-1 expressions. These effects of the Sativex-like preparation were CB1 and CB2 receptor-dependent (Valdeolivas et al., 2012).

QUINOLINIC ACID-INDUCED STRIATAL DAMAGE

In this model, intrastriatal WIN 55,212-2 attenuated the striatal damage (Pintor et al., 2006). WIN 55,212-2 increased the expression of neuronal cytoskeletal proteins, synuclein expression, number of synaptic vesicles, and thickness of the postsynaptic densities in rat brain. This sprouting phenomenon observed after 2 weeks therapy of WIN 55,212-2 is likely to be involved in the neuroprotective effects of cannabinoids (Tagliaferro et al., 2006). Quniolinic acid-induced striatal neuroinflammation, loss of neurons and motor symptoms also decreased following treatment with selective CB2 receptor agonists (Palazuelos et al., 2009).

In Vitro Studies

In cell culture model of striatal neurons, treatment with ACEA or anandamide increased CB1 promoter activity, mRNA, and protein expression. Moreover, in cells expressing the mutant huntingtin protein, cannabinoid treatment increased CB1 mRNA levels, improved ATP production, increased the expression of brain derived neurotrophic factor-2, and the mitochondrial regulator PGC1α, and reduced spontaneous GABA release (Laprairie, Kelly, & Denovan-Wright, 2013).

GENETIC MODELS OF HUNTINGTON DISEASE

The administration of Δ^9-THC to mice expressing human mutant huntingtin exon 1 exerted a therapeutic effect (Blázquez et al., 2011). In R6/1 transgenic mice, however, eight weeks of daily treatment with the cannabinoid agonists Δ^9-THC and HU210, or the inhibitor of endocannabinoid metabolism URB597 did not alter the progressive deterioration in motor performance. The cannabinoid agonists did not alter the ligand binding of cannabinoid CB1, dopamine D1, D2, serotonin 5HT2A or GABA (A) receptors, nor CB1 or fatty acid amide hydrolase mRNA expression (Table 95.5). URB597, however, preserved striatal CB1 receptors. Surprisingly, HU210 increased ubiquitinated aggregates in the striatum, suggesting a different effect CB1 receptor agonists and endocannabinoids on disease process (Dowie et al., 2010). In pheochromocytoma cells expressing exon 1 of mutant

TABLE 95.5 Effect of Cannabinoids in Genetic Models of Huntington Disease

Model	Agent	Neuroprotection	Suggested mechanism/CB receptor involvement	Study
R6/2 genetic HD mouse model mice	$CB2^{-/-}$	√√√ Accelerates the onset of motor deficits ↑ Severity of motor deficits	CB2 receptors are neuroprotective	Bouchard et al. (2012)
R6/2 transgenic HD mouse model	$CB2^{-/-}$	↑ Motor deficits ↓ Lifespan	↑ Microglial activation (CB2 receptors ↓ microglial activation)	Palazuelos et al. (2009)
R6/2 transgenic HD mouse model	CB2 receptor agonist	√√√ ↓Motor deficits ↓Synapse loss ↑ Lifespan	↓ Interleukin-6 (IL-6) blood levels and neuroinflammation (CB2 receptor mediated)	Bouchard et al. (2012)
R6/2 transgenic HD mouse model	Δ^9-THC	√√√ ↓Motor deficits ↓Synapse loss	↓ Excitotoxic damage (CB2 receptor mediated)	Blázquez et al. (2011)
R6/1 transgenic HD mouse model	HU210 (nonselective cannabinoid agonist)	↑ Seizure events ↑ Ubiquitinated aggregates in striatum	—	Dowie et al, (2010)
R6/1 transgenic HD mouse model	Δ^9-THC	↑↓ Motor deficits	—	Dowie et al. (2010)
R6/1 transgenic HD mouse model	URB597 (inhibitor of endocannabinoid metabolism)	↑↓ Motor deficits Preserved striatal CB1 receptors	—	Dowie et al. (2010)
R6/2 transgenic HD mouse model	$CB2^{-/-}$	↑ Motor deficits ↓ Lifespan	↑ Microglial activation	Palazuelos et al. (2009)
Striatal neurons in culture expressing the mutant huntingtin protein	ACEA (selective CB1 receptor agonist) Anandamide	√√√	↑ ATP production ↑ BDNF-2 expression ↑ Mitochondrial regulator PGC1α expression ↓ Spontaneous GABA release (CB1 receptor-mediated effects)	Laprairie et al. (2013)
Pheochromocytoma cells expressing exon 1 of mutant huntingtin	HU210 (nonselective cannabinoid agonist)	√ Small yet significant ↓ in cell death ↑ Mutant huntingtin aggregates	CB1 receptor mediated	Scotter et al. (2010)

√√√, Neuroprotective; ↑, increase; ↓, decrease; ↑↓, no effect.

huntingtin, HU210 also increased mutant huntingtin aggregates. This occurred despite a small, yet significant, protective effect for HU210 on mutant huntingtin-induced cell death. It was suggested that the protective potential of CB1 receptor stimulation is limited by coupling of CB1 to G-protein alpha subtype s (Gs) G-protein, the stimulation of cAMP formation and increased aggregate formation and that therapies selective for the G(i/o), ERK pathway are likely to be of benefit (Scotter, Goodfellow, Graham, Dragunow, & Glass, 2010).

Studies suggested a role for CB2 receptors in preventing neurodegeneration (Palazuelos et al., 2009; Bouchard et al., 2012). In R6/2 mice, genetic deletion of CB2 receptors, enhanced microglial activation, aggravated disease symptomatology and reduced mice lifespan. Moreover, in $CB2^{-/-}$ mice, quinolinic acid induced more striatal neurodegeneration and inflammation. CB2 receptor stimulation leads to decreased activation of microglia cells, the resident immune cells of the CNS (Palazuelos et al., 2009). Other researchers found increased IL-6 blood levels (though not TNF-α) in $CB2^{-/-}$ R6/2 mice. IL-6 levels decreased following treatment with a selective CB2 receptor agonist which also improved motor deficits, synapse loss, neuroinflammation, and extended mice life span, effects that were prevented by the selective CB2 receptor antagonist SR144528. These data suggested a role for peripherally released IL-6 in the neuronal damage and symptomatology in HD and which could be modulated by CB2 receptor signaling in peripheral immune cells (Bouchard et al., 2012).

MINI-DICTIONARY

Akinesia Absence of movement which occur in advancing PD.
Bradykinesia This describes difficulty in starting and slowness of voluntary movements.
Chorea Involuntary, spontaneous, irregular, and jerky movements.
Dystonia Excessive involuntary motor contractions resulting in unusual fixed postures lasting seconds to minutes.
Hyperkinesia Excessive, spontaneous, involuntary, irregular movements. It might be local involving the hands or more generalized involving the limbs and trunk.
L-dopa-induced dyskinesia Involuntary hyperkinetic movements that develop after years of L-dopa therapy. These are caused by excessive levels of dopamine in brain.
Rigidity Muscle stiffness or increased muscle tone resulting in increased resistance to movement.

Medical Cannabis for the Treatment of Inflammatory Bowel Disease

A. Lahat

Department of Gastroenterology, Chaim Sheba Medical Center, Tel-Hashomer, Israel

SUMMARY POINTS

- Crohn disease (CD) and ulcerative colitis (UC) are chronic inflammatory bowel diseases (IBD).
- While CD can affect the whole digestive system from mouth to anus, UC affects mainly the colon.
- Both diseases cause diminished life quality.
- The main symptoms in IBD include abdominal pain, diarrhea, and loss of appetite.
- Cannabis was shown in animal models to reduce intestinal motility and inhibit inflammatory processes.
- Cannabis was also shown to stimulate appetite and cause weight gain.
- Cannabis is a known potent analgesic.
- Clinical data assessing the utility of cannabis in treating IBD patients is only available from recent years.
- In small clinical studies, cannabis was shown to cause significant improvement in patients' abdominal pain and diarrhea.
- Cannabis was also shown to increase appetite, cause weight gain, and improved quality of life in IBD patients.
- More studies are warranted in order to assess the utility, indications, and contraindications to medical use of cannabis in IBD patients.

KEY FACTS OF IBD

- Crohn disease (CD) and ulcerative colitis (UC) are chronic inflammatory bowel diseases (IBD).
- The incidence and prevalence of IBD is rising. The diseases are more prevalent in Europe and in the US.
- The highest annual incidence of UC is 24.3 per 100,000 person-years in Europe, and the highest annual incidence of CD is 12.7 per 100,000 person-years in Europe.
- The highest reported prevalence values for IBD were in Europe (UC: 505 per 100,000 persons; CD: 322 per 100,000 persons) and North America (UC: 249 per 100,000 persons; CD: 319 per 100,000 persons).
- CD and UC are autoimmune diseases. Theirs cause is believed to be multifactorial—the result of the interaction of environmental and genetic factors.
- The main symptoms include abdominal pain, vomiting, diarrhea, rectal bleeding, and weight loss.
- Both diseases can cause major morbidity and diminished life quality.
- Treatment is individualized according to disease characters and severity. It mainly includes antiinflammatory drugs as 5-aminosalicylic acid (5 ASA), and immunosuppressive drugs as as prednisone, TNF inhibition, azathioprine methotrexate, or 6-mercaptopurine, etc.

LIST OF ABBREVIATIONS

5-ASA	5-Aminosalicylic acid
AER	Ascending enteric reflex

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00111-3

anti-TNFα	Antitumor necrosis factor alpha
CB1, CB2	Cannabinoid receptors type 1 and 2
CD	Crohn disease
CDAI	Crohn disease activity index
IBD	Inflammatory bowel disease
LES	Lower esophageal sphincter
LPS	Lipopolysaccharides
SIBDQ	Short inflammatory bowel disease questionnaire
UC	Ulcerative colitis

INTRODUCTION

Crohn disease (CD) is a chronic inflammatory disorder that may affect the gastrointestinal (GI) tract from the mouth to the anus. The inflammation is transmural, and might therefore be complicated by fistula and abscess formation, perforations, and fibrotic strictures. Ulcerative colitis (UC) is a form of inflammatory bowel disease (IBD) which affects mainly the colon, thus causing abdominal pain, bloody diarrhea, and weight loss. Both diseases may cause significant morbidity and diminished life quality (Love, Irvine, & Fedorak, 1992; Casellas, López-Vivancos, Badia, Vilaseca, & Malagelada, 2001; Rubin, Hungin, Chinn, & Dwarakanath, 2004; Canavan, Abrams, Hawthorne, Drossman, & Mayberry, 2006; Hjortswang et al., 2003).

Treatment options include a variety of antiinflammatory and immunosuppressant agents. Most commonly used are the 5-aminosalicylic acid (5- ASA) antiinflammatory drugs, corticosteroids, thiopurine drugs (azathioprine and 6-mercaptopurine), methotrexate and antitumor necrosis factor alpha (anti-TNFα) agents. Most of these treatments, however, carry a considerable risk for severe side effects. (Gearry, Barclay, Burt, Collett, & Chapman, 2004; Fraser, Orchard, & Jewell, 2002; Colombel et al., 2004; Schnitzler et al., 2009; Sandborn & Loftus, 2004; Lichtenstein et al., 2004).

Cumulative data suggest that endocannabinoids have a role in various important physiological and pathophysiological functions in the GI tract. The relevance of these effects to IBD patients could be speculated to stem from its effect on GI motility, on the immune system and its potent action as analgesics.

The plant *Cannabis sativa* is the source of more than 60 aromatic hydrocarbon compounds called cannabinoids, of which Δ^9-tetrahydrocannabinol is the main psychotropic constituent. This agent acts via at least two types of cannabinoid receptors, named CB1 and CB2 receptors (Pertwee, 1997). CB1 receptors are located mainly on central and peripheral neurons, and in the GI tract in the enteric nervous system. Through these receptors, the cannabinoids cause inhibition of the gastrointestinal motility, mainly by inhibiting ongoing contractile transmitter release) (Shook & Burks, 1989; Izzo, Mascolo, Pinto, Capasso, & Capasso, 1999; Pertwee, 2001).

The CB2 receptors are located mainly on immune cells (Hornby & Prouty, 2004), but also on some afferent (sensory) nerve terminals (Stander, Schmelz, Metze, Luger, & Rukwied, 2005).

Cannabinoid receptor agonists were shown to inhibit small bowel peristalsis both in vitro (Izzo, Mascolo, Tonini, & Capasso, 2000; Heinemann, Shahbazian, & Holzer, 1999) and in vivo (Shook & Burks, 1989) in animal models. This effect was produced by activating CB1 receptor of rodents. When activated, CB1 receptor suppresses propulsive peristalsis and ascending enteric reflex (AER) contractions by inhibiting cholinergic and noncholinergic transmission. Cannabinoids were also shown to delay gastric empting in rodents (Shook & Burks, 1989), and to reduce both contractile activity of stomach and duodenum, and intragastric pressure (Shook & Burks, 1989; Krowicki, Moerschbaecher, Winsauer, Digavalli, & Hornby, 1999).

This inhibitory effect is probably also mediated through the CB1 receptor. Another action of the cannabinoids is the inhibition of gastric acid secretion (Coruzzi, Adami, Coppelli, Frati, & Soldani, 1999).

This effect was shown also in 90 heavy cannabis smokers (Nalin et al., 1978). These inhibitory effects on GI tract motility and secretion may be beneficial in patients with diarrhea. Indeed, some anecdotal reports suggest the effective use of cannabis against dysentery and cholera (Mechoulam, 1986)

Cannabinoid receptor agonists were shown to inhibit (through CB1 receptor activation) LES (lower esophageal sphincter) relaxation in dogs (Lehmann et al., 2002) and ferrets (Partosoedarso, Abrahams, Scullion, Moerschbaecher, & Hornby, 2003).

This effect was shown to decrease gastroesophageal reflux (Lehmann et al., 2002), and was caused by central and peripheral vagal mechanisms. In the inflamed gut, both CB1 and CB2 receptor activation may reduce inflammation-associated hypermotility. In a mouse model of ileitis induced by irritant croton oil, intestinal CB1 receptors are hyperexpressed, and cannabinoid agonists were proven effective in reducing intestinal motility compared to control sham-treated mice (Izzo et al., 2001).

In CB1 receptor-knockout mice, experimental colitis is significantly more severe than in wild-type mice, indicating that CB1 receptors have a role in protecting the bowel from inflammation (Massa et al., 2004)

Activation of CB2 receptors also inhibits both the accelerated intestinal motility (Mathison, Ho, Pittman, Davison, & Sharkey, 2004) and the extent of inflammation (Kimball, Schneider, Wallace, & Hornby, 2006) in experimental bowel inflammation.

The effect of cannabinoids on the immune system is complex, and mediated through CB1 and CB2 receptors

(Klein, 2005). Both receptors are expressed on B cells, NK cells, and mast cells (Klein et al., 2003; Samson et al., 2003). Cannabinoid receptors are also found on gut-associated lymphoid tissue (Lynn & Herkenham, 1994; Kulkarni-Narla & Brown, 2000).

Cannabinoids suppress cell mediated immunity and Th1 cytokine production, and enhance adaptive immunity and Th2 cytokine production, primary via CB2 receptors (Roth, Baldwin, & Tashkin, 2002). Secretion of TNF-α is directly inhibited by cannabinoids (Samson et al., 2003; Facchinetti, Del Giudice, Furegato, Passarotto, & Leon, 2003; Chang, Lee, & Lin, 2001).

Cannabinoids inhibit LPS-evoked macrophage activation (Chang et al., 2001), suppress activated macrophages, and mast cells (Small-Howard, Shimoda, Adra, & Turner, 2005; Vannacci et al., 2003).

The use of cannabis is also known to stimulate appetite and cause weight gain (Abel, 1975), (Berry & Mechoulam, 2002). Recent studies show involvement of the plant in the regulation of appetite, food intake, and energy metabolism (Di Marzo & Matias, 2005; Sharkey & Pittman, 2005; Pagotto, 2006).

Cannabinoids are also potent analgesics, mainly affecting chronic neuropathic and inflammatory pain (Richardson, Aanonsen, & Hargreaves, 1998; Siegling, Hofmann, Denzer, Mauler, & De Vry, 2001).

Visceral sensory nerves of the gut are inhibited by CB1 and CB2 receptor selective agonists (Sanson, Bueno, & Fioramonti, 2006; Hillsley et al., 2007).

CB2 receptor agonists normalize sensory hypersensitivity caused by colon distension in experimental colitis (Sanson et al., 2006).

Thus, treatment with cannabis may have a beneficial effect in patients with IBD who suffer from alerted bowel movements, abdominal pain, and loss of appetite. However, despite the fact that sporadic patients self-administer cannabis, investigational data in the literature are scarce.

CANNABIS TREATMENT IN IBD

The beneficial effect of cannabinoids on the GI tract has been recognized for centuries, and, apparently, many IBD patients self-administrated the plant in order to control their symptoms. However, until recently, little attention was attributed toward the medical usage of cannabis in patients suffering from IBD. Searching the literature reveals only seven papers addressing this topic, all of them published during the past years. Of these papers, only four are clinical trials in IBD patients, one is a trial performed in a murine model of colitis, and the rest are review articles.

This chapter will focus on clinical data from clinical trials in IBD patients. The first paper published in 2011 is a survey conducted on IBD patients in Mount Sinai Hospital, Toronto, Canada (Lal et al., 2011). The aim of this study was to evaluate cannabis use in IBD patients attending the outpatient clinic. Patients were asked to complete an anonymous questionnaire regarding their disease, treatment, demographic, and psychological data. Approximately 50% of 291 patients included reported lifetime cannabis use. Fifty percent of CD patients and 33% of UC patients that reported lifetime cannabis use consumed the cannabis in order to relief IBD symptoms, including pain relief, loss of appetite, and diarrhea. Patients were more likely to use cannabis for symptom relief if they had a history of abdominal surgery (60% vs 32%), chronic analgesic use (71% vs 31%), used complimentary alternative medicine (55% vs 32%) or had a lower short inflammatory bowel disease questionnaire (SIBDQ) score (45.1 ± 2.1 vs 50.3 ± 1.5) Notably, this survey did not asses the clinical efficacy of cannabis in IBD patients, only its consumption.

The first study that directly measured the impact of cannabis treatment on IBD patients' quality of life, weight and disease activity was published in 2012 (Lahat, Lang, & Ben-Horin, 2012).

In this prospective study, a small group of long standing severe IBD patients initiated treatment with inhaled cannabis. Disease activity, weight, and quality of life were assessed before and after 3 months treatment. After 3 months treatment patients reported improvement in general health perception, social functioning, ability to work, physical pain, and depression (Tables 96.1 and 96.2).

Patients had a weight gain of 4.3 ± 2 kg during treatment, and an average rise in BMI of 1.4 ± 0.61 (Fig. 96.1). Disease activity Harvey–Bradshaw index was reduced from 11.36 ± 3.17 to 5.72 ± 2.68 ($p = 0.001$) (Table 96.3). No adverse events were reported.

A small prospective placebo controlled study was published in 2013 (Naftali et al., 2013).

In this study, 21 patients with severe active CD were randomized to receive either inhaled cannabis or placebo containing cannabis flowers from which THC had been extracted. Patients were treated with inhaled cannabis for 8 weeks. CD activity index (CDAI) was calculated before treatment, after 2 and after 8 weeks treatment. After 8 weeks treatment, 45% of the study group achieved complete remission, as compared to 10% in the placebo group. However, these results did not reach statistical significance—probably due to the small sample size (11 patients in the study group, 10 in the placebo). The response rate (decrease of more than 100 points in the CDAI) was 90% in the study group, as compared to 30% in the placebo group ($p = 0.05$).

Patients in the study group reported a significant improvement in quality of life as measured by a rise in the SF-36 health survey results (from 68 at week 0–86

TABLE 96.4 Beneficial Effects of Cannabis Use in Patients With IBD

Symptoms where cannabis helps	
Abdominal pain	47 (83.9)
Abdominal cramps	43 (76.8)
Joint pain	27 (48.2)
Diarrhea	16 (28.6)
Fever	5 (8.9)
Fistula problems	5 (8.9)
CANNABIS USE	*YES*
Allowed me to decrease the dose of my conventional IBD medications	11 (19.6)
Allowed me to stop my conventional IBD medications	7 (12.5)
Made me need to increase my conventional IBD medications	2 (3.6)
Allowed me to avoid surgery that was recommended to me	6 (10.7)
Was a waste of my money	1 (1.8)
Cured my inflammatory bowel disease	4 (7.1)
Caused only side effects	3 (5.4)

Data shown as *n* (%).
From Storr M., Devlin S., Kaplan G. G., Panaccione R., Andrews C. N. (2014). Cannabis use provides symptom relief in patients with inflammatory bowel disease but is associated with worse disease prognosis in patients with Crohn disease. Inflammatory Bowel Disease, 20*(3), 472–480. With permission from Wolters Kluwer Health publishers.*

after 8 weeks treatment, $p = 0.05$). Patients in the control group showed no statistically significant improvement (71 vs 79, $p = 0.5$).

There were no significant changes laboratory results during the study period.

Side effects did not differ between the study groups. Patients from the study group reported significantly less pain, a rise in appetite, and higher satisfaction from the treatment.

The most recent study assessing cannabis' impact on IBD patients was published in 2014 (Storr, Devlin, Kaplan, Panaccione, & Andrews, 2014).

In this study, patients from the University of Calgary Gastroenterology outpatient clinic were asked to complete an anonymous questionnaire regarding self-administration of cannabis for the treatment of IBD and IBD related symptoms. Patients' demographic and clinical characteristics, as well as overall effectiveness and side effects were evaluated. Approximately 18% of patients used cannabis specifically to relieve IBD related symptoms, 96% of them used inhaled cannabis. Eighty four percent of patients reported improved abdominal pain and 77% reported improvement in abdominal cramps with cannabis use. Other beneficial effects were reduced joint pain (48%) and diarrhea (29%). (Table 96.4)

Patients that used cannabis for IBD tented more to suffer from sever disease (32% vs 22%, $p < 0.001$), to have more abdominal pain (59% vs 31%, $p < 0.001$) and to had more IBD relates hospitalizations (85% vs 31%, $p < 0.001$) than patients who did not use cannabis (Table 96.5)

Patient that used cannabis were at higher risk for surgery (OR 5) and for hospitalization (OR 2.855) than patients that did not use cannabis. The study could not assess causality. However, a reasonable option is that patients that used cannabis suffered from a more severe disease, and therefore underwent more operations and more IBD related hospitalizations.

TABLE 96.5 Activity, Clinical Characteristics, and Current Treatment of IBD Patients: Users Versus Nonusers of Cannabis

Variable	Total (*n*=319)	Nonusers (*n*=263)	Users (*n*=56)	*p* Value
ACTIVITY OF IBD				
Inactive	6 (1.9%)	4 (1.5%)	2 (3.6%)	0.515

Patients in this study did report side effects—more than 75% reported dry mouth, drowsiness, increased appetite, and sensation of "high." However, in most cases, these symptoms were described as mild.

In conclusion, cannabis was shown to be beneficial for IBD symptoms relief. Patients reported significant improvement in abdominal pain, diarrhea, increased appetite, and improved quality of life. Side effects, if any, were mild. However, these small studies are insufficient to establish the role of cannabis in IBD treatment. More double-blind placebo-controlled large volume studies are warranted in order to assess the utility, indications, and contraindications to cannabis use as therapeutic tool in IBD patients.

MINI-DICTIONARY

5-ASA 5-Aminosalicylic acid (mesalamine), a group of antiinflammatory drugs for IBD treatment.
anti-TNFα Antitumor necrosis factor alpha, a biological medication composed of IgG1 monoclonal antibody against tumor necrosis factor alpha.
CDAI Crohn disease activity index is a research tool used to quantify the symptoms of patients with Crohn disease. The index is based on the number of liquid or soft stools , abdominal pain, general wellbeing, presence of complications, treatment with antidiarrhea drugs, and presence of an abdominal mass.
EQ 5D A standardized instrument for use as a measure of health outcome.
Harvey–Bradshaw index A simpler version of the Crohn disease activity index (CDAI) for data collection purposes. It consists of

only clinical parameters: the first three items are scored for the previous day. Harvey–Bradshaw index is far simpler to use than the CDAI and does not require biochemical tests.

SF 36 The Short Form (36) Health Survey is a patient-reported survey of patient health.

SIBDQ Short inflammatory bowel disease questionnaire (SIBDQ), a health-related quality of life (HRQoL) tool measuring physical, social, and emotional status (score 10–70, poor to good HRQoL).

CHAPTER

97

Cannabidiol for the Treatment of Drug Use Disorders

R.G. dos Santos, J.E.C. Hallak, A.W. Zuardi, J.A. de Souza Crippa

Department of Neuroscience and Behavior, Ribeirão Preto Medical School, University of São Paulo, Ribeirão Preto, SP, Brazil

SUMMARY POINTS

- This chapter focuses on cannabidiol (CBD), which is a naturally occurring plant-derived compound.
- CBD is produced by the cannabis plant, which produces several other chemically related compounds collectively called phytocannabinoids or simply cannabinoids.
- CBD does not produce the psychoactive effects typically produced by Δ^9-tetrahydrocannabinol (Δ^9-THC), which is the main active compound in cannabis.
- Preclinical evidence suggest that CBD has antiaddictive effects in animal models using opiates/opioids and stimulants.
- Preliminary studies in humans suggest that CBD reduces cigarette consumption and reduces symptoms of cannabis dependence/withdrawal.
- Given the good safety profile of CBD and its promising antiaddictive effects, there is a clear need to perform randomized, controlled clinical trials with this phytocannabinoid.

KEY FACTS OF CANNABIDIOL

- Cannabis is a plant original from Central Asia that has been used for ritual and medicinal purposes for thousands of years.
- The cannabis plant is rich in unique chemical compounds called cannabinoids.
- The main cannabinoids are Δ^9-tetradydrocannabinol (THC), responsible for producing most of the subjective effects of cannabis, and cannabidiol (CBD), which lacks the psychoactivity of THC.
- The chemical structure of CBD was elucidated in 1963, while THC, the main active component in cannabis, was isolated in a pure form and its structure determined in 1964.
- Preclinical evidence suggest that CBD has antiaddictive effects in animal models using opiates/opioids and stimulants.
- Preliminary studies in humans suggest that CBD reduces cigarette consumption and reduces symptoms of cannabis dependence/withdrawal.

LIST OF ABBREVIATIONS

CB_1	Cannabinoid receptor 1
CB_2	Cannabinoid receptor 2
CBD	Cannabidiol
CNS	Central nervous system
COMT	Catechol-O-methyl transferase
COX	Cyclooxygenase
D_2	Dopaminergic receptor 2
FAAH	Fatty acid amide hydrolase
fMRI	Functional magnetic resonance imaging
GABA	γ-Aminobutyric acid
$GABA_A$	GABAergic receptor A
$GABA_B$	GABAergic receptor B
GluR1	Glutamatergic AMPA receptor 1

11-HO-delta-8-THC	11-Hydroxy-delta-8-tetrahydrocannabinol
5-HT$_{1A}$	Serotonergic receptor 1A
IFN-γ	Interferon-γ
ICSS	Intracranial self-stimulation
NAc	Nucleus accumbens
NO	Nitric oxide
PGE2	Prostaglandin E2
rCBF	Regional cerebral blood flow
SAD	Social anxiety disorder
SPECT	Single photon emission computed tomography
Δ^8-THC	Δ^8-Tetrahydrocannabinol
Δ^9-THC	Δ^9-Tetrahydrocannabinol
TNF	Tumor necrosis factor
TRPV$_1$	Transient receptor potential vanilloid 1 (vanilloid receptor 1)
TRPV$_2$	Transient receptor potential vanilloid 2 (vanilloid receptor 2)
VTA	Ventral tegmental area

INTRODUCTION

Although cannabis and stimulants (cocaine, amphetamine, methamphetamine) are among the most consumed illegal recreational drugs worldwide (Nutt, King, & Phillips, 2010; Greydanus, Hawver, Greydanus, & Merrick, 2013; Morgan, Noronha, Muetzelfeldt, Fielding, & Curran, 2013a; van Amsterdam, Pennings, Brunt, & van den Brink, 2013; Hall & Degenhardt, 2014; United Nations Office on Drugs & Crime, 2014), there is no established medication for use in the treatment of cannabis or stimulant use disorders to date (Haile, Mahoney, Newton, & De La Garza, 2012; Stoops & Rush, 2013). Moreover, there has been a noticeable increase in the number of persons seeking treatment for cannabis use disorders over the past decade, particularly in the Americas, Oceania and Europe (Hall & Degenhardt, 2009; United Nations Office on Drugs & Crime, 2014). In the case of the opiates, although treatment strategies including methadone have improved substance abuse outcome in opiate-dependent subjects, these treatment strategies do not effectively block opiate craving in all patients. Considering this context, new molecules should be explored for the treatment of drug use disorders that lack an effective treatment.

Preliminary evidence suggests that cannabidiol (CBD), a phytocannabinoid devoid of the subjective and harmful effects associated with Δ^9-tetrahydrocannabinol (Δ^9-THC), may have therapeutic effects for treating drug use disorders (Hine, Torrelio, & Gershon, 1975; Bhargava, 1976; Chesher & Jackson, 1985; Parker, Burton, Sorge, Yakiwchuk, & Mechoulam, 2004; Zuardi, 2008; Ren, Whittard, Higuera-Matas, Morris, & Hurd, 2009; Crippa, Zuardi, & Hallak, 2010; Crippa et al., 2013; Katsidoni, Anagnostou, & Panagis, 2013). CBD is not associated with adverse cognitive effects, presents good safety and tolerability profiles in humans, and has a broad pharmacological spectrum of action (Zuardi, 2008; Crippa et al., 2010; Bergamaschi, Queiroz, Zuardi, & Crippa, 2011; Zhornitsky & Potvin, 2012; Niesink & van Laar, 2013).

The objective of this chapter is to review data from preclinical and human studies suggesting that CBD has potential therapeutic effects for the treatment of drug use disorders.

CANNABIDIOL

Cannabis contains over 100 compounds called cannabinoids, which are unique to the plant (Mechoulam & Carlini, 1978; Mechoulam & Hanus, 2012). THC is the cannabinoid most closely associated with euphoria, dependence, and mental health side effects associated with cannabis consumption (Bhattacharyya et al., 2010; Morgan, Freeman, Schafer, & Curran, 2010; Maldonado, Berrendero, Ozaita, & Robledo, 2011; Carbuto et al., 2012; Niesink & van Laar, 2013). The other main cannabinoid in the *Cannabis* plant, CBD, lacks the psychoactivity of THC (Zuardi, 2008; Bhattacharyya et al., 2010; Morgan et al., 2010; Niesink & van Laar, 2013).

Human studies reported that CBD has sedative, anxiolytic, antidepressant, mood stabilizer, and anticraving properties (Mechoulam & Carlini, 1978; Zuardi, 2008; Crippa et al., 2010; Bergamaschi et al., 2011; Crippa et al., 2011; Schier et al., 2012; Zhornitsky & Potvin, 2012; Niesink & van Laar, 2013; Robson, 2014).

CBD has multiple mechanisms of action, and its pharmacology is not completely understood. CBD has little affinity to cannabinoids receptors CB$_{1/2}$, antagonizes CB$_{1/2}$ receptor agonists, inhibits the reuptake of the endocannabinoid anandamide and the activity of fatty acid amide hydrolase (FAAH), the enzyme that catalyzes anandamide, and also activates 5-HT$_{1A}$ serotonergic receptors (Zuardi, 2008; Crippa et al., 2010; Bergamaschi et al., 2011; Zhornitsky & Potvin, 2012).

Single photon emission computed tomography (SPECT) and functional magnetic resonance imaging (fMRI) studies reported that CBD effects are associated with the modulation of the functional activity of tempo-ro-limbic structures (amygdala-hippocampus complex and parahippocampal gyrus) and paralimbic regions, including the cingulate cortex (Crippa et al., 2010, 2011; Schier et al., 2012). The central effects of CBD on regional cerebral blood flow (rCBF) were investigated using SPECT in patients with social anxiety disorder (SAD) and in healthy volunteers (Crippa et al., 2010, 2011; Schier et al., 2012). Relative to placebo, CBD (400 mg) produced significant decreases in subjective anxiety

induced by the SPECT procedure in patients with SAD, and these effects were associated with an action on limbic and paralimbic brain areas (Crippa et al., 2010, 2011; Schier et al., 2012). The same brain areas were modulated by CBD in healthy volunteers (Crippa et al., 2010, 2011; Schier et al., 2012). Other neuroimaging studies reported that CBD (600 mg) attenuated fMRI responses during the recognition of fearful facial expressions in the amygdala and the anterior cingulate (Crippa et al., 2010, 2011; Schier et al., 2012).

CBD VERSUS OPIATES/OPIOIDS

Although opiates/opioids top the list of problem drugs that cause the most burden of disease and drug-related deaths worldwide, only a minority of dependent subjects receives treatment, which has traditionally targeted μ-opioid receptors and do not effectively block opiate craving in all patients (Nutt et al., 2010; Morgan et al., 2013a; van Amsterdam et al., 2013; United Nations Office on Drugs & Crime, 2014).

Some studies have investigated the effects of CBD and other cannabinoids in inhibiting withdrawal in morphine-dependent rodents. A study in rats reported that CBD (10 mg/kg) had little effect on abstinence scores in morphine-dependent rats, but significantly increased the abstinence attenuating properties of THC (2 mg/kg) (Hine et al., 1975). A study in mice reported that THC (2.5–20 mg/kg), Δ^8-tetrahydrocannabinol (Δ^8-THC) (5–10 mg/kg), 11-hydroxy-delta-8-tetrahydrocannabinol (11-HO-delta-8-THC) (5–10 mg/kg), cannabinol (CBN) (5–20 mg/kg), and CBD (5–20 mg/kg), significantly inhibited the naloxone-precipitated withdrawal in morphine-dependent mice (Bhargava, 1976). The relative effectiveness of the cannabinoids in inhibiting morphine abstinence appeared to be in the following order: THC > Δ^8-THC > 11-HO-delta-8-THC > CBD > CBN (Bhargava, 1976). Another study in rats reported that THC (5–10 mg/kg) and CBN (5–80 mg/kg) produced a significant reduction in withdrawal symptoms, while CBD (5–80 mg/kg) did not produce any effect (Chesher & Jackson, 1985).

The effect of CBD on heroin self-administration and drug-seeking behavior was investigated using an experimental rat model (Ren et al., 2009). CBD (5–20 mg/kg) did not alter stable intake of heroin self-administration, extinction behavior, or drug-seeking induced by a heroin prime injection. However, CBD specifically attenuated heroin-seeking behavior reinstated by exposure to a conditioned stimulus cue, both 24 h and 2 weeks after treatment with the cannabinoid. The expression of cannabinoid CB_1 and glutamatergic AMPA GluR1 receptors mRNA and protein levels were significantly increased in the nucleus accumbens (NAc) in heroin-treated rats that received vehicle treatment, and CBD reversed these effects both 24 h and 2 weeks after treatment. These results suggest that CBD has neurobiological effects to counter long-lasting neuroadaptations that specifically govern conditioned cue-induced drug-seeking behavior and relapse.

A recent study in rats investigated the effects of CBD on brain reward function and on the reward-facilitating effect of morphine using the intracranial self-stimulation (ICSS) paradigm (Katsidoni et al., 2013). CBD (5 mg/kg) inhibited the reward-facilitating effect of morphine, and this effect was reversed by pretreatment with an intradorsal raphe injection of a selective 5-HT_{1A} receptor antagonist. Moreover, CBD (5 mg/kg) did not affect the reinforcing efficacy of brain stimulation, whereas higher doses (10–20 mg/kg) increased ICSS thresholds, suggesting that acute administration of CBD reduces brain reward function. Morphine lowered ICSS thresholds while CBD increased it, suggesting that CBD is not likely to have abuse potential (Katsidoni et al., 2013).

Table 97.1 shows the effects of CBD in animals exposed to opiates/opioids.

Taken together, these results suggest that CBD may be clinically useful in attenuating the rewarding effects of opiates/opioids. Moreover, these data reinforce the strong neurobiological interactions between the cannabinoid and opioid systems (Ren et al., 2009; Maldonado et al., 2011).

CBD VERSUS STIMULANTS

The development of pharmacotherapies for the treatment of stimulant dependence has been a high priority in addiction research for more than two decades, yet no medication has been approved by the Food and Drug Administration (FDA) in the United Sates or by similar agencies in other countries for this disease (Haile et al., 2012; Stoops & Rush, 2013). The main mechanism of action associated with the euphoria and abuse potential of stimulants is the increase in dopamine levels in the brain, and a growing preclinical and clinical literature suggest that dopamine uptake blockers and releasers (*d*-amphetamine, methamphetamine, methylphenidate, bupropion, and modafinil) may be efficacious for treating stimulant abuse and dependence (Haile et al., 2012; Stoops & Rush, 2013). However, methylphenidate and *d*-amphetamine have significant abuse and diversion potential, and bupropion and modafinil appear to have limited clinical efficacy (Haile et al., 2012; Stoops & Rush, 2013). Thus novel approaches are necessary to help those with problematic stimulant use who are seeking treatment.

CBD inhibits the uptake of dopamine, but the pharmacological relevance of this effect in humans is unknown (Zuardi, 2008; Crippa et al., 2010; Bergamaschi et al., 2011; Zhornitsky & Potvin, 2012). A study

Cocaine- and amphetamine-induced conditioned place-preference	Rats	Extinction of conditioned place-preference	(+)	5 mg/kg	Parker et al. (2004)
Rewarding effects of cocaine/intracranial self-stimulation	Rats	Reward-facilitating effect of cocaine	(–)	5–20 mg/kg	Katsidoni et al. (2013)

[a] *(+)therapeutic action, (–) no therapeutic action.*

evaluated if THC and CBD could potentiate extinction of a cocaine-induced and amphetamine-induced conditioned place-preference in rats (Parker et al., 2004). THC (0.5 mg/kg) and CBD (5 mg/kg) potentiated the extinction of both cocaine-induced and amphetamine-induced conditioned place-preference learning, and this effect was not reversed by a CB_1 receptor antagonist, suggesting that other neurochemical mechanisms may be involved. Moreover, CBD was not hedonic on its own (Parker et al., 2004). On the other hand, a recent study in rats investigating the effects of CBD on brain reward function and on the reward-facilitating effect of cocaine using a self-stimulation paradigm reported that CBD (5–20 mg/kg) did not inhibit the reward-facilitating effect of cocaine (Katsidoni et al., 2013).

Table 97.2 shows studies of the effects of CBD in animals exposed to stimulants.

CBD VERSUS NICOTINE

A recent pilot study assessed the impact of the ad-hoc use of low dose CBD in smokers who wished to stop smoking (Morgan, Das, Joye, Curran, & Kamboj, 2013b). In a double-blind, placebo-controlled study, 24 smokers were recruited from the community and were randomized to receive an inhaler of CBD (n = 12; 6 females) or placebo (n = 12; 6 females) for 1 week, and they were instructed to use the inhaler when they felt the urge to smoke. Each depress of the solution aerosol in the inhaler administered a dose of 400 μg CBD. CBD significantly reduced the number of cigarettes smoked by ~40% over the treatment week, while the placebo group showed no differences in number of cigarettes smoked. Moreover, results also indicated some maintenance of this effect at follow-up. The reduction in the number of cigarettes smoked occurred in the absence of a change in cigarette craving reported daily across the week, suggesting that participants using the CBD inhaler reduced the number of cigarettes they smoked, without increased craving for nicotine.

The authors suggested that the decrease in smoking could be related to three putative mechanisms produced by CBD: (1) action at the CB_1 receptor, given previous literature on similar reductions following treatment with rimonabant, a CB_1 receptor antagonist; (2) FAAH inhibition, as recent research has shown that the reinforcing and neurochemical effects of nicotine in rats are reduced

TABLE 97.3 Effects of CBD in Smokers

Study design	Volunteers/methods	Results (symbol)[a]		Dose with significant results	Reference
Pilot double-blind, placebo-controlled study	24 smokers randomized to receive an inhaler of CBD (n = 12; 6 females) or placebo (n = 12; 6 females) for 1 week	Number of cigarettes smoked (~40% reduction)	(+)	CBD inhaler used when volunteers felt the urge to smoke (each depress = 400 μg CBD)	Morgan, Das, Joye, Curran, and Kamboj (2013b)
Pilot double-blind, placebo-controlled study	24 smokers randomized to receive an inhaler of CBD (n = 12; 6 females) or placebo (n = 12; 6 females) for 1 week	Daily cigarette craving	(–)	CBD inhaler used when volunteers felt the urge to smoke (each depress = 400 μg CBD)	Morgan et al. (2013b)

[a] *(+) Therapeutic action, (–) no therapeutic action.*

by FAAH-inhibitors; and (3) modulation of the salience of smoking cues and subsequent reduction of the attentional bias of smokers to smoking stimuli, consistent with preclinical studies (Ren et al., 2009) and a naturalistic study that found CBD to reduce the attentional bias of dependent cannabis users to cannabis stimuli (Morgan et al., 2010).

These preliminary data suggest that CBD may be a potential treatment for nicotine addiction, and warrants further exploration. The therapeutic effects of CBD described by Morgan et al. (2013b) are summarized in Table 97.3.

CBD VERSUS CANNABIS

In 2010, there were an estimated 13.1 million cannabis dependent people globally, and in 2012, of the approximately 31.7 million Americans who reported using cannabis at least once, over 13% (4.3 million people) reported cannabis dependence or abuse (Degenhardt et al., 2013; Balter, Cooper, & Haney, 2014). Nevertheless, no currently available pharmacological therapy is considered adequate to treat cannabis abuse, dependence, and withdrawal (Budney, Vandrey, & Stanger, 2010; Crippa et al., 2010; Danovitch & Gorelick, 2012; Crippa et al., 2013; Balter et al., 2014).

An approach that has been investigated for treating cannabis withdrawal is the use of agonist replacement therapies. This approach can be implemented using THC, synthetic THC (dronabinol), a synthetic THC analogue (nabilone), or Sativex (GW Pharmaceuticals, United Kingdom), a buccal spray with an approximately 1:1 ratio of THC and CBD (Budney et al., 2010; Danovitch & Gorelick, 2012; Balter et al., 2014). Other substances also produce some improvement in symptoms of cannabis withdrawal, like the antidepressants mirtazapine (norepinephrine/serotonin modulator) and nefazodone (norepinephrine/serotonin reuptake inhibitor, 5-HT_2 antagonist), the mood stabilizer lithium, the α_2 adrenergic receptor agonist lofexidine, the $GABA_A$ receptor agonist zolpidem, the glutamatergic drug *N*-acetylcysteine, and the antiepileptic and analgesic gabapentin (Budney et al., 2010; Danovitch & Gorelick, 2012; Balter et al., 2014). On the other hand, the antidepressants buproprion (norepinephrine/dopamine reuptake inhibitor), venlafaxine (serotonin/norepinephrine reuptake inhibitor), fluoxetine and escitalopram (selective serotonin reuptake inhibitors), the $GABA_B$ receptor agonist baclofen, the atypical antipsychotic quetiapine (dopamine/serotonin/norepinephrine receptors antagonist), as well as the anticonvulsant and mood stabilizer divalproex, failed to produce positive results, or even worsened some symptoms (Budney et al., 2010; Danovitch & Gorelick, 2012; Balter et al., 2014).

Regarding cannabis dependence, a treatment option with positive results is agonist replacement with THC, dronabinol, or nabilone, but other drugs also showed promising results, like the catechol-O-methyl transferase (COMT) inhibitor entacapone, the selective norepinephrine reuptake inhibitor atomoxetine, the anxiolytic buspirone (5-HT_{1A} agonist, D_2 antagonist), gabapentin, and *N*-acetylcysteine (Budney et al., 2010; Danovitch & Gorelick, 2012; Balter et al., 2014). Many of the drugs that failed to reduce cannabis withdrawal symptoms (mirtazapine, escitalopram, buspirona, fluoxetine, venlafaxine, baclofen, and quetiapine) also failed to produce positive results on cannabis dependence symptoms (Budney et al., 2010; Danovitch & Gorelick, 2012; Balter et al., 2014).

An alternative to using exogenous cannabinoid agonists (THC, dronabinol, or nabilone) as a potential treatment for cannabis use disorders is to increase cannabinoid signaling by modulating the endogenous endocannabinoids (Budney et al., 2010; Danovitch & Gorelick, 2012; Balter et al., 2014). CBD inhibits the reuptake and hydrolysis of anandamide, and has little affinity to cannabinoids receptors $CB_{1/2}$, although it is capable of antagonizing $CB_{1/2}$ receptor agonists (Zuardi, 2008; Crippa et al., 2010; Bergamaschi et al., 2011; Zhornitsky & Potvin, 2012). Moreover, CBD has a broad spectrum of pharmacological effects, including sedative, anxiolytic, antidepressive, mood stabilizer, and anticraving properties (Mechoulam & Carlini, 1978; Zuardi, 2008;

TABLE 97.4 Effects of CBD on Cannabis Withdrawal

Study design	Patient	Results	Dose with significant results	References
Case report	19-year-old female (4–8 cigarettes/day) since 13 years	Reduction in withdrawal, dissociative, depression and anxiety symptoms[a]	Day 1: 300 mg Day 2–10: 600 mg/day divided into two doses Day 11: 300 mg	Crippa et al. (2013)

[a] *Withdrawal discomfort score, marijuana withdrawal symptom checklist, Beck anxiety inventory, and Beck depression inventory.*

Crippa et al., 2010, 2011; Bergamaschi et al., 2011; Schier et al., 2012; Zhornitsky & Potvin, 2012; Niesink & van Laar, 2013; Robson, 2014).

Among the various symptoms present in cannabis withdrawal, anxiety and insomnia are the principal manifestations and are considered disruptive to daily living (Budney et al., 2010; Crippa et al., 2010, 2013; Danovitch & Gorelick, 2012; Greydanus et al., 2013; Balter et al., 2014). Moreover, across laboratory and survey studies, sleep difficulty is one of the most common and highest magnitude cannabis withdrawal effects, and was the withdrawal symptom most associated with relapse to cannabis use across multiple studies (Budney et al., 2010; Crippa et al., 2010, 2013).

Based on previous evidence suggesting anxiolytic and sedative/hypnotic properties of CBD, our group recently investigated the effects of this cannabinoid in a subject with cannabis dependence and a history of cannabis withdrawal syndrome (Crippa et al., 2013). A 19-year-old female had a history of heavy and continued use of cannabis (four to eight cigarettes/day) since 13 years of age. She denied co-use or dependence on any other substance, and used almost all her salary to buy cannabis, dedicating much time and effort to obtain the substance. The patient complained of memory, concentration, and attention problems, which interfered with her studies and performance at work. She had tried to stop using cannabis at least 4 times, always presenting, among others, with insomnia, anxiety, total loss of appetite, restlessness, migraines, irritability, nightmares, and sudoresis around the 4th to 6th day after cessation of use. Resuming cannabis use resulted in immediate relief of symptoms. The subject was hospitalized and received oral CBD (300 mg) on the 1st day, CBD 600 mg/day, divided into two doses, from the 2nd to the 10th day, and CBD 300 mg on the 11th day. Serum levels of hepatic enzymes and plasma levels of CBD and THC were monitored daily. Under CBD, the patient did not report any cannabis withdrawal symptoms (Crippa et al., 2013). The therapeutic effects of CBD described by Crippa et al. (2013) are summarized in Table 97.4.

CBD can antagonize or inhibit some behavioral effects of THC both in animals and in humans (Zuardi, 2008; Bhattacharyya et al., 2010; Crippa et al., 2010; Morgan et al., 2010; Bergamaschi et al., 2011; Niesink & van Laar, 2013). Smokers of high CBD:THC strains showed reduced attentional bias to drug and food stimuli, compared with smokers of low CBD:THC, and also showed lower self-rated liking of cannabis stimuli (Morgan et al., 2010). An fMRI study in healthy volunteers reported that THC (10 mg) and CBD (600 mg) had opposite effects on brain activation in the striatum, hippocampus, amygdala, superior temporal cortex, and occipital cortex (Bhattacharyya et al., 2010).

Considering that CBD antagonizes/inhibits some behavioral effects of THC, inhibits the reuptake and hydrolysis of anandamide, thus increasing cannabinoid signaling, and has anxiolytic and hypnotic properties, the anticraving and antiaddictive properties of this cannabinoid should be further investigated in randomized, controlled clinical trials.

CONCLUSIONS

The problematic use of psychoactive substances like cannabis, stimulants, opiates/opioids, and nicotine, carry a series of health, economic, and social costs to individuals and society. Although pharmacological treatments for opiates/opioids (methadone or buprenorphine) and nicotine (nicotine patch, etc.) abuse or dependence are available, there is no approved medication for the treatment of cannabis and stimulant disorders.

CBD antagonizes behavioral effects of THC, inhibits the reuptake and hydrolysis of anandamide, increases cannabinoid signaling, and has anxiolytic and hypnotic properties. CBD has showed therapeutic effects in animal models of opiate/opioid and stimulant dependence and withdrawal, and preliminary studies in humans suggest that CBD may reduce cigarette consumption, and the symptoms of cannabis dependence/withdrawal.

The anticraving and antiaddictive effects of CBD should be investigated in controlled clinical trials.

MINI-DICTIONARY

Anandamide *N*-arachidonoylethanolamine. From the Sanskrit word "ananda"—bliss, delight. Endogenous cannabinoid neurotransmitter.

Cannabidiol (CBD) One of the main phytocannabinoids. It lacks the psychoactive characteristics of Δ^9-Tetradydrocannbinol (THC), and has several therapeutic potentials.

Cannabinoid receptors G-protein-coupled receptors present in the endocannabinoid system.

Cannabinoids Chemical compounds present exclusively in the *Cannabis* plant. More than 100 cannabinoids have been identified. Cannabinoids are also called phytocannabinoids, in opposition to endocannabinoids.

Cannabis A plant of the Cannabaceae botanical family, with three different species: *Cannabis sativa*, *Cannabis indica*, and *Cannabis ruderalis*.

CB_1 cannabinoid receptor Cannabinoid receptors mainly distributed in the central nervous system. CB_1 receptors are densely distributed in the frontal cerebral cortex, basal ganglia, cerebellum, hippocampus, hypothalamus, and anterior cingulate cortex, but rarely in the brainstem nuclei.

CB_2 cannabinoid receptor Cannabinoid receptors mainly distributed in immune cells. CB_2 receptors are also expressed in microglia, spinal cord, and sparsely in several brain regions, such as, the cerebellum, cortex, and brainstem.

Drug dependence A psychiatric disorder characterized by tolerance, impaired control over drug use, difficulty in ceasing drug use despite harms caused by it, and by personal, family, and professional problems.

Endocannabinoids Endogenous cannabinoid neurotransmitters. Endocannabinoids are chemically and pharmacologically related to phytocannabinoids, both groups of substances acting at the endocannabinoid system, which is basically composed by endocannabinoids, cannabinoid receptors, and the enzymes responsible for endocannabinoid synthesis and degradation.

Δ^9-Tetrahydrocannabinol (Δ^9-THC) The main chemical in the cannabis plant responsible for producing the typical subjective effects reported for cannabis consumption.

SUMMARY POINTS

- This chapter focuses on the role of cannabinoids in gut motility.
- It describes the location of the ECS in the myenteric plexus and other structures innervating the gut.
- Cannabis receptor type 1 (CB1R) in the excitatory myenteric neurons reduce acetylcholine release, leading to a decrease in smooth muscle contractility and delayed gastrointestinal transit.
- Stimulation of cannabinoid receptors may alleviate chemotherapy-induced nausea and vomiting (CINV), gastroesophageal reflux disease (GERD), ulcerative colitis (UC), and Crohn disease (CD).
- Conversely, inactivation of CB1R receptors could be useful in the treatment of paralytic ileus.
- The major limitations of cannabinoids for the treatment of gastrointestinal disorders are their central side effects.
- Chronic cannabinoid use may induce cannabinoid hyperemesis syndrome.

KEY FACTS OF CINV

- CINV is the most feared cancer treatment-related side effect.
- Usually classified into three categories: acute onset, occurring within 24 h of the initial administration of chemotherapy; delayed onset, occurring 24 h to several days after initial treatment; and anticipatory nausea and vomiting, triggered by taste, odor, sight, thoughts, or anxiety secondary to a history of poor response to antiemetic agents.
- The introduction of 5-HT3 antagonists has controlled CINV in many patients.
- Conventional antiemetics are not as successful in treating nausea as they are in treating emesis.
- Cannabinoids are frequently used to prevent CINV.

KEY FACTS OF CANNABINOID HYPEREMESIS SYNDROME

- First reported in the Adelaide Hills of South Australia, by (Allen, de Moore, Heddle, & Twartz, 2004).
- Cyclic nausea and vomiting can be induced by the long-term and intense marijuana use.
- Synthetic cannabinoids may also induce it.
- Relief can be obtained with hot water bath, or cannabis cessation.
- Dysregulation of peripheral enteric nerves causing delayed gastric emptying could be implicated.

LIST OF ABBREVIATIONS

CB1R	Cannabinoid receptor type 1
CB2R	Cannabinoid receptor type 2
CD	Crohn disease
CINV	Chemotherapy-induced nausea and vomiting
CNS	Central nervous system
DMV	Dorsal motor nucleus of the vagus
ECS	Endogenous cannabinoid (or endocannabinoid) system
ENS	Enteric nervous system
FAAH	Fatty acid amide hydrolase
GERD	Gastroesophageal reflux disease
GI	Gastrointestinal
IBD	Inflammatory bowel disease
IBS	Irritable bowel syndrome
LES	Lower esophageal sphincter
MAGL	Monoacylglycerol lipase
PPAR	Peroxisome proliferator-activated receptor
TLESRs	Transient lower esophageal sphincter relaxations
Δ^9-THC	Δ^9-Tetrahydrocannabinol
TRPV1	Transient receptor potential vanilloid type 1
UC	Ulcerative colitis

INTRODUCTION

Cannabis has been used empirically and traditionally to treat different disorders including those of the gut, ranging from enteric infections and inflammatory conditions to motility alterations, emesis, and abdominal pain (Izzo & Coutts, 2005). Cannabis is also the most widely used recreational drug in the Western world for its psychotropic properties, mainly exerted by its major component, Δ^9-Tetrahydrocannabinol (Δ^9-THC) (Di Carlo & Izzo, 2003). Other cannabinoids contained in cannabis, with fewer psychotropic actions, include cannabidiol, Δ^9-tetrahydocannabivarin, cannabichromene, cannabigerol, cannabidivarin, and acidic cannabinoids, such as, Δ^9-tetrahydrocannabinolic acid and cannabidiolic acid (Kumar, Chambers, & Pertwee, 2001).

All the components of the endogenous cannabinoid system (ECS), including the CB1 and CB2 receptors (CB1R and CB2R), "nonclassical" receptors, such as GPR55, peroxisome proliferator-activated receptors (PPAR) α and γ, and transient receptor potential vanilloid-1 (TRPV1) channels, endogenous ligands (anandamide, 2-arachidonoylglycerol, noladin ether), their biosynthetic and degradative enzymes [fatty acid amide hydrolase (FAAH), monoacylglycerol lipase (MAGL)], and a hypothetical membrane transporter have been investigated in the gut. Another Chapter 56 in this book (*Cannabis and Cannabinoids, and the Effects on Gastrointestinal Function: an Overview*) offers an overview of the different actions exerted by cannabinoids within the gastrointestinal (GI) tract. Here we will focus on their involvement exclusively in GI motor function.

THE ECS AND GUT INNERVATION CONTROLLING MOTILITY

The enteric nervous system (ENS) is the major site of action of cannabinoids in the gut. The ENS is composed of two major plexuses found within the gut wall: the myenteric plexus that lies between the external muscle layers (namely, the inner circular and the outer longitudinal layers), and the submucosal plexus that is located in the submucosa. The myenteric plexus is the main system responsible for control of GI motility. Coordinated GI motor patterns, such as peristalsis, do not need any inputs from the central nervous system (CNS), although these may additionally modify gut motility (Brookes & Costa, 2002).

The main myenteric neuronal populations are represented in Fig. 98.1. Immunohistochemical methods have allowed the identification of the myenteric neuronal populations immunoreactive for different components of the ECS within the ENS, as shown also in Fig. 98.1 for CB1R. Table 98.1 offers a summary of the immunohistochemical findings for CB1R, CB2R, TRPV1, and FAAH in the main myenteric neuronal populations. These data suggest that the excitatory component of peristalsis may be modified by cannabinoids, whereas the inhibitory component of the peristaltic reflex seems to lack the necessary receptors and enzymes (Kulkarni-Narla & Brown, 2000; Izzo & Sharkey, 2010).

The extrinsic innervation of the gut controlling motility is represented in Fig. 98.2. The GI tract from the esophagus to the proximal parts of the colon is innervated by parasympathetic vagal efferent fibers from the dorsal motor nucleus of the vagus (DMV) in the medulla oblongata. CB1R have been detected in the DMV, the medial, and gelatinous subnuclei of the nucleus tractus solitarius and the area postrema. CB1R in the nodose ganglion and DMV are involved in the control of GI motility (Vianna et al., 2012). Additionally, the efferent fibers from the pontine Barrington nucleus project to the sacral spinal cord and terminate in the region of the preganglionic pelvic nerve. This pelvic nerve is also parasympathetic and projects to the distal colon and rectum. In rats, activation of this pelvic nerve regulates distal colonic and rectal motility under physiological conditions (Suda, Setoyam, Nanno, Matsumoto, & Kawai, 2013). To our knowledge, the ECS in these pelvic efferents to the distal gut has not been studied.

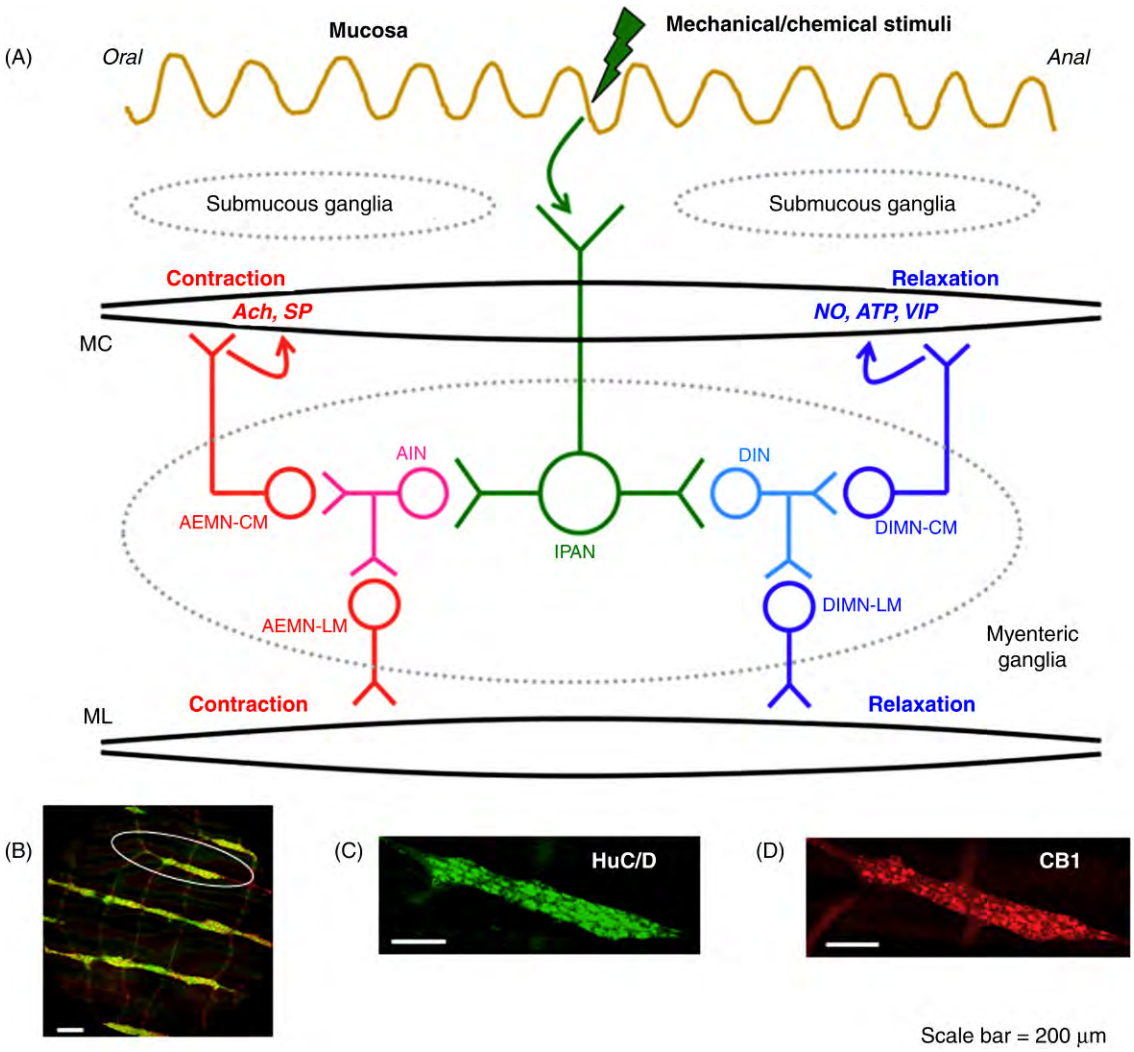

FIGURE 98.1 **Myenteric neurons and the endocannabinoid system.** (A) Schematic representation of the myenteric plexus and its main neural components involved in the intrinsic control of gastrointestinal motor function. Main myenteric neuronal populations are: intrinsic primary afferent neurons (IPAN) which detect mechanical (distension of the gut wall) and/or chemical stimuli acting upon the mucosa; ascending interneurons (AIN); ascending excitatory motor neurons to longitudinal and circular muscle (AEMN-LM and AEMN-CM, respectively), which induce contraction of the smooth muscle layers oral to the stimulus via the release of excitatory neurotransmitters (*Ach*, acetylcholine; *SP*, substance P); descending inhibitory interneurons (DIN); descending inhibitory motor neurons to longitudinal and circular muscle (DIMN-LM and DIMN-CM), which induce relaxation of the smooth muscle layers anal to the stimulus via the release of inhibitory neurotransmitters (*NO*, nitric oxide; *ATP*, adenosine triphosphate; *VIP*, vasoactive intestinal peptide). (B—D): Microphotographs of whole-mount preparations from guinea pig ileum processed immunohistochemically to show the neurons immunoreactive for the pan-neuronal marker HuC/D (C, *green*), the cannabinoid CB1 receptor (D, *red*) or both (B, *yellow*, due to merging of C and D). The myenteric ganglion encircled in B is shown in C and D. CB1R are present in most but not all myenteric neurons.

CANNABINOIDS AND GASTROINTESTINAL MOTILITY

Cannabinoid effects on GI motility have been reviewed previously (Abalo, Vera, López-Pérez, Martínez-Villaluenga & Martín-Fontelles, 2012; Izzo & Sharkey, 2010; Izzo & Coutts, 2005) and are summarized in Table 98.2.

Both central and peripheral cannabinoid receptors are likely to be involved in the regulation of GI motility. As shown in vitro for multiple species (mouse, rat, guinea pig, human) and different GI preparations, CB1R agonists inhibit GI muscle contraction via the presynaptic reduction of excitatory neurotransmitter release (acetylcholine, substance P) from the myenteric neurons (Roth, 1978; Abalo et al., 2012). Gastrointestinal CB1R appears to exert tonic control over ENS circuits, and operates as a "brake" for neural overreactivity (Schicho & Storr, 2011; Abalo et al., 2012). Furthermore, the selective GPR55 agonist O-1602 concentration-dependently

TABLE 98.1 Components of the Endocannabinoid System in the Main Myenteric Neuronal Populations Responsible for Control of Gastrointestinal Motor Function

Function	Chemical code	CB1R[a,b,c]	CB2R[d,e]	TRPV1[f,g]	FAAH[h]
Ascending excitatory motor neurons to circular muscle (AEMN-CM)	SP/ACh/±ENK/NFT	+	+	+	+
Ascending excitatory motor neurons to longitudinal muscle (AEMN-LM)	SP/ACh/CR	+	+	+	+
Descending Inhibitory motor neurons to circular muscle (DIMN-CM)	VIP/NOS/ATP/DYN/GRP/NFT	?	?	–	–
Descending inhibitory motor neurons to longitudinal muscle (DIMN-LM)	VIP/NOS	?	?	–	–
Ascending interneurons (AIN)	SP/ACh/ENK/NFT/CR	+	+	+	+
Descending interneurons (DIN)	5-HT/ChAT/NFT/SOM	+	+	–	+
Intrinsic primary afferent neurons (IPAN)	CALB/SP/ACh	+	+	+	+

For each myenteric neuronal population, its function, its characteristic chemical code (in the guinea pig ileum) and the presence of the main components of the endocannabinoid system are specified. ACh, Acetylcholine; ATP, adenosine triphosphate; CALB, calbindin; CB1R, CB2R, cannabinoid receptors 1 and 2; CR, calretinin; DYN, dynorphin; ENK, enkephalin; FAAH, fatty acid amidohydrolase; GRP, gastrin releasing peptide; 5-HT, serotonin; NFT, neurofilament triplet protein; NOS, nitric oxide synthase; SOM, somatostatin; SP, substance P; TRPV1, transient receptor potential vanilloid 1; VIP, vasoactive intestinal peptide.

reduced evoked contractions in muscle strips from mouse colon and ileum. These effects were reversed by cannabidiol, but not by CB1R or CB2R antagonists (Li et al., 2013). Indirect elevation of endocannabinoids by pharmacological blockade of FAAH also inhibited contractility of the mouse colon (Fichna et al., 2014). In human colonic tissue in vitro, anandamide and 2-arachidonoylglycerol suppressed cholinergic contractility via a noncannabinoid receptor-mediated pathway, suggesting that cholinergic contraction may be tonically modulated by endocannabinoids and/or other products of arachidonate metabolism (Smid, Bjorklund, Svensson, Heigis, & Revesz, 2007).

In vivo, synthetic and natural CB1R agonists decrease intragastric pressure and inhibit gastric emptying, pyloric contraction, and intestinal motility (Izzo & Coutts, 2005; Abalo et al., 2012). In humans, Δ^9-THC significantly reduced gastric emptying of solid food (McCallum et al., 1999) and dronabinol decreased postprandial colonic tone and increased compliance (Esfandyari et al., 2007), but did not affect colonic transit (Esfandyari et al., 2006).

More recently, Abalo and colleagues (Abalo et al., 2009, Abalo, Cabezos, Vera, Fernández-Pujol, & Martin, 2010) analyzed the in vivo effects of the nonselective cannabinoid agonist WIN55,212-2 in the rat, using radiographic techniques. WIN55,212-2 dose-dependently reduced motility throughout the gut and this effect was sensitive to CB1R blockade (Abalo et al., 2009, 2010a). However, at doses capable of delaying gastric emptying (2–5 mg/kg), higher than those already capable of reducing intestinal transit (0.5–1 mg/kg), WIN55,212-2 induced significant central effects. These were not found after administration of the selective CB1R agonist AM841 at a dose also capable of delaying gastric emptying, suggesting that central CB1R are not essential to alter GI motility (Abalo et al., 2010b). Some effects of natural and synthetic cannabinoid agonists are nonetheless mediated throughout CNS-located receptors. These include, for example, contractions of the lower esophageal sphincter (LES) (Izzo & Sharkey, 2010).

CB1R antagonists increased motility, suggesting that GI motility is under tonic suppression by the ECS (Izzo & Sharkey, 2010). Moreover, it has been shown that

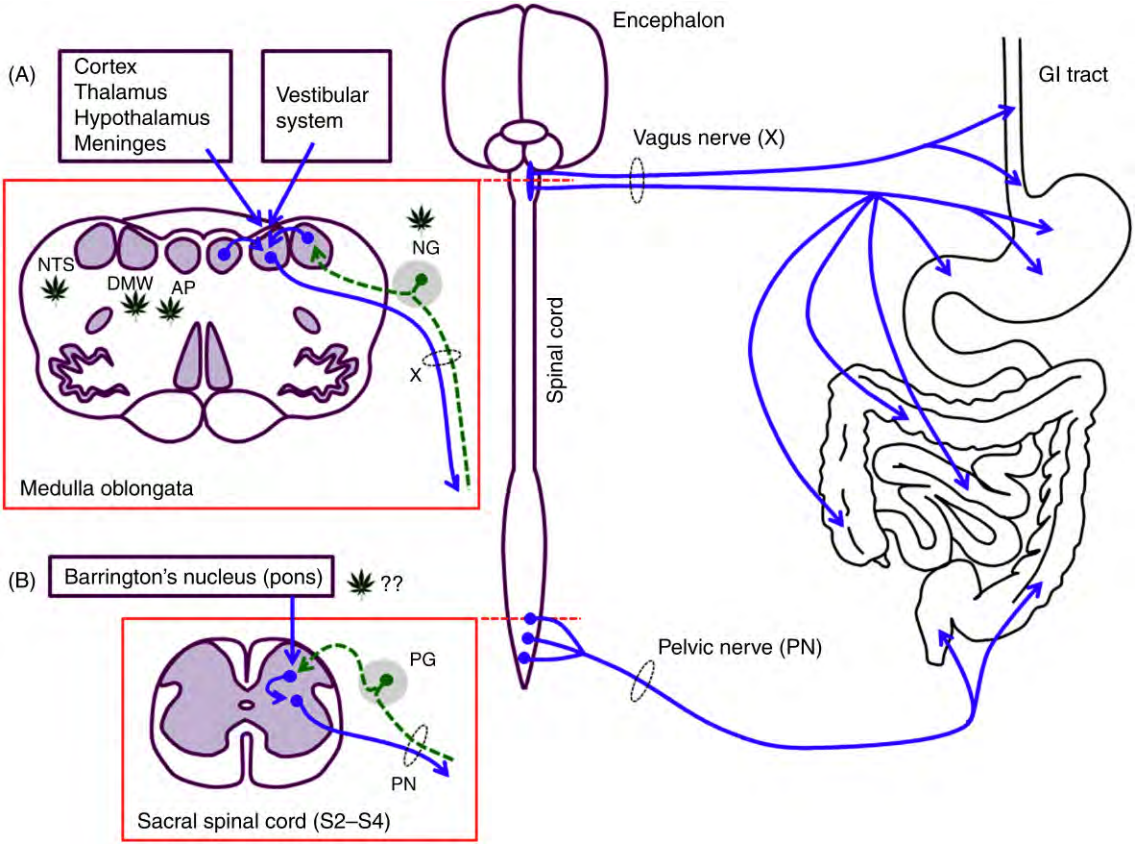

FIGURE 98.2 **Extrinsic neural control of gastrointestinal motor function and the endocannabinoid system.** Two main parasympathetic pathways control gastrointestinal motility: the vagus nerve (X cranial nerve) arises from the dorsal motor nucleus of the vagus (DMV) in the medulla oblongata, and innervates the stomach, small intestine, and proximal parts of the large intestine; the pelvic nerve (PN) arises from the sacral segments S2–S4 of the spinal cord, and innervates distal colon and rectum. (A) cross section of the medulla oblongata: the DMV receives inputs from other structures of the dorsal vagal complex, namely, the nucleus of the tractus solitarius (NTS, which receives inputs from the viscera, including the GI tract, via the nodose ganglion, NG) and area postrema (AP or chemoreceptor trigger zone, which detects emetogenic stimuli in the blood), as well as the vestibular system and other encephalic structures whose stimulation may induce an emetic reflex. CB1R have been demonstrated immunohistochemically in NTS, DMV, AP, and NG (marijuana leave symbol). (B) Cross section of the sacral spinal cord: the preganglionic fiber of the pelvic nerve receives inputs from colonic afferents with their somata in pelvic ganglia (PG), and also from the pontine Barrington nucleus. The involvement of the endocannabinoid system in this pathway has not been deeply investigated. *Blue lines*: parasympathetic efferents to the gut. *Green dotted lines*: parasympathetic afferents from the gut.

pharmacological blockade of FAAH delays whole GI transit and colonic propulsion in mice, and these effects are reversed by selective CB1R antagonists, suggesting the involvement of endogenous CB1R ligands in this effect (Fichna et al., 2014). The clinical trials using the CB1R antagonists rimonabant and taranabant, in patients with metabolic disorders and obesity, showed that diarrhea and other GI motor side effects like nausea and vomiting are observed frequently, though often transient (Ruilope et al., 2008; Despres, Golay & Sjostrom, 2005; Addy et al., 2008). From these trials, it seems that GI motility in humans is also under control of the ECS.

Besides CB1R, other "classical" and "nonclassical" cannabinoid receptors can regulate GI motility. Interestingly, endocannabinoids stimulate intestinal primary sensory neurons via TRPV1, resulting in enteritis and enhanced motility (Izzo & Coutts, 2005). In fact, exogenous and endogenous cannabinoids have an important role in GI inflammation (Izzo & Camilleri, 2009). On the other hand, CB2R stimulation may regulate motility in pathophysiologic conditions (Li et al., 2010). Other cannabinoid ligands also modulate gut motility in vivo. *N*-palmitoylethanolamine administered peripherally inhibited upper GI transit in mice, and this effect was not blocked by CB1R or CB2R antagonists (Capasso et al., 2001). The selective GPR55 agonist, O-1602, also decelerated whole gut transit. Interestingly, activation of GPR55 receptors was not associated with central sedation; thus it could be useful as a future target for the treatment of colonic motility disorders (Li et al., 2013).

Surprisingly, the effects of chronic administration of cannabinoid agonists on GI motor function have deserved relatively little attention. This is important, since cannabinoids are being proposed for the treatment of

TABLE 98.2 Effects of Drugs Targeting the Endocannabinoid System on Alterations in Gastrointestinal Motor Function

Pathology	↓CB tone	↑CB tone
GERD		*CB1 agonists* reduce transient lower esophageal sphincter relaxation in dogs and humans
Gastroparesis	*CB1 antagonists* increase gastric emptying in mice	*Δ^9-THC* reduces gastric emptying of solid food in humans *WIN 55,212-2* and other cannabinoid agonists reduce gastric emptying in rodents
Emesis	*CB1 antagonists* induce vomiting in humans, and conditioned taste avoidance and gaping in the taste reactivity test in rats	*CB1 and CB2 agonists, FAAH blockers,* reuptake inhibitors and MAGL inhibitors reduce emesis in animal models. *2-AG* decreases nausea-like behavior in rats *Nabilone, dronabinol and Sativex* are used as antiemetics in humans, intense use of *Cannabis* induces hyperemesis
Diarrhea	The *CB1 antagonists rimonabant-* and *taranabant-*induced diarrhea as a frequent side effect in clinical trials	*CBl and CB2 agonists, FAAH blockers* and *reuptake inhibitors* reduce gastrointestinal transit and hypermotility in mice and rats.
Constipation	*CB1 antagonists* increase gastrointestinal transit in mice	*Dronabinol* decreases postprandial colonic tone and increases compliance in humans
Ileus	*CB1 and CB2 antagonists* increase gastrointestinal transit in septic ileus in animal models *CBD* was also beneficial in a model of ileus in mice	Increased release of *endocannabinoids* is involved in development of ileus
IBS		*CB1 and CB2 agonists* reduce visceral pain, secretion, hypermotility and diarrhea in animal models *PEA* may decrease intestinal transit via CB1R and TRPVl *Δ^9-THC* delays gastric emptying in humans *Dronabinol* may reduce fasting colonic motility in patients with IBS-D or with IBS-A
IBD		*CB1 and CB2 agonists* reduce intestinal inflammation and visceral pain in mice and humans *FAAH blockers* and *reuptake inhibitors* reduce gastrointestinal inflammation in mice *Activation of QPR55 receptors* reduces colonic motility *Cannabis* use is common in patients with Crohn disease and subjectively improves pain and diarrheal symptoms

The increase or decrease in cannabinoid tone exerts the pharmacological effects indicated in the different motility alterations. See text for references. 2-AG, 2-Arachidonoylglycerol; CBD, cannabidiol; CB1R, cannabinoid receptor type 1; CB2R, cannabinoid receptor type 2; FAAH, fatty acid amide hydrolase; GERD, gastroesophageal reflux disease; IBD, inflammatory bowel disease; IBS, irritable bowel syndrome; IBS-D, IBS with diarrhea; IBS-A, IBS alternating diarrhea and constipation; MAGL, monoacylglycerol lipase; PEA, palmitoylethanolamide; Δ^9-THC, Δ^9-tetrahydrocannabinol; TRPV1, transient receptor potential vanilloid 1.

different chronic diseases (including those affecting the gut), and also because of the high prevalence of chronic cannabinoid abuse. The effect of different patterns of repeated administration of WIN55,212-2 has been investigated radiographically in the rat. Upon daily administration, tolerance developed to the effect of WIN55,212-2 in the intestine, but gastric emptying was still delayed after the 14th systemic administration of the drug (Abalo et al., 2009). Interestingly, upon intermittent (weekly) administration, the gastric effect of WIN55,212-2 was enhanced (Abalo et al., 2011). CB1R were involved in both cases, but an additional, not yet identified receptor could also be implicated in WIN55,212-2-induced delayed gastric emptying upon weekly administration. In both studies, GI motility was normal again 1 week after the end of treatment, suggesting that the effect of cannabinoids on GI motility might not be long-lasting.

Finally, although generally considered efficient antiemetics (see later), cannabinoids (natural, such as Δ^9-THC; or synthetic, such as K2; Ukaigwe, Karmacharya & Donato, 2014) may induce paroxysmal vomiting or cannabinoid hyperemesis syndrome (CHS), first described by Allen et al. (2004). CHS is characterized by a striking pattern of cyclic nausea and vomiting among long-term marijuana users, which can be relieved by compulsive hot water bathing. Other symptoms include abdominal pain. CHS resolves with cannabis cessation, but recurs when patients resume the use of cannabinoids after hospital discharge (Simonetto, Oxentenko, Herman & Szostek, 2012). Different mechanisms have been suggested to contribute, such as central effects of long-term cannabis use on the hypothalamic-pituitary-adrenal axis, but also dysregulation of peripheral enteric nerves causing delayed gastric emptying and abdominal pain

(Simonetto et al., 2012; Izzo and Sharkey, 2010). Our results showing persistent or even aggravated gastric dysmotility upon chronic cannabinoid administration in the rat support this hypothesis.

POTENTIAL THERAPEUTIC APPLICATIONS OF CANNABINOIDS

Pharmacological manipulation of the ECS could have important applications in the treatment of GI motility alterations, such as, emesis, gastroesophageal reflux, paralytic ileus, or diarrhea.

Gastroesophageal Reflux Disease (GERD)

GERD is a common disorder with symptoms like heartburn, regurgitation, and retrosternal pain (Heading, 1999), resulting from prolonged acid exposure of the esophageal mucosa. The LES regulates the flow across the gastroesophageal junction by generating a tonic pressure to prevent reflux of gastric contents into the esophagus. Transient lower esophageal sphincter relaxations (TLESRs) are the main mechanism underlying gastroesophageal reflux and a potential pharmacological treatment target (Holloway, 2000). CB1R have been located in brain areas involved in the triggering of TLESRs in the ferret (Van Sickle et al., 2001) and the cannabinoid agonist WIN55,212-2 was shown to reduce the occurrence of TLESRs in dogs (Lehmann et al., 2002). Also, Δ^9-THC significantly reduced basal LES in humans (Beaumont et al., 2009). GERD and esophageal motility disorders occur in obesity; these alterations could be secondary to reduced endocannabinoids or CB1R expression (Mushref & Srinivasan, 2013).

Nausea and Emesis

Nausea and vomiting is an integral defense mechanism against toxin ingestion, but is an unpleasant side effect associated with medications (opiates, chemotherapeutics, interferon…). The introduction of 5-HT3 antagonists, together with the corticoid dexamethasone and aprepitant (a neurokinin 1 receptor antagonist), has largely controlled chemotherapy-induced nausea and vomiting (CINV). However, these conventional antiemetics are not as successful in treating nausea as they are in treating emesis (Abalo et al., 2012). *Cannabis* has been used for several centuries for the attenuation of nausea and vomiting. Moreover, cannabinoids were found to inhibit emesis in animal models (ferrets; least shrews, *Cryptotis parva*; house musk shrews, *Suncus murinus*…) of acute cisplatin-, morphine- and radiation-induced emesis, as well as in cisplatin-induced delayed emesis, and in motion sickness (Izzo & Sharkey, 2010; Parker, Rock, & Limebeer, 2011). Also, the FAAH inhibitor URB597 suppressed cisplatin- and nicotine-induced vomiting in the house musk shrew through CB1R (Parker et al., 2009).

Since rodents and mice lack the vomiting reflex, it is necessary to use other markers of nausea and emesis in order to evaluate the antiemetic potential of drug therapies in these species. There are two possibilities: first, conditioned taste avoidance and conditioned gaping, which are disgusting reactions to flavors or foods paired with illness; and pica, which is the consumption of nonnutritive substances (eg, kaolin clay) in response to nausea-inducing agents, a behavior which may represent an adaptive response to reduce the adverse effects of toxins in the organism. In addition, delayed gastric emptying is temporally related to pica induced by emetogenic stimuli in rodents (Cabezos et al., 2008; Cabezos, Vera, Martín-Fontelles, Fernández-Pujol, & Abalo, 2010). In rats, taste avoidance and gaping are suppressed by pretreatment with Δ^9-THC, HU-210, the FAAH blocker URB597, and cannabidiol (review in Abalo et al., 2012). However, the synthetic cannabinoid WIN55,212-2, administered in a weekly fashion together with the antineoplastic drug cisplatin in the rat at doses that prevented the development of neuropathic signs, was not able to reduce pica, anorexia or delayed gastric emptying, and small intestinal motility was even further delayed (Vera et al., 2007; Abalo, Cabezos, Vera, López-Pérez & Martín, 2013; see Fig. 98.3). This suggests that, although cannabinoids are used in humans to prevent CINV, gastric dysmotility is still likely to be present and may be aggravated when cannabinoids and antineoplastic drugs are combined.

In humans, nabilone (Cesamet), a synthetic analog of Δ^9-THC, was specifically licensed for the suppression of CNIV. Furthermore, the synthetic Δ^9-THC dronabinol is used as an antiemetic and an appetite stimulant (Pertwee, 2009). Dronabinol was found to be superior to neuroleptics (Machado Rocha, Stéfano, De Cássia Haiek, Rosa Oliveira, & Da Silveira, 2008) and similarly effective to ondansetron (Meiri et al., 2007) for the treatment of CINV. Unfortunately, the clinical usefulness of these cannabinoid agonists is restricted due to psychotropic side effects. A logical step is thus to examine the action of nonpsychotropic cannabinoids, such as cannabidiol. Sativex, a mixture of cannabidiol and Δ^9-THC, was effective in preventing delayed CINV in a phase II trial; unfortunately, one patient withdrew due to neuropsychiatric side effects (Duran et al., 2010).

Overall, the data suggest that—although cannabinoids are effective antiemetics—current formulations have unacceptable side effects.

Intestinal Inflammatory Conditions

This section includes irritable bowel syndrome (IBS) and inflammatory bowel disease (IBD), which have

similar symptoms, although their pathogenesis and treatment could differ.

IBS is a functional disorder characterized by abdominal discomfort, bloating, and altered bowel habits, including alterations in gut motility, visceral hypersensitivity, and bacterial overgrowth. IBS presents in three different forms: diarrhea-predominant (D-IBS), constipation-predominant (C-IBS), or alternating (A-IBS; episodes of either diarrhea or constipation). Due to their effects on motility and secretion, CB1 agonists may be useful to treat D-IBS, whereas CB1 antagonists could be useful to treat C-IBS. Activation of CB2R, which are overexpressed in the gut under inflammatory conditions, may also be used to treat D-IBS.

IBD includes Crohn disease (CD), ulcerative colitis (UC), and much less frequent diseases, for example, nonspecific colitis, collagenous colitis, and eosinophilic colitis. Therapeutic strategies target the underlying inflammatory process, but some patients continue to have chronic diarrhea. Experiments on human intestinal biopsies revealed increased expression of cannabinoid receptors and/or enhanced endocannabinoid levels in patients with UC and CD (Izzo & Camilleri, 2009). Many in vivo studies in various animal models of IBD demonstrated that administration of CB1 and/or CB2 agonists improved colitis (for review Izzo & Sharkey, 2010; Sałaga, Sobczak, & Fichna, 2013). Clinical trials have demonstrated that Δ^9-THC may be useful in the treatment of CD (Naftali et al., 2013). Anecdotal reports suggest that some UC and CD patients experience relief when smoking marijuana (Di Marzo & Izzo, 2006); accordingly, *Cannabis* use is common amongst patients with IBD for symptom relief (Lal et al., 2011). In contrast, in a recent study in CD patients, *Cannabis* use was associated with higher risk of surgery (Storr, Devlin, Kaplan, Panaccione & Andrews, 2014).

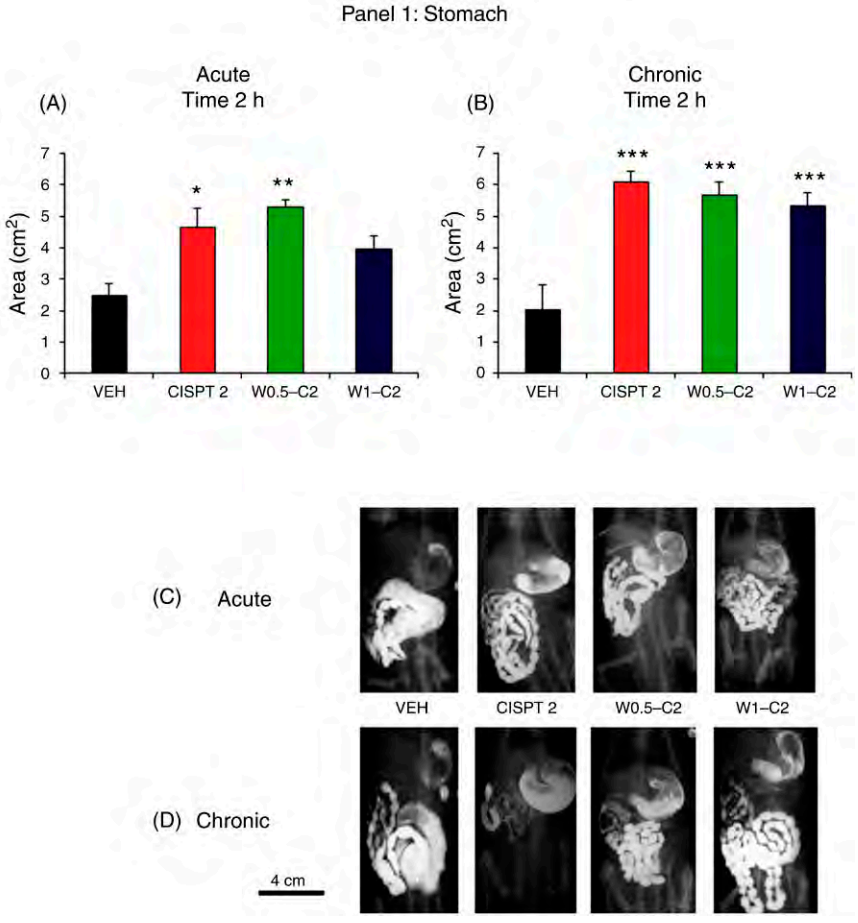

FIGURE 98.3 Effect of acute and chronic administration of the cannabinoid agonist WIN55,212-2 on gastrointestinal motor function in cisplatin-treated rats. Gastrointestinal motor function was analyzed using radiological methods. Stomach (Panel 1) and cecum (Panel 2) size were measured after contrast administration in rats treated once a week for 4 weeks with WIN55,212-2 (W; 0.5 or 1 mg/kg) or its vehicle, together with cisplatin (CISPT, 2 mg/kg) or saline. Barium sulfate was intragastrically administered immediately after the first (acute effect: A, C) or the last administration (chronic effect: B, D) and X-rays of the GI tract were obtained. No anesthesia was applied to avoid GI motility alterations. X-rays were digitized and morphometrically analyzed using an image processor (Image J; NIH). (A and B) Data represent mean ± SEM for images obtained 2 (Panel 1) or 4 (Panel 2) h after contrast administration. $N \geq 8$, each group. *$p < 0.05$, **$p < 0.01$, ***$p < 0.001$ versus vehicle (one-way ANOVA). (C and D) Representative X-rays obtained 2 (Panel 1) or 4 (Panel 2) h after contrast. Scale bar: 4 cm. Unpublished.

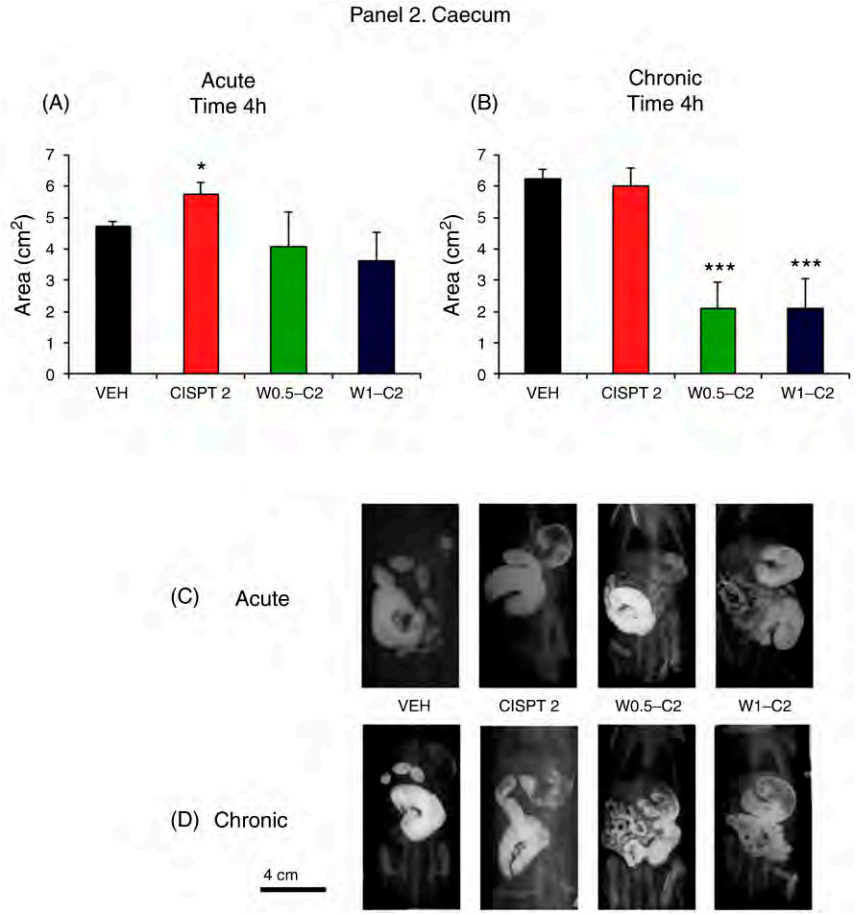

FIGURE 98.3 (*cont.*)

These inflammatory pathologies and ECS involvement have been more deeply reviewed in the chapter *Cannabis and Cannabinoids, and the Effects on Gastrointestinal Function: An Overview*.

Paralytic Ileus and Slow Transit Constipation

Paralytic ileus is defined as a long-lasting inhibition of GI motility in response to nociception initiated at the abdominal level. It may occur following peritonitis, surgery, or other noxious situations. Patients with paralytic ileus accumulate gas and secretions, leading to bloating, distension, emesis, and visceral pain (Di Carlo & Izzo, 2003). The intraperitoneal administration of acetic acid in mice, which mimics paralytic ileus, reduced intestinal motility and this occurred together with an increase in anandamide levels and overexpression of CB1R in the myenteric plexus; these effects were alleviated by rimonabant, but not by CB2R inactivation (Mascolo et al., 2002). In contrast, inactivation of either CB1R or CB2R led to normalization of motility in a model of septic ileus in the rat (Li et al., 2010). Cannabidiol was also beneficial in a mouse model of ileus (Lin et al., 2011), possibly via a reduction in nitric oxide production. In animal models, FAAH activity was significantly decreased (Camilleri & Katzka, 2012). In patients with constipation, the amounts of anandamide, 2-arachidonoylglycerol, and *N*-palmitoylethanolamine, which are negatively correlated with enzyme activity, were significantly higher in the constipation group (Zhang et al., 2014).

Thus the release of endogenous cannabinoids may be involved in the development of paralytic ileus and different strategies aimed at normalizing endocannabinoid levels could be therapeutically useful in these conditions.

CONCLUSIONS

The ECS within the gut is an important system involved in controlling motility. It is present both in the intrinsic and the extrinsic innervation of the GI system. Cannabinoid agonists and antagonists, as well as enzymes involved in the synthesis and degradation of the endocannabinoid ligands, have been demonstrated to exert prominent effects that could be useful to treat nausea/emesis, gastroesophageal reflux, paralytic ileus or diarrhea in different circumstances. Future studies should include strategies for reducing or abolishing the

adverse effects of cannabinoids and cannabinoid-related compounds without attenuating their beneficial therapeutic effects.

MINI-DICTIONARY

Area postrema Chemoreceptor trigger zone, lies outside the blood-brain barrier and detects chemical emetogenic stimuli in the blood.

Cannabinoid hyperemesis syndrome A disorder characterized by recurrent nausea, vomiting and abdominal pain; associated with chronic cannabis use in humans.

Chemotherapy-induced nausea and vomiting A common side effect of many cancer treatments.

Dorsal motor nucleus of the vagus It serves vagal fibers to the gastrointestinal tract, lungs, and other thoracic and abdominal viscera; related to the gastrointestinal tract, it receives inputs from different structures (including those detecting emetogenic stimuli) and innervates the stomach, small intestine, and proximal large intestine.

Dorsal vagal complex Group of nuclei in the medulla oblongata including the nucleus of the tractus solitarius, dorsal motor nucleus of the vagus, and area postrema.

Enteric nervous system One of the divisions of the peripheral nervous system that governs the function of the gastrointestinal system.

Gastroesophageal reflux disease A common disorder resulting from prolonged acid exposure of the esophageal mucosa due to increased relaxation of the lower esophageal sphincter.

Gastroparesis Delayed gastric emptying, a medical condition resulting in food remaining in the stomach for an abnormally long time.

Myenteric plexus Part of the ENS that controls gastrointestinal motility; it is located between the longitudinal and circular muscle layers in the gut.

Nucleus of the tractus solitarius It receives sensory information from the viscera, including the GI tract.

Paralytic ileus Disruption of the normal intestinal motility following surgery or noxious situations.

Pica The consumption of nonnutritive substances (eg, kaolin-clay) in response to nausea-inducing agents, typical in nonvomiting species like rodents.

Potential Medical Uses of Cannabigerol: A Brief Overview

S. Deiana

CNS Diseases Research Department, Boehringer Ingelheim Pharma GmbH & Co. KG, Birkendorfer straße, Biberach an der Riss, Germany

SUMMARY POINTS

- This chapter focuses on medical uses of cannabigerol (CBG), a phytocannabinoid present in the *Cannabis* plant.
- CBG is a short-life precursor of tetrahydrocannabinol (THC), cannabidiol (CBD), and cannabichromene (CBC), which explains its low concentration in the plant.
- CBG acts on serotoninergic, cannabinoid, peroxisome proliferator-activated receptors, α2-adrenoceptors, vanilloid, melastatin, and ankyrin channels.
- CBG modulates enzymes activity including monoacylglycerol lipase (MAGL), *N*-acylethanolamine acid amide (NAAA) hydrolase, cyclooxygenase (COX), phospholipase-A2 (PLA2), prostaglandin-E2 production (PGE2), and inhibits dopamine, norepinephrine, GABA, and serotonin reuptake.
- By inhibiting prostaglandin production at different levels, CBG owns antinflammatory and analgesic properties.
- CBG possesses antiproliferative effects and it has been suggested for cancer therapy.
- Its effects on preclinical models of mood disorders granted the filing of a patent for CBG use to treat mood disorders, particularly depression.
- CBG has been suggested for skin conditions, glaucoma, sex hormonal dysregulations, eating disorders, and bone healing.
- Due to its difficult availability, CBG has received attention only recently, and further research is required before its clinical efficacy can be demonstrated.

KEY FACTS OF CANNABIGEROL CONTENTS IN *CANNABIS* PLANT

- Cannabigerol (CBG) concentrations in the *Cannabis* plant are usually extremely low.
- This is due to its rapid conversion into tetrahydrocannabinol (THC), cannabidiol (CBD), and cannabichromene (CBC).
- Recent genetic techniques allowed the inactivation of the devoted synthases to prevent the natural conversion of CBG into its metabolites.
- This permitted the selection of *Cannabis* plant strains with high CBG contents.

KEY FACTS OF FIRST MEDICAL USES OF *CANNABIS*

- First *Cannabis* uses are documented in the Chinese herbarium Pen-ts'ao (2800 BC), a pharmacopeia describing several drugs.
- Pen-ts'ao described *Cannabis* as "*ma,' meaning* chaotic.
- *Cannabis* pain-relieving, stupefying, hallucinogenic properties were described together with its use for malaria, menstrual irregularities, constipation, gout and rheumatism.

LIST OF ABBREVIATIONS

5HT$_{1A}$R	5-Hydroxytryptamine-1A Receptors
BBB	Blood–brain barrier
BDS	Botanical drug substance
CB$_1$R, CB$_2$R	Cannabinoid receptors type 1 and 2
CBC	Cannabichromene
CBD	Cannabidiol
CBG	Cannabigerol
COX	Cyclooxygenase
DNBS	Dinitrobenzene sulfonic acid
EAE	Experimental autoimmune encephalomyelitis
IBD	Inflammatory bowel disease
iNOS	Inducible nitric oxide synthase
IOP	Intra ocular pressure
MAGL	Monoacyl glycerol lipase
MS	Multiple sclerosis
MSCs	Mesenchymal stem cells
NAAA	*N*-acylethanolamine acid amidase
NSAIDs	Nonsteroidal antiinflammatory drugs
PCCs	Prostate cancer cells
PGE2	Prostaglandin-E2
PLA2	Phospholipase-A2
PPARs	Peroxisome proliferator-activated receptors
THC	Tetrahydrocannabinol
TLM	Testosterone lowering medicaments
TMEV	Theiler's murine encephalomyelitis virus
TRP	Transient receptor potential
TRPA	Transient teceptor potential ankyrin
TRPM	Transient receptor potential melastatin
TRPV	Transient receptor potential vanilloid

INTRODUCTION

Medicinal use of *Cannabis* dates back to 2800 BC, with suggested use in treating constipation, malaria, gout, rheumatism, pain, asthma, and menstrual anomalies (Iversen, 2007).

The main constituent of the *Cannabis* plant, tetrahydrocannabinol (THC), possesses psychotropic effects, thus limiting its therapeutic use; attention now focuses on nonpsychotropic phytocannabinoids, such as cannabidiol (CBD), cannabichromene (CBC), and cannabigerol (CBG) as potential therapeutic agents for conditions ranging from cancer to inflammation and to mental disorders. For instance, CBD has been suggested to be beneficial for schizophrenia (Deiana, 2013; Zuardi et al., 2012), while the oromucosal spray Sativex (THC and CBD) is approved for the treatment of spasticity in multiple sclerosis (MS) (GW Pharmaceuticals, 2014).

Described for the first time in 1964 (Gaoni & Mechoulam, 1964), CBG is the least studied among phytocannabinoids (a Pubmed search using keyword "cannabigerol" results in 69 publications only), primarily due to its low availability in the *Cannabis* plant (~10% of the cannabinoid fraction) (de Meijer & Hammond, 2005). Specific synthases rapidly metabolize CBG into THC (Taura, Morimoto, Shoyama, & Mechoulam, 1995), CBD (Taura, Morimoto, & Shoyama, 1996) and CBC (Gaoni & Mechoulam, 1966) thus reducing CBG availability in the plant (Fig 99.1). Plants carrying a recessive allele which reduces the efficacy of these synthases contain higher CBG concentration (94% of the cannabinoid fraction) and genetic engineering allows the generation of CBG-predominant *Cannabis* plants (de Meijer, 2004; GW Pharmaceuticals, 2014), facilitating research into CBG pharmacology, and hence fostering the knowledge on its potentials as a therapeutic agent.

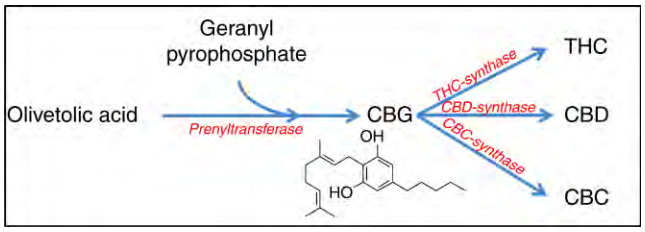

FIGURE 99.1 Biosynthesis and metabolism of cannabigerol. A prenyltransferase catalyzes the conversion of olivetolic acid into CBG, which is then converted into THC, CBD, or CBG by specific synthases. *Source: Information collected from Hill, Williams, Whalley, and Stephens (2012) and Marks et al. (2009).*

PHARMACOKINETICS AND PHARMACOLOGY OF CANNABIGEROL

The mechanism of action of CBG was until recently unknown. In recent times, novel studies revealed its polypharmacological profile, making it an interesting molecule for direct use as medicament itself or as a possible starting molecular structure for the development of more selective/potent chemical entities.

Pharmacodynamics and pharmacokinetic figures are fundamental for profiling and selecting a drug for medical use. Human CBG exposure and bioavailability are still unknown, but its pharmacokinetics in rodents have been described (Deiana et al., 2012). Plasma and brain pharmacokinetics of CBG (120 mg/kg) were studied in rats and mice, following acute oral and intraperitoneal administration (Table 99.1).

CBG readily crossed the blood–brain barrier (BBB) and, in general, in both species, intraperitoneal administration provided higher plasma and brain concentration being the difference only marginal in rats. Indeed, C_{max} values were similar in rats receiving oral or intraperitoneal CBG administration, whereas in mice, C_{max} values

TABLE 99.1 Pharmacokinetics of Cannabigerol

	Mouse				Rat			
	Plasma		Brain		Plasma		Brain	
Measure	po	ip	po	ip	po	ip	po	ip
C_{max} (μg/mL)	0.67	40.8	0.42	3.48	1.05	0.81	0.97	1.23
T_{max} (min)	30	120	60	120	30	60	120	60
Apparent elimination half-life (min)	193	176	≤121	252	100	560	96	447
$AUC_{0–6\,h}$ (μg/mL, g min)	57	4324	≤44	679	98	≤199	181	335
$AUC_{0–24\,h}$ (μg/mL, g min)	ID	5563	≤65	1103	ID	≤514	ID	884
$AUC_{0–\infty}$ (μg/mL, g min)	67	5571	≤86	1117	106	≤617	205	992

$n = 4$; po, *per os*; ip, intraperitoneal; ID, insufficient data available for analysis; C_{max}, maximal drug concentration in tissue; T_{max}, time to reach C_{max}; AUC, area under the curve. Mouse and rat pharmacokinetic values in plasma and brain following 0.5, 1, 2, 4, 6, and 24 h oral and intraperitoneal CBG (120 mg/kg) administration. Apparent elimination half-life (minutes) 2–6 h for po; 4–24 h for ip.
Data from Deiana et al. (2012).

were higher after CBG intraperitoneal compared to oral administration. Mice brain/plasma ratios were 0.77 and 0.15 for oral and intraperitoneal treatments, respectively, and in rats ratios were similar in the two administration routes (1.84 oral and 1.68 intraperitoneal).

Considerably broadening the knowledge of CBG pharmacology, Cascio, Gauson, Stevenson, Ross, and Pertwee (2010) conducted a set of experiments elucidating CBG ability to produce G-protein-coupled-receptor activation or blockade. CBG demonstrated partial agonism/antagonism at cannabinoid type-1 (CB_1R) and type-2 (CB_2R) receptors (Cascio et al., 2010; Gauson et al., 2007). Additionally, CBG has been demonstrated to act as an agonist for α2-adrenoceptors, but receptor subtypes selectivity awaits further elucidation. Like other α2-adrenoceptor ligands, CBG also binds at 5-hydroxytryptamine-1A receptors ($5HT_{1A}R$), acting as a neutral antagonist (Cascio et al., 2010).

At transient receptor potential (TRP) channels, CBG induced a TRPA1- but not TRPM8-mediated Ca^{++} elevation; however, it antagonized the menthol- or icilin-induced Ca^{++} elevation TRPM8-mediated (De Petrocellis et al., 2008). This effect was confirmed and expanded by pharmacological experiments using the botanical drug substance (BDS) CBG (De Petrocellis et al., 2011), derived from CBG-predominant genetically selected *Cannabis* plants. Notably, "CBG-free-CBG-BDS" was inactive, but when added to pure CBG, it became more potent and efficacious at antagonizing TRPM8 than CBG alone. This suggests a synergistic effect between CBG and noncannabinoids contained in its BDS. In cells overexpressing recombinant rat TRPV2 or human TRPV1, CBG also stimulated and then desensitized TRPV1 and TRPV2 (De Petrocellis et al., 2011).

CBG acts on several enzymes involved in prostaglandin production pathways. In an in vitro enzyme based cyclooxygenases (COX)-inhibition assay, it showed full inhibition of COX-1 and ~70% of COX-2. In tumor-necrosis-factor-α-stimulated human colon adenocarcinoma cell line HT29, CBG barely decreased prostaglandine-2 (PGE2) production (~5%) (Ruhaak et al., 2011). More potent activity has been seen in human rheumatoid synovial cells stimulated by the proinflammatory agent 12-0-tetradecanoylphorbol-13-acetate where CBG caused 90% inhibition of PGE2 release (Barrett, Gordon, & Evans, 1985).

CBG further modulates the inflammatory pathway by acting on phospholipase-A2 (PLA2), with high doses reducing its activity and low doses enhancing it (Evans, Formukong, & Evans, 1987). It is, therefore, hypothesized that CBG-mediated activation of PLA2, triggers the hydrolysis of phospholipids, inducing increase in arachidonic acid and subsequent inflammatory cascade (Fig 99.3). Vice versa, high doses of CBG may decrease the lipids metabolites, and hence PGE2 synthesis.

CBG-BDS was also shown to inhibit *N*-acylethanolamine acid amidase (NAAA), which hydrolyzes fatty-acid ethanolamides, such as *N*-palmitoylethanolamine (an endogenous antinociceptive and antiinflammatory fatty acid), anandamide cellular uptake, and monoacyl glycerol lipase (MAGL), which hydrolyze the endocannabinoid 2-arachidonoylglycerol and intracellular triglycerides to fatty-acids and glycerol. Pure CBG and the "CBG-free-CBG-BDS" were less potent than CBG-BDS, indicating that both cannabinoid and noncannabinoid substances present in the BDS might synergistically contribute to MAGL inhibition (De Petrocellis et al., 2011).

CBG was found to be active at L-type Ca^{++} and Na^{+} channels (Duncan et al., 2014), it demonstrated partial agonism at peroxisome proliferator-activated receptors (PPARγ), (Granja et al., 2012), and it inhibited the uptake of dopamine (Duncan et al., 2014), 5HT, norepinephrine (in rat hypothalamic synaptosomes) and GABA (in cerebrocortical synaptosomes) (Banerjee, Snyder, & Mechoulam, 1975); all these effects are not fully elucidated so far.

TABLE 99.2 Pharmacological Targets and Actions of Cannabigerol

Target	Action	Pharmacology	References
5HT uptake	Inhibition	K_i = 50 μM	Banerjee et al. (1975)

α2-Adrenoceptors	Agonism	EC50 = 0.2 nM	Cascio et al. (2010)

Cellular target, pharmacological action and values of CBG and/or CBG-BDS. BDS, Botanical drug substance; CBG, cannabigerol; CBR, cannabinoid receptor; EC50, half maximal effective concentration; IC50, half maximal inhibitory concentration; COX, cyclooxygenase; K_i, receptor-ligand inhibition constant; MAGL, monoacyl glycerol lipase; NAAA, *N*-acylethanolamine acid amidase; NE, norpinephrine; PPARs, peroxisome proliferator-activated receptors; PLA2, phospholipase-A2; PGE2, prostaglandin-E2; TRPA, transient receptor potential ankyrin; TRPM, transient receptor potential melastatin; TRPV, transient receptor potential vanilloid.
Data collected from several publications (see references in the table).

Table 99.2 summarizes CBG in vitro pharmacology as determined via different methodological approaches, which suggests caution in the direct comparison of individual data.

POTENTIAL MEDICAL USES OF CANNABIGEROL

Medical use of *Cannabis* has been recognized for millennia for the treatment of a multitude of conditions. Intrigued by its complex and diverse pharmacology, scientists are currently addressing renewed attention on CBG's therapeutic uses (Fig. 99.2).

Analgesia and Inflammation

There exists an increasing body of evidence from in vivo experiments showing that cannabinoids reduce sensitivity to pain.

Acting through inhibition of COX, nonsteroidal anti-inflammatory drugs (NSAIDs) are the most widely used drugs for the treatment of pain and inflammation. COXs catalyze the conversion of arachidonic acid into prostaglandins, hormone-like lipids responsible for homeostatic regulation of pathogenic mechanisms, including inflammatory response (Fig. 99.3). In this context, CBG may hold potential as an antiinflammatory agent by acting at different levels of

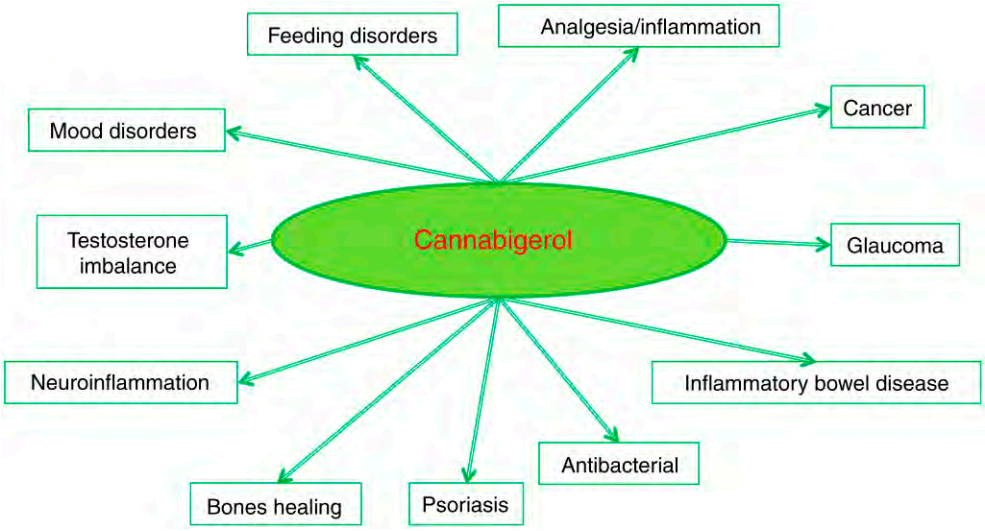

FIGURE 99.2 **Possible therapeutic applications of cannabigerol.** Cannabigerol has been suggested as a possible therapeutic agent for several conditions. To date, for most of these the exact mechanism of action awaits elucidation.

the prostaglandin synthesis pathway: by direct inhibition of PGE2 production, by inhibition of the upstream enzyme PLA2 and by unselective inhibition of the COX enzymes. Its inhibitory activity on MAGL, could also result in reduced prostaglandin synthesis by inhibiting 2-arachidonilglycerol conversion into arachidonic acid.

Data from in vivo experiments showed that CBG was more potent, although less maximally effective, than THC and aspirin in the phenyl benzoquinone (PBQ) model of peripheral inflammatory pain (Formukong, Evans, & Evans, 1988). CBG showed 61% maximum percent inhibition of PBQ-induced writhing behavior in mice with an ED50 = 1.26 mg/kg, a remarkable effect especially in comparison with Aspirin (65%, ED50 = 15 mg/kg) or THC (100%, ED50 = 25 mg/kg).

CBG agonism at α2-adrenoceptor triggered in vivo investigations of its analgesic effects. Comelli et al. (2012) integrated computational and pharmacological studies where the three-dimensional structures of α2A, α2B, and α2C isoforms of murine and human adrenoceptors were modeled by comparative techniques and molecular dynamics simulations. In this computational model, CBG affinity for the receptor appeared higher than that of the α2-adrenoceptor-agonist clonidine. Measured in behavioral models of acute inflammatory pain, CBG dose-dependently reduced the first and second nocifensive phases associated with intraplantar-injection of formalin and reduced λ-carrageenan-evoked hypersensitivity. Both models are α2-adrenoceptor-mediated, as they are blocked by the α2-adrenoceptor-antagonist yohimbine.

Although, to date, there are no supportive in vivo studies, it is interesting to note that CBG is active at the analgesic targets: $5HT_{1A}$Rs, TRPVA1, TRPM8, TRPV2, NAAA, and MAGL. Definitive analgesic efficacy of CBG through these pathways has not yet been reported (Fig. 99.3).

Notably, in 2012, at the 14th World Congress on Pain, CBG was highlighted as one of the phytocannabinoids that may have therapeutic effects on pain (Canadian Consortium for the Investigation of Cannabinoids, 2012).

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) describes a group of inflammatory conditions of the colon and intestine caused by dysregulated immune response. It primarily includes ulcerative colitis limited to the colon, and Crohn disease, which can affect any section of the gastrointestinal tract.

TRP channels play a role in gastrointestinal inflammation as they function as sensors of innocuous and noxious chemical/physical stimuli; indeed, they are involved in the antiinflammatory effects of phytocannabinoids in in vivo models of intestinal inflammation (De Petrocellis et al., 2012). In a model of intestinal inflammation induced by the irritant croton oil, CBG exerted a significant TRPV3-mediated elevation of intracellular Ca^{++} with an efficacy (determined by comparing its effect with the analogous effect observed with 4 μM ionomycin, a Ca^{2+} ionophore that mobilizes intracellular calcium stores), lower (18%) and a potency higher (EC50 = 1 μM) than that of typical TRPV3 agonist carvacrol (41.4% and EC50 = 547 μM). When administered 5 min earlier, CBG also desensitized TRPV3 to carvacrol-mediated cell stimulation (IC50 = 66.7 μM).

CBG induced a significant TRPV4-mediated elevation of intracellular Ca^{++} with low efficacy (23.7% of the effect of ionomycin) and medium-low potency (5.1 μM). Despite its low efficacy, CBG desensitized TRPV4 to the action of its agonist 4αPDD with an EC50 value lower than that at which it activates it at low efficacy (De Petrocellis et al., 2012).

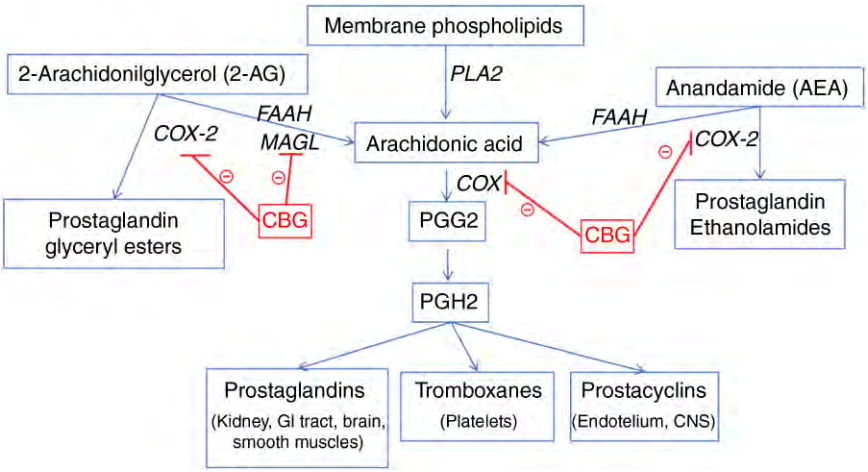

FIGURE 99.3 **Cannabigerol in prostaglandin biosynthesis.** In inflammatory processes arachidonic acid is produced by phospolipase-A2 (PLA2) from membrane phospholipids and it is then metabolized by COX into the instable prostaglandine-G2 (PGG2) which is then converted into prostaglandin-H2 (PGH2). Depending on the tissue, PGH2 is converted into prostaglandins, tromboxanes and prostacyclines. 2-Arachidonilglycerol and anandamide are also substrates of the COX-2, and are metabolized into prostaglandin-glycerol ester and prostaglandin-ethanolamide, respectively. Nonsteroidal antiinflammatory drugs (NSAIDs) and cannabigerol (CBG) inhibit COX and MAGL thereby reducing prostaglandin production. *GI*, gastrointestinal tract; *CNS*, central nervous system. *Source: Information collected from Alhouayek and Muccioli (2014).*

If also in vivo CBG desensitizes TRPV to endogenous stimuli and at doses lower than that required to activate them, its use as a TRPV desensitizer might be employed to develop novel therapies for diseases associated to altered TRPV activity.

In a dinitrobenzene sulfonic acid (DNBS) model of murine colitis, CBG showed protective and curative effects by reducing colon weight/length ratio (an indicator of the inflammatory response severity), it reduced DNBS-induced overexpression of the inducible nitric oxide synthase (iNOS), but not of COX-2. In lipopolysaccharide-activated macrophages, it inhibited nitric oxide production and iNOS protein overexpression. DNBS induced an increase in colonic interleukin-1β and interferon-γ and a decrease in interleukin-10 levels; these alterations were all counteracted by CBG. Finally, CBG restored the DNBS-induced decrease of superoxide-dismutases thus restoring antioxidant protection in intestinal epithelial cells (Borrelli et al., 2013).

Neuroinflammation in Multiple Sclerosis

Neuroinflammation is a component of disorders, such as multiple sclerosis (MS), Alzheimer and Parkinson diseases. It can be initiated as a response to traumatic brain injury, infections, aging, toxic metabolites, or autoimmunity. Acute neuroinflammation involves a rapid activation of microglia and no peripheral immunoresponse. In chronic inflammation, the microglia induces a sustained production of inflammatory modulators that may alter the integrity of the BBB, and recruit peripheral immune cells for inflammatory responses, leading to neuronal dysfunction/neurodegeneration.

In MS, a chronic inflammatory demyelinating disease, microglial activation contributes to the pathology through secretion of proinflammatory mediators.

Effects of CBG and its quinone derivate, VCE-003 (obtained by CBG oxidation), on neuroinflammation have been investigated and they both revealed neuroprotective action by preventing glutamate-induced cell viability decline. In the Theiler's murine encephalomyelitis virus (TMEV) model of MS, VCE-003 improved the motor functions, and locomotor activity was restored to normal levels. VCE-003 also reduced microglia reactivity in the spinal cord of TMEV-infected mice, it outperformed CBG in terms of capacity to inhibit cytokine release, and was as efficient as CBG at inhibiting the release of PGE2 (Granja et al., 2012).

Extending the studies on VCE-003, recently, the same group reported that in the autoimmune model of MS (EAE), VCE-003 attenuated EAE by activating CBR_2 and PPARs. A reduction of CD4+ and T cells infiltrates, inhibition of Th1 and Th17 (T-helper cells involved in different stages of the pathogenesis of autoimmune diseases, including MS) responses in the spinal cord of VCE-003-treated mice, a decreased microglial activation, a structural protection of myelin sheets and reduced axonal damage were reported (Carrillo-Salinas et al., 2014).

Taken together, these data support a potential therapeutic use of quinone derivate of CBG for the treatment of human immune diseases with inflammatory and autoimmune components, such as MS.

Cancer

Cannabinoids are used in the treatment of nausea and vomiting associated with chemotherapy. Their use in oncology is currently receiving increasing interest

as they inhibit the growth of various cancer cell types, inducing apoptosis, cell-cycle arrest, cell growth inhibition, and affecting angiogenesis, and cell migration (Guzman, 2003).

Like other phytocannabinoids, CBG was reported to reduce cell proliferation in several cancer cell lines, including human breast, prostate, colorectal carcinoma, gastric adenocarcinoma, C6-rat glioma, rat basophilic leukemia, and transformed thyroid cells (Ligresti et al., 2006). Interestingly, prostate carcinoma cells were found to be unresponsive to most phytocannabinoids, only CBD and CBG elicited antiproliferative effects.

Although the exact mechanism of action is not fully elucidated, TRPV1, TRPV2, and TRPM8 are involved in prostate cancer, all being CBG-sensitive channels. Specifically, TRPV1 agonist capsaicin induces antiproliferative and proapoptotic effects on prostate cancer cells (PCCs) (Diaz-Laviada, 2010), TRPV2 activation stimulates PCCs migration (Gkika & Prevarskaya, 2011), whereas TRPM8 is overexpressed in androgen-dependent PCCs, and TRPM8 antagonists have been suggested as being effective during the early androgen–responsive stage of prostate cancers (Liu & Qin, 2011). These findings suggest CBG as a relevant agent for prostate cancer since it antagonizes TRPM8 channels and activates/desensitize TRPV2 and TRPV1 (De Petrocellis et al., 2011). In line with this, together with other phytocannabinoids, CBG showed to inhibit PCCs viability in androgen receptors-positive and receptors-negative PCC lines (De Petrocellis et al., 2013). Moreover, CBG activated the proapoptotic proteases caspase3/7 under conditions of serum deprivation and it increased intracellular Ca^{++} (indicating endoplasmic reticulum stress) in PCC lines. It is therefore suggested that phytocannabinoids and, albeit at lower potency/efficacy, CBG can retard PCC proliferation, and cause apoptosis.

CBG showed the greatest growth-inhibitory activity against human oral epitheloid carcinoma cell lines and fibroblasts, when compared to olivetol, geraniol, and cannabinol-methyl-ether (Baek et al., 1998). Although CBG was not the most potent phytocannabinoid, it demonstrated antiproliferative action in human breast cancer cells (McAllister, Christian, Horowitz, Garcia, & Desprez, 2007) and mouse skin melanoma cells (Baek, Han, Yook, Kim, & Kwak, 1996).

The exact mechanism by which CBG acts against cancer remains to be elucidated, and further research is required; however, mounting evidence suggests that this phytocannabinoid possesses several properties, which may counteract cancer cell proliferation.

Mood Disorders

The endocannabinoid system has bidirectional influence on anxiety; its inhibition results in anxiogenic responses, while a moderate increase leads to anxiolytic effects. Anandamide itself possesses a bidirectional profile, acting as an anxiolytic agent at CB_1R, and an anxiogenic at TRPV1 (Rubino et al., 2008).

The CB_1R inverse agonist/antagonist, rimonabant, marketed in the past as an antiobesity drug, was withdrawn as chronic administration induced undesirable anxious and depressive-like states along with suicide (Janero & Makriyannis, 2009).

This discovery sparked interest in the role of cannabinoids in anxiety/depression and a number of studies addressed this subject.

O'Brien et al. (2013) recently investigated acute and chronic effects of CGB in rats in the light/dark immersion model of anxiety-like behavior and in a test of palatability processing for depression-like behavior, that is, the saccharin hedonic reactions in the taste reactivity test. While CBG revealed no effects in the light/dark test, its acute administration produced a slight enhancement of saccharin palatability, indicative of possible antidepressant effect.

El-Alfy et al. (2010) found 20 and 80 mg/kg CBG ineffective in mice locomotor activity, catalepsy, body temperature, and nociception and in the forced swimming test (assessing depression-like behavior). However, in a different study performed in mouse the tail suspension test, CBG (40 mg/kg) reduced the time spent immobile (which in this test is interpreted as a predictor of antidepressant activity), with effects comparable to the antidepressant imipramine (Musty & Deyo, 2006).

Following this finding, the same authors filed several US patents (the latest in 2014: *US20,140,039,043-A1*) claiming the use of CBG for mood disorders, preferably in depression.

Other Potential Medical Uses of Cannabigerol

Further expanding the knowledge on its potential medical uses, CBG effects on rats' feeding behavior have been investigated, revealing to be ineffective when tested at doses up to 17.6 mg/kg (Farrimond, Whalley, & Williams, 2012). In a later study, higher doses of CBG (120 and 240 mg/kg) induced a dose-dependent increase of food intake, number of meals, a decrease of latency to first meal and an enhanced locomotor activity suggesting that at higher doses, CBG stimulates appetite, and enhances consummatory feeding behavior (Brierley, Whalley, & Williams, 2013). Preliminary results also indicate that pure CBG (120 mg/kg) can attenuate weight loss induced by the chemotherapy agent cisplatin (Brierley et al., 2015). Given these findings, CBG was suggested to be useful for feeding disorders associated with chemotherapy but also for the treatment of weight loss in cancer anorexia-cachexia syndrome.

CBG was found to inhibit testosterone synthesis in rat testis Leydig cells more potently than THC (Jakubovic, McGeer, & McGeer, 1979; Burstein, Hunter, & Sedor, 1980). Testosterone lowering medicaments (TLM) are often prescribed for men with prostate cancer, hypersexuality, male contraception, gender reassignment. For women, TLM are prescribed for severe cases of acne, amenorrhea, seborrhea, hirsutism, androgenic alopecia, and hyperandrogenism. TLM are also administered in sex offender treatment, in addition to psychotherapy (Turner, Basdekis-Jozsa, & Briken, 2013).

CBG effects on skin conditions have also been explored. Psoriasis is an inflammatory skin disease characterized by epidermal keratinocyte hyperproliferation paralleled by increased expression of skin proinflammatory mediators. CBG inhibited keratinocyte proliferation in a CB_1/CB_2-receptors-independent manner, and with a greater potency than THC, suggesting a possible therapeutic use for psoriasis (Wilkinson & Williamson, 2007). Effects of CBG on the epigenetic regulation of epidermal differentiation genes have been investigated and CBG acted as transcriptional repressors controlling cell proliferation and differentiation by increasing DNA methylation of keratin-10 gene in a CBR-independent mechanism (Pucci et al., 2013).

Acting through an indirect mechanism regulated by accessory cells, CBG stimulated recruitment of quiescent mesenchymal stem cells (MSCs) in bone marrow (Scutt & Williamson, 2007). The induction of MSC migration by suitable agents, such as in this example CBG, could represent an attractive cell-based therapy to treat osteoporosis and bone regeneration issues by accelerating healing and/or regeneration.

A number of cannabinoids have been shown to reduce intra ocular pressure (IOP) in a CBR-mediated mechanism (Oltmanns et al., 2008). CBG's chronic and, although to a lesser extent, acute administration reduced ocular tension in cats such that IOP of CBG-treated eyes resulted in 4–8 mmHg lower than untreated contralateral eyes (Colasanti, Craig, & Allara, 1984). Additionally, CBG was devoid of ocular toxicity and neurotoxicity, it did not change overall brain electrical activity, but it prolonged the onset of sleep/REM sleep. Possessing such IOP lowering action, CBG may be a possible candidate for the treatment of glaucoma.

CBG possesses antibacterial properties (Mechoulam & Gaoni, 1965) with activity against gram-positive bacteria, mycobacteria, and fungi superior to that of THC, CBD, and CBC (Eisohly, Turner, Clark, & Eisohly, 1982). Additionally, CBG has potent activity against various methicillin-resistant *Staphylococcus aureus* strains of current clinical relevance (Appendino et al., 2008). Finally, and importantly, CBG (1, 3, 10 mg/kg) showed low potential abuse when assessed in a rat model of drug discrimination (Duncan et al., 2014).

CONCLUSIONS

CBG owns a broad pharmacological profile stimulating interest on this nonpsychotropic phytocannabinoid as a potential polydrug or as a starting molecular structure for chemical engineering aimed at developing more selective/potent drugs.

The expanding knowledge on its multifaceted pharmacology allowed intercepting numerous possible medical uses inspiring several attempts to patent its pharmaceutical use for a number of conditions. Among all, its antiinflammatory and anticancer properties stimulated tremendous interest pointing CBG as a possible candidate in the development of novel drugs to prevent, control, and treat conditions where pathological inflammatory responses and abnormal cell proliferation represent a threat.

While the recent research finding summarized in this chapter highlighted the vast potentials of CBG, it is clear that extensive work is needed before its clinical benefits can be definitively stated. Decisive is the fact that, currently, there is no material on CBG pharmacokinetics/pharmacodynamics in humans, and clinicians should remain cautious until more definite studies demonstrate the safety and efficacy of CBG. Further pharmacological and preclinical experiments, together with human toxicological and proof of concept studies, should be performed to confirm the number of reports suggesting CBG value in medical practice.

MINI-DICTIONARY

Botanical drug substance (BDS) Botanical unrefined material from the *Cannabis* plant where a specific cannabinoid, in this case CBG, has at least 95% purity. The amount of the main cannabinoid in the corresponding BDS, expressed as a %w/w of extract, is used to calculate the amount of BDS necessary to achieve the equimolar amount of the corresponding pure cannabinoid. Cannabinoid and noncannabinoid components of the BDS are always identified, and vary between different BDS. "CBG-free CBG BDS" is a BDS extracted from a CBG-predominant *Cannabis* plant virtually devoid (but it may still contain traces) of CBG.

Cyclooxygenase (COX) The enzyme that catalyzes the biosynthesis of prostaglandins from arachidonic acid, produced on demand from arachidonate through PLA2. Two isoforms of the COX exist: COX-1 is constitutively expressed in the gastrointestinal tract, kidneys, and platelets, and it regulates the prostaglandins responsible for the integrity of the gastric mucosa, for the normal platelet function and for the regulation of renal blood flow. COX-2 is expressed in immune system cells, and is inducible by inflammatory stimuli, thereby producing prostaglandins mediating inflammation, pain, and fever.

Transient receptor potential (TRP) Ligand-gated cation channels are a group of ion channels found in the plasma membrane of several cell types mediating a multiplicity of sensations including hotness, pain, warmth or coldness, tastes, pressure, and vision. Endogenous lipids modulate TRP channel activity by direct binding, acting as endogenous ligands. Endocannabinoids interact with several types of TRP channels.

TRP ankyrin 1 (TRPA1) Expressed in trigeminal and dorsal root ganglia neurons. It is activated by low temperatures (17°C), mustard oil, and environmental irritants, such as unsaturated aldehydes, causing painful burning sensation. Its function in cold transduction is still debated; it contributes to inflammatory hypersensitivity, vasodilation, and nociception to irritants.
TRP melastatin 8 (TRPM8) Expressed in nociceptive and nonnociceptive neurons and it is gated by medium–low (25°C) temperatures, as well as chemical cooling agents, such as spearmint, menthol, and eucalyptol. Anandamide binds to TRPM8. Above its role in nociception, which is to date still under discussion, TRPM8 channel has been linked with cancer cell proliferation.
TRP vanilloid type 1 (TRPV1) Activated by heat temperatures (42°C) and basic pH (5.9). Anandamide binds this channel, and CBG activates and desensitizes TRPV1 being this responsible for some of CBG analgesic and antiinflammatory actions.
TRPV type 2 Shares nearly 50% DNA sequence identity with TRPV1, but unlike TRPV1, it is not modulated by vanilloids. It is activated by high temperatures (~52°C), physical stimuli, such as mechanical stretch, osmotic swelling, and modulators, such as hormones, growth factors, chemotactic peptides, lysophospholipids, and cannabinoids. Its physiological role remains one of the most controversial. It has been proposed to be involved in the transduction of high-temperature heat responses in sensory ganglia and to function as a noxious heat thermosensor. However, TRPV2-knockout mice show normal sensory transduction, suggesting that TRPV2 does not function as a noxious heat and mechanical sensor and that it has other, as yet unknown, functions. *Cannabis* derivatives are the most potent TRPV2 activators.

[†]CEDIR, Center for Diagnosis and Rehabilitation, San Martín Santa Fe, Argentina

[‡]Addiction Program, Institute of Neuropsychiatry and Addiction—INAD, and Hospital del Mar Medical Research Institute—IMIM, Barcelona, Spain

SUMMARY POINTS

- This chapter focuses on the cannabis and fibromyalgia and begins with the diagnosis and treatment of this condition.
- Therapy includes nonpharmacological and pharmacological treatments.
- Some drugs have demonstrated efficacy in randomized controlled trials (pregabalin, duloxetine, milnacipran, amitriptyline, serotonin selective reuptake inhibitors, and cyclobenzaprine).
- Cannabis products are frequently used in patients with fibromyalgia. Different surveys showed that most of the patients who tried medical marijuana found it to be effective or very effective for the therapy of symptoms of the condition.
- Evidence of efficacy is based on some noncontrolled studies and two randomized-controlled clinical trials using oral nabilone for the treatment of pain and sleep difficulties in fibromyalgia patients.
- Nabilone appears to have beneficial effect with significant reduction in pain and functional improvement, and it is well tolerated. Nabilone is more effective than amitriptyline in improving sleep in fibromyalgia.
- More studies are needed to evaluate the efficacy and safety of cannabinoids in fibromyalgia.

KEY FACTS OF FIBROMYALGIA

- Fibromyalgia is a chronic disorder characterized by widespread pain and tenderness, often accompanied by fatigue, memory problems, and sleep disturbances.
- The origin of fibromyalgia is unknown but it seems to be related to a sensitization of the central nervous system.
- The diagnosis of fibromyalgia is based on clinical symptoms, and routine laboratory and diagnostic tests are normal.
- There is no specific treatment for fibromyalgia. Nonpharmacological and pharmacological therapies could help patients.
- Some drugs are often used in the treatment of fibromyalgia pain. Three of them have been approved for this indication (pregabalin, duloxetine, and milnacipran).
- Cannabinoids by oral or smoked route can be useful to alleviate pain in fibromyalgia. However, more studies are needed in order to recommend their use.

SSNRI	Selective serotonin and norepinephrine reuptake inhibitor
SSRI	Selective serotonin reuptake inhibitor
TCA	Tricyclic antidepressants
THC	Δ^9-Tetrahydrocannabinol

INTRODUCTION

Fibromyalgia

Fibromyalgia is a chronic condition characterized by widespread pain and tenderness. It is the second most common rheumatologic disorder and approximately 2–8% of the world's population meets the 1990 and 2010 American College of Rheumatology (ACR) diagnostic criteria. Fibromyalgia is more common in women and can appear at any age with a similar worldwide prevalence. Most patients have had a previous medical history of chronic pain throughout the body or chronic pain experienced in their first-degree relatives. Roughly 10–30% of patients with fibromyalgia meet criteria for other chronic pain disorders such as osteoarthritis, rheumatoid arthritis, and lupus (Rahman, Underwood, & Carnes, 2014).

As in most illnesses, fibromyalgia has a genetic component, and some studies have focused on specific genetic polymorphisms associated with the risk of developing this disorder. Findings related to polymorphisms involved in pain neurotransmission, essentially those concerning serotonin receptors and transporters, and dopamine receptors, are, however, contradictory. In addition, environmental factors play a role in triggering development of the illness. It is known that infections (Epstein–Barr virus infection, hepatitis C, parvovirus infection, and Lyme disease) and psychological stress contribute to the precipitation of this condition (Clauw, 2014).

The pathophysiological bases for fibromyalgia pain are related to a sensitization of the central nervous system (CNS) which amplifies the peripheral nociceptive inputs and maintains chronic pain. Patients with fibromyalgia feel pain in conditions that nonsufferers perceive as touch, this signifies that the former have problems with augmented pain or sensory processing in the CNS. For this reason, they display diffuse hyperalgesia (increased pain from painful stimuli) and/or allodynia (pain from nonpainful stimuli). There are, however, no abnormalities in the region of the body where pain is experienced. A number of factors are related with an individual's sensitivity to pain. The neurotransmitters involved in pain control are also known to control other functions such as mood, fatigue, memory, and sleep, often altered in the illness. To date, it has been suggested that endogenous opioidergic activity may be normal or even increased while there is decreased activity in the endogenous serotonergic and noradrenergic systems. In addition, the glutamatergic system is also involved in the pathogenesis of fibromyalgia. Recent findings suggest an imbalance in the levels of the neurotransmitters that affect pain and sensory transmission: high levels of neurotransmitters increase pain transmission and/or low levels of neurotransmitters decrease it. Neuroimaging studies have contributed to demonstrating the neurotransmitter hypothesis, and to finding the structures implicated in fibromyalgia such as the insula. Moreover, sensitivity to different stimuli such as heat, cold, electrical stimuli, and auditory tones is also augmented (Kuttikat & Shenker, 2013; Clauw, 2014, 2015; Rahman et al., 2014)

The symptoms of fibromyalgia include musculoskeletal pain in various groups of muscles, especially in the proximal shoulder girdle muscles, which is poorly localized, of severe intensity, and difficult to ignore. It is present most of the day, appears every day, and for at least 3 months. Another characteristic of this disorder is the appearance of focal, triggered point tenderness in affected muscles. In addition, patients complain of fatigue, muscular weakness, sleep disturbance, mood disorders, and impairment of some cognitive domains such as concentration and alertness. Depending on the somatic and psychological symptoms, fibromyalgia can cause functional disability (Clauw, 2014; Rahman et al., 2014).

In 1999, the ACR published the classification criteria for fibromyalgia syndrome which have been used widely used in therapeutic clinical trials. These criteria had a sensitivity of 88% and a specificity of 81% in a patient population (Table e16.1). Subsequently, the ACR published in 2010 further preliminary diagnostic criteria, taking into account the relevance of somatic symptoms such as fatigue and cognitive difficulties associated with this syndrome. These new criteria developed for clinical use have a symptom severity scale which can be useful for longitudinal monitoring. One major difference is that they do not require a tender point count (Table e16.2). In addition, there is a patient self-report version (Clauw, 2014, 2015).

Routine laboratory and radiographic tests are normal, focused on excluding other diagnoses and evaluating pain generators and comorbid conditions. It is important to carry out a differential diagnosis because some symptoms can overlap with other chronic pain conditions such as headaches, facial/jaw pain, regional myofascial

TABLE e16.1 American College of Rheumatology 1990 Classification Criteria for Fibromyalgia

Criteria

A. History of widespread pain for at least 3 months. Pain is considered widespread when it is present at all of the following sites (b):
   - the left side of the body
   - the right side of the body
   - above the waist
   - below the waist
   - in the axial skeletal (cervical spine or anterior chest or thoracic spine or low back)

B. Pain on digital palpation in at least 11 of the 18 tender point sites; all sites bilateral (c):
   (a) For purposes of classification, patients will be said to have FMS if both criteria A and B are satisfied. The presence of a second clinical disorder does not exclude the classification of fibromyalgia
   (b) Pain in a patient in for instance the left shoulder, right buttock, and cervical spine is generalized, according to these criteria
   (c) Digital palpation should be performed with an approximate force of 4 kg. For a tender point to be considered positive, the palpation has to be painful. "Tender points" that are only tender are not tender points

TABLE e16.2 American College of Rheumatology 2010 Preliminary Diagnostic Criteria for Fibromyalgia

Criteria

A patient satisfies diagnostic criteria for FMS if the following three conditions are met:

1. Widespread pain index (WPI) ≥7 and symptom severity (SS) scale score ≥5, or WPI between 3 and 6 and Symptom Severity (SS) scale score ≥9
2. Symptoms have been present at a similar level for at least 3 months
3. The patient does not have a disorder that would otherwise explain the pain

Ascertainment

1. Widespread pain index (WPI)
   - Note the number of areas in which the patient has had pain over the last week. In how many areas has the patient had pain? Shoulder girdle (left, right); Hip (left, right); Jaw (left, right); Upper back: Lower back; Upper arm (left, right); Upper leg (left, right); Chest; Lower arm (left, right); Lower leg (left, right); Abdomen and Neck
     Score will be between 0 and 19
2. Symptom severity (SS) scale score: fatigue, waking unrefreshed, cognitive symptoms
   - For the each of the three symptoms above, indicate the level of severity over the past week using the following scale: 0 = no problem, 1 = slight or mild problems, generally mild or intermittent, 2 = moderate, considerable problems, often present and/or at a moderate level, 3 = severe: pervasive, continuous, life-disturbing problems
   - Considering somatic symptoms in general[a], indicate whether the patient has: 0 = no symptoms, 1 = few symptoms, 2 = a moderate number of symptoms, 3 = a great deal of symptoms
   - The somatic symptoms scale score is the sum of the severity of the three symptoms (fatigue, waking unrefreshed, cognitive symptoms) plus the extent (severity) of somatic symptoms in general
   - The final score is between 0 and 12

[a] *Somatic symptoms that might be considered muscle pain, irritable bowel syndrome, fatigue/tiredness, thinking or remembering problem, muscle weakness, headache, pain/cramps in the abdomen, numbness/tingling, dizziness, insomnia, depression, constipation, pain in the upper abdomen, nausea, nervousness, chest pain, blurred vision, fever, diarrhea, dry mouth, itching, wheezing, Raynaud's phenomenon, hives/welts, ringing in ears, vomiting, heartburn, oral ulcers, loss of/change in taste, seizures, dry eyes, shortness of breath, loss of appetite, rash, sun sensitivity, hearing difficulties, easy bruising, hair loss, frequent urination, painful urination, and bladder spasms.*

pain in the neck or back, and arthritis. Visceral pain complaints involving the gastrointestinal tract, bladder, and pelvic or perineal region are also often present (Crofford, 2013; Clauw, 2014, 2015).

Treatment of Fibromyalgia

Treatment strategies include nonpharmacological and pharmacological therapies including medicines and cannabis. It has been demonstrated that education, cognitive behavioral therapy, and exercise (passive and active) are effective in dealing with fibromyalgia with a response that usually surpasses pharmacological therapies. There is also limited evidence from a systematic review and a summary of reviews concerning the benefits of acupuncture, homeopathy, and mind-body therapies, including hypnotherapy, biofeedback, and stress reduction (Clauw, 2014; Ablin & Buskila, 2010; Häuser, Walitt, Fitzcharles, & Sommer, 2014; Rahman et al., 2014).

Pharmacological treatment includes drugs approved by the agencies of various countries; however, a wide number of medications are used in an off-label indication (Ablin & Buskila, 2010; Häuser et al., 2014). Three drugs (pregabalin, duloxetine, and milnacipran) have been passed by the United States Food and Drug Administration (FDA) but not by the European Medicines Agency (EMA). The use of cannabinoids is described in section cannabinoids and fibromyalgia (p. 1095).

Taking into account the moderate efficacy of the available pharmacological therapies, drug therapy is not

mandatory in all fibromyalgia cases. Mean efficacy from systematic reviews with metaanalysis (SR-MAs) pooled data found that 19% of patients had at least a 50% reduction in pain but that 11% stopped treatment due to adverse events. It is recommended to choose the drug according to the main symptoms (pain, fatigue, and sleep disorder), physical and psychological comorbidities, and side effects. In addition, it is crucial to monitor efficacy, tolerability, and safety in order to achieve responsible prescribing practices. In most cases, treatment includes a combination of drugs with different mechanisms of action (Rahman et al., 2014).

Gabapentinoids (pregabalin, gabapentin), serotonin norepinephrine reuptake inhibitors (duloxetine and milnacipran), tricyclic antidepressants (TCAs), and selective serotonin reuptake inhibitors (SSRIs) are currently prescribed as standard treatment for fibromyalgia. These options have been studied in randomized clinical trials (RCT); nevertheless, their clinical benefits remain limited for most patients (Häuser et al., 2014; Rahman et al., 2014).

Pregabalin

A gamma-aminobutyric acid (GABA) analog, that binds to an auxiliary subunit (alpha2-delta protein) of voltage-gated calcium channels in the CNS. Pregabalin is approved in Europe for the treatment of peripheral and central neuropathic pain in adults, as adjunctive therapy in adults with partial seizures, and for the treatment of generalized anxiety disorder (GAD) in adults. In the United States, pregabalin has the following approved indications: neuropathic pain associated with diabetic peripheral neuropathy, postherpetic neuralgia, adjunctive therapy for adult patients with partial onset seizures, fibromyalgia, and neuropathic pain associated with spinal cord injury. In the management of fibromyalgia, doses must be titrated to reach the recommended dose of 300–450 mg/day (divided in two administrations). Higher doses, such as 600 mg/day, do not confer additional benefit and are less well tolerated. Most common adverse effects are dizziness, somnolence, dry mouth, edema, blurred vision, weight gain, and difficulty concentration/attention (>5% patients). The efficacy of pregabalin in fibromyalgia has been demonstrated in several RCTs and SR-MA (Moore, Straube, Wiffen, Derry, & McQuay, 2009; Moore et al., 2012a; Üçeyler, Sommer, Walitt, & Häuser, 2013; Rahman et al., 2014).

Duloxetine

A selective serotonin and norepinephrine reuptake inhibitor (SSNRI) indicated in the United States for: major depressive disorder, GAD, diabetic peripheral neuropathic pain, chronic musculoskeletal pain, and fibromyalgia, but in Europe not approved for fibromyalgia. The recommended dose for fibromyalgia is 60 mg/day. Nausea, somnolence, insomnia, dry mouth, constipation, decreased appetite and dizziness, and sexual dysfunction are the main side effects (>5% of patients). Its efficacy in fibromyalgia has been demonstrated in several RCTs and SR-MAs (Häuser, Bernardy, Uçeyler, & Sommer, 2009; Häuser, Urrútia, Tort, Uçeyler, & Walitt, 2013, Lunn, Hughes, & Wiffen, 2014; Rahman et al., 2014).

Milnacipran

It is an SSNRI more selective for norepinephrine uptake. The recommended dose is 100 mg in two divided daily doses. Common side effect are nausea, headache, constipation, dizziness, insomnia, hot flush, hyperhidrosis, palpitations, dry mouth, and hypertension (>5% patients). Its efficacy in fibromyalgia has been demonstrated in several RCTs and SR-MAs (Häuser et al., 2009, 2013; Derry, Gill, Phillips, & Moore, 2012; Rahman et al., 2014).

Amitriptyline

Amitriptyline 10–50 mg daily is used in fibromyalgia to treat sleep problems and fatigue as an off-label indication. Common (>5% frequency) side effects include dizziness, headache, weight gain, hypotension, somnolence, sexual dysfunction, and dry mouth. Its efficacy in fibromyalgia has been demonstrated in several RCTs and SR-MAs (Häuser et al., 2009, 2014; Moore et al., 2012a,b).

Selective Serotonin Reuptake Inhibitors

There are some studies that found some evidence in favor of fluoxetine (12–80 mg/day), paroxetine (20–60 mg/day), and citalopram (20–40 mg/day) (Häuser et al., 2009, 2014; Rahman et al., 2014).

Cyclobenzaprine

A muscle relaxant marketed in the United States, but unavailable in most European countries. The recommended dose is 5 mg 3 times a day. Most common side effects were drowsiness (38% of patients), dry mouth (24%), and dizziness (10%). Its use in fibromyalgia is based on six RCTs (with small samples) and a SR-MA (Tofferi, Jackson, & O'Malley, 2004; Häuser et al., 2014).

Gabapentin

It is similar to pregabalin, and with approved use for adjunctive therapy of epilepsy and treatment of peripheral neuropathic pain/postherpetic neuralgia in adults. The recommended dose for pain varies between 1200–2400 mg/day (maximum 3600 mg/day). Gabapentin has shown similar efficacy and adverse effects as pregabalin in fibromyalgia, but there is less evidence from RCTs and SR-MA (Üçeyler et al., 2013; Moore, Wiffen, Derry, Toelle, & Rice, 2014).

Strong opioids (tramadol, oxycodone) and nonsteroidal antiinflammatory drugs, either as a prescription or on-demand, are not recommended as a strategy in

TABLE e16.3 Drug Classes That Failed to Show Superiority Over Placebo in Reducing Fibromyalgia Syndrome Symptoms

Antidepresssants (sertraline, venlafaxine)
Antiviral agents (valacyclovir)
Anxiolytics (alprazolam, bromazepam)
Dopamine agonists (pramipexole, ropinirole, terguride)
Hormones (calcitonin, dehydroepiandrosterone, prednisone)
Hypnotics (zolpidem)
Interferons
Ketamine (intravenous)
Local anesthesics (lidocaine, intravenous)
Neuroleptics (ritanserin, quetiapine)
Opioids (oxycodone, tramadol)
Serotonin receptor antagonists (tropisetron, ondansetron)
Sodium oxybate (gamma-hydroxybutyrate)

Based on data from Hauser et al. (2014).

fibromyalgia because of the lack of evidence from published RCTs and the potential risk of side effects (Häuser et al., 2014).

A number of other drugs have been studied for treating fibromyalgia, none of them; however, show any superiority with respect to placebo (Table e16.3). Recent research, based on few studies with small sample sizes, has shown efficacy of nabilone for pain and sleep disturbance (see section randomized controlled clinical trials, p. e164), growth hormones for pain and fatigue, and quetiapine or naltrexone to reduce pain and depression (Häuser et al., 2014).

CANNABINOIDS AND FIBROMYALGIA

Biological Basis

The endogenous cannabinoid system mainly includes the cannabinoid receptors CB1 and CB2, the ligands anandamide (AEA) and 2-arachidonoylglycerol (2-AG), and their metabolic enzymes (fatty acid amide hydrolase 1 or FAAH, and monoacylglycerol lipase or MAGL). CB1 is the most abundant G protein-coupled receptor expressed in the brain, in nonneuronal cells such as adipocytes and hepatocytes, and in musculoskeletal tissues. CB2 is principally associated with immune cell function, although it may also be expressed in the CNS. Endocannabinoids have the particularity of act as retrograde messengers by binding to presynaptic CB1 receptors. Cannabinoids are neuromodulators of the glutamate, GABA, serotonin, dopamine, norepinephrine and acetylcholine release (Pacher, Bátkai, & Kunos, 2006; McPartland, Guy, & Di Marzo, 2014). The endocannabinoid system and its role are extensively reviewed in other chapters.

The endocannabinoid system has a number of physiological actions. It is implicated in the modulation of embryological development, neural plasticity, neuroprotection, immunity and inflammation, apoptosis and carcinogenesis, pain and emotional memory, stress response, neuroendocrine regulation and cognitive functions, alimentary behavior (hunger, feeding), and metabolism.

Various authors (Russo, 2008; Smith & Wagner, 2014) have suggested that some diseases are associated with the suboptimal functioning of the endocannabinoid system. Known collectively as clinical endocannabinoid deficiency syndromes (CEDS), these dysfunctions have been proposed as being responsible for migraine, fibromyalgia, irritable bowel syndrome, and related conditions. It has been suggested that interventions enhancing the endocannabinoid system—upregulating cannabinoid receptors, increasing ligand synthesis, and inhibiting ligand degradation—could be useful for CEDS (McPartland et al., 2014).

Kaufmann et al. (2008) evaluated the plasma concentrations of catecholamines, cortisol AEA, and neutrophil function in 22 patients with primary fibromyalgia and 22 age- and sex-matched healthy controls. The results showed that the fibromyalgia patients had significantly higher norepinephrine and AEA plasma levels than controls. Adhesion and phagocytosis capabilities of neutrophils correlated positively with AEA plasma levels.

Studies on the Use of Cannabinoids in the Treatment of Fibromyalgia

There is a limited number of clinical studies assessing the efficacy of cannabinoids (natural or synthetic) in the treatment of fibromyalgia symptoms. Most evidence comes from surveys and observational studies with a few RCTs (Lynch & Campbell, 2011; Lynch & Ware, 2015).

Surveys

In a study carried out at the University of Washington in a regional pain clinic (Aggarwal et al., 2009), the retrospective chart review of a total of 139 patients using medicinal cannabis showed that 19% were taking it for fibromyalgia pain.

A survey was performed in pain clinics in Germany where medicinal dronabinol was prescribed for pain in addition to the current treatment (Weber et al., 2009). Complete data were collected from 124 patients suffering from refractory central neuropathic pain and fibromyalgia. The subjects participated in a standardized, retrospective, telephone interview survey that included changes in pain intensity using the Numeric Rating Scale (NRS), the Pain Disability Index (PDI), the Medical Outcomes Short-Form (SF-12), the Quality of Life Impairment by Pain (QLIP), Hospital Anxiety Depression Scale (HADS), and concomitant pain medication. In the 32 fibromyalgia patients included, mean pain intensity prior

to dronabinol administration was on average 7.9 ± 1.5 units, which was reduced to 4.4 ± 1.5 units during/after THC-treatment. On average, maximum pain intensity was recorded at 9.3 ± 1.1 units, prior to dronabinol and 6.1 ± 2.1 thereafter. Other results of the survey were presented collectively from all the patients: opioid doses were reduced, and patients perceived THC therapy as effective, with relatively good tolerability (25% did not tolerate the treatment).

The prevalence of cannabinoid use in 457 fibromyalgia patients who had been referred to a tertiary care pain center was assessed in Canada (Ste-Marie, Fitzcharles, Gamsa, Ware, & Shir, 2012). The study included a retrospective chart review of all the patients. It was found that 1 in 8 (n = 59, 13%) were using cannabis, of these 80% consumed herbal cannabis (marijuana), 24% took prescription cannabinoids (n = 13 nabilone, and n = 1 dronabinol), and 3% took both herbal cannabis and prescription cannabinoids. All 47 patients using herbal cannabis declared smoking marijuana between 0.5 and 6 g/day, and 34 (72%) reported the use of 1 g or less a day. The clinical data of the 59 subjects employing cannabinoids were compared with the 308 nonusing patients. The cannabinoid users were more frequently male, took more opioids, and presented greater drug-seeking behavior. A subanalysis of the sample, taking into account only those reporting herbal cannabis administration (47 vs 410 subjects), was carried out. Herbal cannabis users presented more current unstable mental illness (36% vs 23%) and opioid drug-seeking behavior (17% vs 4%), and were more frequently male (26% vs 7%). The conclusions of the study, that herbal cannabis use is associated with negative psychosocial parameters, should be cautiously interpreted due to the design of the protocol (a retrospective medical chart review).

An online survey performed by the National Fibromyalgia and Chronic Pain Association (NFCPSA; Bener, 2014) obtained a response from 1200 of its members: 44% had tried marijuana or cannabis for their pain. Positive responses were obtained for sleep (8.4 points in a 0–10 scale), pain (8.2 points), and fatigue (6 points). 22% of the responders used marijuana on a daily basis for their pain. Most subjects did not report side effects (66%), but some described sedation (165), cognitive dulling (6%), anxiety (5%), weight gain (4%), and addictive craving (3%).

A recent survey from the National Pain Foundation showed that medical marijuana may top currently available medicines for treating fibromyalgia (Anson, 2014). The survey, which was conducted online, asked more than 1300 patients with fibromyalgia to rate the effectiveness of the treatments that they had used. Medical marijuana was compared with the three drugs approved by the FDA for fibromyalgia: milnacipran (Savella), pregabalin (Lyrica), and duloxetine (Cymbalta) (Table e16.4).

TABLE e16.4 Effectiveness of Some Pharmacological Treatments Rated by Fibromyalgia Patients in an Online Survey (n = 1300)

Drug	Very effective (%)	Helps a little (%)	Does not help at all (%)
Pregabalin (Lyrica)	10	29	61
Duloxetine (Cymbalta)	8	32	60
Milnacipran (Savella)	10	22	68
Medical marijuana	62	33	5

Patients rated the efficacy as "Very effective", "Helps a little," and "Does not help at all". Results are presented as percentages [based on data from Anson (2014)].

Only 8% of the patients that tried duloxetine, and 10% that tried pregabalin or milnacipran, found the drugs to be "very effective" for managing symptoms of the disorder. Over 60% of the patients reported that each of three drugs "does not help at all." On the other hand, 62% of the patients who tried medical marijuana found it to be "very effective." Another 33% said it "helps a little," and 5% felt that using cannabis for fibromyalgia "does not help at all."

Nonrandomized and Noncontrolled Clinical Trials

In Spain, Fiz, Durán, Capellà, Carbonell, and Farré (2011) conducted a case-control study in patients suffering from fibromyalgia, some were cannabis users (n = 28), and others not (n = 28). The participants completed a series of quality of life questionnaires including the Fibromyalgia Impact Questionnaire (FIQ), the Pittsburgh Sleep Quality Index (PSQI), and the Short Form 36 Health Survey (SF-36). They were further asked to record the perceived benefits of cannabis on a range of symptoms (pain, stiffness, relaxation, drowsiness, and well-being) using 100 mm VAS scales (VAS) prior to and at 2 h of cannabis consumption. Based on a list of symptoms, the occurrence and frequency of side effects were evaluated. Demographics and clinical variables were similar in both groups. Of the 28 fibromyalgia cannabis users, 11 (40%) reported a duration of cannabis consumption of less than 1 year, 9 (32%) between 1 and 3 years, and 8 (29%) more than 3 years. Only eight patients in the cannabis group had previously tried it recreationally. The cannabis derivate in every case was marijuana, and the route of administration was smoking (54%), oral (46%), and combined (43%). Patients employed cannabis not only to alleviate pain but for almost all the symptoms associated with fibromyalgia, and

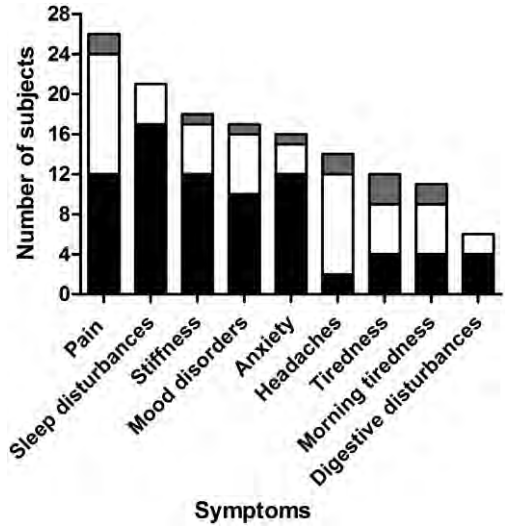

FIGURE e16.1 Symptoms and perceived relief reported by fibromyalgia patients using cannabis. Perceived relief was recorded using 5-point Likert scale (strong relief, mild relief, not change, slight worsening, great worsening). The histogram shows the number of subjects for each relief category (*black* color, strong relief; *gray* color, mild relief; *white* color, no change.). *Source: Based on data from Fiz et al. (2011).*

none reported worsening of symptoms. The proportion of patients who described strong relief ranged from 81% for sleep disorders to 14% for headache (Fig. e16.1). In relation to quality of life, only the mental health component summary score of the SF-36 questionnaire was slightly, but significantly higher, in the cannabis group than in the nonuser group. After 2 h of cannabis use, VAS scores showed a statistically significant reduction of pain and stiffness, enhancement of relaxation, and an increase in somnolence and feeling of well-being (Fig. e16.2). The

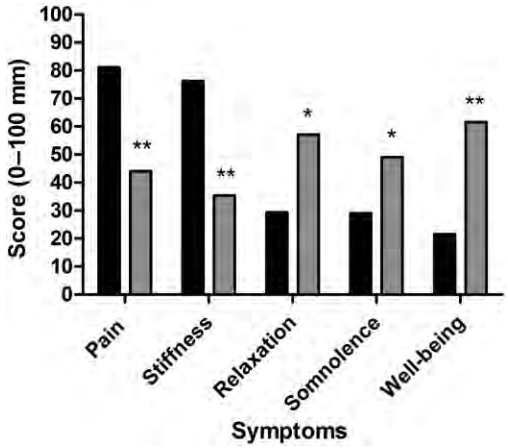

FIGURE e16.2 Perceived effects of cannabis self-administration in some symptoms (scores at baseline and 2 h after cannabis use). Perceived benefits of cannabis recorded by patients on a range of symptoms using 100-mm VAS scales before and at 2 h of cannabis consumption. *Gray* bars, pre-cannabis; *black* bars, post-cannabis. [**, $p < 0.001$; *, $p < 0.05$; *with permission from Fiz et al. (2011)*].

most frequent side effects were somnolence ($n = 18$), dry mouth ($n = 17$), sedation ($n = 12$), dizziness ($n = 10$), feeling high ($n = 9$), tachycardia ($n = 8$), conjunctival irritation ($n = 7$), and hypotension ($n = 6$).

In nine fibromyalgia patients, the effect of oral THC on electrically induced pain, axon reflex flare (vasodilatation), and psychometric variables was investigated (Schley et al., 2006). The study was noncontrolled, and subjects were compared before and after cannabinoid administration. The participants received a daily oral dose of 2.5–15 mg THC. Starting with 2.5 mg, the dosage was increased weekly by 2.5 mg THC, as long as no severe side effects were reported. Once a week, 24 h after the last THC medication and a day before any dose increase, an electrically induced pain was performed. The pain intensity was recorded daily by means of a numeric pain scale, from 0 (no pain) to 10 (maximum pain imaginable). In the four participants who completed the 3-month study, pain decreased on average by 67% (mean pain score difference –5.3 ± 2.3). All four experienced a pain reduction by more than 50% (mean pain score difference –2.8 ± 5). The experimentally induced pain was significantly reduced by THC at a dose of 10 and 15 mg. Daily recorded pain intensity was lowered on average from 8.1 at the beginning of the study, to 2.8 after 3 months. THC had no effect on the axon reflex flare, and no differences were found in the psychometric variables. Five of the nine participants dropped out of the study before achieving the maximum dose of 15 mg due to severe side effects (primarily sedation, dizziness, fatigue, and continuous tiredness).

Randomized Controlled Clinical Trials

In one of the few published RCTs, Skrabek, Galimova, Ethans, and Daryl (2008) carried out a double-blind, randomized, placebo-controlled clinical trial to analyze the effects of oral nabilone and placebo on pain and quality of life in patients with fibromyalgia. After 4 weeks of treatment (nabilone group = 0.5 mg once daily in week 1, 0.5 mg twice daily in week 2, 0.5 mg in the morning, and 1 mg in the evening in week 3, and 1 mg twice daily in week 4), patients who received nabilone ($n = 15$) experienced significant improvements in clinical pain, measured on a visual analog scale (–2.04 cm, $p < 0.02$), FIQ score (–12.07, $p < 0.02$) and the 10-point anxiety scale of the FIQ (–1.67, $p < 0.02$) in comparison to placebo. After a 4-week washout period at the end of the trial, all benefits were lost in the nabilone cohort, who returned to their baseline levels of pain and quality of life. Patients who received placebo ($n = 18$) experienced no change throughout the study. Side effects were more common in the nabilone treated subjects, compared with placebo controls at both 2 and 4 weeks of treatment. The most common side effects reported by subjects in the

nabilone group include drowsiness (7/15), dry mouth (5/15), vertigo (4/15), and ataxia (3/15). No serious adverse events appeared during the study.

A randomized, double-blind, active-control, equivalency crossover trial was carried out in fibromyalgia patients with chronic insomnia (Ware, Fitzcharles, Joseph, & Shir, 2010). The compared oral treatments were nabilone and amitriptyline (0.5–1.0 mg and 10–20 mg before bedtime, respectively). Subjects received each drug for 2 weeks with a 2 week washout period between the two treatment phases. The primary outcome was quality of sleep as measured by the Insomnia Severity Index and the Leeds Sleep Evaluation Questionnaire (LSEQ). Secondary outcomes included pain, mood, quality of life, and adverse events. A total of 31 subjects were included and 29 completed the study (26 women, mean age 49.5 years). Sleep was improved by both amitriptyline and nabilone, although nabilone was superior to amitriptyline (Insomnia Severity Index difference 3.2; 95% confidence interval 1.2–5.3). No significant differences were found in the LSEQ. No effects on pain, mood, or quality of life were observed. Preference at the end of the trial for nabilone was higher (41% of the subjects) than for amitriptyline (32%). Adverse events were mostly mild to moderate and were more frequent with nabilone. Fifty-three and ninety-one adverse events were deemed possibly or probably related to amitriptyline and nabilone therapy, respectively. Adverse events occurring in more than two subjects, and which were more common for nabilone, were dizziness ($n = 10$ subjects), nausea ($n = 9$), dry mouth ($n = 7$), drowsiness ($n = 6$), headache ($n = 4$), constipation ($n = 4$), insomnia ($n = 3$), and vomiting ($n = 3$). In the case of amitriptyline they were headache ($n = 6$ subjects), dizziness ($n = 4$), dry mouth ($n = 3$), and blurred vision ($n = 3$). The researchers concluded that "nabilone is effective in improving sleep in patients with fibromyalgia and is well tolerated. Low-dose nabilone given once daily at bedtime may be considered as an alternative to amitriptyline."

Health Professionals' Opinions on the Use of Cannabinoids

There are no specific studies about opinions or surveys concerning the use of cannabinoids in fibromyalgia pain. A recent online survey carried out with rheumatologists in Canada evaluated their confidence concerning their knowledge of cannabinoid molecules and mechanisms relevant to rheumatology, and their ability to advise patients about cannabinoid treatments (Fitzcharles et al., 2014b). Results showed that over three quarters of the 128 respondents lacked confidence in their knowledge with respect to cannabinoid molecules. A total of 45% of respondents believed there was no current role for cannabinoids in rheumatology patient care, and only 25% supported any use of herbal cannabis. Most of them had never previously prescribed or recommended any cannabinoid treatment (70%). Their uncertainty regarding good prescribing practices was very prevalent. The authors suggested that "Guidance is required to inform rheumatologists on the evidence regarding cannabinoids." The results were similar to a survey that was conducted among Canadian family doctors to determine the educational needs regarding the use of cannabis for therapeutic purposes (Ziemianski et al., 2015).

Fitzcharles, Clauw, Ste-Marie, and Shir (2014a) commented recently on the increasing hiatus among public advocacies for herbal cannabis as a therapeutic agent in rheumatic conditions. Shortfalls included uncertainty of compound content, unknown dosing, recommendations not to use by inhalation, and the indicators of harm, both in the acute as well as chronic setting, and the medical evidence for efficacy and side effects. They concluded that "Taking all factors into consideration, health care professionals should currently dissuade rheumatology patients from using herbal cannabis as a therapy."

CONCLUSIONS

In the near future, the worldwide increase of countries with authorized use of medicinal cannabis, and the augment in licenses for doctors to prescribe it, will raise the number of patients legally employing cannabis products as compassionate disease therapy.

In the case of fibromyalgia, evidence of cannabinoid use is very limited. There are only two short-term RCTs with a limited number of subjects experiencing positive results from oral dronabinol. Noncontrolled studies have shown positive effects in pain after the administration of natural cannabinoids by different administration routes. Patient surveys have reported that some of them employ cannabinoids, mainly herbal cannabis, to control pain and other symptoms in fibromyalgia.

The use of cannabinoid medicines in fibromyalgia pain must be assessed through standard scientific methods. More studies are needed to know the role of the endocannabinoid system in their pathogenesis, and to evaluate efficacy and safety of cannabinoids in fibromyalgia.

MINI-DICTIONARY

Allodynia A pain response from stimuli which do not normally provoke pain (eg, mild tactile pressure on a muscle).
Crossover clinical trial A study in which subjects receive more than one treatment, usually a sequence of two or more different treatments (or exposures).
Double-blind clinical trial A study in which neither the participants nor the researchers know which treatment the participants are taking.

Fibromyalgia A disorder characterized by chronic widespread pain, and a heightened and painful response to pressure, often accompanied by fatigue, memory problems, and sleep disturbances.
Hyperalgesia An increased pain response. Pain is more painful than it should be considering the stimuli.
Metaanalysis A statistical method for contrasting and combining results from different studies, usually randomized clinical trials, to resolve uncertainty when studies have a small number of subjects, or results from different studies do not concur.
Off-label use The use of drug agency-approved pharmaceutical drugs for different indications including an unapproved indication, an unapproved age group, unapproved dosage, and unapproved form of administration.
Randomized-controlled trial or Randomized-controlled clinical trial A type of scientific experiment in which the people being studied are randomly allocated to one (control) or other (test) of the different treatments under study. It is considered the gold standard for the efficacy evaluation of medical therapies. Sometimes the control group is placebo.

CHAPTER

100

The Cannabis Abuse Screening Test (CAST) and Its Applications

L. Bastiani, R. Potente, M. Scalese, V. Siciliano, L. Fortunato, S. Molinaro

Institute of Clinical Physiology, The Italian National Research Council (IFC-CNR), Pisa, Italy

SUMMARY POINTS

- This chapter focuses on self-report screening to detect the problematic use of cannabis (CAST).
- For a European standardized definition of problematic use of cannabis, the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA) suggests the use of the Cannabis Abuse Screening Test (CAST).
- Cannabis Abuse Screening Test (CAST) is short and easy to administer.
- Not all European countries have tested and validated the CAST in the adolescent or general population.
- Few studies have investigated the association between the PCU detected by the CAST and other components relating to the subject and social and family environments.
- The positive relationship between problematic cannabis use and other risk behaviors, such as use of other substances (tobacco, alcohol and other, illegal substances), truancy at school and poor scholastic performance, and gambling for money.
- The protective variables regarding the PCU are high self-esteem and satisfaction with health status.
- These results must be taken into consideration when designing interventions of prevention and treatment targeting young people and families.

KEY FACTS OF DSM-5

- In the DSM-5, issued in May 2013 (www.dsm5.org), the diagnostic criteria for the identification of individuals with problematic substance use (now called Substance Use Disorders – SUD) underwent substantial changes.
- SUD is defined as a set of behavioral, cognitive, and physiological phenomena that arise after repeated substance use. They include typically a strong desire to consume the substance, difficulty controlling its use, persistence in its use despite harmful consequences, a preference for consumption with respect to other activities/duties, increased tolerance, and sometimes the onset of physical symptoms of abstinence.
- The changes in classification criteria of SUD include (1) omission of the criterion "recurrent legal problems," (2) addition of the criterion "craving," (3) combination of abuse and addiction.
- SUD is divided into light (two or three criteria met), moderate (four or five criteria), or severe (six or more criteria).
- The changes in the DSM-5 are the result of several international studies. The reason for the removal of the criterion "recurrent legal problems" is related to a low prevalence and a low discriminating power, in both the adult and adolescent populations. This criterion did not appear to be correlated highly with the other ones and would provide little information about the definition of SUD (Piontek, Kraus, Legleye, & Buhringer, 2011; Shmulewitz, Keyes, Wall, Aharonovich, & Aivadyan, 2011). Some studies,

such as Sinha (2011) and Weiss (2005), supported the addition of the criterion of "craving" for a better definition of SUD. Research on the association between abuse and addiction were performed by Hasin and Beseler (2009), Beseler and Hasin (2010) and specifically among adolescents, by Perron, Vaughn, Howard, Bohnert, & Guerrero (2010), Piontek et al. (2011) and Wu, Ringwalt, Yang, Reeve, & Pan (2009).

THE CANNABIS ABUSE SCREENING TEST AND APPLICATIONS

Cannabis is the most widely used illegal psychoactive substance in the world, both in general and in the school population. Adolescence is a period of great change when teens may experiment with new behaviors, such as drug use. The 2012 report of the United Nations Office on Drugs and Crime (UNODC, 2012) indicates that cannabis use throughout Europe is concentrated particularly among young people aged 15–24 years, 14% of whom have used cannabis at least once a year.

According to the latest data provided by the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA), in Europe, in 2011 about 13% of students (aged 15–16 years) used cannabis at least once during the year preceding the survey (Hibell et al., 2013). Although most students are limited to a one-time use of the substance, the percentages of those using cannabis in "an intensive way", that is, 40 or more times during lifetime, ranges from 1% to 8% (Finland 1%, Germany 2%, Italy 4%, France 8%). Cannabis use 20 days or more in a month is defined as daily-use (or near-daily use), or frequent use reported by 1% of the students in Belgium and Germany, by 2% of Italian and 3% of French students.

A study involving 30 countries from Europe and North America was performed among 15-year-old students, who use cannabis in "an intensive way" (Ter Bogt, De Looze, Molcho, Godeau, & Hublet, 2014). In Western Europe, the frequency of cannabis use has decreased in recent years. This trend has not been observed in the developing countries of Eastern, Central, and South Europe. In the past decade, the use of cannabis has become less typical of rich countries (those with a high per capita gross domestic product) and of young people from wealthy families.

Family context has an enormous influence on teenagers. Parents play an important role in determining the risk of drug use. Laxity toward drug use and lack of parental monitoring are factors related to the use of cannabis. A recent study carried out in Spain (Becoña, Martínez, Calafat, Fernández-Hermida, & Juan, 2013) on a sample of students from Mallorca aged between 11 and 19 years shows that young people who perceive their parents as permissive are more likely to use cannabis.

A study performed among French teenagers shows that a higher family socioeconomic status has a protective effect against daily-use of cannabis (Legleye, Janssen, Beck, Chau, & Khlat, 2011). This study points out that, although adolescents from families with a high socioeconomic status have a higher risk of experimental cannabis use, they have a lower chance of using the substance in a problematic way.

Regarding problematic cannabis use, monitored through self-report screening, one in three students who used cannabis in the last year (LY) are classified as at high risk of developing problematic cannabis use. The prevalence of this use ranges from 1% to 9% in the various European countries, with an average of 5% (Hibell et al., 2013). A small number of studies have examined the notion of problematic cannabis use, comparing the frequent/daily use of the substance with and without addiction (Copeland, Swift, & Rees, 2001; Looby & Earleywine, 2007; Van der Pol, Liebregts, De Graaf, Ten Have, & Korf, 2013). According to the study population, between 25% and 50% of daily cannabis users met the criteria that define its problematic use (NIDA, 2014).

For cannabis and any other legal/illegal substances, any description of the forms of consumption is complicated due to the lack of a shared terminology, especially when the goal is the identification of subjects presenting a problematic use of the substance. In order to compare the various studies in different countries, and to effectively monitor phenomena related to substance use, the EMCDDA has established the criteria of substance consumption patterns approved by the scientific community, also referring to the recent version of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5), which substantially modifies the criteria for diagnosis of problematic use of substances (Substance Use Disorders – SUD) (see Key facts).

Although the evaluation of problematic cannabis use and of other substances is based on univocal criteria

shared by the scientific community, several tools for assessing this phenomenon can be used.

It is necessary to verify whether the problematic cannabis use is investigated in a clinical or in a general population.

In the first case, evaluations (clinical assessments) are to be performed by accredited and skilled professionals to issue a diagnosis and to investigate the severity of substance use. In the second case, the tools generally used are screenings for a preliminary evaluation, for example, self-report questionnaires, with the aim of detecting the use of problematic and potentially harmful cannabis use in a larger population.

Although screening does not allow a clinical diagnosis, it has the advantage of being simple, easy to administer, cheap, and able to involve very large populations.

There are many self-report screenings that are designed to detect the problematic use of cannabis. Many of these have been adapted from previous specific instruments for alcohol, for example, the 139 items of the problem-oriented screening instrument for teenagers (POSIT) or the drug abuse screening test (DAST-28). Many of these tools (and similar ones) are too long and complex, and inappropriate for investigating the phenomenon in nonclinical populations.

In recent years, the EMCDDA, in collaboration with several national experts, has developed methodologies for the monitoring of "intensive forms of drug use". In fact, for a standardized definition of problematic use of cannabis in the educated population, the EMCDDA suggests the use of the Cannabis Abuse Screening Test (CAST), developed by French researchers (Legleye, Karila, Beck, & Reynaud, 2007).

WHAT IS THE CANNABIS ABUSE SCREENING TEST?

The CAST questionnaire is composed of 6 items related to the past year:

1. Have you smoked cannabis before midday?
2. Have you smoked cannabis when you were alone?
3. Have you had memory problems when you smoked cannabis?
4. Have friends or family members told you that you should reduce or stop your cannabis consumption?
5. Have you tried to reduce or stop your cannabis use without succeeding?
6. Have you had problems because of your cannabis use (argument, fight, accident, poor results at school, etc.)?

All items are answered on a 5-point scale (0 "never," 1 "rarely," 2 "from time to time," 3 "quite often," and 4 "very often"). In the original version (Legleye et al., 2007), positive response thresholds vary across questions. The threshold was set at "from time to time" for the first two questions as they do not screen problems but frequencies of use in different contexts, and at "rarely" for the others. Using this algorithm, individual test scores can range from 0 to 6 and the cutoff points were ≥2.

Computing a score using the full range of items (Legleye et al., 2011) responses yield a total score ranging from 0 to 24 and the cutoff points ≥3.

In the Italian validated version (Bastiani et al., 2013), the scores were associated with different kinds of responses that vary attributing a different importance to the options of response and the cutoff points were ≥7 (Table 100.1).

TABLE 100.1 Computing a Score Using the Italian Validated Version

CAST	Never	Rarely	From time to time	Quite often	Very often
(1) Have you smoked cannabis before midday?	0	1	2	3	4
(2) Have you smoked cannabis when you were alone?	0	1	2	3	4
(3) Have you had memory problems when you smoked cannabis?	0	1	2	3	4
(4) Have friends or family members told you that you should reduce or stop your cannabis consumption?	0	2	3	4	4
(5) Have you tried to reduce or stop your cannabis use without succeeding?	0	2	3	3	4
(6) Have you had problems because of your cannabis use (argument, fight, accident, poor results at school, etc.)?	0	2	2	3	4

Original (Legleye et al., 2011) and Italian version of the CAST have the same questions, the content and order of items are equivalent. In relation to items characteristics, through the multiple correspondence analysis (MCA) (Gifi, 1990), we observed that the various response items of the five questions of CAST contributed with different weight to the total score (Bastiani et al., 2013).
Italian version scores were equal to the original version for the first three items [(1) consuming before midday; (2) consuming alone; and (3) memory problems]. On the contrary for the fourth, fifth, and sixth items, scores were associated with different kinds of response that vary attributing a particular and greater importance to the options of more moderate response (rarely) to these questions. So, we obtained the better score in relation to the importance of the response categories for each question of CAST. The score was obtained as the sum of items recoded after MCA results, and permitted maximizing item homogeneity from the scale and a best estimate of the phenomenon.

APPLICATION OF THE CAST: AN ITALIAN EXPERIENCE

Although several studies have investigated the factors associated with problematic use of cannabis, after a review of the scientific literature and to our knowledge, few of them aimed to investigate the association between the severity of cannabis use detected by the CAST and concurrently, components relating to the subject and the social and family environments. For this purpose, the Italian Epidemiology Group of the National Research Council – Institute of Clinical Physiology planned this study using data collected from the ESPAD Italia conducted in 2013. The survey is designed to monitor drug use among European youth, and in 2013, a total of 32,564 Italian adolescents (15–19 years) participated. The mean age of participants was 17 years, and 51.3% of them were males. Prior to the survey, participants were informed about the purpose of the study and were guaranteed complete anonymity; participation was voluntary. The response rate of schools participating in the survey was 85%. The present analyses were restricted to adolescents reporting cannabis use in the previous year ($n = 7915$) and shows that 24.7% of Italian students reported LY use (males = 30%; females = 19.2%).

The final sample comprised 6924 young cannabis users who completed the CAST in its entirety and with complete data on gender and age. These students were divided into two groups based on the CAST score: ≥7 is labeled as "problematic cannabis user" (PCU) and <7 as "nonproblematic cannabis user" (NPCU).

The prevalence of Italian students who are PCUs is 5.6% (22.8% of current users) and the rate is higher among males than females (7.7% vs 3.5%). It should be underlined that the average age at first use of cannabis is significantly lower among PCUs than NPCU students [14.4 years (d.s. 1.9) vs 15.6 years (d.s. 1.5); $p < 0.0001$] and that among PCU students the percentage of "frequent cannabis users" (20 or more times in the last month) is 39.7% (vs 5.5% among NPCUs).

In addition to variables regarding gender, age and age at first use of cannabis, we selected independent variables concerning specific topics (Fig. 100.1):

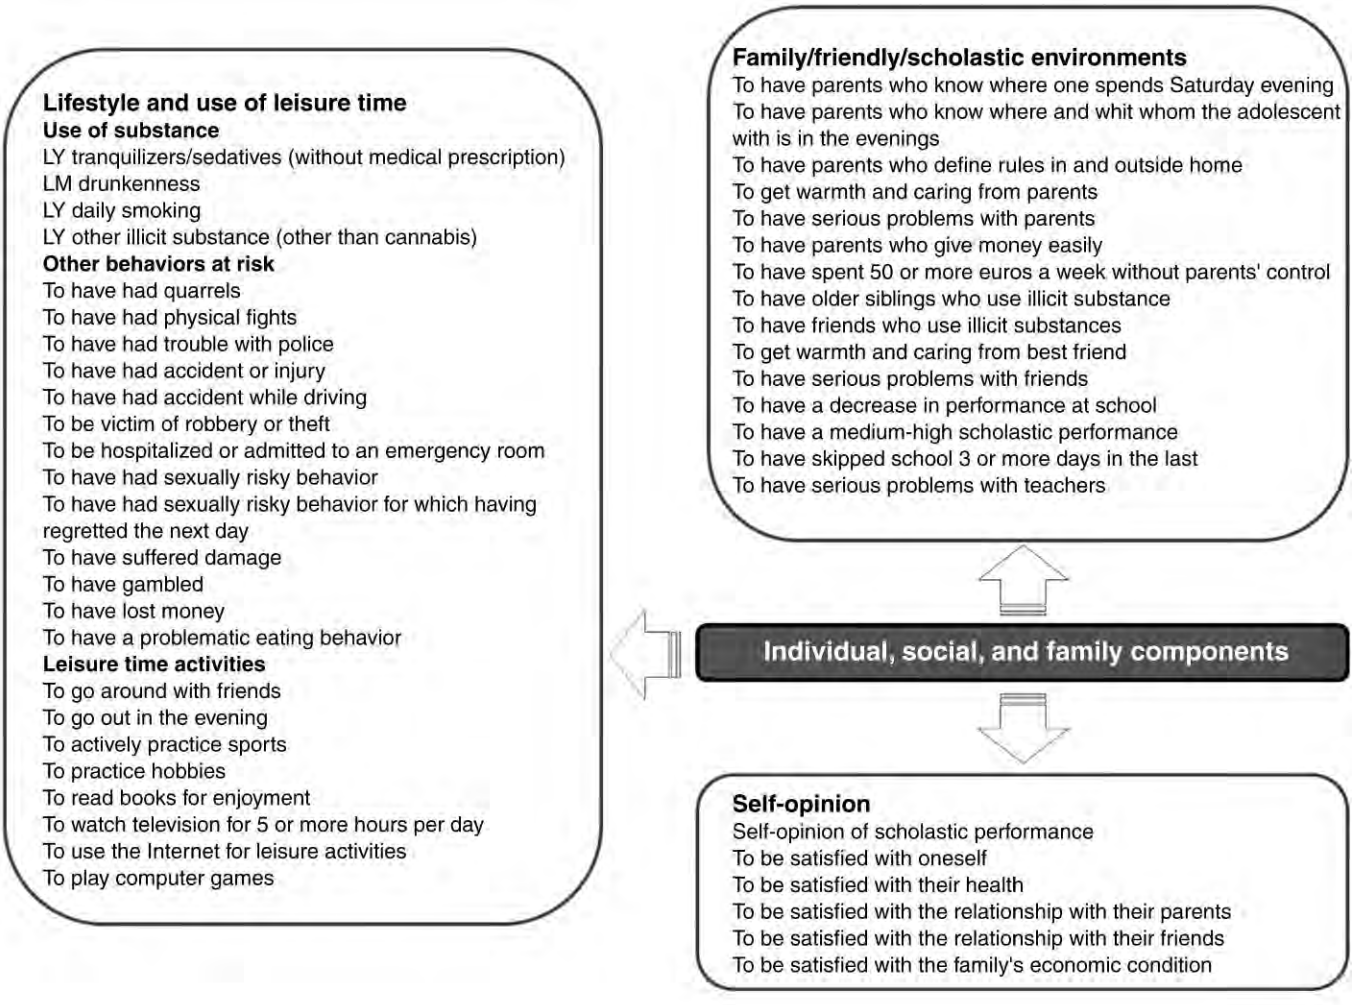

FIGURE 100.1 **Independent variables considered (except gender, age and age at first use of cannabis).** LY, last year; LM, last month.

1. Family/friendly/scholastic environments,
2. Lifestyle and use of leisure time,
3. Self-opinion.

The statistical analyses performed were divided into two phases. The first phase consists of univariate logistic regression analysis corrected by gender, age and age at first cannabis use. A significance of 0.05 was required for a variable to be included in the second stepwise analyses, consisting of a multivariate logistic regression model. We computed two separate multiple logistic regression analyses using respectively variables associated positively and inversely at univariate analysis. Results are reported as adjusted odds ratio (OR) with a 95% confidence interval. Statistical significance was set at $p < 0.05$.

THE MAIN EVIDENCE

First Phase: Univariate Logistic Regression

The univariate analysis shows association between single covariates and problematic use of cannabis (Table 100.2).

First, males were more likely to be PCU than females, while increasing age of initiation decreases the odds of being PCU. On the other hand, comparing students who have tried cannabis at the same age, it is highlighted that older students were more likely than younger ones to be PCU.

What the association with other covariates shows is covered in subsequent sections.

TABLE 100.2 Univariate Logistic Regression Correct by Gender, Age and Age of First Cannabis Use

Variables	Students with PUC	
	OR (95% CI)	*p* value
Sex: male versus female	1.46 (1.29–1.66)	<0.001
Age	1.12 (1.07–1.17)	<0.001
Age at first cannabis use	0.60 (0.58–0.63)	<0.001
Family/friendly/scholastic environments		
Having parents who know where one spends Saturday evening: always/often versus sometimes/usually don't know	0.42 (0.37–0.48)	<0.001
Having parents who know where and with whom the adolescent is in the evenings: almost always/often versus sometimes/seldom/almost never	0.48 (0.42–0.55)	<0.001
Having parents who define rules in and outside home: almost always/often versus sometimes/seldom/almost never	0.84 (0.74–0.94)	<0.004
Receiving personal warmth and care from parents: almost always/often versus sometimes/seldom/almost never	0.49 (0.43–0.57)	<0.001
Having serious problems with parents: yes versus no	2.86 (2.53–3.23)	<0.001
Having parents who give money easily: almost always/often verss sometimes/seldom/almost never	0.71 (0.63–0.80)	< 0.001
Spent 50 or more Euros a week without parents' control: yes versus no	3.15 (2.66–3.72)	<0.001
Having older siblings who use illicit substances: yes versus no	2.13 (1.81–2.51)	<0.001
Having friends who use illicit substances: yes versus no	1.04 (0.72–1.50)	ns
Receiving personal warmth and care from best friend: almost always/often versus sometimes/seldom/almost never	0.68 (0.59–0.79)	< 0.001
Having serious problems with friends: yes versus no	2.22 (1.95–2.53)	<0.001
Having a decrease in performance at school: yes versus no	2.20 (1.95–2.47)	<0.001
Having a medium-high scholastic performance: yes versus no	0.48 (0.40–0.56)	<0.001
Have skipped school 3 or more days in the last month: yes versus no	2.33 (2.04–2.65)	<0.001
Having serious problems with teachers: yes versus no	2.32 (2.05–2.63)	<0.001
Use of substance		
LY tranquilizers/sedative (without medical prescription): ≥1 time versus never	2.35 (2.02–2.74)	<0.001
LM drunkenness: ≥1 time versus never	2.44 (2.17–2.75)	<0.001
LY daily smoking: ≥1 cigarette/day versus <1 cigarette/day	4.40 (3.80–5.09)	<0.001
LY other illicit substances (other than cannabis): ≥1 time versus never	6.48 (5.64–7.44)	<0.001

Variables	Students with PUC	
	OR (95% CI)	*p* value
Other at risk behaviors		
Having quarrels: yes versus no	1.23 (1.05–1.44)	ns
Having physical fights: yes versus no	1.58 (1.41–1.79)	<0.001
Had trouble with police: yes versus no	3.84 (3.33–4.43)	<0.001
Had accident or injury: yes versus no	1.60 (1.42–1.80)	<0.001
Had accident driving vehicle: yes versus no	1.85 (1.61–2.13)	<0.001
Been victim of robbery or theft: yes versus no	1.67 (1.42–1.97)	<0.001
Been hospitalized or admitted to an emergency room: yes versus no	1.13 (0.99–1.29)	ns
Have performed sexually risky behavior: yes versus no	2.28 (2.02–2.58)	<0.001
Have performed sexually risky behavior and regretted the next day: yes versus no	2.30 (2.03–2.62)	<0.001
Have suffered damage: yes versus no	1.66 (1.47–1.86)	<0.001
Have gambled: almost every day/at least once a week versus never/few times a year/1–2 times a month	2.20 (1.88–2.58)	<0.001
Have lost money: yes versus no	1.79 (1.59–2.01)	<0.001
Have problematic eating behavior: yes versus no	1.89 (1.56–2.29)	<0.001
Leisure time activities		
Going around with friends: almost every day/at least once a week versus never/few times a year/ 1–2 times a month	0.96 (0.75–1.22)	ns
Going out in the evening: almost every day/at least once a week versus never/few times a year/ 1–2 times a month	1.39 (1.17–1.65)	<0.001
Actively practice sports: almost every day/at least once a week versus never/few times a year/ 1–2 times a month	0.64 (0.57–0.73)	<0.001
Practicing hobbies: almost every day/at least once a week versus never/few times a year/ 1–2 times a month	1.07 (0.96–1.20)	ns
Reading books for enjoyment: almost every day/at least once a week versus never few times a year/ 1–2 times a month	0.95 (0.82–1.10)	ns
Watching television for 5 or more hours per day: yes versus no	1.80 (1.44–2.24)	<0.001
Use of the Internet for leisure activities: almost every day/at least once a week versus never/few times a year/1–2 times a month	0.60 (0.45–0.80)	<0.001
Playing computer games: almost every day/at least once a week versus never/few times a year/ 1–2 times a month	0.98 (0.86–1.11)	ns
Self-opinion		
Self-opinion of scholastic performance: excellent/above average versus average/below average	0.79 (0.69–0.91)	<0.001
Being satisfied with oneself: very satisfied/satisfied versus not satisfied and not unsatisfied/not very satisfied/ not satisfied	0.76 (0.67–0.86)	<0.001
Being satisfied with their health: very satisfied/satisfied versus not satisfied and not unsatisfied/not very satisfied/not satisfied	0.51 (0.45–0.59)	<0.001
Being satisfied with the relationship with their parents: very satisfied/satisfied versus not satisfied and not unsatisfied/not very satisfied/not satisfied	0.68 (0.59–0.77)	<0.001
Being satisfied with the relationship with their friends: very satisfied/satisfied versus not satisfied and not unsatisfied/not very satisfied/not satisfied	0.69 (0.59–0.82)	<0.001
Being satisfied with the family's economic condition: very satisfied/satisfied versus not satisfied and not unsatisfied/not very satisfied/not satisfied	0.86 (0.76–0.97)	0.012

ns, Not significant.

Family/Friendly/Scholastic Environments

To be monitored by parents regarding leisure and Saturday evening activities, to have parents who establish rules of behavior in and outside the home and who often give money are variables negatively associated with being PCU. Similarly, students who experience warmth and caring by parents are less likely to be PCU.

On the other hand, to have had serious relational problems with parents and to have spent more than 50 Euros a week without their control, as well as having older siblings who use illegal substances, have a strong positive association with the odds of being PCU.

To feel accepted and emotionally supported by friends is negatively associated with being PCU, while relational problems with peers increase the odds of being PCU.

To have a medium-high scholastic performance is negatively associated with being PCU, while to have had serious problems with teachers, worse scholastic performance, and to have skipped school 3 or more days in the last month increase the probability of being PCU.

Lifestyle and Use of Leisure Time

The odds of being PCU are very high for students who in the LY had used other illegal substance other than cannabis, had used psychotropic drugs (tranquillizers/sedatives without a doctor's prescription) and had smoked cigarettes or gotten drunk in the past month.

Other at risk behaviors, such as having had physical fights and/or accident or injury, also when driving, having had trouble with police and/or sexually risky behaviors or for which having regretted the next day are variables positively associated with being PCU. Having been a victim of robbery or theft increases the odds of being PCU, such as having gambled and/or lost money often.

On the other hand, to be engaged in leisure time activities, such as active participation in sports or athletics and/or used the Internet for pleasure/recreation decrease the odds of being PCU

Instead, going out often in the evening (to a disco, cafe, party, etc.) and watching television for 5 or more hours a day are negatively associated with being PCU.

Last, having a problematic eating behavior (detected through the use of the screening test EAT-26) increases the odds of being PCU.

Self-Opinion

Students who have high self-esteem, who report being very satisfied with their health status, and/or with relationships with parents and friends, and/or with the economic situation of their families, have low probability of being PCUs. The low probability of being PCU is also highlighted among students who consider their scholastic performance above average.

SECOND PHASE: MULTIVARIATE MULTINOMIAL ANALYSIS

The variables described previously are included in a multivariate analysis for assessing the independent associations of each variable given the impact of the others. Figs. 100.2 and 100.3 present the results of the multivariate multinomial logistic regression separately by the variables negatively and positively associated with being PCU.

The variables that increase the odds of being PCU mainly concern the use of other illicit drugs (in addition to cannabis) in the past year, being a daily smoker of cigarettes, and getting drunk in the past month. A positive association with being PCU is frequent gambling, and having been in trouble with the police.

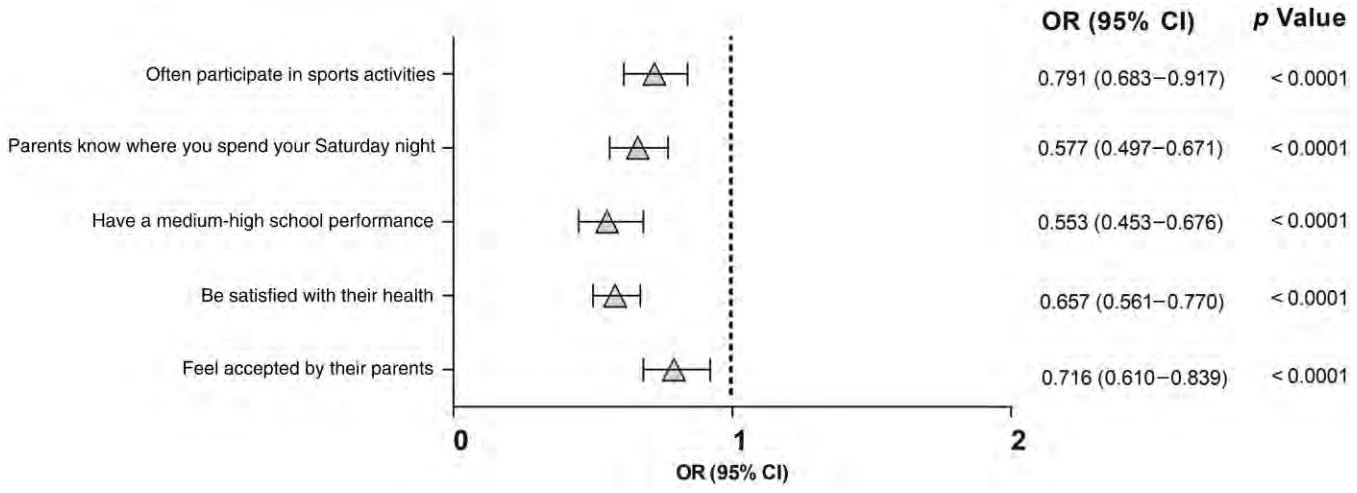

FIGURE 100.2 **Multivariate multinomial logistic regression: behaviors associated negatively with being PCU (OR < 1).**

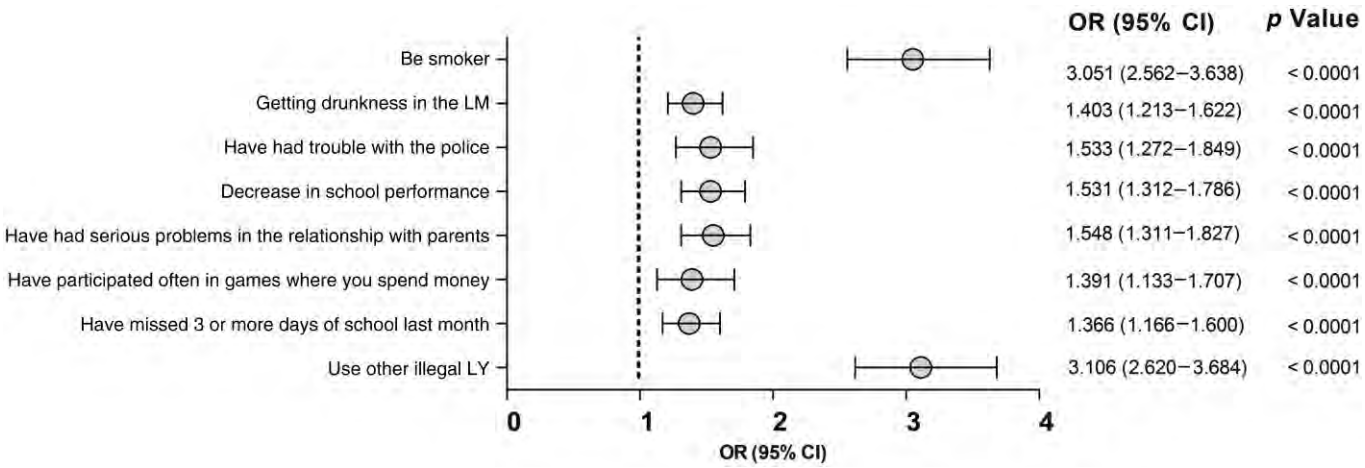

FIGURE 100.3 **Multivariate multinomial logistic regression: behaviors associated positively with being PCU (OR > 1).** LY, last year; LM, last month.

The students who have serious relational problems with the parents and/or have a poor scholastic motivation have a high probability of being PCU rather than NPCU.

On the other hand, for cannabis users who are monitored by parents and who experience warmth and caring from them the probability of being PCU is lower, as well as for the students who are engaged in sports or who use the Internet for fun and leisure.

Last, student cannabis users who have a good scholastic performance and who are satisfied with their health have a lower probability of being PCU rather than NPCU.

CONCLUSIONS

This study emphasizes the application of CAST regarding problematic cannabis use in a national survey that investigates adolescents' behaviors. In order to assess the problematic cannabis use in European adolescent school population, the 2007 ESPAD survey included the CAST as an optional module for the first time (Hibell et al., 2009). In 2007, the CAST module was used by 17 of 36 ESPAD countries and in 2011 by 13 of 35 countries. Although all of these countries have included CAST in their survey, not everyone has provided a validation study for this screening (Hibell et al., 2009, 2012). In order to test and validate this tool for the adolescent or general population, recent national studies, in France (Legleye et al., 2007; Legleye, Piontek, Kraus, Morand, & Falissard, 2013), Portugal (Cuenca-Royo et al., 2012; Cuenca-Royo, Sánchez-Niubó, Torrens, Suelves, & Domingo-Salvany, 2013), Spain (Thanki et al., 2013), Italy (Bastiani et al., 2013), Hungary (Gyepesi et al., 2014) and others are currently in progress or completed. The importance of a standardized tool to assess problematic-cannabis-use has also drawn attention at the European level, promoting, by EMCDDA, a validation study across European countries.

In ESPAD Italia, CAST has been included since 2009, while validation of the screening-tool was carried out in the 2011 Italian survey. In the Italian experience, the annual administration of this screening-test allows monitoring the evolution and characteristics of the phenomenon at the national level, as well as comparison with the other European countries. The application of CAST in the Italian context has allowed estimation of the proportion of young people who are at risk of developing problematic cannabis behavior or addiction and, at the same time, at the level of more limited geographic areas such as regional contexts, provides timely and relevant data for addressing future policies, programs and surveillance activities. The studies have provided statistical evidence useful in the planning and modulation of universal and selective prevention interventions aimed at adolescent and young people, significant adults and the general population.

Indeed, using a very large sample of adolescents aged 15–19 years, our study has analyzed the association of several psychosocial domains with PCU and has examined their simultaneous effects, using a multivariate approach, and not only the effects of each variable, as instead is done by many other studies.

Although several variables were significantly associated with PCU at the univariate level, only a few of them were significant in the multivariate model.

The multivariate analyses clearly pointed out the positive relationship between PCU and other risk behaviors, such as use of other substances (tobacco, alcohol and other illegal substances), truancy at school and low scholastic performance, gambling and being in trouble with

the police. This may be taken to indicate that the psychosocial environment underlying problematic cannabis consumption is similar to other problematic behaviors (often analyzed separately) and therefore responsible for their association.

Our results show that problematic-cannabis-use among secondary school students is strongly and significantly associated with consumption of other illegal substances and gambling during the past year and with well-established use of legal psychoactive substances, such as daily cigarette smoking and excessive alcoholic drinking in the last month, as shown in other studies (eg, Walther, Morgenstern, & Hanewinkel, 2012; Peters, Budney, & Carroll, 2012; Grevenstein & Kröninger-Jungaberle, 2014).

Regarding the family and friendly environments, in univariate analysis illicit substance use by friends, the quality of relationship and the emotion support by them, such as parental monitoring, the presence of rules, the relationship with parents and their emotional support, are all related to problematic-cannabis-use. However, in the multivariate model the friendly environment is not significantly associated, while only monitoring and emotional support by parents have a greater impact, highlighting the key role of the family in adolescent behavior. In fact, as pointed out by many recent as well long-standing studies, one of the risk factors for cannabis use and for PCU, is poor parental monitoring and a bad relationship with parents (Choquet, Hassler, Morin, Falissard, & Chau, 2007; Becoña et al., 2013; Maniglio & Innamorati, 2014).

A good school performance is negatively associated with PCU (Malhotra & Biswas, 2006; Iyalomhe, 2009; McCaffrey, Pacula, Han, & Ellickson, 2010; Brook, Lee, Finch, Koppel, & Brook, 2011; Grevenstein & Kröninger-Jungaberle, 2014); this could be related to the fact that adolescents with a good educational level are more knowledgeable about potential effects or risks associated with use of the substance. Furthermore, our results show that high self-esteem and satisfaction with their health status are protective variables regarding use of cannabis.

In conclusion, we can assume that PCU does not occur as an isolated and unique risk behavior, but is part of a pattern of risk behaviors; this aspect must be taken into consideration when designing interventions of prevention and treatment targeted at young people and families. Given the ease of administration and understanding, CAST has proved to be an efficient and valuable tool for evaluating the severity of cannabis use among adolescents and youth, and for this reason its large-scale application as early as possible may suggest intervention strategies for decreasing the involvement of adverse effects in young adults (eg, Swift et al., 2012) and reducing the costs associated with health care and social services (Degenhardt et al., 2013).

MINI-DICTIONARY

Cannabis Abuse Screening Test (CAST) The tool was developed by the French Monitoring Centre for Drug and Drug Addiction The CAST questionnaire is a 6-item scale screening for problematic patterns of cannabis use among adolescents and general population.

Craving (compulsion) An intense and uncontrollable desire, supported by an obsessive thought of taking the drug, the effects of which have already been previously tested and/or the absence of which results in a state of severe psychological and physical discomfort.

Diagnostic and Statistical Manual of mental disorders (DSM) The Manual was prepared by the American Psychiatric Association, which classifies all diseases or mental disorders, including abuse and dependence on psychoactive substances (including alcohol). Over the years it has been updated and improved several times in the following editions: DSM-I, DSM-II, DSM-III, DSM-III-R, DSM-IV, DSM-IV-TR, DSM-5 (last edition).

Eating attitude test-26 (EAT-26) The EAT-26 is a screening test that can detect a tendency towards anorexia, bulimia, and in general behaviors indicating a problematic relationship with food. The EAT-26 is a shortened version of the original EAT-40 and was first published in 1979.

European Monitoring Centre for Drugs and Drug Addiction (EMCDDA) A decentralized agency of the European Union, the reference point for drugs and drug addiction information. The EMCDDA is located in Lisbon since 1995.

European School Survey Project on Alcohol and Other Drugs (ESPAD) A European study repeated every 4 years. It investigates tobacco, alcohol and substance use among European students aged between 15 and 16 years. 39 European countries participated in the last survey in 2011.

Frequent use It defines the consumption of cannabis repeated 20 or more times in the last month (also called "daily use" or "near daily use").

Odds ratio (OR) In epidemiology it is one of the indexes used to measure the association between two factors and therefore to quantify the relationship between exposure and a health outcome.

***National Criminal Investigation Service (NCIS) Norway, Forensic Science Department, Oslo, Norway

SUMMARY POINTS

- Synthetic cannabinoids are increasingly important as drugs of abuse, and correspondingly important to include in drug screening panels.
- New synthetic cannabinoids are often first discovered in seized products.
- The number of available substances is increasing, making it difficult for screening methods to keep up.
- Concentrations in biological media are often low, making very sensitive screening methods important.
- Conventional screening assays for THC or THC acid will usually not give response for synthetic cannabinoids, as they are structurally very different from natural cannabinoids.
- Most analytical methods are based on separation by gas or liquid chromatography, followed by mass spectrometric detection, after conventional sample preparation as liquid–liquid or solid phase extraction.
- Some immunoassay kits for urine are on the market, but so far no kits covering all synthetic cannabinoids are available.
- High-resolution mass spectrometry is increasingly being used both for screening and metabolite elucidation.
- Several compounds may give the same metabolites, making the determination of the ingested compound difficult.
- Similar compounds (structural isomers) may pose both analytical problems and problems with interpretation, as all isomers are not necessarily on the prohibited list.

KEY FACTS OF CHROMATOGRAPHY

- The word chromatography is a combination of the Greek words "chroma," color, and "graphein," to write.
- The phrase was used first by the Russian–Italian botanist Mikhail Tsvet in two articles from 1906, describing the separation of a solution of chlorophyll in petroleum ether by adsorption to calcium carbonate in a column.
- Chromatography is used to separate and identify analytes in complex mixtures.
- Separation is based on the partitioning of analytes between a stationary phase and a mobile phase.
- The mobile phase will bring the analytes through the chromatographic column; compounds with little interaction with the stationary phase will elute early, and compounds with larger interaction will elute late.
- The time of elution, called retention time, can be used to identify the analyte by comparison with the retention time of a reference standard.

UNODC	United Nations Office on Drugs and Crime
UV	Ultra violet spectroscopy

INTRODUCTION

Synthetic cannabinoids are cannabimimetic compounds that interact with the endocannabinoid system, and are full cannabinoid receptor agonists with high potency and high efficacy (Wintermeyer et al., 2010). This makes them popular as alternatives to marijuana, and they are in many cases marketed as legal to use and distribute. The psychoactive effects of synthetic cannabinoids are perceived to be as strong as or stronger than cannabis (Griffiths, Sedefov, Gallegos, & Lopez, 2010), and adverse effects can be significant (Spaderna, Addy, & D'Souza, 2013). The need for screening for synthetic cannabinoids in seized products, intoxication cases, work place testing, driving under the influence cases, and general drug screening is therefore evident.

To circumvent legislation, new compounds are being produced continuously by clandestine laboratories, and rapid changes in methods for both biological media and plant material/solid substances are consequently required. Detection times in naïve users have been reported to be relatively short, 2–3 days for urine (de Jager, Warner, Henman, Ferguson, & Hall, 2012), hours to days for oral fluid (Coulter, Garnier, & Moore, 2011; Oiestad, Johansen, Christophersen, & Karinen, 2013), and 1–2 days in blood (Teske et al., 2010). The fact that estimated terminal elimination half-lives of up to 41 days for JWH-081, JWH-122, and JWH-210 with continuous decrease of serum concentration levels have been reported (Kneisel, Teske, & Auwärter et al., 2014), does however imply that as with THC accumulation in adipose tissue for heavy users could be possible. Analysis intended to determine new intakes of synthetic cannabinoids must therefore be evaluated by caution.

Only a few synthetic cannabinoids resemble the natural cannabinoids, as the classification is based on the binding to the cannabinoid receptors CB1 or CB2. An overview of the different classes of synthetic cannabinoids from an article by Barnes et al. (2014) can be found in Fig. 101.1. THC and other classical cannabinoids are dibenzopyranes, and the first synthetic cannabinoids were nonclassical cannabinoids like the cyclohexylphenoles. The naphthoylindoles JWH-018 and JWH-073 were among the first aminoalkylindoles to come on the market, followed by a large number of similar compounds. The creativity of clandestine drug manufacturers is clearly evident in the so-called 3rd, 4th, and 5th generation synthetic cannabinoids like UR-144, APINACA, and 5F-PB-22.

ANALYTICAL TECHNIQUES

For synthetic cannabinoids (SC), the analysis of plant material or pure substances is very important, as the higher concentrations compared to biological media facilitates the discovery of novel compounds. In May 2013, United Nations Office on Drugs and Crime (UNODC) published a manual for use by national drug analysis laboratories. This manual describes recommended methods for the identification and analysis of synthetic cannabinoid receptor agonists in seized materials (UNODC, 2013). In general, the identity of a controlled drug should be determined with at least two uncorrelated parameters, one of which should provide information on the chemical structure of the analyte (mass spectrometry (MS), infrared spectroscopy (IR), nuclear magnetic resonance spectroscopy (NMR)) (UNODC, 2013). Also in 2013, minimum recommendations for method selection were published by Scientific Working Group for the Analysis of Seized Drugs (SWGDRUG, 2013). Gas chromatography mass spectrometry (GC–MS) is a fast and sensitive technique that separates active compounds before each compound is identified due to its retention time and its fragmentation pattern (mass spectrum). It verifies the presence of new compounds (Choi et al., 2013; Dresen et al., 2010) as they occur and if reference spectra exist, this technique can give a positive identification.

For serum/blood and alternative matrixes as oral fluid or hair, chromatographic methods will usually be utilized. While GC has been a very common technique for drugs of abuse analysis, liquid chromatography (LC), which is directly compatible with aqueous biological samples, is increasingly being used for bioanalysis (Maurer, 2007, 2013). For forensic methods and many clinical applications, mass spectrometry is the preferred detector due to its high specificity.

Urine screening is commonly performed with either immunoassays or chromatographic analysis. Immunoassay screening is a very efficient technique for screening of large numbers of samples, especially when many of the samples are expected to be negative. SC do not cross-react on traditional marijuana immunoassay tests, as most of these cannabimimetic compounds are structurally unrelated to traditional cannabinoids. Kits for some SC have become commercially available. The rapid change of repertoire for SC is, however, a challenge as the development

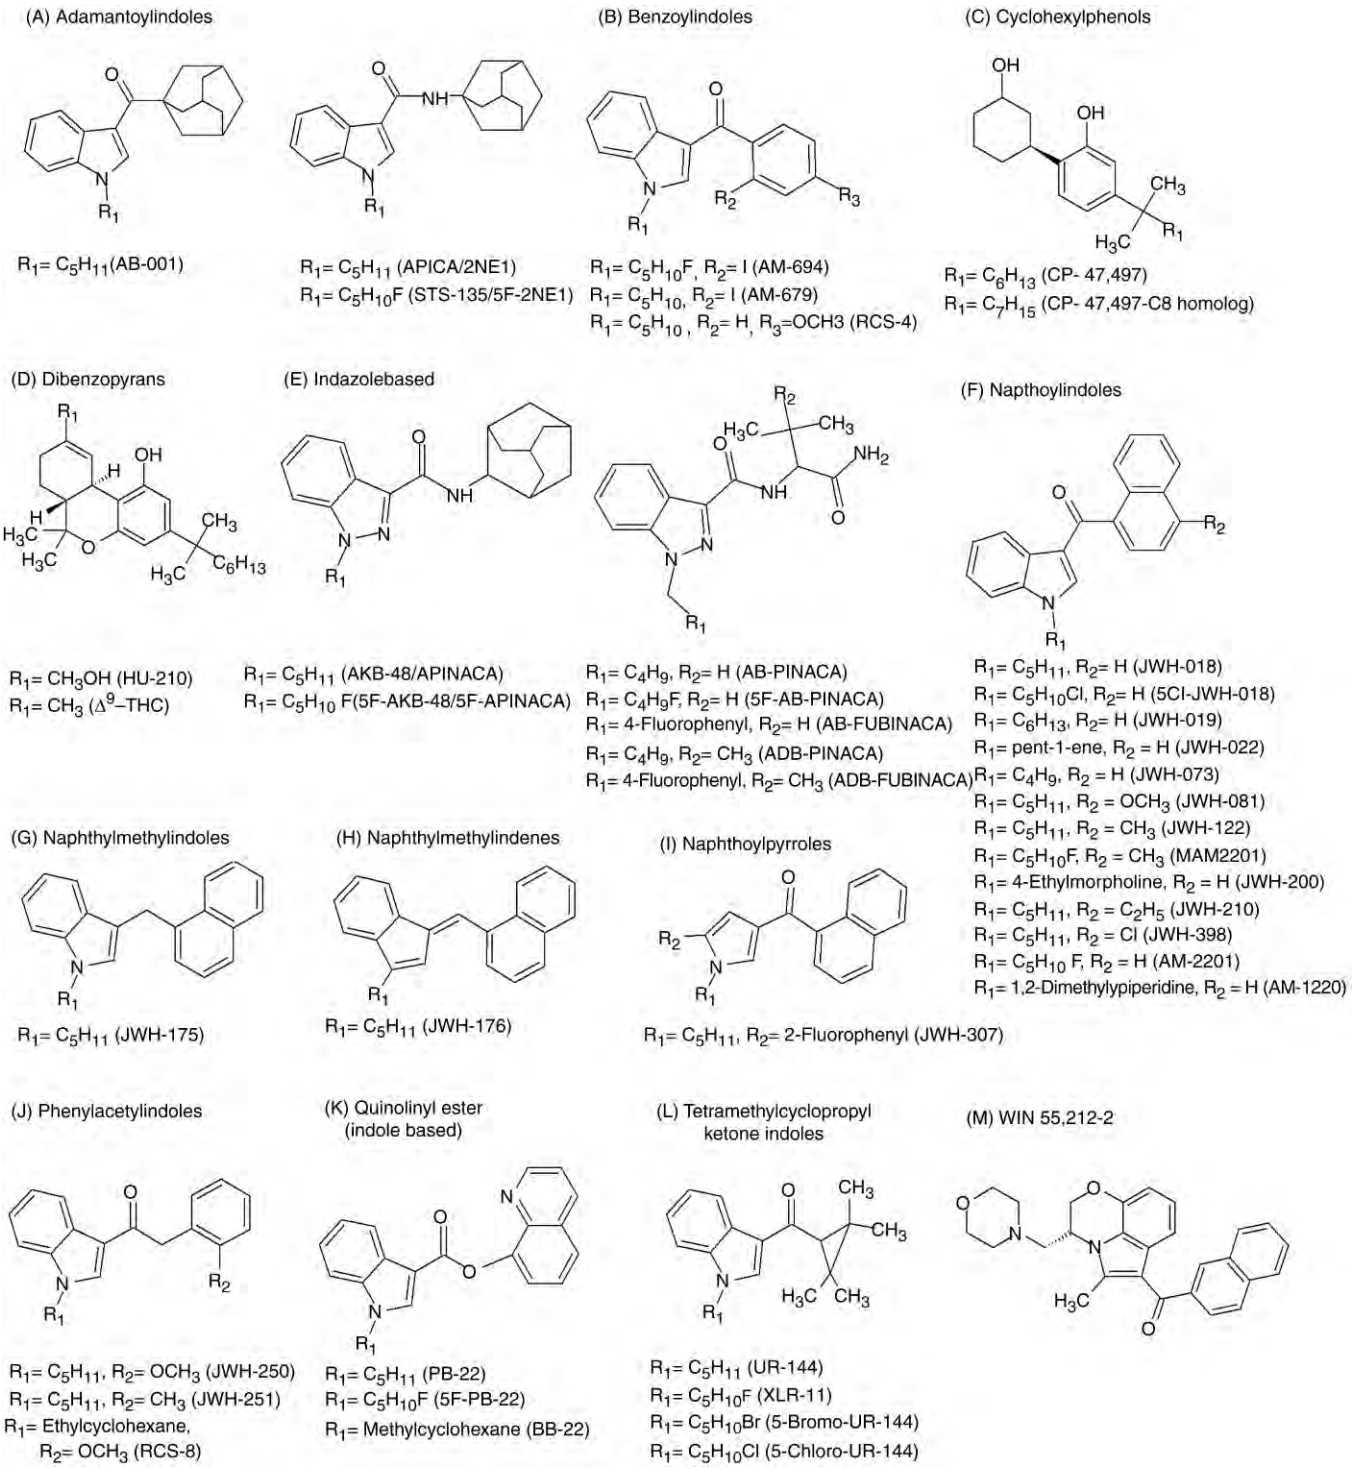

FIGURE 101.1 **Structures of synthetic cannabinoids.** General structures of synthetic cannabinoids from Barnes et al. (2014). Copyright (2014) reproduced by permission from Elsevier.

of new immunoassay kits is time-consuming. On the other hand, several SC have been found to have cross-reactivity with the commercially available assays, as the specificity of the antibodies used is not absolute.

To elucidate metabolic patterns of synthetic cannabinoids and identify possible urine biomarkers, high resolution mass spectrometry (HR-MS) has become an important tool (Gandhi et al., 2013; Holm, Pedersen, Dalsgaard, & Linnet, 2014; Hutter, Broecker, Kneisel, & Auwarter, 2012a). The high resolving power makes the distinction between ions with small mass differences possible. The instrument can in addition be used

both for screening and quantitative analysis (Favretto, Pascali, & Tagliaro, 2013). Another great advantage of HR-MS is the data-dependent acquisition of nontargeted compounds, enabling the recording of almost every ion generated. The data files can then be analyzed retrospectively. Lists of theoretically possible metabolites can be generated based on knowledge of the metabolism of earlier investigated SC of the same type or from knowledge of microsomal transformations (Peters & Meyer, 2011).

ANALYTICAL CHALLENGES

The number of SC is large and growing, and the ones most popular changes rapidly as substances become scheduled. In 2013, 29 new synthetic cannabinoids were reported by the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA, 2014). Pure substances of new SC and metabolites are often unavailable, and it is difficult for the manufacturers of reference substances to be abreast of the development as metabolism studies of each substance might be necessary to find the right metabolites.

An increasing challenge is to determine position isomers. This is of great importance when only one form is a controlled substance. An example of position isomers are JWH-201 (para), JWH-250(ortho), and JWH-302 (meta). As demonstrated for GC–MS analysis by Harris, Hokanson, Miller, & Jackson (2014), these compounds have the exact same mass, the same fragmentation pattern, and similar retention times.

For alkylindole compounds analyzed with, for example, LC–MS/MS, the charge is retained commonly on the naphthalene part of the molecule after fragmentation. Fig. 101.2 shows two pairs of isobaric compounds

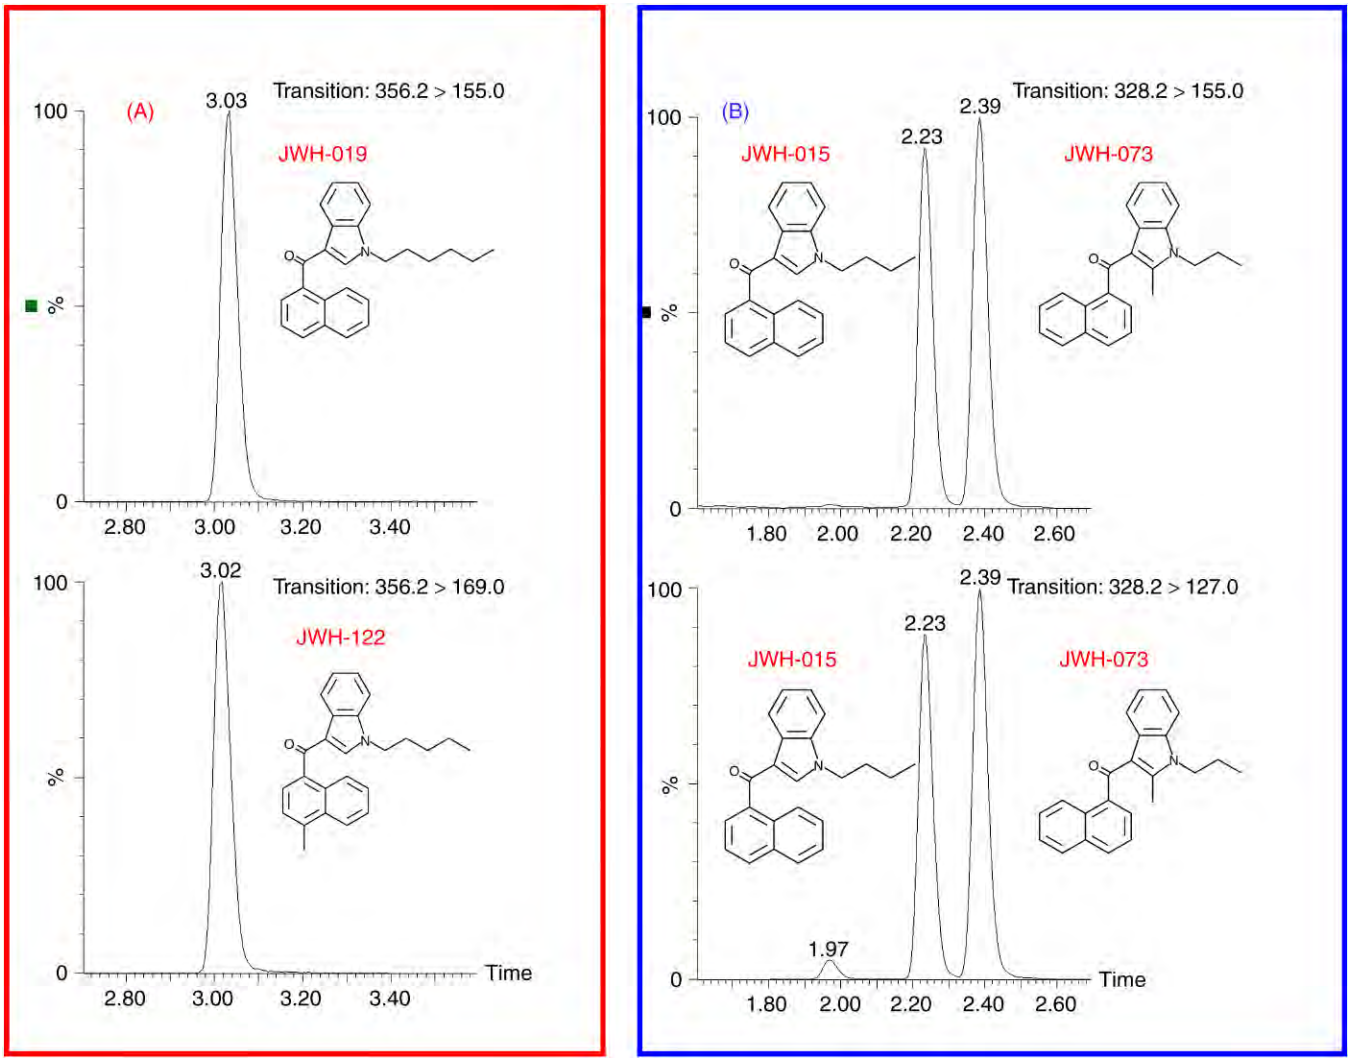

FIGURE 101.2 Separation of isobaric synthetic cannabinoids. (A) Coeluting isobaric compounds JWH-019 (upper panel) and JWH-122 (lower panel) separated due to different mass (B) Isobaric compounds JWH-015 and JWH-073 with identical fragments separated by different elution time.

(compounds with identical elemental composition) JWH-019 and JWH-122 (A) and JWH-015 and JWH-073 (B). As JWH-122 has an *N*-pentyl rather than *N*-hexyl group on the indole and correspondingly a methyl group on the naphthalene part, the mass of the resulting fragment is shifted from 155 for JWH-019 (Fig. 101.2A, upper panel) to 169 for JWH-122 (Fig. 101.2A, lower panel). For the isobaric compounds, JWH-015 and JWH-073, identical fragments are generated as the alkyl groups remain on the uncharged indole part of the molecule (Fig. 101.2B). The compounds are, however, chromatographically separated making the differentiation of the two compounds possible (Oiestad et al., 2013). If distinction is not possible either by chromatographic or mass separation, the two isomers cannot be discerned.

Ingested amounts of synthetic cannabinoids are usually in the low mg range, resulting in very low concentrations in biological media, Table 101.1. The lower range of concentrations are low compared to, for example, the guidelines of the Substance Abuse and Mental Health Services Administration (SAMHSA, 2014) for cannabis, suggesting screening cutoff concentrations of 50 ng/mL for marijuana metabolites and 15 ng/mL for confirmation of THC acid, or the recommended cutoff of 50 pg/mg for THC in hair (Salomone, Gerace, D'Urso, Di Corcia, & Vincenti, 2012). Although high concentrations for single cases can be seen, a majority of published papers demonstrate quite low median concentrations demonstrating the need for very sensitive instrumentation.

Extensive metabolism and no or only very low concentrations of the parent compounds in urine seem to be a common trait for most of the synthetic cannabinoids. In addition, the potency of these new drugs is as mentioned high, and the expected concentration of each of the many metabolites correspondingly low. This makes the detection of new compounds in urine difficult. Though hydroxylation on the alkyl chain have been found to be a major metabolite for many synthetic cannabinoids, such as JWH-015, JWH-018, AM-2201, etc.(Sobolevsky, Prasolov, & Rodchenkov, 2010, Sobolevsky, Prasolov, & Rodchenkov, 2012; Wintermeyer et al., 2010; Zhang, Ma, Cole, & Wang, 2006), other substances, such as APINACA and 5F-APINACA are hydroxylated on the adamantylgroup as the first step (Gandhi et al., 2013; Holm et al., 2014).The elucidation of the metabolism of these compounds illustrates the difficulty in suggesting metabolites. APINACA *N*-(4-hydroxypentyl) and 5F-APINACA *N*-(4-hydroxypentyl) are commercially available, but alas biologically less relevant. Structural similarities of metabolites further complicate the picture. The formation of identical metabolites from several compounds has been described in the literature (Hutter et al., 2012a; Moran et al., 2011), and care must be taken with interpretation.

ANALYSIS OF PLANT MATERIAL AND PURE SUBSTANCES

Synthetic cannabinoids are sold primarily as herbal smoking blends (EMCDDA, 2013, 2014) where one or more active substances are mixed together with or sprayed on to plant materials. The actual content of a product is hard to predict as the active substance are subject to changes over time (Dresen et al., 2010; Langer, Lindigkeit, Schiebel, Ludger, & Beuerle, 2013; Li & Lurie, 2014).

Synthetic cannabinoids are also sold as powder, in either bulk or as smaller amount of "research chemicals". The purity of research chemicals is almost the same as for reference materials (Ginsburg, 2012), while a study from Korea showed that bulk powders had a purity of 70–95% (Choi et al., 2013) Fig. 101.3 shows examples of seized products as bags with herbal products or powder (research chemicals).

Since the number of synthetic cannabinoids is increasing rapidly (EMCDDA, 2014), there is a great need for a universal screening method to verify the existence of a new substance whenever these occur. GC-MS is one of the most commonly used techniques for analysis of seized materials (Choi et al., 2013; Li & Lurie, 2014; Uchiyama, Kikura-Hanajiri, Ogata, & Goda, 2010) and is regarded as the golden standard for qualitative analysis (UNODC, 2013). If no GC–MS reference spectrum is available, the sample might be analyzed with LC–MS or LC–UV (Ernst, Krüger, Lindigkeit, Schiebel, & Beuerle, 2012; Li & Lurie, 2014; Uchiyama, Kawamura, Kikura-Hanajiri, & Goda, 2013; Uchiyama et al., 2010) to get a positive identification, GC–TOF (Ernst et al., 2012) can be used for exact mass determination or Fourier transform infrared spectroscopy (FT-IR) can be used to get information about functional groups. Common for all these techniques is the need for a reference spectrum, and reference spectrums are the key challenge for identification work. Some libraries are available commercially, some must be made in-house, while others are shared between different laboratories, examples are GC-MS libraries (NIST, MPW,ENFSI, SWGDRUG, Cayman Chemicals) and FT-IR libraries (ENFSI, SWGDRUG). If no such reference spectrums exist, NMR can be applied as a powerful tool in unambiguous structure elucidation (Ernst et al., 2012; Uchiyama et al., 2013). In order to distinguish types of compound, MS^n might be helpful (Smith, DeRuiter, Abdel-Hay, & Randall Clark, 2014). If not, FTIR is used for material containing pure substances (Smith et al., 2014). When the sample contains more than one compound, the separation power of GC is needed, making GC-IRD a valuable tool for determination of similar molecules.

ANALYSIS OF BIOLOGICAL SAMPLES

Blood

The screening for synthetic cannabinoids in whole blood or serum has been important since the onset of the recreational use of synthetic cannabinoids, due to their potency and possibility for intoxication. From 2004, synthetic cannabinoids were sold as herbal mixtures "Spice" in European countries, and, in 2008/2009, Auwärter and coworkers poised the question: "'Spice' and other herbal blends: harmless incense or cannabinoid designer drugs?" (Auwärter et al., 2009). Overdosing with these products lead to hospitalization, and different smoking blends were analyzed to find the substances responsible. Regular drug screening did not give any results, and a self-experiment with the smoking blend "Spice diamond" was therefore performed. The serum samples gave no result when screened with an 11-nor-9-carboxy-delta9-THC specific immunoassay. Analysis with GC-EI/MS after solid phase extraction did however reveal two steric isomers of a homologue of the nonclassical cannabinoid CP 47,497.

After this initial finding, several methods for synthetic cannabinoids in blood or serum have been published. In addition to evaluation of hospital admissions, the analysis of SC has become important in forensics, both for determination of driving under the influence and for post mortem case work. Chromatographic methods using GC and especially reversed phase LC coupled to mass spectrometry are the common choice for screening in blood or serum, and liquid-liquid extraction seems to be the preferred sample preparation method.

A comprehensive serum method was described by Dresen, Kneisel, Weinmann, Zimmermann, & Auwarter (2011). The method was applied to approximately

JWH-018	JWH-018 *N*-(4-hydroxy-pentyl)	JWH-018 *N*-(5-hydroxy-pentyl)	JWH018-5-Pentanoic acid	JWH018-6-OH-pentanyl	3-(3-(1-Naphthoyl)-1H-indol-1-yl) propanoic acid	JWH-019
0.05–11 (n = 115)						0.08–0.78 (n = 7)
<0.15–1.2 (n = 6)						<0.15–0.61 (n = 2)
0.6–70.5 (n = 9)						
3.1–17.3 (n = 3)						3.8–4.1 (n = 2)
	0.1–351 (n = 29)	0.4–706 (n = 33)	0.7–458 (n = 49)			
		10.2–5530 (n = 17)	2.1–27256 (n = 17)	3.1–36 (n = 6)	4.7–944 (n = 49)	

JWH-203	JWH-210	JWH-250	RCS4	MAM-2201	UR-144
	0.05–8.1 (n = 76)	0.14–0.73 (n = 3)	0.09–3.6 (n = 4)	0.05–21.3 (n = 151)	0.05–25.9 (n = 181)
<0.15–0.51 (n = 2)	<0.10–457[a] (n = 16)		0.1–5.3 (n = 3)	0.41 (n = 1)	
		1.5–729 (n = 8)			
		4.8–83 (n = 6)			

100 serum samples. JWH-081 was the most prevalent sample, followed by JWH-250, JWH-018, and JWH-073. Median concentrations of 0.88, 1.04, 0.64, and 0.42 ng/mL, respectively, demonstrate the need for sensitive screening methods. The method was later improved and extended (Kneisel & Auwärter, 2012) to cover 30 synthetic cannabinoids. Routine application of the method between August 2011 and January 2012 showed a dramatic change in user pattern during only few months.

For analysis in forensic cases whole blood, and not serum, will usually be the available material. In a method published by Kacinko et al. (2011), the authors present whole blood concentrations from a patient, who smoked a herbal incense blend known to contain JWH-018 and JWH-073. The samples were taken 19, 53, 107, and 199 min after smoking. JWH-018 and JWH-073 concentrations decreased from 4.8 and 4.2 to 0.2 ng/mL from the first sampling to the last sampling. Several authors have later published methods for whole blood. Examples of such methods with a summary of the included components and limits of quantitation can be found in Table 101.2.

The appearance of so called third generation synthetic cannabinoids, as UR-144 and XLR-11, and fourth generation synthetic cannabinoids, AKB-48 (APINACA), STS-135 etc., has made new methods or modification of previously published methods necessary. Adamowicz, Zuba, & Sekula (2013) have published a method for UR-144 and its pyrolysis product in blood, where they describe determination of UR-144 and its isomer in a blood sample, collected on admission to hospital. The measured UR-144 concentration was 6.1 ng/mL. Likewise the extensive method by Kneisel and Auwärter (2012) was extended to include AKB48, AKB48-5F, AM-1248, AM-2232, APICA, JWH-370, STS-135, and UR-144, as well as XLR-11 (Hermanns-Clausen, Kneisel, Hutter,

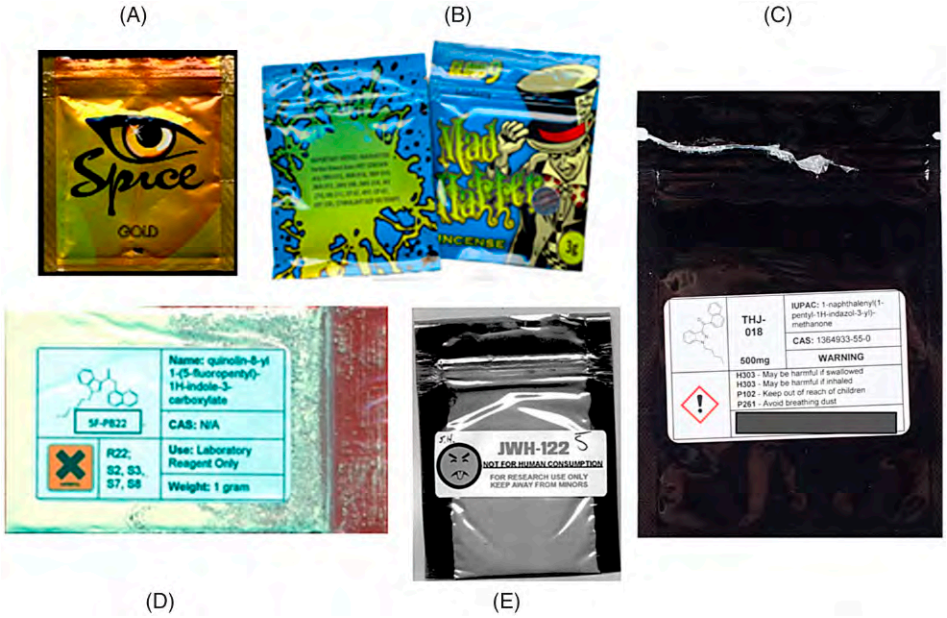

FIGURE 101.3 **Seized products and research chemicals.** Seizures from Norway; (A) a Spice Gold herbal blend package; (B) herbal blend "Mad Hatter" with the description "does not contain JWH-015, JWH-018, JWH-019, JWH-200, JWH-250, HU-210, HU-211, CP 49.497, Stimulant BZP, or TEMPP"; (C) Research chemical containing THJ-018 labelled with IUPAC name, CAS number, weight, molecular structure, and risk and safety statements; (D). Research chemical containing 5-fluoro-PB-22 labelled with IUPAC name, weight, molecular structure, and risk and safety statements; (E) bag containing JWH-122 marked not for human consumption.

Szabo, & Auwärter, 2013). The method was then used for the evaluation of acute intoxications.

Urine

Urine is historically the most common medium for drugs of abuse screening. Screening has often been performed using immunoassays; whereas, nowadays, chromatographic screening is also common. Methods for urine analysis that can easily be expanded with new compounds are advantageous as new SC appear on the market when others are scheduled. Chromatographic analysis is easier to adapt to this ever-changing regimen, and the majority of published urine methods are based on either GC–MS, LC–MS/MS, or LC–HR–MS. Commercial immunoassay kits have, however, become available for some SC metabolites. The antibodies can show cross-reactivity towards other structures than the targeted one, thus expanding the usefulness of the assays, and also enabling the detection of new SC.

Arntson et al. (2013) reported two enzyme-linked immunosorbent assays (ELISA) that were designed to detect the 5-OH metabolite of JWH-018 and the 4-OH metabolite of JWH-250 in urine. The JWH-018 assay had moderate to high cross-reactivity with 17 SC or SC metabolites. The JWH-250 assay had very limited cross-reactivity, with JWH-250-5-OH-pentyl and JWH-250-5-carboxypentyl metabolites at 50% being the only ones with a cross-reactivity >1%, compared to the JWH-250-4-OH calibrator. Compared to a confirmation method using LC–MS/MS, the specificities and sensitivities for both methods were more than 95%. Using the same immunalysis homogeneous enzyme immunoassay (HEIA) K2 Spice kit with JWH-018 *N*-pentanoic acid as calibrator, Barnes et al. (2014) and Kronstrand, Brinkhagen, Birath-Karlsson, Roman, & Josefsson (2014) presented sensitivity/specificity results of 92/98% and 87/82%, respectively. In total, 76 SC and metabolites were tested and of these 19 were classified as moderately to highly cross-reactive. Neither the HEIA nor ELISA assays showed cross-reactivity with the newer SC, such as UR-144 or XLR-11, or metabolites.

Many papers addresses the metabolism of different SC, as knowledge of the metabolites formed is crucial for the detection of the SC since the mother substances are usually not excreted in urine. In most of these papers, chromatographic methods based on GC–MS, LC–MS/MS, or LC–HR–MS, or combinations are utilized. In a few cases, volunteers had smoked or digested a SC and subsequent monitoring of urine allows the elucidation of different metabolites. More often, metabolite patterns are studied using mice models or in vitro experiments with either human liver microsomes or human hepatocytes. Several reports are also based on real samples from

Examples of quantitative methods for synthetic cannabinoids in serum or blood with analytical technique, sample amount, type of sample preparation and method characteristics.
[a]Qualitative; [b]g; [c]ng/g ; S, serum; B, blood

single cases, or more routine analyses. Several examples can be found in the mini-review by ElSohly, Gul, Wanas, & Radwan (2014). The formation of a large number of metabolites is a common finding, with the metabolic pathways usually involving hydroxylation and carboxylation, followed by glucuronidation.

Examples of quantitative methods with components, limits of quantitation and linear range are given in Table 101.3. In all these methods, urine samples are either chemically or enzymatically hydrolyzed previous to analysis, as the SC are known to form glucuronidated metabolites in urine. The predominant sample preparation methods used were LLE and SPE, with the exception of Moran et al. (2011) who diluted the urine samples with methanol and Yanes and Lovett (2012) who used a salting out technique (SALLE). For GC–MS methods, derivatization might be necessary before analysis (Emerson, Durham, Gidden, & Lay, 2013).

With the increasing number of synthetic cannabinoids on the market, urine methods are getting extensive; the LC–MS/MS method presented by Scheidweiler and Huestis (2014), targeting 53 compounds, is perhaps the most comprehensive quantitative urine SC method to-date. LC–HR–MS screening methods, such as presented by Kronstrand et al. (2014) and Sundström et al. (2013) are becoming more common, as they are able to screen for a large number of substances, but these methods are usually more qualitative than quantitative.

Other Matrixes

As with serum or blood the synthetic cannabinoid parent compounds can be found in oral fluid (Coulter et al., 2011), although in very low concentrations, making it an interesting medium for noninvasive screening of synthetic cannabinoids. Chapter 103 is dedicated to cannabinoids and oral fluid.

Hair is another matrix where the determination of parent drugs usually represents the target analyte (Salomone, Luciano, Di Corcia, Gerace, & Vincenti, 2014). Compounds are incorporated into hair from the blood stream or from sweat, and in some instances by external contamination (Auwärter, Wohlfarth, Traber, Thieme, & Weinmann, 2010). In addition hair analysis allows for retrospective analysis

Examples of quantitative methods for synthetic cannabinoids/metabolites in urine with analytical technique, sample amount, type of sample preparation, and method characteristics.

of compounds. This can be very beneficial for epidemiological studies, as the synthetic cannabinoids might appear and disappear from the market before the analytical laboratories are ready to analyze them.

Salomone et al. (2012) included five synthetic cannabinoids in a UHPLC–MS/MS method for analysis of THC, cannabidiol (CBD) and cannabinol (CBN) (Salomone, Gerace, D'Urso, Di Corcia, & Vincenti, 2012). The hair (50 mg) was washed with dichloromethane, digested by sodium hydroxide (NaOH), and extracted with *n*-hexane/ethylacetate 90: 10 (v/v). Quantitation limits (LOQ) ranged from 0.07 pg/mg for JWH-200 up to 18 pg/mg for CBD. Analysis of 179 real samples collected from cannabis consumers revealed 14 synthetic cannabinoid positive samples. Concentrations ranged from 0.60–70.5 pg/mg (Jwh-018), 0.50–413.3 pg/mg (JWH-073) and 1.50–729.4 pg/mg (JWH-250). Analysis of 179 real samples collected from cannabis consumers revealed 14 synthetic cannabinoid positive samples. The authors compared the concentrations with the internationally accepted cut-off for THC of 50 pg/mg, and found 6 of the 14 samples above this tentative limit. No such limit has however been set for synthetic cannabinoids, and thus further experience is needed to divide between chronic and occasional use. The same authors (Salomone et al., 2014) later expanded their method to 23 synthetic cannabinoids and reduced the amount of hair to 10 mg. The reported LOQ values varied between 0.7 and 4.3 pg/mg, except for HU-201 (80 pg/mg). The need for low detection limits is likewise illustrated in the paper by Gottardo et al. (Gottardo et al., 2014) reporting concentrations from 0.1 to 1.3 ng/mg in 100 mg hair.

While hair often is digested enzymatically or by use of NaOH for THC analysis, other compounds are often extracted from hair by incubation with buffers or organic solvents. A method for the analysis of 22 synthetic cannabinoids in hair presented by Hutter, Kneisel, Auwarter, & Neukamm (2012b), extracted the synthetic cannabinoids by incubation with ethanol, after washing with water, acetone, and petroleum ether. Concentrations in eight patient hair samples were reported to range from below 1 pg/mg to more than 1000 pg/mg. As rather poor correlation was found between self-stated consumption and the corresponding concentrations in hair samples; incorporation of the drugs in head hair via side-stream smoke condensation was offered as a possible explanation.

CONCLUSIONS

Synthetic cannabinoids are increasingly important as drugs of abuse, and effects as inebriation, severe intoxication, and even death have been reported. Consequently, inclusion of synthetic cannabinoids in drug screening panels is very important. Analysis of seized products are important to discover novel compounds, but incorporation of these compounds into standard drug tests are difficult due to the continuous appearance of new substances, and often low concentration in biological media. Seized products are mainly analyzed by GC–MS or IR; in addition NMR, LC–MS, LC–UV and high resolution mass spectrometry can be useful. Standard drug screening assays for cannabis will not test positive for these compounds, as they are mainly not structurally related to natural cannabinoids. Some immunoassay kits for urine are on the market, but so far no kits covering all synthetic cannabinoids are available, and gas or liquid chromatography coupled with mass spectrometry are commonly used for screening. Standard sample preparation includes liquid–liquid extraction or solid phase extraction. To analyze urine the relevant metabolites must first be discovered by analysis of drug user urine or experiments with microsomes or hepatocytes, and high resolution mass spectrometry has become an important tool in the elucidation of the structure of the multiple metabolites usually formed. The technique is in addition increasingly being used for screening. Definite determination of ingested compounds can be difficult, as several compounds may give the same metabolites. An added complication when analyzing these substances are the fact that structural isomers may pose both analytical problems and problems with interpretation. Several multicomponent methods for blood/serum, urine, oral fluid, and hair have been published, and are continuously being extended to keep up with the ingenuity of clandestine laboratories and the apparently increasing demand for recreational drugs of abuse.

MINI-DICTIONARY

Gas chromatography Separates analytes by interaction between a gaseous mobile phase (usually helium or nitrogen) and a stationary phase which often is a liquid film impregnated on the walls of a capillary column.

Immunoassay Screening technique based on the reaction between an antibody and an antigen. In immunoassay drug screenings the detection is usually not specific, but based on group analysis of, for example, opiates.

Liquid chromatography Separates analytes by interaction between a mobile liquid phase and a stationary solid phase.

Mass spectrometry A mass spectrometer is a very sensitive and specific detector, analyzing ions based on their mass to charge ratio.

CHAPTER

102

On-Site Drug Testing for Cannabis

A.A. Fernández

Forensic Laboratory Institute of Legal Medicine of Catalonia, Barcelona, Spain

SUMMARY POINTS

- On-site devices have been developed to detect and analyse cannabis use in populations.
- On-site devices are based in immunoassays.
- Performance of the tests must be assessed based on sensitivity, specificity and accuracy of results.
- Immunoassay is only applicable and valid for drug screening. Confirmation of results are required to corroborate presence of drug.
- On-site devices testing for cannabis use fluids collected from a subject, such as urine, blood, or oral fluid.
- Use of on-site cannabis devices: roadside scenarios, workplaces, drug treatment centres, law enforcements, emergency departments, primary health care, schools and forensic autopsies.
- On-site drug testing for cannabis is useful to obtain results in a short period of time.

KEY FACTS OF ON-SITE DRUG TESTING FOR CANNABIS

- Cannabis is the most prevalent drug of abuse around the world.
- Cannabis is an illegal drug and addicted people consider it as not dangerous for their wealth.
- On-site devices were developed to detect cannabis and another drugs by a simple and rapid proof of immunoassay.
- When results are positive for the presence of the drug, it is necessary to confirm the results by a more exact analysis as the chromatography gas/mass or chromatography liquid/mass.
- Urine, blood and oral fluid are the main samples specimens collected from a subject to conduct a cannabis drug test.
- On-site tests for cannabis are useful to have rapid results in clinical settings, emergency departments, primary health care, driving under the influence of drugs scenarios, forensic autopsies and schools.
- Gas-Chromatography-Mass Spectrometry (GC/MS) and Liquid Chromatography-Mass Spectrometry (LC/MS) are analytical techniques used to separate, identify and quantify drugs and medicaments. These techniques use a gas or a liquid solvent to carry the substances to be analyzed. Both of them are confirmatory and specific techniques to identify substances in samples. Cannabis and other drugs may be confirmed by these methods after the screening tests provide positive results for the drug.
- National Institute on Drug Abuse (NIDA) is an institution providing all information on drug abuse and addiction detecting and responding to emerging drug abuse trends. NIDA supports research and training on causes and consequences of drug abuse, on prevention and treatment of drugs, relationship to mental illness, genetic and social mechanisms, as well as epidemiological aspects.

LIST OF ABBREVIATIONS

DRUID	Driving under the influence of drugs
GC-MS	Gas chromatography-mass spectrometry
LC-MS	Liquid chromatography-mass spectrometry
NIDA	National Institute on Drugs Abuse
ng/mL	Nanogram per millilitre
ROSITA	Roadside testing assessment
THC	Δ^9-Tetrahydrocannabinol
THC COOH	11-nor-9-carboxi-Δ^9-tetrahydrocannabinol

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00119-8

ON-SITE DRUG TESTING FOR CANNABIS

Rapid on-site drug tests or point-of-collection (POC) drug tests are used to obtain samples for the rapid detection of cannabis and other drugs of abuse by immunoassay both from living subjects and cadavers in the fields of toxicology, legal and forensic medicine, and clinical medicine. These tests use antibody and antigen complexes to measure the presence of a specific analyte in a sample by competitive binding to an antibody, between the toxic substance present in the sample, which acts as an antigen, and that same toxic substance/antigen, which forms a complex with its corresponding antibody. One of the two components of this complex is labeled for detection and quantification when it is liberated from the complex. Immunoassays are classified as competitive or noncompetitive by measuring technique and as homogeneous or heterogeneous depending on the medium in which the measurement is made (Repetto & Repetto, 2009). The use of immunoassays for initial screening of cannabis remains the most cost-effective and efficient tool to eliminate "negative specimens" and to "identify those that require further confirmation" (Substance Abuse & Mental Health Services Administration, 1994).

On-site drug tests feature easy-to-follow protocols and provide preliminary results immediately. Two samples are required to conduct these tests and the stability, chain of custody, and storage conditions of samples must be ensured since the results require confirmation testing. On-site testing devices have evolved with time. On-site urine tests are the oldest, and they range from the simple ones with visual urine test strips to the more complex ones that include automated readers. As of 1990, year in which the first oral fluid drug tests were marketed, the effectiveness of urine drug testing was questioned, since the confirmation of results showed that their sensitivity and specificity for the detection of cannabis and other drugs of abuse were low. However, with time, the new technologies have enabled the development of new kits with enhanced performance (George & Braithwaite, 1995). Subsequent comparative studies have shown that there were significant differences between results and between the detection limits and cutoff levels set by different manufacturers due to the lack of standard specifications (Langel et al., 2008). According to several comparative studies, in general, many tests are effective for detecting other drugs of abuse, but are not reliable for detecting cannabis (Walsh, Flegel, Crouch, Cangianelli, & Baudys, 2003).

DRUG DETECTION KITS

There is a wide variety of drug detection kits in the market and new versions are being released on an ongoing basis. Many of them are testing kits that include a sample collection device and an analyzer of test results. Other test kits feature visual interpretation of results only, without the analyzer providing results analysis. An independent evaluation of the sensitivity and specificity, the positive and negative predictive values, and the accuracy of the method used is of technical and scientific interest. However, this is rarely done. It requires confirmation by gas chromatography–mass spectrometry (GC/MS) or liquid chromatography–mass spectrometry (LC/MS) in order to identify false positive and false negative results, estimate the statistical parameters, evaluate test performance, and compare the findings with the data supplied by the manufacturer. Most controlled studies of the performance of on-site tests for cannabis and drugs of abuse do not reveal these data, they only provide the number of accurate results, and the false positive and false negative rates. The sample size in the published studies providing independent confirmation of results is not always large enough to provide adequate reliability, and to allow to extrapolate results and to determine sensitivity and specificity parameters.

MATRICES

The matrix of choice for cannabis on-site testing is urine, in which 11-*nor*-9-carboxy-Δ^9-tetrahydrocannabinol (THC—COOH) is detected as a metabolite of Δ^9-tetrahydrocannabinol (THC), which is the primary constituent of cannabis. The presence of THC—COOH in urine indicates recent use but does not determine whether an individual is under the effect of the drug. Cannabis is one of the most widely used illegal drugs, and its detection is important for the assessment of the prevalence of its use. It is known that chronic use increases cannabinoid detection time in urine. According to several studies in the forensic medicine literature, the advantages of urine testing for cannabis use are that urine collection is easier than blood sampling, and that it significantly decreases the number of unnecessary blood analyses (Raes & Verstraete, 2005). Blood is also used as a matrix for cannabis testing; however, it is less applicable to rapid screening because blood sampling is invasive.

The utility of oral fluid as a sample matrix for the detection of cannabis abuse is largely due to collection advantages, since it can be used in various settings and situations, such as roadside drug testing (Speedy et al., 2007; Quintela, Crouch, & Andrenyak, 2006). It is widely recognized as a non-invasive and tamper-resistant screening method, which can identify drug use as accurately as blood testing, given the high correlation between the two fluids. However, from a technical point of view, recovery of the sample from the collection device is a major problem, especially for lipophilic drugs such as cannabinoids, although several authors report 94.5

and 91.4% THC recovery from different devices (Speedy, Baldwin, Jowett, Gallina, & Jehanli, 2007).

Oral fluid testing has some disadvantages. For example, the volume of specimen collected may be too low for testing and for subsequent laboratory confirmation testing. Moreover, contamination of the sample by food, beverages, or other adulteration agents may pose additional problems to this analytical method. Smoked cannabis may cause contamination of the oral cavity, increasing concentrations and disrupting correlations with blood concentrations. THC is detected in oral fluid. It has been observed that plasma THC concentrations drop at 30 min postsmoking while oral fluid concentrations are much higher. Issues related to detection times for marijuana have prevented wide acceptance of oral fluid drug test devices. Detection of THC in oral fluid has been reported 34 h after administration of smoked cannabis 20–25 mg (Niedbala et al., 2001). Several experimental performance studies have focused on oral fluid/plasma cannabinoid ratios at different times and at various concentrations (r = 0.84) in groups of marijuana smokers, taking into account THC contamination of the oral cavity (Ramaekers et al., 2006). In addition, oral fluid test results may be influenced by exposure to second hand marijuana smoke, yielding a positive result. However, many studies have shown that positive passive cannabis exposure results are not statistically significant (Huestis & Cone, 2004).

In Europe, many efforts have been made to develop roadside drug testing devices for cannabis and other drugs of abuse. At the end of the 1990s, the European Union launched the Roadside Testing Assessment (ROSITA) project (López-Rivadulla, 2002), involving an extensive evaluation of nine commercial brands of on-site testing devices. The performance of six of the devices was modest, with a malfunction rate of 25%, the highest percentage being related to screening for cannabis use. The ROSITA-I assessment evaluated the sensitivity and specificity of the devices; some on-site urine tests showed sensitivity and specificity of over 90% and an accuracy rate in excess of 95% compared with reference methods; however, none had good overall results. Sensitivity values for cannabis screening ranged from 0% to 97%, and specificity from 70% to 100%. Belgian police officers reported that, in their opinion, the devices were unsuitable for cannabis (Laloup et al., 2006).

Cannabis drug testing is of great interest, and a broad range of studies has evaluated which testing devices and matrices are most effective for detecting drug-related impairment of driving ability. For roadside testing, oral fluid has been found to be more effective than urine in correlation between drug detection in oral fluid and serum and in driver impairment symptoms (Toennes, Kavert, Steinmeyer, & Moeller, 2005). Several European countries have addressed the issue of road safety and cannabis abuse detection. In another assessment, German police officers collected specimens of body fluids (blood, saliva/sweat, and urine) in cases of suspected driving under the influence of drugs of abuse. Roadside drug test results yielded a positive predictive value of 79%. In view of this, these tests were seen as effective drug use screening tools and as evidence for legal proceedings (Steinmeyer, Ohr, Maurer, & Moeller, 2001).

DETECTION LIMITS

In on-site drug screening, detection limits refer to the lowest amount of cannabis or other drugs of abuse in a sample that can be detected by a given test. They are set by the laboratory or the device manufacturer and there are significant differences between them. As a rule, the detection limit values used are those set by the National Institute on Drug Abuse (NIDA), and the screening cutoff level in the NIDA guidelines for THC is 50 ng/mL. In the ROSITA project, the SAMHSA guidelines recommend a cutoff level of 4 ng/mL and a confirmation cutoff level of 2 ng/mL for THC in oral fluid (Verstraete, 2005). An assessment of four drug-testing devices applying the SAMHSA cutoff level for THC reported that their performance was not satisfactory (Walsh et al., 2003). Table 102.1 shows the cutoff levels set by different device manufacturers.

TABLE 102.1 Cutoffs for Cannabis in Different Devices

Device	Cutoff (ng/mL)
Drugwipe II	30
Orallab (Varian)	100
Oralscreen drugmeter (Avitar)	250–500
Oral Fluid Drug Screen (Acon)	12
OralStat (AmericanBiomedic Corporation)	25
Oratec II (Branan Medical Corporation)	40
Cozart Rapiscan (Cozart Bioscience Ltd)	150
Salicheck (Bamburg Marrsh LLC)	12
Dräger Drug test (Orasure Technologies)	20
Multiline Twist (Acon Lab)	100
Oraline (Sun Biomedical)	4
Saliva Screen 5 (Ultimed Products)	2
Alere DDS V Test (Fig. 102.1)	25

Unpublished table: Data adapted from Raes and Verstraete (2005), ROSITA-2 Project. Cannabis cutoffs were assessed by the manufacturers of different devices. The matrix tested was oral fluid. A great variability was observed among the devices

ON-SITE URINE TESTING

Recent studies conducted in Germany evaluated the performance of screening tests for drugs of abuse in urine with a cutoff level of 10 ng/mL for THC—COOH showed that accuracy rates were high (Agius, Nadulski, & Moore, 2012). Urine samples were screened by CEDIA immunoassay. Average relative sensitivities and relative specificities were 99.7 and 98.4%, respectively for ELISA, higher than those for CEDIA (Agius, Nadulski, Kahl, & Dufaux, 2013). Moody and collaborators compared two on-site testing devices to discriminate urine samples for cannabinoids and other drugs of abuse. The respective accuracies in respect to confirmation results were 94.4 and 95% for cannabinoids (Moody, Fang, Andrenyak, Monti, & Jones, 2006). A field study was performed at two police agencies to evaluate the accuracy of five commercial on-site urine analysis drug-testing devices. For marijuana, the laboratory confirmation cutoff level was 4 ng/mL and all devices had ≤0.25% false-positive rates, which were slightly higher for other drugs. However, it was concluded that the devices were useful in DRUID investigations (Crouch, Hersch, Cook, Frank, & Walsh, 2002). Another study of several on-site drug-testing devices for the detection of drugs of abuse in urine specimens reported that all devices determined the presence of THC—COOH and that results differed upon confirmation at different cutoff levels (Peace, Tarnai, & Poklis, 2000). In addition, recent studies evaluated the effectiveness of several rapid urine-screening tests for detection of cannabis, other drugs of abuse, and psychoactive substances at the workplace in Italy. Positivity rates were lower than expected due to the application of Italian legislation for workplace drug testing (Rosso, 2013). Table 102.2 shows assessment results for several cannabis screening devices.

TABLE 102.2 Sensitivity and Specificity for Cannabis in Different On-Site Testing Devices

Devices	Sensitivity	Specificity
LUCIO-direct ELISA (Agius et al., 2012)	99.7	98.4
Triage Plus TCA CB1 panel of Drugs (Peace et al., 2000)	90.5	90.8
QuickScreen (Peace et al., 2000)	97.5	78.5
Syva Rapid d.a.u.5 and d.a.u 2 (Peace et al., 2000)	97.5	92.4
Rapid Drug Screen (Peace et al., 2000)	97.5	83.3
Drug Screen NAL (Musshoff, 2014)	93	39
Syva Rapid Test d.a-u 10 (Attema-de Jonge, 2012)	>93	>93
Triage TOX Drug (Attema-de Jonge, 2012)	>93	>93
Test Tcard 9 (Attema-de Jonge, 2012)	>88	>93

Table unpublished. Data adapted from different articles published in specialized journals. Table includes recent studies. The matrix tested was urine

ON-SITE ORAL FLUID TESTING

A large number of published evaluations of on-site oral fluid testing focus on roadside testing for drug driving. Many points-of-collection test (POCT) devices have been assessed although many of them are not available any more or have been modified to enhance performance (Bosker & Huestis, 2009). A comparison of results is difficult due to the fact that the experimental methods in current use in this field have not been validated. Devices with absorbing components may cause analyte absorption into the collection device and the percentage of analyte recovery is low. The recovery of the analyte being measured is, therefore, a very important parameter in the evaluation (Langel et al., 2008), since absorption may lead to false-negative results (Gallardo & Queiroz, 2008). This was not known when the first devices came out, so data sensitivity was low. Device manufacturers tried to eliminate the problem by eluting the sample with buffers, thereby reducing sample thickness. Moreover, they had to comply with regulatory requirements during product development in order to achieve marketing approval for the new medical device (Kadehjian, 2005; Biermann et al., 2004; Blencowe et al., 2011). An ineffective sample collection method or errors in the reading of results may produce biased results. Malfunctions have been reported in some devices at temperatures lower than 10°C, or due to excessive test duration, or to extremely low sample volume. In European countries such as Germany, Denmark, Finland, Norway, and Sweden, researchers have assessed the efficacy of oral fluid drug testing devices for roadside testing. The assessments revealed that 75% of the results were accurate, although testing for marijuana yielded more false-positive results and test sensitivity to cannabis was not satisfactory in eight of the devices (Biermann, Schwarze, Zedler, & Betz, 2004). Another roadside study of three oral fluid screening devices reported that the devices were able to detect about 70% of all cannabis users in a roadside setting and that one showed a sensitivity of 93% (Wille, Samyn, Ramírez-Fernández, De Boeck, & de Boeck, 2010). Table 102.3 shows the sensitivity and specificity values in some devices.

It is important to compare the results for cannabis with oral fluid drug testing devices versus other matrices, such as blood and urine, with variable confirmation test results. Tables 102.4 and 102.5 show comparative data for two devices from a study conducted in Wisconsin, and in Belgium within the ROSITA project.

TABLE 102.3 Sensitivity and Specificity for Cannabis in Oral Fluid in Different On-Site Devices

Devices	Sensitivity (%)	Specificity (%)
Cozart DDS 801 (Arroyo et al., 2013)	87	86
Drugwipe 5 (Wille et al., 2010)	71	50
Rapistat (Wille et al., 2010)	71	51
Draeger DrugTest 5000 test (Desrosiers et al., 2014)	86–90	75–77
Drugtest 5000 A	72	93
Drugtest 5000 B (Wille et al., 2010)	50	71
Druggertest 5000 (Vanstechelman, 2012)	81	>88
Cozart DDS (Vanstechelman, 2012)	23	>88

Dräger (ROSITA Spain, 2004)	58	89

Unpublished table. Data adapted from various articles published in specialized literature. Matrix tested: oral fluid. Old and new versions of devices in the market throughout the years up to this date. It is noteworthy that even very recent studies indicate that there are significant sensitivity and specificity differences for detection of cannabis in oral fluid

[a] Cutoff 50 ng/mL.

[b] Cutoff 1 ng/mL.

USE OF ON-SITE TESTING

A number of recent studies have focused on the evaluation of on-site testing devices in both urine and saliva matrices, indicating a growing interest in these devices

TABLE 102.4 Comparison of Results of On-Site Devices for Cannabis in Three Matrices

Oralab	Oral fluid (%)	Blood (%)	Urine (%)
Sensibility	37.5	50	25
Specificity	100	100	100
Accuracy	58	71	45
RapiScan	**Oral fluid (%)**	**Blood (%)**	**Urine (%)**
Sensibility	65	75	66
Specificity	70	73	90
Accuracy	67	74	74

Unpublished table. Data adapted from ROSITA-2 Project, Wisconsin (2004–2006). The devices were tested in different matrices, oral fluid, blood, and urine, and the results per matrix were compared

TABLE 102.5 Comparison of Results of On-Site Devices for Cannabis in Two Matrices

Dräger Drug Test	Oral fluid (%)	Plasma (%)
Sensibility	47	50
Specificity	95	84
Accuracy	53	59
Drugwipe	**Oral fluid (%)**	**Plasma (%)**
Sensibility	45	50
Specificity	96	84
Accuracy	51	56

Unpublished table. Data adapted from ROSITA-2 Project, Belgium (2004–2006). The devices were tested in oral fluid and plasma and the results per matrix were compared

and its relevance to road traffic (Strano-Rossi et al., 2011; Pehrsson et al., 2011) and roadside enforcement activities, in which the detection time for marijuana in oral fluid becomes a major issue (Desrosiers et al., 2014). Urine testing devices have been longer in the market and have shown many advantages in terms of sensitivity, accuracy, and precision. Reagent test strips allow on-site testing of urine specimens in all types of settings, and are useful for the monitoring and control of marijuana use in large populations; however, they are not commonly used for roadside testing. According to recent reports, the introduction of new derivatives of cannabis, the synthetic cannabinoids, has prompted researchers to study these substances for detection by immunoassay (Barnes et al., 2014). Oral fluid testing devices are far from being able to deliver optimal performance in terms of the parameters discussed in this chapter, but they hold promise and their use is discussed in many reports that provide valuable data on this technology and on their performance levels. Furthermore, on-site testing devices should detect cannabis at low cutoff levels to allow for optimal detection.

The main use for cannabis drug testing is in roadside driving-under-the-influence-of-drugs (DRUID) scenarios. In Spain, a project was launched using the Cozart DDS 801 on-site drug test device, which was evaluated in the Laboratory of Institute of Legal Medicine of Catalonia (Barcelona). The parameters to evaluate the efficacy of this device were determined through the analysis of 2180 oral fluid samples. The results showed that the device is effective for detecting cannabis use and its use has continued (Arroyo et al., 2013).

These devices can also be useful in other settings, although drug-testing policies may differ from country to country. Such settings are:

- workplace,
- primary health care/health care,
- emergency departments/psychiatric emergency departments,
- schools,
- home use (children-parents),
- antidoping,
- forensic autopsies.

Schools

Adolescents are more vulnerable to drug abuse than any other age group because their bodies and brains are not yet fully formed. In Spain, about 26.6% of students aged 14–18 years have used cannabis, according to the State Survey of Drug Use in High Schools 2012–2013, and the age of onset of drug use is 14.9 years. (Delegación del Gobierno, 2013). In the United States, some schools have implemented drug-testing programs based on the Federal Workplace Drug-Testing Programs, including random testing and reasonable suspicion/cause testing (NIDA, 2014). A study conducted in 2005 and supported by the NIDA estimated the proportion of US public schools districts that have high school grades in which random drug testing was conducted. Almost all districts randomly tested athletes and 65% randomly tested students engaged in extracurricular activities; however, 28% randomly tested all students (Ringwalt et al., 2008).

Emergency Departments

Marijuana was involved in 376,467 emergency department visits, amounting to 122.6 visits/100,000 people. The rates for emergency department visits were higher for males, especially among individuals aged 18–20 years (Substance Abuse & Mental Health Services Administration, 2010). About 25% of patients admitted to emergency departments are hidden drug users. On-site drug testing should be performed when there is a reasonable suspicion of drug use (Sanjurjo et al., 2005). On-site drug testing is also used in clinical settings. In

a study involving patients admitted to acute psychiatric treatment, initial evaluation included oral fluid collection with an on-site device and whole blood collection. The median oral fluid/blood drug concentration ratio for cannabis was 4.7 (Gjerde, Morland, Christophersen, & Bramness, 2010). Another study evaluated an on-site oral fluid test device in patients admitted to a psychiatric emergency unit; the accuracy was 94.7% for cannabis (Bagøien, Morken, Zahlsen, Aamo, & Spigset, 2009). The results of yet another study of a routine on-site testing in clinical psychiatric practice were 55% sensitivity and 82% specificity (Mordal, Holm, Morland, & Bramness, 2010).

Among patients with major trauma, initial screening of urine for drugs revealed a prevalence of 13% for cannabinoids (Carrigan, Field, Illingworth, Gaffney, & Hamer, 2000). A study was conducted in Spain to describe the prevalence of recent use of alcohol, medication, and illegal drugs in patients admitted to emergency departments for injuries due to external causes. The results revealed that the prevalence of cannabinoid use in trauma patients was 15.9% for males and 5.2% for females under 40 years of age. The prevalence of cannabinoid use according to cause of injury for male and female patients was found to be: violence 18.1/6.5%, falls 10.9/6.7%, domestic 13.8/0%, sport 8.8/10.5%, road traffic 21.9/4.5%, and workplace 7.9/6.7%, respectively (Pérez et al., 2009). A descriptive retrospective study of substance abuse in under-age patients admitted to emergency departments reported that the prevalence of cannabis use, determined by urine drug testing, was 13.5% in patients with a median age of 16.2 years, 33.8% of which had a psychiatric history. Most emergency admissions occurred during weekends, and the most frequent causes of admission were altered state of consciousness and agitation.

Primary Health Care

On-site testing for cannabis use can be an important clinical tool in patient management, if used correctly. The use of on-site testing devices contributes to medication safety by identifying the risk of overdose and serious drug interactions.

- Aids the physician in evaluating the efficacy of the therapeutic treatment plan, in chronic pain management, and in treatment of substance abuse disorders.
- Ensures medication safety, and reduces the risk of potentially harmful drug interactions during surgery or other medical procedures.
- Helps in the detection, evaluation, and diagnosis of substance abuse disorders, even though on-site testing has limited diagnostic value for such disorders.
- Detects cannabis drug use in pregnant women, or those who are planning to get pregnant.
- Identifies newborns at risk.
- Monitors abstinence, or identifies relapse in patients with known addiction to cannabis.
- Checks the validity of the information provided by the patient and/or relatives regarding the patient's drug use.

Forensic Autopsies

On-site testing devices are used in autopsy rooms for forensic toxicology. The results of an assessment of on-site testing for drugs of abuse in postmortem blood were substandard for the detection of cannabis (Moriya & Hashimoto, 1996). Although no cases of overdose deaths from cannabis have been reported (unlike other drugs of abuse, such as opioids and cocaine), it has been demonstrated that smoking marijuana is a rare trigger of acute myocardial infarction: "the risk of myocardial infarction onset was elevated 4.8 times over baseline (95% confidence interval, 2.4–9.5) in the 60 minutes after marijuana use, although the elevated risk rapidly decreased thereafter." (Mittleman, Lewis, Maclure, Sherwood, & Muller, 2001). In accordance with these findings, recent studies indicate that there is a link between cannabis consumption and myocardial infarction (Hartung, Kauferstein, Ritz-Timme, & Daldrup, 2014).

CONCLUSIONS

In conclusion, on-site testing for cannabis has been proved to be useful in a wide variety of settings, and there are many types of on-site tests available. As shown in this chapter, the most commonly used biological matrices for drug testing are: urine, blood, hair, oral fluid, sweat, and, recently, exhaled breath (Himes et al., 2013). Given that testing methods vary in terms of costs and reliability, the method of choice is that which best fits the needs of each setting.

MINI-DICTIONARY

Accuracy The closeness of a quantity of measurement to the true value.
Cut-off limit of detection Lowest detectable level permitted by the detection system used.
Gas chromatography–mass spectrometry (GC–MS) A technology by which many drugs and substances may be analyzed and identified according to a specific method using a gas to separate different compounds.
Immunoassay device A drug-testing device which incorporates a simple sample preparations step and an immunoassay.
Lipophilic To describe chemical entity which dissolves well is lipid-based system rather than aqueous-based systems as cannabis.
Liquid chromatography–mass spectrometry (LC–MS) Using a liquid to separate different compounds.

Matrix Different fluids collected from a subject as blood, urine, and oral fluid.
ng/mL Nanogram per millilitre, unit of concentration used to express the concentration of drug in a particular biological specimen. 1ng/mL is equivalent to 1 part per billion (ppb).
On-site test A test that can be conducted at the point of collection.
Oral fluid Fluid produced by glands in the mouth which contains a mixture of saliva, proteins, and other materials.
Sensitivity The ability of a particular test to determine a positive test result when it should. This is often expressed as a percentage—100% is completely sensitive, 0% is completely insensitive.
Specificity The ability of particular test to correctly determine a negative result when it should. This is often expressed as a percentage—100% is completely specific, 0% is completely unspecific.
THC COOH The principal metabolite of cannabinol without clinical effect.
THC Δ^9-Tetrahydrocannabinol The principal active substance of cannabis. It has clinical effects in the subject.

Cannabinoids in Oral Fluid: Identification and Interpretation of Analytical Results

C. Moore

Toxicology Research and Development, Immunalysis Corporation, Pomona, CA, United States

SUMMARY POINTS

- The detection of marijuana in biological specimens for numerous applications is of significant interest. Oral fluid is becomingly increasingly preferred as a test matrix because of its ease of collection, improved analytical techniques, and more scientifically-based interpretative value than urine. The window of drug detection represented by oral fluid for active drugs is relatively short; therefore it is an ideal specimen for collection in situations such as "for-cause" testing and traffic accident investigations.
- There are important variables surrounding oral fluid collection and analysis. Areas affecting the analytical result include: collection of a known volume of sample; characterization of the collection system; cannabinoid recovery and pad residence time; stability of cannabinoids in the transportation system, and storage conditions.
- The analysis of cannabinoids in oral fluid is a relatively routine procedure in most test facilities because of improved sensitivity of laboratory instrumentation. Problematic metabolites are 11-hydroxy-delta 9-tetrahydrocannabinol (11—OH—THC) and 11-nor-9-carboxy-delta 9-tetrahydrocannabinol (THC—COOH), present in such low concentration that their identification requires highly efficient extraction protocols, and sensitive analytical methods.
- Following marijuana smoking, which is still the most common route of cannabis self-administration, the active component tetrahydrocannabinol is predominantly detected in oral fluid. Other plant constituents such as cannabinol (CBN) and cannabidiol (CBD) are also present; other metabolites are detectable in low concentration.
- The interpretive value of oral fluid analysis depends on the reason for the test. Recent marijuana intake may be established by detection of tetrahydrocannabinol; historical use by metabolite identification at low detection levels. The addition of cannabinol and cannabidiol to the confirmation panel can assist in identifying recent smoking of marijuana; a closer look at cannabinoid ratios may give information on the use of medicinal preparations. The reliable interpretation of cannabinoid concentrations in oral fluid requires further research, but preliminary data is encouraging.

KEY FACTS OF ORAL FLUID ANALYSIS

- The main advantages of testing oral fluid for illicit or medicinal drugs include fast, easy, noninvasive, observed collection; as well as potential detection of an active compound, indicating recent intake.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00120-4
Copyright © 2017 Elsevier Inc. All rights reserved.

- The identification of recent drug use, particularly marijuana, is a key component in "for cause" testing or traffic accident investigations.
- The development of valid procedures for the quantification of drugs in oral fluid must include an awareness and understanding of the variability of collection devices, measurement of drug recovery from collection systems, evaluation of pad residence time (if appropriate), and determination of drug stability during transportation and storage.
- Potential positive results for marijuana (THC) as a result of passive exposure to cannabis may occur; the metabolite 11-nor-9-carboxy-delta 9-tetrahydrocannabinol (THC—COOH) should be included in analytical procedures to minimize this possibility.
- At this time, there is no definitive THC concentration in oral fluid that is indicative of causing impairment; however, research is continuing in this area.

LIST OF ABBREVIATIONS

11—OH—THC	11-Hydroxy-delta 9-tetrahydrocannabinol
CBD	Cannabidiol
CBN	Cannabinol
GC/MS	Gas chromatography–mass spectrometry
LC–MS/MS	Liquid chromatography with tandem mass spectrometry
OF	Oral fluid
THC	Δ^9-Tetrahydrocannabinol
THC—COOH	11-Nor-9-carboxy-delta 9-tetrahydrocannabinol

INTRODUCTION

Marijuana cultivation, transport, and use are common throughout the world. According to the World Health Organization (2014), about 147 million people, or 2.5% of the world population, consume cannabis. It used to be classified as the world's most prevalent illicit drug, but increasingly it is being legalized for medical and recreational use. While it remains largely illegal in most countries, many jurisdictions have decriminalized the possession of small quantities; however, laws on cultivation, transport, and sale are distinct from laws on possession and personal use.

Oral Fluid

The biochemical composition of saliva has been described (Schenkels, Veerman, & Nieuw Amerongen, 1995). Oral fluid (OF) is a combination of gingival crevicular fluid, and fluid from salivary parotid, submandibular, and sublingual glands. It consists predominantly of water (> 95%), proteins, electrolytes, mucin, enzymes, epithelial cells, cholesterol, and vitamins. Composition can vary with the time of day, diet, age, and artificial stimulation; a lack of saliva production which is often caused by drug use can result in issues with infection, swallowing, chewing and tooth decay. Oral fluid in healthy individuals is pH 6.5 (range 6.0–7.8); therefore drugs that have entered into the blood stream are more easily diffused into saliva, if they have basic properties rather than acidic; drugs such as amphetamine and cocaine accumulate well into oral fluid, while derivatives of carboxylic acids do not. As marijuana use becomes more socially acceptable throughout the world, its detection in biological specimens remains of high importance in areas of traffic and workplace safety, where recent use is suspected. In the 2007 National Roadside Survey (National Highway Traffic Safety Administration, 2010) randomly stopped drivers were tested for drug use using oral fluid as a sample matrix. Overall, 8.6% of the drivers were positive for tetrahydrocannabinol (THC), the active component in marijuana. The results showed that OF analysis provides data on drug use by drivers that is as least as reliable as blood, in terms of window of detection, which was collected simultaneously.

The convenience of oral fluid collection compared to other matrices is a distinct benefit. MacCall, Ritchie, & Sood (2013) studied patient preferences for drug testing collections. 85% of patients opted for OF rather than urine; 15% preferred to donate urine, citing a reluctance to try something new.

An observed collection makes it difficult to adulterate the specimen, and the identification of active drug reflects recent drug use, an advantage in "for cause" testing. Several publications have reviewed OF as a drug testing matrix (Drummer, 2006; Bosker & Huestis, 2009; Moore & Crouch, 2013) and discussed the current knowledge regarding cannabinoids in OF (Lee & Huestis, 2014).

COLLECTION DEVICES, MARIJUANA RECOVERY, AND DRUG STABILITY

Collection Devices

While saliva can be collected via expectoration (ie, "spitting"), the use of a device is preferred for hygienic reasons, as well as improved drug stability when buffers are included in the collection system. A significant variable in OF analysis is the collection device; it has been well documented that the method of collection affects

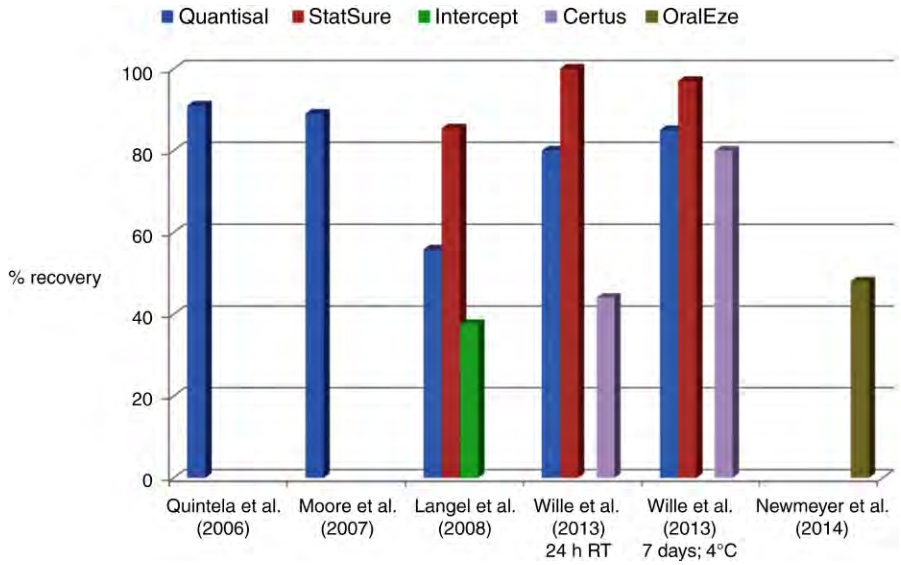

FIGURE 103.1 THC recovery from oral fluid collection devices. THC recovery from different commercially available OF collection devices is shown, based on data from peer-reviewed publications. Not all collection devices were evaluated by all authors.

the analytical result (Crouch, 2005; Drummer, 2008). The most effective and widely used devices have the following desirable characteristics:

- Collection pad (preferably with no added stimulants) and transportation buffer
- Examples include Quantisal, Omni-Sal, OralEze, Intercept, Certus
- Relatively fast, consistent collection
- Indication of adequate specimen volume
- Assessment of drug recovery from the collection pad under realistic conditions
- Documented stability of drugs during storage and transportation

THC Recovery

The adhesion of parent THC to many surfaces is a general concern in analytical techniques, therefore recovery assessment of THC within a collection system must be part of any validated assay development. Crouch, Day, & Baudys (2004) studied several collection devices in an attempt to determine whether oral fluid was suitable as an alternative to urine for workplace testing. The residence time of the pads in the transportation buffers in order to release drug into the liquid is of critical importance. As an example, the minimum residence time for the pad in the Quantisal system is 4 h; for Oral Eze ≥12 h are recommended. Quintela, Crouch, & Andrenyak (2006) reported high THC recovery for the Quantisal device; Langel et al. (2008) compared the recovery of several drugs, including THC, from nine different oral fluid collection devices. Some were simply unacceptable; but many of the currently commercially available devices were reported to have reasonable marijuana recovery. The authors acknowledge that the residence time for some of the pads was less than recommended by the manufacturers. More recently, Wille, Di Fazio, Ramirez-Fernandez, Kummer, & Samyn (2013) reported THC recovery from three devices under different storage conditions. Published recovery of THC from various devices by numerous authors is shown in Fig. 103.1. It should also be noted that there are considerable improvements with collection systems from most manufacturers so published recoveries may not be currently reflective of the efficiency of oral fluid THC recovery.

THC Stability

In contrast to other biological specimens, THC is relatively stable in oral fluid collection devices because of the composition of the transportation buffers. While fluorescent light and exposure to plastic surfaces will degrade THC, the overall stability particularly when refrigerated is acceptable (Moore et al., 2006a). More recently, Lee et al. (2012a) indicated the importance of device selection particularly when considering stability by stating: *"… because each collection device contains proprietary stabilizing buffers, cannabinoid stability in OF must be determined for each type of collection device, limiting generalization of results to other collection devices, and strongly supporting the need for additional stability studies. These data emphasize the importance of oral fluid collection device design."*

ANALYTICAL ISSUES

THC

Parent drugs are generally detected in higher concentration than metabolites in oral fluid (Allen, 2011). While the identification of THC in oral fluid has historically been considered difficult, recent improvements in analytical techniques have allowed its detection to become routine and there are numerous publications reporting its determination in oral fluid using immunoassay screening (Schwope, Milman, & Huestis, 2010; Moore & Crouch, 2013); confirmatory techniques using gas chromatography–mass spectrometry (GC/MS); liquid chromatography with tandem mass spectrometry (LC–MS/MS) or time of flight (TOF) detection (Bylda, Leinenbach, Thiele, Kobold, & Volmer, 2012; Lee, Chang, Lin, & Chang. 2012; Quintela, Andrenyak, Hoggan, & Crouch, 2007).

Immunoassays

Immunoassays have been developed for oral fluid targeting parent drugs because, as noted previously, they tend to be higher in concentration than metabolites. Immunoassay developments have also included improved sensitivity in homogeneous formats, to assist in laboratory throughput (Moore, 2011); but they also suffer the same drawbacks as immunoassays for other specimen types, such as the potential for false positive results caused by similarly structured compounds; or false negative results caused by inadequate sensitivity or interference.

Mass Spectrometry (MS)

MS-based detection systems are used when specific identification or quantitation of a drug/metabolite is needed. Disadvantages are mainly associated with ion suppression, or isobaric compounds having identical transitions, similar to those encountered with other matrices (Vogeser & Seger, 2010; Tuyay, Coulter, Rodrigues, & Moore, 2012). As long as drugs are efficiently extracted from transportation buffers to avoid injection of stabilizers and surfactants directly into instruments, then many issues can be avoided.

Other Cannabinoids

In addition to the parent compound, there are other naturally occurring cannabinoids, such as cannabidiol (CBD), cannabinol (CBN) and the precursor 2-carboxy-tetrahydrocannabinol that may be detected in oral fluid (Moore, Rana, & Coulter, 2007a). The metabolites 11-hydroxy-delta 9-tetrahydrocannabinol (11—OH—THC) and 11-nor-9-carboxy-delta 9-tetrahydrocannabinol (THC—COOH) have also been detected in very low concentration. In order to maximize the detection of THC—COOH, a hydrolysis procedure may be incorporated into the analysis, because THC—COOH has been found to be conjugated in oral fluid (Day, Kuntz, Feldman, & Presley, 2006; Moore, Coulter, Rana, Vincent, & Soares, 2006; Moore et al., 2007b). Various LC–MS/MS procedures which achieve the required sensitivity for the detection of THC—COOH in oral fluid have recently been published (He, Kozak, & Nimkar, 2012; Coulter, Garnier, & Moore, 2012; Scheidweiler, Himes, Chen, Liu, & Huestis, 2013).

There are fewer reports of 11—OH—THC being identified in oral fluid, but the detection of THC—COOH is a key issue in the potential differentiation between passive exposure to marijuana smoke and actual cannabis intake. THC—COOH is not present in cannabis smoke and in recent research was not measurable in OF collected from subjects passively exposed to cannabis in a Dutch "coffee-shop." THC was detectable in all specimens taken 3 h after realistic exposure to marijuana smoke (Moore et al., 2011).

DISPOSITION OF CANNABINOIDS IN ORAL FLUID

Several studies have attempted to characterize the disposition of THC and its metabolites in oral fluid, and to understand the relationship between THC concentrations in OF and plasma/serum. THC is deposited in the buccal cavity after smoking, and contamination may result in high OF concentrations, with C_{max} reported in most publications 0.25–0.5 h after smoking. Cannabinoid measurement in both blood and OF following controlled dosing has given some insight into OF:plasma ratios, although inter-subject variability is widely documented. Cannabis can be administered in several ways – most commonly smoking, but oral (Marinol) and oromucosal formulations (Sativex) are also available. There is a great deal of interest in determining a meaningful testing concentration for THC in oral fluid that correlates with blood THC and/or impairment; however, to date, such a concentration has not been well established. As this would be particularly useful in cases of driving under the influence of drugs, many projects have focused on traffic safety. Van der Linden, Silverans, & Verstraete (2014) noted that self-reported cannabis use is largely underestimated by drivers and, therefore the analysis of biological specimens is necessary. Gjerde, Langel, Favretto, & Verstraete (2014) recently reported the estimation of equivalent cutoff concentrations in OF and blood for 12 commonly used drugs, including THC in oral fluid, collected with the Statsure device. Multiplying the cutoff thresholds in

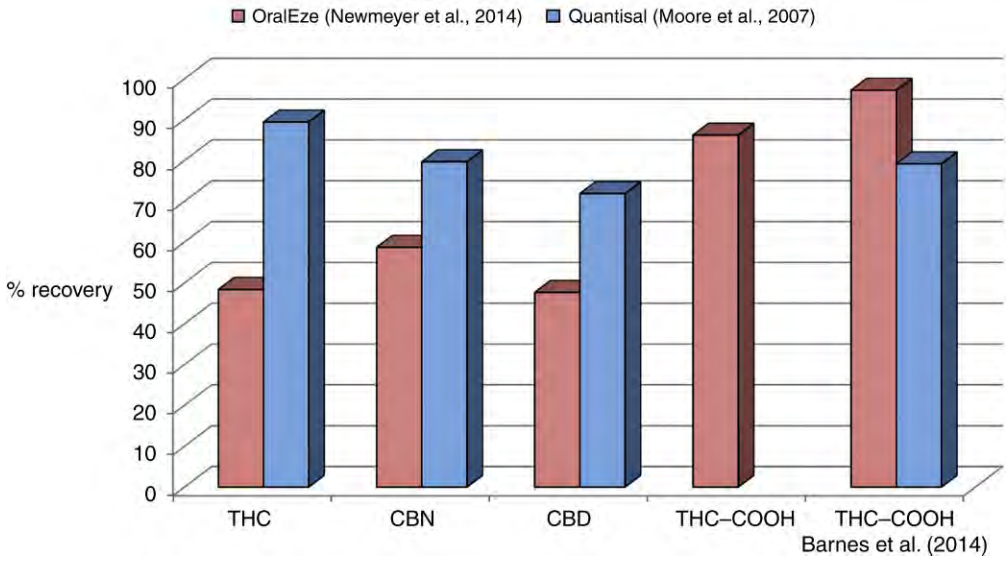

FIGURE 103.2 Cannabinoid recovery from oral fluid collection devices. Cannabinoid recovery from two different OF collection devices is shown based on data from peer-reviewed publications. Moore et al. (2007) did not include recovery data for THC—COOH; Barnes et al. (2014) only reported on THC—COOH.

blood with the average and median OF:blood ratios to estimate equivalent cutoffs in oral fluid were investigated. Using a THC concentration of 1 ng/mL in blood, an equivalent cutoff concentration in OF was estimated to be 44 ng/mL (range 27–90 ng/mL).

Marijuana Smoking

Kauert, Ramaekers, Schnieder, Moeller, & Toennes (2007) collected blood and oral fluid samples for 6 h from 10 participants, following low and high dosage cigarette smoking. Mean oral fluid THC concentrations in specimens collected after 15 min were 900 ng/mL (±589; median 797) and 1041 ng/mL (± 652; median 894), respectively. The OF:serum ratios were extremely high: 46 ± 27 (low dosage) and 36 ± 20 (high dosage); the authors concluded that kinetics of THC in oral fluid are not yet satisfactorily understood.

In subjects admitted to a psychiatric facility, Gjerde, Mordal, Christophersen, Bramness, & Morland (2010) reported a median OF:blood ratio for THC of 4.7. In a later publication, some of the same authors reported a median OF:blood ratio of 14, based on suspected drug users in Europe (Langel et al., 2014); the oral fluid was taken with a different collection device.

Anizan et al. (2013) studied chronic and occasional marijuana smokers. They compared THC and metabolites in OF collected with the Statsure device from 19 h before smoking a marijuana cigarette, to 30 h afterward. No significant differences between the two groups (chronic and occasional smokers) were noted. All OF specimens were THC-positive up to 13.5 h after smoking; CBD was detected up to 4 h after smoking; CBN up to 8 h. THC—COOH not surprisingly provided a longer detection window (>30 h) than THC in all frequent smokers.

Fabritius et al. (2013) collected both whole blood and OF from subjects before and up to 3.5 h after smoking marijuana. OF specimens were analyzed for THC, THC—COOH, CBN, and 2-carboxy-tetrahydrocannabinol. Measured THC concentrations in frequent smokers ranged from 19 to 3170 ng/mL, and in occasional smokers from 367 to 3110 ng/mL, with the highest levels being reached within 30 min of intake.

In a controlled study, Newmeyer et al. (2014) reported cannabinoid disposition in OF after cannabis smoking in frequent and occasional smokers, using saliva collected with the OralEze device. Specimens were analyzed for THC, 11—OH—THC, THC—COOH, CBN, and CBD. While the recovery of THC from collection devices is often reported (Fig. 103.1), efficiency for the other cannabinoids is not always included in research papers. The recovery of CBD and CBN from OralEze or Quantisal devices has only been reported in two publications (Newmeyer et al., 2014; Moore et al., 2007b, respectively); however, a recent paper (Barnes, Scheidweiler, & Huestis, 2014) compared the recovery of THC-COOH from two different devices (Fig. 103.2). Newmeyer et al. (2014) determined that frequent cannabis smokers had significantly higher concentrations of THC—COOH in their OF, compared to occasional smokers, and were positive for longer periods after smoking. The concentration of cannabinoids in OF collected from frequent marijuana smokers is shown in Table 103.1; the median concentration of THC, CBD, and CBN in OF taken from frequent

TABLE 103.1 Concentration of Cannabinoids in Oral Fluid From Frequent Marijuana Smokers

	Median (range) after marijuana smoking								
	THC (ng/mL)		**CBN (ng/mL)**		**CBD (ng/mL)**		**THC—COOH (pg/mL)**		**OF device**
Time after smoking	0.25 h	0.5 h	0.25 h	0.5 h	0.25 h	0.5 h	0.25 h	0.5 h	
Anizan et al. (2013) (n = 14)		517 (189–6508)		37 (16–476)		21 (4.5–255)		126 (59–430)	StatSure
Milman et al. (2012) (n = 9)	2629 (265–22,370)	527 (311–1524)	230 (0–1964)	40 (5.8–45)	121 (8.8–1000)	22 (3.6–49)	148 (0–468)	82 (0–157)	None
Fabritius et al. (2013) (n = 23)		636 (19–3170)		81 (6–310)				300 (100–2400)	Quantisal
Kauert et al. (2007) (n = 10)	894 (247–>2500)								Intercept
Newmeyer et al. (2014) (n = 14)		803 (135–4146)		32 (3.3–284)		14.8 (1.4–162)		168 (70–1107)	OralEze

The median reported range of cannabinoid concentrations in OF collected from frequent marijuana smokers at different time points is shown; not all researchers measured all cannabinoids.

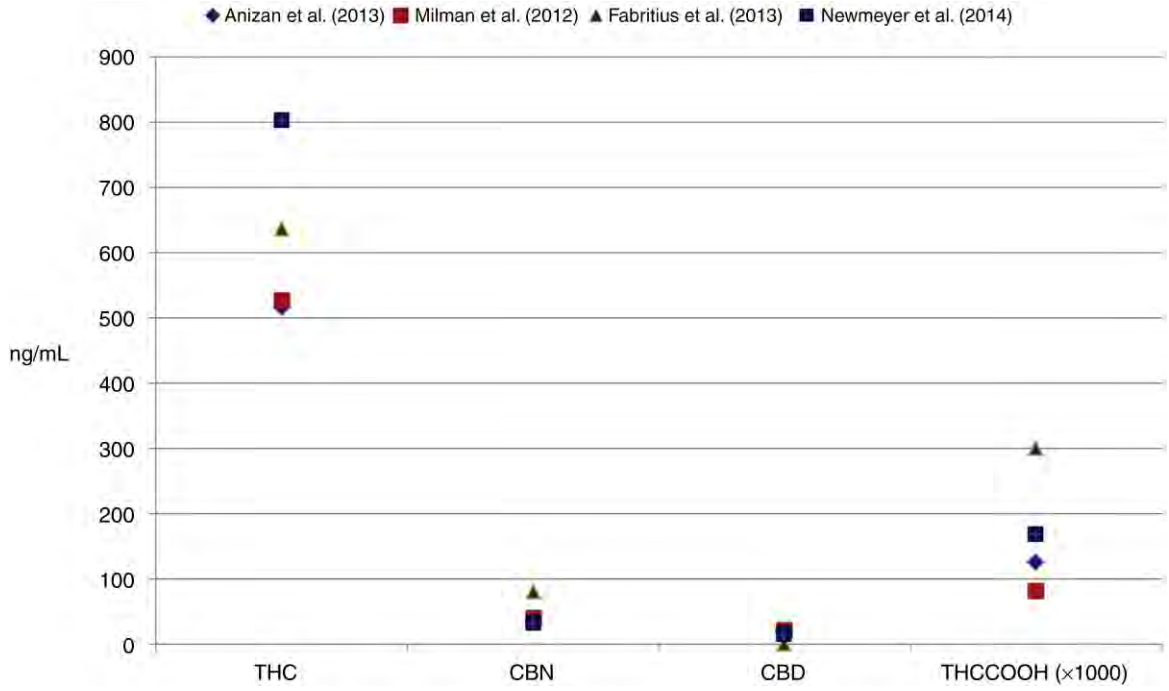

FIGURE 103.3 Median concentration of cannabinoids in OF from frequent marijuana smokers. Median concentrations of THC, CBD, and CBN in OF specimens taken from frequent marijuana smokers 30 min after the end of smoking sessions. Results published by different researchers are shown; the concentrations are remarkably similar.

marijuana smokers 30 min after the end of a smoking session has been reported by different research groups. While the range of concentrations was wide, the medians were remarkably similar (Fig. 103.3).

Smoking and Oral Administration

Lee et al. (2013a) reported OF:plasma ratios following both controlled oral THC administration and smoked cannabis in eleven chronic cannabis smokers. OF and plasma specimens were analyzed for THC, 11—OH—THC, THC—COOH, CBN, and CBD. Following cannabis smoking, the OF:plasma THC ratios extended over a wide range (median, 6.1; range, 0.2–348.5), likely due to oral contamination from the smoke. As the oral contamination dissipated over time, the median (2.1) and range (0.1–20.7) OF:plasma ratios decreased.

Milman, Schwope, Gorelick, & Huestis (2012) measured THC and metabolites in expectorated OF, following controlled cannabis smoking (n = 10). THC (>0.25 ng/mL) was detected in 95.2% of the OF samples; THC—COOH (> 5 pg/mL) was present in 94.7%; CBN (> 1 ng/mL) in 62.3%; CBD (> 0.25 ng/mL) in 69.3%; and 11—OH—THC (>0.25 ng/mL) in 2.9%. No information on plasma concentrations was given.

The consensus from these various studies is that there is a wide variation in THC concentrations and in OF:blood ratios following marijuana smoking.

Oral Administration

Oral administration shows a somewhat different disposition of cannabinoids in oral fluid. Over 9 days, Milman et al. (2010) administered 20 mg doses of oral THC to 10 participants reporting daily cannabis smoking, and cannabis use within 24 h of entering the study. OF samples (n = 440) were collected with Quantisal devices before, during, and after the dosing schedule. THC concentrations in OF actually decreased and reflected previously smoked cannabis, rather than orally administered Marinol. In contrast, the metabolite THC—COOH was present in 98.3% of specimens collected on days 2–7. CBD and CBN were in less than 2% of specimens; 11—OH—THC was not identified. Expectorated OF specimens gave similar results (Milman et al., 2011a).

The same research group of Milman et al. (2011b) collected OF and plasma samples from 10 daily cannabis smokers who were given synthetic THC in oral dosage form (dronabinol, Marinol) for 8 days. While the concentration of THC in plasma increased throughout daily dosing, the OF THC concentration generally decreased. THC—COOH concentrations increased in both matrices. The authors concluded that the time courses in OF and plasma were different, oral fluid monitoring did not reliably detect oral marijuana intake, and there was considerable interindividual variation.

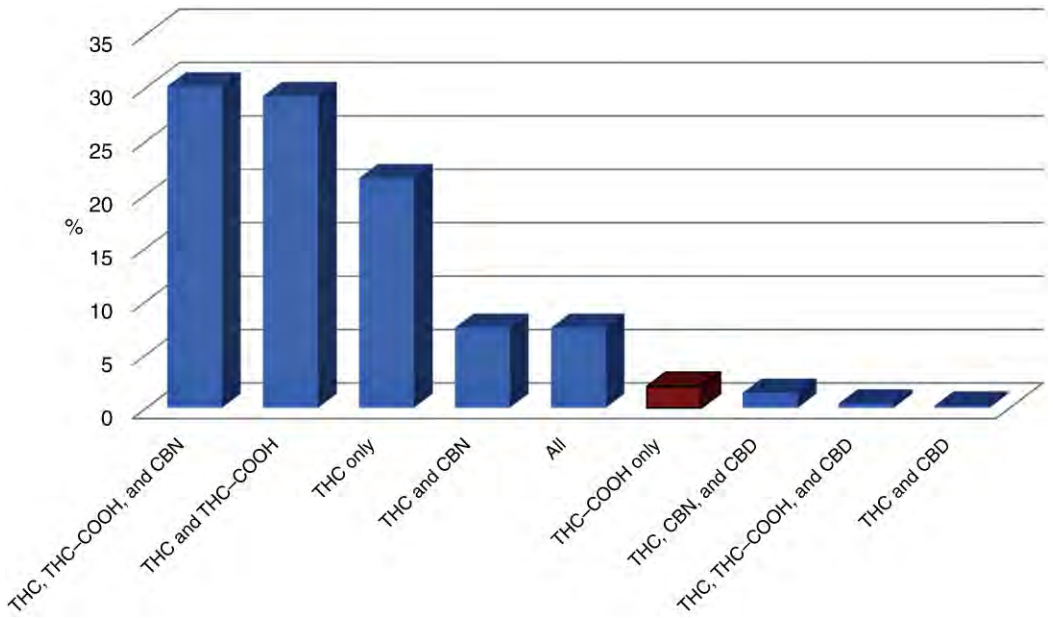

FIGURE 103.4 **Cannabinoid composition in marijuana positive oral fluid samples.** A breakdown of the composition of THC, THC—COOH, CBD, and CBN in oral fluid specimens positive for marijuana is depicted. 98% of samples contained the parent, active drug THC; only 2% showed the presence of the metabolite THC—COOH alone.

INTERPRETATION OF RESULTS

Variability in THC oral fluid concentrations especially after recent smoking can skew the data, making interpretation of concentrations problematic. The window of detection for marijuana intake depends on the route of administration, and the sensitivity of the analytical procedure. Lee et al. (2011) discussed the use of seven different cutoffs that, when applied, would give insight into the last use of marijuana. 28 frequent cannabis smokers were recruited and resided on a closed ward for approximately 30 days. Oral fluid specimens were collected periodically throughout the research period; the specimens were analyzed for THC, THC—COOH, CBD, and CBN. From a subset of 21 subjects, THC was detected for 24 h in the oral fluid of 9 participants (42%); for 48 h in 5 subjects (24%); and in no participants after 72 h. CBD and CBN were detected only at admission. However, THC—COOH in some cases was detectable for as long as 29 days (median 13 days). Correlation between THC and THC—COOH levels improved over time, as biological equilibrium likely occurred. In the remaining seven subjects, two were completely negative; one was positive at 48 h, but not at 24 h. One was positive at admission and on day 4, but not in between; others were negative on admission, and then positive several days later—data which are not easily explained in a closed monitored ward situation—a drawback acknowledged by the researchers. However, the concept of using different cutoff criteria to interpret oral fluid drug concentrations has some merit, and can be applied to different test scenarios:

Recent Use

For situations in which marijuana use or exposure is required to be recent (eg, driving incidents, "for-cause" testing), Lee et al. (2011) concluded that four of their seven studied cutoffs decreased the window of detection, thereby increasing the identification of recent smoking. The four criteria suggested were:

1. THC ≥ 2 ng/mL, and THC—COOH ≥ 20 pg/mL
2. THC—COOH (pg):THC (ng) ratio ≤ 4
3. THC ≥ 2 ng/mL, and CBD ≥ 0.5 g/mL
4. THC ≥ 2 ng/mL, and CBN ≥ 1 ng/mL

THC ≥ 1 ng/mL, plus CBD ≥ 1 ng/mL or CBN ≥ 1 ng/mL suggests cannabis intake within the previous 13.5 h (Anizan et al., 2013). CBN and/or CBD indicates recent use as these dissipate from oral fluid very quickly (<8 h).

Intuitively, a higher THC concentration indicates more recent drug exposure; therefore adoption of a specific cutoff concentration relating to cannabis intake within the last 2–3 h would be helpful for driving situations. Use within 8 h is arguably not impairing in individuals who have developed tolerance to the effects of marijuana.

TABLE 103.2 Median cannabinoid ratios in oral fluid from Sativex users and drivers

	CBD:THC	CBN:THC
Specimens collected after Sativex administration (Lee et al., 2013b)	0.82–1.34	0.04–0.06
Specimens from drivers involved in a research study (unpublished data)	0.014 (0.002–0.815)	0.039 (0.003–1.00)

A potential ratio of CBD:THC was established by Lee et al. (2013b) to differentiate Sativex patients from marijuana smokers. Based on the application of that ratio to CBD and THC concentrations detected in OF from research study specimens, none of the drivers would be considered Sativex users

Proof of Use

For applications where the proof of actual marijuana intake is required, as opposed to potential environmental exposure (workplace testing; child custody, etc.), the detection of the metabolite THC—COOH is advocated.

Historical Use

The lower the cutoff concentration the longer the window of detection of a drug, therefore historical use may be indicated if lower limits of quantitation are used analytically. The presence of THC—COOH in oral fluid from chronic users during abstinence has been reported for up to 29 days (median 13 days).

Medicinal Use

Marinol and Sativex are legal formulations of marijuana. Researchers have shown that THC does not accumulate well into oral fluid, after oral THC administration, but THC—COOH concentrations increase. Sativex is a cannabinoid medicine for the treatment of spasticity due to multiple sclerosis, and it is legally approved for use in over 25 countries. It was recently granted "Fast Track" designation by the US Food and Drug Administration (FDA) for the treatment of pain in patients with advanced cancer. The active compounds in Sativex are THC and CBD, and it is administered as an oromucosal spray. The possibility of differentiating the use of prescription Sativex from illicit marijuana smoking by measuring the ratio of CBD to THC in oral fluid has been addressed by two research groups:

1. Molnar, Fu, Lewis, Allsop, & Copeland (2014) analyzed oral fluid collected from ten participants, following high or low doses of Sativex. Results showed high concentrations of THC (5,356–15,468 ng/mL) and CBD (3,826–17,233 ng/mL) in the oral fluid up to 20 min after dosing. The oral fluid remained positive for THC and CBD for 2 h after the Sativex dose was given. CBN was also detected in the oral fluid of participants.
2. Lee et al. (2013b) characterized cannabinoid disposition in oral fluid following the administration of dronabinol (Marinol) or Sativex in low and high dosage forms. Following oral administration, CBD and CBN were rarely detected, and the THC concentration declined; in contrast following Sativex intake, THC, CBD, and CBN all increased with maximum concentrations 15–60 min after administration. The median CBD:THC ratio was 0.82–1.34; median CBN:THC ratio was 0.04–0.06. The authors reported that lack of measurable THC, CBD, and CBN following oral THC administration and high CBD:THC ratios after Sativex use can distinguish the mode of intake from marijuana smoking.

A retrospective study was performed on a subset of marijuana positive specimens collected from drivers involved in a research study (unpublished data). THC (>1 ng/mL) was detected in 97.9% of the oral fluid samples; THC-COOH (>20 pg/mL) was present in 69.3%; CBN (>0.2 ng/mL) in 46.6%; and CBD (>1 ng/mL) in only 9.5% of the samples (Fig. 103.4). An analytical confirmatory procedure detecting THC and THC—COOH would have confirmed all the specimens; however, the information provided by the CBD and CBN concentrations in proportion to the THC appears to have interpretive value (Table 103.2).

While the CBN:THC ratio was not markedly different between the two groups, the CBD: ratio in oral fluid from drivers was 0.014 (0.002–0.815; n = 52), compared to 0.82–1.34 (as described by Lee et al., 2013b). CBN and CBD are present to varying degrees in naturally occurring marijuana, so their presence in oral fluid is likely after recently smoking cannabis. If the median ratio of CBD:THC in Sativex users is 0.82–1.34, then none of the drivers was likely to be a Sativex user, as the concentration of CBD in the oral fluid is either zero (90.5%) or far lower than would be expected from use of a 1:1 CBD:THC (Sativex) medicinal preparation. Further, the median THC—COOH (pg) to THC (ng) ratio in the drivers was 4, implying that 50% of the drivers had smoked marijuana recently (Lee et al., 2011).

MINI-DICTIONARY

Cannabinoids Cannabinoids are naturally occurring substances which are found in the plant *Cannabis Sativa*. Δ^9-Tetrahydrocannabinol (THC) is primarily responsible for the psychoactive effects of cannabis; other cannabinoids within the plant are thought to moderate its effects.

Immunoassays Immunoassays are generally employed as screening techniques within a laboratory for the analysis of compounds in biological specimens. They tend to be used as an inexpensive first stage of analysis to identify samples that do not contain the drug of interest (negative specimens). Samples that are presumptively positive using the immunoassay should then be confirmed using a more specific, usually quantitative technique, such as mass spectrometry.

Mass spectrometry Mass spectrometers are complex, relatively expensive laboratory instruments, used for the detection of compounds in biological extracts, generally following separation through a gas or liquid chromatographic technique. Mass spectral detection methods are used as quantitative measures for drugs in biological samples, and are more specific than immunoassay techniques.

Oral fluid "Oral fluid" is the term used for the clear, viscous fluid predominantly excreted from salivary parotid, submaxillary, and sublingual glands. While the amount of saliva produced by an individual can vary, in healthy adults the reported volume is between 0.75 and 1.5 L per day. Drugs can be detected in oral fluid through buccal contamination or via diffusion from blood depending upon the chemical properties of the compound.

FINANCIAL DISCLOSURES

Christine Moore is employed by Immunalysis Corporation that manufactures the Quantisal oral fluid collection device and immunoassay reagents for oral fluid analysis.

CHAPTER

104

Cannabinoids in Exhaled Breath

O. Beck

Department of Laboratory Medicine, Section of Clinical Pharmacology, Karolinska Institutet, Stockholm, Sweden

SUMMARY POINTS

- Tetrahydrocannabinol (THC) is present in exhaled breath for a short time after smoking cannabis.
- THC is the principal cannabinoid present in exhaled breath.
- Nonvolatile compounds exit lung as part of aerosol particles.
- The aerosol particles are formed from the airway lining fluid during normal breathing.
- The aerosol particles in exhaled breath can be sampled by a simple procedure.
- Analytical investigations must be done in a laboratory using sophisticated instrument.
- Exhaled breath is a specimen that can be used for drug testing.

KEY FACTS OF BREATH DRUG TESTING

- Nonvolatile substances exit lung as part of aerosol particles.
- Cannabis, as well as other drugs of abuse, contaminates the airway system following exposure.
- Following cannabis exposure tetrahydrocannabinol is present in the exhaled particles.
- Technology exists to collect a specimen of the exhaled particles.
- The collection of an exhaled breath specimen is considered as noninvasive.
- Methodology exists to examine the exhaled particles for drug content.

LIST OF ABBREVIATIONS

CBN	Cannabinol
LC	Liquid chromatography
LC-MS/MS	Liquid chromatography-tandem mass spectrometry
MS	Mass spectrometry
THC	Tetrahydrocannabinol
THCCOOH	Tetrahydrocannabinol carboxylic acid

INTRODUCTION

The idea that cannabinoids can be present in exhaled breath is very obvious since cannabis is administered by inhalation of smoke. The consequence of cannabis smoking is that lung tissue becomes heavily contaminated with cannabinoids from the inhaled smoke. It is therefore likely that the remains of this smoke will be part of the exhaled breath for at least some time. However, one complicating circumstance for this idea is that once the cannabinoids become deposited in the lung, it is unlikely that they will reenter the gas phase again. Support of this conception is the experience from bioanalytical work that shows tetrahydrocannabinol (THC) extracts can be dried by blowing with hot nitrogen, without any significant loss of THC.

The first indication that THC is present in exhaled breath is from the study of Manolis, McBurney, & Bobbie (1983) who were able to detect THC for 10–12 min following termination of the smoking session. After this work was published in 1983, no study has been reported on this subject for any abused drug until amphetamine was more recently reported to be present in exhaled breath after recovery from intoxication (Beck, Leine, Palmskog, & Franck, 2010).

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00121-6

This new observation has triggered renewed interest in exhaled breath as a possible specimen for drugs of abuse testing and for toxicology investigations in general (Beck, 2013). As detection of cannabis use is a major objective of drug testing, a series of studies have now examined the detectability of cannabinoids in exhaled breath.

MANOLIS STUDY FROM 1983

Manolis et al. (1983) studied the presence of THC, 11-hydroxy-THC, and THC carboxylic acid (THC-COOH) in exhaled breath, as part of a larger trial aimed at documenting effects from cannabis smoking on psychomotor function. Their interest in pursuing this task was based on a desire of developing a noninvasive test for marijuana exposure. At that point in time, urine drug testing was about to be developed for use on a larger scale, for both clinical and forensic applications, which is today's routine worldwide. The work was also based on earlier observations using more simple analytical technologies that had suggested but not been able to provide convincing evidence of the presence of THC in exhaled breath (McCarthy & van Zyl, 1972; Hauck & Moll, 1974; Valentine, Bryant, Gutshall, Owen, & Niu, 1979). Of concern for Manolis et al. (1983) was the possibility that any sample of exhaled breath collected through the mouth could potentially have become contaminated with saliva.

The study of Manolis et al. (1983) used experienced marijuana smokers classified as healthy male volunteers. Subjects were exposed to placebo cannabis material fortified (or not) with THC standard substance. After the 30 min smoking session, subjects rinsed their mouth and teeth. Components in exhaled breath were collected either using a Tenax tube (a polymer material used for trapping volatiles from air) or by bubbling the air through a collection solution. The collection using Tenax tube provided best recovery and results but suffered from the fact that individuals had problems applying high enough pressure to blow through the tube. Using a gas chromatographic-mass spectrometric method modified after a plasma analysis procedure, the authors were able to detect THC but not the two metabolites (11-hydroxy-THC and THC-COOH) in exhaled breath. The results were convincing from the fact that nonfortified cigarettes were used for control. Moreover, analytical reliability was high, and measures were taken to protect the specimen from saliva contamination. One disappointing fact was that THC was only detected in samples collected between 10 and 12 min after termination of smoking. THC was detected in 7 of 8 individuals using the Tenax collection method, and the amount measured was 0.32–5.7 ng/L ($n = 7$). At the time-point 20 min the amounts had decreased more than 10-fold to below the detection limit.

Manolis et al. (1983) concluded that since a longer detection time than 10–12 min is needed, it would require improvement in analytical sensitivity and in effectiveness of sample collection before exhaled breath can be used for detecting cannabis smoking.

EXHALED BREATH FOR DRUG TESTING

Development of bioanalytical methodology based on liquid chromatography-mass spectrometry (LC-MS) has been rapid during the past two decades and has triggered interest in alternative specimens for drug testing (Gallardo & Queiroz, 2008). Therefore a project was started in pursuing the possibility to use exhaled breath for drugs-of-abuse testing and making it as convenient as alcohol testing. Beck et al. (2010) were able to construct a sampling procedure for exhaled breath using a solid-phase extraction filter that is known to trap amphetamine from water solution and collected exhaled breath for 10 min, from 12 individuals recovered from amphetamine intoxication. Analytical investigation of extracts was done with an ultrasensitive LC-tandem MS (LC-MS/MS) method. The study demonstrated successfully that amphetamine was present in exhaled breath as long as 24 h after drug intake. No amphetamine was detected in controls and the detection of amphetamine in exhaled breath agreed with self-reports as well as urine and plasma analytical data.

Following this promising work, exhaled breath has now been shown to be of general interest for detecting exposure of abused drugs (Beck, Stephanson, Sandqvist, & Franck, 2013). In addition, a new technology for sample collection has been developed, which is even more rapid and convenient.

PARTICLES IN BREATH

From studies of exhaled breath condensate, it is known that nonvolatile components can exit the lung with breath (Montuschi, 2007; Kuban & Foret, 2013). Components like lipids and proteins have been measured in this specimen. Exhaled breath contains aerosol particles that are formed from the airway lining fluid during the normal breathing process (Papiniemi & Rosenthal, 1997; Almstrand et al., 2010). These particles are of micrometer size (median diameter 0.3 μm) (Schwarz, Biller, Windt, Koch, & Holhfeld, 2014), and are a possible vehicle for nonvolatile components to exit lung. The sampling device developed for drug testing using exhaled breath selectively collects the aerosol particles using electrostatic filter technology (Fig. 104.1), with a sampling time of 1–3 min.

FIGURE 104.1 Pictures of the exhaled breath sampling device that has been developed for the purpose of drug testing. (A) Components of the kit come in two plastic bags. (B) One plastic bag is mounted on the filter manifold together with the mouth piece. The plastic bag is used for controlling the length of the sampling process. The mouth piece protects the filter from being contaminated with saliva. (C) Device with filled bag after sampling, which takes 1–3 min. The sampling procedure is finished when the bag is full. Meanwhile, most of the exhaled air is going through the filter manifold, and aerosol particles from the lung are trapped on the filter. The sample donor can breathe normally since the back pressure from the device is low. (D) The filter manifold is sealed, labeled, and sent to laboratory for analysis.

STUDIES ON CANNABINOIDS IN BREATH

A first confirmation that cannabis smoking can be detected in drug testing using exhaled breath was obtained in a study on 10 occasional cannabis users (Beck, Sandqvist, Dubbelboer, & Franck, 2011). The subjects smoked their regular dose and volunteered to donate a breath sample 1–12 h later. In this study, the exhaled breath specimen was collected by passing the air through a 47 mm C18 Empore disk for 10 min by using underpressure from a pump. The THC collected on the filter was extracted using organic solvent and analyzed using LC-MS/MS. One hour after smoking, the mean value of THC in breath was 35 pg/min (n = 7), after 2 h it was 40 pg/min (n = 2), and after 12 h it was 9 pg/min (n = 1). Traces of the main urinary metabolite THCCOOH were detected in three samples.

A controlled administration experiment was performed at the National Institute on Drug Abuse (NIDA, National Institutes of Health, United States) involving 13 chronic and 11 occasional cannabis smokers (Himes et al., 2013). Participants smoked all or parts of a prepared cigarette with 54 mg THC for 10 min duration. Exhaled breath was collected for 3 min using the SensAbues collection device at several time-points during 0.5–21 h after termination of smoking. In addition to THC, the analytical investigation comprised THCCOOH and cannabinol (CBN) and analysis performed with LC-MS/MS.

THC was detected in the exhaled breath in 23 out of the 24 subjects (96%). THCCOOH was not detected at all and CBN was detected in one sample. The longest detection time of THC was 4 h and the detection rate at the 2.4 h time point in the chronic user group was 54%. A graphical presentation of results overtime is given in Fig. 104.2.

In another study, 13 university students having occasional cannabis smoking habits were recruited for an experiment where the subject smoked self-supplied cannabis cigarettes (estimated to contain 13–52 mg THC) (Coucke, Massarini, Ostjin, Beck, & Verstraete (2016). The collection procedure of exhaled breath used the SensAbues collection device and followed the instructions to fill a plastic bag (1–3 min). Repeated sampling was done in the time interval 15–180 min postsmoking. The analytical investigation used LC-MS/MS.

The results from this study deviated from the two previous ones. Four subjects reporting recent smoking had high levels of THC at time zero (before smoking). One of these had smoked 6 h before, two the day before and one a week before. Levels of THC were generally one to two orders of magnitude higher than seen before. All subjects had detectable THC at the longest time-point studied, 180 min. The mean value at 60 min was 4.2 ng/filter. A graphical presentation is seen in Fig. 104.3. No THCCOOH was detected.

Exhaled breath testing for cannabis was evaluated in a clinical setting where patients with cannabis smoking habits were in out-patient treatment with the goal of achieving a better life style (Skoglund, Hermansson, & Beck, 2015). Drug testing was part of the treatment model in order to validate self-reported drug use or abstinence. Samples of urine, plasma, and exhaled breath were taken in parallel. In 35 cases, the presence of THCCOOH in urine was analytically confirmed. In 14 of those cases, THC was detected in plasma indicating a recent intake and in 11 of these THC was detected in

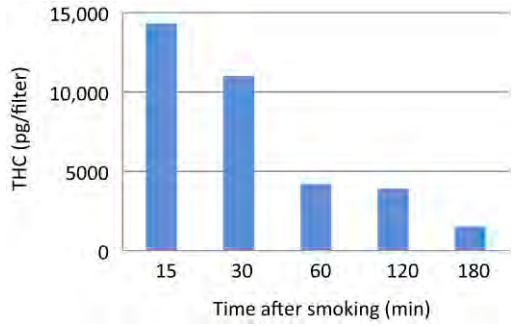

FIGURE 104.3 Mean concentration of THC in exhaled breath collected from 13 occasional cannabis users after smoking self-supplied cannabis. *Source: Data from Coucke et al. (2016).*

exhaled breath (79%). The results suggested that presence of THC in breath is a promising marker for recent cannabis exposure with sensitivity and detection rate similar to plasma.

Drug testing using exhaled breath was used in a few workplaces in Sweden for about a year with good results regarding acceptance of the sampling procedure from a practical perspective and acceptance of reported positive results. When comparing the rate of positive samples for cannabis during the same time period, it was 0.4% with oral fluid testing, 0.8% with exhaled breath testing and 1.3% with urine (Stephanson, Sandqvist, Shafaati Lambert, & Beck, 2014).

A study evaluating the feasibility of exhaled breath drug testing was performed on patients treated for acute intoxication (Beck et al., 2013). The patients were sampled after recovery from intoxication which was estimated to be 12–24 after drug intake. Twenty of the patients had THCCOOH detected in urine. Nine of those had THC detected in plasma, whereof eight had THC present in exhaled breath (89%). There was no possibility that these patients had been smoking cannabis for at least 12 h before sampling since they were inpatients at an emergency treatment clinic.

SAMPLING OF EXHALED BREATH

The main attraction of using exhaled breath as a biological specimen is the noninvasive nature of the sampling procedure. It is the experience from alcohol breath testing that this sampling procedure is well accepted both by donor and collector.

There are several procedures that can be used for sampling of exhaled breath (Buszewski, Kesy, Ligor, & Amann, 2007). These are developed mainly and used for collecting volatile components. For nonvolatile components, exhaled breath condensate is the most commonly used (Kuban & Foret, 2013), and that is known to work also for drugs of abuse (Beck, Sandqvist, Eriksen, Franck, & Palmskog, 2011). However, the procedure requires a special instrument, the collection time is often 10 min, and the collected sample is more complex as it contains not only the nonvolatile fraction, but also volatiles and condensed water. Another alternative is to use selective collection of particles separated by impactor technology (Almstrand et al., 2009), but this again requires an instrument and might need a longer sampling time due to low recovery. A very simple and disposable device that has been used in the above cited recent work is to use an aerosol particle filter (Fig. 104.1) that is of low cost and provides a rapid sampling that has been found to be well accepted by addiction patients and prison inmates (Beck, 2014; Skoglund et al., 2015).

ANALYTICAL ASPECTS

The amounts of drugs in exhaled breath are low, and analytical work needs to be performed using highly sensitive state-of-the-art technology. The work so far has been done using exclusively liquid chromatography-mass spectrometry that provides not only the sensitivity needed, but also provides secure identifications needed for forensic applications and for confident scientific results (Fig. 104.4). The LC-MS/MS technique has the advantage of providing selectivity that enables a simple sample preparation procedure to be applied (Beck et al., 2013; Stephanson et al., 2014) (Fig. 104.5). For further development of the field of exhaled breath drug testing, alternative detection instruments might be needed for enabling instant results on-site as for alcohol testing. One such possibility is to use surface enhanced Raman spectroscopy (SERS) that is known to provide the required sensitivity (Stiles, Dieringer, Shah, & van Duyne, 2008).

MINI-DICTIONARY

Exhaled breath condensate This specimen is collected by letting exhaled air pass through a cold trap. The specimen collected consists of a mixture of volatile and nonvolatile substances. The main component is condensed water. During a collection period of 10 min about 1 mL of sample is produced.

Gas chromatography-mass spectrometry This hyphenated technology was the most selective and sensitive bioanalytical technique of small molecules before LC-MS was developed. Chromatographic separation is achieved in the gas phase and detection with mass spectrometry working in high vacuum.

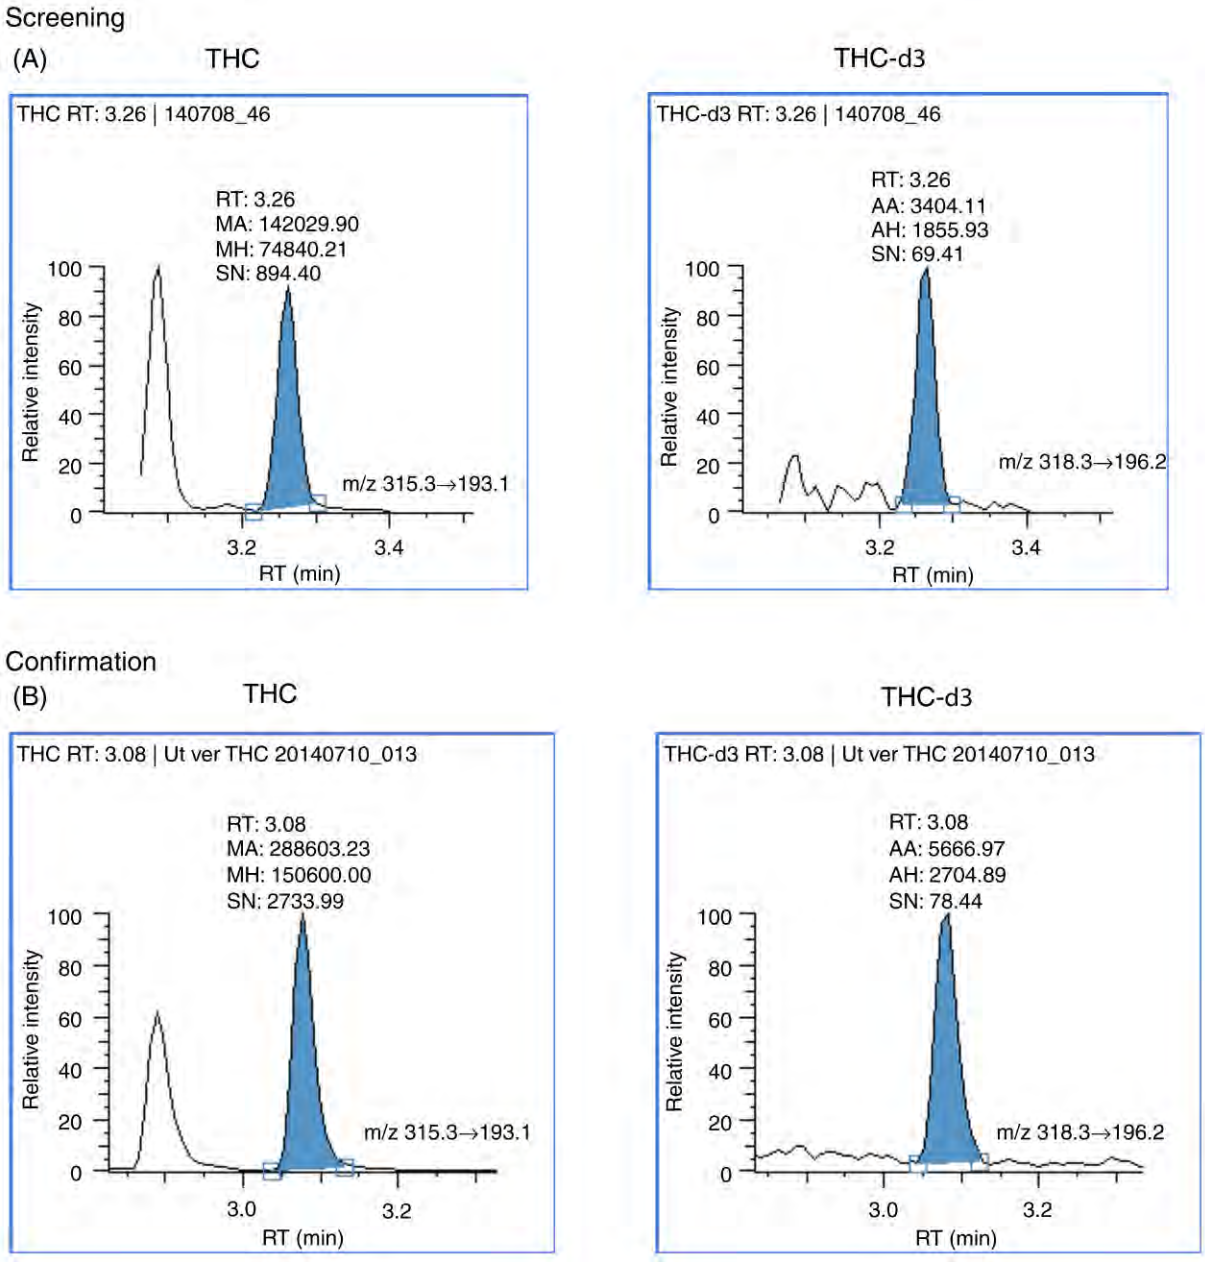

FIGURE 104.4 **Chromatograms from the analysis of THC in a sample collected from a patient in treatment for drug addiction disorder. The sample was taken for purpose of drug testing.** Panel (A) shows results from the screening analysis. THC-d3 is the internal standard added for securing exact quantification. Panel (B) shows results from the confirmation analysis. Both procedures use liquid chromatography-tandem mass spectrometry (LC-MS/MS) in selected reaction monitoring mode. Two product ions are monitored for securing identification fulfilling forensic standard.

Workflow of exhaled breath drug testing:

- Sampling of breath at site, 1–3 min, in controlled environment
- Seal device and send to laboratory with request form
- In laboratory, the device is extracted with solvent using a simple procedure
- Prepared extract is analyzed for many drugs with LC-MS/MS
- Final result reported

FIGURE 104.5 **Short summary of the workflow for using exhaled breath in routine drug testing.**

Impactor technology This collection technique of small particles collects fractions of particles according to size after the air flow is passed through a cascade of impactor stages. Several different designs exist but they are all based on the fact that large particles deviate from the air flow when directed toward a surface while small particles follow the air stream.

Liquid chromatography-mass spectrometry This is a hyphenated technology that has provided unique simplicity and performance to the field of bioanalysis when it was put into practice in the 1990s. The aqueous mobile phase containing water is introduced to the mass spectrometry system, working in high vacuum, using an electrospray interface. The tandem MS

technology for detection has provided additional selectivity and sensitivity.

Specimen for drug testing The most common specimen for drug testing is urine. Alternative specimens are of interest mainly because of the risk for adulteration that a supervised collection procedure may cause inconvenience for both the donor and collector. Alternative matrices are hair, oral fluid, blood, nails, sweat, and exhaled breath.

Tetrahydrocannabinol The main psychoactive component of cannabis and the substance targeted in most laboratory investigation except for urine.

Tetrahydrocannabinolcarboxylic acid The main metabolite of tetrahydrocannabinol. This metabolite is excreted in urine in a conjugated form and the primary target compound in urine drug testing.

Barriers to Treatment Seeking for Cannabis Dependence

P. Gates, J. Copeland

National Cannabis Prevention and Information Centre, University of New South Wales, Sidney, NSW, Australia

SUMMARY POINTS

- This chapter focuses on the barriers to seeking treatment for managing cannabis use disorder (CUD).
- CUD is a psychiatric diagnosis of clinical importance relating to dependence on cannabis. It is characterized typically by a lack of control overuse, or use despite known harms.
- Although treatment is thought to be effective in assisting cannabis use reduction and abstinence, few individuals with cannabis use disorder seek treatment.
- Barriers to cannabis treatment may help explain this underutilization of services. The most commonly cited barriers include a lack of a perceived need for treatment and a desire to reduce use without assistance.
- Other important barriers include a desire to avoid negative views from the community or employers and the belief that treatment is ineffective.
- In contrast, cannabis treatment seeking may be facilitated if information on the effectiveness of treatments, and how they can be accessed, are promoted and the treatments are easily accessible.
- Cannabis treatment services must address the concerns of cannabis users who are likely to lack information on their services, and feel that they are better off reducing their use without assistance should they believe that is required.

KEY FACTS OF CANNABIS USE DISORDER

- Approximately 9–15% of cannabis users will develop a cannabis use disorder at some point in their lives.
- The risk of developing cannabis use disorder is further increased by early onset use, chronic use patterns and other substance use.
- Although some individuals with cannabis use disorder are able to quit using cannabis, failure to do so is associated with being a male of younger age, being unmarried, obtaining low educational achievement, and having mental health concerns.

KEY FACTS OF CANNABIS TREATMENT SEEKING

- Treatment seeking for cannabis use problems is particularly low, compared to other illicit drugs, even among those meeting criteria for cannabis use disorder.
- The rates of individuals seeking treatment have increased over the last two decades in the United States, Europe, and Australia.
- Due to the prevalence of cannabis use, just over one in five of substance use treatment episodes were principally for cannabis use. This is despite the proportionately few cannabis users who seek treatment.

KEY FACTS OF CANNABIS USE DISORDER TREATMENT

- Those cannabis users who do seek treatment often have a long history of use over many years, and a record of previous failed quit attempts.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00123-X
Copyright © 2017 Elsevier Inc. All rights reserved.

- Although some pharmacotherapies have shown promise, none is approved currently to treat cannabis use disorder.
- There is growing evidence for the effectiveness of counseling, particularly the combination of cognitive behavioral therapy and motivational enhancement therapy over multiple sessions, for assisting with cannabis use reductions.

CUD Cannabis use disorder
UNODC United Nations Office on Drugs and Crime

INTRODUCTION

Most individuals who try using cannabis do so experimentally; however, those who go on to develop a cannabis use disorder (CUD) cease their use typically after encountering undesirable consequences over time (Von Sydow et al., 2001; Swift, Coffey, Carlin, Degenhardt, & Patton, 2008; Ellingstad, Sobell, Sobell, Eickleberry, & Golden, 2006). In contrast, those cannabis users who report heavy, persistent, and early-onset use are more likely to require intervention to achieve long-term abstinence (Swift et al., 2008). Despite a need for intervention, rates of cannabis-related treatment seeking are low even among the most entrenched users. Indeed, before seeking treatment, the average cannabis user is likely to first attempt to abstain from use without assistance at least 6 times and report using cannabis almost daily for more than 10 years on average (Stephens, Roffman, & Simpson, 1993), and meet criteria for CUD for at least 3–5 years (Stinson, Ruan, Pickering, & Grant, 2006).

Moreover, there are clear differences among those individuals with CUD who do and don't seek treatment. Large samples of treatment seekers in the United States have revealed that those seeking treatment for cannabis use are more likely to be male, single, failed to graduate high school, previously attended treatment for mental health or other substance use problems (particularly alcohol use disorder), and report comorbid major depression, and alcohol dependence (Strike, Urbanoski, & Rush, 2003; Agosti & Levin, 2004). Similarly, in Australia, mandatory reporting data from publicly funded substance use treatment services show that cannabis treatment seekers are typically male (69.4%), with a mean age of 29 years (Copeland & Allsop, 2014). The cannabis treatments which are most commonly delivered across these services were counseling services (34.1%; with 11.6% receiving counseling at a cannabis-specific clinic) (Copeland & Allsop, 2014).

Rates of cannabis treatment-seeking are increasing and existing treatments have shown efficacy in assisting with reducing use (Copeland, Clement, & Swift, 2014). Despite this, a large gap remains between the proportions of those who are in need of cannabis treatment (that is, those who meet criteria for CUD) and the numbers who actually seek treatment. Specifically, current estimates report that approximately 4% of the global population aged 14–65 years used cannabis in the past 12 months (UNODC, 2013), and approximately 1 in 10 of these individuals are likely to meet criteria for a CUD (Hall & Pacula, 2003). According to data from the US National Epidemiologic Survey on Alcohol and Related Conditions, among those with a CUD, only between 6.4% and 18.1% report accessing treatment. This chapter explores the literature on the barriers to cannabis treatment, and why so few individuals in need of such treatment actually report accessing treatment.

BARRIERS TO SEEKING CANNABIS TREATMENT

Several studies on the barriers to substance use treatment have been conducted, although only a handful are specific to cannabis treatment (Gates, Copeland, Swift, & Martin, 2012; Ellingstad et al., 2006; Vendetti et al., 2002; Fernández-Artamendi, Fernández-Hermida, García-Fernández, Secades-Villa, & García-Rodríguez, 2013; Mariani et al., 2011; Stephens et al., 1993; van der Pol et al., 2013). As shown in Fig. 105.1, the prevailing barriers to substance use treatment are a low perceived need for treatment, a desire to make improvements without help among those who recognize a need for treatment, concerns regarding negative views from the community (including employers) and concerns regarding treatment availability and cost (Andrade et al., 2014; Mojtabai, Chen, Kaufmann, & Crum, 2014; Chen, Strain, Crum, & Mojtabai, 2013; Wisdom, Cavaleri, Gogel, & Nacht, 2011; Mojtabai & Crum, 2013). Also important is a lack of belief in the effectiveness of treatment (Mojtabai & Crum, 2013).While these attitudinal barriers to treatment are likely to be shared by cannabis users, recent research has identified some beliefs to be particularly important for these individuals.

An initial study of interest in cannabis-specific treatment identified a significant demand for such treatment, but that those who reported interest were significantly less likely to be abusing other substances (Stephens et al., 1993). The authors concluded that such individuals may be less interested in treatments which group all illicit drug using clients together (Stephens et al., 1993). Building on this research, Vendetti et al. (2002) investigated a sample of nontreatment seeking, adult daily cannabis users who showed interest in a large cannabis

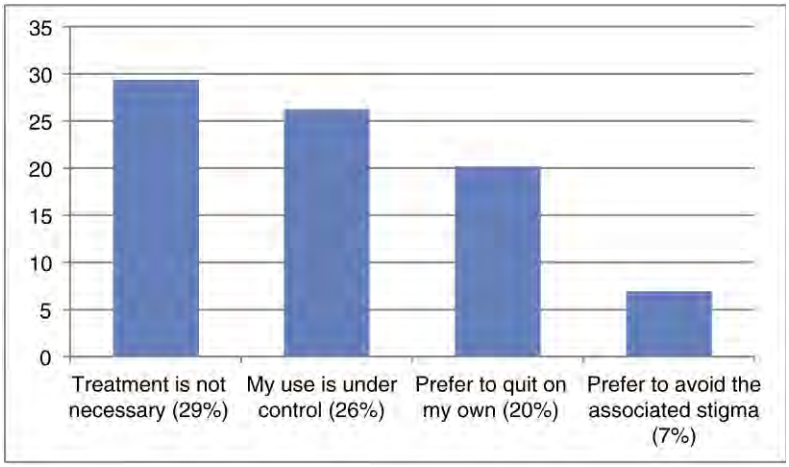

FIGURE 105.1 Barriers to cannabis treatment reported by cannabis users (n = 1021). This pie-chart depicts the percentage of participants reporting the most commonly described barriers to treatment from a pooled sample of the studies reviewed in this chapter (Ellingstad et al., 2006, n = 25; Fernández-Artamendi et al., 2013, n = 261; Gates et al., 2012, n = 494; van der Pol et al., 2013, n = 241).

treatment trial but did not go on to participate (n = 363) and those that did participate (n = 450). This comparison focused on factors associated with *pretreatment* dropout. Factors which predicted this kind of dropout were a lack of self-perceived dependence on cannabis, membership in Asian or Native American ethnic groups, social instability (not married, unemployed, low education), young age, and use of other drugs (sedatives and cocaine). Without directly assessing barriers to cannabis treatments, these two studies were important in identifying that cannabis treatment was not uniformly appealing to all those who may benefit from such treatment.

In the first study to directly investigate barriers to cannabis-specific treatment, 25 individuals who reported at least 1 year of recent abstinence from long-term daily cannabis use were interviewed regarding their past substance use, their successful quit attempt and any perceived barriers to treatment (Ellingstad et al., 2006). As it is common among other illicit substance users, the participants most commonly reported the belief that their cannabis use was not enough of a problem to warrant treatment (80%). In addition, the participants also commonly reported that treatment was not sought due to wanting to quit without treatment (76%), and the desire to avoid the stigma of being labeled a drug user (48%). Importantly, given the sample consisted of individuals who had successfully quit their cannabis use on their own, it is not surprising that support for treatment would be low.

Subsequently, a larger study of different samples of regular cannabis users throughout Australia also investigated beliefs regarding treatment barriers (Gates et al., 2012). Specifically, the sample included cannabis users who were in treatment services in New South Wales (CT; n = 100), others who were not in treatment in the same area (NT; n = 100), and a separate group participating from throughout Australia via online survey (IS; n = 294). In line with earlier research on illicit drug treatment, the most commonly reported barrier from the total sample was the feeling that treatment is not necessary to reduce cannabis use. This study also compared the responses between the sample groups, and investigated the importance of the participants' demographic characteristics. The belief that treatment is unnecessary was reported significantly more frequently by those not in treatment, compared to those in treatment (44% of NT, and 61% of IS, compared to 36% of CT), and by females compared to males (58% compared to 48%). The next most commonly reported barrier was the opinion that cannabis users are not likely to be ready to stop their use. This barrier was mentioned significantly more frequently by those in treatment, compared to not in treatment (34% of CT compared to 14% of NT, and 23% of IS), and by participants aged 24–29 years, compared to older age groups. Other commonly reported barriers included a lack of awareness of treatment options (14% of all participants), and a preference for avoiding the stigma associated with being labeled a drug user in need of treatment (12% of all participants) (Gates et al., 2012). Again; however, this study did not specify that the participants were in need of treatment (that is, were diagnosed with a CUD) and so, as with Ellingstad and colleagues (2006), such results could be expected.

A more recent study addressed this concern by recruiting individuals who were dependent on cannabis use and had not sought treatment [n = 241; including subsamples of those who felt they would "probably not" seek "specialized addiction treatment" for their cannabis use (n = 160) and those who felt "the need for professional help with their cannabis problem" in the past year (n = 30)] (van der Pol et al., 2013). In line with previous

studies, the most commonly reported barrier was a desire to be self-reliant (47.8%; with little difference between the subsamples). Also common was a preference to seek informal help (19.4%), and a feeling that treatment is not needed (17.0%). Notably, there was little difference in these more commonly cited barriers between participant groups.

Recognizing that previous studies on barriers to cannabis treatment recruited only adult participants, an additional study investigated the opinions of 261 high-school students who reported past-year cannabis use (selected from nine high-schools in Spain) (Fernández-Artamendi et al., 2013). The participants were presented with a list of previously cited barriers (and two not previously used due to the nature of the sample: "ignorance of resources available" and "fear of the family becoming involved"), and were asked to rate their influence in preventing treatment seeking on a Likert-type scale. In addition, the participants' intention to change their cannabis use was assessed. Consistent with previous research, the barriers to treatment which were most frequently cited by the young people were a lack of perceived problem (50.6%), the desire to solve one's problems alone (27.6%), and fear of family finding out (24.9%). In contrast, feelings of shame (11.5%) and financial cost (13.3%) were less commonly cited. Notably, the desire to solve one's problems alone was particularly relevant to those who reported high motivation to change their cannabis use.

IMPLICATIONS OF THE BARRIERS TO TREATMENT

These commonly cited attitudinal barriers to cannabis treatment (lack of treatment need and a desire to reduce use without assistance) stand in contrast to barriers to treatment for other illicit drug use that more commonly include concerns regarding negative views from the community and employers, and the inconvenience and cost of accessing services (Mojtabai et al., 2014; Wisdom et al., 2011). Treatment services can address these attitudinal barriers to treatment that are expressed by cannabis users in two main ways. First, available services may attempt to minimize the professional contact involved, so as to appeal to those resisting formal assistance, and those concerned about any negative views from the community. As such, self-guided interventions, such as, computer-based interventions that minimize the roles of therapists—sometimes operating completely without face-to-face contact—may be appropriate. Indeed, early research has supported the efficacy of such interventions (Budney et al., 2011; Kay-Lambkin, Baker, Lewin, & Carr, 2009; Rooke, Copeland, Norberg, Hine, & Mccambridge, 2013; Tossmann, Jonas, Tensil, Lang, & Struber, 2011) and they are currently freely available online (for example, www.reduceyouruse.org.au). In addition, the utility of smartphone apps to assist with substance use monitoring is beginning to get recognized by users (Savic, Best, Rodda, & Lubman, 2013), and pilot work on an initial smartphone app to assist with cannabis use reductions has been completed (Norberg et al., 2013). Further research is required to assess the appropriateness of implementing these low threshold interventions.

Second, given the prevalence of cannabis use, it is desirable that services extend their accessibility so as to reach the minority of users interested in accessing professional help. This could be done by promoting knowledge of treatment and by improving the accessibility of treatment. Indeed, the particular influence of advertising cannabis treatments has been demonstrated in an initial investigation on the impact of promoting substance use treatment. That is, a study of 489 individuals reporting substance use problems found that those seeking treatment for cannabis use were significantly more likely, compared to other illicit substance users, to report that they would seek treatment upon hearing or seeing an advertisement regarding treatment. Moreover, in the study by Gates et al. (2012) of almost 500 cannabis users in the community and in treatment, the participants were asked to report on any facilitating factors that may help to increase rates of entry into cannabis treatment. The most commonly reported facilitator was the improvement of available information regarding treatments (30%). Notably, other reported facilitators included increasing the availability or accessibility of cannabis specific services (27%), and introducing additional options, such as, telephone counseling (12%).

Importantly, existing treatments for cannabis use are known to be effective—particularly, treatments based on cognitive behavioral therapies and motivational enhancement therapies for adults, and family systems approaches for youths (Copeland et al., 2014). In addition, the prevalence of cannabis use is such that cannabis is the most likely drug of concern among those in illicit drug treatment services (UNODC, 2013). As such, the important focus may no longer be developing appropriate interventions, but rather addressing the barriers to treatment with the aim of increasing the likelihood that those in need of treatment will access the treatments that are available.

CONCLUSIONS

Despite increasing rates of cannabis treatment seeking (UNODC, 2013), there remains an important proportion of cannabis users who lack control over their use, but yet do not feel treatment is necessary or desirable to stop using. As treatment is known to be effective for these individuals (Copeland et al., 2014), it is necessary

for treatment services to increase their awareness and accessibility. Consistent with this need are highly accessible and easily promoted computer-based interventions. Future work is required to establish a large and long-term evidence-base for these interventions; however, early work is promising.

MINI-DICTIONARY OF TERMS

Cannabis use disorder Refers to a psychiatric diagnosis of clinical importance relating to mild to severe dependence on cannabis which is typically characterized by a lack of control over use, or use despite known harms.

Early onset cannabis use Refers to the use of cannabis during adolescence. There is a well-established link between early onset cannabis use and an increased risk of harms to both physical and mental health, as well as decreased odds of high-school completion.

Stigma Refers to a mark of disgrace or shame which is associated with a particular circumstance or quality. For example, an individual entering treatment for substance use may feel stigma upon being labeled a drug user, and thus avoid treatment.

United Nations Office on Drugs and Crime (UNODC) Refers to an extensive network of field offices throughout the world dedicated to the fight against illicit drugs and international crime. Its operations include field-based technical operation and normative work, as well as research and analytical work.

CHAPTER

106

Pharmacotherapies for Cannabis Use Disorders

A.L. McRae-Clark

Medical University of South Carolina, Charleston, SC, United States

SUMMARY POINTS

- This chapter reviews medication development efforts in the area of cannabis use disorders.
- Medications have been evaluated targeting reduction of cannabis withdrawal symptoms, abstinence initiation, and relapse prevention.
- Promising medications for treatment for cannabis withdrawal include agents targeting sleep disturbances and agonist therapy.
- *N*-acetylcysteine and gabapentin have shown preliminary utility in treatment of cannabis dependence in randomized, placebo-controlled trials.
- Medications have also been evaluated for treatment of cannabis dependence and comorbid psychiatric disorders without positive findings.
- To date, there are no approved medications for treatment of either cannabis withdrawal or cannabis dependence.

KEY FACTS OF CANNABIS TREATMENT

- Nearly 1 million Americans seek treatment for cannabis use disorders annually.
- Psychosocial treatments for cannabis use disorders include relapse prevention, cognitive behavioral therapy, motivational enhancement therapy, and motivational incentives.
- Range of 1-year abstinence rates was between 10% and 30 % for the various behavioral approaches.
- Other mental disorders commonly cooccur with cannabis dependence, including alcohol dependence, antisocial personality disorder, conduct disorder, and anxiety and mood disorders, and may lead to a poorer prognosis for treatment.
- Although an area of active research, there are no currently approved pharmacotherapy treatments for cannabis use disorders.

LIST OF ABBREVIATIONS

ADHD	Attention deficit hyperactivity disorder
FDA	US food and drug administration
GABA	Gamma-aminobutyric acid
NAC	*N*-acetylcysteine
THC	Δ^9-Tetrahydrocannabinol

INTRODUCTION

In 2012, nearly 1 million Americans received treatment for cannabis-related problems (SAMHSA, 2013). Although a high demand for effective interventions obviously exists, few specific treatments have been developed for cannabis use disorders. Further, the treatments that have been examined have had limited efficacy, with few individuals achieving abstinence (Dennis et al., 2004; Kadden, Litt, Kabela-Cormier, & Petry, 2007; McRae, Budney, & Brady, 2003; Nordstrom & Levin, 2007; Vandrey & Haney, 2009). In the Marijuana Treatment Project, the largest controlled trial of treatment

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00124-1
Copyright © 2017 Elsevier Inc. All rights reserved.

for cannabis dependence to date, the highest abstinence rate achieved was 23% (Marijuana Treatment Project Research Group, 2004). As such, there is significant interest in the development of new treatment approaches for cannabis dependence. One potential avenue is exploring the role of pharmacological interventions, either targeting withdrawal symptoms in early cannabis abstinence, or as complements to psychosocial treatments in abstinence initiation, or relapse prevention (Hart, 2005; Vandrey & Haney, 2009). Further, medications may also play a role in treatment of individuals with comorbid cannabis dependence and other psychiatric disorders.

PHARMACOTHERAPY FOR THE TREATMENT OF CANNABIS WITHDRAWAL SYNDROME

A valid and reliable cannabis withdrawal syndrome has been documented in both controlled laboratory and clinical evaluations (see Budney & Hughes, 2006 for review). Common symptoms associated with cannabis withdrawal include irritability, anxiety, restlessness, appetite changes, and sleep disturbances. A number of studies have been conducted evaluating the potential use of medications to treat cannabis withdrawal, on the presumption that withdrawal symptoms may contribute to difficulty achieving or maintaining abstinence (Table 106.1).

Antidepressants

An initial human laboratory study evaluated the effects of sustained-release bupropion, an antidepressant with norepinephrine and dopamine reuptake inhibition properties that has been approved for cigarette smoking cessation, in nontreatment seeking, heavy cannabis smokers. During an inpatient abstinence period, participants receiving bupropion reported increased irritability, depressed mood, and trouble sleeping compared to participants receiving placebo (Haney et al., 2001). However, a recent preliminary outpatient study reported more promising results with a paradigm similar to cigarette smoking cessation guidelines (Penetar, Looby, Ryan, Maywalt, & Lukas, 2012). In this study, withdrawal symptoms were greater in the placebo-treated participants, and cannabis craving increased in participants receiving placebo, but not in those receiving bupropion.

The effects of nefazodone, a norepinephrine and serotonin reuptake inhibitor, have also been evaluated in an inpatient laboratory model (Haney, Hart, Ward, & Foltin, 2003). Nefazodone decreased reports of anxiety and muscle pain during withdrawal, but did not reduce feelings of irritability or improve sleep quality, compared to placebo. The antidepressant mirtazapine had no impact on cannabis withdrawal symptoms (Haney et al., 2010).

TABLE 106.1 Medications Evaluated to Treat Cannabis Withdrawal Symptoms

Positive	Negative	Mixed data
Oral THC	Nefazodone	Bupropion SR
Oral THC/Lofexidine	Divalproex	
Zolpidem	Mirtazapine	
	Baclofen	
	Lithium	
	Quetiapine	

Summary of results from published studies evaluating medication effects on cannabis withdrawal symptoms. Data is from published studies.

Cannabinoid Agonists

Several studies have evaluated the utility of the oral cannabinoid agonist Δ^9-tetrahydrocannabinol (THC) on ameliorating cannabis withdrawal symptoms. An initial inpatient human laboratory investigation found that oral THC 10 mg administered five times daily decreased both withdrawal symptoms and cannabis craving (Haney et al., 2004). A subsequent outpatient trial also found oral THC at doses of 10 mg three times daily, and 30 mg three times daily to be effective in suppressing cannabis withdrawal symptoms (Budney, Vandrey, Hughes, Moore, & Bahrenburg, 2007). Of note, a follow-up human laboratory study found that administration of oral THC 20 mg three times daily reduced only a subset of cannabis withdrawal symptoms, and did not attenuate cannabis craving (Haney et al., 2008). The alpha$_2$-receptor agonist lofexidine was also evaluated, and did not decrease cannabis craving or most mood symptoms of withdrawal; however, when coadministered, oral THC and lofexidine significantly improved measures of withdrawal symptomatology, as well as decreased relapse in a laboratory model.

Mood Stabilizers

Divalproex has also been tested in a laboratory model of cannabis withdrawal, as divalproex has been used previously to treat mood lability and irritability (Haney et al., 2004). Although divalproex was shown to decrease cannabis craving during abstinence, its use was also associated with increased ratings of anxiety, irritability, tiredness, and "bad effect." In addition, divalproex administration worsened subject performance on psychomotor tasks. A small, open-label evaluation suggested some utility for lithium carbonate for management of cannabis withdrawal; however, the lack of a placebo-control condition limited interpretation (Winstock, Lea,

& Copeland, 2009). A recent randomized trial failed to show an effect of lithium treatment on withdrawal symptoms (Johnston et al., 2014).

Sedative Hypnotics

Sleep disturbances are reported commonly in cannabis withdrawal, and recent research has examined the utility of hypnotic medication targeting abstinence-induced sleep disruptions. In a within-subject crossover study, extended-release zolpidem attenuated the effects of cannabis abstinence on sleep architecture, and also normalized sleep efficiency scores (Vandrey, Smith, McCann, Budney, & Curran, 2011). No differences in withdrawal severity or cannabis craving were noted between placebo-abstinence and zolpidem-abstinence periods.

Other Medication Classes

The $GABA_B$ receptor agonist baclofen had limited impact on cannabis withdrawal symptoms in an inpatient human laboratory evaluation (Haney et al., 2010). Quetiapine, an atypical antipsychotic, improved some symptoms of cannabis withdrawal, but increased cannabis craving and relapse (Cooper et al., 2013). As discussed previously, lofexidine, an $alpha_2$-receptor, did not demonstrate utility on its own for cannabis withdrawal, but may act synergistically with oral THC to ameliorate symptoms (Haney et al., 2008).

PHARMACOTHERAPY FOR THE TREATMENT OF CANNABIS USE DISORDERS

As with other dependencies, pharmacotherapy clinical trials for cannabis use disorders also incorporate generally other treatment modalities, such as cognitive behavioral, motivational enhancement, and contingency management therapies. The inclusion of a behavioral platform has several advantages, including alleviating ethical concerns of providing a placebo or nonproven pharmacotherapy intervention, as all patients receive some form of psychosocial counseling. Further, a behavioral platform may improve study retention and compliance, particularly in studies of medications that may take several weeks to reach therapeutic blood levels or effects, and may increase the statistical power for an intention-to-treat analysis by decreasing the variability and protocol deviations commonly associated with pharmacotherapy trials (Carroll, Kosten, & Rounsaville, 2004). Medications evaluated for cannabis disorder treatment have included antidepressants and anxiolytics, agonist therapy, and agents targeting other specific neurotransmitters thought to be involved in cannabis addiction.

TABLE 106.2 Medications Evaluated to Treat Cannabis Dependence

Positive	Negative
N-Acetylcsyteine	Divalproex
Gabapentin	Oral THC
	Nefazodone
	Bupropion SR
	Escitalopram
	Atomoxetine
	Buspirone

Summary of results from published studies evaluating medication effects on cannabis dependence. Data is from published studies.

Antidepressants and Anxiolytics

Several antidepressant medications have been evaluated for the treatment of cannabis dependence (Table 106.2). Nefazodone and sustained-release bupropion were studied in a placebo-controlled trial of cannabis-dependent adults; neither medication had a significant effect on cannabis use or cannabis withdrawal symptoms (Carpenter, McDowell, Brooks, Cheng, & Levin, 2009). A recent evaluation of escitalopram in an adult population also failed to find a positive effect of treatment on abstinence or withdrawal outcomes (Weinstein et al., 2014).

Preclinical evidence suggests a role of the 5-HT1A receptor in the pharmacological actions of cannabinoids. Buspirone, a nonbenzodiazepine anxiolytic, is a partial 5-HT1A agonist, and showed limited preliminary evidence as a potential treatment for cannabis use disorders (McRae, Brady, & Carter, 2006; McRae-Clark et al., 2009). In a pilot, randomized controlled trial, buspirone combined with motivational enhancement therapy was associated with a trend for reduced positive urine drug screens, as compared to placebo; when only protocol completers were included, the difference reached statistical significance (McRae-Clark et al., 2009). However, no significant differences between treatment groups were observed in the intent to treat analysis.

Cannabinoid Agonists

Based on the proven utility of agonist medication in other addictions and data in cannabis withdrawal, oral THC was evaluated in a large randomized, placebo-controlled trial for treatment of cannabis dependence (Levin et al., 2011). Although oral THC was shown to improve retention in the trial and to reduce withdrawal symptoms, there was not a medication effect on cannabis use.

Glutamatergic Agents

Glutamate has recently emerged as a promising neurochemical target for addictive disorders medication development. *N*-Acetylcysteine (NAC) is an *N*-acetyl prodrug of the naturally occurring amino acid cysteine. NAC administration has been shown to increase nonsynaptic glial release of glutamate via stimulation of the cystine-glutamate exchange that becomes dysregulated after chronic drug use. As a result of normalization of this exchange process, NAC has been shown to reduce the reinstatement of drug seeking in animal models across multiple substances. An open-label trial of NAC in young (18–21 years old) cannabis users demonstrated reductions in self-report of cannabis use and cannabis craving (Gray, Watson, Carpenter, & Larowe, 2010). A follow-up placebo-controlled study showed that NAC, when paired with contingency management (CM) to promote abstinence, and brief counseling, doubled the odds of negative urine cannabinoid tests during treatment among cannabis-dependent adolescents (Gray et al., 2012).

Other Medication Classes

Atomoxetine, a nonstimulant medication approved for treatment of attention deficit disorder (ADHD), increases levels of both dopamine and norepinephrine in the prefrontal cortex, but does not appear to increase dopamine in subcortical areas where there are few noradrenergic nerve terminals. An open-label study of atomoxetine reported a trend toward reduction in cannabis use on self-report; however, this finding was not supported with urine drug screen results (Tirado, Goldman, Lynch, Kampman, & Obrien, 2008). Further, adverse events were commonly reported, with 77% of subjects experiencing mild to moderate gastrointestinal side effects.

Levin et al. (2004) conducted a double-blind, placebo-controlled, crossover study of the mood stabilizer divalproex in cannabis dependent adults. Both treatment groups reported less cannabis craving and drug use, over the course of the study; however, there were no significant differences between treatment groups on psychological or cannabis use outcomes.

Gabapentin is an analogue of the neurotransmitter gamma-aminobutyric acid (GABA), and is FDA-approved for the treatment of epilepsy and neuropathic pain. Although the precise mechanism of action is unclear, gabapentin binds to the alpha-2-delta subunit of voltage-gated calcium channels (VGCCs), and changes their conformation, reducing calcium influx at nerve terminals. Gabapentin also reduces the release of several neurotransmitters, including glutamate, noradrenaline, and substance P, and increases central GABAergic activity. Cannabis withdrawal is associated with increased CRF release in the amygdala, and gabapentin normalizes CRF-induced GABA activation in the amygdala, providing a basic science rationale for the use of gabapentin in cannabis dependence (Rodriguez de Fonseca, Carrera, Navarro, Koob, & Weiss, 1997). Mason et al. (2012) conducted a 12-week, placebo-controlled trial exploring the use of gabapentin in 50 cannabis-dependent individuals. The gabapentin-treated group demonstrated significantly less cannabis use by both self-report and urine toxicology, significantly decreased cannabis withdrawal symptoms, and greater improvement in executive function.

PHARMACOTHERAPY FOR THE TREATMENT OF COMORBID DISORDERS IN INDIVIDUALS WITH CANNABIS USE DISORDERS

The comorbidity of psychiatric and substance use disorders, including cannabis disorders, is associated with poor treatment prognosis. Patients with both disorders have been shown to have higher rates of substance use and more psychosocial impairment than patients without this comorbidity, as well as a more complicated course of treatment (Rounsaville, Weissman, Crits-Christoph, Wilber, & Kleber, 1982; Rounsaville et al., 1991; Strakowski, Tohen, Stoll, Faedda, & Goodwin, 1992). Importantly, improved substance abuse outcomes have been reported with pharmacological treatment of cooccurring psychiatric disorders such as depression, anxiety disorders, and bipolar disorder (Kranzler et al., 1994; Brady, Sonne, Anton, & Ballenger, 1995; Nunes et al., 1998). Data from the National Comorbidity Survey found that 90% of cannabis-dependent individuals had a lifetime psychiatric disorder, compared with 55% of individuals without cannabis dependence (Agosti, Nunes, & Levin, 2002).

A limited number of studies have evaluated the pharmacological treatment of cannabis use disorders in individuals with other psychiatric diagnoses. The selective serotonin receptor inhibitor fluoxetine significantly reduced cannabis use in depressed, adult alcohol-dependent individuals (Cornelius et al., 1999). A recent trial in adolescents and young adults with comorbid major depression and cannabis use disorders did not find a significant effect of fluoxetine on cannabis-related outcome measures (Cornelius et al., 2010); lack of effect may have been attributable to the strong psychosocial platform used (cognitive behavioral therapy plus motivational enhancement therapy), as there were significant improvements in both depressive and cannabis symptoms in both the placebo and fluoxetine-treated groups.

A recent trial examined the utility of venlafaxine-extended release combined with cognitive behavioral

therapy for cooccurring cannabis dependence and major depressive disorder or dysthymia (Levin et al., 2013). Venlafaxine was not better than placebo in reducing depressive symptoms. Further, participants receiving venlafaxine were less likely to reduce their cannabis use, or become abstinent, than participants receiving placebo.

An evaluation of atomoxetine combined with motivational enhancement therapy on the symptoms of ADHD and cannabis use in cannabis-dependent adults found greater improvement in some ADHD measurements, but not on cannabis use outcomes (McRae-Clark et al., 2010). These results, taken together with the atomoxetine aforementioned study, suggest that atomoxetine does not reduce cannabis use in this population.

CONCLUSIONS

It is clear that more research on the pharmacotherapy of cannabis use disorders is necessary. Some promising results have been reported in the treatment of cannabis withdrawal symptoms; however, these findings have not yet translated to improved clinical outcomes. Encouraging findings have also recently been reported in clinical trials of NAC and gabapentin. However, to date, there is no FDA-approved medication for either cannabis withdrawal or cannabis dependence. As cannabis use disorders frequently occur in individuals with other psychiatric disorders, more research is also needed in the area of dual diagnosis. With increased recognition of cannabis abuse and dependence as a significant public health concern, more attention should be focused on the development of effective treatments for this disorder.

MINI-DICTIONARY

Agonist therapy Use of a medication that stimulates the same brain receptors as a drug of abuse.
Cannabis use disorders A problematic pattern of cannabis use leading to clinically significant impairment or distress; specific criteria are defined in the fifth edition of the Diagnostic and Statistical Manual.
Cannabis withdrawal Signs and symptoms developing after cessation of heavy, prolonged cannabis use including irritability, anxiety, difficulty sleeping, reduced appetite, restlessness, and depressed mood.
Comorbidity A psychiatric disorder coexisting with a substance and/or alcohol use disorder.
Pharmacotherapy Use of a medication to treat a disease or symptom.

SUMMARY POINTS

- This chapter focuses on key predictors of self-initiated cannabis cessation in adolescents and emerging adults using the triadic theory of influence (TTI) as a means of organizing empirical studies.
- Predictors are categorized as intrapersonal (biological), cultural/attitudinal (socio-environmental), or interpersonal (social context) factors related to cannabis cessation.
- Intrapersonal predictors of self-initiated cessation include neurobiological disposition (eg, positive and negative affect), self-image, deviant behaviors, and cognitive processing (eg, decision-making).
- Cultural and attitudinal predictors of self-initiated cessation include one's larger social environment (eg, neighborhood/community approval or disapproval of cannabis use, neighborhood safety), acculturation, emerging adulthood, cannabis-related consequences attitudes, and pro-drug use myths.
- Interpersonal predictors of self-initiated cessation include peer social norms, peer approval or disapproval of marijuana cessation, and familial interactions.
- Strategies discussed thus far pertaining to self-initiated marijuana cessation include "distraction" and "stimulus removal."
- These predictors and strategies can and should be used in future cannabis formal and nonformal (self-initiated, naturally occurring) prevention and intervention programs, along with a better understanding of their long-term impacts.

KEY FACTS OF TRIADIC THEORY OF INFLUENCE

- A theory developed by Petraitis, Flay, and Miller in 1995 (Petraitis, Flay, & Miller, 1995).
- TTI was originally used to look at predictors for experimental substance use (ESU).
- Petraitis et al. (1995) examined 14 multivariate theories associated with ESU and combined the main constructs of these theories into a more comprehensive theoretical framework.
- ESU predictors are separated into three causal streams: intrapersonal, cultural/attitudinal, and interpersonal.
- These streams can be further delineated as ultimate, distal, and proximal influences on behavior; describing a "distance" from engagement in the behavior.

SELF-INITIATED CANNABIS CESSATION IN ADOLESCENTS AND EMERGING ADULTS[a]

Adolescent prevention and intervention programs have the ability to delay onset, decrease the frequency of cannabis use, facilitate quitting, and limit passive exposure to cannabis smoke and risky contexts of use (Sussman & Ames, 2008). These programs aim to reduce the likelihood of prolonged cannabis use in an individual's lifetime by targeting and counteracting effects of antecedents associated with substance use behavior. Unfortunately, the number of studies among adolescents looking at antecedents associated with cannabis cessation pale in comparison to the number of studies that look at antecedents associated with cannabis initiation (Sussman, Stacy, Dent, & Simon, 1996), leading to development of prevention (but not cessation) programming. Furthermore, research on evidence-based cannabis cessation programs are tailored toward heavy and dependent cannabis users (Boyd et al., 2005), and most of those studies focus on adults (eg, Davis et al., 2014).

Most cannabis users have attempted to quit at least once on their own and have failed (Copersino et al., 2006; Weiner, Sussman, McCuller, & Lichtman, 1999). While cessation rates among regular cannabis users trying to quit is similar to other substances (only around 25% after three months on average; Sussman et al., 1996), research has shown that prolonged cannabis use can induce some negative general health, psychological, and behavioral consequences (Van den Bree & Pickworth, 2005). For youth, the decision to quit using cannabis may not typically occur until a formalized institutional program is forced to intervene.

Further discussion is warranted regarding the differences between those who choose to quit on their own (self-initiated) and those who quit via more structured programs. Experimentation with cannabis oftentimes begins at adolescence, and becomes habitual by early adulthood. Research that compares adolescents who continue prolonged use of cannabis with other users that stop using cannabis will help tailor more effective adolescent cannabis intervention programs, and will create a better understanding of how social contextual variables might assist in cessation. Relatedly, perhaps the success and failures of cessation are not only dependent on the context of how cannabis intervention programs are implemented, but also on the characteristics of individuals and their surrounding environment.

The present chapter focuses on identifying the antecedents associated with self-initiated cannabis cessation in adolescents and emerging adults (ages 11–25). Self-initiated cessation or "self-managed change" can be defined as individuals who do not seek any sort of formal treatment (eg, clinical, school-based interventions, internet interventions), but rather, attempt to quit in the real-world setting (Rooke, Norberg, & Copeland, 2011; Hughes, Peters, Callas, Budney, & Livingston, 2008). We will discuss the intrapersonal and extrapersonal factors that contribute to why some adolescents are more likely to quit cannabis on their own using the theory of triadic influence (TTI) as a guide. Furthermore, we will describe the implications of these factors on formal cannabis cessation programming and on sustained cessation.

THEORY OF TRIADIC INFLUENCE AND CANNABIS CESSATION

The theory of triadic influence (TTI) was first developed to explain experimental substance use, including cannabis use (Petraitis et al., 1995). TTI posits there are three levels (or streams) of causation that influence behavior: intrapersonal, cultural/attitudinal, and interpersonal levels (Little et al., 2013; Petraitis et al., 1995). These three levels of causation are further delineated as ultimate causes (ie, factors beyond the individual's immediate control), distal factors (ie, factors dealing with the interaction between the individual and his immediate social environment), and proximal factors (ie, factors directly related to the immediate decision-making process of a particular behavior, which are usually less stable and more interchangeable; Flay, Snyder, & Petraitis, 2009). The constituents of this theory may be viewed from the lens of facilitating or deterring cannabis use. This theory is used as a heuristic for placing predictors of self-initiated cannabis cessation into a conceptual framework (Table 107.1).

[a]A literature search was conducted for data based on self-initiated teen cannabis use cessation papers published up to July 29, 2014 using the following databases: Google Scholar, PubMed, and OvidSp Medline. Different combinations of the following keywords were used in our search: cannabis cessation, marijuana cessation, adolescent(s), emerging adult(s), self-initiated, self-managed, non-treatment seeking. Our literature search yielded a total of 239 papers. After initial review of the paper title and abstract, duplicate papers and papers that were not specific to adolescents or emerging adults and non-treatment seeking cannabis cessation were removed. Only 6 papers remained relevant to the current review topic. These papers are signified by an asterisk (*) where they appear in the "Reference" section.

TABLE 107.1 Triadic Theory of Influence Matrix on Cannabis Cessation

Level of influence	Types of influence		
	Intrapersonal	**Cultural/attitudinal**	**Interpersonal**
Ultimate	*Definition:* Biological and/or personality attributes that influence the individual's self-efficacy to quit cannabis use	*Definition:* Characteristics of the individual's immediate environment that shapes attitudes towards cannabis cessation	*Definition:* Characteristics of the people that comprise the adolescent's most intimate social networks
	Constructs: Neurobiological (eg, positive and negative affect)	*Constructs:* Large social environment (eg, neighborhood/community (dis)approval of cannabis use and cessation), Neighborhood safety (ie, possibilities for victimization)	*Constructs:* Familial interactions
Distal	*Definition:* Psycho-physiological factors that motivate an individual to discontinue cannabis use	*Definition:* General values and behaviors an adolescent has that influences attitudes towards cannabis cessation	*Definition:* Social interactions between adolescents and their social networks (ie, role models) that encourage cannabis cessation
	Constructs: Self-image, deviancy, decision-making[a] (eg, avoidance and confidence)	*Constructs:* Acculturation, emerging adulthood (eg, vocational, education, family[b]), attitudes toward consequences of cannabis-related behavior, pro-drug use myths	*Constructs:* Peer social norms, peer (dis)approval of cannabis use and cessation
Proximal	*Definition:* Belief about ability to quit cannabis use	*Definition:* Subjective beliefs and evaluations about the costs and benefits of using or not using cannabis	*Definition:* Norms associated with cannabis cessation and pressure to use or quit
	Constructs: Self-efficacy to quit using cannabis	*Constructs:* Expected costs and benefits of using or quitting cannabis	*Constructs:* Desire to conform with others (eg, peers and role models)

This table lists the identified predictors associated with cannabis cessation within the framework of the triadic theory of influence.
Notes:
[a] *Considered as a coping style, facets of decision making are placed into the intrapersonal stream of TTI. Considered as a process of evaluation, other facets of decision-making might be placed into the cultural/attitudinal stream.*
[b] *Resolution of EA when one begins to establish a family would be considered a cultural/attitudinal variable according to TTI, whereas the quality of family attachments created would be considered an interpersonal variable.*

INTRAPERSONAL PREDICTORS

Intrapersonal predictors are biological and/or personality attributes influencing the individual's self-efficacy to avoid or use cannabis (Little et al., 2013, Petraitis et al., 1995). Intrapersonal factors include an individual's neurobiological systems (ultimate), self-image, and deviancy (distal), and establishment of cognitive functions (distal). The quality of development of neurobiological systems and cognitive function during childhood and adolescence can be shaped to help maximize social and emotional competence, which are influential in the self-regulation processes to help one quit cannabis use (Riggs & Greenberg, 2009). Also, it is plausible that subjective ability to refuse cannabis offers may be related to maintenance of self-initiated quitting, as a proximal intrapersonal factor (Petraitis et al., 1995), though no empirical studies exists on proximal factors and self-initiated quitting among adolescents.

Neurobiological

Youth susceptible to the positive reinforcing effects of cannabis may find it more difficult to quit using on their own. The potentially key active ingredient in cannabis, Δ^9-Tetrahydrocannabinol (THC), binds to cannabinoid receptors in the central nervous system, which leads to an altered psychological state of heightened perception or a "high" (APA, 2013). Positive affect associated with cannabis include feeling relaxed and calm, more sensation, reduced stress, mood enhancement (eg, evokes positive feelings and diminishes negative feelings), heightened sense of humor, and gaining insight/personal development (Iversen, 2003; Sussman et al., 1996). The positive affect(s) elicited during cannabis use may be a fortifying factor in cannabis (psychological) dependency. For those who initially obtain positive effects from use, subsequent adverse effects of cannabis use, such as anxiety, dysphoria, social withdrawal, impaired memory, paranoia, and possibly laziness or sleepiness (Sussman et al., 1996) may be a contributing factor in the decision to quit (Iversen, 2003). That is, subjective negative costs associated with regular use may lead to quitting.

Negative reinforcing effects (eg, withdrawal symptoms) may also apply to maintenance of cannabis dependency. Not surprisingly, frequency of cannabis use is a strong predictor of whether or not one will self-initiate cannabis cessation (Sussman & Dent, 2004; Chen & Kandel, 1998; Little et al., 2013; Kandel & Raveis, 1989; Rooke et al., 2011; Van den Bree & Pickworth, 2005). Less

frequent cannabis use leads to higher likelihood of successful quitting. Dependent users are relatively more likely to enter a formalized program and possibly seek out self-help groups (eg, Marijuana Anonymous; MA—Marijuana Anonymous, 1989), and are often sent to rehabilitation programs by an authority figure (eg, judge, teacher, family member; Rooke et al., 2011). After a half century of debate over the topic (Budney, Novy, & Hughes, 1999; Sussman et al., 1996) among clinicians and researchers, the *Diagnostic and Statistical Manual for Mental Disorders, Fifth Edition* (DSM-5) now acknowledges the existence of cannabis use withdrawal symptoms generally among heavy and prolonged users (eg, irritability, anxiety, sleep problems, decreased appetite, restlessness, depressed mood, and pain, such as headache or abdominal, and shakiness; APA, 2013). At least 50% of those adolescents and adults in treatment for cannabis dependence report such symptoms, which last up to 2 weeks (APA, 2013). Thus, at high levels of use, withdrawal symptoms may exist and cannabis users may wish to avoid them, making quitting more difficult.

Finally, cannabis may not be the drug of choice among some youth; that is, there may be individual difference moderators of whether or not youth will continue using cannabis. In a study by Chen and Kandel (1998), those who were depressed or expressed more depressive symptoms as an adolescent were more likely to self-recover from cannabis use later in life. Although the reasons for cannabis cessation among depressed individuals in the study was unclear, the authors posit cannabis may not provide the same psychoactive benefits, or "high," sought by their nondepressed counterparts, and were more likely to progress from cannabis to other illicit drugs (Chen & Kandel, 1998). However, other studies have found contradictory results—depressed individuals were more likely to continue using cannabis and were more likely to relapse after quitting (Rooke et al., 2011), possibly experiencing self-medicating benefits of use. Clearly, more work is needed on how aspects of depressed mood might be predictive of self-initiated cessation.

Self-Image and Deviant Behavior

Individuals who are concerned with their self-image are more likely to stop using cannabis (Sussman & Dent, 2004). This may be associated with the belief that engaging in cannabis-related behaviors may be linked with negatively perceived social labels. Self-image can be both a construct of individual perception and one's interaction with his or her social environment. In a study assessing factors predicting cannabis cessation, two of the top six social images identified by high risk youth were negative (eg, "silly," "spaced out"); however, it is important to note that adolescents continue to identify with perceived positive social images associated with cannabis use (Weiner et al., 1999).

Deviance is also correlated with self-initiated cannabis cessation in youth. Individuals who have a history of drug-related problems and legal issues are less likely to quit on their own (Sussman & Dent, 2004; Van den Bree & Pickworth, 2005). Those who show a pattern of delinquency may find themselves in a continuous cycle of drug exposure; for example, selling drugs, buying drugs, and using drugs. Conversely, those who are aware of and concerned about the consequences of cannabis use (eg, "getting in trouble," "jail," and "probation") are more likely to discontinue using on their own (Sussman & Dent, 2004; Van den Bree & Pickworth, 2005; Weiner et al., 1999). For these individuals, the consequences associated with cannabis use may outweigh the benefits.

Cognitive Processing

Those who have better executive cognitive processing (eg, attentional processes, planning) are less likely to continue cannabis use. Cognitive processing can be explicit (more conscious) or implicit (more automatic) (Sussman, Sun, Rohrbach, & Spruijt-Metz, 2012). Cessation is dependent on a deliberate or explicit effort to remove oneself from the stimuli that may trigger cannabis use (Rooke et al., 2011). For individuals who choose to self-manage quitting, mindful action to stop using are first steps to cannabis use reduction and cessation.

Decision-making is an explicit, deliberate, executive cognitive process that influences the decision to stop using cannabis. Individuals who exhibit higher avoidant and/or confident decision-making skills are more likely to quit on their own (Little et al., 2013). Though seemingly contrary decision-making styles, being decision-making avoidant and decision-making confident serve similar roles in cannabis cessation. Individuals who are decision-making avoidant tend to avoid making high-risk decisions, and are more risk adverse than their nonavoidant counterparts (Franken & Muris, 2005; Maner et al., 2007). Prolonged cannabis use may be seen as being of high risk, and may comprise unforeseeable consequences the decision-making avoidant individual may want to avoid.

Decision-making confidence is defined as exhibiting confidence in the decisions one makes (Mann, Harmoni, & Power, 1989). Individuals who perceive themselves as decision-making confident tend to be independent and decisive of their resolutions, and are happy with the choices they make (Paese & Sniezek, 1991). Individuals with a confident decision-making attitude may be less likely to seek or need the help of formal treatment programs because they believe they have the inherent competency to quit.

CULTURAL/ATTITUDINAL

Cultural/attitudinal predictors of self-initiated cannabis cessation include such variables as the large social environment (ultimate), acculturation (distal), emerging adulthood (distal), perception of pro-drug use myths (distal), and attitudes towards negative consequences of cannabis use in the short-term and long-term (distal). Inputs from ultimate (eg, large social environment) and distal (eg, acculturation) variables are influential in proximal cultural/attitudinal factors associated with quitting, which are the subjective beliefs and evaluations about the costs and benefits of using or not using a particular drug (Petraitis et al., 1995).

Larger Social Environment

A safe neighborhood social environment may facilitate a shorter duration of cannabis use. For example, individuals who report being relatively less victimized are more likely to quit (Sussman & Dent, 1999, 2004). One may speculate that those who are victimized seek the help of cannabis to cope with experiences of victimization (and this may occur in locations where cannabis is relatively widely distributed), whereas those who feel less victimized may be surrounded by a more protective and more encouraging social context that discourages cannabis use.

Social environmental-level variables may interact with intrapersonal-level variables to impact self-initiated cessation. For example, decision-making avoidant individuals tend to let others make decisions for them or go along with the decisions of the people they are surrounded by; thus, depending on the larger social context within which their family members, peers, and neighbors reside, self-initiated quitting may be greater or might be less likely. If persons live in a neighborhood that strongly disapproves of drug use or generally does not use drugs, then they are more likely to disapprove of and stop using cannabis (Rooke et al., 2011).

Acculturation

One's social environment is shaped in part by how acculturated one is within his or her community, which can serve as a protective or risk factor for cannabis use. Acculturation occurs when an individual becomes integrated to the mainstream values of the society he or she has entered. That is, there is a multi-dimensional process of blending one's own ethnic heritage with that of a new culture where the values of one's "home" country are joined with or replaced with new-country values and beliefs (Schwartz, Unger, Zamboanga, & Szapocznik, 2010). If the home country tends to be less favorable towards regular cannabis use than in the new country, then the less acculturated one is, the more likely one is to quit (Little et al., 2013). For example, there may be inherent factors present in some non-American cultures that prevent prolonged cannabis use (Lac et al., 2011). As a more specific example, Latino adolescents are more likely to self-initiate cannabis cessation than Whites in southern California (Sussman & Dent, 2004), possibly reflecting differences in culture. Values associated with family cohesion in the Hispanic culture may foster family and neighborhood bonding and increased parental and neighbor monitoring, which may divert the individual away from continued use of cannabis (Lac et al., 2011). Conversely, American culture may be more accepting of drug use and may create environments in which drug exposure is more common, especially since cannabis became legal in two states in the United States (Washington and Colorado; Donlan, 2013) and medical use of cannabis is widespread. For these reasons, the more acculturated one becomes to American culture, the more likely one's beliefs and values towards cannabis may adapt to tolerate its use.

Emerging Adulthood

Emerging adulthood (EA) is defined as a distinct time period between the ages of 18 and 25 where individuals transition from adolescence to young adulthood. During EA, individuals have the freedom to explore values and beliefs in their lives distinct from previously identified authority figures in childhood and are not confined to the limitations associated with adulthood. EA is characterized by five areas of development: (1) establishing one's own identity, (2) a time of feeling in-between, (3) a time of being self-focused, (4) a time of believing there are endless possibilities, and (5) a time where lifestyle is one of instability (Arnett, 2000). Perhaps the most important aspect of cannabis cessation associated with EA is how strongly an individual feels the current period of his life is a time of experimentation. Those who treat EA as a period to maximally experiment with individual lifestyles (eg, adhere to such expressions as "You Only Live Once" or "YOLO") are relatively less likely to quit (Little et al., 2013; Sussman & Arnett, 2014).

There is a strong association between older age and self-initiated cannabis cessation; many adolescent cannabis users tend to stop use around their mid-to-late twenties as societal roles of adulthood become relevant (Chen & Kandel, 1998; Kandel & Raveis, 1989). Those that hold traditional values consistent with mainstream societal norms are more likely to self-initiate cessation. For example, these individuals are motivated to quit to avoid testing positive on a drug test at work, and believe that using cannabis may pose vocational problems or prevent them from obtaining a job (Sussman & Dent, 1999, 2004;

Weiner et al., 1999). Individuals who are goal oriented (eg, have higher job aspirations or are actively seeking employment, who seek higher education or hold a degree higher than a high school education) are also more likely to discontinue use (Chen & Kandel, 1998; Sussman & Dent, 1999, 2004; Weiner et al., 1999). The duties established in adult life may act as other stimuli that detract from persistent cannabis use.

Perhaps the most influential EA event that determines whether one will self-recover from cannabis use is having a child or children. The construction of one's own nuclear family creates a socially defined "adult" role in which perceived acceptability of substance use may become rejected. This is particularly true for females who are about to embark on motherhood. When a female becomes pregnant, she usually quits using for fear of hurting the fetus (Chen & Kandel, 1998). Also, males who have children or are becoming a parent for the first time are also more likely to quit than males without children (Little et al., 2013; Kandel & Raveis, 1989; Sussman & Dent, 1999, 2004). Having a family (ie, marriage and becoming a parent) can be considered adaptive life strategies that may motivate individuals to quit and reinforce the quitting process (Rooke et al., 2011).

Attitudes and Pro-Drug Use Myths

Attitudes regarding the harmfulness of using cannabis are predictive of self-initiated cannabis cessation. Some studies have found that adolescents who believe cannabis is harmful to one's health are more likely to quit (Copersino et al., 2006; Sussman & Dent, 2004). In a study by Kandel and Raveis (1989), adolescents who later stopped using cannabis reported feeling healthier than young people who continued using cannabis. Additionally, individuals who have the attitude that it is wrong to use drugs (generally), and that it is wrong to use cannabis (specifically), showed shorter durations of cannabis use (Sussman & Dent, 2004). These attitudes may decrease the frequency of one's use and decrease the likelihood of socializing with people who approve of cannabis use because of the perceived consequences associated with the behavior.

Pro-drug use myths are inaccurate perceptions or expectancies related to drug use that individuals perceive to be true (Sussman & Ames, 2008). Those who hold more pro-drug use myths tend to believe their peers engage in similar cannabis-use behaviors, and expect the relative benefits of engaging in the behavior to outweigh the consequences of the behavior; for example, that smoking cannabis is relaxing (Kandel & Raveis, 1989). Those who endorse fewer pro-drug use myths—more accurate perception about the effects and consequences of drug and cannabis use—are more likely to stop using (Little et al., 2013; Sussman & Dent, 1999, 2004).

INTERPERSONAL PREDICTORS

Interpersonal predictors of cannabis use describe the microsocial environmental context through which individuals traverse. Self-initiated cessation may be influenced by perceptions or behaviors of the people who compose the adolescent's most intimate social support system (Petraitis et al., 1995). Salient adolescent interpersonal factors include peer social norms (distal), peer approval/disapproval of cannabis use (distal), and familial interactions (ultimate), which in turn affect proximal motivation to comply with significant others, or beliefs that significant others discourage cannabis use; that is, one may quit using cannabis to either fit in or please important people within one's social community.

Peer Influence

Peer norms and disapproval of cannabis are strong predictors of an individual's decision to quit using cannabis (Chen & Kandel, 1998; Kandel & Raveis, 1989; Little et al., 2013; Sussman & Dent, 1999, 2004; Van den Bree & Pickworth, 2005). If one perceives that one's friends believe there are negative consequences associated with cannabis use and disprove of cannabis-related behavior, then one is more likely to quit. Additionally, users who have friends who smoke cannabis less frequently, also tend to quit more so than those who have friends that smoke frequently (Sussman & Dent, 2004). These outcomes are consistent with other drug use cessation literature and social network analyses that emphasize the importance of peer influences on drug use behavior (Valente et al., 2007).

Youths who use cannabis solely as a social activity are more likely to quit than individuals who use cannabis alone (nonsocial use; Kandel & Raveis, 1989). Furthermore, those who perceive cannabis as a recreational activity are more likely to quit than individuals who experience and focus on the positive affect of cannabis use, for example, cannabis use is pleasurable, helps them feel more relaxed, and/or enhances sex (Kandel & Raveis, 1989). This finding is consistent with addiction literature that suggests once an individual is unable to choose the setting in which the drug use will take place (using perhaps more of necessity than recreationally), there has been a loss of control and a sense of compulsivity associated with the drug use (Sussman, Lisha, & Griffiths, 2011) (Table 107.2).

TABLE 107.2 Summary of Findings From Empirical Articles Included in the Review

Author name and year	*N*; age; follow-up	Definition of cannabis cessation	Analyses	Predictors of cessation
Chen and Kandel (1998)	*N* = 706; 15–16 year olds; 20 year follow-up	Having not use marijuana for the past year	Multivariate analyses of life event histories based on discrete-time methods.	Less marijuana use; older age; female; higher education; older age at initiation; more perceived harm of marijuana; used to cope; used socially; less delinquency; more depressive symptoms; became married; became parent
Kandel & Raveis (1989)	*N* = 1222; 15–16 year olds; 13 year follow-up	Having not use marijuana for the past year	Multivariate logistic regression	Less marijuana use; less illicit drug use; used marijuana for social reasons; excellent health self-rating; became married; lower household income
Little et al. (2013)	*N* = 522; 14–20 year olds; 1 year follow-up	Having not use marijuana for the past 30 days	Hierarchical logistic regression	Less baseline marijuana use; less peer substance use; less pro-drug use myths; believing that this was a time of life for experimentation (emerging adulthood)
Sussman and Dent (1999)	*N* = 566; 14–19 year olds; 1 year follow-up	Having not use marijuana for the past 30 days	Logistic regression	Older; less approval for drug use; negative drug use attitudes; less victimization
Sussman and Dent (2004)	*N* = 339; 14–19 year olds; 5 year follow-up	Having not use marijuana for the past 30 days	Logistic regression	Less baseline marijuana use; female gender; young adult; became married; less peer substance use
Van Den Bree & Pickworth (2005)	*N* = 13,718; 11–21 year olds; 1-year follow-up	Having not use marijuana for the past year	Multivariate logistic regression	Less delinquency; less peer substance use; more time spent doing activities with mother

This table provides a summary of the six empirical articles included in the review of the literature, organized around the Theory of Triadic Influence.

Family Influence

Compared to peer influences, parental and sibling influences play a minimal (or indirect) role in cannabis cessation. Contradictory studies show that living with both parents may be integral in self-initiated cessation (Sussman et al., 2012) or have no effect on cessation (Little et al., 2013). Yet, another study by Van den Bree and Pickworth (2005) show that parental bonding, especially for females, may play a contributing role in cessation. That is, girls who engage in activities with their mother are more likely to discontinue cannabis use (Van den Bree & Pickworth, 2005). Spousal interaction may also become influential in the cessation process as engaging in similar activities (ie, cannabis use) reinforces cannabis behavior (Chen & Kandel, 1998).

STRATEGIES NOTED TO HAVE BEEN USED FOR SELF-INITIATED CESSATION

Individuals who self-initiate cannabis cessation appear to employ several strategies for quitting. Most often, individuals divert their attention to other activities and remove themselves from social contexts that may encourage prolonged cannabis use (Boyd et al., 2005; Rooke et al., 2011). *Distraction* (ie, diversion, reinforcement of alternative behavior) and *stimulus removal* (ie, of cannabis and associated stimuli and contexts) are both strategies that help individuals quit, and have been found to be equally effective (Rooke et al., 2011). That is, individuals, on their own, will tend to keep busy doing activities generally incompatible with cannabis use, while, at the same time avoiding cannabis-related cues. Some distraction methods include exercising, seeking social support, and keeping busy (Hughes et al., 2008). Setting life goals, such as obtaining higher education, getting a job, and raising a family are all distraction methods that can deter cannabis use. Stimulus removal includes avoiding people who use cannabis, staying away from situations and environments where cannabis may be present, and throwing away all cannabis and cannabis related items from one's home (Rooke et al., 2011;Weiner et al., 1999). Early on in cessation, some persons may avoid other cues (eg, reading news items) related to cannabis use as well (Fig. 107.1).

IMPLICATIONS FOR FUTURE INTERVENTIONS

Identification of antecedents and strategies associated with self-initiated cannabis cessation has implications for future (formal and nonformal) intervention

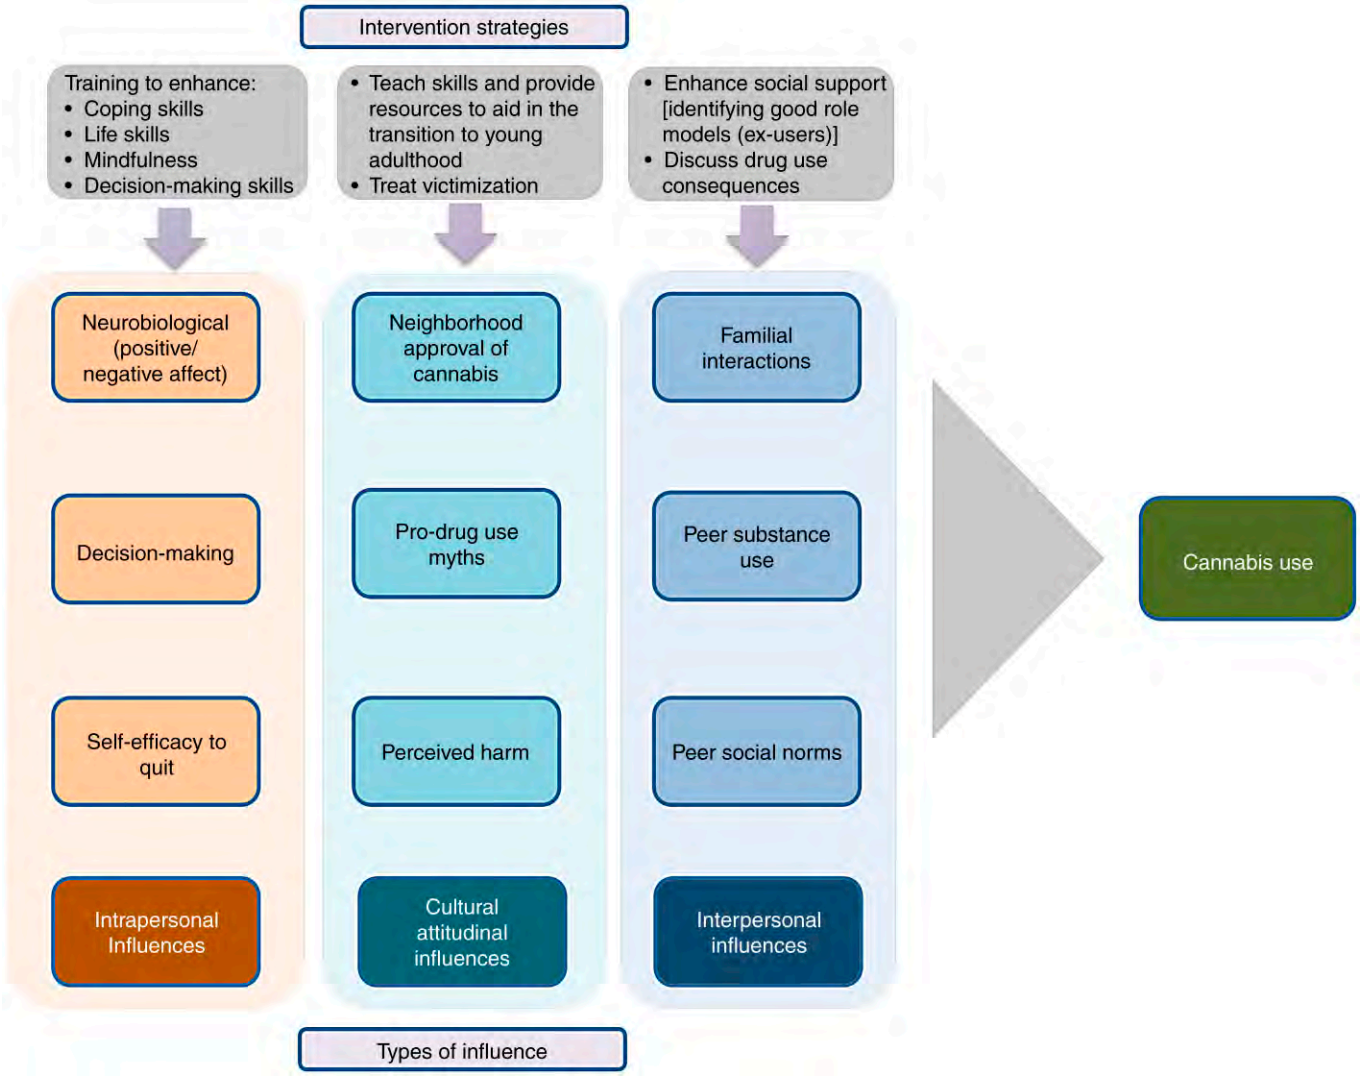

FIGURE 107.1 **Intervention strategies for self-initiated cannabis cessation.** This figure demonstrates possible intervention strategies for self-initiated cannabis cessation using the three streams of the Triadic Theory of Influence as a guide.

programs, and suggests successful programming that targets different streams of the TTI.

Intrapersonal Stream-Derived Interventions

Though much of the brain is developed during the childhood years (under the age of 5), neurobiological functions associated with emotional and social competence continue to be developed during the adolescent years (eg, understanding social cues, facial expressions, and stress adaptation). Adolescence is a critical time period for emotional and social processing that influences the ability to self-regulate one's behavior (Riggs & Greenberg, 2009). Knowing which of these neurobiological systems are most prominent in self-initiated cessation can provide an understanding of general tools necessary to quit. Introducing skills to cope with or reduce stress, such as coping skills, life skills, and mindfulness during childhood and throughout adolescence, may help individuals face stressful situations, and may aid in the quitting process (Sussman et al., 2012). Also, learning decision-making skills that may make one more risk-adverse or confident can have implications for current cannabis users – to lead them to avoid cannabis use situations and initiate distraction strategies, respectively.

Cultural/Attitudinal Stream-Derived Interventions

Cultural/larger social environments can be restructured to foster cannabis intolerant settings. Awareness of the inherent risks associated with acculturation implies the need to recognize the protective factors

for cannabis use associated with certain cultures (eg, family cohesion, parental attachment; Lac et al., 2011). Reinforcement of these cultural values can serve as preventive measures for prolonged cannabis use. Perhaps becoming more involved with one's ethnic culture may act as a distraction mechanism. Furthermore, prevention and/or treatment of victimization may be important to help individuals decide to quit using cannabis. Importantly, helping individuals define life goals and plan for the future, especially as one enters EA, can play a critical part in self-cessation. Introducing the concept of responsibility and learning skills and resources that will help individuals take on such responsibilities may assist in successful transition to young adulthood.

Interpersonal Stream-Derived Interventions

Social support for cannabis cessation, including promoting significant others to be good role models, and identifying good alternative role models, are important factors to be considered in informal future cannabis cessation. Generating discussions among adolescents and their peers about the consequences of cannabis use may discourage continued use, if carefully guided by a facilitator (Sussman & Ames, 2008). Teaching adolescents to be positive role models for their friends and children can cultivate a sustainable environment of cannabis disapproval, if established at a young age. Finally, future interventions should create an open dialogue between ex-users and adolescents about personal experiences associated with the drug. High-risk adolescents for drug use have reported they believe ex-users to be the most credible sources for offering advice on how to quit (Weiner et al., 1999). Interventions that introduce ex-users as positive role models can prompt adolescents to quit once they have seen others succeed.

CONCLUSIONS

Relatively little is known about the prolonged success and failures of self-initiated cannabis cessation. Most studies have been cross-sectional (Little et al., 2013; Sussman & Dent, 1999) or only of short duration (eg, no longer than five years; Kandel & Raveis, 1989; Sussman & Dent, 2004; Van den Bree & Pickworth, 2005), and only one study has looked at adolescent antecedents associated with cannabis cessation through young adulthood and adulthood (Chen & Kandel, 1998). Additional research is needed to determine whether self-initiated cessation is sustainable. For young persons who use cannabis regularly, and who seek the psychosocial benefits of cannabis use, quit attempts may be short lived (Table 107.3). Individuals who have psychological problems (eg, depression, anxiety, externalizing difficulties), and have problems coping with stressful situations are also more likely to relapse as they search for other outlets to cope with their problems (Copersino et al., 2006). Seeking out mental health resources may indirectly result in self-initiated cannabis use cessation. Research has suggested that prevalence of relapse in individuals who choose to quit on their own is much higher, compared to those who have participated in formal treatment (Rooke et al., 2011). Although most adolescents believe that quitting on one's own is the most effective means of achieving cannabis cessation, followed by clinical treatment (ie, "inpatient stay") and jail (Weiner et al., 1999), the susceptibility of nontreatment seeking adolescents to relapse suggest additional assistance may be necessary. On the other hand, while in-depth formalized treatments (eg, inpatient stays) may facilitate more sustained quitting, there is an increased likelihood young persons will become stigmatized through becoming officially labeled as a "cannabis addict." We speculate that a stepped-care approach may be most useful to adolescents, in which treatment begins with as informal an approach as possible.

In the past decade, self-reported cannabis use in adolescents has been on the rise (Johnston, O'Malley, Bachman, & Schulenberg, 2013), and recent legislative measures have placed cannabis in the forefront of political agendas (Donlan, 2013). A concern in most clinic-based programs is the ability to prevent relapse in clinical patients who must face the realities of life once they leave the clinical setting. However, with the study of self-initiated cessation, we at least begin to understand how young persons may manage, and have managed, these obstacles in the real world. This has implications for translational research practices, and may someday provide an evidence-based approach to generate more applicable settings and relatively informal means to assist with cannabis cessation in adolescents and emerging adults.

MINI-DICTIONARY

Acculturation A multidimensional process of blending one's ethnic heritage with that of a new culture where values of one's "home" country are joined with or replaced with new-country values.
Cultural/attitudinal predictor Cultural and attitudinal factors that influence one's subjective beliefs and values about cannabis use.
Decision-making avoidant A decision-making style where one prefers to avoid making high-risk decisions.
Decision-making confident A decision-making style where one exhibits confidence in the decisions one makes.
Emerging adulthood (EA) A developmental period that occurs generally between the ages of 18 and 25

Note: If discrepancy exists in the literature, the effect of the psychosocial predictor on cannabis cessation was evaluated based on whether more than two articles found the same effect.
This table provides a summary of the psychosocial predictors of cannabis cessation from the six empirical articles included in the review of the literature, organized around the theory of triadic influence.

where individuals transition from adolescence to young adulthood. EA is characterized by five areas of development: (1) establishing one's own identity, (2) a time of feeling in-between, (3) a time of being self-focused, (4) a time of believing there are endless possibilities, and (5) a time where lifestyle is one of instability.

"High." An altered psychological state of heightened perception that occurs as a result of cannabis use. This occurs (in part) when Δ^9-tetrahydrocannabinol (THC), an active ingredient found in cannabis, binds to cannabinoid receptors in the central nervous system.

Intrapersonal predictor Biological/personality factors that influence one's self-efficacy to avoid or use drugs.

Interpersonal predictor Social interaction factors that influence one's desires to conform to the social norms of the individual's immediate social circle.

Pro-drug use myths Inaccurate perceptions or expectancies related to drug use that individuals perceive to be true.

Self-initiated Cessation Self-initiated cessation refers to quitting without seeking formal treatment for cannabis cessation; that is, managing cessation in the real-world setting.

Theory of triadic influence (TTI) A theoretical framework developed by Petraitis, Flay, and Miller (Petraitis et al., 1995) that placed antecedents associated with experimental substance use into a theoretical framework.

CHAPTER

108

Treating Cannabis-Dependent Adolescents with Family Therapy: The case of Multidimensional Family Therapy

H. Rigter

Youth Interventions Foundation, Curium, Department of Child and Adolescent Psychiatry, Leiden University Medical Center, Leiden, The Netherlands

SUMMARY POINTS

- In adolescents, cannabis dependence often is part of multiple problem behavior. Treatment should focus on all problem behaviors to yield lasting effects on cannabis abuse and other behaviors.
- Cannabis dependent adolescents need treatment when there is a risk the condition will persist into adulthood. Risk factors for persistence are early start in life of cannabis use, and the combination of cannabis abuse with other problem behaviors.
- There is a range of cannabis treatments. The best treatment option for cannabis dependent adolescents consists in family/systems therapies, most notably Multidimensional Family Therapy (MDFT).
- An important feature of MDFT is its exceptional ability to interest adolescents and their parents to accept and follow the treatment. Key here are so-called motivational interventions, a rich arsenal of ways to enhance treatment motivation.
- MDFT is effective in populations with different ethnic backgrounds, and across countries (United States, Western Europe), despite huge variations in referral practices, treatment settings, and treatment policies.
- Implementation of a treatment program is hard work, requiring interventions at the levels of the therapist, the team, the treatment center, the funding agency, and local/regional and national policy makers. Each country has its own set of implementation challenges.

KEY FACTS OF CANNABIS DEPENDENCE

- Personal and social troubles of adolescents more strongly predict that they will develop cannabis dependence, than do the dose and potency of the cannabis preparation.
- At least half of cannabis dependent youth exhibit other problem behaviors as well, such as truancy, or criminality. Mental comorbidity is common.
- In many young adults, cannabis dependence dissipates without any treatment being given. However, in adolescents starting to take cannabis early in life, and showing other problem behaviors as well, cannabis dependence often persists, unless treatment is being offered.
- Cannabis dependence in youth is sensitive to treatment.
- Treatment works best if it takes into account the multiplicity of problem behaviors, rather than focusing on just one condition, such as cannabis dependence.

DO CANNABIS DEPENDENT YOUTH NEED TREATMENT?

This chapter focuses on adolescents, aged 12 through 18 years. Many youth experiment with taking cannabis, often occasionally but sometimes frequently. Across European Union member states and allied countries, at least 2% of youth consume cannabis daily or nearly every day (European Monitoring Centre for Drugs and Drug Abuse (EMCDDA), 2014a).

Frequent use of the drug does not necessarily lead to a cannabis use disorder, such as cannabis dependence. There is no simple dose-response relationship here. Personal and social troubles are stronger predictors of upcoming cannabis dependence than the number of joints smoked and the potency of the cannabis preparation are (van der Pol et al., 2013b).

Cannabis dependence may be transient. Over the years, many adults stop using cannabis or diminish their level of consumption on their own accord, without treatment. In a Dutch study, seven out of ten young cannabis dependent adults reduced their level of consumption of the drug in 3 years' time such that the diagnosis "cannabis dependence" no longer applied. Most of them had not sought any professional help (van der Pol, 2014).

In adolescents, however, cannabis dependence is quite persistent if starting at a young age and when combined with other problem behavior (Chassin, 2008; Hussong, Curran, Moffitt, Caspi, & Carrig, 2005). If untreated, cannabis dependence may affect education and life satisfaction levels of the users (Fergusson & Boden, 2008). When cannabis dependence might get persistent, treatment is to be recommended (van der Pol, 2014).

Frequent use of cannabis and cannabis dependence are associated with concurrent problem behavior, such as aggression, delinquency and truancy, and with mental comorbidity (Hussong et al., 2005; Phan et al., 2011; van der Pol et al., 2013a). Many young people with cannabis dependence are best described as youth with multiple problem behavior. Therefore, treatment needs to be multifocal, that is, it should not only address cannabis use, but other problems as well. The therapist may help the adolescent in reducing drug consumption, but if other problems as the ones mentioned are ignored, the youth will soon relapse into abusing drugs. For a treatment to be lastingly successful, it should target not just cannabis, but all major problem behaviors (Rigter et al., 2014).

So, cannabis dependent youth may need treatment. However, they rarely seek treatment on their own initiative. Treatment seeking for cannabis dependence is on the increase for adults, but less so for adolescents (European Monitoring Centre for Drugs & Drug Abuse, 2014a). In the five-cities European cannabis treatment trial INCANT—to be discussed subsequently—few adolescents sought treatment themselves. Quite a few youth in Brussels and Paris were referred to treatment by parents, one important reason in Paris being interim school reports warning their child might fail to pass to the next class at the end of the year (which, in Paris, would mean the young person would have to be expelled from school). One way to look at referral is by distinguishing externally coerced from noncoerced (self-determined) treatment seeking. Coercion is not only executed by Justice authorities, but also by treatment and care agencies or sometimes schools when the youth is sanctioned for not accepting treatment, such as "being kicked out." Coerced referral was common in The Hague (88%), Geneva (73%) and Berlin (54%), and uncommon in Brussels and Paris (Phan et al., 2011). Clearly, treatment and referral systems vary widely between countries. A positive outcome noticed in just one country cannot be taken as evidence for universal effectiveness of the intervention program concerned.

WHICH TREATMENTS ARE EFFECTIVE IN YOUTH WITH A CANNABIS USE DISORDER?

Adolescents with problem behavior can be treated individually or in groups of peers. Another treatment option is systems therapies, comprising family therapies as discussed in this chapter. Family therapies include sessions with the parents and with the family (parents plus youth), respectively, while other sessions—depending on the type of program—target the individual adolescent.

To reach youth who shy away from face to face treatment, treatment centers are experimenting with interventions to be offered on the computer or through internet. These interventions may be based on algorithms giving the youth access to information and to relevant tips to reduce substance use. Other interventions are similar, but allow for limited internet guidance by a therapist. According to a recent meta-analysis (Tait, Spijkerman, & Riper, 2013), such computer and internet assisted interventions are helpful in reducing cannabis use. However, the size of the effect is small—smaller than for treatments with face-to-face contact between user and therapist.

The cannabis users participating in the research studies analyzed were of all ages, but mostly adolescents and young adults (Tait et al., 2013). They were regular users of cannabis, often without clearly established cannabis dependence.

As for face to face treatment, interventions such as motivational interviewing, contingency management and cognitive behavioral therapy (CBT) should be mentioned. Elements of these approaches have been incorporated in family therapies. In adults, CBT appears to diminish cannabis and other substance abuse. This conclusion is tentative as an important part of the evidence relies on the outcomes of randomized trials in which CBT was compared with placement of persons on a waiting list (Davis et al., 2015), which is not top of the bill research methodology.

Also in adolescents, CBT may decrease cannabis and other substance use, but the evidence here is even weaker. Going from meta-analysis to meta-analysis, the balance for adolescent substance abuse CBT swings from effective to noneffective. Taken together, the verdict tends to be "effective" (Bender, Tripoli, Sartechi, & Vaughn, 2011; Waldron & Turner, 2008).

Family therapies are evidence based treatments for substance abusing adolescents (Baldwin, Christian, Berkeljon, & Shadish, 2012; Bender et al., 2011). In meta-analyses, these therapies as a group—data pooled for analysis purposes—are at least as effective as CBT in diminishing substance use. In trials directly comparing family therapy, such as Multidimensional Family Therapy (MDFT), with CBT, family therapy scored better in particular subgroups (the most impaired youth) and on several key measures. One example is a trial comparing MDFT with CBT. Both treatments helped adolescents to reduce their substance use as measured at 6-months follow-up, but the effect of MDFT grew stronger afterwards while the effect of CBT became weaker (Henderson, Dakof, Greenbaum, & Liddle, 2010).

Family therapies include MDFT, Multisystemic Therapy (MST), Functional Family Therapy (FFT) and Brief Strategic Family Therapy (BSFT). Analyses of pooled data indicate that these treatment programs are beneficial for adolescents in several ways. Cannabis consumption and other substance use decline. Delinquency, measured by the number of criminal offenses committed, decreases (Baldwin et al., 2012; Von Sydow, Retzlaff, Beher, Haun, & Schweitzer, 2013).

MDFT, MST, FFT, and BSFT have never been compared with each other in randomized controlled trials. The presently available meta-analysis data do not allow us to tell which family therapy works best (Baldwin et al., 2012). The EMCDDA decided to evaluate outcome data of cannabis treatment programs for adolescents using strict effectiveness criteria. This expert center concluded that only one treatment program met all criteria set, that is, MDFT (European Monitoring Centre for Drugs & Drug Abuse, 2013). A systematic literature review by the EMCDDA confirmed MDFT's value (European Monitoring Centre for Drugs & Drug Abuse, 2014b). The US Ministry of Health acknowledges just one family therapy as being helpful in combating adolescent substance abuse and other problem behavior, while being implementable in daily clinical practice. That family therapy was MDFT, http://www.nrepp.samhsa.gov/CERSeries.aspx.

The remainder of this chapter will focus on MDFT.

MULTIDIMENSIONAL FAMILY THERAPY IN A NUTSHELL

MDFT has been developed by Howard Liddle, presently at the University of Miami Medical Center, and his colleagues. It is a comprehensive, family-centered and developmentally-oriented treatment program for adolescents presenting with single or multiple problem behavior combinations of substance abuse, truancy and delinquency (Liddle & Rigter, 2013; Rigter et al., 2014). Mental and behavioral comorbidity is common among these youth.

Underlying theory in MDFT is the notion that an adolescent's problem behavior is multidimensionally determined, that is, is being shaped by factors from all major domains in the life of the youth. The first domain is the youth themselves: their personality, their experiences, their stage of development, their genes. The second one pertains to the parents, and the third one to the family: parents and young people in mutual interaction, possibly extending to other family members. The fourth domain consists of systems—social groups and structures—outside the family. Friends and peers of the youth are important. School, work, and leisure time activities do matter, as well. Police, Justice, and probation officers are also part of the fourth domain, especially when the young person has been arrested or convicted. In line with the distinction in domains, an MDFT therapist holds four types of sessions, that is, with the young person alone; with the parent(s) alone; with the family (youth and parents); and with representatives of other systems (friends, school mentor, etc.) present.

Aim of MDFT is to reduce substance abuse, to decrease antisocial behavior, and to prevent criminal recidivism, by achieving improvement in all four domains. The means to get these goals realized include the interventions listed in Table 108.1.

MDFT is carried out by certified MDFT therapists, who work in teams, one being the supervisor of the team. Training is practice-oriented, with the trainer regularly visiting the treatment center, and holding detailed consultation calls, and with the trainee sending in video-

TABLE 108.1 Main Interventions in MDFT

- Enhancing the motivation of the youth and parent(s) to accept and complete treatment
- Teaching the youth how to avoid and handle risky, problem behavior eliciting situations and how to be more selective in the choice of friends and leisure time activities
- Relapse prevention: helping the youth to resist substance abuse and crime provoking stimuli
- Improving family functioning and communication between family members, and resolving and preventing conflicts between parent(s) and their child
- Strengthening parental skills
- Outreaching interventions: the therapist contacts other systems as mentioned and wins support for arrangements (eg, adapted school program; or diverting the youth away from detention to community) that would benefit the youth.

tapes of treatment sessions in order to receive feedback and advice (Rigter et al., 2014).

MDFT is based on a manual, but is to some extent flexible. The therapist is expected not to just follow rules, but to take his or her own responsibility as well. On average, there are two sessions per week, for 4–6 months. The sessions take place at the therapist's office, or the family's home, or any other convenient place. Being an MDFT therapist means being the spider in the web for all treatment and guidance issues relevant to the particular young person and their family.

THE EFFECTS OF MULTIDIMENSIONAL FAMILY THERAPY

MDFT, delivered in outpatient settings, has been examined extensively in the United States. Eight randomized trials have been completed and another three are underway (Liddle & Rigter, 2013; Rigter et al., 2014). In these trials the researchers followed a methodologically strong approach by not comparing MDFT with an inactive control condition, but rather with active comparison treatments, namely:

- Youth: individual counseling,
- Youth: group counseling,
- Parents/families: group counseling,
- Youth: individual CBT,
- Youth: residential treatment.

An independent replication study has been carried out in Europe (2006–10). The study was named INCANT, the International Cannabis Need of Treatment trial (2006–10). It was set up on the initiative of government members of five Western European countries (Rigter et al., 2010). Subjects were 450 adolescents and their parents visiting treatment sites in Brussels, Berlin, Paris, The Hague, and Geneva (60–120 cases per site). The sites were quite different (Table 108.2), yet treatment results were similar.

INCANT was a randomized controlled trial with an open-label, parallel group design. The study compared 6 months of MDFT with individual psychotherapy, including CBT, at and across the sites mentioned. Assessments were at baseline and at 3, 6, 9, and 12 months after randomization. Fig. 108.1 shows the trial flow diagram. Note the low percentage of cases that were lost to 12-months follow-up (no more than about 10%); the data are strong because most study participants were willing to remain in the study. Of note, too, was the choice of the researchers to not exclude cases from the trial if not absolutely needed. The trial population reflected the diversity of adolescents and families seen in every day's clinical practice, which lends credence to the validity of the study outcomes. 85% of the INCANT adolescents were male. They all had a cannabis disorder, mostly

TABLE 108.2 Characteristics of the Treatment Sites in the International Cannabis Need of Treatment Trial

Site	Treatment sector	Location	Public or private
Belgium	Addiction care; mental health care	Brussels University affiliated outpatient clinic	Public MDFT funded by the federal government
France	Addiction care	Paris and suburbs Part of national addiction treatment infrastructure	Public MDFT funded by the federal government
Germany	Addiction care and youth care	Berlin Part of regional (state level) addiction treatment infrastructure	Public MDFT funded by federal and local governments
The Netherlands	Addiction care Forensic youth care	The Hague Part of national and regional addiction and forensic treatment infrastructures	Public Reimbursed by health insurance funds
Switzerland	Addiction care	Geneva Part of regional addiction and forensic treatment infrastructures	Public–private mix Mostly reimbursed by health insurance and social funds

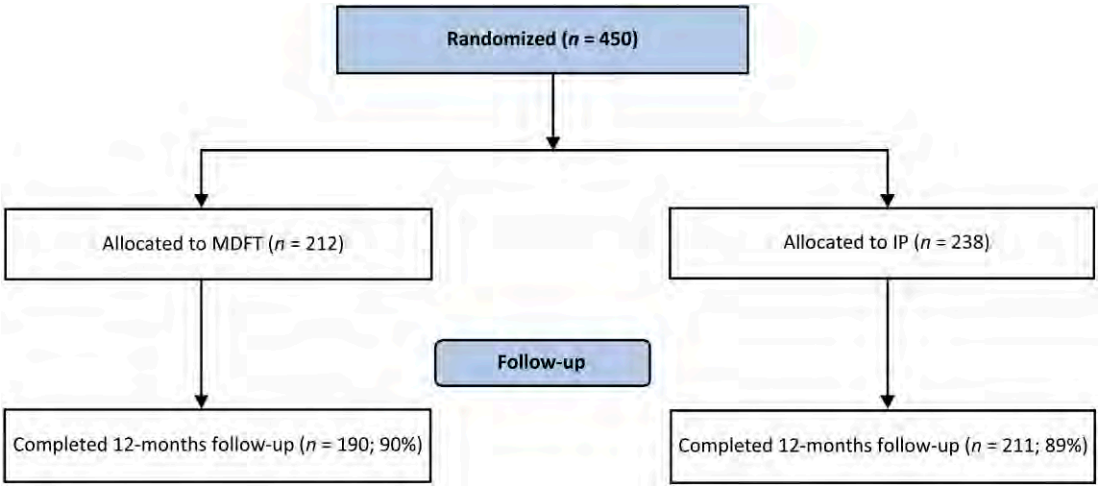

FIGURE 108.1 The International Cannabis Need of Treatment trial flow diagram. Across five West European sites, 450 adolescents plus one or both of their parents were included in the INCANT study, randomized across two treatment conditions and followed up for 3, 6, 9, and (shown here) 12 months. MDFT, Multidimensional Family Therapy; IP, individual psychotherapy (comparison treatment); *n*, the number of families. *Adapted from Rigter et al. (2011b). Copyright holder H. Rigter, the present author.*

(80%) cannabis dependence. One-third was delinquent (Phan et al., 2011).

INCANT trial outcomes included:

- The ability of European therapists to properly carry out MDFT,
- Treatment retention of adolescents and their parents,
- Treatment satisfaction,
- Reduction of cannabis-related problems,
- Reduction of criminality-related behavioral symptoms.

MDFT-trained European therapists scored well on measures of treatment integrity, also called "adherence," even somewhat better than American colleagues in US MDFT trials (Rowe et al., 2013). In INCANT, like in the US trials, MDFT succeeded in engaging and retaining 90% of the adolescents and their parents in treatment, while the corresponding percentage for the comparison treatment, with one exception, was two to three times lower (Rowe et al., 2013). Adolescents and parents were pleased with MDFT, more so than with the comparison treatment. Adolescents and parents agreed when rating treatment satisfaction. High treatment satisfaction scores predicted better treatment outcomes (Phan, 2014).

Following treatment, the diagnosis "cannabis dependence" became less prevalent. In MDFT, six out ten originally cannabis dependent youth were no longer classified as such 1 year after randomization. The comparison treatment was less effective in this regard (Fig. 108.2; Rigter et al., 2013). In addition, both treatments reduced rates of cannabis consumption. In adolescents who were the most severe users of cannabis at baseline—the "heavy cases"—MDFT outperformed individual psychotherapy, the comparison treatment, in decreasing cannabis use rates (Rigter et al., 2013).

As for so-called secondary outcomes, MDFT more than comparison treatment diminished symptoms of externalizing mental disorders, which are commonly seen as risk factor for developing criminal behavior (Schaub et al., 2014). The five European sites differed markedly in terms of addiction care, youth care, school policies and juvenile Justice procedures (Table 108.2; Rigter et al., 2011b). MDFT was effective in all settings and under all circumstances (Rigter et al., 2011a, 2013). One-third of the INCANT adolescents was part of an ethnic minority group. MDFT was effective regardless of ethnic background and also regardless of referral being coerced or not (Rigter et al., 2013; Schaub et al., 2014).

IMPLEMENTATION OF MDFT IN EUROPE

When the word of MDFT spread, therapists in the Netherlands wished to be trained in this treatment program. To this end, MDFT Academy was established in 2008. The Academy is now part of the Youth Interventions Foundation. In other words, a move was made from research to implementation. We shall address a few implementation issues here.

Accreditation

Increasingly, treatment programs need the green light of accreditation authorities and professional societies to

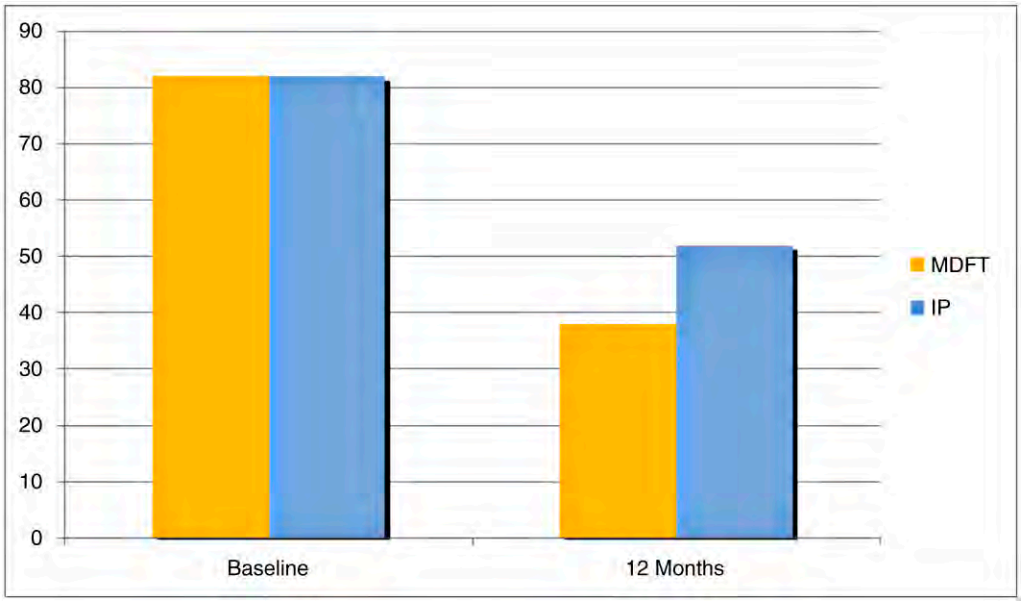

FIGURE 108.2 Multidimensional family therapy exceeds active comparison treatment in decreasing the rate of cannabis dependence. Proportion (percentage) of adolescents presenting with cannabis dependence diagnosis across treatment sites at baseline and 12-month follow-up. Results from the International Cannabis Need of Treatment trial trial. Proportion: percentage; MDFT, Multidimensional Family Therapy; IP, individual psychotherapy. *Adapted from Rigter et al. (2013), courtesy of Drug and Alcohol Dependence.*

get accepted and reimbursed as evidence based therapies. MDFT has been acknowledged and recommended by a number of US bodies, including the Substance Abuse and Mental Health Services Administration of the federal Ministry of Health (SAMSHA) (NREPP, 2014), and the National Institute of Justice (Crime Solutions, 2012). SAMSHA not only confirmed that MDFT is effective, but also selected MDFT as the only family therapy among five top treatment programs that "can be implemented with many different populations by providers of mental health and substance abuse services" (NREPP, 2014).

Accreditation of a treatment program in the United States does not suffice for European policy makers to follow suit. It needs to be proven that a treatment such as MDFT is effective and implementable in European context. INCANT provided the evidence. MDFT has now been accepted at the European Union level (EMCDDA, 2014b) and in several Western European countries. The highest hurdle to take was the Accreditation Committee of Behavioral Interventions, set up by the Dutch Ministry of Safety and Justice. This Committee uses ten accreditation criteria, requiring massive documentation. The treatment program needs to be effective and should be based on a convincing theory. Its target group—the persons to be treated—should be clearly delineated. Risk factors and protective factors should be spelled out and should be reflected in the treatment interventions to be undertaken. The treatment program should be phased, with motivating clients to accept and follow treatment at the beginning and offering aftercare at the end. Having a treatment quality assurance monitor is deemed essential. The Committee accredited MDFT in 2013. The accreditation status helped treatment centers to get MDFT reimbursed by funding agencies, such as health and social insurance companies.

Therapists

For a therapist, MDFT means breaking with old routines. From one session with the young person/family once every 2 or 3 weeks, to two or three sessions a week. From sessions exclusively held at the office of the therapist to sessions also in the family's home. From focus on just one problem behavior, such as cannabis abuse, to addressing all major problem behaviors and also family dysfunction. From being just one of the professionals helping the adolescent and the family to being the family's spider in the web. From working 9–5 to being accessible for the family also outside office hours.

One would expect that therapists would resist such changes in routines. Rather, therapists—more than treatment centers and policy makers—were the driving force in getting MDFT implemented.

Managers of Treatment Centers

Therapists may wish to change their ways, but they depend on the managers of their units. Implementation of a treatment program is bound to fail if managers are ignored or neglected. In MDFT, practitioners regularly visit the managers and convene meetings of managers to discuss issues that are relevant for their work.

Requirements for MDFT Teams

As said, MDFT therapists are part of a team. The team consists of 3 to 6 therapists, one being the supervisor. The team meets once every week or 2 weeks to discuss cases using session planning documentation, intervision, and videotaped recordings of treatment sessions. In addition, the supervisor carries out live supervision, that is, watching a session proceed by looking through a mirror screen.

Training

Candidate therapists and supervisors have a college or university education. They are psychologists, social workers, psychiatrists, and others, having at least a couple of years' experience in delivering psychosocial help and treatment to youth and families. The candidates are keen to learn, pragmatic, caring, nonjudgmental, energetic and skilled in communication. The supervisor must have leadership qualities. Training is given by certified trainers, recruited from the ranks of MDFT supervisors. At present in Europe, there are eight Dutch, two Belgian, three German, one French and one Swiss trainers.

Training to become a MDFT therapist or supervisor takes place in two 1-year steps. There is limited classroom (theoretical) training, namely 8 days in Year 1, followed by written exams. Training emphasis is on guiding therapists and supervisors on "the work floor," that is, in their daily clinical work. MDFT candidates videotape treatment and (supervisors) supervision sessions. The recordings are rated for treatment adherence and for treatment and supervision competence by the trainers and by independent evaluators, with ample feedback being given. The trainer regularly visits the team (site visits) for case review and live supervision. In addition, there are biweekly consultation calls between the trainer and the team.

At the end of Year 1, candidates (therapists and supervisors) passing certification requirements receive the MDFT Basic Level certificate. Training continues in Year 2, in a similar way with booster training sessions by top experts being added. At the end of Year 2, candidates meeting the requirements will be handed the MDFT Master Level certificate, which is valid indefinitely (Table 108.3).

Licensing

MDFT Academy will grant a free license to practice MDFT to teams having at least three Master Level certified members. Once every 3 years, the license is to be renewed, following an audit showing that the team is still doing fine.

Number of MDFT Teams in Europe

Between 2008 and 2014, close to 40 MDFT teams have been trained in the Netherlands or are still in training. Other countries are gearing up. Belgium has two teams, Finland nine, France four (with five more to come), Germany four, and Switzerland one. In 2015, five teams will be trained in Estonia. In the United States, approximately 60 MDFT teams are operational.

Innovation

MDFT is flexible. It allows for practice adaptations rendering this treatment program suitable for use in new target groups and in new treatment settings.

From the start, MDFT was an outpatient treatment program. It still is, but nowadays MDFT is also practiced in residential settings, such as Juvenile Detention Units in the Netherlands. Family oriented work (by all prison personnel) and MDFT are started right after the young person has been detained (Mos, Jong, Eltink, & Rigter, 2011). Sessions are held inside the Unit, during visiting hours of the parents, and during furlough when the young person is allowed to go home during weekends, initially under guidance, and then unguided. Sessions are frequent at the beginning of detention, infrequent in the middle part of detention, and increase in frequency a few months before the young person is being released. When the young person is free, MDFT continues for a while in an outpatient setting. Detention may take years. Therefore, detained/released young people may remain in MDFT treatment until the age of 23.

In the Netherlands, MDFT has also been adapted for use in residential youth care settings, targeting youth being placed out of home for any nonpenal reason (Rigter, Erftemeyer, & Mos, 2011a). In these settings, MDFT is applied to shorten residential stay, and to provide continuity of care for young people leaving the institution. One other application is to prevent residential placement at the last moment. Think of troubled families

TABLE 108.3 Requirements for Therapists Certified to Carry Out MDFT

- MDFT psychotherapists are *social workers, psychologists, or psychiatrists* with experience in treating youth/families
- The therapist is the key figure for the family for all problems (*spider in the web*)
- The therapist works in a *team* (3–6 therapists, one being the team's supervisor)
- *Caseload* at any given time: eight families per therapist
- The therapist is prepared to *leave the office* (eg, for sessions at the family's home), and to be contacted outside office hours
- He or she is interested in combining treatment and outreaching *case management*

with a young person to be placed out of home, with a juvenile judge's blessing, being offered the last-minute option of MDFT to avoid getting separated. In our initial experience in the residential youth care institute in The Hague in 2012, 81% of the families (youth and parents) concerned opted for placement-avoiding MDFT. MDFT healed families. None of the youth returned to be taken in after all. Preventing residential placement would save costs, adding to earlier findings that MDFT is a cost saving treatment program (French et al., 2003; Zavala et al., 2005).

Finally, MDFT has been adapted for use in youth with mild mental retardation. The effects of this application will be monitored in the next few years.

MINI-DICTIONARY

Accreditation Strict assessment of a treatment program by an authority, resulting in formally acknowledgment that the program is useful.

Cannabis dependence In DSM-IV, the most severe of the two cannabis use disorders, the other one being cannabis abuse. To classify for the diagnosis cannabis dependence, one must meet at least 3 out of 7 criteria relating to tolerance, withdrawal, inability to stop consumption, interference with daily activities and disruption of social life.

Certification Providing trainees with a diploma as testimony for having met the training requirements.

Domain Important and treatment relevant social realm in the life of adolescents. Domains include parents, family and systems (social structures) outside the family, such as friends, school, work, leisure time activities.

Evidence based Proof that a treatment program is consistently achieving its intended outcomes. There are "grades" of evidence. In this chapter, the term applies to the highest grade of evidence, with the judgment being based on practice-relevant data from at least several randomized controlled trials, involving active comparison treatments, with at least one trial having been conducted by researchers independent of the developers of the treatment program.

Family therapy A form of systems therapy. "Systems" include the family (the youth, his or her parents, other family members), but also other social structures (see Domain). Family therapy usually involves sessions with the parents and with the family (= youth plus parents). Some family therapies, such as MDFT, also have sessions with the youth alone.

Implementation Transferring insights from research to daily clinical and managerial practice through a diverse set of interventions at a variety of policy levels.

System A social circle, network. For instance, family, friends, school.

Treatment integrity Also called treatment adherence. The extent in which a therapist delivers the treatment properly, that is, according to preset specifications. This is assessed in MDFT by having treatment session tapes rated by independent staff. Also by having a trainer formally evaluate treatment competence, session planning, case assessment and the drawing up of the treatment plan.

Treatment program The word "program" signifies that the therapy is not just a single intervention, but an array of interventions, varying across stages of treatment and per domain and treatment goal.

Treatment retention The extent in which a youth and his or her parents accept the treatment offered and remain in treatment for a specified time or until a particular treatment goal has been achieved.

[§]Department of Psychology, Canik Basari University, Samsun, Turkey

SUMMARY POINTS

- Cannabis Use Disorder is a treatable psychiatric disorder; however, diagnosis and treatment can be a challenge.
- Cognitive Behavior Therapy (CBT) has no adverse effects, and can be combined with any other treatments of cannabis addiction.
- CBT is very effective in achieving abstinence and maintaining sobriety.
- Using CBT as a relapse prevention tool is known to increase the likelihood of maintaining sobriety and decrease the possibility of relapse.
- As much as its power, CBT seems to be underutilized in CUD and qualified therapists are scarce.

KEY FACTS OF CUD

- Because of the myths that cannabis is not harmful, even the users have problems they don't want to relate it with cannabis.
- Either because of that reason or because they are afraid of being stigmatized, patients have difficulty getting help from health care institutions.
- Treatment of CUD could be used as a prevention strategy from other substance use disorders.
- Lapse is inevitable in addiction of cannabinoids. But the lapse process can be used as an opportunity to hinder relapses.
- According to cognitive behavioral approach, because the use of cannabis is a learned behavior, it can be reverted.

KEY FACTS OF CBT

- The Cognitive Behavioral Model (CBM) doesn't see using cannabis as a personal trait, but as a behavior learned later in life.
- Learning which way to follow for not using cannabis, what may occur when the patient starts using cannabis again, and what are the harmful effects of cannabis may help patient quit using it more permanently.
- It is important for a patient to gain self-efficacy, learn how to deal with crisis, improving cognitive skills. It works better than stimulus control.
- It is scientifically proved that CBT techniques are effective not only in stopping using cannabis, but also in preventing relapses.
- Behavioral techniques aim at improving new behavior and attitudes that are incompatible with using cannabis. Once the behavior is changed, it can be reinforced by rewarding.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00127-7
Copyright © 2017 Elsevier Inc. All rights reserved.

- Cognitive techniques help the gained behaviors to become permanent. Otherwise, the learned behavior will be extinguished in time. If the patient is confronted with the stimulus that gives pleasure, addiction behavior may be reminded again.
- In high risk situations, the addicted person may think that everything is alright, but then the probability of using cannabis may rise again.

LIST OF ABBREVIATIONS

AVE	Abstinence-violation effects
BTs	Behavioral therapies
CBM	Cognitive Behavioral Model
CBT	Cognitive Behavioral Therapy
CNS	Central nervous system
CUD	Cannabis use disorder
HCV	Hepatitis C virus
SUDs	Substance use disorders
RP	Relapse prevention
THC	Tetrahydrocannabinol

INTRODUCTION

The word used for "cannabis" or "marijuana" is "esrar" in Turkish, has it is originated from Arabic meaning "mysteries, secrets" (Turkish Language Association, 2014). Cannabis is known to intervene with the normal synaptic effects of endogenous cannabinoids (endocannabinoid) along the reward circuitry which in turn disrupt memory and learning functions (Wolf, 2006).

Cannabis users tend to minimize, ignore, or completely deny the functional problems they face and which are associated with cannabis, and tend to continue using it. One of the most important reasons that the cannabis users are ambivalent to get help is the widely held opinion that the cannabis plant is not harmful as much as the other illegal addictive substances, which apparently can be regarded as a cognitive distortion. Every one person out of nine who tries cannabis may develop dependence, and also one in six people who try it in their teens have probably a higher risk of developing dependence (Wagner & Anthony, 2002; Hall & Degenhardt, 2009; UNODC, 2014). In addition, it has been suggested that cannabinoid use might be an independent factor in the development of mental disorders (Caspi et al., 2005). In the last decade, the demand to cannabis addiction treatment has significantly increased, especially in Europe, America, and Oceania (European Drug Report, 2013). Furthermore, it has been known that cannabis use increases the likelihood of codependence to both licit and illicit substances (Budney, Vandrey, & Fearer, 2011).

From a cognitive perspective, holding a belief that socialization could only be possible by using cannabis will cause addiction by decreasing self-efficacy (Witkiewitz & Marlatt, 2007). Unfortunately, living in an environment where the usage of cannabis is encouraged and confirmed, users tend to take risks in terms of health and having maladaptive cannabis related beliefs such as "Cannabis is not harmful for me, I'm impervious to it" that might be encouraging the use of cannabis, especially for teenagers and young adults (Connor et al., 2013). There may be different motivating factors to use cannabis: some of reported motives include enjoyment, feeling high, conformity, experimentation, social enhancement, getting rid of boredom, relaxation, and emotional regulation (Lee, Neighbors, & Woods, 2007; Zvolensky et al., 2009; Bonn-Miller, Vujanovic, & Zvolensky, 2008b). Conversely, cannabis use has been shown to be related with aggression, impulse control problems (Macdonald, Erickson, Wells, Hathaway, & Pakula, 2008), accidental problems (Asbridge, Hayden, & Cartwright, 2012), crime (Pedersen & Skardhamar, 2010), and sexually risky behaviors (Hendershot, Magnan, & Bryan, 2010; Andrea, Carroll, & Petry, 2013).

Cognitive Behavioral Therapy (CBT) is a well-defined and structured psychosocial treatment for cannabis-related disorders (Marijuana Treatment Project Research Group, 2004; Work Group on Substance Use Disorders, 2010; Sampl, Kadden, Hamilton, & Webb, 2002). CBT programs for Cannabis Use Disorder (CUD) have been suggested to be equally effective as other evidence-based psychosocial treatments in cannabis cessation (Hendriks, van der Schee, & Blanken, 2012). Evidence-based controlled studies have shown it to be more effective in maintaining sobriety (Nordstrom & Levin, 2007; Davis et al., 2015).

Modification of misbeliefs about the drugs achieved by CBT is assumed to help maintaining the sobriety state (Beck, Wright, & Newman, 1993; Wright, Sudak, Turkington, & Thase, 2010). So, CBT is considered superior to other treatments for Relapse Prevention (RP) in the treatment of SUDs (Witkiewitz & Marlatt, 2007). RP is based on cognitive skill development to lapse (a single instance) management for intervene relapse (problematic levels of use) (Marlatt & Gordon, 1985).

While CUD is a recurrent mental disorder as other Substance Use Disorders (SUDs) (Moore & Budney, 2003) with the help of improved self-efficacy, abstinence could be maintained (Stephens, Roffman, & Simpson, 1994).

In a more recent study conducted by Hoch et al. (2012), the effect of CBT was monitored in the third and sixth months in adults with CUD. The outcomes have indicated that CBT could be an effective treatment modality for achieving abstinence following both short-term and long-term cannabis use.

Evidence from numerous large scale trials supports the efficacy of CBT in SUDs, and larger treatment effect sizes were found for treatment of cannabis, followed by treatments for cocaine, opioids, and, with the smallest effect sizes, polysubstance dependence (McHugh, Hearon, & Otto, 2010). In this chapter, we would like to provide theoretical knowledge and practical advice for clinicians about Cognitive Behavioral Therapy approach in CUD.

CANNABIS USE AS A LEARNED BEHAVIOR

The Cognitive Behavioral Model (CBM) is not considered an alternative to the Neurobiological Model; these two models are complementary. According to both models, decreased tetrahydrocannabinol (THC) level in central nervous system (CNS) would trigger craving for cannabis (Marks, 2005; Wolf, 2006). Presumed changes that occur in the neurological pathway of reward circuitry could be underlying reason why individuals attribute positive thoughts to cannabis.

Learning Models

In view of CBM, addictive behaviors such as alcohol and drug dependence are acquired through experience. There are three suggested learning models in behavioral change: learning by association ("Pavlovian" or "classical" conditioning), learning by consequences ("operant" conditioning) (Kadden, 2001), and learning by expectancies (social learning) (Bandura, 1971). In learning by association, stimuli that are initially neutral can become triggers for cannabis cravings and repeated associations between those stimuli and cannabis use. Associations are reinforced with compulsive use, and would cause cravings. Cannabis use is also thought be reinforced by psychological factors well. An immediate result of cannabis smoking is decreased social anxiety and relaxation which could also play a role in positive reinforcement. As cannabis use reduces anxiety and tension, the contingency of the future use is increased. This process is called "negative reinforcement;" avoidance from cannabis withdrawal leads to continue using cannabis. Learning by expectancies and contribution of environmental factors to cannabis addiction is not well understood (Connor, Gullo, Feeney, Kavanagh, & Young, 2014).

Development and Maintenance of Cannabis Addiction

1. Predisposing factors. Having cognitive distortions in general (Leahy, 2003) or cognitive distortions specifically about cannabis (regarded as nonaddictive, herbal medicine, etc.) (Table 109.1), living in an environment that approves consumption of marijuana (environmental normalization), untreated psychiatric disorders, ongoing abuse of other substances, presence of psychosocial stressors, poor coping skills, social isolation and lack of a good support system (Witkiewitz & Marlatt, 2007).
2. High risk situations (HRS) might be environmental (cue objects, triggering events and places, or family members one uses with regularly) or individual (thoughts, emotions, or attitudes) (Witkiewitz & Marlatt, 2007). Being exposed to environments

TABLE 109.1 Cognitive Distortions About Cannabis Examples Are Given

Cognitive distortions[a]	Example
Control fallacy	"I am not addicted to cannabis, if I really want I can quit"
Selective abstraction (tunnel effect)	"Calm down there is no harm in it" "I won't become an addict" "No matter how much I smoke it doesn't bother me" "Only the weak become addicted" "If I don't smoke cannabis I can't relax"
Polarized thinking	"Cannabis is the only friend I have"
Minimization (negative effects of cannabis)	"Cannabis is not harmful to me" "No bad comes from use only once"
Magnification (positive effects of cannabis)	"I can't be happy/enjoy myself without cannabis"
Personalization	"My neighbor was rude to me because I am an addict"
Excuses	"I can't help myself, I just need to smoke cannabis" "I am a victim of my pothead friends, it is their fault"
Ignoring the evidence	"You can't quit once you became addicted "
Stigmatism	"I am a pothead" "I am a failure"
What if ?…	What happens if I don't quit? "I will be homeless"
Discounting the positive	"I can quit smoking for three months but anyone can do that"
Should statements	"I should have been a better parent now...."
Overgeneralization and selective abstraction	"Nothing is more pleasurable than smoking cannabis"

[a] *Leahy, R. (2003).*

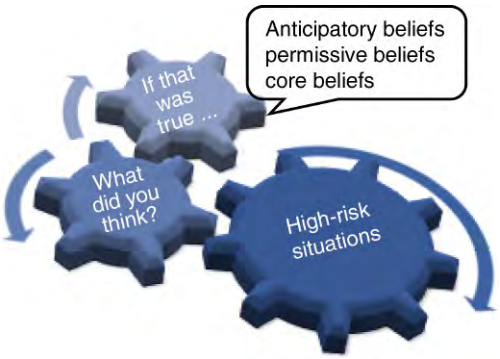

FIGURE 109.1 **High risk situations lead to change in internal states of cannabis addicted patients.** To learn the patient's beliefs, the therapist asks open ended questions "What did you think at that time?," complete the sentence "If that was true exactly…" (Vertical descendent method) (Leahy, 2003).

where cannabis is consumed, people who consume cannabis and any environmental cues could initiate the craving process. It is suggested that anticipatory beliefs will emerge when cannabis is being consumed, for example there might be cognitive distortions such as "smoking marijuana will make me look sexy"; therefore anticipatory thoughts might lead to permissive and core beliefs (Beck et al., 1993; Rangé & Mathias, 2012). An example for a permissive cognition would be "this actor smokes marijuana in every scene, and all girls are interested in him." High risk situations lead to change in internal state of cannabis addicted patients (Fig. 109.1).

3. Compulsive use usually reinforces existing precipitating, predisposing and perpetuating factors which lead to the emergence of automatic thoughts that intensify craving. Craving for cannabis follows a decision-making process about how to obtain the substance, and it is suggested that drug-seeking behaviors are controlled by automatic thought processes (Bowen, Chawla, & Marlatt, 2011).

APPROACHES IN CUD

CUD is a treatable chronic mental disorder. Comprehensive psychiatric interview and obtaining a detailed substance use history is crucial for early diagnosis.

Evaluation and Diagnosis

The interview about the history of addiction and diagnosis in CUD can be challenging for variety of reasons. Individuals might not be willing to admit their use, either because cannabis is illegal in most countries in the world, or because of the common cannabis-related belief is that is not a harmful substance (Pérez, Ariza, Sánchez-Martínez, & Nebot, 2010). As part of the evaluation it is important to focus on comorbid psychiatric or substance use disorders to determine the context in which cannabis may be used. It is common that cannabis is consumed as a self-medication for anxiety disorders, coping with stressful situations, or frequently for socialization (Zvolensky et al., 2009). Motivational Enhancement Therapy (MET) and Behavioral Therapies (BPs) facilitate establishing a rapport, and maintaining the therapeutic alliance (Sampl & Kadden, 2001; Nordstrom & Levin, 2007). Loss of functionality, spending large amounts of time and financial means in order to obtain or use cannabis, continued use despite the harmful consequences, and loss of control are some of the diagnostic symptoms (American Psychiatric Association, 2013). In cases of polysubstance abuse, withdrawal syndrome can overlap.

Comorbidity

It is known that cannabis abuse is a common comorbidity of depressive and anxiety disorders (Boden, Babson, Vujanovic, Short, & Bonn-Miller, 2013). Cannabis use and its association with psychotic syndromes have long been of academic interest (Griffin & Botvin, 2010). Codependence to other substances is common (Budney et al., 2011) (Bonn-Miller, Zvolensky, Bernstein, & Stickle, 2008a; Chadwick, Miller, & Hurd, 2013).

COGNITIVE-BEHAVIORAL APPROACH FOR CUD TREATMENT

CBT is designed to help patients to acquire certain behavioral skills to achieve and maintain abstinence. (Marks, 2005). CBT technique will focus on maladaptive thoughts which can be modified and, in turn, associated behaviors and emotions could be modified (Beck et al., 1993). Being an evidence-based approach, the CBT model has some unique advantages in addiction treatment since addictive behavior can also be empirically modeled as a learning model.

By definition, addictive behavior is resistant to change and recurrence is common. Stage of change, as defined by the Transtheoretical Change Model by Prochaska, DiClemente, and Norcross (1992), needs to be identified at the time of the initial evaluation. (Fig. 109.2).

During the remission phase, incidental use is usually considered as within the concept of "lapse," whereas going back to regular use is considered "relapse." As in other SUDs, CBT strategies are utilized during all three stages of CUD treatment, which are: preparation, achieving abstinence, and maintenance of sobriety

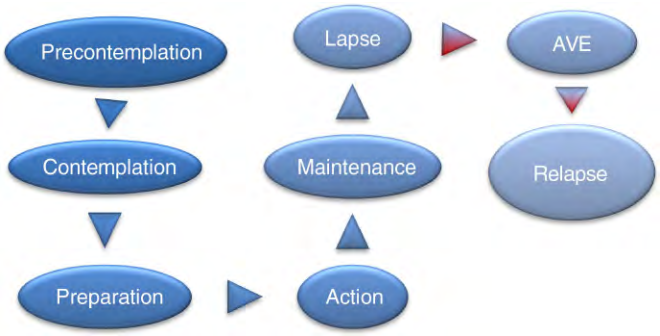

FIGURE 109.2 **Cognitive independence model.** The *red arrows* show that dealing with lapse and abstinence violation effects are two stages of change that will lead to be free from cannabis.

(Kadden, 2001). Main CBT principles to treat CUD are summarized in Table 109.2.

CBT METHODS FOR CUD

Establishing a therapeutic alliance is a priority. During an initial interview by using "guided discovery," a CBT method, the pattern of use and personal high risk situations (emotions, thoughts, attitudes, events, places) are determined. The suitable treatment method (group or personal therapy), intervals and duration of interview, targets of treatment can be assessed.

General principles of CBT will be applied to CUD, as it is applied to any other substance dependence. CBT can be used only by itself or along with medical treatment.

Seeing the Big Picture

Identifying cognitive distortions can help seeing the big picture. Patients usually have a variety of cognitive distortions about cannabis (Table 109.1) CBT techniques can be effectively used to modify cognitive distortions (Perkins, Conklin, & Levine, 2007). The therapist can start off by motivating the patient by sharing successful self-experiences, and positive outcomes in cannabis dependence therapy, as a technique used for improving self-efficacy.

The main initial target of the treatment is to achieve abstinence, and to make it as easy as possible for the patient. Using metaphors in therapy can be useful, as it would reduce the duration of sessions (Stott, Mansell, Salkovskis, Levander, & Cartwright-Hatton, 2012). While using metaphors, similar situations are used as examples to show the patient the connections between thought and behavior.

Cognitive Restructuring

In order to simplify the concept of cognitive restructuring, it might be useful to consider humans as living computers that consist of hardware and software. It is possible to terminate, uninstall, or even update a malfunctioning application that slows down the system. Updated applications can be considered similar to thought modification which can be used to modify cognitive distortions such as "there is no life without marijuana" can be modified with "marijuana is not a basic necessity."

Some of the methods (cognitive, behavioral, and emotional) that are used in cognitive restructuring are listed below (Marks, 2005):

Cognitive Methods

1. Assessing or interrupting negative automatic thoughts. Becoming aware of thoughts that involve in cannabis use.

TABLE 109.2 Main CBT Principles and Clinical Features of CUD Are Relatively Shown

Main principles of CBT	Clinical features of CUD
CBT is time limited and well-structured.	Difficulty of purposeful act, sense of time, memory and learning defects occur due to cannabis abuse.
It is individualized and reformulated based on patient's needs.	CUD has not only a heterogeneous clinic table but also a wide of range comorbidity.
It encourages the patient to ask questions of himself/herself.	Causes tendency of blaming himself/herself or significant others, finding excuses and wangling.
Patient shares the responsibility of treatment with the therapist.	Patient spends too much time to find and use cannabis, avoids and tries to delay responsibilities.
Can be put into practice with motivation enhancement techniques.	Patients usually don't accept change unless they face a critical problem.
"Quitting day" will be decided by patient and therapist together.	Cannabis cessation needs professional help, especially, in case of intensive and long term use.
Total abstinence is not a realistic target: increasing sobriety duration is the target.	Stimulus control is not always possible for user.

2. Understanding effective and self-beneficial explanations. Self-blaming is a sign of bad progress. It can be automatic, and can remain over time.
3. Self-imagine: learning to listen to the voice of a new person who don't use marijuana. Listening to the sound that would help you most. "Who do you want to be?"
4. Distraction: when exposed to high risk situations, distraction method helps immediately; but its effect is temporary.
5. Modifying maladaptive cognitive processes: maladaptive cognitions are modified with functional ones. For example, positive beliefs about marijuana can be modified by neutral or negative ones.
6. Focusing: choosing and managing what needs to be focused.
7. Imaginary: new behaviors can be imagined using past experience.

Behavioral Methods

1. Acceptance: quitting cannabis is a radical behavioral change.
2. Developing a negative attitude to cannabis: for example, the therapist can facilitate this by associating it with his/her respiratory system problems due to covered sensitization.
3. Becoming aware of the financial burden of the addictive behavior (Carroll et al., 2006).
4. Targeting the situations, habits, and environmental cues associated with cannabis use: alcohol, bong, friends using cannabis, and places where cannabis is used habitually.
5. Stimulus control: removing cannabis and triggering factors from sight.
6. Making an agreement: listing personal reasons for quitting cannabis use: individual and environmental disadvantages associated with the use (Litt, Kadden, & Petry, 2013).
7. Rewarding the behaviors: saving the money that patient would have spent on cannabis weekly or monthly, and using it for leisure (Stephens et al., 2002).

Emotional Methods

1. Relaxation exercises
2. Mindfulness-based relapse prevention
   a. Using mindfulness on a daily basis
   b. Using mindfulness activities for HRS (Bowen et al., 2011).

In CBT-oriented cannabis treatment programs, all methods should be individualized and tailored into patient's needs.

COGNITIVE BEHAVIORAL APPROACHES TO STAGES OF CUD

Regardless of the situation question needs to be asked: "What is the meaning of cannabis in you life?" should always be asked.

Preparation for Cannabis Cessation

Ambivalent patients may be using the substance as a way of dealing with the stressful situations, a coping strategy with unpleasant feelings, a way of spending time, or a break from stressful workloads. The ones brought by their family or referred for consultation by another doctor may not be ready for the treatment process. Psycho-education can be utilized as an effective technique with these patients. The cannabis users not aware of the negative effects of cannabis may think that using cannabis doesn't cause as much harm as smoking; but, for instance, if pregnant women are informed about the harmful effects of using cannabis in pregnancy, they may be kept away from using cannabis (Work Group on Substance Use Disorders, 2010). Educating the patients on withdrawal symptoms and reassuring them that these symptoms are temporary may also make a difference (Weinstein et al., 2010).

The Patients Who Are Ready for Change

As a first step, the patient's pattern of use should be questioned in detail. After that, patient and therapist can decide on a date together. Following detoxification, the next phase should be the Relapse Prevention (RP) process.

Maintaining Sobriety

In order to maintain positive behavioral change, the patient should be constantly motivated to stay in the RP stage. For the patients who are reluctant to ask for help, the therapist can use behavioral rehearsals (Wright et al., 2010). Social support has critical importance to recognize early signs of relapse (Bowen et al., 2011).

RP, developed by Marlatt and Gordon (1985) is widely used as a cognitive behavioral strategy. Relapse is not considered a stage itself but it's an unwanted return to an earlier stage from the maintenance or action stages. In the event of relapse, RP strategies and coping skills are likely to be compromised.

Intervention Strategies in "Lapse" Situations (Witkiewitz & Marlatt, 2007)

1. If behavioral techniques utilized during remission are compromised, the immediate result is usually "lapse," which is considered as an incidental use of substance without resuming regular dependence pattern. "Lapse" should be interpreted as an alarm signal.

2. "Lapse" as "mistake" is an opportunity for learning, therefore, focus on treatment can be resumed.
3. It may be difficult to remotivate the patient following a lapse. Focus should be given to take away the blame, if any, and reemphasizing the initial personal reasons for abstinence.
4. Possible reasons for lapse: HRS and triggering reasons for lapse should be questioned in detail, including the situation that it occurred, emotions and thoughts involved which can help further strengthening the RP strategies.
5. Preparing for immediate aftermath: note cards can be prepared for a crisis situation, including people to reach out, places to go. If possible, the clinician can allow the patient to contact him/her in the case of a lapse situation.

It is important to be aware of abstinence violence effects (AVE): cognitive restructuring period is a difficult process, and the general approach of the therapist should be gentle and considerate in a situation of a lapse. This kind of approach helps the patient focus on the crisis instead of regretting and blaming self.

Relapse Prevention Strategies (Witkiewitz & Marlatt, 2007)

1. Psychoeducation: teaching on relapse/lapse concepts, identifying early alarm signals, treatment plan in general (formulation).
2. It is asked from the patient to list HRS and managing techniques with them. The therapist should show how to do it in the session (role play).
3. Acquiring cognitive skills: setting boundaries in interpersonal relationships is important. Patients should also acquire communication skill of opposing insistences.
4. Realizing that emotions themselves and controlling reactions resulting from emotions should be considered differently.
5. Understanding cannabis craving: dealing with craving and exercising how to regain control of it.
6. Learning cognitive distortions and setbacks: helping the patient to modify cognitive perspectives for preventing relapse.
7. The ongoing medical treatment for other comorbid conditions and special situations should be taken into the consideration. Clinicians should also consider potential risks of co-dependence such as benzodiazepines and/or alcohol use.

CASE EXAMPLES

Establishing Therapeutic Alliance

A 32-year-old male photographer was referred to our clinic from the emergency room presenting with "Cannabis Related Problems." It was reported that while he was smoking cannabis he had a fall in his bedroom. The patient was brought to the hospital by his wife.

Dr Guven: Hi there, I hope you are doing better, I understand that you fell. I just wanted to let you know that urine toxicology came positive for cannabis. Is it possible that you were intoxicated with cannabis yesterday?

Patient: Yes, maybe.

Dr Guven: Would you feel comfortable talking about this?

Patient: Yes, we can do that.

Dr Guven: First off, I would like to ask you some questions about your past and current cannabis if that is okay with you. When was the first time you used cannabis?

Patient: About 10 years ago, I started sharing a joint with a friend. It eventually became a daily habit, I have been using regularly for about 5 years. I smoke a couple of joints a week.

Dr Guven: Okay, so how much exactly do you smoke daily?

Patient: Over the last few months I have smoked at least a joint almost every day. Some days two, other days up to four joints.

Dr Guven: It looks like you smoke more on some days than others. Any particular reason for that?

Patient: I don't know (smiles). If I don't smoke in the evening I can't sleep.

Dr Guven: So you have been using cannabis for sleeping? Is there anything else that marijuana helps you with?

Patient: I believe marijuana makes me creative.

Dr Guven: I understand that you think when you smoke marijuana you are more creative. Have you ever had a period when you remained abstinent for a while?

Patient: Two years ago I was preparing for my first photo exhibition. At that time I didn't use for three months.

Dr Guven: You said that cannabis makes you creative. I find it quite interesting that you didn't smoke cannabis while preparing for the exhibition.

Patient: I get handshakes when I smoke, so I try to be abstinent when I am preparing for exhibitions.

Dr Guven: I see, I would like to know you better in order to find out why this is happening.

Patient: How?

At the beginning their therapeutic alliance therapist (Dr Guven) suggested that they could work together to understand some of incomprehensible situations.

The session ended with a plan that focused on monitoring cravings until next follow-up (Table 109.3).

Unsuccessful Outcome

A 24 year old male university student who is studying Town Planning, living by himself in a metropolitan city. Initially using marijuana with friends at the weekends, he escalated to daily use over the past few months. As his use has increased, he has lost his interest in academics. Despite the significant increase in his use he reported less pleasure from smoking. He has noticed loss of excitement in relationship with his girlfriend and a decrease in socialization, if not associated with cannabis use. He was spending most of his money on cannabis, and he wasn't going out as often. He started to show problems with

TABLE 109.3 Cannabis Craving Diary Example

When?	What happened?	What did I think?	What did I feel?	Craving level (%)	What did I do?
05/05/14 Evening	I saw a bong on the shelf	I must not smoke marijuana anymore	Sad	80	Looking for some marijuana, automatically

his self-care. As his girlfriend started to worry about him, she decided to talk to his family about worsening functioning.

He was encouraged to enter our outpatient addiction treatment and was treated with the diagnoses of CUD and Psychosis NOS. However, he discontinued treatment against medical advice, within the third month of treatment. He continued thinking that he was not "addicted to" marijuana during this period. He dropped out from college. Within a year, he had a lapse when he was out. He thought that there was "nothing wrong" with taking just couple of puffs of at times. At that time he tried using synthetic cannabis. As his use escalated, he was brought to the psychiatric clinic by his family, but refused to enter treatment. With increasing pressure from the family and girlfriend, he decided to move in with his grandmother, who was then living in the suburbs.

After one year passed, he presented himself to our addiction center with request for help. Apparently he has been addicted to intravenous heroin, and was told that he contracted HCV. He reported that he started using heroin during a period when he was abstinent from cannabis, then he started using cannabis once a day to quit heroin, and ended up increasing both heroin and cannabis use. He apparently was able to remain sober from all substances for about 4 months; however, about 2 months later, he relapsed on marijuana and resumed his regular heavy use during an intense craving episode. He has succeeded in remaining abstinent from heroin since then, despite his strong cravings. He reported that he had increased cannabis cravings when he spent time in his bedroom where he used to use cannabis most of the time. Despite lack of full compliance with treatment recommendations, he shared how much he enjoyed applying some the techniques that he learned here in sessions (Table 109.4).

Successful Outcome

A 32-year old, high-school graduate single woman working as an accountant referred to our addiction services by the order of the traffic court, after she had a car accident and was found to have cannabis in her possession. She started using cannabis when she was in boarding school. At that time she was living away from her parents who lived in the suburbs. She was abstinent intermittently when her finances were not good. Eventually her use progressed to regular use, 3–4 times per week.

Dr Guven: My understanding is you have been sent here by the court with regards to your cannabis use. I am sure you are motivated to take care of the legal issues. Is there anything else that also could motivate you to quit using?

Patient: I guess, my parents would be very happy if I quit. I have caused enough trouble and worry for them.

Dr Guven: So you are saying that there may be more reasons to quit other than the legal trouble. That sounds wonderful.

Patient: I have been performing low in the past couple of months and was suspended from my job. I couldn't pay some of my bills, and asked help from my family. My parents refused to help me financially. I have had couple of no-shows lately, as well, because I would not wake up early following the nights that I smoke cannabis too much. My boss is also aware of my use, he suggested that he would be supportive if I seek professional help. My position at work is still vacant, and they are interested in having me back if I can get sober.

Dr Guven: That sounds like a good reason to quit. Anything else that motivates you?

Patient: I just don't want to lose everything. I don't want to be like my brother. His wife left him and his kid is now under legal protection because of his addiction problem. (tearful)

Dr Guven: It looks like you might be depressed about all this. Did you know that cannabis use commonly cause depression?

Patient: I guess it might be right. I am a little worried about losing some of my friends if I quit.

Dr Guven: Now, we will try to write down your reasons for quitting and the potential obstacles that could get in the way (Table 109.5). Perceived obstacles are usually maladaptive thoughts. If we work together, we can modify these thoughts.

TABLE 109.4 The Patients' Reasons and the excuses for not Using Cannabis Are Given

I don't want to use it, because…	I want to use it, because
It doesn't relieve me any more when I use it	It gives me pleasure
It makes me numb and I don't want to see anybody around	Helps me forget my loneliness
I need to see that I can give it up	It doesn't harm anybody
I want to say "no" when somebody offers me to use it	I am not addicted. I can use it whenever I want
I want to see what happens if I stop using it	My problems are not because of cannabis
When I am not awake I am losing my money and having economic problems	I can't sleep if I don't use it

TABLE 109.5 Reasons for Quitting Cannabis Use and Thoughts That Make Quitting Difficult Are Listed

Reasons	Obstacles
I may get arrested	Nobody can quit using cannabis
My family would be happy	I don't want to quit
I may lose my job	It makes me forget my debts
My coughing scares me	I can't sleep If I don't smoke

FIGURE 109.3 **Cannabis craving scale.**

I do think that some of this process has already started during this conversation. You remarked two different times about how much cannabis is making your life difficult and, in the beginning you gave it 30 points, which was increased to 60 points in the end (Fig. 109.3). As an assignment, you will list the events or situations in which your craving is triggered.

She completed 12 sessions carried out every other week. Before each session she gave urine toxicology tests part of the treatment contract. She has been sober for more than a year, and has founded the local chapter of "Marijuana Anonymous" in her hometown.

MINI-DICTIONARY

Attribution An individual's explanation why a result occurred.
Classical conditioning An originally neutral stimulus becomes a conditioned stimulus when paired with an unconditioned stimulus or with a conditioned stimulus.
Cognitive restructuring The general term applied to the process of changing the patient's thought patterns.
Contingency management This behavioral technique attempts to change those environmental contingencies that may influence substance abuse behavior. The goal is to increase certain behaviors that are incompatible with use.
Functional analysis A process used in cognitive behavioral therapy that probes the situations surrounding the patient's cannabis addicted.
Operant learning Refers to the process by which behaviors that are reinforced increase in frequency.
Social learning It occurs when individuals observe the behaviors in their own environment and at the end of a latent period, they finally obtain these behaviors by trial through some expectations.
Therapeutic alliance The development of a positive relationship between the therapist and patient.

Acknowledgments

First and foremost, I would like to thank The Head of Turkish Association of CBT, Prof Dr Mehmet Zihni SUNGUR and all other teachers who contributed to our knowledge. For translation of the chapter from Turkish to English I would like to thank Psychological Counselor Esra ALICI, Gülçin ŞENYUVA, Burcu SEVİM, and Sevgi KARADUMAN.

CHAPTER

110

The Cannabis Withdrawal Syndrome—Symptoms and Time Course

M. Hesse, B. Thylstrup

Center for Alcohol and Drug Research, Aarhus University, Copenhagen Department, Copenhagen, Denmark

SUMMARY POINTS

- The literature on cannabis withdrawal phenomena and symptoms shows a fairly consistent picture.
- With the publication of the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) in 2013, a cannabis withdrawal syndrome is now officially recognized with defined criteria.
- The cannabis withdrawal syndrome begins within few days after cessation or reduction of use, symptoms peak after approximately 10 days, and are generally gone after around 30 days.
- The time course of the cannabis withdrawal syndrome may vary due to a wide range of underlying biological and psychological mechanisms.
- Individual symptoms vary in terms of their onset, with some symptoms beginning immediately after cessation or reduction (eg, insomnia and nervousness), and others typically developing later (eg, irritability and vivid, unpleasant dreams).
- The problem of demand characteristics which can be explained as the totality of cues that convey an experimental hypothesis to the subject may
- Study findings speak against the significance of demand characteristics in determining the course of the symptoms of cannabis withdrawal.
- The withdrawal symptoms listed in the DSM-5 are not the only symptoms that have been studied in clinical and experimental research, and other symptoms have been listed as symptoms that also may occur.
- The building evidence underlines the need for specific interventions that target symptoms related to cannabis withdrawal.

KEY FACTS

- Withdrawal or discontinuation syndromes occur after the discontinuation or reduction of use of a particular substance or a group of substances.
- Evidence is growing that the cannabis withdrawal syndrome is common, of clinical significance, and has a clear time course.
- Implications of withdrawal symptoms include the risk of relapse and effects on the wellbeing of patients.
- The symptoms are listed in the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) and contains: (A) cessation of heavy and prolonged cannabis use; (B) three or more of the following within several days after cessation: (1) irritability, (2) nervousness, (3) sleep difficulty, (4) decreased appetite, (5) restlessness, (6) depressed mood, (7) physical symptoms and discomfort.
- The withdrawal symptoms listed in the DSM-5 are not the only symptoms that have been studied, and other symptoms may occur, including increased appetite (about as common as decreased appetite), and vivid unpleasant dreams.

INTRODUCTION

The Phenomenon of Cannabis Withdrawal Symptoms

Withdrawal or discontinuation syndromes occur after the discontinuation or reduction of use of a particular substance or a group of substances. The cannabis withdrawal phenomenon has received growing interest in recent years. Cannabis withdrawal does not cause significant medical or psychiatric problems comparable to opioid, alcohol, or benzodiazepine withdrawal (Tompkins, Smith, Mintzer, Campbell, & Strain, 2014). However, studies have found that cannabis withdrawal symptoms increases the risk of relapse and affect the wellbeing of patients, calling for targeted clinical interventions (Budney & Hughes, 2006; Budney, Hughes, Moore, & Vandrey, 2004; Kubarych et al., 2014).

With the publication of the Diagnostic and Statistical Manual of Mental Disorders (DSM)-5 in 2013, a cannabis withdrawal syndrome is now officially recognized with defined criteria (APA, 2013) as a result of several earlier studies and discussions. Carroll, Rounsaville, and Bryant (1994) found that withdrawal was rarely endorsed by cannabis users, and Guttman scaling showed that only the most severely affected cannabis dependent patients reported cannabis withdrawal. However, the absence of specific criteria may have meant that the study sample did not interpret symptoms that occurred after cannabis cessation as withdrawal symptoms. Accordingly, later research has produced a different picture (see, for example, Budney & Hughes, 2006; Budney et al., 2004; Vandrey, Budney, Kamon, & Stanger, 2005). The cannabis withdrawal syndrome appears to be comparable to the tobacco withdrawal syndrome in severity, is associated with severity of cannabis problems at a later stage (Chung, Martin, Cornelius, & Clark, 2008; Cornelius, Chung, Martin, Wood, & Clark, 2008), and most symptoms increase immediately after cessation of use and decline over the next weeks (Allsop, Norberg, Copeland, Fu, & Budney, 2011; Budney, Moore, Vandrey, & Hughes, 2003; Milin, Manion, Dare, & Walker, 2008); see however Preuss, Watzke, Zimmermann, Wong, & Schmidt (2010).

SYMPTOMS OF CANNABIS WITHDRAWAL IN THE DSM-5

The symptoms of cannabis withdrawal that are listed in the DSM-5 contains: (A) cessation of heavy and prolonged cannabis use; (B) three or more of the following within several days after cessation: (1) irritability, (2) nervousness, (3) sleep difficulty, (4) decreased appetite, (5) restlessness, (6) depressed mood, (7) physical symptoms, and discomfort (APA, 2013). Some of the studies that have supported the inclusion of these symptoms involve the following.

Irritability

Most studies support the relevance of irritability and anger as common and significant symptoms of cannabis withdrawal (for example, Allsop et al., 2011; Arendt, Rosenberg, Foldager, Sher, & Munk-Jorgensen, 2007; Budney, Hughes, Moore, & Novy, 2001; Budney et al., 2003; Chung et al., 2008; Copersino et al., 2006; Haney, Ward, Comer, Foltin, & Fischman, 1999; Kouri & Pope, 2000; Levin et al., 2010; Mennes, Ben Abdallah, & Cottler, 2009). Irritability and anger has a later onset, and a longer duration than most other withdrawal symptoms (Budney et al., 2003; Hesse & Thylstrup, 2013). Additionally, more severe expressions of aggression, such as physical attacks, may occur later than milder symptoms of irritability (Levin et al., 2010).

Nervousness

Nervousness is a commonly reported symptom (Arendt et al., 2007; Budney et al., 2003; Chung et al., 2008; Copersino et al., 2006; Cornelius et al., 2008; Haney et al., 1999; Kouri & Pope, 2000; Levin et al., 2010; Mennes et al., 2009). Prospective research has found that nervousness associated with cannabis withdrawal is a source of significant distress (Allsop et al., 2011) that gradually declines in severity after cannabis cessation (Budney et al., 2003; Milin et al., 2008). However, not all studies have supported the significance of nervousness as a symptom of cannabis withdrawal (eg, Budney et al., 2001).

Sleep Difficulty

Sleep difficulty or insomnia is a frequently reported withdrawal symptom (Allsop et al., 2011; Arendt et al., 2007; Budney et al., 2001, 2003; Chung et al., 2008; Cornelius et al., 2008; Levin et al., 2010; Mennes et al., 2009) that decreases with time since cessation (Budney et al., 2001, 2003; Milin et al., 2008). However, studies have found some uncertainty regarding the time

course: prospective studies using self-report measures suggest that sleep problems decline fairly linearly after cessation of cannabis use (Budney et al., 2003; Milin et al., 2008), whereas a study using polysomnogram data indicated that sleep quality declined with no reversal (Bolla et al., 2010).

Decreased Appetite or Weight Loss

Decreased appetite or weight loss has been robustly reported across studies (Allsop et al., 2011; Budney et al., 2001, 2003; Copersino et al., 2006; Haney et al., 1999; Kouri & Pope, 2000; Levin et al., 2010; Mennes et al., 2009), with quick onset, followed by a relatively quick reversal (Budney et al., 2003).

Restlessness

Restlessness has generally been supported as a common and significant symptom of cannabis withdrawal (Allsop et al., 2011; Arendt et al., 2007; Budney et al., 2003; Chung et al., 2008; Cornelius et al., 2008; Levin et al., 2010; Mennes et al., 2009; Milin et al., 2008), with a slightly later onset than most symptoms (Budney et al., 2003).

Depressed Mood

Depressed mood is commonly reported (Arendt et al., 2007; Chung et al., 2008; Copersino et al., 2006; Cornelius et al., 2008; Kouri & Pope, 2000; Levin et al., 2010; Mennes et al., 2009). Some prospective studies have failed to show that it follows a clear withdrawal pattern (Budney et al., 2003), but other research supports its inclusion as a valid withdrawal symptom (Allsop et al., 2011).

Physical Symptoms

Physical symptoms including stomach pain, shakiness/tremors, sweating, fever, chills or headache have been reported at variable rates, and generally at lower rates compared with other symptoms (Chung et al., 2008; Cornelius et al., 2008; and for example Arendt et al., 2007; Haney et al., 1999; Kouri & Pope, 2000; Levin et al., 2010; Mennes et al., 2009), but some research has supported most of these symptoms as indications of withdrawal (Allsop et al., 2011); see however Budney et al. (2001).

Other Symptoms Related to Cessation of Cannabis Use

The withdrawal symptoms listed in the DSM-5 are not the only symptoms that have been studied in clinical and experimental research, and other symptoms have been listed as symptoms that may also occur (APA, 2013). A frequently reported symptom is increased appetite, about as common as decreased appetite (Copersino et al., 2006; Levin et al., 2010; Mennes et al., 2009), although Allsop et al. (2011) have reported that it was not valid as a withdrawal criterion.

One of the most commonly reported symptoms is vivid unpleasant dreams, which appears to be as common as the symptoms listed for the DSM-5 (Allsop et al., 2011; Arendt et al., 2007; Budney et al., 2001, 2003; Cornelius et al., 2008; Hesse & Thylstrup, 2013); see however Mennes et al. (2009). The time course of these dreams differs from other symptoms with a later onset and a longer duration (Budney et al., 2003; Levin et al., 2010), and the criterion "vivid unpleasant dreams" is not easily subsumed under any of the symptoms in the DSM-5. However, strange and unpleasant dreams are listed in the DSM-5 criteria for amphetamine and cocaine withdrawal.

VARIATIONS IN TIME COURSE OF WITHDRAWAL SYMPTOMS

The consistent findings that the time course of individual cannabis withdrawal symptoms varies may be caused by a wide range of underlying mechanisms. Some symptoms may occur as soon as cannabis use ceases and blood-levels of tetrahydrocannabinol (THC) and other components in cannabis begin to drop, whereas other symptoms may not occur until THC is nearly completely eliminated from the blood stream. For instance, a study by Kouri and Pope (2000) showed that self-reported increased anxiety, increased physical tension, and appetite loss began immediately after cessation of cannabis use, whereas irritability, low mood, and other physical symptoms, accelerated somewhat more slowly as THC levels dropped further (Kouri & Pope, 2000).

Similarly, the study by Hesse and Thylstrup (2013) found that nervousness increased immediately after cessation, whereas irritability showed an initial increase followed by a decrease (Hesse & Thylstrup, 2013). It is likely that medications affect the time course of cannabis withdrawal symptoms, although the study by Hesse and Thylstrup found that antipsychotics and antidepressants did not change the results of experienced severity of withdrawal symptoms across time (Hesse & Thylstrup, 2013). Other mechanisms that also may affect the time course and severity are the psychological factors, such as expectations to certain sensations after cessation of drug use, or other life stressors related to cessation of drug use or entering treatment. It is possible that these factors create a temporary increase in experienced stress over the first few days after

cessation of cannabis use, for example, when patients entering treatment become increasingly aware of both physical and psychological symptoms, or when they decide to make a change in lifestyle. This may be the case especially for patients entering residential treatment, and patients who experience multiple changes in their everyday life at the same time.

The Question of Demand Characteristics

Overall, the literature on cannabis withdrawal phenomenon and symptoms shows a fairly consistent picture that is largely in line with the cannabis withdrawal criteria in the DSM-5. However, a potential limitation is the problem of demand characteristics that can be explained as the totality of cues that convey an experimental hypothesis to the subject (Orne, 1962). In this case, giving patients cues that a given instrument is designed to measure withdrawal from cannabis may prompt them to respond in ways that they perceive matches what they believe about sensations related to withdrawal symptoms in general. If patients believe that withdrawal symptoms refer to a temporary cluster of specific symptoms that begin after cessation of a specific drug use, they may be more prone to report these symptoms after cessation of use, and stop reporting these symptoms after a while. Such cues may range from writing "cannabis withdrawal" in the heading of the study questionnaire, to asking on the same form, how many days it has been since the subject last used cannabis, or to having a cannabis craving scale on the same questionnaire. Some studies have addressed some aspects of demand characteristics, for example, by using filler items (Allsop et al., 2011), alternative headings, such as "Behavior Checklist" (Budney et al., 2001), or by asking participants to fill in other measures simultaneously with marijuana craving questionnaires (Budney et al., 2003). However, these studies have clearly stated the study focus on marijuana cessation during the recruitment phase, and have asked patients to specifically choose a quitting date for marijuana use.

One of the ways to reduce the impact of demand characteristics is to study cannabis withdrawal symptoms in polydrug use. Up until recently, very limited data exist on the cannabis withdrawal symptoms in patients with concurrent substance use disorders, other than cannabis use and tobacco use (Budney, Vandrey, Hughes, Thostenson, & Bursac, 2008; Vandrey, Budney, Moore, & Hughes, 2005). Arguably, there are good reasons for omitting studies of patient samples with polysubstance use when establishing the validity and time course of the cannabis withdrawal syndrome per se. For example, other drugs may influence mood, physical discomfort, sleep, appetite, and overall wellbeing that may mask or exacerbate specific symptoms that are associated with the cannabis withdrawal. However, polysubstance use is quite common in substance users (Carter et al., 2013), and polydrug dependent patients make up a large proportion of patients in substance abuse treatment services (Onyeka et al., 2012; Savant et al., 2013). If this patient group experiences clinically significant cannabis withdrawal symptoms, psychoeducation, behavioral, and pharmacological interventions that target the cannabis withdrawal symptoms interventions should be made available (Budney, Higgins, & Wong, 1996; Kidorf, Neufeld, King, Clark, & Brooner, 2007). Vorspan et al. (2010) conducted a small cross-sectional study that indicated that sleep disturbances, but not other cannabis withdrawal symptoms, were exacerbated in patients with comorbid opioid dependence (Vorspan et al., 2010). Hesse and Thylstrup (2013) conducted the first study to assess the DSM-5 cannabis withdrawal syndrome as described in the coming manual and the time course of the recommended withdrawal symptoms, based on 90 polydrug users' self-reports from residential illicit drug abuse treatment institutions in Denmark (Hesse & Thylstrup, 2013). To assess whether the DSM-5 symptoms would follow a curvilinear time course from cessation of cannabis use, characterized by an increase in severity immediately after cessation of use followed by a decrease in severity, the study used a scale that consisted of all the criteria listed in the DSM-5 for cannabis withdrawal. To reduce demand characteristics, the patients were not instructed to complete the scale questionnaire on the day that they last used cannabis, but were asked to describe how they felt right now. Additionally, the questionnaire included withdrawal symptoms currently listed for other substances; cocaine, amphetamine, opioids, tranquilizers, and alcohol. Study findings supported the existence of a cannabis withdrawal syndrome independent of other drug use that followed a clear time course with a peak in overall severity 10 days after last use, and a gradual decline over the next weeks (see Fig. 110.1).

The figure is divided into two, so that assessments conducted in week 1 are in the left panel, and assessments conducted in week 2 are in the right hand panel. Within each panel, severity of self-reported symptoms is shown as a function of days since last use of cannabis, with locally weighted regression estimation. As can be seen, the symptom severity increased from day 1 to day 10, and dropped gradually after this. For assessments from week 2, no patients reported using cannabis less than 7 days ago, so only an almost linear decline is seen, following roughly the same values as in the left-hand panel. Thus within this group, withdrawal symptoms follow a time course that is determined by days since last cannabis use, rather than time of assessment.

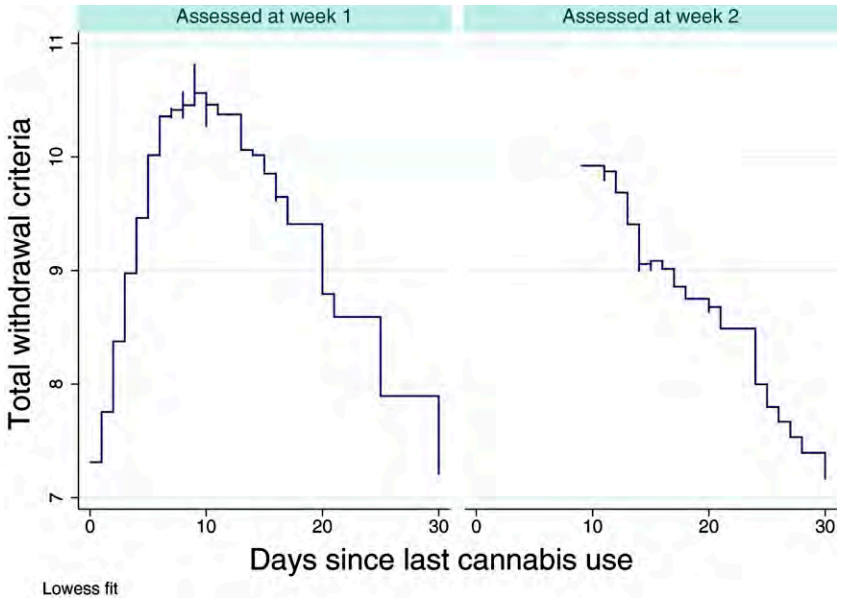

FIGURE 110.1 **Symptom severity for overall cannabis withdrawal syndrome.**

In sum, much of the research conducted supports the evidence and the inclusion of the cannabis withdrawal syndrome in the DSM-5. Although study findings also show diversities concerning which specific withdrawal symptoms that may be more prevalent than others, the cannabis withdrawal syndrome is partly independent of other drug use, and follows a clear time-course with a peak in overall severity 10 days after last use, followed by a gradual decline over the next 15–20 days.

CLINICAL IMPLICATIONS

Psychosocial Treatment

The building evidence on cannabis withdrawal syndrome underlines the need for specific interventions that target symptoms related to cannabis withdrawal, especially within the first month after cessation or reduction of use. This need that is stressed by the fact that adults seeking treatment for marijuana abuse or dependence average more than 10 years of near-daily use, and more than six serious attempts at quitting (Budney, 2006; Stephens, Babor, Kadden, Miller, & Marijuana Treatment Project Research, 2002). However, despite the accumulating evidence of the need for targeted interventions, psychosocial intervention studies on treatment of cannabis withdrawal symptoms are lacking. These studies are important for several reasons. For one, psychoeducation may better the patients' and family members' understanding of dependence and discomforts related to cessation or reduction of cannabis use, countering possible discomforts, such as, irritability, restlessness, or insomnia by giving advice on good sleep hygiene, relaxation, and avoidance of caffeine (Winstock, Ford, & Witton, 2010). Some studies have investigated patient motives for cannabis use, including positive and negative expectancies to cessation of use (Bonn-Miller, Zvolensky, & Bernstein, 2007; Zvolensky et al., 2007), while other studies have investigated specific interventions that address patient motives for use (Banes, Stephens, Blevins, Walker, & Roffman, 2014; Bonn-Miller et al., 2007; Zvolensky et al., 2007). One of the findings from these studies is that cognitive-behavioral therapy may work as relapse prevention by identifying situations and internal states that trigger use, and teach the patients relevant coping skills (Banes et al., 2014; Bonn-Miller et al., 2007; Zvolensky et al., 2007).

Because withdrawal symptoms may put patients at risk of relapse, treatment requires specific clinical attention on the specific cannabis withdrawal symptoms, besides the withdrawal syndrome itself. Besides information on relevant demographic factors, such as education, employment, marital status (Vendetti, McRee, Miller, Christiansen, & Herrell, 2002), screening for cannabis, tobacco and alcohol use, and other polydrug use, treatment should also consider screening for broader lifestyle questions that may be linked to the specific cannabis withdrawal symptoms, such as questions about sleep and eating problems (Chesney, Matsos, Couturier, & Johnson, 2014). As is the case for other drug use, cannabis dependence and withdrawal symptoms coexist with other mental disorders (Di Forti, Morrison, Butt, & Murray, 2007), for example, schizophrenia (Evins, Green, Kane, & Murray, 2012; Koskinen, Lohonen, Koponen, Isohanni, & Miettunen, 2010), anxiety (Crippa

et al., 2009), depression, bipolar disorder (Lev-Ran, Le Foll, McKenzie, George, & Rehm, 2013a), and personality disorders (Lev-Ran, Le Foll, McKenzie, George, & Rehm, 2013b). Clinical assessment may therefore include screening of relevant mental health problems, including age of onset, family history, externalizing and internalizing disorders, and temperament (Babor, Webb, Burleson, & Kaminer, 2002), as well as physical problems, such as deficits in memory and executive functions (Fisk & Montgomery, 2008; Meier et al., 2012; Solowij & Battisti, 2008), respiratory symptoms (Lee & Hancox, 2011; Tessmer et al., 2012), cardiovascular problems (Cottencin et al., 2010; Thomas, Kloner, & Rezkalla, 2014).

Pharmacological Treatment

Despite the strong focus on how pharmacological treatment can target the cannabis withdrawal syndrome, limited evidence is available concerning the effect of pharmacological treatment per se (Budney, Vandrey, Hughes, Moore, & Bahrenburg, 2007; Hart, 2005). However, there are currently ongoing trials that study the efficacy of this type of treatment. An interesting option is to either maintain or taper patients on THC-based medications (Haney et al., 2004; Milman et al., 2014). In a recent study, Allsop et al. (2014) evaluated the safety and efficacy of the cannabis extract nabiximols (Sativex), originally developed as a multiple sclerosis treatment, in a randomized clinical trial (Allsop et al., 2014). The study found that nabiximols attenuated cannabis withdrawal symptoms, and improved patient retention in a treatment-seeking cohort, but that placebo was as effective as nabiximols in promoting long-term reductions in cannabis use following medication cessation (Allsop et al., 2014). Other studies have looked at medications that traditionally have been used for somatic and mental health problems. For example, a study by Weinstein et al. (2014) on the use of escitalopram, (used in depression, panic disorder, anxiety disorder, and obsessive compulsive disorder), found that the medical treatment did not provide additional benefits compared to placebo (Weinstein et al., 2014). Also, a study by Vandrey, Smith, McCann, Budney, and Curran (2011) found that medications directed at particular symptoms, such as sleep disturbances, might reduce overall discomfort , and Mariani et al. (2014) are at the time of writing evaluating quetiapine, a short-acting atypical antipsychotic approved for the treatment of schizophrenia, bipolar disorder, and, along with an antidepressant, for the treatment of cannabis dependence (Mariani et al., 2014). Finally, a case study found that baclofen, an agonist for the $GABA_B$ receptors that until now was primarily used in the treatment of spasticity, may be of clinical utility for reduction of cannabis withdrawal symptoms, and the subjective effects of cannabis (Imbert, Labrune, Lancon, & Simon, 2014).

The diversity in studies on medication strategies, and their study findings, reflects the complexity in cannabis withdrawal syndrome that is also found in the related symptoms. The complexity indicates that different medications may be needed in targeting the various aspects of withdrawal symptoms. A review by Balter, Cooper, & Haney (2014) on recent medication development for the treatment of cannabis use disorder (CUD) describes that laboratory studies found that medication strategies, such as the cannabinoid receptor agonist, nabilone, and the adrenergic agonist, lofexidine, alone and in combination with dronabinol (synthetic THC), decreased cannabis withdrawal symptoms, whereas antidepressant, anxiolytic, and antipsychotic drugs targeting monoamines (norepinephrine, dopamine, and serotonin) in general failed to decrease withdrawal symptoms or laboratory measures of relapse. In clinical trials, dronabinol and multiple antidepressants (fluoxetine, venlafaxine and buspirone) seemed to fall short in decreasing cannabis use, whereas controlled clinical trials with gabapentin and *N*-acetylcysteine supported further research concerning medical use, as did open label and laboratory studies on lithium and oxytocin (Balter et al., 2014).

CONCLUSIONS

The abuse of cannabis may lead to specific cannabis withdrawal symptoms after cessation or reduction of use. Research literature on the cannabis withdrawal phenomena and withdrawal symptoms shows a fairly consistent picture that is largely in line with the cannabis withdrawal criteria in the DSM-5. The need for specific treatment interventions that target the cannabis withdrawal syndrome calls for further research on efficacious behavioral or pharmacological interventions of the withdrawal symptoms. Future research needs to take other substance-related problems, including the medical treatment of comorbid mental and physical health problems, into consideration when establishing the effect of psychosocial and pharmacological treatment.

MINI DICTIONARY

Demand characteristics The experimental artifact where participants form an interpretation of the experiment's purpose and subconsciously change their behavior to fit that interpretation.
Discontinuation The cessation or reduction of a pattern of substance use.
DSM-5 The Diagnostic and Statistical Manual, 5th edition.
Polydrug use The use of multiple substances by the same individual in a given time frame.
Residential treatment A drug and/or alcohol addiction treatment program, where patients reside at the residential treatment facility during treatment, which may be short-term (30 days or less) or long-ter (more than 30 days).

Symptom Any single complaint or problem that is caused by and shows a more serious and general problem.
Syndrome A group of signs and symptoms that occur together and characterize a particular abnormality or condition.
Time course The variation of a quantity over time.
Withdrawal A withdrawal syndrome, also called a discontinuation syndrome is a set of symptoms occurring in discontinuation or dosage reduction of some types of substances.

CHAPTER

111

School-Based Cannabis Prevention Programs

C. Ariza, F. Sánchez-Martínez, A. Pérez

Evaluation and Intervention Methods Service, Public Health Agency, Barcelona, Spain

SUMMARY POINTS

- Some transition periods in the natural history of cannabis use are good opportunities to intervene.
- There are a set of established evidence principles that a good school-based prevention needs to observe.
- The delivery methods are more important than the program's content for effectiveness.
- Cannabis, like other addictive substances, has its own social marketing that prevention programs need to deal with.
- Eight school-based drug prevention programs are described in this chapter.

KEY FACTS OF SCHOOL-BASED CANNABIS PREVENTION PROGRAMS

- School-based cannabis prevention programs are a set of cannabis preventive strategies, usually implemented in school settings.
- Based on the social influence model, these programs try to motivate young people to avoid using cannabis.
- Compared with other treatment resources, preventive programs are addressed to cannabis nonuser population, of school age.
- Little reductions in the incidence of new cannabis users obtained with these strategies have important impact in the individual and social burden of illness.
- The effect size of school-based cannabis prevention programs is low, but consistent, and can be maintained over time.

LIST OF ABBREVIATIONS

ADCA	Alcohol and other Drugs Council of Australia
ASSAD	Australian Secondary Students' Alcohol and Drug survey
CDC-YRBS	Centers for Disease Control and Prevention—Youth Risk Behavior Surveillance
CG	Control group
EDDRA	Exchange on Drug Demand Reduction Action
EG	Experimental group
EMCDDA	European Monitoring Centre for Drugs and Drug Addiction
ESPAD	European School survey Project on Alcohol and other Drugs
NREPP	National Registry of Evidence-Based Programs and Policies
RADAR	Register of Australian Drug and Alcohol Research
SAMHSA	Substance Abuse and Mental Health Services Administration

INFLUENCE OF THE NATURAL HISTORY OF CANNABIS CONSUMPTION ON PREVENTION

The natural history of cannabis consumption offers the principal stages that happen in the process that takes a person from occasional to regular user, and the exposure to the risk of becoming addicted. It is possible to identify relevant transition periods for prevention.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00129-0

TABLE 111.1 Comparative Data of Main Prevalences in the Progression of Cannabis Consumption (United States, Australia, and Europe, 2011[a])

	United States (%)	Australia (%)	Europe (%)
Tried cannabis the first time before 13 years	6.3–15.2	3.4	3.1–8.4[b]
Lifetime cannabis consumption	39.9	14.8	17.0
Current cannabis use (past month)	23.1	6.8	7.0

The table presents a comparative description of the main cannabis prevalence indicators in United States, Australia, and Europe in 2011.
[a] *United States: CDC (2012); Australia: White et al. (2012); Europe: Hibell et al. (2012).*
[b] *Range between European countries with extreme differences in figures about cannabis use (see Kokkevi, Gabhainn, & Spyropoulou, 2006).*

The first is the starting age for cannabis consumption. The prevalence of youngsters who tried cannabis before 13 years old is higher in US adolescents (6.3–15.2%) (CDC, 2012) than Europeans (3.1–8.4%) (Hibell et al., 2012) and Australians (White et al., 2012) (3.4%) (Table 111.1).

The best moment to start with school-based prevention programs is not clear. One study followed-up a representative sample of schoolchildren from secondary schools in Spain (n = 1056) from 7 to 10th grades (Guxens, Nebot, & Ariza, 2007). Participants completed a self-administered lifestyle questionnaire each year. Data about the progression on lifetime cannabis consumption is shown in Fig. 111.1.

The main relative increase in the prevalence occurs between the two first years of secondary school (13–14 years old). It is important to pay attention to this transition period, because early consumers have higher risk of persisting in long-term use and becoming addicted (Kokkevi et al., 2006) and exhibiting cannabis use-related problems and low academic results in later years (Ellickson, Tucker, Klein, & Saner, 2004). However, the quantitative increase occurred when students changed from 15 to 16 years old (Guxens et al., 2007), so this is the transition period when the majority of the target population come into contact with the drug. Thus, the most opportune age range to intervene is 14–15 years. Recent surveys showed that the average starting age for cannabis use was 14.7 years in a European country, Spain (Plan Nacional sobre Drogas, 2012), or 14.9 in a North American country, Canada (CAMH, 2013), However, cannabis consumption in the United States begins before 13 years, and cannabis preventive programs among American youngsters should probably start earlier than in the European or Australian context.

Two main indicators are important, "lifetime" and "current cannabis use." Whereas lifetime consumption can represent a milestone in the socialization process, the majority of authors accepted the progression to current use (30-day prevalence) as the first significant event to avoid (Thompson, 2001; Monshouwer, Smit, De Graaf, van Os, & Vollebergh, 2005). In 2011, 23.1% of United States (CDC, 2012), 6.8% of Australian (White et al., 2012), and 7% of European (Hibell et al., 2012) adolescents used cannabis the 30 days before the survey (Table 111.1). In a study prior to the design of school-based cannabis prevention program carried out in Spain, students' cannabis use was measured twice between the ages of 15 and 16 years. 23.7% of nonusers at baseline had started to consume 15 months later (23.0% boys and 24.2% girls). Among those who had reported lifetime cannabis

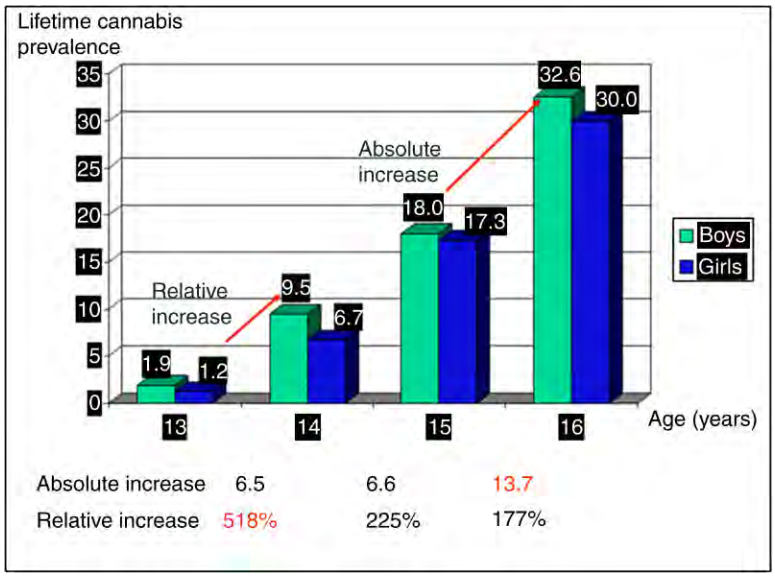

FIGURE 111.1 **Progression of lifetime cannabis consumption in a cohort from 13 to 16 year olds (Barcelona, 1998–2001).** The figure shows the turning points in the progression of lifetime cannabis use in a cohort of Barcelona teenagers.

use, 30.3% reported consumption during the previous month at the follow-up (Pérez, Ariza, Sánchez-Martínez, & Nebot, 2009). It seems that avoiding the progression to current use could be one of the main objectives for universal school-based cannabis prevention.

The third aspect with implications for prevention consists in associated factors that can predict the consumption. Factors associated with cannabis initiation among boys and girls are smoking, risky alcohol use, intention to consume cannabis, antisocial behavior, low academic performance (Thompson, 2001; Von Sydow, Lieb, Pfister, Hofler, & Wittchen, 2002; Ellickson et al., 2004; Guxens et al., 2007; Pérez et al., 2009). Cannabis use is more frequent in males than in females (Von Sydow et al., 2002), and the influence of socioeconomic status is controversial (Thompson, 2001). Other associated factors were: among boys, frequenting bars or discotheques, and not having organized activities in leisure time; among girls, having cannabis-using friends (Guxens et al., 2007; Pérez et al., 2009). This highlights the important influence of social norms, and especially peer influence in adolescent behavior and drug consumption. Preventive programs must cope with these influences, trying to consider these variables in the design of strategies. These data, on the other hand, underlines the role of behavioral and contextual variables.

MAIN CHARACTERISTICS OF SCHOOL-BASED CANNABIS PREVENTION PROGRAMS

School, community, and family are suitable settings for the implementation of cannabis prevention programs. Adolescents spend most of their time at school, being an appropriate place to implement prevention (National Crime Prevention Centre, 2009; Newton, Vogl, Teesson, & Andrews, 2011; Porath-Waller, Beasley, & Beirness, 2010). Faggiano et al. (2005) point out three reasons why schools are such a good place: prevention of substance use must focus on school-aged population because their beliefs and expectations are not still established; school is the best way of reaching a large number of young people; many countries can enforce educational policies.

Types of School-Based Cannabis Prevention Programs

School-based programs can be classified into; (1) *universal*, focused on the general student population, and (2) *selective* or *targeted*, focused on high-risk populations. In terms of components of the intervention, there are programs with only the school-based component (unimodal) and approaches that use family, peer, community, and school-based components (multimodal) (Nation et al., 2003; Norberg, Kezelman, & Lim-Howe, 2013).

Besides, school-based programs can be classified based on two criteria. The first criterion is according to the delivery method of the program. *Interactive programs* are those in which the students have the opportunity of interaction with peers and to experiment what they are learning (eg, role-play) (Faggiano et al., 2005; McGrath, Sumnall, McVeigh, & Bellis, 2006). *Noninteractive programs* are based on passive didactic methods, being the communication unidirectional from educator to students (Faggiano et al., 2005; Porath-Waller et al., 2010; Tobler, Lessard, Marshall, Ochshorn, & Roona, 1999).

The second criterion depends on the nature of the program content, which can be classified in three approaches: *skills-focused programs* (also known as social influence programs), *affective-focused programs* and *knowledge-focused* (Newton et al., 2011; Porath-Waller et al., 2010).

Skills-focused programs aim to improve students' abilities in generic, refusal and safety skills. This approach suggest that drug use originate direct or indirect in social influences from peers or media (McGrath et al., 2006; Botvin, 2000a) and aims to increase an awareness of social influences regarding drug use and to teach skills which allow adolescents to face pressure to consume drugs. It incorporates three components: (1) *information* given to youth must be appropriate and based on outcomes relevant to them (Newton et al., 2011); (2) *normative education* try to correct the misconception that the majority of population use drugs and to promote safer choices regarding drug consumption (Newton et al., 2011; McGrath et al., 2006; Botvin, 2000a). Correcting normative expectations is very important for resistance skills training programs to be successful (Botvin, 2000a); (3) *resistance skills training* provide adolescents with the abilities necessaries to identify and cope peer and media pressure to consume drugs, having a positive impact on cannabis use (Newton et al., 2011; McGrath et al., 2006; Botvin, 2000a). Botvin describes three resistance skills training: teaching students to recognize high-risk situations with peer pressure, increasing the awareness of media influences and teaching students abilities for refusing drugs' offers (Botvin, 2000a).

Affective-focused programs aim to modify inner qualities and to promote affective development increasing self-esteem, self-awareness, and self-acceptance (Faggiano et al., 2005; Porath-Waller et al., 2010; McGrath et al., 2006).

Knowledge-focused programs objective is to enhance students' knowledge of drugs, drug effects and their consequences in order to build negative attitudes toward drugs (Faggiano et al., 2005; McGrath et al., 2006).

Most authors agree on supporting that interactive methods for preventive interventions are more effective than noninteractive (Norberg et al., 2013; Porath-Waller

TABLE 111.2 Main Characteristics of School-Based Cannabis Prevention Programs

Types of school-based cannabis prevention programs	Population	*Universal:* general population
		Selective: high-risk population
	Components	*Unimodal:* only school-based component
		Multimodal: some of the family, peer, community, and school-based components
	Delivery methods	*Interactive*: students have the opportunity of interaction between peers
		Noninteractive: based on passive didactic methods, unidirectional communication from teacher to student
	Content	*Skills-focused program:* aim to enhance student's abilities in generic, refusal and safety skills
		Affective-focused program: aim to modify inner qualities and to promote affective development
		Knowledge-focused program: aim to improve students' knowledge of drugs and their effects
Individual components of school-based cannabis prevention programs	*Timing of delivery*: appropriate age of the participants for the intervention	
	Program facilitators: teachers, external educators, and peers are the most frequent program deliverers	
	Program intensity: dosage of the intervention (session length, number of sessions, spacing of sessions, and duration of the program)	
	Booster sessions: additional sessions which reinforce the progress made for the preliminary ones	

The table shows that school-based cannabis prevention programs can be classified regarding their target population, the components, the delivery methods used or their content.

et al., 2010; Tobler et al., 1999; McGrath et al., 2006). Also, here is strong evidence that skill-focused programs are the most effective form of school-level intervention for preventing youth drug use (Faggiano et al., 2005; Norberg et al., 2013; Porath-Waller et al., 2010; Tobler et al., 1999; Botvin, 2000a) (Table 111.2).

Individual Components of a School-Based Cannabis Prevention Program

The main components of a school-based prevention program are those:

Timing of Delivery

The optimal time of delivery is during early adolescence (Norberg et al., 2013; Porath-Waller et al., 2010). As mentioned before, the periods when preventive programs are more likely to work are: immediately before to initial experimentation, when most students are experiencing initial exposure, and when prevalence of use are high (McBride, 2003). However, literature regarding the optimal participant age for implementation is inconclusive (Porath-Waller et al., 2010; Gottfredson & Wilson, 2003).

Program Facilitators

Teachers, external educators and peers are the most frequent program deliverers. Some studies indicate that programs led by nonteachers are the most effective (Porath-Waller et al., 2010; McGrath et al., 2006). However, most of school-based programs are delivered by the teachers (Porath-Waller et al., 2010; Gottfredson & Wilson, 2003) because they are the nearest person to students. Insufficient motivation and lack of training, awareness or time are some of the main problems related to teachers' weak implementation. Therefore, teacher training and support from prevention experts is essential to give them the confidence necessary to implement properly the programs (Dusenbury & Falco, 1995; Elias, Gager, & Leon 1997).

Program Intensity

Participants must be exposed to sufficient dosage of intervention (Nation et al., 2003). Some authors reported that programs often offer fewer than 10 sessions and it could explain the decay of effects over time (Dusenbury & Falco, 1995).

Booster Sessions

Some studies report the benefit of including boosters in the program design for the maintenance of long-term reductions of drug use because they reinforce messages sometime after the intervention (Skara & Sussman, 2003; McBride, 2003).

The positive effects achieved by school-based preventive programs are often lower than expected, most of the

times due to an inadequate implementation (Sánchez-Martínez et al., 2010). Two dimensions have been defined to assess the implementation of a program: (1) *completeness* provides information on the amount of the intervention that has been applied, (2) *fidelity* measures the degree of implementation agreement to the initial design of the intervention (Sánchez-Martínez et al., 2010). The success of a preventive intervention is based largely on a correct implementation of the intervention.

BEST PRACTICES IN SCHOOL-BASED CANNABIS PREVENTION PROGRAMS

The purpose of this section is to select a group of programs that could be representative of the best practices that different researchers had been developing recently in the North American, Australian, and European contexts. This is not a systematic review. The information has been taken from review studies, but also from some intervention databases with the intention of providing an overview about what is doing now in this field, and also what appears to be working and can be considered as best practice for school-based cannabis prevention.

To select the interventions that we describe and compare in Tables 111.3 and 111.4 we take into account those of the three contexts we explored (North America, Australia, and Europe), and also reported the outcome evaluation and the quality rating obtained in each corresponding database.

North American Programs

The National Registry of Evidence-based Programs and Policies (NREPP) from the Substance Abuse and Mental Health Services Administration (SAMHSA) is the reference database. At the date of writing this text, 335 interventions are included in the registry, 117 of them about "substance abuse prevention." 86 of 117 were school-based programs.

There are three programs among the 86 school-based interventions that could be considered as best practices (Fig. 111.2): they feature the quality ratings obtained for design, implementation and materials and also for the level of effective evaluation. These are: LifeSkills Training (LST; Life Skills Training, 2014) (universal), promoted and evaluated in New York city and coordinated in the Cornell University; Project Alert (Alert Project, 2014) (universal, selective), designed at RAND corporation and evaluated in California, Oregon, and South Dakota, among other places; and Project Towards No Drug Use (TND; Towards No Drug Abuse, 2014) (universal, selective, indicated), promoted and evaluated from University of Southern California. All three programs focus on tobacco, alcohol and cannabis use, but none of them have specific content on cannabis.

Australian Programs

The Register of Australian Drug and Alcohol Research (RADAR) from the Alcohol and other Drugs Council of Australia (ADCA) is the source that we use in the selection of programs. This register contains 345 projects of which 146 are about school-based prevention and 33 of them including cannabis as a content, or their measurement variable in the objectives (Fig. 111.2). The two selected interventions have specific contents on cannabis. The first one, Climate Schools Model (CSM; Climate Schools Model, 2014) program, is a well-recognized intervention, even included in SAMHSA North American database. This program is classified as a universal prevention and integrated in a wider project that includes prevention intervention on alcohol and other illicit drugs and also Internet procedures (Newton, Teesson, Vogl, & Andrews, 2010). The second program is the Gatehouse prevention intervention (The Gatehouse Project, 2014), also universal prevention, that includes contents about health risk behaviors (cannabis use among them), but strategies for social and emotional support (Patton, Bond, Butler, & Glover, 2003) too.

European Programs

European programs are found on the Exchange on Drug Demand Reduction Action (EDDRA) database of the European Monitoring Centre for Drugs and Drug Addiction (EMCDDA). This register contains 560 projects of which 470 are about school-based prevention and 251 include cannabis as a content or the measurement variable in the objectives (Fig. 111.2). From cannabis content, only eight obtained the classification "top level" quality. We excluded five projects for: (1) being addressed at 6–10 age group; (2) being implemented in special schools; and (3) concentrating their objectives in reducing or quitting cannabis. Consequently, we selected the other three for this section, which are included in Tables 111.3 and 111.4.

The first project is "Unplugged" (European Drug Addiction Prevention Trial, 2014), a universal program, targeted at adolescents from 12 to 14 years old. It is aimed to reduce the initiation, use and abuse of tobacco, alcohol and cannabis. The study was evaluated in a large European collaborative trial (EU-Dap) in seven European countries and coordinated in Italy. The second project is also a universal program, entitled "xkpts.com" (taking its name from the webpage resource it was based around; xkpts.com, 2014), and aimed at adolescents from 14 to 16 years old. The contents of this site were specifically about cannabis prevention and was

TABLE 111.3 Main Characteristics of the Eight Selected Best Practices for School-Based Cannabis Prevention Programs (United States, Australia, and Europe)

Program	Author(s)	Country of origin	Start year	Type of prevention	Target population	Specific versus multidrug prevention	Program leader	Number of sessions	Materials	Quality rating
Life Skills Training (LST)	Botvin, Baker, Dusenbury, Botvin, and Diaz (1995)	United States, New York City, Cornell University	1995	Universal	13–17 year olds	Substance use (alcohol, tobacco, cannabis, inhalants, polydrug)	Teachers	LST: 15 sessions—15 boosters (in 2 years)	Teacher's manual, student handouts, video material. Training workshop	4/4 (SAMHSA)
ALERT (revised)	Ellickson et al. (2004)	United States, RAND Corporation	1995	Universal	13–17 year olds	Substance use (alcohol, tobacco, cannabis)	Teachers	ALERT: 11 sessions—3 boosters	Teacher's manual, Peer teen manual, video material. Training workshop.	3.8/4 (SAMHSA)
Towards No-Drug Abuse (TND)	Sussman, Dent, Stacy, and Craig, (1998)	United States, California, University of Southern California	1994	Universal; selective	13–17 year olds	Alcohol and tobacco use; Cannabis and "hard drug" use	Teachers; Health educators	TND: 9 sessions (8 h)	Teacher's manual, student workbook, video material, board game. Training workshop.	3.1/4 (SAMHSA)
Climate Schools Model (CSM)	Newton et al. (2011)	Australia, University of New South Wales	2006	Universal	13–17 year olds	Alcohol and cannabis use	Teachers	CSM: 12 sessions (8 h)	Implementation guide for teachers and students, quizzes. Online course.	2.8/4 (SAMHSA)
The Gatehouse Project (GP)	Bond et al. (2004)	Australia,Victoria University of Melbourne	1997	Universal	13–17 year olds	Cannabis use	Teachers	GP: 20 sessions (15 h)	Team guidelines	—
Unplugged(EU-Dap Project)	Faggiano et al. (2005)	Europe, Italy, Turin, ASL TO3, Epidemiology Unit	2004	Universal	12–14 year olds	Substance use (alcohol, tobacco, cannabis, inhalants, cocaine, polydrug)	Teachers	Unplugged: 12 sessions (12 h)	Teacher's handbook, students workbook, cards. Training workshop	3/3 (EDDRA)
Xkpts.com	Ariza et al. (2013)	Europe, Spain, Barcelona Public Health Agency	2006	Universal	14–16 year olds	Cannabis use	Teachers	Xkpts.com: 4 sessions (10 h)	Teacher's guide, student workbook, video material, parents brochure. Training workshop	3/3 (EDDRA)
Pre-Venture	Conrod, Castellanos-Ryan, and Strang (2010)	Europe, UK, London, King's College London	2003	Selective; indicated	13–16 year olds	Substance use (alcohol, tobacco, cannabis, inhalants, cocaine, polydrug)	Health professionals	PreVenture: 2 sessions (3 h)	Health professional manual	3/3 (EDDRA)

SAMHSA, Substance Abuse and Mental Health Services Administration; EDDRA, Exchange on Drug Demand Reduction Action. The table describes the structure of each best practice selected for the article.

TABLE 111.4 Other Intervention and Evaluation Details of the Eight Selected Best Practices for School-Based Cannabis Prevention Programs (United States, Australia, and Europe)

Program	Theoretical model	Interactivity	Components	Family involvement	Evaluation design	Sample	Comparison group	Control group	Follow-up period	Outcome measure	Post-test effect	Effect size (Cohen "*d*"[a])
Life Skills Training (LST)	Social influence and competence enhancement model	Interactive	Unimodal	No family involvement	Blocked randomized trial	56 schools; 5954 students	Training provided by videotape	Treatment as usual	72 months	Monthly use (yes: 1, no: 0)	0.10 (E, high fidelity) versus 0.14 (C)[b]	0.09 (36)[c]; 0.09 (72)[c]
ALERT (revised)	Social influence model	Interactive	Multimodal	No family involvement	Cluster-randomized trial	55 schools; 4276 students	Treatment(Alert revised)	No treatment	18 months	Lifetime use; monthly use	13% (E) versus 17% (C)[b]; 9% versus 11%	0.15 (18)[c]; 0.08 (18)
Towards No-Drug Abuse (TND)	Motivation-skills-decision-making model	Interactive	Unimodal	No family involvement	Blocked randomized trial	21 schools; 1578 students	Classroom + School-as community condition	Treatment as usual	60 months	Monthly use	39.6% (E) versus 42.1% (C); 30.6% versus 34.5% (60)	0.07 (12); 0.04 (60)
Climate Schools Model (CSM)	Social influence model	Interactive	Unimodal	No family involvement	Cluster-randomized trial	10 schools; 764 students	—	Treatment as usual	6 months	Mean of times/ week in last 90 days	–0.06 (E) versus 0.20 (C)[b]	0.16 (6)
The Gatehouse Project	Attachment theory; social skills	Mixed: Noninteractive and interactive	Multimodal	No family involvement	Cluster-randomized trial	26 schools; 2678 students	—	Treatment as usual	24 months	Weekly new use in last 6 months	3.2% (E) versus 4.4% (C)	0.12 (24)
Unplugged (EU-Dap Project)	Comprehensive social influence approach	Interactive	Multimodal	Intensive skill training workshop	Randomized control trial	143 schools; 7079 students	Basic curriculum and peers; basic and parents	No treatment	18 months	Prevalence in last 30 days	3.3% (E) versus 5.3% (C)[b]	0.17 (18)[c]
Xkpts.com	ASE (attitudes-social influences-self-efficacy) model	Interactive	Multimodal	Handbook as basis for discussion	Quasi experimental pre-post	86 schools; 4848 students	Treatment as usual	—	15 months	New users in last month	8.3% (E) versus 11.7% (C)[b]	0.19 (15)[c]
Pre-Venture	Personality traits linked to risk for addictive and nonaddictive psychopatology	Noninteractive	Multimodal	No family involvement	Randomized control trial	732 high-risk students	—	Treatment as usual	24 months	Frequency of use in last 6 months	29.7% (E) versus 35.3% (C)	0.20 (24)[c]

E, experimental; C, comparison or control. The table explains how is the program of intervention and the evaluation for each one of the eight selected best practices.

[a] *Cohen's* d *was reported by authors or calculated from results.*

[b] *Statistically significant as* $p < 0.05$.

[c] *Statistically significant as 95% CI does not contain zero.*

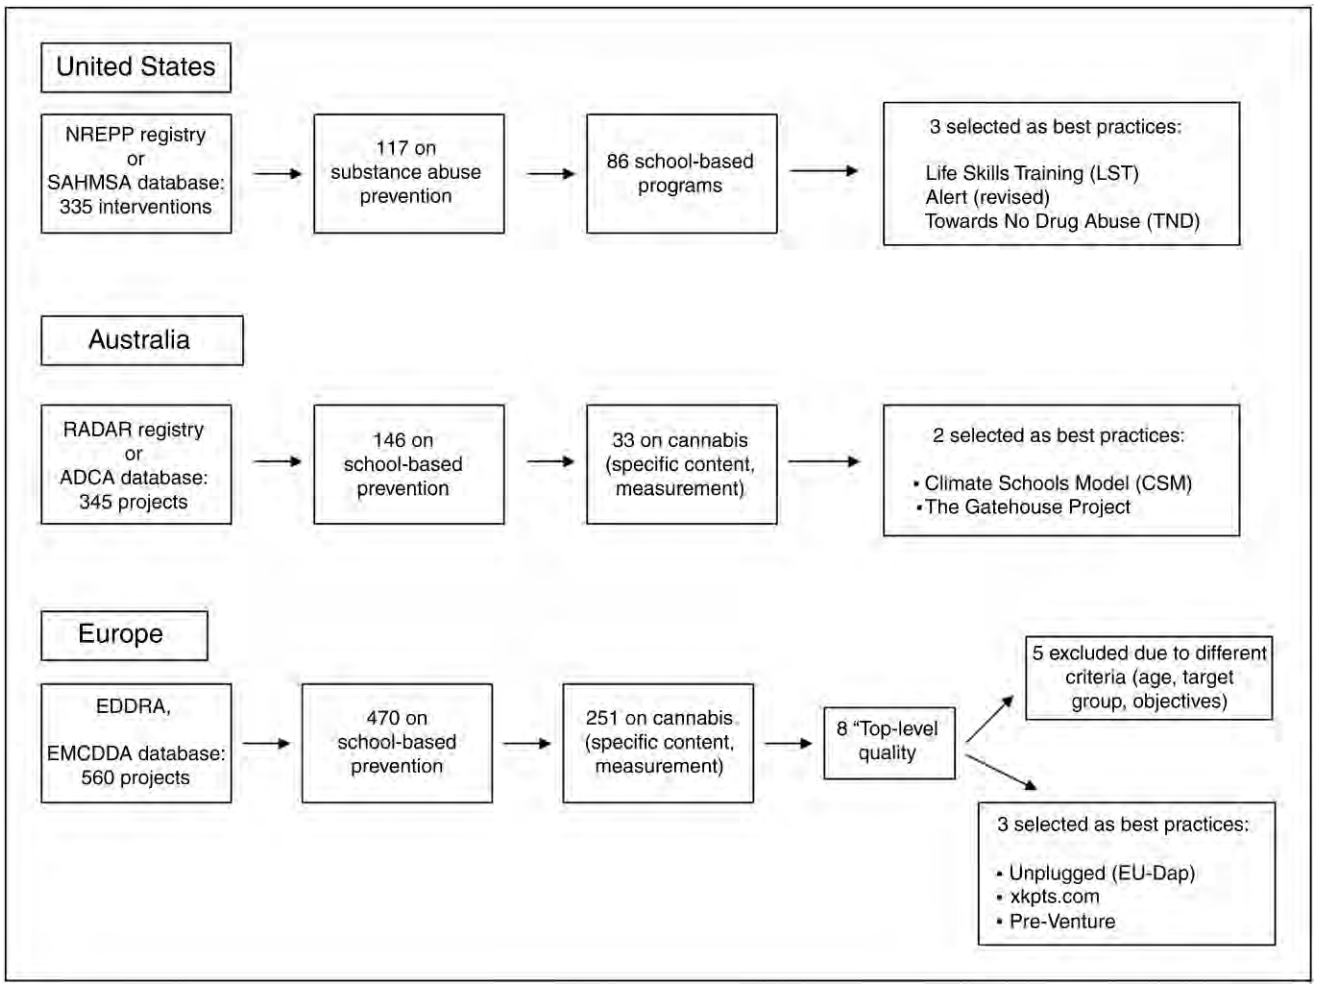

FIGURE 111.2 Flow-diagram of the identification process for best practices. The figure includes the flow-diagram with the detailed process for the selection of the eight best practices described in the article. *NREPP*, National Registry of Evidence-based Programs and Policies; *SAMHSA*, Substance Abuse and Mental Health Services Administration; *RADAR*, Register of Australian Drug and Alcohol Research; *ADCA*, Alcohol and Other Drugs Council of Australia; *EDDRA*, Exchange on Drug Demand Reduction Action; *EMCDDA*, European Monitoring Centre for Drugs and Drug Addiction.

promoted in Barcelona, Spain. The third is "Pre-Venture" (Pre-Venture, 2014), a selective program or personality-targeted cognitive behavioral intervention to reduce alcohol and drug misuse (with cannabis among these drugs). Implemented and coordinated in London, it is addressed to pupils aged 13–16.

Characteristics of the Selected Best Practices

The main characteristics of the selected best practices are shown in Table 111.3. The North American programs and the Gatehouse Australian Project are the older and started between 1994 and 1997. The three European projects and the Australian Climate Schools Model came later (2003–06).

Among the American projects, "Life Skills Training" (LST) was developed in New York City and the other two, project "Alert" and "Towards No Drug Abuse" (TND), in California. From Australian interventions, the "Climate Schools Model" (CSM) was created in New South Wales and the "Gatehouse Project" (GP) in Victoria. The first of three European programs, "Unplugged" (European Drug Addiction Prevention Trial, 2014) was tested in Austria, Belgium, Germany, Greece, Spain, Sweden and Italy and designed and coordinated in this last country. The program "xkpts.com" (xkpts.com, 2014) was designed and evaluated in Barcelona (Spain), and the project "Pre-Venture" (Pre-Venture, 2014) took place in London (United Kingdom).

The majority of the projects are of universal prevention, due to the fact that the classroom component is the element, which allows contact with the greatest number of population. However, two of the selected programs offered the possibilities to focus the intervention on high risk groups: (1) in the case of TND Project offering also actions to the remaining "normalized" population, and

(2) in the case of "Pre-venture," paying total attention to pupils with drug problematic behavior.

The majority of programs have a similar target population age range, of 13–17 year olds. Only "Unplugged" concentrated the intervention in the 12–14 age range.

Only two programs (CSM and "xkpts.com") include a specific session about cannabis in their content. GP worked on developing affective and emotional skills content in the classroom, which could be later applied to preventing students' cannabis use. The rest of the projects targeted substance use in general (tobacco, alcohol, and cannabis, and also other drugs, in combination).

All the universal prevention programs have the teacher as the main provider of the intervention. In the case of selective or indicated programs, health educators or health professionals were the main project leaders.

According to the number of sessions and length, program duration can be defined as short (ranging from 0 to 10 h) or long (more than 10 h) (Norberg et al., 2013). TND, CSM, "xkpts.com" and "Pre-Venture" are classified as short interventions, while LST, Project Alert, GP, and "Unplugged" are defined as long projects.

All the programs have a manual for teachers or the main provider of the intervention. In the case of five of these projects, a training workshop was provided for teachers. The remaining programs offered an online course and/or support. The majority of interventions also included a student workbook. In four cases (the three American programs and "xkpts.com") video material is offered among the resources.

The last column of Table 111.3 indicates the quality rating that the different databases classified their programs; thus, the reference punctuation is different according to the geographical procedure. North American programs were rated between 3.1 and 4 from SAMHSA score. The Australian RADAR database does not rate interventions; for this reason we use the SAMHSA rating for CSM. However, GP is not included in SAMHSA and therefore no rating is available. According to the EDDRA quality rating, the three European selected programs were classified as "top-level" score.

Other Intervention and Evaluation Details of the Selected Best Practices

The details that complement the intervention and effectiveness evaluation of each program are included in Table 111.4.

"LifeSkills Training" (LST) is based on both the social influence and competence enhancement models of prevention (http://www.lifeskillstraining.com/). This program helps young people to face the most important risk factors associated with alcohol, tobacco, and cannabis and, in an interactive format, develop the skills to understand and resist prodrug influences. Broad dissemination of LST started in 1995 and, since then, approximately 50,000 teachers, 10,000 schools, and 3 million students have participated in the program. LST has been extensively evaluated in different studies, several of which were conducted by its author, Gilbert Botvin and his coworkers (Botvin et al., 1995, 2000b). In one of them, carried out in 56 schools, an effect size of 0.09 in the monthly use of cannabis remained 6 years after the beginning of the study (Botvin et al., 1995).

Project "Alert" is based on the social influence model of prevention and designed to help young people to avoid using drugs (http://www.projectalert.com/). The project helped to develop an interactive scenario incorporating skills to resist cannabis and other social influences related to drugs. Its author, Phyllis Ellickson, and her coworkers participated in the majority of evaluation studies. In the second major evaluation, in 55 middle schools in South Dakota, was achieved an effect size of 0.15 in lifetime use of cannabis and from 0.08 in the monthly use at 18 months follow-up (Ellickson, McCaffrey, Ghosh-Dastidar, & Longshore, 2003). The dissemination of Project Alert began in 1995 and from then more than 50,000 teachers have been trained to deliver the intervention.

Project "Towards No Drug Abuse" (TND) is designed to help students to develop self-control and communication skills for resisting drug use, improving decision-making strategies and developing motivation to not use drugs (http://tnd.usc.edu). It was initially addressed at high-risk students and later adapted for all students attending traditional high schools. The project was designed by Steve Sussman and coworkers, who conducted some of the evaluations of the program between 1998 and 2009 (Sussman et al., 1998; Sun et al., 2006). In the last of these studies, a long-term outcome evaluation was carried out. Self-reported frequency of cannabis use in the past 30 days decreased by 22% among students in Project TND 12 months after the intervention, which was statistically significant compared to students in control group schools. The effect size at 60 months follow-up was 0.04 (Sun et al., 2006).

"Climate Schools Model" (CSM) is based on a social influence approach to prevention and uses cartoon storylines to engage student involvement (http://www.climateschools.com.au). Each lesson has two parts: an Internet-based activity (students log onto the CSM website and follow an episode of cartoon-based drama about real-life situations involving cannabis use); and a teacher-led activity that reinforce the information of cartoons and allows interactive communication between students. The intervention was developed in Australia in 2006 and also reviewed by NREPP of SAMHSA to assess quality of research. The program has been delivered to approximately 4000 students in Australia and also in the United Kingdom. The evaluation was conducted by

Newton et al. (2010). They showed that, in 10 Sydney metropolitan area schools, there was a decrease of intervention group frequency of cannabis use (mean difference, –0.06 times per week) compared to the control group (with a mean difference, 0.20 times per week) ($p < 0.02$), 6 months after the program. This significant difference between groups in cannabis use diminished 12 months following the intervention ($p = 0.11$). In terms of effect size, at 6 months follow-up Cohen's "*d*" was 0.16 (Newton et al., 2010).

The "Gatehouse Project" (GP) was developed in 1997 in Victoria, Australia, by George Patton and coworkers from the University of Melbourne (http://www.gatehouseproject.com). It includes a prevention program, derived from attachment theory and focused on three aspects of the social context: security, communication and participation. In addition, the curriculum in the early years of high school focused on skills for social functioning and emotional adjustment (Patton et al., 2003). The project was evaluated using a randomized controlled trial in 26 metropolitan Melbourne schools and the prevalence and incidence of cannabis use was examined 1 and 2 years after the program commenced. The intervention revealed a reduction of 0.8 in the incidence of weekly cannabis use in the intervention group (3.2%), related the control group (4.0%), which is not statistically significant. The reduction increased among nonsmokers at baseline. In terms of effect size these results supposed values of Cohen's "*d*" of 0.12 at 24 months (Bond et al., 2004).

"Unplugged" is a school-based drug prevention program based on the comprehensive social influence approach, that has been evaluated in the context of the European collaborative randomized controlled trial EU-Dap (http://www.eudap.net). It was conducted by Fabrizio Faggiano and coworkers in Turin (Italy), coordinating other six European countries between 2004 and 2007. The interactive program, with 12 classroom sessions, is delivered weekly by teachers and includes social skills, personal skills, knowledge, and normative education. The program is multimodal, with peers meetings, and also seminars for parents. The evaluation of the effectiveness of the prevention program, 18-month follow-up, showed a prevalence of any use of cannabis in the past 30 days of 3.3% in the intervention group versus 5.3% in control schools. That represented an absolute risk reduction in the multilevel model of the prevalence of cannabis use in past 30 days of 2.2% (Faggiano et al., 2010). That also supposes a Cohen's "*d*" of 0.17, the two values being statistically significant.

The program "xkpts.com" is a cannabis prevention intervention addressed to facing the progression from experimental use to current use (that is, any use in the past 30 days) (http://www.aspb.cat/quefem/escoles/canyes-petes.aspx). It is based on social influences model and skills training. The four-session program, developed over 10 h, spends two sessions on general issues regarding drug dependence and two specific sessions centered on group pressure to use cannabis and skills training to cope with the offer of cannabis. Parents are also involved and provided with a brochure about how to speak at home with their children about cannabis. The program also offers a webpage for students (http://www.sortimbcn.cat/xkpts/) with other different content related to that covered at school. Carles Ariza and coworkers conducted the effectiveness evaluation with a quasi-experimental pre-post controlled study. 4848 students from 86 Barcelona schools participated in the evaluation. Data showed an incidence of new users in past 30 days of 8.3% in the experimental group related to 11.7% in the control group, which was a statistically significant difference (Ariza et al., 2013). The effect size of this difference represents 0.19, according to Cohen's "*d*."

Finally, "Pre-Venture" is a personality targeted cognitive behavioral intervention to reduce alcohol and drug misuse (http://legacy.nreppadmin.net/ViewIntervention.aspx?id=264). Four personality dimensions have been linked to cannabis and other drug use: anxiety-sensitivity, hopelessness, impulsivity and sensation seeking. "Pre-Venture" began in Jan. 2004 and is currently being conducted in 25 mainstream schools in London boroughs. It was piloted by Patricia Conrod, in Canada (Conrod et al., 2010), and then developed at the National Addiction Centre to be developmentally and culturally appropriate for UK youth. The program offers psycho-educational manuals within interactive group sessions with students aged 13–16 years. Group sessions focuses on motivational factors for risky behaviors and provide students with coping skills to aid their decision making in situations involving anxiety and depression, thrill seeking, aggressive and risky behavior (eg, theft, vandalism and bullying), drugs and alcohol misuse. A randomized control trial was conducted with 732 high-risk students in London secondary schools. The intervention was associated with a decrease of frequency of cannabis use in the past 6 months from 5.6% at 24 months after the brief intervention (29.7% (EG) versus 35.3% (CG). This difference and a Cohen's "*d*" effect size of 0.20 were both statistically significant (Conrod et al., 2010).

MINI-DICTIONARY

Best practice Refer to interventions that are supposed to lead to desired outcomes.

Comparison group Group of people whose members have characteristics and demographics similar to those of the intervention group, but didn't receive the intervention.

Comprehensive intervention Array of interventions to address the main precursors or mediators of the target problem.

Comprehensive interventions include two dimensions: multiple interventions (about information, awareness, attitudes, social influences, skills…) and multiple settings (parents, peers, school, community…).

Effect size Effect of treatment for a study. Usually defined as the difference in means between the intervention and control groups, divided by the standard deviation of the control or both groups.

Interactive program Interventions which foster interpersonal skills and active engagement between students and teachers.

Outcome evaluation Systematic examination of the outcomes (changes, usually benefits), resulting from a set of activities implemented to achieve a stated goal, and a systematic examination of the extent to which those activities actually caused those outcomes to occur.

Selective prevention Strategies targeted to subsets of the total population that are deemed to be at risk for substance abuse by virtue of their membership in a particular population segment.

Skills-focused programs Preventive programs which content aim to increase an awareness of social influences regarding drug use and to teach skills which allow adolescents to face pressure to use drugs.

Unimodal/multimodal program Preventive programs can use an exclusive component (unimodal) (ie, school-based or family-based) or different components (multimodal) as family, peer, community, school-based…

Universal prevention Strategies addressed to the entire population (national, local community, school, neighborhood), with messages and programs aimed at preventing or delaying the abuse of alcohol, tobacco, and other drugs.

CHAPTER

112

The CapOpus Trial for Cannabis Use Disorders

C.R. Hjorthøj, M. Nordentoft

Mental Health Center Copenhagen, Copenhagen University Hospital, Copenhagen, Denmark

SUMMARY POINTS

- CapOpus was a randomized trial of 6 months' specialized psychosocial intervention compared to treatment as usual (TAU) for cannabis use disorder in people with schizophrenia and other psychoses.
- There was no effect on the primary outcome, that is, no reductions in frequency of cannabis use.
- People receiving CapOpus reduced the quantity of cannabis used, namely using less per day, albeit on the same number of days.
- People receiving CapOpus had more psychiatric treatment contacts, but admissions were shorter, probably indicating a more adequate level of treatment.
- CapOpus does not appear to be sufficient to implement as a treatment, but it may be useful in future combination treatment paradigms.

KEY FACTS ON THE CapOpus TREATMENT

- CapOpus was a randomized trial of cognitive behavior therapy and motivational interviewing for cannabis use disorder in people with schizophrenia and other psychoses.
- CapOpus specialized intervention did not reduce frequency of cannabis consumption.
- CapOpus reduced the amount of joints used to 27.3, compared to 48.2 per month in the comparison group.
- CapOpus led to fewer days admitted in psychiatric hospitals (IRR 0.72).
- CapOpus led to more psychiatric emergency room contacts and hospital admissions (IRR 3.47 and 2.24, respectively).

LIST OF ABBREVIATIONS

95% CI	95% Confidence interval
BACS	Brief assessment of cognition in schizophrenia
CBT	Cognitive behavior therapy
CSQ	Client satisfaction questionnaire
EQ-5D	Euroqol's five item quality of life instrument
ICD-10	International classification of diseases, 10th edition
IRR	Incidence rate ratio
MANSA	Manchester short assessment of quality of life
OR	Odds ratio
PANSS	Positive and negative syndrome scale for schizophrenia
SCAN	Schedules for clinical assessment in neuropsychiatry
SD	Standard deviation
TAU	Treatment as usual
THC	Δ^9-Tetrahydrocannabinol
TLFB	Timeline follow-back

INTRODUCTION

As discussed in much detail elsewhere in this book, cannabis is the most commonly used illicit substance in the world, and it is especially prevalent in people with severe mental illness such as schizophrenia. Both current use and current misuse of cannabis is much more prevalent in people with schizophrenia than in the background population, the observation of which has implicated cannabis as a potentially etiological component in schizophrenia. The fact that cannabis can trigger cannabis-induced psychosis, which is probably phenotypically indistinguishable from schizophrenia, lends further credibility to this potential causal role.

Regardless of this potential role as a trigger for schizophrenia, a number of studies have observed that people with schizophrenia have a poorer prognosis on a range of outcomes if they use cannabis. More severe levels of psychotic symptoms, more hospitalizations, reduced adherence to antipsychotic medication, and a greater risk of homelessness, have all been linked to cannabis use in people with schizophrenia. Conversely, studies have also indicated that people with schizophrenia who use cannabis have fewer negative symptoms and better cognitive skills, compared to their noncannabis-using counterparts. However, randomized, blinded studies on the acute effects of Δ^9-tetrahydrocannabinol (THC) versus placebo given to people with schizophrenia indicate that negative symptoms are increased, and cognitive abilities decreased in the groups receiving THC. As such, it appears that cannabis is associated with worse outcomes on most if not all of the relevant studied outcomes, in people with schizophrenia. While this could be a case of confounding by indication (ie, the self-medication hypothesis), it raises the question whether, perhaps, the prognosis of this group of people with schizophrenia could be improved if they were to reduce or completely discontinue their use of cannabis.

Unfortunately, most trials conducted on cannabis use disorders in people with schizophrenia have been unsuccessful, and it appears that it may be easier to treat other types of substance use disorders in this population. For this reason, the CapOpus trial was initiated in 2007 under the leadership of Professor Merete Nordentoft from the Copenhagen University Hospital. The trial was a 6-month, parallel-group, observer-blinded superiority trial comparing CapOpus plus treatment as usual (TAU) with TAU alone, including patients—from Sep. 2007 to Dec. 2010—in Copenhagen, Denmark. Patients were referred from Danish early psychosis intervention services (Opus teams) (Petersen et al., 2005), Community Mental Health Centers (Nordentoft et al., 1996), Assertive Community Treatment teams (Vendsborg, Nordentoft, Hvenegaard, & Søgaard, 1999), and psychiatric wards. Patients were required to meet both the ICD-10 criteria for a schizophrenia spectrum psychosis (F2) and for a cannabis use disorder (F12); the participants included were aged 17–42 years, had to reside in the Copenhagen area, be able to participate in the trial without the aid of an interpreter, and be able and willing to give informed consent. Dependence to other substances was allowed, if participants themselves designated cannabis as their primary substance of abuse. The diagnosis of schizophrenia spectrum psychosis was usually established by the referring agent and, in cases of doubt, was established by the Schedules for Clinical Assessment in Neuropsychiatry (SCAN) interview (Wing et al., 1990). At this point, participants were randomized to receive either CapOpus as an add-on to TAU, or TAU alone.

INTERVENTIONS

CapOpus

CapOpus was an add-on intervention to TAU (see section Treatment as Usual), which all patients received. Full details are given in the design paper (Hjorthøj et al., 2008) and full protocol (www.capopus.dk). The intervention was based on the EPPIC manual, and was similar to the Midas trial (Hinton, Elkins, & Edwards, 2002; Barrowclough et al., 2010). CapOpus lasted 6 months, with one or two weekly sessions. The intervention was centered around motivational interviewing (Miller & Rollnick, 2002; Miller, 1983) and cognitive behavior therapy (CBT). Emphasis was placed on analyzing advantages and disadvantages of continued use, and instructions in development of personal strategies, in relation to craving trigger situations. The sessions could take place in CapOpus offices, at the patient's home, or treatment facility.

An important part of the CapOpus treatment was to help the patient understand the mechanisms that complicate cessation of cannabis use. The overall target was harm reduction, that is, that harm from cannabis consumption is thought to be alleviated, even if consumption is not terminated, but only reduced.

Upon inclusion, the patient's case manager at the referring institution was offered education and supervision by one of the addiction consultants employed in the CapOpus trial.

To increase adherence to treatment, positive reinforcement was applied through contingency management in the form of complimentary food and social experiences, which may enhance outcomes of cognitive behavioral therapy or motivational enhancement (Denis, Lavie, Fatseas, & Auriacombe, 2006). Contingency management in the CapOpus trial had no connection to whether or not the use of cannabis is decreased. The uptake of this was minimal and was deemed to have influenced the consultant-participant alliance in a maximum of six participants.

The experimental CapOpus intervention was offered in addition to TAU. The interventions offered to the patients were registered, so that it was possible to estimate if the two intervention groups receive different forms of treatment as usual.

Caseload was intended to be 1:10, but was usually between 1:6 and 1:7.

Treatment as Usual

TAU consisted of the treatment available to patients had they not participated in the trial, provided by staff not employed by CapOpus. TAU was carried out in Opus, Community Mental Health Centers, or Assertive Community Treatment teams (Petersen et al., 2005; Nordentoft et al., 1996; Vendsborg et al., 1999). These facilities do not have explicit manuals regarding the treatment of substance use disorders. Caseload is approximately 1:10 in Opus and Assertive Community Treatment teams, and 1:20 to 1:30 in Community Mental Health Centers.

The primary outcome was the number of days with cannabis use in the past month, with recall assisted by Timeline Follow-Back (TLFB; Sobell & Sobell, 1992). This also allowed for quantification of number of "standard joints" last month (defined as 0.5 g of cannabis resin). TLFB-assisted self-report has been shown to validly estimate cannabis consumption in dual diagnosis patients (Hjorthøj, Hjorthøj, & Nordentoft, 2012; Hjorthøj, Fohlmann, Larsen, Arendt, & Nordentoft, 2012). Baseline information on other abuse diagnoses was collected using SCAN. Secondary outcomes were the Positive and Negative Syndrome Scale (PANSS; Kay, Fiszbein, & Opler, 1987), Global Assessment of Functioning (Endicott, Spitzer, Fleiss, & Cohen, 1976), WHO's Disability Assessment Schedule (WHO, 2000), EuroQol's Quality of Life Interview (EQ-5D; Brooks, 1996), Manchester Short Assessment of Quality of Life (MANSA) (Priebe, Huxley, Knight, & Evans, 1999), Brief Assessment of Cognition in Schizophrenia symbol coding (BACS; Keefe et al., 2004), Trail Making Tests A + B (Bowie & Harvey, 2006), Continuous Performance Test—Identical Pairs (Cornblatt, Lenzenweger, & Erlenmeyer-Kimling, 1989), Hopkins Verbal Learning Test (Brandt, 1991), Neuropsychological Assessment Battery mazes (Stern & White, 2003), and the Danish adaptation of the National Adult Reading Test (Nelson & O'Connell, 1978; Hjorthøj, Vesterager, & Nordentoft, 2012). The Client Satisfaction Questionnaire (CSQ) was administered posttreatment (Larsen, Attkisson, Hargreaves, & Nguyen, 1979). Outcome measures on healthcare utilization will be published separately.

Analyses were also conducted based on register-data, on which there was information for all participants in CapOpus. This was done using the nationwide Danish Psychiatric Central Research Register (Mors, Perto, & Mortensen, 2011). Information from this register was condensed into the following variables: time at risk of first psychiatric hospital admission; time at risk of first psychiatric emergency room visit; time at risk of either admission or emergency room visit; number of psychiatric hospital admissions; number of psychiatric emergency room visits; and number of days admitted to psychiatric hospitals.

Patients were randomized to CapOpus plus TAU (n = 52) or TAU alone (n = 51), with no indications of skewed distribution of cannabis consumption or other baseline characteristics between intervention groups. There was a follow-up rate of 66%.

EFFECT OF INTERVENTION ON CANNABIS CONSUMPTION

The effect of treatment on cannabis use is presented in Table 112.1 as incidence rate ratios (ratio-of-days) for the CapOpus group compared with the TAU group, showing no significant differences posttreatment or at follow-up. The absolute consumption of cannabis is also shown in Fig. 112.1. The ratio of cannabis-using days in CapOpus versus TAU was 0.76 [95% confidence interval (CI) 0.38–1.50] (p = 0.42) posttreatment, and 0.80 (95% CI 0.21 –3.10) (p = 0.75) at follow-up. CapOpus-participants smoked 20.9 (95% CI –1.0 to 42.9) fewer joints posttreatment per month than TAU participants (p = 0.06), whereas the difference was 13.3 (95% CI –8.5 to 35.1) (p = 0.23) at follow-up. There was no difference in rates of complete abstinence from cannabis in the two groups (OR = 1.31 (95% CI 0.47–3.64), p = 0.61 posttreatment, and OR = 0.64 (95% CI 0.25–1.68), p = 0.37, at the 10-month follow-up).

Did It Work Better on Some People?

Table 112.1 also shows the effect of treatment on different subpopulations within the randomized trial. It appeared that CapOpus was particularly efficient among those not abstinent at baseline, with a relative reduction of 26.1 (95% CI 3.5–48.7) standard joints per month (p = 0.02). CapOpus also appeared to be effective among the younger patients, defined as those who were 17–21 years old upon inclusion into the trial. Such CapOpus-participants reduced their number of cannabis-using days posttreatment by a third, and their number of monthly joints by half. Young TAU-participants increased their cannabis use to nearly daily consumption, and 40% more joints. Unemployed patients in CapOpus more than halved their number of posttreatment monthly joints, whereas unemployed patients in TAU did not alter their consumption (p = 0.03).

TABLE 112.1 Ratio of Number of Days (incidence rate ratios) of Days With Cannabis Use in the CapOpus Group Compared to TAU (95% Confidence Intervals)

	Baseline	Posttreatment		Follow-up		
Subgroups	**IRR (95% CI)**	**IRR (95% CI)**	**CapOpus versus TAU**	**IRR (95% CI)**	**CapOpus versus TAU**	***P* (group* time)**
All patients (*n* = 103)	0.94 (0.85–1.04)	0.76 (0.38–1.50)	*p* = 0.42	0.80 (0.21–3.10)	*0* = 0.75	0.25

CONTACT WITH TREATMENT FACILITIES

Table 112.2 shows the relative use of psychiatric services in CapOpus, compared to TAU. Participants in the CapOpus group had 3.47 (95% CI 2.64–4.57) times as many psychiatric emergency room contacts as those who had received TAU. The time to first emergency room contact was also much faster in the CapOpus group, as indicated by a hazard ratio of 2.02 (95% CI 1.22–3.34). Those who received CapOpus also had more psychiatric hospital admissions. However, those who received CapOpus were admitted fewer days to psychiatric inpatient wards (incidence rate ratio 0.72 (95% CI 0.68–0.75).

Time to first psychiatric emergency room contact and first psychiatric admission following inclusion into the trial are illustrated in Figs. 112.2 and 112.3, respectively.

TABLE 112.2 Effects of CapOpus on Level of Psychiatric Treatment

	TAU (n = 50)	CapOpus (n = 51)	
Cox proportional hazards regression analyses; hazard ratios and 95% confidence intervals			
Time to psychiatric emergency room contact	1 (ref.)	2.02 (1.22–3.34)	$p = 0.006$
Time to psychiatric hospital admission	1 (ref.)	1.48 (0.91–2.41)	$p = 0.12$
Time to any psychiatric contact	1 (ref.)	1.54 (0.96–2.46)	$p = 0.07$

It is evident from these figures that the CapOpus group had a much faster contact with both types of psychiatric services in the period immediately following inclusion. This was at least partly explained by CapOpus consultants facilitating contact with other treatment facilities when needed.

CONCLUSIONS

The CapOpus intervention appeared to be somewhat effective in reducing the monthly number of joints used, but not in reducing the number of days on which this use took place. Those not abstinent at baseline,

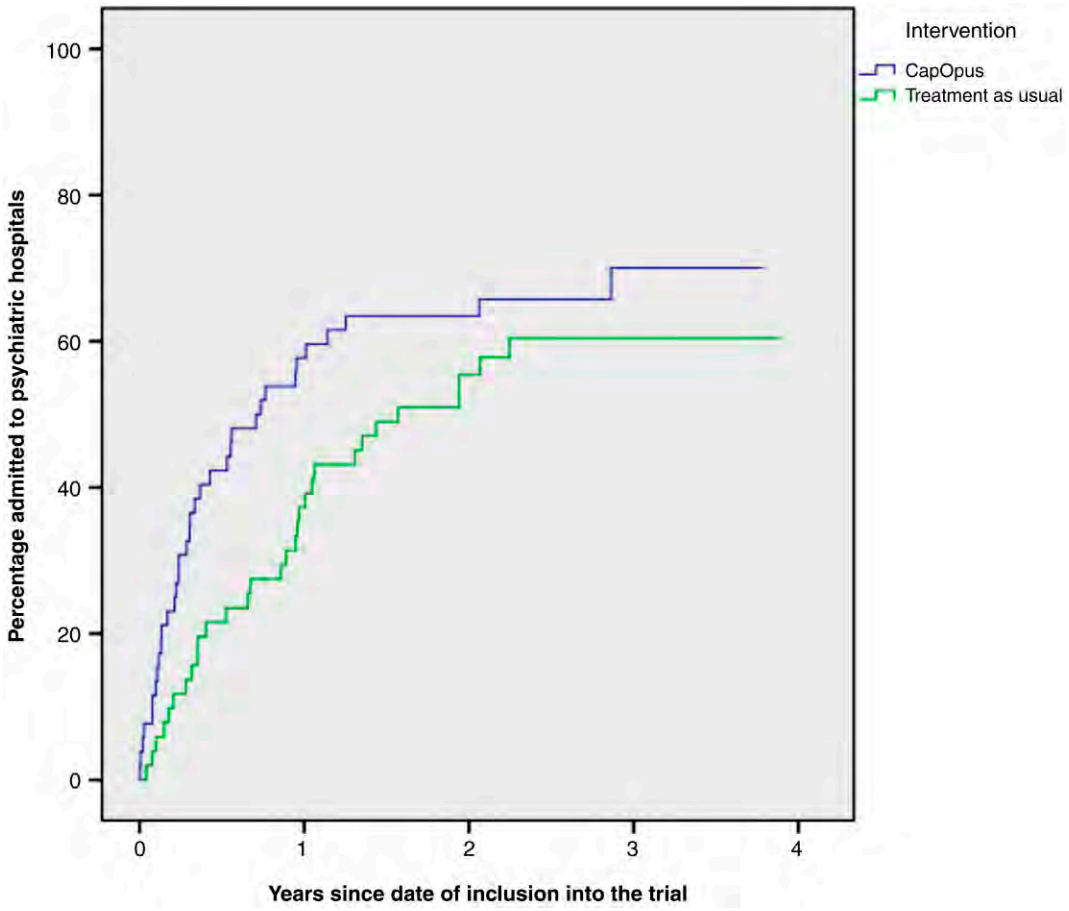

FIGURE 112.3 **Time to first psychiatric hospital contact by intervention group.** *Source: Reproduced from Hjorthøj et al. younger participants, and unemployed participants appeared to have particularly positive effects of the CapOpus treatment. Although CapOpus increased the rates of psychiatric hospital admission and emergency room visits, those inpatient stays were of shorter duration when summed over the complete follow-up. This combination of results probably indicates that CapOpus patients were given more adequate treatment, and that those only receiving TAU had fewer inpatient contacts because they were undertreated, leading to prolonged stays in psychiatric wards, once they were finally admitted. This may have occurred by facilitation of referrals or admissions by the CapOpus consultants, or by the patients learning by the CapOpus consultants when to seek additional treatment on their own. The possibility that the increased treatment contact in CapOpus patients could be a detrimental consequence of CapOpus cannot be fully excluded, however. It may be a stressor for patients to start a new type of intervention with new staff, and stressors have been shown to exacerbate psychotic symptoms (Myin-Germeys & van Os, 2007; Norman & Malla, 1993). The odds of abstinence were similar in CapOpus and TAU, so it is unlikely that the increase in treatment contact was related to more withdrawal symptoms in the CapOpus group.

MINI-DICTIONARY

Negative symptoms Symptoms indicating a loss from normal function, such as affective flattening, apathy, and social withdrawal.

Odds ratio (OR), hazard ratio (HR) and incidence rate ratio (IRR) Different statistical terms that are typically all interpreted as indicating relative risk, that is, how much more likely it is that something occurs in one group compared with another.

Psychosis A mental state involving such elements as hallucinations and delusions.

p-value A statistical indicator of whether an association is likely the product of statistical chance rather than reflecting a true association. The number is interpreted as the percentage likelihood that the association could be due to chance. Usually, *p*-values below 0.05 (5%) are considered most likely to reflect true associations rather than statistical chance.

Randomized trial Study design in which participants are randomly assigned to the different interventions. This is considered the gold standard for testing interventions in medical research.

Schizophrenia A mental illness usually characterized by psychosis and negative symptoms.

Treating Cannabis Use Disorders Through Technology-Assisted Interventions: the Telephone and Internet

P. Gates, J. Copeland

National Cannabis Prevention and Information Centre, University of New South Wales, Randwick, NSW, Australia

SUMMARY POINTS

- This chapter focuses on the use of technology-assisted interventions for managing cannabis use disorder.
- Treatment seeking for cannabis use disorder is particularly low compared to other illicit drugs despite meeting criteria for cannabis use disorder. Potential barriers include a fear of being stigmatized as a substance user and difficulty in accessing treatments even when they are available.
- Technology-assisted interventions may address these barriers by providing a low-cost treatment that is easily accessible and avoids potential stigma by minimizing personal contact with treatment providers.
- High-tech computer-based interventions are currently available to treatment seekers via the internet. These interventions have been shown to be comparable to face-to-face interventions in a handful of studies; however, little is known with regards to the mechanisms that work toward assisting with cannabis use reductions. Younger individuals and males seem to respond more positively to this treatment format, compared to older females. Dropout is a particular concern, as less than half of those who were involved with trials of these interventions were likely to complete them.
- Low-tech telephone counseling cannabis use interventions are not widely available to treatment seekers, with some exceptions. Two randomized controlled trials have assessed the efficacy of this form of delivery, although neither trial assessed the effectiveness of such an intervention in the long-term. Although not directly compared, the reported abstinence rates following this intervention type were comparable to face-to-face intervention. These interventions may be better received by older individuals and by females, compared to younger males. As with computer-based interventions, participant attrition has been a concern.

KEY FACTS OF COGNITIVE BEHAVIORAL THERAPY (CBT)

- CBT teaches management, coping and problem-solving skills to assist clients in recognizing and managing any actions that lead to an unwanted behavior.
- When applied to substance use, coping skills are paramount in order to avoid the unwanted behavior of failing to avoid substance use.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00132-0
Copyright © 2017 Elsevier Inc. All rights reserved.

- Substance use is perceived as a learned behavior following predictable outcomes and cognitive behavioral therapy aims to disrupt the connection between substance use and these outcomes.
- CBT is the most consistently evaluated form of substance use treatment and has been shown to be effective in helping adults reduce their use.

KEY FACTS OF MOTIVATIONAL ENHANCEMENT THERAPY

- Motivational enhancement therapy (MET) encourages talk about change but also provides feedback and education regarding the client's substance use.
- The client can "take stock" of their substance use as the therapist assists them in using information as a means of encouraging reductions to use.
- MET is commonly combined with cognitive behavioral therapy (CBT), where MET enhances and solidifies readiness to reduce use, and CBT is delivered when the client is ready to begin making this change.

KEY FACTS OF TECHNOLOGY-ASSISTED INTERVENTIONS IN TREATING CANNABIS USE DISORDER

- Technology-assisted interventions are being developed to treat cannabis use disorder in an attempt to enhance treatment accessibility, and avoiding potential stigma by minimizing personal contact with treatment providers.
- Telephone counseling is considered a "low-tech" intervention. When relating to management of cannabis use disorder, it refers to a treatment delivered by a trained counselor to the treatment seeker, via the telephone.
- Computer-based interventions are considered "high-tech" treatment. When relating to management of cannabis use disorder, this refers to a treatment delivered on a computer, giving a treatment seeker access to a predesigned intervention, with or without the assistance of a treatment provider and may be web based.

INTRODUCTION

Although most cannabis users do not feel the need to access drug treatment, it is due to the substantial prevalence of cannabis users (approximately 4% of the global population aged 15–64 years report recent use; UNODC, 2013), that cannabis treatment is important from a public health perspective (Copeland, Clement, & Swift, 2014). The literature on treating cannabis use disorders dates back to the 1970s, when the first national evaluation of substance use treatment in the United States found that most young people were entering treatment due to their cannabis use (Dennis, Babor, Roebuck, & Donaldson, 2002). Over the last 40 years, the efficacy of several face-to-face cannabis use interventions have been supported—most notably one to nine sessions of motivational enhancement therapy, combined with cognitive behavioral therapy [motivational enhancement therapy (MET) + cognitive behavioral therapy (CBT)] (Copeland et al., 2014; Denis, Lavie, Fatseas, & Auriacombe, 2006). Unfortunately, there remains to be a large "research to practice gap" hampering the large scale implementation and dissemination of MET + CBT treatments (Gotham, 2004). Attempts to address this gap have been hindered by a treatment system that is chiefly face-to-face, where the number of individuals reached is limited by the capacity and location of services (Bender, Tripodi, Sarteschi, & Vaughn, 2011; Dennis et al., 2002).

In an attempt to close this research-practice gap, some recent research has focused on technology-assisted interventions (Litvin, Abrantes, & Brown, 2013). That is, interventions which are supported by "high technology" (high-tech) such as computer-based programs, or applications and the internet, or by "low technology" (low-tech) such as interventions that use mobile and landline telephones to communicate. In particular, high-tech computer-based interventions have proven effective in large scale dissemination of treatments for illicit (Gainsbury & Blaszczynski, 2011; Moore, Fazzino, Garnet, Cutter, & Barry, 2011) and licit drug use (Rooke, Thorsteinsson, Karpin, Copeland, & Allsop, 2010). In addition, mobile-based interventions (Cohn, Hunter-Reel, Hagman, & Mitchell, 2011; Whittaker et al., 2009), interactive voice response interventions (Corkrey & Parkinson, 2002) and videoconferencing (often collectively referred to as telehealth or telemedicine) also show promise for licit drug treatment (Young, 2012; Benavides-Vaello, Strode, & Sheeran, 2013). Unlike these high-tech interventions that are rapidly increasing, comparatively low-tech interventions such as telephone counseling (telecounseling) remain largely overlooked, with two exceptions. First, telecounseling is a well-established treatment for tobacco smoking (Tzelepis et al., 2013; Stead, Perera, & Lancaster, 2006), and

thought to be cost-effective (Hollis et al., 2007). Second, the utility of the telephone is also beginning to be recognized as a promising modality for delivering continuing care (treatment that follows an initial episode of more intensive care) (Blodgett, Maisel, Fuh, Wilbourne, & Finney, 2014; Mckay, 2009).

The attractiveness of exploring technology-assisted interventions lies in their ability to transcend the limitations of traditional face-to-face treatments, particularly by being more accessible and low cost (improving treatment dissemination), and by reducing the work-load of service providers (improving the ease of treatment integration). In addition, as the treatment seeker does not need to physically enter treatment, the associated interactions with receptionists and dress codes are avoided, which may reduce any threats to personal space (Ranan & Blodgett, 1983; Hughes, Riggs, & Carpenter, 2001). This lack of face-to-face interaction may also reduce any experiences of stigma as treatment becomes more individualized (Livingston, Milne, Fang, & Amari, 2012), and anonymity can be maintained (thus reducing any potential threats to, eg, employment or child custody). The treatment itself can also be ended more easily by the treatment seeker (by logging off or hanging up the phone), which may result in greater candor and honesty (Reese, Conoley, & Brossart, 2006). Finally, the nature of the treatment also allows for greater operation hours, which may result in a greater ability to address in real time any experiences of craving or relapse to use (Borland, Balmford, Segan, Livingston, & Owen, 2003). Given these advantages of technology-assisted interventions, and an increasing need for cannabis-specific treatments, the findings from research on technology-assisted cannabis interventions are explored here.

DELIVERING A HIGH-TECH CANNABIS USE INTERVENTION

A recent systematic, metaanalytic literature review of computer-based cannabis use interventions has shown some initial support for their utility upon reviewing 10 studies; although the overall effect size was small [g = 0.16 (0.09–0.22); number-needed-to-treat ≈11] (Tait, Spijkerman, & Riper, 2013). As previous literature reviews on high-tech substance use interventions failed to find any cannabis-specific interventions (Gainsbury & Blaszczynski, 2011; Moore et al., 2011), Tait et al. (2013) expanded their inclusion criteria to identify any internet or computer delivered intervention with or without therapist guidance, conducted prior to Sep., 2012. All included studies were conducted in the past decade, with the initial study conducted in 2007 by Ondersma, Svikis, and Schuster (2007), who recruited a sample of new mothers.

In this review, only two interventions were classified as treatment for cannabis use (Tossmann, Jonas, Tensil, Lang, & Struber, 2011; Kay-Lambkin, Baker, Kelly, & Lewin, 2011), with the rest identified to be prevention programs. In addition, not included in this review, due to its nonrandomized design, was a computer-based counselor-guided cannabis use intervention (Budney et al., 2011), and a randomized controlled trial of a self-guided computer-based cannabis use intervention conducted after the review was published (Rooke, Copeland, Norberg, Hine, & Mccambridge, 2013). As such, a total of four separate trials of computer-based cannabis use treatment have been conducted, one of which was self-guided (Rooke et al., 2013). Some of the more pertinent information from these trials is described in Table 113.1.

In comparison to advice only, computer-based treatments (with and without guidance) were effective in reducing cannabis use frequency and quantity. Moreover, these treatments were comparative to similar interventions that were delivered face-to-face. Given the reduced costs involved with delivering such a cannabis intervention (minimal or no therapist guidance, compared to full therapist contact), the cost-effectiveness of computer-based interventions is likely.

With the research only just building, it is hard to determine the common mechanisms leading to positive outcomes across these treatments (Rooke et al., 2010). In particular, the ideal number of sessions to achieve positive treatment outcomes should be of particular interest in future research. Interestingly, only one trial found an association between treatment adherence (number of treatment sessions completed) and any reductions to cannabis use frequency at follow-up (Rooke et al., 2013). This is important, as few participants actually completed the treatments as they were intended. As such, it may be that initiating the computer-based treatment is more important in predicting treatment outcomes, as compared to actually completing it. If this is the case, the availability and ease of implementing these interventions is of particular advantage. Ideally, future research will address whether the number of intervention sessions or length of engagement to treatment predicts long-term outcomes.

Limitations of High-Tech Cannabis Use Interventions

The promising results from these trials are tempered by some limitations. First, a large number of participants were lost to follow-up, even when these interventions could be completed at the convenience of the participant and in their homes. Given that the reason for discontinuation is not known in most cases, it should not be assumed that the majority of dropouts felt that they could continue to reduce cannabis

TABLE 113.1 Summary of the Literature: Computer-Based Cannabis Use Interventions

[c] *Treatment completion was related to past month smoking days.*

use without intervention, as compared to dropouts exiting treatment with the belief that it may not work for them. In addition, the intention-to-treat statistical approaches used to account for missing data can not completely correct for this problem. As such, future work should address the high treatment attrition rates before this form of intervention delivery can be truly considered efficacious. Second, computer-based interventions may be at particular risk of breaching participant anonymity, unless proper protection protocols are ensured. That is, some computer-based interventions may require email address registration—which could be made available or accessed by other individuals (Tossman et al., 2011), or require the use of a shared computer. Third, as mentioned, given that the research is in preliminary stages, relatively little is known about the specific mechanisms of change that result in positive treatment outcomes. Even regarding the broader literature associated with computer delivered interventions for alcohol and tobacco use, there have been no statistically significant differences in treatment outcome reported, when considering the role of normative feedback, availability of a discussion feature, inclusion of entertainment features, emphasis on relapse prevention, or in the number of treatment sessions that are completed (Rooke et al., 2010). As such, further research is required to refine and improve these high-tech interventions.

DELIVERING A LOW-TECH CANNABIS USE INTERVENTION

To date, two studies have investigated the feasibility of delivering a specific cannabis use intervention by telephone (Gates, Norberg, Copeland, & Digiusto, 2012b; Fernandes et al., 2010). As with high-tech interventions, these trials of low-tech telecounseling interventions were conducted relatively recently, and offer an initial investigation to a promising treatment delivery option.

In the first trial of a telephone-based cannabis intervention, 1744 adult participants were recruited from callers to a Brazilian cannabis-specific helpline, over 21 months. These participants were mostly male (74%), with a mean age of 25 years. The intervention was a single 20 min MET + CBT-based session with complimentary self-help materials (n = 873), while the control group received only the self-help materials (n = 871). In addition, participants were free to access external treatment, and over one third of participants reported doing so (38%). Follow-up data was collected at eight time points, over a 6-month period, and the first 262 individuals from each group to complete the 6-month follow-up assessment were selected for analysis. There was notable dropout from the trial, with less than half (47%) of participants completing the first follow-up assessment (conducted 1 day from the call), and less than one-third (30%) completing the 6-month follow-up. Unfortunately, the authors did not attempt any statistical control to address this rate of dropout, meaning that results reflect only the most motivated treatment completers.

The cannabis-use outcome reported was "abstinence," although the period of abstinence was not defined. Encouragingly, 73% of the intervention and 59% of the control group reported abstinence at 6 months, meaning that intervention participants were 160% times more likely to report abstinence at 6 months (95% CI = 120–200%). The intervention effect was greater for females, compared to males, and those that reported high motivation to reduce cannabis use at the baseline assessment. This rate of abstinence was particularly impressive, even among the control group who had spoken with helpline counselors prior to participation. Indeed, the reported rate of abstinence was comparable to an effective face-to-face intervention of eight sessions of MET + CBT that included contingency management, where 54% of participants reported abstinence at 6-month follow-up (Carroll et al., 2006).

In the second trial of a telephone-based cannabis intervention, 160 adult participants were recruited from an Australian cannabis-specific helpline over 14 months. These participants were mostly male (61.9%), with a mean age of 36 years. The intervention was four CBT + MET sessions, delivered over 4 weeks, with complimentary self-help materials (n = 79), and a wait-list control group protocol was implemented (n = 81). Follow-up data was collected posttreatment, and at 3 months from baseline, with the majority of participants being assessed (68.7%).

In this trial, there was no significant treatment effect on cannabis use frequency or quantity (which reduced in both groups; d = 0.6 and 0.4, respectively); however, intervention participants reported greater improvements to cannabis-related problems (d = 0.5) and cannabis dependence (d = 0.9), compared to control participants, at 3 months. In depth analysis showed that the intervention effect was due to increasing the participant's confidence to quit cannabis use that was found to be more important than session attendance in predicting positive outcomes. Importantly, this trial controlled for dropout effects, and addressed treatment attendance, including the use of medications and any external treatment. In addition, the promising treatment outcomes were comparable with a more comprehensive and intensive trial of 12 sessions of therapist delivered MI + CBT (improvement in the percentage of abstinent days reached 74% on average in the telephone trial, compared to 64% of days at 4 months in the face-to-face treatment) (The Marijuana Treatment Project Research Group, 2004).

Limitations of Low-Tech Cannabis Use Interventions

As with high-tech interventions, the promising results from these trials are tempered by some limitations. First, participant dropout was again a concern. Although this may be somewhat compensated for by an increased reach of technology-assisted interventions, future work will need to find a way to improve retention in the same way that face-to-face treatment motivates return visits (although treatment dropout is a problem common to any treatment type for substance use). Second, the short 3–6 month follow-up assessment periods of these technology-assisted interventions prevent any predictions of their longer term effectiveness. In broader substance use intervention research, even the treatments themselves continue for at least 3 months (Dutra et al., 2008), and longer term follow-up is the norm. Third, participants were not blind to their allocation into the telecounseling interventions or control groups, in these two trials. According to trial quality checks encouraged by the Cochrane Collaboration when conducting systematic reviews of interventions (The Cochrane Collaboration, 2011), this lack of blinding introduces a risk of bias in participant self-report. As such, future work that includes adequate blinding is recommended. Finally, although not assessed in the trials reported here, telephone services are known to suffer from infrastructure problems that warrant consideration. In fact, a 2002 review of 115 Australian helplines reported that for every two calls answered, one person would have failed to contact the service, despite trying an average of 3.95 attempts to make contact (Urbis Keys Young, 2002).

COMPARING TECHNOLOGY-ASSISTED CANNABIS USE INTERVENTIONS

The technology-assisted cannabis use interventions reviewed here show great promise. Currently, however, high-tech and low-tech cannabis use interventions are not widely disseminated throughout real-world treatment practices. This is reflective of the fact that the associated research is in its infancy, and that there is a subsequent absence of a "gold star" standard intervention. That said, technology-assisted interventions offer a promising solution to overcoming many cannabis treatment seeking barriers, such as the feeling that accessing face-to-face treatment will invoke stigma, or the barriers of treatment location and wait list problems (Gates, Copeland, Swift, & Martin, 2012a). So, which technology-assisted intervention is best and for whom?

In a study comparing two similar MET + CBT-based cannabis use interventions that were delivered via the telephone (Gates et al., 2012b) and the web (Rooke et al., 2013) (available at www.reduceyouruse.org.au), several notable differences relating to treatment effects, sample characteristics, treatment engagement, and relationships among these variables were noted (Rooke, Gates, Norberg, & Copeland, 2014). First, the overall treatment effect on cannabis use outcomes was greater for the telephone study, compared to the web-based study. Given that the treatment fundamentals were similar across platforms, this difference may have reflected the nonvisual human interaction present in the telephone study, compared to the self-guided web study. In addition, the participants were reportedly more motivated to quit cannabis in the telephone study (reporting lower study dropout, greater external treatment seeking, and greater self-efficacy)—which was found to be a key predictor of treatment outcome.

Second, participant age and gender may be important in regards to treatment seeking behaviors relating to technology-assisted interventions. That is, participants in the web study were younger than those in the telephone study, and treatment engagement and satisfaction was higher among males, compared to females in the web study. Notably, treatment outcomes were greater for females, compared to males in the initial investigation of a telephone-delivered cannabis intervention (Fernandes et al., 2010). Taking these findings into consideration, it may be important for treatment providers to be mindful of their client's age and gender, and motivations to quit, prior to suggesting a technology-assisted intervention for cannabis use disorder. That is, younger males may respond better to a computer-based intervention, with the possible exception of those with severe dependence or lower motivation to quit. Similarly, older females may respond better to a telephone-based intervention. Obviously, given the early stages of research into these interventions, further research on this issue is required before such recommendations should be firmly made.

CONCLUSIONS

Technology-assisted interventions for cannabis use disorder offer a promising means to address the increasing need for treatment (Copeland & Swift, 2009). While early research shows that these interventions are capable of achieving treatment outcomes that are similar to face-to-face delivered services, very little is known in regards to how this may generalize to a population of heavy cannabis users with a history of other illicit substance use, or any comorbid mental health conditions. In addition, little is known regarding how many sessions should be delivered, and what content is associated with greater treatment outcomes. Regardless, the advantages

of technology-assisted interventions with regards to increased treatment accessibility at a low cost, warrant future research to refine and improve these interventions, and discover how to best implement both high-tech and low-tech interventions.

MINI-DICTIONARY

Cannabis use disorder Refers to a psychiatric diagnosis of clinical importance, relating to mild to severe dependence on cannabis that is typically characterized by a lack of control over use, or use despite known harms.

Cognitive behavioral therapy (CBT) Refers to a style of counseling that assists clients to recognize and manage any actions leading to unwanted behavior. This is primarily done through teaching management, coping, and problem-solving skills.

Motivational enhancement therapy Refers to a variant of motivational interviewing that utilizes motivational interviewing techniques (such as expressing empathy and supporting self-efficacy) in the treatment of substance use. In addition to these techniques, motivational enhancement therapy includes feedback and education regarding the client's substance use, and comparisons with population norms.

Motivational interviewing Refers to a style of counseling originated in 1983 that involves a conversation about making change while attending to any ambivalence. This is done through the expression of empathy, the support of self-efficacy, and the highlighting of areas where the client's ideals are discrepant from their reality.

Technology-assisted interventions Refers to any intervention which utilizes communications technology, such as computers and/or telephones, to assist in delivering treatment. In some cases, the therapist is not required, as the treatment can be delivered completely through the use of technology, as seen in some computer-based interventions.

Treatment attrition Refers to the number of clients who are selected to participate in a given treatment but, for various reasons, either do not begin the treatment or leave prematurely, and do not complete the treatment as it was intended. Treatment attrition is a particular concern with regards to technology assisted interventions.

CHAPTER

114

Reducing Cannabis Use With a Real-Time Intervention Using Mobile Technology

M. Kells, L.A. Shrier***

***Division of Adolescent/Young Adult Medicine, Boston Children's Hospital, Boston, MA, United States**
****Division of Adolescent/Young Adult Medicine, Boston Children's Hospital, and Department of Pediatrics, Harvard Medical School, Boston, MA, United States**

SUMMARY POINTS

- Most young people who use marijuana frequently are not seeking treatment. Primary care settings can provide marijuana treatment to this population as part of routine care.
- Motivational interventions are effective for reducing substance use in adults, and may be effective for adolescents as well.
- Motivational enhancement therapy (MET) utilizes the principles of motivational interviewing (MI), as well as personalized feedback to enhance motivation for behavior change.
- Although marijuana may be used to cope with negative affect, chronic and frequent use may result in increased negative affect, leading to a cycle of dependence.
- Marijuana is frequently used in social settings. Social interaction is linked to higher dose and level of intoxication.
- Ecological momentary assessment (EMA) is a method of collecting real-time reports in the natural environment via mobile technology. Ecological momentary interventions (EMIs) use EMA data to provide intervention in real time.
- Designed for frequently-using youth not in treatment, the MOMENT intervention combines brief in-person MET in primary care with real-time self-assessment and responsive messaging in the natural environment using mobile technology.

KEY FACTS OF ECOLOGICAL MOMENTARY INTERVENTIONS

- EMIs deliver behavior-change treatment in real-life contexts, in real time.
- EMIs allow for practice of coping, avoidance, and other skills learned during in-person counseling in daily life, as factors influencing behavior are being experienced.
- EMIs include self-monitoring, a major component of cognitive behavioral therapy (CBT) and mindfulness training, often used in substance use reduction and relapse prevention.
- EMIs can target an individual's personal triggers for behavior, and provide treatment during that vulnerable time.
- EMIs are delivered using mobile technology, allowing for privacy and discretion, which may be particularly important for sensitive or stigmatizing behaviors.
- EMIs are feasible and acceptable to a range of populations, and appear effective for intervening on a variety of health behaviors, including substance use.

CBT	Cognitive behavioral therapy
EMA	Ecological momentary assessment
EMI	Ecological momentary intervention
MET	Motivational enhancement therapy
MI	Motivational interviewing
SBIRT	Screening, brief intervention, and referral to treatment

FREQUENT MARIJUANA USE AMONG ADOLESCENTS AND YOUNG ADULTS

Marijuana continues to be the most common illicit drug of abuse by youth in the United States (Johnston, O'Malley, Bachman, & Schulenberg, 2012) and Europe (European Centre for Drugs and Drug Addiction, 2010). Frequent marijuana use among adolescents has been rising. The rate of US 12th graders who report daily marijuana use increased from 2.4% in 1993 to 6.5% in 2013 (Johnston et al., 2012). Declines in personal disapproval of use and perceived risk of regular use among youth, as well as the growing legalization of marijuana for both medical and recreational use, may herald further increases in marijuana use and abuse (Johnston et al., 2012).

Frequent marijuana use is associated with structural brain changes and negative effects in all domains of cognitive functioning (reviewed in Batalla et al., 2013). For those who initiate marijuana use during adolescence, these effects may persist despite cessation (Meier et al., 2012). Young people who use marijuana frequently are more likely to engage in polydrug use, have low academic intentions, and poorer academic outcomes (Ellickson, Tucker, Klein, & Saner, 2004b), less favorable developmental outcomes than their abstinent peers (Ellickson, Martino, & Collins, 2004a), and increased risk of developing a substance use disorder (Chen, Storr, & Anthony, 2009).

NEED FOR BRIEF TREATMENT IN PRIMARY CARE

Many young people recognize problems associated with their marijuana use, and try to quit (Copersino et al., 2010; Rhoads, Burke, Fredette, & Shrier, 2012), but often return to use (Hughes, Peters, Callas, Budney, & Livingston, 2008). Most individuals with marijuana use disorders are not in treatment programs. Adults cite lack of awareness of options, lack of perceived need for treatment, desire to continue use, and stigma as reasons for not seeking treatment (Gates, Copeland, Swift, & Martin, 2012). For adolescents, concerns regarding access, cost, and confidentiality (Sterling, Weisner, Hinman, & Parthasarathy, 2010), as well as limited specialized facilities and suboptimal care (Knudsen, 2009; SAMHSA, 2010) may also impede receipt of treatment. There is a need to develop engaging, effective, and accessible treatment options for the increasing population of youth with problematic marijuana use.

Primary care settings serving youth, in which providers are already identifying problematic substance use (Harris, Louis-Jacques, & Knight, 2014) and young people have already overcome barriers to accessing care, can offer time- and resource-efficient treatment. Screening, brief intervention, and referral to treatment (SBIRT) is recommended as part of routine health care for adolescents (Committee on Substance Abuse, 2011), as well as adults (Madras et al., 2009).

Because young persons may not adhere to lengthy treatment, a substance use intervention ideally would be effective after only 1 or 2 sessions. Brief interventions for drinking (Monti et al., 2007) and possibly for substance use in general (D'Amico, Miles, Stern, & Meredith, 2008) can be effective in youth. Research has begun to investigate the utility of brief interventions for marijuana-using young people in the primary care setting (Walton et al., 2013, 2014), with some focus on young persons not seeking treatment (de Gee, Verdurmen, Bransen, de Jonge, & Schippers, 2014; Martin & Copeland, 2008; Stein, Hagerty, Herman, Phipps, & Anderson, 2011; Walker & Roffman, 2006). The limited research thus far has been challenged by the need for parental involvement, mandated treatment, and multiple office visits.

MOMENTARY AND CONTEXTUAL FACTORS RELATED TO MARIJUANA USE

Several emotional, social, and environmental factors have been identified as antecedents and correlates of marijuana use (Bonn-Miller & Zvolensky, 2009; Shrier, Ross, & Blood, 2014b), and thus may be important targets for intervention. In particular, affective states have shown a strong link to marijuana desire and use behaviors in young people who are frequent users. As momentary positive affect increases, desire to use marijuana decreases and, as momentary negative affect increases, desire to use marijuana increases (Shrier, Walls, Kendall, & Blood, 2012). Further, young people report increased negative affect during the 24 h before marijuana use (Shrier et al., 2014b). Poorer mental health, including higher negative affect and anxiety, has also been linked to increased level of high from a marijuana use event (Shrier, Walls, Rhoads, & Blood, 2013b). Frequent users have reported overall anxiety reduction, compared to those who use less frequently (Metrik, Kahler, McGeary, Monti, & Rohsenow, 2011). Although anxiety reduction can occur in the immediate period following

use, long-term use may lead to overall increase in anxiety symptoms (Buckner et al., 2014), resulting in a negative cycle of use. In addition, young people have reported pleasure as a motivation for marijuana use (Shrier & Blood, 2014). In frequent users, marijuana use increases positive subjective-effect ratings, reduces tension, and produces a sense of euphoria (Hart et al., 2010). In this way, use may be tied to the desire to reduce unpleasant emotional states and enhance pleasurable states, consistent with an affect regulation model of marijuana use (Khantzian, 1997).

Setting is also associated with marijuana use behaviors. Young persons who use marijuana frequently report lowest desire for marijuana in the morning, and highest dose of marijuana per use event on weekend days (Shrier, Rhoads, Wall, & Blood, 2013a). Adolescents and young adults report that they desire marijuana more, and are more likely to use marijuana, when with friends versus alone (Shrier et al., 2012, 2013a), and individuals with social anxiety are more likely to use if they are with other users, when they are feeling more anxious (Buckner, Crosby, Wonderlich, & Schmidt, 2012b). Social environments also influence the amount of drug used and degree of high sought (Monti, Colby, & O'Leary, 2001). Social relationships that include using marijuana together and lack support for cessation have been cited as barriers to quitting (Rhoads et al., 2012).

ECOLOGICAL MOMENTARY ASSESSMENT AND INTERVENTION

Ecological momentary assessment (EMA), frequent, real-time data collection in the participant's natural settings, offers one approach to ascertaining marijuana-related social, environmental, and affective contexts as they vary throughout the day (Shrier et al., 2012). EMA reduces the likelihood of recall bias, enhances the ecological validity of results, and allows for multiple data collection opportunities over time, which has the potential to uncover pattern development (Heron & Smyth, 2010). Contextual and affective states immediately prior to marijuana use (Shrier et al., 2014b), as well as characteristics of use events (Shrier et al., 2013b), desire to use (Shrier et al., 2012), and reasons for use (Shrier & Blood, 2014) have been described through EMA.

Given that the factors influencing use are within the real-time situation, the ability to intervene at the moment of use or desire to use may be vital to affecting meaningful change in substance use behaviors. Ecological momentary intervention (EMI) delivers an intervention in real time in the natural setting, generally via mobile technology (eg, handheld computer, mobile phone). EMI may extend the effects of clinic-based interventions in which new skills are taught by allowing the opportunity to practice these skills in the context of real-life experience. EMI has been used to influence a number of health conditions and behaviors, including mental health disorders (Pramana, Parmanto, Kendall, & Silk, 2014), smoking cessation (Wetter et al., 2011), and alcohol dependence (Voogt, Kuntsche, Kleinian, Pelen, & Engels, 2014). In general, EMI appears feasible and acceptable, and may produce long-term benefits (Whittaker et al., 2012).

EMI offers particular advantages for changing addictive behaviors. Frequent electronic reporting on marijuana use and associated factors is a form of self-monitoring, which has been effective in changing health behavior (eg, to promote weight loss; Burke, Wang, & Sevick, 2011), although there is conflicting evidence about the effect of self-monitoring on substance use (Hufford, Shields, Shiffman, Paty, & Balabanis, 2002; Simpson, Kivlahan, Bush, & McFall, 2005). Cognitive behavioral therapy (CBT), which includes self-monitoring, may be effective in marijuana use treatment (Magill & Ray, 2009). In focusing on momentary experience, EMI may also enhance mindfulness (Kabat-Zinn, 1990), of which deficits may exist among individuals who abuse substances (Dakwar, Mariani, & Levin, 2011). Mindfulness training has been included in interventions for substance abuse treatment (de Dios et al., 2012) and relapse prevention (Witkiewitz, Marlatt, & Walker, 2005). EMIs can also be administered at times specific to an individual's needs (Heron & Smyth, 2010), for example, when experiencing personal emotional and social triggers for substance use (Shrier et al., 2014b). EMI administered on a mobile device offers privacy, which is of particular importance for managing stigma associated with substance abuse and its treatment (Luoma et al., 2007). Challenges of EMI research and intervention include upfront technological support and cost, as well as provider skepticism about new technology (Heron & Smyth, 2010).

THE MOMENTARY SELF-MONITORING AND FEEDBACK + MOTIVATIONAL ENHANCEMENT THERAPY (MOMENT) INTERVENTION

Based in the need for brief treatment for marijuana use in primary care, the importance of context in marijuana use, and the feasibility and potential effectiveness of EMIs for substance use disorders, we developed the MOmentary self monitoring and feedback + Motivational ENhancement Therapy (MOMENT) intervention to reduce marijuana use among frequently-using youth by intervening on the contextual influences of marijuana use in the natural environment. MOMENT has three components: (1) two 1-h MET sessions separated

by a week, (2) 2 weeks of momentary self-monitoring of affect, social contexts, and marijuana desire and use, and (3) feedback immediately following report of self-identified contextual factors that may lead to use.

Intervention Design

The brief MET component was adapted from interventions to reduce marijuana use among young people not seeking treatment (Walker & Roffman, 2006; Martin & Copeland, 2008; Walker et al., 2011). Brief face-to-face counseling creates a human connection that may enhance the EMI components of the intervention (Shrier et al., 2013a). MET includes the motivational interviewing (MI) concepts of expressing empathy, supporting self-efficacy, rolling with resistance, and developing discrepancy (Miller & Rollnick, 2012), plus personalized feedback on individualized assessment (Miller, Zweben, DiClemente, & Rychtarik, 1994). During the first MET session, the individual identifies personal emotional, social, and environmental triggers for marijuana use and selects his/her top 3, information that is used to individualize the feedback message component of the intervention (Table 114.1). Momentary self-monitoring of marijuana triggers, desire, use, and avoiding use is accomplished using a programmable mobile device (eg, handheld computer or mobile phone). When young persons indicate a "top 3" trigger context on a momentary report, they immediately receive a feedback message designed to support self-efficacy, and prompt consideration of their individualized coping strategies (Tevyaw & Monti, 2004), building on the second MET session. The young person will also receive messages after reports of desiring marijuana, having used marijuana, and having avoided use (Fig. 114.1).

Formative Research

In interviews with youth who use marijuana frequently and experts in MI, substance abuse treatment, and adolescent health, the approach of using counseling plus mobile technology to deliver an intervention to reduce marijuana use was explored (Shrier et al., 2013a). Both youth and clinicians gave the device human attributes such as caring and encouraging. Clinicians thought the device would be experienced as an extension of the counselor (eg, "virtual sponsor," "counselor in your pocket"), and that the momentary self-monitoring would be an intervention in itself. Young people and clinicians felt that the messages immediately following report of triggers for marijuana use might encourage reflection and alter behavior. Young people expressed the feeling that the timely messages would be well-received if they were personalized, and not too frequent or repetitive.

Pilot Study

In a pilot study, we tested the feasibility, acceptability and preliminary efficacy of the MOMENT intervention (Shrier, Rhoads, Burke, Walls, & Blood, 2014a). Of 27 young persons enrolled, 16 completed the intervention, and 14 provided complete follow-up data. The sample was primarily female (70%), had a median age of 19 years, and was ethnically and racially diverse. At baseline, marijuana use in the previous week was a median of 6 times. The study collected individual-, daily-, and momentary-level data at baseline, during the intervention, and 3 months postintervention (Tables 114.2 and 114.3).

During MET, young people most commonly selected as triggers for marijuana use negative affective states (stress, frustration, boredom, or anxiety; 86% of top-3

TABLE 114.1 Components of the MOMENT Intervention

Component	Description	Goals	Time
Motivational enhancement therapy	1:1 Motivational interview following a standardized manual	*Session 1:* Develop discrepancy between use and personal values and goals Identify top 3 triggers for use *Session 2:* Give personalized feedback. Evoke motivation for change Explore and enhance self-efficacy Develop a "game plan" for reducing use, including managing triggers	Two sessions 1 week apart 1 h each
Momentary self-monitoring	Report emotional states, social context, marijuana thoughts and behaviors, and other substance use	Enhance self-monitoring and recognize triggers for use	4–6/day × 2 weeks 2–4 min each
Immediate feedback	Message after reporting top-3 trigger, marijuana desire, use, avoiding use	Support self-efficacy Prompt use of coping strategies	<1 min each

Components of the MOMENT intervention include brief motivational enhancement therapy followed by 2 weeks of mobile self-monitoring of marijuana use and related factors, plus feedback messages immediately following report of self-identified triggers for use.

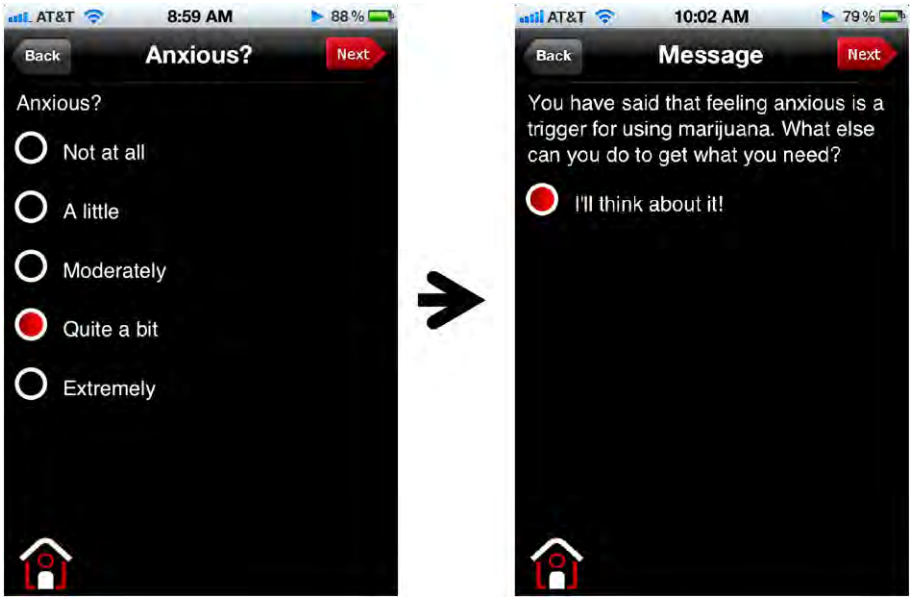

FIGURE 114.1 **Example of MOMENT momentary reporting and responsive messaging.** On the left is a momentary report of an individual's anxiety level. On the right is the responsive motivational message prompting the individual to think about strategies discussed during counseling to manage anxiety.

triggers), followed by being in comfortable or relaxed settings and states, being with friends (55%), being at own, friend's, or relative's home (45%), and hanging out resting/about to sleep (45%). The proportion of momentary reports of being in a personal top-3 trigger context did not change significantly over the study: 36% at baseline, 43% during intervention, and 38% at follow-up (p = 0.77). However, desire to use marijuana when in a top-3 trigger context and marijuana use after trigger exposure both declined from baseline to follow-up (Table 114.4 and Fig. 114.2). The pilot study was not powered to detect differences at a daily or individual level. However, nonsignificant trends for these outcomes were similar to those observed for the momentary-level outcomes (Table 114.4).

Participants indicated that they enjoyed the MET sessions, and found them useful. They reported ease with the technology, and low burden of participation. They felt that mobile messaging encouraged them to avoid use, and increased their awareness of triggers.

In sum, the pilot results suggest that the MOMENT intervention is acceptable to young persons with problematic marijuana use, and feasible to administer in primary care. The observed decrease in marijuana desire and use associated with exposure to triggering contexts, the target of MOMENT, may indicate an intervention effect, and warrants further study.

Randomized Controlled Trial

A randomized controlled trial is underway to further evaluate the feasibility and efficacy of the MOMENT intervention. Patients of primary care clinics affiliated with a large, urban, pediatric hospital in the northeastern

TABLE 114.2 MOMENT Pilot Study Data Collection

			Study phase		
Data level	**Data source**	**Variable example**	**Baseline**	**Intervention**	**3-Month follow-up**
Individual	Timeline follow-back calendar	30-day percent days abstinent	x		x
	Computer survey	Problems with use	x		x
Daily	Mobile device diary	No. of marijuana use episodes in 24 h	x	x	x
Momentary	Mobile device reports 4–6 times/day	Desire to use marijuana;	x	x	x
		marijuana use since last report	x	x	x

Daily diaries and momentary reports were collected for 1 week at baseline, 2 weeks during the intervention, and 1 week at 3-month follow-up. The timeline follow-back calendar (Sobell & Sobell, 1992) assessed marijuana use for the past 30 days.

TABLE 114.3 Individual-Level Mean and Standard Deviation for Momentary, Daily, and Individual Outcomes, by Phase of MOMENT Pilot Study

	Baseline	Intervention	Follow-up
Momentary outcomes, *N*[a]	518	677	377
Desire to use marijuana score (possible 0–9)	3.23 (1.75)	2.53 (1.98)	1.32 (1.50)
Use reported after context exposure, proportion of reports	0.28 (0.17)	0.26 (0.19)	0.19 (0.17)
Daily outcomes, *N*[a]	68	106	50
Use events per day	1.00 (0.61)	0.80 (0.66)	0.73 (0.72)
Readiness score (possible 0–9)	3.72 (2.21)	3.84 (2.26)	4.19 (3.16)
Importance score (possible 0–9)	4.03 (2.28)	4.67 (2.64)	4.18 (3.50)
Confidence score (possible 0–9)	5.76 (2.32)	5.85 (2.33)	4.76 (3.14)
Individual outcomes, *N*	27		15
Percent days abstinent (past 30 days)	37.9 (27.8)		47.3 (28.5)
POSIT score (possible 0–17)	5.67 (4.40)		3.93 (4.00)

POSIT, problem-oriented screening instrument for teenagers, substance use/abuse scale (Rahdert, 1991).

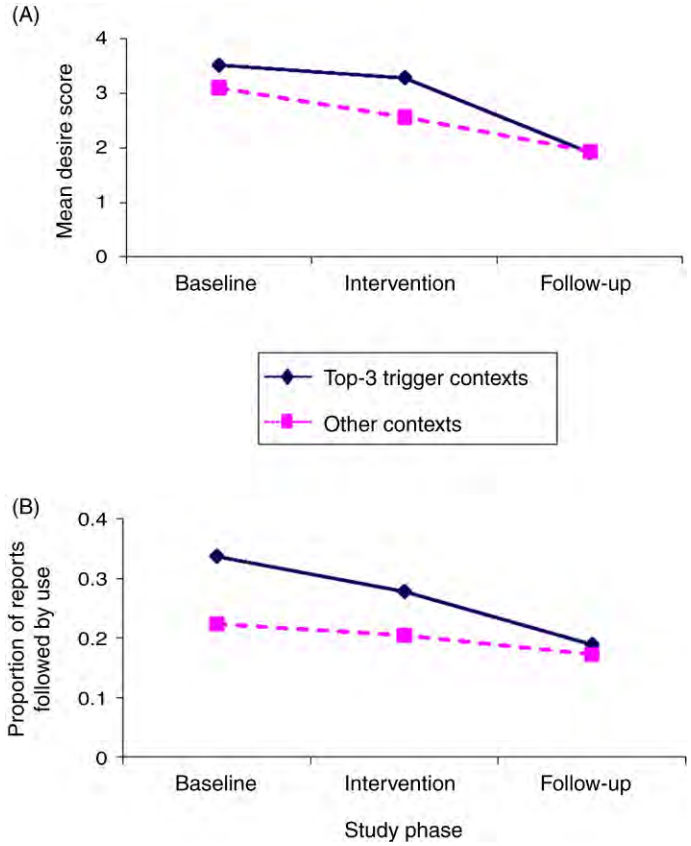

FIGURE 114.2 Mean momentary desire to use marijuana (A) and proportion of reports followed by marijuana use (B), by study phase and context type. In the MOMENT pilot study, desire to use marijuana tended to be higher in top-3 trigger contexts versus other contexts at baseline, but there was no difference in desire between context types at follow-up. Similarly, over the study marijuana use decreased after exposure to a top-3 trigger context more than after other contexts. *Source: Reprinted from Shrier, L. A., Rhoads, A. M., Burke, P. J., Walls, C. E., & Blood, E.A. (2014a). Real-time, contextual intervention using mobile technology to reduce marijuana use among youth: a pilot study.* Addictive Behaviors, *39(1), 173–180, copyright 2014, with permission from Elsevier.*

United States are being recruited if they are between 15 and 24 years of age, and use marijuana at least 3 times per week, on average. Research staff and clinical providers offer age-eligible patients who use marijuana the opportunity be screened and brochures in the clinics allow for self-referral.

Participants are randomly assigned to one of three arms: (1) MOMENT intervention including two MET sessions, momentary and daily self-monitoring via smartphone, and context- and behavior-dependent feedback, (2) no-feedback (MET and momentary self-monitoring), or (3) MET only. Regardless of arm, participants complete a computerized survey and timeline follow-back calendar, and collect momentary and daily data via smartphone for 1 week at baseline, and 3 months after intervention.

We will determine change in outcomes from baseline to 3 months postintervention for each arm, and then compare change in outcomes between arms. Analyses will examine individual-level outcomes (eg, 30-day percent days abstinent from marijuana), daily-level outcomes (eg, number of marijuana use events per day), and momentary-level outcomes (eg, marijuana desire when in a personal top-3 trigger context). Comparisons between MOMENT and each of the other arms will evaluate the value of adding feedback messages to the self-monitoring.

Field Notes From MOMENT MET Sessions

Most participants have reported social and negative affective states as triggers for use, consistent with previous research (Bucker, Crosby, Silgado, Wonderlich, & Schmidt, 2012; Shrier et al., 2014b). Additionally, many have believed that the high from marijuana helps them to focus on home- or school-related tasks (eg, household chores, completing a paper). However, several participants have recognized that their working memory is impaired after years of use, such that they have a hard time remembering and manipulating recent information, consistent with previous research (Vo, Schacht, Mintzer, & Fishman, 2014). Most participants have struggled to see a possible connection between identified negative outcomes (eg, inability to secure work, complete self-directed goals, perform in academic situations) and their frequent marijuana use. Some participants have

commented that marijuana use "can't be that bad" if local governments have decriminalized possession and begun to permit legal medicinal and/or recreational use for adults. Marijuana as a natural substance has also been a common theme among participants, and seems related to lower perceived harm of use.

Potential Challenges to Implementing the MOMENT Intervention

The use of mobile technology to deliver EMI can involve large upfront investments in time and monetary resources (Heron & Smyth, 2010). MOMENT includes only two manual-based counseling sessions, which limits the requirements for staff time and training. Nonetheless, staff time is needed to administer the MET, program the mobile device, and instruct the young persons. Clinic space is required for private sessions. Additional resources may be needed to provide MOMENT-compatible mobile devices for those adolescents who do not have one. MOMENT is designed for young people who are at high risk for adverse outcomes related to their frequent marijuana use, for whom it may be appropriate to allocate more resources (Shrier et al., 2014a).

The MOMENT intervention requires use of a mobile device, raising questions around usability, privacy, and confidentiality. Most young people in the United States and Europe have mobile phones, and are accustomed to using them to send and receive personal information (Nielsen, 2013; Sánchez-Martínez, & Otero, 2009). Our feasibility research has shown that young people are comfortable with the technological aspects of MOMENT, and are not concerned about using a mobile device to complete reports or to receive motivational messaging about marijuana (Black, de Moor, Kendall, & Shrier, 2014; Shrier et al., 2013a).

Young people with problematic substance use may have difficulty with adherence to brief treatment in primary care (D'Amico et al., 2008). Most attrition in the MOMENT pilot study was seen prior to the intervention phase, and may be related to misunderstanding the study burden or expectations. Of pilot participants who had the first MET session (n = 22), 73% (n = 16) completed the MOMENT intervention (Shrier et al., 2014a), similar to rates seen in other pilot studies of marijuana interventions for youth (de Dios et al., 2012; Walker & Roffman, 2006). The expectation for momentary reporting multiple times a day creates additional challenges with adherence. The momentary response rates in the MOMENT pilot study were slightly lower than EMA studies on substance use in adolescents and young adults, which typically range from approximately 60–80% (Black et al., 2014; Shrier et al., 2012), possibly reflecting difficulties associated with the effects of frequent marijuana use of our participants. Current research is seeking to identify strategies to enhance adherence to the momentary self-monitoring component of MOMENT.

Features of a young person's personality and history may need to be considered when administering the MOMENT intervention. For example, the intentional focus of the momentary assessments on negative affective states may exacerbate hypervigilance and sensitivity for those with a trauma history. Additionally, although face-to-face engagement during MET sessions may be beneficial to some, individuals with attachment disorders may lack the ability to make the connection to the counselor, limiting the utility of EMI as an extension of this relationship.

CONCLUSIONS

The MOMENT intervention aims to provide treatment for problematic marijuana use to the many affected adolescents and young adults who present to primary care but may not be actively seeking treatment. MOMENT offers brief motivational treatment in the medical home, where young people have already overcome concerns regarding access and confidentiality. Building on this established trust, MOMENT MET can quickly move into discussions and activities designed to elicit motivation to reduce marijuana use. The MET sessions are individualized in responding to the young person's thoughts and behaviors, standardized in following a detailed manual, and brief in limiting counseling time to only 2 h.

Recognizing that young people are engaging in their marijuana behaviors in variable social, emotional, and physical contexts outside of the clinical setting, MOMENT also uses mobile technology to extend the clinic-based counseling into the natural environment, via self-monitoring and responsive motivational messaging. The self-monitoring may bring the individual's attention to contextual factors related to their marijuana use as they arise, and thus may be tapping into processes that contribute to effectiveness in other treatments, such as CBT and mindfulness-based relapse prevention. Because they appear immediately following report of personal triggers for marijuana use, the messages are tailored to the individual's momentary experience. In this way, the automated messages may be experienced as personalized and relevant.

The MOMENT intervention appears feasible to administer in primary care, and acceptable to young people who use marijuana frequently and are not in treatment. Preliminary findings indicate that MOMENT may be associated with reductions in marijuana desire, and use related to real-life triggering contexts. Ongoing MOMENT research will continue to address issues of feasibility and efficacy, as well as begin to explore possible mechanisms for the observed changes in behavior.

In marrying the benefits of in-person motivational counseling with the advantages of mobile assessment and intervention in daily life, MOMENT offers a promising new approach to reducing marijuana use that may appeal to both the young people in need of treatment and the primary care clinicians who see them.

MINI-DICTIONARY

Ecological momentary assessment (EMA) Frequent, real-time data collection of feelings, thoughts, behaviors, and contexts in the natural environment.

Ecological momentary intervention (EMI) Behavioral intervention delivered via mobile technology in real time, in the natural environment.

Motivational enhancement therapy (MET) Client-driven behavior-change counseling technique based on Motivational Interviewing that provides personalized feedback to enhance behavior change.

Motivational interviewing Client-driven counseling technique that aims to increase motivation for and commitment to behavior change.

Screening, brief intervention, and referral to treatment (SBIRT) The evidence-based practice of identifying, managing, and preventing problem substance use and substance use disorders in the primary care setting.

****University of Westminster, School of Life Sciences, Department of Biomedical Science, London, United Kingdom**

KEY POINTS

- Cannabis (also commonly called marijuana) may have implications for various neuropathologies.
- Cannabis use has harmful effects in some individuals. On the other hand, it has been proposed that cannabis or its metabolites can confer therapeutic benefits.
- There is a vast amount of literature on cannabis in the public domain: literally hundreds of thousands of web pages.
- This chapter lists the most up-to-date resources on the regulatory bodies, journals, books, professional bodies, and websites that are relevant to an evidence-based approach to the investigation of cannabis.

INTRODUCTION

Addiction to cannabis (also commonly called marijuana) is a chronic relapsing neuropathological disorder which affects the neural circuits for memory, motivation, and executive decision making. It is associated with characteristic behaviors that focus on obtaining and using cannabis regardless of the consequences. Cannabis misuse is associated with specific cognitive disturbances, and imaging evidence of brain dysfunction (Ghosh & Basu, 2015). Significant biochemical and structural abnormalities have also been reported in postmortem studies of addicted individuals (Ghosh & Basu, 2015). Although cannabis has significant potential for addiction, it does have some reported therapeutic benefits. For example, cannabis has been shown to reduce some painful symptoms of multiple sclerosis (Whiting et al., 2015). Medicines that act via the endocannabinoid receptor pathway may have other novel therapeutic uses in the future.

Although cannabis has been in use since time immemorial, it is only relatively recently that the understanding of the neuropathology of addictions began to increase exponentially. Vast amounts of data on cannabis are now easily available to anyone with an interest. It is challenging, even for experienced scientists, to remain up-to-date. For those without experience and extensive knowledge of the literature, it is difficult to determine which sources are reliable. This is especially important as there are literally hundreds of thousands of pages on the web that have information on cannabis, from personal to scientific perspectives.

To assist colleagues who are interested in understanding more about this subject, we have therefore produced tables containing reliable, up-to-date resources on cannabis in this chapter. These resources have been recommended by the authors of the chapters of this book, all of whom are eminent researchers in the field. The experts who assisted with the compilation of these tables of resources are acknowledged further.

Tables 1–5 list the most up-to-date information on the regulatory bodies and organizations (Table 1), professional bodies (Table 2), journals (Table 3), books (Table 4), and websites (Table 5) that are relevant to cannabis.

SUMMARY POINTS

- A systematic review of the literature identified 20 self-administrable, brief, and simple instruments that assess a broad spectrum of cannabis-related problems.
- Eleven instruments which had not undergone validations outside the clinical context were subsequently removed from the preliminary list.
- The remaining nine instruments (ASSIST, CAST, CPQ-A, CRAFFT, CUDIT, CUPIT, DAST-10, PUM, SIP-AD) were subject to further in-depth analysis.
- Several instruments theoretically were very promising (eg, CUPIT, PUM). However, only few had proven their usefulness in empirical studies.
- CAST and CUDIT were finally selected as present-day's most appropriate instruments for use in general population surveys.

KEY FACTS OF GENERAL POPULATION CANNABIS SCREENING INSTRUMENTS

Epidemiological research among the general population can usually afford neither the time nor the cost of complex, lengthy or face-to face interviews. Thus, screening instruments should conform to the following criteria:

- be *simple* and easy to understand.
- be brief, that is, *short* and *quick* to administer.
- be *self-administrable* or at least do not require specific training to administer.
- be *in* the *public domain*, or at least inexpensive to obtain.
- *encompass a broad spectrum of cannabis-related problems*, and identify those individuals displaying initial signs of problems that have not (yet) reached pathological level.
- *validated in general population samples*, as results from clinical trials are not necessarily transferable to the general population.
- *validated for adolescents and young adults*, as tools designed for screening adults are not automatically suitable for screening adolescents too, and vice versa.
- *validated among cannabis users*, as tools designed and tested for other substance use are not necessarily also suitable for cannabis users.

LIST OF ABBREVIATIONS

ADIS	Adolescent drug involvement scale
ASSIST	Alcohol, smoking and substance involvement screening test
AUDIT	Alcohol use disorders identification test
CAGE-AID	Cut down-annoyed-guilty-eye opener—adapted to include drugs
CAST	Cannabis abuse screening test

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00116-2

CPQ-A-S	Cannabis problems questionnaire, adolescent, short version
CRAFFT	Car-relax-alone-family-forget-trouble
CUDIT	Cannabis use disorders identification test
CUPIT	Cannabis use problems identification test
DAP	Drug and alcohol problem—quick screen
DAST	Drug abuse screening test
MPS	Marijuana problem scale
POSIT	Problem oriented screening instrument for teenagers
PUM	Problematic use of marijuana
RAFFT	Relax-alone-friends-family member with alcohol/drug problem-trouble
SASI	Substance abuse screening instrument
SIP-AD	Short inventory of problems—alcohol and drugs
SMAST-AID	Short Michigan alcohol screening test—adapted to include drugs
SSI-SA/-AOD	Single screening instrument for substance abuse/alcohol and other drugs
TICS	Two-item conjoint screening
THC	Tetrahydrocannabinol

WHY AND HOW TO ESTIMATE THE PREVALENCE OF "PROBLEMATIC" CANNABIS USE IN THE GENERAL POPULATION

This chapter identifies and analyzes existing screening instruments that are adequate for estimating the prevalence of "problematic" cannabis use in social-epidemiological, general population, studies.

Although illegal, using cannabis is widespread (see Chapter 19 in this handbook). Nevertheless, a majority of users smoke cannabis in moderation, and in a socially integrated manner. They use it for purposes of leisure, relaxation, or pleasure. For a minority of users, however, their cannabis use is more like a coping strategy to deal with the challenges of everyday life and can be associated with health, social, legal, financial, and other problems (eg, Asbridge, Duff, Marsh, & Erickson, 2014; Beck & Legleye, 2008).

There is a public health interest in quantifying those people whose cannabis use is related to such problems, as it would make it possible to estimate the magnitude of the "cannabis problem" in the general population, and aid in the development of adequate prevention strategies and treatment measures. Although only a small proportion of cannabis users will ever require medical treatment, cannabis use is still important from a public health perspective due to the large number of users involved (eg, Asbridge et al., 2014; Beck & Legleye, 2008). Furthermore, even recreational use can be linked to a series of potential health and psychosocial hazards (Hall, 2014). The field of public health, therefore, must have at its disposal instruments that estimate the proportion of individuals who encounter problems related to their cannabis use.

Screening seems an appropriate method to estimate the proportion of such individuals within the population and to observe trends over time. Screening does not produce formal diagnoses of substance use disorders. It is conducted in the preclinical phase of a disease and refers to a preliminary assessment which is designed to identify individuals in a broad population whose substance use is potentially harmful or problematic. Screening the general population usually involves short questionnaires, which enable the classification of respondents as either "positive" or "negative," indicating substance use that is "problematic," "harmful," or "risky," while the latter indicates "nonproblematic" or "controlled" use (Babor et al., 2007).

In contrast to tobacco and alcohol, where the use of *Fagerström Test for Nicotine Dependence* (Fagerström, 1978) and AUDIT (Saunders, Aasland, Babor, de la Fuente, & Grant, 1993) or CAGE (Ewing, 1984) are common, none of the existing instruments that screen for cannabis-related problems has yet to emerge as an international standard (Asbridge et al., 2014; Piontek, Kraus, & Klempova, 2008).

In the absence of an agreed-upon and validated screening instrument for cannabis-related problems, some scholars suggest to simply measure frequency and quantity of use, as is often done in alcohol research (Newton et al., 2011; Rehm et al., 2013). Yet, such instruments are not specific enough, and can lead to a high rate of false positive cases (see also Asbridge et al., 2014). Though this might be reasonable in the clinical context, for general population surveys, a screening instrument needs to show high specificity. With cannabis, measuring quantity is even more challenging than frequency of use. Quantity can vary widely with the same frequency. Daily use, for example, can mean having only one puff, or smoking several "joints" (cannabis-cigarettes) in 1 day. Additionally, THC content of consumed cannabis or cannabis-tobacco ratios of a joint can differ dramatically (Temple, Brown, & Hine, 2011; Zeisser et al., 2012). Evidence also suggests that potency of cannabis is increasing in many countries (McLaren, Swift, Dillon, & Allsop, 2008), thereby increasing the risk of adverse consequences. Furthermore, specific frequencies and quantities may be associated with a range of consequences whose severity can vary across individuals. These concerns point to the need for more sensitive means of determining "problematic" cannabis use, as opposed to

simple quantity-frequency measures (see also Asbridge et al., 2014).

Another approach suggests using structured diagnostic interviews according to the International Classification of Diseases (ICD) or the Diagnostic and Statistical Manual of Mental Disorders (DSM). Again, while this approach might be suitable for the clinical context, it is less than satisfactory for social-epidemiological, general population surveys. First, since such tests are long, complex, and costly, they are often difficult to implement in large nationwide surveys. Self-administered surveys can be difficult for individuals with literacy problems (who are more at risk to present cannabis related problems) to complete. Others can also perceive self-administered surveys as boring, which can lead to a very high number of missing answers. Furthermore, face-to-face administration can require special training for interviewers. Second, in terms of public health, it makes more sense to assess a broader spectrum of cannabis-related problems. Thus, a strict focus on clinical diagnoses may exclude important information about users who do not fulfil the whole criteria for substance use disorders (Degenhardt, Coffey, Carlin, Swift, & Patton, 2008). On the contrary, a diagnosis of cannabis use disorder does not necessarily equate to *concrete* harm or problems (see Temple et al., 2011).

To this end, one can conclude that an early and rough estimation of the prevalence of "problematic" cannabis use through general population surveys is vital, and specific cannabis screening instruments are the most appropriate tools to employ.

General population screening must comply with a number of conditions. First, it must be short, quick, efficient, and as nonintrusive as possible (Pilowsky and Wu, 2013). General population screening instruments should be simple, easy to understand, and able to be self-administered, for a maximum degree of accuracy. As mentioned earlier, such instruments should encompass a broad spectrum of cannabis-related problems for the purposes of identifying individuals who display initial signs of problems, but have not necessarily reached a pathological level, yet. Optimally, such screening instruments should be suitable for adolescents, as well as adults, and in the public domain.

However, to this day, no consensus exists for a validated screening instrument that conforms to these criteria. A clear definition is also lacking regarding what constitutes *"problematic" cannabis use*. The European Monitoring Centre for Drugs and Drug Addictions (EMCDDA) has set up a working group to resolve the issue (EMCDDA, 2007). At present, and until a definition is agreed upon, the EMCDDA applies the term to simply refer to consumption patterns "*...leading to negative consequences on a social or health level, both for the individual user and for the larger community*" (Beck & Legleye, 2008, p. 31).

Although an agreed-upon and validated screening instrument for "problematic" cannabis use has yet to be established, many instruments already exist. While some were conceptualized for clinical screening and must therefore be administered by a trained professional, others are capable of being self-administered, making them ideally suited for general population studies where face-to-face interviews are not feasible. Certain instruments are cannabis-specific, while others cover all illegal drugs and, in some instances, alcohol as well. Several reviews of cannabis screening instruments have already been undertaken (Annaheim, 2013; Beck & Legleye, 2008; Bashford, 2010; Obradovic, 2013; Piontek et al., 2008; Stephens & Roffman, 2005; Mdege & Lang 2011). At present, however, none of these reviews includes all of the following criteria: up-to-date, cannabis-specific, focused on population-based (but not clinical) screening, exhaustive, and grounded on a systematic selection of screening instruments.

The present chapter contains a systematic review of the literature, and analyzes and selects the instrument best suited to screen for cannabis-related problems in general population surveys.

SELECTION OF ADEQUATE INSTRUMENTS FROM THE LITERATURE

To identify publications dealing with nonclinical cannabis screening instruments, we first searched in PubMed, and in Web of Science (these searches included publications in English, French, German and Spanish, dating from 1990 onward, ie, to July 2014). Then, we checked our findings by performing a Google Scholar search, restricted to recent publications (ie, from 2010 to July 2014) for *reviews* not previously discovered, with the EMCDDA Evaluation Instruments Bank and the US Alcohol and Drug Abuse Institute (ADAI) Library of the University of Washington.

All tests had to conform to the following criteria for eligibility and relevance (checklist): the tests had to be simple and easy to understand, brief (maximum 20 items/10 minimum), capable of being self-administered or not requiring specific training for administration. They also had to be in the public domain, measuring a broad concept of "problematic" cannabis use (not solely frequency of use, craving, or dependence, for example), as described in the preceding section. Tests that addressed drug use in general were excluded if the same test was available in its cannabis-specific version [eg, *Drug Use Disorders Identification Test* (DUDIT) was excluded in favor of *Cannabis Use Disorders Identification Test* (CUDIT)].

Consequently, 20 brief cannabis screening instruments were preselected for closer inspection concerning their empirical approval.

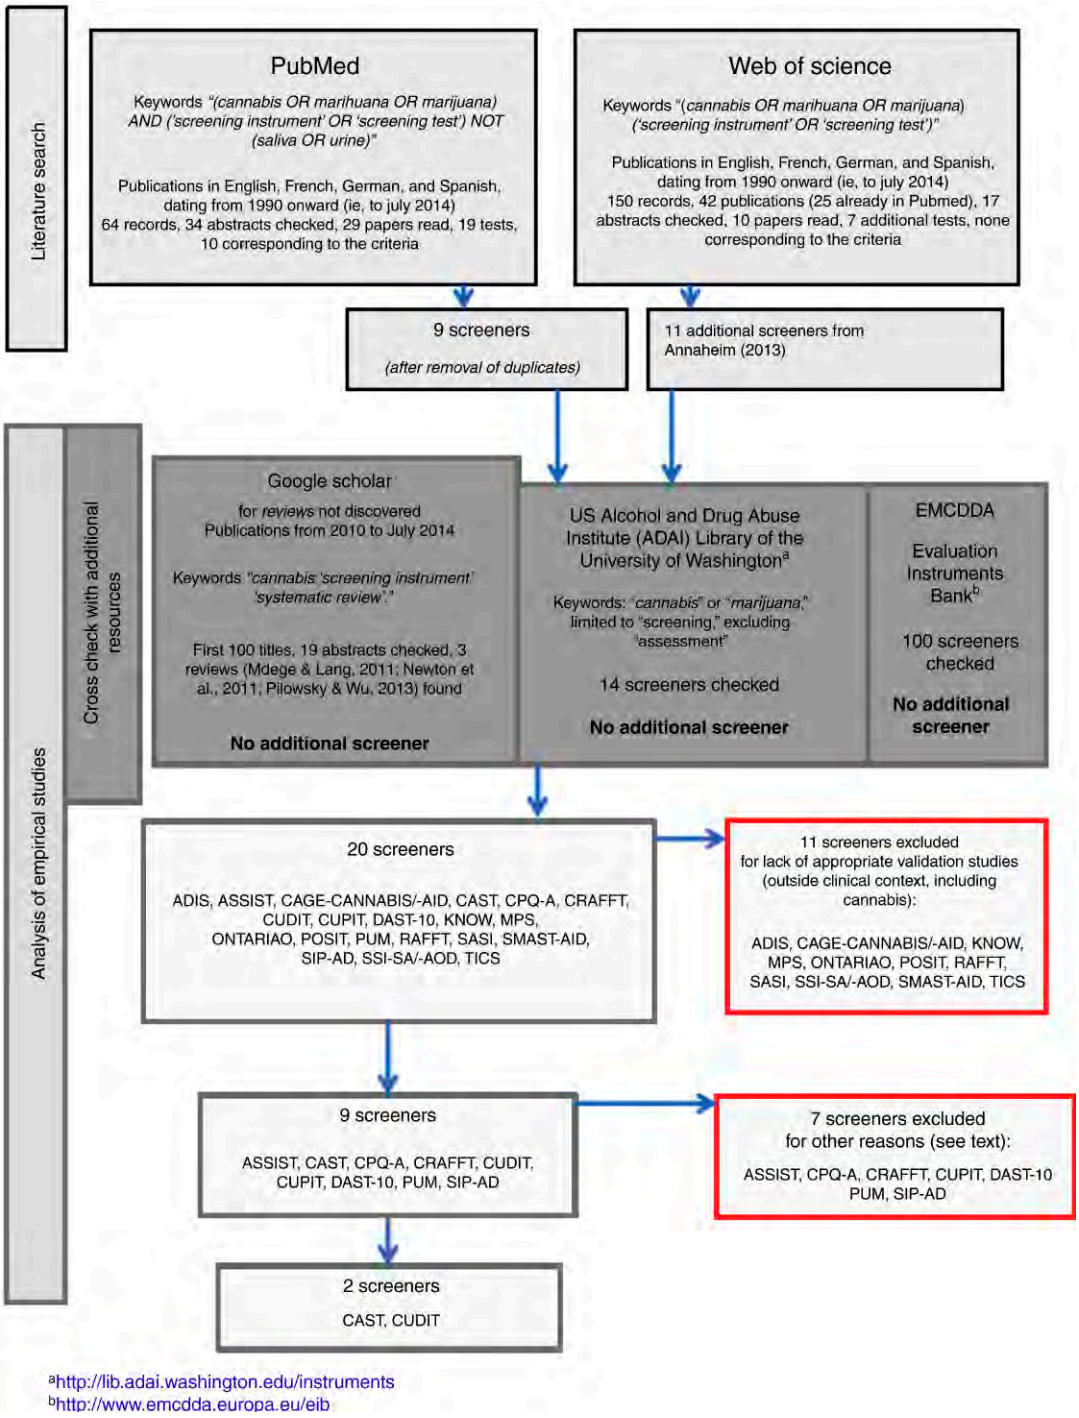

FIGURE e17.1 The process of selecting and analyzing screening instruments. *Source: Based on the PRISMA flow diagram [cf. Moher, D., Liberati, A., Tetzlaff, J., & Altman, D. G. The PRISMA Group (2009)]. Preferred reporting items for systematic reviews and meta-analyses: the PRISMA Statement.* PLoS Medicine, *6(6), e1000097) and shows the way the most useful screening tests (screeners) were identified. For the tests' spelled-out names see List of Abbreviations.*

Thus, in a second step, 11 tests—although potentially useful—had to be excluded from the preselected list, because they had not yet undergone an evaluation in a general population sample. With lacking nonclinical empirical investigations, a concrete judgment about the suitability of those tests, for use in general population surveys, was not possible. Nine tests were finally selected. The detail about the literature search is provided in Fig. e17.1.

CHARACTERISTICS OF SELECTED SCREENING INSTRUMENTS

The remaining nine instruments (see Fig. e17.1) were subjected to a more detailed analysis (see Table e17.1).

ASSIST: The *Alcohol, Smoking and Substance Involvement Screening Test* was developed by a working group of the World Health Organization (WHO) to identify

TABLE e17.1 Brief, Self-Administrable (Cannabis) Screening Instruments

Name (acronym)	Basic reference/origin	Purpose (measured concept)/ dimensions/items	Validation studies outside clinical context	Gold standard, cut-off, sensitivity/ specificity
Alcohol, Smoking and Substance Involvement Screening Test (*ASSIST*)	WHO ASSIST Working Group (2002)	To detect psychoactive substance use and related (moderate and severe) problems, that is, risky, hazardous, harmful use (WHO ASSIST Working Group, 2002)	Davis, Thomas, Jesseman, and Mazan (2009): cannabis-specific validation in two Canadian adult general population samples (n = 13,909/1235; n = 1181/160 past 3 months users)	Any problem with cannabis in the last 12 months, cutoff 8, 77/67
		Theoretical dimensions (items): 1. Frequency of use (1, 2) 2. Abuse/dependence [craving (3), failed to do what expected (5), concerned others (6), loss of control (7)] 3. Problems [health, social, legal, financial (4)]	Thake and Davis (2011): cannabis-specific validation in Canadian adult general population sample (n = 16,674; n = 1179 past 3 months users)	Cannabis before driving, cutoff 8, 53/78; any other illicit drug use in the last 12 months, cutoff 8, 52/70; any harm because of use in the last 12 months, cutoff 8, 69/77
			Asbridge et al. (2014): cannabis-specific evaluation[a] in Canadian adult population sample (n = 13,082; n = 775 past 3 months users) and long-term, socially integrated regular cannabis users sample from four Canadian cities (n = 165)	None
			Barreto, de Oliveira Christoff, and Boerngen-Lacerda (2014): noncannabis-specific validation (different psychoactive substances) in Brazilian convenience student sample (n = 170)	None: ASSIST (interview format) as gold standard for self-administered ASSIST
Cannabis Abuse Screening Test (*CAST*)	French Monitoring Centre for Drugs and Drug Addictions OFDT (in collaboration with EMCDDA): based on a review by Reynaud (2002) and validated by Legleye, Karila, Beck, and Reynaud (2007)	Description of different aspects of harmful cannabis use and screening of "problematic cannabis use" (EMCDDA, 2007; Beck & Legleye, 2008)	Legleye et al. (2007)—lifetime; binary CAST: cannabis-specific validation in French convenience sample among scholars from schools and universities (n = 1728 aged 14–22)	POSIT, cutoff 4 (binary CAST), 93/81

		Items: morning use (1), smoking alone (2), memory problems (3), concerned others (4), tried to cut down (5), other problems (6)	PNSD (2009): cannabis-specific validation in Spanish student sample (n = 26,454; n = 3569 past 12 months users aged 14–18)	DSM-IV TR dependence, cutoff 5, 83/87
			Legleye, Piontek, and Kraus (2011): cannabis-specific validation in French nationwide random sample (n = 2566 past 12 months users aged 17–18)	DSM-IV TR (M-CIDI) dependence, cutoff 3, 84/72 DSM-IV-TR (M-CIDI) abuse, cutoff 3, 79/81
			Cuenca-Royo et al. (2012): cannabis-specific validation among Spanish volunteers (n = 245 past 12 months users aged 18–25)	DSM-IV TR (PRISM-IV), SUD, cutoff 9, 74/69; dependence, cut-off 12, 57/84
			Fernandez-Artamendi et al. (2012): cannabis-specific validation in Spanish convenience sample (n = 144 past month users aged 16–20)	DSM-IV TR, dependence, cut-off 3, 83/77
			Bastiani et al. (2013): cannabis-specific validation in Italian nationwide random sample of pupils (n = 5787 past 12 months users aged 15–19)	DSM-IV TR, ≥4 criteria, cut-off 7, 80/80
			Legleye, Piontek, Kraus, Morand, and Falissard (2013): cannabis-specific validation in French random nationwide adolescent sample (n = 2566 past 12 months users aged 17–18)	Latent class analysis of DSM-IV TR (M-CIDI) Moderate/severe, cut-off 3, 78/81 Severe, cut-off 7, 88/85
			Gyepesi et al. (2014): cannabis-specific validation in almost pure random sample among Hungarian high school and college students (n= 476 and 439 past 12 months users mean aged 19–24 years)	DSM-IV TR (M-CIDI) High school: CUD, cut-off 2, 62/97; dependence, cutoff 2, 86/95; college: CUD, cutoff 2, 68/97; dependence, cutoff 2, 78/94
			Legleye et al., 2015: cannabis-specific validation in French nationwide random sample (n = 550 past 12 months users aged 15–62)	DSM-IV TR (M-CIDI), CUD, cut-off 3, 80/75, dependence, cutoff 5, 81/79 Latent class analysis, moderate/severe, cut-off 3, 78/82; severe, cutoff 7, 97/86 or cutoff 8, 94/89
Cannabis Problems Questionnaire for adolescents, short version (*CPQ-A-S*)	Proudfoot, Vogl, Swift, Martin, and Copeland (2010): based on adolescent version (CPQ-A) (Martin, Copeland, Gilmour, Gates, & Swift, 2006) of CPQ (Copeland, Gilmour, Gates, & Swift, 2005)	Problems related to cannabis use (Proudfoot et al., 2010); [CPQ-A: intended to supplement DSM-IV diagnostic in exploration of cannabis-related problems (Martin et al., 2006)]	Proudfoot et al. (2010): cannabis-specific validation in Australian student sample (n = 1734; n = 126 past 3 months users), combined with a community sample (n = 99 past 3 months users aged 14–18)	None: strong predictor of cannabis heavy use in logistic modeling

(*Continued*)

TABLE e17.1 Brief, Self-Administrable (Cannabis) Screening Instruments (*cont.*)

Name (acronym)	Basic reference/origin	Purpose (measured concept)/ dimensions/items	Validation studies outside clinical context	Gold standard, cut-off, sensitivity/ specificity
		Items: loss of control (1), paranoia (2, 11), concerned others (4), financial problems (5), social reduction (3, 12), trouble with police (6), health problems (7–10)	Fernandez-Artamendi, Fernandez-Hermida, Muniz-Fernandez, Secades-Villa, and Garcia-Fernandez (2012): cannabis-specific validation in Spanish student sample (n = 748; n = 144 past month users)	DSM-IV TR dependence, cutoff 3, 83/78
Car-Relax-Alone-Forget-Family-Trouble (*CRAFFT*)	Knight et al. (1999): constructed by combining and modifying items from RAFFT, DAP, and POSIT	Harmful use of alcohol and drugs (Knight et al., 1999)	Cummins et al. (2003): validation for alcohol and other drug use, in American-Indian and Alaska-Native adolescents (13–19 years) from US public schools and outpatients clinics (n = 70)	Frequent cannabis use, cutoff 2, 100/75
		Items: driving while intoxicated (1), motives for use (2), smoking alone (3), memory problems (4), concerned others (5), gotten into trouble (6)	Bernard et al. (2005): validation for alcohol and other drug use of a French version, in Swiss mixed, substance using treatment (n = 83) and general population (n = 80) adolescent sample (14–19 years)	ADAD, cutoff 4, 74/65; MINI, cutoff 3, 94/61
			Karila et al. (2007): validation for alcohol and other drug use, in French school student sample (n = 1728)	POSIT, cutoff 2, 93/77
			Subramaniam, Cheok, Verma, Wong, and Chong (2010): validation for alcohol and other drug use, in Singapore military recruits (16–26 years) male sample (n = 22,248)	CIDI auto 2.1, cutoff 1, 71/74
			Pérez Gomez and Scoppeta Diaz-Grandos (2011): validation for alcohol and other drug use, in Colombian student (14–18 years) sample (n = 432)	None: item response analysis
			Skogen, Boe, Knudsen, and Hysing (2013): validation for alcohol and other drug use, in Norwegian general population adolescents (17–19 years) sample (n = 9680)	Self-report of "any problem with drug use," cutoff 1, 81/72

Cannabis Use Disorders Identification Test (*CUDIT*)	Adamson and Sellman (2003): adaptation of Alcohol Use Disorders Identification Test (AUDIT) (Saunders et al., 1993)	Originally: DSM-IV abuse and dependence (Adamson & Sellman, 2003), when used in general population: "problematic cannabis use" (Annaheim, Rehm, & Gmel, 2008; Annaheim, Scotto, & Gmel, 2010); CUDIT is based on AUDIT (see Saunders et al., 1993) that theoretically measures alcohol-related problems and the following three subconcepts: 1. original version (items): a. frequency/quantity (1–3) b. symptoms of dependence [loss of control (4), failed to do what expected (5), morning use (6)] c. negative consequences (guilt (7), memory problems (8), injuries (9), concerned others (10) 2. revised version CUDIT-R (Adamson et al., 2010): deleting 2 and replacing 3 items (3, 6, 7, 9, 10) with hazardous use, devoting a great deal of time, thoughts about quitting 3. revised version for general population (Annaheim et al., 2010): replacing 3 items (2, 7, 9) with motives for use, social reduction, difficulties at work/school	Annaheim et al. (2008): cannabis-specific validation in Swiss adolescents and young adults general population sample (n = 5025; n = 593 past 6 months users) Annaheim et al. (2010): cannabis-specific validation in Swiss adolescents and young adults general population sample (n = 5722; n = 558 past 6 months users) Thake and Davis (2011): cannabis-specific validation in Canadian adult general population sample (n = 16'674; n = 1179 past 3 months users) Bruno, Marshall, and Adamson (2013): cannabis-specific validation among adult, nontreatment seeking cannabis users in New Zealand (n = 368)	Different accepted indicators of problematic use: smoking before school/work, cutoff 8, 64/69; smoking before driving, cutoff 6, 58/59; depressive symptoms, cutoff 6, 50/59; coping motives, cut-off 6, 66/67; self-evaluation, cutoff 7, 71/70 None: item response analysis Cannabis before driving, cutoff 6, 51/83; any other illicit drug use in the last 12 months, cutoff 6, 53/76; any harm because of use in the last 12 months, cutoff 6, 63/83 DSM-IV TR dependence, cutoff 11, 78/79; DSM-5 mild, cutoff 9, 75/77; DSM-5 moderate, cutoff 11, 80/77; DSM-5 severe, cutoff 13, 86/81
Cannabis Use Problems Identification Test (*CUPIT*)	Bashford, Flett, and Copeland (2010)	Currently diagnosable and potentially problematic cannabis use Theoretically three sub-concepts according DSM-IV/ICD-10 (items): 1. risky use [frequency (1, 2)] 2. dependence/using behavior [times using (3), morning use (4), being stoned (5), loss of control (9), craving (6, 7, 8, 10)] 3. health/social problems [work/school problems (11), lack of energy (12), social reduction (13, 14), memory problems (15), loss of control (16)]	Bashford et al. (2010): cannabis-specific validation among volunteers in New Zealand, who had been using cannabis at least once during the last 12 months, from general population (n = 36), drug treatment clinics (n = 36), justice system (n = 55), and students/job seekers (n = 83)	DSM-IV TR/ICD-10 CUD: cutoff 20, 87/79

(*Continued*)

TABLE e17.1 Brief, Self-Administrable (Cannabis) Screening Instruments (*cont.*)

Name (acronym)	Basic reference/origin	Purpose (measured concept)/ dimensions/items	Validation studies outside clinical context	Gold standard, cut-off, sensitivity/ specificity
Drug Abuse Screening Test (*DAST-10*)	Skinner (1982): Adaption of Michigan Alcohol Screening Test (MAST) (Selzer, 1971)	Drug abuse or dependence; DAST-10 is the shortened version of the original DAST (28 items) and the DAST-20	Bedregal, Sobell, Sobell, and Simco (2006): noncannabis-specific validation among Spanish speaking individuals (Hispanics/ Latinos) without alcohol/drug problems (n = 127), drug and (n = 60) alcohol abusers (n = 35) in the United States	Drug abusers in treatment programs: cutoff 4, 90/97
		Items: (poly-) drug use in general (1, 2), loss of control (3), "blackouts" (4), guilt (5), concerned others (6), social reduction (7), illegal activities (8), withdrawal (9), medical problems (10)	McCabe, Boyd, Cranford, Morales, and Slayden (2006): noncannabis-specific validation among undergraduate students in the United States (n = 4500; n = 1735 past 12 months drug users)	None: correlation analyses
			Grekin et al. (2010): noncannabis-specific validation among 300 low-income (mostly African-American) women in the United States, recruited right after giving birth (in clinical setting)	Biological drug screening, sensitivity = 0.47
			Pérez Gálvez, García Fernández, de Vicente Manzanaro, Angustias Oliveras Valenzuela, and Lahoz Lafuente (2010): noncannabis-specific validation of Spanish version in 259 Spanish adults (n = 121 drug addicts/n = 138 healthy controls)	DSM-IV TR, cutoff 3, 96/95
			Evren, Ogel, Evren, and Bozkurt (2014): noncannabis-specific validation of Turkish version among 202 prisoners (n = 78 with drug problems/n = 124 without drug problems)	Addiction Profile Index-Short, cutoff 4, 88/74
			Yongseok (2014): noncannabis-specific validation of Korean version in general population adults (n = 1000; n = 503 "normal" residents/n = 497 at risk adults, ie, from prisons, on probation or working at bars)	Being arrested because of use, cutoff 2, 66/93

Problematic Use of Marijuana (Cannabis) [*PUM (PUC)*]	Okulicz-Kozaryn and Sieroslawski (2007)	ICD-10 harmful use, problems in interpersonal relationships/psychophysical functioning and abuse (Bashford, 2010) Items: skipped school (1), arguments with family/friends (2, 3), bought cannabis (4), memory problems (5), smoking alone (6), craving (7), financial problems (8)	Okulicz-Kozaryn and Sieroslawski (2007): cannabis-specific validation among general population cannabis using adolescents recruited through snow-ball sampling in Poland (n = 1277)	ICD-10 dependence, cutoff 2, 81/88
Short Inventory of Problems—Alcohol and Drugs (*SIP-AD*)	Blanchard, Morgenstern, Morgan, Lobouvie, and Bux (2003): shortened version of Inventory of Drug Use Consequences (Tonigan & Miller, 2002)—itself a modified form of the Drinker Inventory of Consequences (Miller, Tonigan, & Longabaugh, 1995)	Problems related to alcohol and substance use in general: Items: being unhappy (1), physical appearance changed (2, 9), failed to do what expected (3), personality changes (4, 13), risk taking (5), impulsiveness (6, 7), financial problems (8, 15), family/friendship was hurt (10, 11), activity reduction (12), damaged reputation (14)	Gillespie, Holt, and Blackwell (2007): noncannabis-specific validation among 421 university students in the United States (n = 287 past year alcohol/drug users) Hagman et al. (2009): noncannabis-specific validation among 469 male regular "clubbers"/club drug users who have sex with men from New York City	None: logistic modeling None: item response analysis

DSM-IV TR, Diagnostic and Statistical Manual of Mental Disorders, Text Revision; M-CIDI, Munich Composite International Diagnostic Interview; PRISM, Psychiatric Research Interview for Substance and Mental Disorders (PRISM-IV); SUD, substance use disorders (dependence or abuse); CUD, Cannabis use disorders (same as SUD in this context).
The table lists basic reference, origins, purpose, and available nonclinical validation studies for every screening test selected after a checklist (see Key Facts).

TABLE e17.2 The Cannabis Abuse Screening Test (CAST)

Questions		Answers (scoring)
Over the past 12 months...		
1	Have you smoked cannabis before midday?	Never (0), rarely (1), from time to time (2), fairly often (3), very often (4)
2	Have you smoked cannabis when you were alone?	Never (0), rarely (1), from time to time (2), fairly often (3), very often (4)
3	Have you had memory problems when you smoked cannabis?	Never (0), rarely (1), from time to time (2), fairly often (3), very often (4)
4	Have friends or family members told you that you should reduce or stop your cannabis consumption?	Never (0), rarely (1), from time to time (2), fairly often (3), very often (4)
5	Have you tried to reduce or stop your cannabis use without succeeding?	Never (0), rarely (1), from time to time (2), fairly often (3), very often (4)
6	Have you had problems because of your cannabis use (argument, accident, poor results at school, etc.)?	Never (0), rarely (1), from time to time (2), fairly often (3), very often (4)

The table displays the CAST in its original, nondichotomized version (Legleye et al., 2011).

substance use and related problems in medical care settings, through face-to-face interaction with a health professional. The tool is composed of seven questions per substance that encompass lifetime and current use, symptoms of dependence, health, social, legal, and financial problems (WHO ASSIST Working Group, 2002). Only recently, its usefulness was also tested in survey research.

Davis et al. (2009) assessed the effectiveness of the cannabis portion of ASSIST to identify "problematic" users, comparing it to self-reported harms. They concluded that a greater balance of sensitivity with specificity could be obtained when using a higher threshold for "problematic" cannabis use than what was suggested in clinical applications of the instrument.

In a subsequent Canadian study, Thake and Davis (2011) confirmed the higher threshold for the nonclinical setting and declared ASSIST more successful in identifying harm than a simple frequency of use measure. At the same time, they found CUDIT (see "Cannabis Use Disorders Identification Test") of better performance for use in general population surveys than ASSIST.

Asbridge et al. (2014) compared ASSIST to a frequency (and quantity) measure. Their results underline a disproportionately high impact that the inclusion of a simple measure of frequency into ASSIST has on defining "problematic" cannabis use. Moreover, they confirmed the higher threshold for general population surveys.

Finally, a new self-report format of ASSIST was compared to the original interview-format in a small convenience sample of Brazilian university students (Barreto et al., 2014). The authors emphasized, however, the inability of extrapolation of their results to the general population or even university students in general.

To conclude, data on ASSIST's psychometric performance in the general population are available, today, and indicates the need for a higher threshold. Nevertheless, that data remain of a very limited nature (eg, no information on dimensionality of the scale). In addition, another short cannabis screening instrument (CUDIT) has shown better psychometric performance than ASSIST when tested in a large general population sample (Thake & Davis, 2011). Thus, based on the present state of knowledge, there is not enough evidence that would prove ASSIST's usefulness outside the clinical setting.

CAST: The *Cannabis Abuse Screening Test* is a six-item cannabis-specific tool aimed at describing some patterns of use and at screening "problematic" use according to Beck and Legleye (2008) and ICD-10 diagnosis. Its items encompass patterns of potential nonrecreational use, symptoms of dependence, social aspects, memory, and other problems. The test originally used five ordered categories for answers (never, rarely, from time to time, fairly often, very often). It was initially designed for the entire lifespan, and used a dichotomization of the answers instead of a full range (Legleye et al., 2007). Subsequently, the time frame was restricted to "the past 12 months" and the dichotomization abandoned (Table e17.2). It was validated using adolescents and young adults (mostly students). Studies were conducted in various countries, including nationwide representative samples using two gold standards: the DSM-IV diagnoses (Bastiani et al., 2013; Cuenca-Royo et al., 2012; Gyepesi et al., 2014; Legleye et al., 2011), or an empirical gold standard obtained by latent class analysis of the DSM-IV (Legleye et al., 2013). Its validity was also assessed in the general population (aged 15–64) in France (Legleye et al., 2015). The difference between binary or full-range scorings were found low in French adolescents (Legleye et al., 2011), as were the gender differences (Legleye et al., 2013), and the same thresholds were found for adolescents and adults.

CAST appears to be unidimensional, and shows good internal consistency and high discriminative power

between diagnoses. Its test-retest reliability was found to be very good (Molinaro, Siciliano, Curzio, Denoth, & Mariani, 2012). It was used for the European School Survey Project on Alcohol and Other Drugs (ESPAD) Study (Pabst, Kraus, & Piontek, 2012), applying a binary scoring. Its structural equivalence across 13 countries was found to be high (Bougeard, Eslami, & Qannari, 2014).

At this time, CAST has proved its psychometric and screening properties in various populations and countries, and with various statistical methods and gold standards. Existing crossnational surveys allow studying its crosscultural invariance. It is the most widely used tool for research among general population adolescents and adults. According to the criteria of our review, it is considered to be one of the most useful tools for use in general population surveys.

CPQ-A-S: The *Cannabis Problems Questionnaire* for adolescents is a 27-item tool which has been found to be a reliable and valid screen for cannabis problems in adolescents. Originally, it was a clinician-administered interview (Martin et al., 2006). More adequate for our purposes, however, is its shortened, 12-item version, CPQ-A-S, which has been constructed also for research in the community, and is intended to identify young people at risk of harm due to their cannabis use (see Proudfoot et al., 2010). CPQ-A-S puts a high emphasize on health aspects, with about half of its items assessing physical or mental health problems (eg, chest infection, cough, paranoia). In addition, it contains items on patterns of use, social, legal, and financial aspects.

When validated in a student and adolescent community sample (Proudfoot et al., 2010), CPQ-A-S has shown good reliability and validity and loaded on a single factor. However, the test has shown rather moderate internal consistency.

Further, CPQ-A-S has been validated in a student sample and compared to CAST (Fernandez-Artamendi et al., 2012). The researchers defined both instruments as reliable and valid to identify "problematic" cannabis use in young people. CPQ-A-S appeared to be a better predictor of cannabis users with psychopathological symptoms and concern about their cannabis use, while CAST had higher internal consistency, as well as higher specificity to detect cannabis dependence according to DSM-IV diagnoses.

At this time, CPQ only has been validated in adolescent samples and there is no short form of the tool that is conceptualized also for adults. Moreover, outside the clinical setting, specificity is at least as important as sensitivity and other instruments (CAST) have shown higher specificity while encompassing less items (ie, take less time to be administered). Therefore, based on the present state of knowledge, CPQ-A-S cannot be counted as one of the most useful tools for research among general population adolescents and adults.

CRAFFT: CRAFFT is a mnemonic, based on six questions that ask for cannabis-related problems from a lifetime perspective. It was constructed by combining and modifying items from other screening tests and consequently validated in the clinical context (Knight et al., 1999). Its items encompass patterns of use, harmful use, cognitive and social aspects, although no health aspects.

The tool has been used in French (Bernard et al., 2005; Karila et al., 2007), Spanish (Pérez Gomez & Scoppeta Diaz-Grandos, 2011), Norwegian (Skogen et al., 2013), and other language versions (Subramaniam et al., 2010). Thus, CRAFFT is a widely used screening instrument among adolescents that has generally been found of adequate psychometric performance (Dhalla, Zumbo, & Poole, 2011).

More specifically, however, among adolescents *outside* the clinical context, CRAFFT has shown insufficient internal consistency and relatively low specificity in several validation studies (see Bernard et al., 2005; Cummins et al., 2003; Karila et al., 2007; Knight et al., 1999; Pérez Gomez & Scoppeta Diaz-Grandos, 2011; Skogen et al., 2013; Subramaniam et al., 2010). Yet, to the knowledge of the authors, CRAFFT has never been used and validated among general population adults older than 26 years. Although there are numerous validation studies from outside the clinical context, there seem to be hardly any studies using a representative general population sample, other than (school) students or military recruits. Moreover, there is, to the knowledge of the authors, not a single evaluation of CRAFFT that focuses on cannabis use instead of analyzing several illegal substances, and often also alcohol, at the same time.

For all these reasons, CRAFFT cannot be one of the most adequate screening instruments for use in general population surveys.

CUDIT: The *Cannabis Use Disorders Identification Test* was constructed as a brief 10-item screen to identify individuals who had used cannabis in a problematic or harmful way during the preceding 6 months (Adamson & Sellman, 2003). It was directly adapted from the established AUDIT (Saunders et al., 1993) and simply created by merely replacing the word "alcohol" with the word "cannabis." CUDIT covers patterns of use, symptoms of dependence, and negative (social) consequences of cannabis use. Originally constructed (Adamson & Sellman, 2003) and revised (Adamson et al., 2010: CUDIT-R) for the clinical context, it was subsequently also used and validated for research in the general population (Table e17.3).

Annaheim et al. (2008) found CUDIT related to accepted concepts of "problematic" cannabis use (eg, coping motives for cannabis use, depressive symptoms), but with a modest internal consistency and a rather weak psychometric performance of some items. Thus,

TABLE e17.3 The Cannabis Use Disorders Identification Test (CUDIT)

	Questions	Answers (scoring)
Have you used any cannabis over the past 6 months? If YES, please answer the following questions about your cannabis use: Over the past 6 months...		
1	... how often have you used cannabis?	Never (0), monthly or less (1), 2–4 times a month (2), 2–3- times a week (3), 4 or more times a week (4)
2	Which of the following statements best fits your personal situation?	"I smoke cannabis for fun, because it's something special" (0), "I smoke cannabis out of habit, because it's part of my daily life" (4)
3	... how often were you "stoned" for 6 or more hours?	Never (0), less than monthly (1), monthly (2), weekly (3), daily or almost daily (4)
4	How often during the past 6 months did you find that you were not able to stop using cannabis once you had started?	Never (0), less than monthly (1), monthly (2), weekly (3), daily or almost daily (4)
5	How often during the past 6 months did you fail to do what was normally expected from you because of using cannabis?	Never (0), less than monthly (1), monthly (2), weekly (3), daily or almost daily(4)
6	How often during the past 6 months did you need to use cannabis in the morning to get yourself going after a heavy session of using cannabis?	Never (0), less than monthly (1), monthly (2), weekly (3), daily or almost daily (4)
7	How often during the past 6 months have you refrained from taking part in leisure time activities that you originally wanted to do, such as going out, sports, hobbies, etc., because of using cannabis?	Never (0), less than monthly (1), monthly (2), weekly (3), daily or almost daily (4)
8	How often during the past 6 months have you had a problem with your memory or concentration after using cannabis?	Never (0), less than monthly (1), monthly (2), weekly (3), daily or almost daily (4)
9	How often during the past 6 months have you had difficulties at work or school, because of using cannabis?	Never (0), less than monthly (1), monthly (2), weekly (3), daily or almost daily (4)
10	Has a relative, friend or a doctor or other health worker been concerned about your use of cannabis or suggested you cut down over the past 6 months?	No (0), yes (4)

The table displays a revised version of the CUDIT for use in general population surveys (Annaheim et al., 2010), based on the original CUDIT (Adamson & Sellman, 2003).

in a follow-up study, Annaheim et al. (2010) suggested revising CUDIT for the social-epidemiological research context, replacing items of unsatisfactory psychometric properties with new ones. Corresponding results indicated generally improved psychometric performance.

In a general population study, Thake and Davis (2011) found—original—CUDIT of good psychometric performance. It outperformed a simple frequency measure, as well as ASSIST, with regards to sensitivity and specificity, when compared to different external criteria as indicators of "problematic" cannabis use (self-evaluation of harm, driving under the influence, use of other illicit drugs).

Recently, another revised version of the tool—CUDIT-R (Adamson et al., 2010), originally amended for the clinical context—was also tested in a community sample of cannabis users (Bruno et al., 2013). CUDIT-R showed unidimensionality, and strongly correlated with measures of frequency of use, as well as cannabis use disorder according to DSM-5.

To conclude, CUDIT is a cannabis-specific brief screening test that measures a broad spectrum of problems related to cannabis use among adolescents and adults. When validated in different (large) general population samples in Switzerland, Canada, and New Zealand, it has shown good psychometric performance.

CUPIT: The *Cannabis Use Problems Identification Test* is a 16-item screen for the detection of currently and future "risky" or "problematic" use, respectively. CUPIT was constructed for the treatment setting but also for use in the community and as a research tool. It is intended to measure a DSM/ICD tridimensional concept of risky use, dependence and using behavior, as well as health and social problems (Bashford et al., 2010). More concretely, its items cover patterns of use, symptoms of dependence, as well as social aspects.

CUPIT was found to be of excellent test-retest reliability, high internal consistency, a high ability to discriminate between different diagnostic subgroups (nonproblematic, risky, problematic use), and of highly significant

longitudinal predictive validity (Bashford et al., 2010). CUPIT's potential to detect future "risky" or "problematic" use is probably its main advantages over other tests. None of the other tests, to the knowledge of the authors, has been tested for predictive validity in longitudinal studies, yet.

However, the only sample that was used to construct and validate CUPIT was of limited representativeness. It was rather small (n = 212), not random, and only consisted of 36 general population adolescents and adults (Bashford et al., 2010).

To this end, regardless of CUPIT's novel capability to classify both currently diagnosable and also potentially problematic cannabis use and its good psychometric properties when tested in a particular sample, evidence from validation studies is lacking currently. Such validation studies could prove this test to be one of the most adequate screening instruments for use in general population surveys.

DAST-10: The *Drug Abuse Screening Test* was designed after the *Michigan Alcohol Screening Test* to provide a 28-item instrument for clinical and nonclinical screening to detect drug abuse or dependence disorders. Shortened, 20- and 10-item versions of the test are also available (see Skinner, 1982). Because of its brevity, the latest version is most relevant for our purposes of review. DAST-10 covers items on illegal (poly-) drug use in general, symptoms of dependence, in addition to health, social, and legal problems.

Outside the clinical setting, the psychometric performance of DAST-10 was analyzed among a small subgroup of Spanish-speaking individuals in the United States. The test was found to be reliable and unidimensional (Bedregal et al., 2006). At about the same time, its psychometric performance was tested among drug using undergraduate students in the United States, and declared a promising instrument for detecting drug abuse among college students (McCabe et al., 2006).

A few years later, it was validated against drug-biomarkers among 300 low-income women, immediately after having given birth, and found of low sensitivity (Grekin et al., 2010). Further, a Spanish version was validated among drug addicts and healthy controls (Pérez Gálvez et al., 2010).

Recently, Evren et al. (2014) have undertaken a validation of a Turkish version of DAST-10 among prisoners. Finally, a Korean version was validated in a sample of "normal" and "at risk" residents (Yongseok, 2014).

Although, not clinical samples in the narrowest sense, those samples cannot be considered representative for the community, as not probabilistic and mostly composed of "at risk" individuals—that is, alcohol and illegal drug users in general, or otherwise especially vulnerable (eg, low-income, prisoners) individuals. Moreover, DAST-10 has never been tested concerning its performance specifically among cannabis users. Therefore, the available studies hardly allow one to draw conclusions about its possible performance concerning cannabis use among general population adolescents and adults and in the (Western) European context. For those reasons, DAST-10 does not conform to this review's preconditions for counting as one of the most adequate screeners.

PUM (PUC): The *Problematic Use of Marijuana (Cannabis)* screening tool is an eight-item scale that intends to measure ICD-10 harmful use, along with problems in interpersonal relationships and psycho-physical functioning. Its items cover patterns of use, symptoms of dependence, as well as cognitive, social, and financial aspects.

PUM was constructed and validated in Poland among adolescent cannabis users, recruited by snowball-sampling, where it has shown good psychometric performance (Okulicz-Kozaryn & Sieroslawski, 2007; Piontek et al., 2008).

Although a promising cannabis-specific screening instrument, since its construction in 2007 and validation in a nonprobabilistic adolescent sample, it has not been further validated (Okulicz-Kozaryn, K., personal communication, Oct. 14, 2014). For that reason, evidence is lacking that would allow one to select the PUM as one of the most adequate screening instruments for use in general population surveys among adolescents and adults.

SIP-AD: The *Short Inventory of Problems—Alcohol and Drugs* was constructed by Blanchard et al. (2003). Its shortened 15-item version covers health, social and financial aspects, as well as risk taking and negative personality changes. Although recently validated in a multitude of clinical settings (Allensworth-Davies, Cheng, Smith, Samet, & Saitz, 2012), there is scarce information on its performance in the general population.

Gillespie et al. (2007) provide some empirical validity for SIP-AD as a useful measure for assessing negative consequences associated with substance use in general. However, they call the representativeness of their sample into question, and state that inferences can neither be drawn to other student bodies, and to an even lesser degree, the general population. Further, they assume that the extension of SIP-AD to nonclinical samples might be unmerited in the test's present incarnation.

Hagman et al. (2009) refined a shortened, 10-item SIP-AD as a unidimensional construct, and found a high degree of reliability and validity. Yet, the results from their study sample—469 regular club drug-using males, who have sex with men—are hardly transferable to the general population.

Moreover, neither of the studies were cannabis-specific, but included a multitude of other illegal drugs, as well as alcohol. For those reasons, it cannot be decided how SIP-AD would actually perform for cannabis use in

general population samples of adolescents and adults of both sexes.

CONCLUSIONS

At the time of this review, two screening tests were found to be sufficiently studied in general population surveys to be considered reliable or promising for adolescent and (young) adult populations: CAST and CUDIT.

CAST is the shortest and the most studied. It was validated in many different contexts toward different gold-standards derived from DSM-IV, and compared to another screening test. The test has proven good psychometric and screening performances, and the study of its transcultural equivalence has begun. However, it has not been yet validated toward DSM-5, nor studied in longitudinal settings.

CUDIT is somewhat longer, and also shows appealing performances in general population samples of three countries and was validated toward DSM-5, although only in a small sample. It has been compared to another screening test but, to date, has not been studied in longitudinal surveys nor studied in cross-national surveys.

CAST and CUDIT cover different aspects of cannabis use and its consequences. These tests have not been compared with each other. Validation studies of these tests used different survey methodologies (self-administered paper or Internet, telephone, etc.), focusing on different population targets (adolescents, young adults, general population). Additionally, despite the use of DSM-derived gold standard, no study focused on the communalities of these tests and the gold standard: what do these tests measure that is common to DSM and what is not? In parallel, no thorough comparison of the CAST with agreed-upon concepts of problematic cannabis use was done. This is a general problem for all tests concerned by this review.

Further development of research may consider: (1) a study of the common structure of CAST and CUDIT and DSM-5, especially the description of what is common and what is not between them, regarding concepts and factorial structures; (2) a survey comparing the tests together; (3) a study of the added value of these tests, compared to frequency threshold and DSM diagnoses in cross-sectional studies; (4) the added value of these tests in predicting evolutions of cannabis use or psychosocial health damages, compared to frequency thresholds and DSM diagnoses; (5) the cultural invariance of these tests in crossnational surveys, especially the determination of specific thresholds for international comparisons. Of course, other compelling tests could also be studied that way.

MINI-DICTIONARY

General population survey In contrast to clinical investigations, a probability-based survey of people that are selected without any link with the topic of the study.

"Problematic" cannabis use There is no generally agreed-upon definition. Commonly, the expression is used to describe a broader concept of cannabis-use-related issues (including Cannabis use disorders as per the international classifications ICD or DSM) and refers to consumption patterns leading to negative consequences on a social or health level, for the individual cannabis user and the larger community.

Psychometric properties The characteristics of a test that is used for psychological, sociological or public health measurement and of its items (questions). Psychometric properties are examined with the intention to construct, develop and improve such tests.

Screening Research or clinical procedure that refers to a preliminary assessment and aims at identifying individuals in a broader population whose substance use is (potentially) harmful. Thus, screening is a method to estimate the prevalence of "problematic" cannabis use within the general population.

Screening instrument/test Brief questionnaires which enable the classification of respondents to a "positive" (problematic) and a "negative" (nonproblematic) group, depending on the answers they give. Screening tools do not produce formal diagnoses.

Acknowledgments

The work of the first author (Beatrice Annaheim) was financed by a grant from the *Swiss Academy of Medical Sciences* (SAMW) and kindly supported by the *Institute for Biomedical Ethics* (IBMB) at University of Basel, Switzerland, headed by Prof Bernice S. Elger. Stéphane Legleye wants to thank the EMCDDA for funding the first validation of CAST and François Beck for his collaboration in this adventure. Both authors would also like to thank Dorit Barlevy (IBMB) for proofreading of the manuscript.

CHAPTER

e18

Self-report of Cannabis Use

T. Van der Linden

Department drugs and toxicology, National Institute of Criminalistics, Brussels, Belgium

SUMMARY POINTS

- This chapter focuses on self-reporting of cannabis use.
- Self-reports are noninvasive, but can be biased.
- Several guidelines are available for conducting surveys on cannabis use through self-report.
- Cannabis is the most widely used illicit drug according to several self-reporting studies.
- Several factors influence the validity of self-report, such as social stigma, acceptance of the drug user identity, problems with cognitive function, the study setting or the fear for (legal) consequences.
- Concordance between self-report and biological measurements varies for different studies, partly depending on the characteristics of the respondents, and the study settings.

KEY FACTS AND TYPES OF SURVEYS

- A survey is a method of using questionnaires or interviews to gather information that can be generalized to a population.
- Collection can be done by: self-administered questionnaires (given in group settings, individual or by mail), personal interviews (conducted in home or other settings), telephone interviews, computer-assisted interviews, or combinations of the aforementioned.
- Census: every individual in the population is studied.
- Sample survey: a subgroup representative of the population is studied.
- Cross-sectional surveys: studying a group of people only at one point in time.
- Panel surveys: collecting data from the same individuals at two or more points in time.
- Cohort studies: combination of cross-sectional and panel design: studying different representative samples from a population at multiple points in time.

KEY FACTS OF EMCDDA

- European Monitoring Centre for Drugs and Drug Addiction.
- Established in 1993, and inaugurated in Lisbon in 1995.
- Exists to provide the European Community and EU Member States with a factual overview of European drug problems, and a solid evidence base to support the drug debate.
- Prevalent numbers on drug use in annual European Drug Reports.

KEY FACTS OF UNODC

- United Nations Office on Drugs and Crime.
- Global leader in fight against illicit drugs and international crime.
- Established in 1997, UNODC operates in all regions of the world.
- Provides field-based technical cooperation projects to enhance the capacity of member states to counteract illicit drugs, crime, and terrorism.
- Provides research and analytical work to increase knowledge and understanding of drugs and crime issues.
- Estimates based on the UNODC annual report questionnaire show that globally 3.8% of 15–64 year-olds have used cannabis in 2012.

THCCOOH	11-nor-9-carboxy-delta-9-tetrahydrocannabinol
UNODC	United Nations Office on Drugs and Crime
WHO	World Health Organization

INTRODUCTION

Gathering information on the prevalence of illicit drug use, such as cannabis use, can be done in several ways. Biological samples are taken and analyzed to get scientifically proven results. Self-reports are less invasive, but these results could be more biased. In this (part of the) chapter, methods of self-reporting questionnaires are briefly mentioned; prevalence for different populations based on self-report are given; points on the validity of self-report are discussed, and concordance between self-report and biological analyses is given (Table e18.1).

METHODS FOR SELF-REPORT

International guidelines are drawn to decide which questions, concepts, and epidemiological indicators (eg, prevalence, frequency, incidence) have to be included in a population survey on illicit drug use and which methodological aspects (eg, data collection method, sample size) are indispensable to use in periodical studies. (Tieberghien, De Moor, De Corte, & Mortelmans, 2009)

In Europe, most countries (eg, Austria, Cyprus, Finland, Hungary, Italy, Lithuania, and Spain) have established national surveys based solely on illicit drug use, mostly in combination with the use of other psychoactive substances, such as alcohol and tobacco. Some countries piggyback drug prevalence measurements to another survey (eg, health survey, crime survey). Both approaches have their (dis)advantages. For example, when conducting a single survey, researchers are free to create the most appropriate questionnaire, research design, and sampling. Piggybacking on the other hand requires a lower budget, but it also implies that the questionnaire and the research design have to be subordinated to the main questionnaire (Tieberghien et al., 2009).

Guidelines in Europe

Prevalence and patterns of drug use among different groups of population (eg, adults, young people) is one of five EMCDDA key indicators that assess and monitor the drugs situation among EU Member States. Data from general and school population drug surveys provide information on patterns of use, risk perceptions, social and health correlates, and consequences of use of psychoactive substances.

For surveys conducted among the adult population (Fig. e18.1) in households, the EMCDDA provides a list

TABLE e18.1 Summary of Concordance Between Self-Report and Biological Measurements in Several Studies

Study	Concordance between self-report and biological measurements
University students Zaldívar Basurto et al. (2009)	High sensitivity and specificity
Driving population (Van der Linden et al., 2014)	Low sensitivity, high specificity and accuracy
Treatment groups	1. High number of false negative self-report (Buchan et al., 2002) 2. High consistency between both methods (Neale & Robertson, 2003) 3. High correlation (Hjorthoj et al., 2012) 4. Low number of false negatives (Akinci et al., 2001)
Armed forces (Mayet et al., 2013)	Good sensitivity, high specificity
HIV-infected youth (Nichols et al., 2014)	Rather good concordance
Emergency department (Macdonald et al., 2014)	Very low number of false negatives
Pregnant women (El Marroun et al., 2011)	Low sensitivity, very high specificity

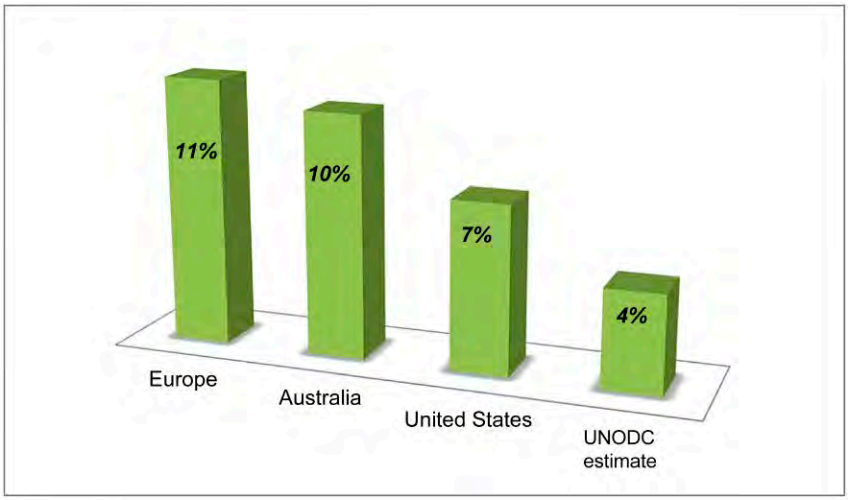

FIGURE e18.1 Prevalence of cannabis use through self-report of adult population. Europe, European Drug Report 2014 (EMCDDA, 2014); Australia, National Drug Strategy Household Survey 2013 (NDSHS, 2014); United States, National Survey on Drug Use and Health (SAMHSA, 2014); UNODC estimate, World Drug Report 2014 (UNODC, 2014).

of core items, called the European model questionnaire (EMQ) that can, for example, be included in questionnaires of national surveys. With the EMQ data on the period, prevalence of drugs can be collected, as well as information on age of first use, and frequency of use (EMCDDA, 2009).

Population surveys on drug use in Europe are less compatible with the recommendations of the WHO or UNODC (Tieberghien et al., 2009).

Methods for representative school surveys may be found in internationally coordinated school survey projects, and several national projects in Europe and the United States. School surveys collect mostly data in classrooms through anonymous questionnaires on the use of alcohol and a range of drugs (EMCDDA, 2009).

Every year, the EMCDDA reports prevalence numbers on drug use in Europe in their *European Drug Report: trends and developments*.

Surveys in the United States and Australia

In Australia, the National Drug Strategy Household Survey (NDSHS) is conducted every 3 years, and the Australian institute of Health and Welfare has been reporting on these surveys since 1998. The survey was commissioned and funded by the Australian Government Department of Health. The scope of the 2013 NDSHS (the 11th survey in the series) was the Australian residential population aged 12 years or older. The 2013 survey collected data from 23,855 people across Australia. The 2013 survey was conducted using a self-completion drop-and-collect questionnaire method (NDSHS, 2014).

The National Survey on Drug Use and Health (NSDUH) is an annual survey (since 1971) on the use of illicit drugs, alcohol and tobacco in the civilian, noninstitutionalized population of the United States aged 12 years and older, involving interviews with approximately 70,000 randomly selected individuals. The Substance Abuse and Mental Health Services Administration (SAMHSA) funds NSDUH, and is an agency of the US Public Health Service in the US Department of Health and Human Services (DHHS) (SAMHSA, 2014).

Global Drug Survey

Every year, the Global Drug Survey (GDS) is launched, an online questionnaire that approaches drug-use. This implicates that automatically drug users are appealed to respond to the questionnaire. The surveyed group is, therefore not representative for the whole population, but gives a unique insight in (the patterns of) drug-use (GDS, 2014).

Youth Surveys

ESPAD (European School Survey Project on Alcohol and other Drugs) is a collaborative effort of independent research teams in more than 40 European countries, and the largest cross-national research project on adolescent substance use in the world. The overall aim with the project is to collect repeatedly comparable data on substance use among 15–16-year-old students in as many European countries as possible (ESPAD, 2012).

HBSC (Health Behavior in School-aged Children) is a pioneer cross-national study gaining insight into young people's well-being (Fig. e18.2), health behaviors, and their social context. It collects data every 4 years on

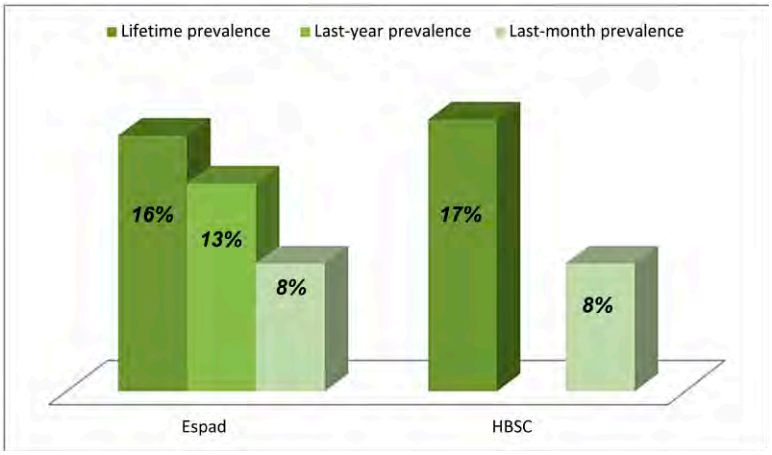

FIGURE e18.2 Prevalence of cannabis use through self-report of youth population. ESPAD: European School Survey Project on Alcohol and other Drugs 2011 (ESPAD, 2012); HBSC: Health Behavior in School-aged Children, 2009–2010 (HBSC, 2012).

11-, 13-, and 15-year-old boys and girls, including information on cannabis use. This research collaboration with the WHO Regional Office for Europe is conducted in 43 countries and regions across Europe and North America (HBSC, 2012).

PREVALENCE DATA BASED ON SELF-REPORT

European General Population

The 2014 European Drug Report published by the EMCDDA revealed that almost one-quarter of the adult population in the European Union, or over 80 million adults, are estimated to have used illicit drugs at some point in their lives. In most cases, they have used cannabis (73.6 million).

An estimated 11% of young Europeans (15–34) used cannabis in the last year, with 14% of these aged 15–24. Cannabis use is higher generally among males, and this difference is usually accentuated for more intensive or regular patterns of use. Just less than 1% of European adults are estimated to be intensive (daily or almost daily) users; over two-thirds of this group are aged between 15 and 34 years, and in this age group over three-quarters are male (EMCDDA, 2014).

General Population in Australia and the United States

Information provided through the 2013 National Drug Strategy household Survey showed that 10% of the Australian population aged 14 years and older recently used cannabis, while lifetime use was 35% (NDSHS, 2014).

Information provided by the 2012 National Survey on Drug Use and Health showed that almost 19 million inhabitants of the United States aged 12 or older (7%) used cannabis in the past month. Daily or almost daily use (used on 20 or more days in the past month) increased from 5.1 million persons in 2007 to 7.6 million persons in 2012. (SAMHSA, 2014)

Global Drug Survey

The GDS2014 conducted during November/December 2013 comprised almost 80,000 responses. 48% of the respondents declared to have smoked cannabis in the last 12 months, with Australia having the lowest percentage (35%), and Mexico the highest (78%) (GDS, 2014).

Youth

Information provided by the 2011 ESPAD revealed that lifetime cannabis use was reported by 16% of the students, with more reporting by boys (19 vs 14% for girls). Cannabis use in the past 12 months was reported by 13% of all students, with 15% among boys and 11% among girls. Use in the past 30 days was claimed by 8% of the boys and 5% of the girls (7% average) (ESPAD, 2012).

Information provided by the 2009/2010 HBSC showed that 17% of the interviewed 15 year olds have ever used cannabis (15% for girls, 20% for boys; highest in Canada, lowest in Macedonia). An average of 8% (6% for girls, 9% for boys) have used cannabis in the last 30 days (HBSC, 2012).

VALIDITY OF SELF-REPORT

Evaluation of drug use based on the subject's self-report is the most widely used practice for epidemiological research in addiction, as it has two very clear advantages, low cost and the possibility of collecting an

abundance of information from many people. However, the validity of estimations based on their use has been questioned frequently.

Points Affecting Validity

The variables that influence validity can be classified generally as (1) social context factors, (2) personal characteristics of the informer, and (3) demands of the task. Also, the design of the self-report on substance use and especially the conditions under which it is used are important factors (Zaldívar Basurto et al., 2009).

The illegal nature of drug abuse, privacy, face-saving, and possible criminal sanctions is all factors associated with social pressure, largely affecting the reliability of self-report outcomes.

Reasons for under- or overreporting of drug use are based mainly on social stigma. As social stigma of the use of a certain drug increases, underreporting of the drug use increases. It has been shown that underreporting is most frequent for heroin, which is the least socially accepted drug. When a person is addicted to a certain drug already for a longer period of time, reporting of drug use will be more truthful, due to the fact that higher acceptance of the drug user identity is expected. Response distortion to avoid social stigma is a serious risk in surveys of value-laden issues, such as illicit drug use. Survey respondents may be unwilling to report drug use to avoid adverse reactions from others, or to present themselves to the interviewer in a favorable way. Conversely, respondents with positive views of drug use may exaggerate their drug use to impress the interviewer or others, or to live up to a self-image that perceives drug us as positive. Many types of behavior viewed as socially desirable are overreported, while those viewed as less desirable are underreported. Several studies also indicate that the tendency to underreport varies across social groups that hold differing norms and values regarding the desirability of the behaviors or traits under investigations. Thus, even when validity studies indicate a bias toward underreporting a stigmatized behavior, the bias cannot be assumed to be constant across all respondents (Harrel, 1997).

Wrongness perceived in drug use and, therefore, the tendency to underreporting cannot be generalized to all populations (eg, a study showed how some teenagers who perceived use of alcohol to be socially desirable tended to increase their use report), so favorable/unfavorable attitudes about use in each specific sample must be known beforehand.

Not all under- or overreporting is deliberate, for example, it is an accepted phenomenon that, especially in the sometimes chaotic life of a drug user, cognitive function may limit accurate reporting. The cognitive complexity of accurately recalling drug use in the past may sometimes also result in errors (Harrel, 1997) They may be unable to report drug use accurately, particularly when questions involve detailed accounts of drug consumption at times in the past. They may not be able to remember the circumstances of use, when they used a drug, or even whether they ever used a particular drug. Heavier drug users are likely to find particular facts more difficult to recall and may experience memory impairment.

Factors other than social desirability also threaten the accuracy of self-reported drug use data. Respondents may fear legal consequences to reporting drug use, if they distrust survey assurances of confidentiality. The assumption is that the assurance of confidentiality and anonymity will offset any potential tendency of the respondent to distort the accuracy of responses, and a greater similarity between self-report and test results will be achieved (Harrel, 1997).

Also, the setting in which self-reports are provided can affect the willingness to report an illegal behavior. For example, arrestees may provide less accurate information on their drug use to intake personnel at a jail, than to a researcher on a self-administered questionnaire given with a guarantee of confidentiality. Reluctance to disclose drug use can occur even in an alternative setting, such as a clinic (which is expected to be less conducive to underreporting), if the respondent is interested in conveying a positive image to the interviewer (Harrel, 1997).

Concordance with Biological Measurements

University Students

Zaldívar Basurto et al. (2009) determined the validity of a self-report on recent drug use (cocaine and cannabis) in a sample of university students. The self-report sensitivity to recent use of cannabis was 91.8%, and specificity 89.6%. Agreement between the self-report on use of cannabis and the urine test is rather high, with a statistically significant kappa of 0.666, and a rather high percentage of agreement (0.89) (Zaldívar Basurto et al., 2009).

Driving Population

Van der Linden, Silverans, and Verstraete (2014) compared the number of Belgian drivers who self-reported cannabis use by questionnaires during a roadside survey to the result of toxicological analysis. The sensitivity of the questionnaire was low, while specificity and accuracy were high. Kappa statistics revealed a fair agreement between self-report and positive findings for tetrahydrocannabinol (THC) in oral fluid and blood, and moderate agreement with 11-nor-9-carboxy-delta-9-tetrahydrocannabinol (THCCOOH) in blood. Self-report largely underestimates driving under the influence of cannabis, particularly recent use. Data also indicated

that maybe some respondents gave a "socially desirable" answer, stating "I smoked cannabis >24 h ago," while in fact it was more recently (Van der Linden et al., 2014).

Drug Users in Treatment

Buchan, L Dennis, Tims, and Diamond (2002) evaluated the agreement between adolescent self-reported cannabis use in outpatient treatment and toxicological analysis. Over two thirds tested positive after stating not to have used in the week prior to examination and one-third even tested positive after stating soberness for 4 weeks. The findings suggest both the advantages of multiple sources of information (Buchan et al., 2002).

Neale and Robertson (2003) compared self-report and oral fluid testing for detecting drug use among individuals starting drug treatment. In 80% of the cases, self-report on cannabis use and oral fluid testing were consistent (Neale & Robertson, 2003).

Hjorthoj, Fohlmann, Larsen, Arendt, and Nordentoft (2012) found that timeline follow-back-assisted self-report correlates highly with plasma THC in patients with comorbid cannabis use disorder and psychosis (Hjorthoj et al., 2012).

Akinci, Tarter, and Kirisci (2001) evaluated the concordance between self-report and urine screen in a study with adolescent sons of fathers with and without a substance use disorder. The researchers observed a discordance rate of 13%, most of it was related to underreporting; however, a small proportion of subjects overreported their marijuana use. Almost one-third of the total sample denied use but screened positive in urine, and more than 10% stated to have used cannabis but screened negative in urine (Akinci et al., 2001).

Armed Forces

Mayet et al. (2013) evaluated the accuracy of self-report of past-month cannabis use in a representative sample of French military staff members, and evaluated the scale of the prevarication bias. The prevalence for self-reported use was 16.1%, and for positive testing 13.4%. The discriminant power of self-report was good, with an area under the receiver operating characteristics curve of 0.90. Specificity was 94.5%, but sensitivity was lower (85.7%). The lowest sensitivity values were observed in the higher categories of personnel and in the Navy, which could suggest some prevarication in these subpopulations who might believe they were more exposed to sanctions if detected (Mayet et al., 2013).

HIV-Infected Youth

Nichols et al. (2014) examined the relationship of self-report measures of substance use with plasma testing of a range of substances of abuse in two groups of youth (youth living with HIV (= YLWH) and uninfected youth). The first showed a percentage of positive self-report over the past 3 months for cannabis of 49% (20% daily use). Positive self-reported use for uninfected youth was 53% (11% daily use). Positive plasma toxicology assays for YLWH were 36%, while for the uninfected group this was 27%. Overall concordance between any self-reported use of cannabis and toxicology assay was 79% for YLWH and 87 for uninfected youth (kappa = 0.587, p = 0.432). The data support, particularly for daily users, self-report as a valid indicator of substance use in research studies of youth with or without HIV-infection (Nichols et al., 2014).

Emergency Department Patients

Macdonald et al. (2014) assessed the concordance of self-reports of cannabis, cocaine, and amphetamines with oral fluid on-site testing in an emergency department setting. Among those who admitted use of cannabis, 21% tested positive. Of those who reported no use 2% had a positive oral fluid test (Macdonald et al., 2014)

Pregnant Women

In the Netherlands, El Marroun et al. (2011) studied the agreement between self-report and urine analysis concerning maternal cannabis use. Sensitivity and specificity of self-report compared to urine analysis were 0.36 and 0.99. The researchers suggest a two-step approach involving self-report information followed by urine analysis. (El Marroun et al., 2011)

DISCUSSION AND CONCLUSION

Some remarks should be taken into account when investigating the concordance between biological analyses and self-reports of cannabis use. Depending on the biological matrix used, the measured analytes and the detection times are different. For instance, THCCOOH is measured in urine, and can sometimes be detected several weeks after consumption, while in oral fluid THC is the analyzed substance, with a much shorter detection window. This could result in false positive self-reports while, in fact, the respondents gave correct information that is not detectable anymore in the biological matrix.

Self-reporting stays the most widely used procedure for gathering information on prevalence numbers on drug use. Since cannabis is the most socially accepted drug, the validity of self-report tends to be the highest for this drug class, but is highly depended on several parameters, such as environment,

anonymity, etc. This review, for instance, has shown that when sanctions (eg, driving population, high ranks in the army) or social stigma are feared (pregnant women), validity tends to be lower. When reporting drug use is part of a treatment (eg, outpatient treatment, people with substance use disorder), validity tends to be higher. It offers a reliable approximation for measuring drug use, if conducted under optimum conditions.

Although the self-reported use of drugs has certain limitations or biases that cannot be obviated, it can offer a reliable approximation for measuring drug use, if conducted under optimum conditions. One of the biggest advantages it has is that it can provide certain information (history of use, determinants, and consequences of use, etc.) that cannot be found in any other type of measure.

MINI-DICTIONARY

Accuracy The proportion of correctly identified positive and negative results from all the test results.

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN}$$

FN False negative: number of cases with a negative self-report and a positive confirmation analysis.
FP False positive: number of cases with a positive self-report and a negative confirmation analysis.
Kappa Cohen's kappa measures the agreement between two raters who each classify N items into C mutually exclusive categories. The equation for κ is:

$$K = \frac{\Pr(a)-\Pr(e)}{1-\Pr(e)}$$

Where $\Pr(a)$ is the relative observed agreement among raters, and $\Pr(e)$ is the hypothetical probability of chance agreement, using the observed data to calculate the probabilities of each observer randomly saying each category. If the raters are in complete agreement then $\kappa = 1$. If there is no agreement among the raters other than what would be expected by chance (as defined by $\Pr(e)$), $\kappa = 0$.
Sensitivity The proportion of positive cases that are correctly identified by the test.

$$Sensitivity = \frac{TP}{TP+FN}$$

Specificity The proportion of negative cases that are correctly identified by the test.

$$Specificity = \frac{TN}{TN+FP}$$

TN True negative: number of cases with a negative self-report and a negative confirmation analysis.
TP True positive: number of cases with a positive self-report and a positive confirmation analysis.

CANDIS Program: Modular Treatment of Cannabis Use Disorders

E. Hoch, H. Rohrbacher***

***Department of Psychiatry, Ludwig Maximilian University, Munich, Germany**
****Practice for Cognitive Behaviour Therapy, Munich, Germany**

SUMMARY POINTS

- Cannabis is the most commonly used illicit drug worldwide.
- Frequent cannabis use increases the risk of psychosocial, mental, and physical health problems, such as cannabis dependence.
- The criteria for cannabis dependence include withdrawal, tolerance, continued use despite cannabis-related problems, and time excess in obtaining and recovering from the drug.
- During the past two decades several psychotherapeutic interventions for primary cannabis use disorders have been developed and evaluated.
- Empirical evidence was found for the effectiveness of cognitive-behavioral therapy (CBT) in combination with motivational interviewing (MI), contingency management (CM) and relapse prevention (RP).
- CANDIS therapy is one of the first manualized cannabis-specific treatment programs in Europe and was developed at the Technische Universität Dresden (Dresden University of Technology), Germany.
- CANDIS program was tailored to the specific problems and needs of adolescents and adults with primary cannabis use disorders and combines motivational enhancement therapy, cognitive-behavioral therapy and problem solving.
- It consists of ten one-on-one sessions, spanning over a period of 8–12 weeks.
- It was shown to be effective in achieving abstinence as well as reducing cannabis use, addiction severity, disability days, and the overall level of psychopathology.
- Treatment effects could also be achieved after translating the intervention to clinical practice.

KEY FACTS OF RANDOMIZED CONTROLLED TRIAL

- A randomized controlled trial (RCT) is a study, in which participants are randomly (by chance) allocated to receive one of several interventions.
- One of the interventions is a control condition.
- Participants in the control condition receive either standard therapy, a placebo therapy or no intervention at all (eg, waiting-control group).
- Effectiveness of the experimental treatment is measured in comparison with the control condition.
- RCT are quantitative studies as outcomes are measured.
- RCT is considered as the gold standard for clinical trials, because it minimizes selection and allocation biases.

KEY FACTS OF MOTIVATIONAL INTERVIEWING

- Motivational interviewing (MI) is a directive, goal-oriented counseling style, aiming to increase the client's intrinsic motivation to change.

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00130-7
Copyright © 2017 Elsevier Inc. All rights reserved.

- MI evolved from experience in the treatment of problem drinkers, and was described and elaborated by Miller and Rollnick (1991).
- MI elicits behavior change by helping clients to explore and resolve ambivalence.
- The central principles of MI are expressing empathy, developing discrepancy, rolling with resistance, and supporting self-efficacy.
- MI affirms the client's freedom of choice and avoids confrontation and argument.

RCT Randomized-controlled trial
RP Relapse prevention

INTRODUCTION

Cannabis is the most commonly used illicit drug worldwide, particularly among young people (UNODC, 2014). There are an estimated number of 3 million Europeans (15– 64 years) who use the drug on a daily or almost daily basis (EMCDDA, 2014). This pattern of regular or heavy cannabis use (CU) continued over years most clearly predicts increased risk of psychosocial, mental and physical health problems (Danovitch & Gorelik, 2012; Hall & Degenhardt, 2014; Hoch et al., 2015; Karila, Roux, & Rolland, 2014; Volkow, Baler, Compton, & Weiss, 2014). The most probable adverse health effects are cannabis use disorders (CUD). Cannabis dependence is a mental disorder with a distressing, chronic and relapsing nature. Core dependence criteria are withdrawal, tolerance, continued use despite cannabis-related problems and time excess in obtaining and recovering from the drug [ICD-10 (WHO, 1992), DSM-V; (APA, 2013)]. The lifetime risk of dependence among all cannabis users has been estimated at about 9%, it increases to one in six among those who initiate in adolescence (Anthony, 2006). Europe has seen the numbers of clients entering drug treatment for the first time for cannabis problems rise in the past 15 years. It is the most frequently mentioned drug among first-time clients and the secondary illegal drug of concern among all treatment seekers (EMCDDA, 2014). In many cases, cannabis is not the only reason for treatment seeking. Epidemiological studies consistently report that comorbidity between CUD and other mental disorders is high (Agosti, Nunes, & Levin, 2002; Grant & Pickering, 1998; Wittchen et al., 2007). In the general population 90% of individuals with CUD meet lifetime diagnostic criteria of at least one further mental disorder in comparison to 55% of individuals without CUD (Agosti et al., 2002). Associations between cannabis use, anxiety and panic disorders, bipolar disorders, symptoms of mania, anxiety disorders, suicidal ideations, major depression, schizoaffective disorders, psychotic symptoms, symptoms of schizophrenia, and use of other legal or illegal drugs were found (Hoch et al., 2015).

The knowledge of how to treat primary cannabis use disorders with or without comorbid conditions has been relatively limited for a long time. It is only during the past two decades that rigorously controlled studies of interventions for cannabis use disorders have appeared in the literature. One metaanalysis (Davis et al., 2015) examined the efficacy of psychotherapeutic interventions for primary cannabis use disorders. A comprehensive literature research produced 10 well-controlled randomized controlled trials (RCTs; n = 2027). Five studies were from the United States (Carroll et al., 2006; Kadden, Litt, Kabela-Cormier, & Petry, 2007; Marijuana Treatment Project Research-group, 2004; Stephens, Roffman, & Simpson, 1994; Stephens, Roffman, & Curtin, 2000), four studies were from Australia (Copeland, Swift, Roffman, & Stephens, 2001; Gates, Norberg, Copeland, & Digiusto, 2012; Martin & Copeland, 2008; Rooke, Copeland, Norberg, Hine, & McCambridge, 2013) and one study was from Europe (Hoch et al., 2012). The metaanalysis found evidence that cognitive-behavioral therapy (CBT) in combination with motivational interviewing (MI), contingency management (CM) and relapse prevention (RP) were effective in treating cannabis use disorders. The average patient receiving a behavioral intervention fared better than 66% of those in the control condition. In this chapter the European cannabis-specific treatment program "CANDIS" is described. It was developed and tested in the framework of a translational cannabis treatment research program (Hoch et al., 2012) at Technische Universität Dresden (Dresden University of Technology) in Germany. From 2004 until 2010, the research program was funded by the German Ministry of Research and Education and the German Ministry of Health.

WHAT IS THE CANDIS TREATMENT PROGRAM?

CANDIS (abbreviation of "Cannabis Disorder") is an empirically supported treatment program tailored to the specific problems and needs of adolescents (≥16 years) and adults with primary cannabis use disorders. It combines motivational enhancement therapy,

cognitive-behavioral therapy and problem solving (treatment modules are described in sections "Cognitive Behavioral Therapy" and "Problem Solving Training"). The treatment consists of two weekly 90-min sessions in-person therapy. A treatment manual (Hoch et al., 2011b) specifies all relevant aims, topics and actions to be covered within each session, including assessments and urine drug screenings. The manual also includes information on cannabis, cannabis-related health effects, cannabis use disorders, the basic therapy principles, case reports and how to address typical problems (eg, ambiguous motivation) during treatment.

Who Can be Treated With CANDIS Treatment Program?

CANDIS was developed for persons with primary cannabis use problems. Many people with CUD are ambivalent with regard to changing their cannabis use patterns or treatment seeking. To participate at the program an individual should at least (1) be willing to participate at a treatment session, and be able to participate regularly and to follow the therapy plan. Further inclusion criteria for CANDIS therapy are: (2) primary cannabis use problems, (3) minimum age of at least 16 years, (4) average intellectual performance capability, (5) stable social integration. The intervention can both be helpful for those who are still using cannabis or those who already quitted. *Exclusion criteria* are: age under 16 years, acute severe alcohol dependence (particularly with withdrawal symptoms) or dependence on other illegal drugs, current medication with psychotropic substances, severe intoxication by opiates and stimulants, severe psychiatric disorder (eg, psychosis) and acute suicidality, severe learning disorders or neurological defects. Young adolescent cannabis users often complain about problems with their parents or at school. For this group of patients family-therapeutic concepts (eg, multidimensional family therapy; Liddle, 2002) may be more helpful than CANDIS therapy because family members, teachers and other relevant contact persons can be involved in the therapeutic process.

What Type of Clinician Should Deliver CANDIS?

Psychologists, psychotherapists, medical doctors, and counselors with experience in the field of addiction treatment can deliver CANDIS program to their clients. A special CANDIS "hands-on" training on the nature of CUD, the treatment manual, content and structure of each therapy session, typical problems in the therapeutic process is recommended. Moreover, ongoing supervision is essential to maintain high levels of treatment fidelity.

What Are the Aims of CANDIS?

The CANDIS program has several targets for the therapeutic process. The patient should learn (1) to recognize his or her cannabis use problems, (2) to accept the therapy and participate regularly, (3) to aim for abstinence as primary treatment goal (if patients are not willing to achieve complete abstinence, a reduction in cannabis use may be an alternative aim for treatment), (4) to stop cannabis consumption, (5) to remain abstinent by using relapse preventive measures, and (6) to learn identifying and solving mental and social problems adequately and efficiently.

Treatment Modules

Motivational Enhancement Therapy

The principles and techniques of Motivational Enhancement Therapy (MET) (Miller & Rollnick, 1991) are applied in the CANDIS-program to resolve motivational issues that inhibit positive behavior change. MET is a client-centered and directive counseling style, aiming to increase intrinsic motivation through exploring and decreasing ambivalent thoughts and attitudes. The central principles of MI are (1) expressing empathy, (2) developing discrepancy, (3) rolling with resistance, and (4) supporting self-efficacy. Typical strategies comprise (1) asking open questions, (2) listening reflectively, (3) affirming, (4) eliciting change talk, (5) exploring the pros and cons of a behavior change, (5) envisioning a changed (or nonchanged) future, and (6) exploring goals and values. MI techniques play an important role in the early therapy sessions (session 1–3) and throughout the whole therapeutic process (session 1–10).

Cognitive Behavioral Therapy

Cognitive-behavioral strategies (CBTs) (Monti, Abrams, Kadden, & Cooney, 1989) build the core of the CANDIS-therapy and help patients to successfully change their problematic cannabis use patterns. They are based on the theory that learning processes play a crucial role in the development and maintenance of substance use disorders and that these maladaptive reactions can be replaced by alternative, more functional behaviors. Patients learn cognitive and behavioral skills that support them in understanding, reducing or stopping their cannabis use and maintaining their treatment goals. Central CBT-elements are as follows:

1. *Psychoeducation:* after getting feedback of the results of the diagnostic session patients receive detailed information on the short-term and long-term effects of the drug cannabis. A biopsychosocial model for the development of cannabis dependence is an important basis for the deduction of the therapy

rational. The patients learn that social factors (eg, peer pressure) as well as psychological learning (operant and classical conditioning, model learning) can initiate cannabis use and progression to harmful use patterns (eg, abuse and dependence). They get information on how THC affects the brain (endocannabinoid system).

2. *Understanding consumption patterns:* before initiating any consumption change the patients are guided to understand their own use patterns (session 3). They are instructed to fill out consumption protocols in order to attentively "self-observe" their (mostly automatic) behavior reactions. Through functional analysis the patients learn to identify their problematic behavior, its triggers as well as its consequences, which continue to maintain it.
3. *Preparation of a target day:* after deciding for a specific goal (abstinence or reduction) the therapist helps the patient in session 4 to prepare the consumption stop/target day. The patient has been informed that abstinence as opposed to reduction is the most promising goal from a physiological as well as psychological point of view. The patient chooses a specific day that lies between session 4 and session 5. He or she explores together with the therapist helpful alternative coping strategies as well as how to prevent high risk-situations. He is further encouraged to increase (new) pleasant activities.
4. *Coping with cravings and urges:* in session 5, the patients learn helpful strategies for coping with cravings and urges. They further learn to identify (and avoid) triggers that increase urges and cravings.
5. *Relapse prevention:* in session 6, the patients are prepared how to foresee and deal with high-risk situations that may threaten their goal to remain abstinent. They further develop a personal emergency plan and learn how to deal with a slip in order to prevent a relapse.
6. *Refusal/social competence training:* the aim of session 10 is to increase the awareness for social situations in which it could be difficult to refuse the offer to smoke cannabis. The patient and therapist practice helpful refusal skills (role-plays are conducted).

Problem Solving Training

Patients with cannabis use disorders often report having severe problems in several life areas (eg, difficulties with the job or university, family or other relational problems, financial or legal issues). These problems can be completely unrelated with the consumptions pattern (eg, illness of a family member), but often are directly (eg, partner does not accept the drug consumption) or indirectly (eg, lack of motivation, concentration problems, or poor work performance) associated with the cannabis use disorder. In most cases these problems hamper a lasting abstinence, as many patients lack problem-solving skills and try to neglect problems and adverse feelings (eg, anger, sadness, frustration, anxiety) through the use of cannabis. Many chronic users describe their situation as a vicious circle of unresolved problems and the heavy use of cannabis. In order to break that negative circle, the goal in session 7 and 8 is to acquire appropriate problem solving strategies (D'Zurilla & Goldfried, 1971). Problem solving training (PST) can be regarded as a form of self-management training, in which the individual learns how to discover the most effective way of responding toward a problem. The problem solving training of D'Zurilla and Goldfried (1971) comprises five stages: (1) general orientation, (2) problem definition and formulation, (3) generation of alternatives, (4) decision making, and (5) verification. Malouff, Thorsteinsson, and Schutte (2007) showed in their metaanalysis of 30 studies encompassing $n = 2895$ participants the efficacy of problem solving training. The intervention was effective in comparison to no treatment ($d = 1.37$), treatment as usual ($d = 0.54$), and attention placebo ($d = 0.54$). Significant moderators included whether the PST included problem-orientation training, and whether homework was assigned.

Therapy Sessions

CANDIS treatment program has a clear structure: each session has special topics to be covered (see Fig. e19.1). According to our experience such a clear structure helps to define targets for the therapeutic interventions and facilitates to learn new behavior. In an initial *informational meeting* the patient is carefully informed about the treatment program. Realistic and positive treatment expectations should be fostered as they help the patients to get the feeling of being in good hands and build up a confidential relationship. According to Rogers, Dorfman, Gordon, and Hobbs (2005) especially suitable interview techniques promoting a confident therapeutic relationship are devotion and receptiveness (active hearing), empathy and acceptance of the other person. Sometimes, it can be necessary to clarify with patients that they usually have to give more information about themselves than they might be familiar with from classical medical treatment situations. In a second meeting with the patient a *diagnostic interview (anamnesis)* is conducted, including screenings for cannabis use, cannabis use disorders, comorbid mental and physical disorders, motivation to change etc. (Hoch et al., 2011b). Drug screenings (eg, urine test) are recommended for diagnostic purposes at the beginning and during the course of treatment. In sessions 1, 2, and 3, enhancement of motivation for change cannabis use patterns and participation in CANDIS treatment are major targets. In *session 1*, psychoeducation about CUD, with an emphasis on how cannabis affects the brain, its

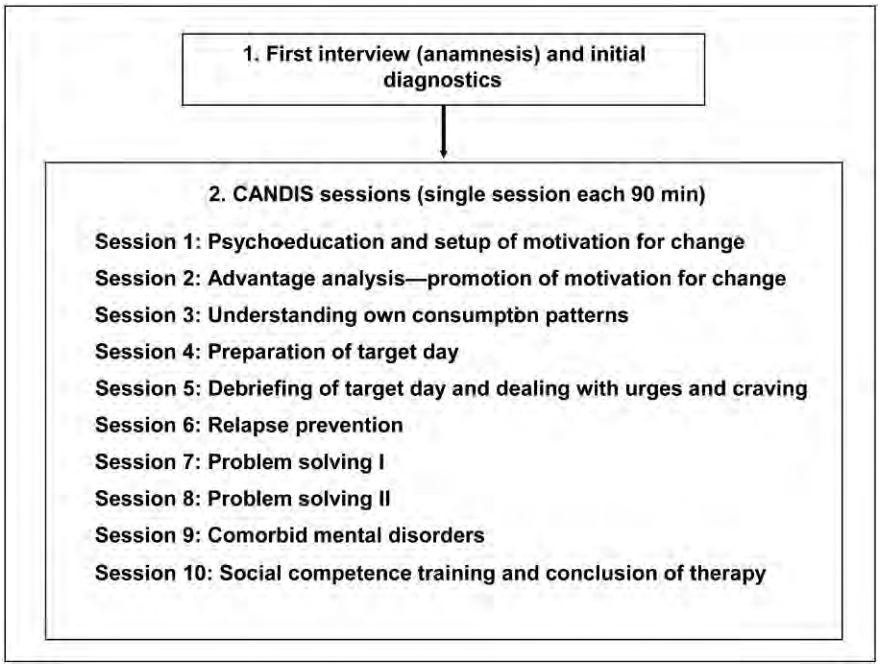

FIGURE e19.1 **CANDIS treatment sessions.**

positive and adverse health effects, and the endogenous cannabinoid system are given. An individual etiological model of CU emphasizing genetic, neurobiological, psychological and social risk factors for CU initiation and maintenance is derived. Principles of classical conditioning, operant conditioning, and model learning are introduced, in order to derive an individual learning history and change concept. Feedback of the results of the diagnostic session it provided to the patients. Motivational enhancement techniques are applied in this context to raise awareness of problems associated with cannabis. In *session 2*, a careful balancing of reasons for abstinence, as well as for cannabis consumption, is performed, in order to create motivational ambivalence. Motivational enhancement therapy techniques are used to resolve ambivalence, to find a treatment goal (eg, cannabis abstinence or reduction in cannabis use), and to promote behavior modification. Therapists worked toward helping patients to address barriers to change and to see the advantages of abstinence. If patients rejected abstinence as a therapy goal, they were supported in pursuing CU-reduction. *Session 3* consists of a discrimination training to help patients in recognizing situations that likely lead to CU. In a functional analysis, patients identified and examined their antecedents and consequences of CU. In *sessions 4–8*, several skills trainings are implemented, for example, quit day preparations, coping with withdrawal and craving, prevention of (re-)lapses, planning for emergencies, refusing cannabis offers, enhancing social support). Patients were also taught how to cope with negative thoughts, how to utilize contingency management (a system of self-reward using material goods and pleasant activities) and how to establish and reinforce positive activities. In *sessions 7 and 8*, the problem solving training is conducted. Patients learn to identify other life problems (eg, unemployment) and to use problem solving strategies (D'Zurilla & Goldfried, 1971). In *session 9*, we elaborate how comorbid mental disorders (anxiety, depression, substance use disorders) may contribute to continued CU and relapse while applying techniques from previous sessions to improve coping. If necessary, patients are given information on treatment providers for treatment after termination from the CANDIS treatment. In *session 10*, social competence training for the rejection of cannabis offers is introduced. Session 10 is also the conclusion of the CANDIS therapy.

A CASE REPORT

Mike is a 25 year old student who participated in the CANDIS treatment project. He had his first joint at the age of 15. Initially, he only smoked cannabis at the weekend, when he met his friends. After some time, his cannabis use became more regular. Mike enjoyed the pleasurable and relaxing effects of the drug after long days at school. Moreover, he was able to relax and sleep better at night. At the age of 18, Mike became a university student. His flatmate was also a regular cannabis user, and the two of them intensively played computer games and smoked bongs (5–10 bongs a day). From that point of time on, cannabis became central to his life. Often, Mike was not able to turn up at the university. He spent a lot of time in his bedroom, stayed in bed, and smoked pot. His desire to do new activities or meet people

was limited. He needed more cannabis to get the effect he wanted, and gave up playing soccer and going out with noncannabis using friends, which was something he had always enjoyed in the past. Mike became very moody, and felt depressed. He conducted several attempts to cut down his cannabis use, but craving and feelings of compulsion to use cannabis were too difficult to manage. Mike decided to take part in the CANDIS project. Within ten therapy sessions he stopped using cannabis, and managed to cope with craving and symptoms of withdrawal.

SCIENTIFIC EVALUATION

To develop and test the efficacy of modular treatment program for older adolescents and adults with cannabis use disorders, we conducted a large translational cannabis treatment research program (Hoch et al., 2011a, 2012, 2014). The first phase was a RCT conducted at Technische Universität Dresden (Dresden University of Technology) in order to develop and test a cannabis-specific intervention combining CBT, MET, and problem-solving training. In a second phase, the intervention was translated to 11 outpatient addiction treatment centers in Germany, where the treatment's effectiveness could be tested in the context of a multisite RCT.

CANDIS I (2004–07)

The aim of this first study phase was to examine the efficacy of modular CANDIS treatment program for older adolescents and adults with DSM-IV cannabis use disorders. A randomized controlled clinical trial of n = 122 patients (aged 16–44 years) with DSM-IV cannabis dependence as the main substance use diagnosis was conducted (Hoch et al., 2012). Patients were randomly assigned to either Active Treatment (AT, n = 90) or a Delayed Treatment Control group (DTC, n = 32) (Fig. e19.2).

Assessments were conducted at baseline, during each therapy session, at posttreatment and at follow-up assessments at 3 and 6 months. Ethical approval to conduct the study was obtained from the Human Research Ethics Committee of the Technische Universität Dresden (Dresden University of Technology). The study was registered in the clinical trials registry of the US National Institute of Health. Patients were recruited and treated (Jan. 26–Dec. 31, 2006) at an addiction outpatient clinic. Patients were referred via other outpatient drug treatment centers, the clinic homepage, newspaper advertisement, flyers, newspaper, radio, word-of-mouth and others sources. Treatment consisted of 10 sessions of therapy, detailed in a strictly enforced manual. Patients randomly assigned to the control group were informed

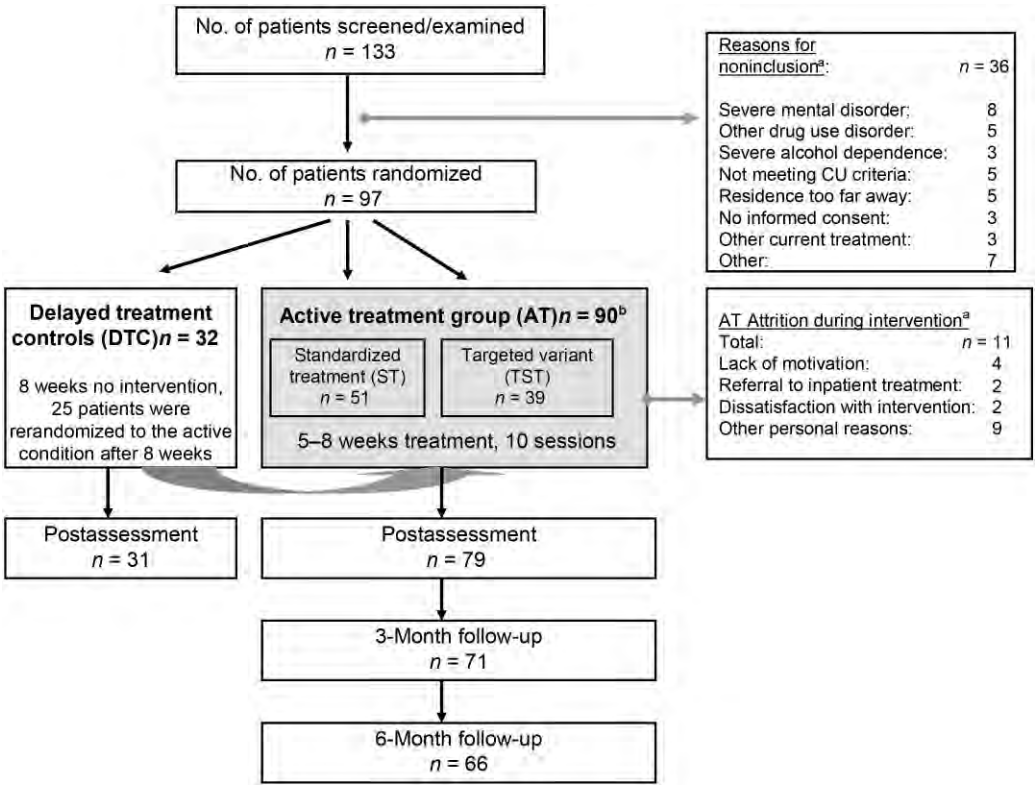

FIGURE e19.2 Patient flow through the study (from Hoch et al., 2012). [a] Multiple reasons possible; [b]Among the n = 90 subjects in the AT group were n = 25 rerandomized subjects from the DTC-condition.

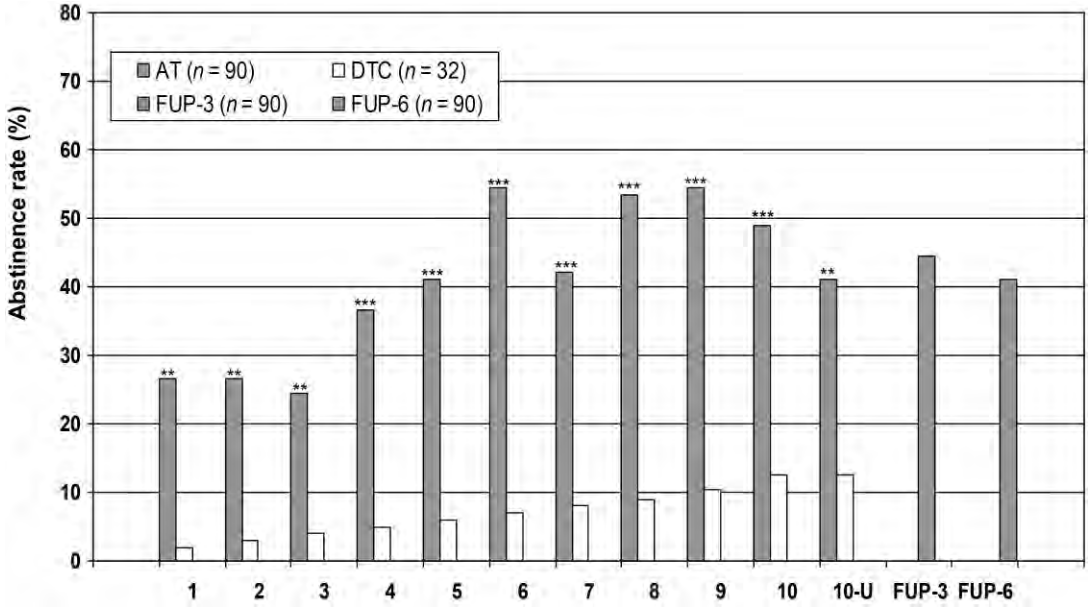

FIGURE e19.3 **Abstinence[a] rates (intention-to-treat-analysis, $n = 122$) (from Hoch et al., 2012).** [a]Abstinence is defined as complete abstinence in the past 7 days, no observations of abstinence at baseline; DTC abstinence rates were interpolated for session 1–9; ***$p < 0.001$ for DTC versus AT; ** $p < 0.01$ for DTC versus AT; session 10 findings are reported without and with (10-U) taking into account positive urine screenings.

that treatment will start in 8 weeks. Identical to AT patients, they were informed about the rationale and study procedures and completed the baseline assessment. They were instructed to reduce or even discontinue their cannabis use during the waiting period. Before starting the delayed treatment, patients completed a second assessment. Study therapists ($n = 10$) were clinical psychologists with training in behavior therapy. All study therapists attended a 1-week training on the treatment manual, which thoroughly addressed the nature of CU and CUD and trained all aspects of the manual using video and role plays. Therapists also received detailed instructions on how to solve frequent administration problems. Throughout the study therapists were supervised every 14 days. Each treatment session was videotaped. 50% were randomly selected and reviewed by supervisors. Feedback was provided to therapists on treatment adherence and therapist competency in a monthly feedback session. The treatment retention rate at the end of treatment was 88%. Abstinence was achieved in 49% of AT patients and in 13% of those in DTC ($p = 0.001$; intend-to-treat (ITT) analysis). Further, AT patients improved significantly ($p = 0.001$) in the frequency of cannabis use per week, addiction severity, number of disability days, and overall level of psychopathology. Program effects were maintained over a 3-month (abstinence rate: 51%) and 6-month follow-up (45%) period. The treatment program was effective in obtaining abstinence as well as reducing cannabis use and improved the associated social and mental health burden (Fig. e19.3).

CANDIS II (2007–10)

In a secondary project phase, the intervention was translated to routine practice. A multisite, randomized controlled trial of 279 treatment seekers with ICD-10 cannabis use disorders, aged 16–63, was conducted in 11 outpatient addiction treatment centers in Germany (Hoch et al., 2014). Patients were randomly assigned to an Active Treatment (AT, $n = 149$) or Delayed Treatment Control (DTC, $n = 130$). Treatment consisted of 10 sessions of fully manualized individual CANDIS. Assessments were conducted at baseline, during each therapy session, at posttreatment and at 3- and 6-month follow-ups. Ethical approval to conduct the study was obtained from the Human Research Ethics Committee of the Technische Universität Dresden (Dresden University of Technology). The study was registered in the clinical trials registry of the US National Institute of Health. Participating therapists recruited and treated patients from May 2, 2008 to Apr. 30, 2009. In order to avoid any systematic selection bias, every new patient to come to each counseling and treatment center who had regularly used cannabis in the previous year was informed about and invited to participate in the study. Patients who reported having been administered any other cannabis-specific treatment in the previous 3-month period were not approached. Patients were asked to provide written informed consent during the initial face-to-face interview, in which they were also asked to complete a prestudy questionnaire designed to determine their eligibility. Anonymized data of eligible patients was reported to the study

headquarter in Dresden, where they were randomized and assigned to one of the two treatment groups within 2 working days. Patients did not receive any payment for their participation. Those who were excluded from the study were treated as usual. Therapists participating in the study were given 2 days' training on the treatment manual, study procedures, assessment instruments, and data collection. They were supervised quarterly by the research staff. Each treatment session was videotaped. Random samples of these tapes (one out of every 30 sessions) were then sent from the study therapists to the study center in Dresden, where the research staff checked them for treatment fidelity using a standardized assessment form. Study therapists were blind to the number and sequence of the selected videotapes. They were given written feedback on treatment adherence and therapist competency. Adherence to the treatment manual was also evaluated after each therapy session, using a standardized questionnaire. Patients were at a mean age of 26.6 years (SD = 8.2, range: 16–63 years), predominantly males (86.7%) and not married (86%). On average, patients reported their first cannabis use at the age of 15.2 years, and their first regular use at 18.8 years of age. Of the total sample, 89.5% had used cannabis in the previous 4 weeks. They had consumed cannabis on mean of 18.8 of the 28 days in this 4-week period, and 42.7% were daily users. The majority of patients (87.1%) met ICD-10 diagnostic criteria for lifetime cannabis dependence (mean number of reported symptoms: 4.9). Prior cannabis quit attempts were reported by 85% of the sample (mean number of quit attempts: 7.9). The only observed baseline difference between groups was the number of cannabis dependence symptoms in the previous 4 weeks (AT vs DTC; $p = 0.005$). At post assessment 53.3% of AT patients reported abstinence (46.3% negative urine screenings) compared to 22% of DTC patients (17.7% negative drug screenings) ($p < 0.001$, intention-to-treat analysis). AT patients improved in the frequency of cannabis use, number of cannabis dependence criteria, severity of dependence, as well as number and severity of cannabis-related problems. Effect sizes were moderate to high. While abstinence rates in the AT group decreased over the 3-month (negative urine screenings: 32.4%) and 6-month (negative urine screenings: 35.7%) follow-up periods, the effects in secondary outcomes were maintained.

CONCLUSIONS

The intervention can successfully be translated to and applied in clinical practice. It has the potential to improve access to evidence-based care for chronic CUD patients.

MINI-DICTIONARY

CANDIS Cannabis disorders

CANDIS program CANDIS therapy is an empirically supported treatment program tailored to the specific problems and needs of adolescents and adults with cannabis use disorders. It combines motivational enhancement therapy, cognitive-behavioral therapy and problem solving.

Contingency management Contingency management is a behavioral treatment approach that is based on the principles of operant conditioning. Patients receive rewards to reinforce positive behaviors such as abstinence.

Cravings Cravings are a hallmark of substance use disorders, and describe the intense desire to use the drug.

Lapse A lapse (or slip) describes a brief return to addictive behaviors after a period of abstinence that can be successfully stopped by the individual, and does not lead to a regression of previous consumption patterns.

Motivational interviewing Motivational interviewing is a client-centered and directive counseling style, aiming to increase intrinsic motivation through exploring and decreasing ambivalent thoughts and attitudes.

Problem solving training Problem solving training is a form of self-management training in which the individual learns how to generate and choose the most effective way of responding toward a defined problem.

Relapse A relapse describes the complete return to addictive behaviors after a period of abstinence.

Relapse prevention Relapse prevention is an essential component of substance abuse treatment. RP techniques involve the identification and prevention of high risk situations as well as the development of individual emergency plans in order to maintain abstinent.

Tetrahydrocannabinol (THC) Tetrahydrocannabinol is the principal psychoactive compound of cannabis and acts on specific molecular targets, called cannabinoid receptors.

The biopsychosocial model The biopsychosocial model is a general model that attributes the development of mental disorders (eg, substance use disorders) to an interplay of certain social, psychological, and biological factors.

SUMMARY POINTS

- This chapter focuses on issues of engaging cannabis users in treatment.
- Cannabis users access traditional substance use treatment services less often than do any other substance users (including alcohol), and report higher rates of dropout.
- Outcomes for cannabis use are significantly improved with longer psychological and behavioral interventions, providing an impetus for better efforts at engaging, and retaining cannabis users in treatment.
- The physiological effects of cannabis, along with the psychological and social consequences of the drug, play a key role in the ability and willingness of cannabis users to engage in treatment targeting their cannabis use directly.
- Generally, cannabis users perceive cannabis as a relatively benign drug, with few consequences for their functioning, wellbeing and long-term health. The reality is quite different.
- Cannabis users have reported difficulties in establishing a bond with their therapist; a key feature of therapeutic alliance that is associated with treatment engagement and retention.
- A range of strategies is suggested to overcome the difficulties with engaging cannabis users in treatment. These include the integration of non-face-to-face treatments (eg, Internet-delivered) that have demonstrated benefits for cannabis users particularly; targeting early treatments for cannabis users to those aspects of their lifestyle for which they are willing to seek treatment (eg, lifestyle, tobacco use); and establishing specialized cannabis clinics where trained therapists can be adequately supported and resourced to treat the complexities of cannabis use.

KEY FACTS OF ENGAGEMENT

- Encouraging people with substance use problems to enter and remain in treatment (treatment engagement) is a key concern and priority of substance use research and service provision.
- Definitions of "engagement" incorporate aspects of treatment attendance, treatment motivation, patient involvement, and the attitude and behaviors of both the client and therapist.
- It is widely acknowledged in the research and clinical literature that engaging clients is particularly difficult in drug and alcohol settings, whether in terms of accessing services, attending appointments, and developing and maintaining motivation for treatment.
- Studies measuring "engagement" are generally focused on exploring aspects related to improving treatment seeking, treatment retention, or the client-therapist relationship (therapeutic alliance).

Handbook of Cannabis and Related Pathologies. http://dx.doi.org/10.1016/B978-0-12-800756-3.00134-4
Copyright © 2017 Elsevier Inc. All rights reserved.

- Exactly which factors influence a person's decision to seek and remain in treatment are not well understood; however, client retention in treatment is consistently related to enhanced treatment outcomes. This is particularly true for cannabis users.
- One of the most influential and studied factors related to treatment engagement and attendance is therapeutic alliance, particularly in the first few weeks. There are three core components of therapeutic alliance: bond (mutual liking, trust and attachment in the therapeutic relationship), tasks (agreement on joint tasks and strategies used in therapy), and goals (agreement on the targeted areas for change).

INTRODUCTION

Over the past decade, as the need for specific cannabis interventions has increased, research has focused on both developing and maximizing the impact of available treatments for cannabis use disorder (Copeland, 2004; Gibbons et al., 2010). Available evidence suggests the benefits of psychological and behavioral therapies in reducing cannabis consumption (Pacek & Vandrey, 2014). Current guidelines for clinicians specifically working with cannabis users (Copeland et al., 2009), emphasize engagement and building a strong therapeutic alliance as critical when working with cannabis clients.

WHY IS ENGAGEMENT PARTICULARLY IMPORTANT FOR CANNABIS USERS?

Early treatment studies have indicated that fewer than 10% of cannabis users access treatment for their cannabis use; a lower proportion than for any other drug type (Stephens et al., 2007; Copeland & Allsop, 2014). In 2008, only 2% of past-year cannabis users in New Zealand received help for cannabis use, yet 13% reported daily consumption (MoH, 2010). Typically, cannabis users do not approach traditional services for fear of being stigmatized (Copeland & Swift, 2009; Gates et al., 2012), or because of a view that they can successfully navigate a quit attempt, and maintain abstinence on their own (Pacek & Vandrey, 2014).

Most cannabis users do not access treatment until their mid-30s, often over concerns about related mental health or lifestyle problems (Teesson et al., 2012), or earlier via coercion from family members or the legal system (Carroll et al., 2006; van der Pol et al., 2013). They have typically used cannabis near-daily for over 10 years and have made more than six serious but unsuccessful attempts to reduce or stop (Swift & Copeland, 2012). When they do seek help, few express a desire to stop using cannabis completely, and opt for reduction goals (Carroll et al., 2006). Many clinicians report reluctance to address cannabis use, and others may not have the expertise required to deliver integrated treatment packages that address the issues most pertinent to cannabis users (Kay-Lambkin et al., 2004). Once they enter treatment, cannabis users have also been shown to have the highest rates of noncompletions (67%) when compared to alcohol (32%) and other illicit substances (ranging from 13 to 34%, Myers et al., 2010).

Importantly; however, the existing literature highlights the benefits of engaging cannabis users in treatment, with unsuccessful cannabis quit attempts being associated with lower exposure to formal treatment programs (Rooke et al., 2011). In addition, a comparison of 87 successful and 78 unsuccessful cannabis quitters attributed the lack of success to a strong desire to quit, but failure to adequately plan strategies for coping with a quit attempt (Rooke et al., 2011).

Brief (one-two) session interventions have demonstrated effectiveness in reducing the quantity and frequency of cannabis use, and associated harms (eg, Swift & Copeland, 2012), especially over the shorter term (eg, 3 months). However, recent research indicates the potential of extended (multisession) cognitive behavioral treatments over and above that achieved by a brief intervention for cannabis use problems. This is somewhat different from people with alcohol use disorders, for whom brief interventions can be highly effective (Heather, 2002) and as effective as longer psychological treatments (Baker et al., 2014). For example, Baker et al. (2009) compared outcomes for 248 participants with alcohol or cannabis use disorders across three clinical trials of psychological treatments consisting of brief advice, one session of motivation enhancement training (MET), or ten sessions of integrated MET and cognitive behavior therapy (CBT). The results indicated that brief interventions (advice or one session) were significantly more effective for alcohol misuse, while more intensive MET/CBT was more effective in reducing cannabis use, even with the inclusion of participants with comorbid mental health diagnoses, such as, major depression and psychosis (Baker et al., 2009). For cannabis users across these studies, effect size changes between baseline and 6-month follow-up were 0.56 (medium) for those in the 10-session MET/CBT intervention, compared to 0.16 (small) for cannabis users who received the brief interventions ($p = 0.03$). Although the longer interventions

were recognized as optimal for cannabis users, the study does not suggest that brief interventions are ineffective. In fact, 50% of cannabis users reduced their use somewhat, and maintained the reduction at 6-month follow-up after receiving a brief intervention, suggesting that it may be a helpful first step into treatment (Baker et al., 2009). However, following brief intervention, cannabis use remained high, with 71% remaining above a cannabis use threshold requiring treatment (Baker et al., 2009). This indicates the potential value of working to optimize engagement and retention of cannabis users in longer-term treatment programs.

WHAT IS UNIQUE ABOUT CANNABIS USERS THAT MAY INFLUENCE TREATMENT ENGAGEMENT?

Physiological Effects of Cannabis

The intoxication and long-term physiological effects of cannabis may in part explain why this group may be unique and challenging to engage and retain in traditional substance use counseling treatments. Euphoria, relaxation, time distortion, perceptual alterations, intensified sensory experience, difficulties with the formation and retrieval of memories, and attention difficulties are all associated with the short-term effects of cannabis use (Hall et al., 1994; NIDA, 2010). These physiological effects may make it difficult for people to remember and regularly attend appointments, and to take on board psychological treatment strategies.

Influence of Cannabis Use on People Presenting for Treatment

Cannabis use also has psychological impacts on anxiety, panic, depressive symptoms, and psychosis, usually associated with chronic consumption (Johns, 2001), and which may affect the ways in which they engage with and respond to treatment. Integrated data across three large longitudinal studies in Australia and New Zealand revealed consistent and clear associations between daily cannabis use before the age of 17 and significantly reduced odds of high school completion, 17–18 times the odds of later cannabis dependence, 7–8 times the risk of other illicit drug use, and 6–7 times the risk of a suicide attempt (Silins et al., 2014). In a 15-year longitudinal cohort study from adolescence to age 29 years, Degenhardt et al. (2013) revealed a strong association between daily cannabis use in adolescence and 2–3 times the odds of developing an anxiety disorder at 29 years.

Cannabis use may also be associated with subthreshold problems that may impact on the therapeutic relationship. In a recent study of 274 people with depression and comorbid alcohol, cannabis, or stimulant use problems (Kay-Lambkin et al., 2011), those who were above threshold for cannabis use (at least once weekly use for the month prior to baseline assessment) were compared to those below threshold on a range of presenting characteristics. People were recruited from the general community in response to media campaigns advertising a treatment trial for people with comorbidity. People who were above threshold for cannabis use in this study reported significantly higher psychoticism (*"the idea that something is wrong with your mind,"* $F(1220) = 6.056$, $p = .015$), interpersonal sensitivity (*"feeling inferior to others,"* $F(1218) = 5.313$, $p = .022$), somatization (*"faintness or dizziness,"* $F(1220) = 8.091$, $p = .005$), paranoid ideation (*"not getting proper credit for your achievements,"* $F(1220) = 11.144$, $p = .001$), obsessive-compulsiveness (*"having to check and double-check what you do,"* $F(1220) = 6.125$, $p = .014$), and phobic anxiety (*"feeling uneasy in crowds,"* $F(1220) = 6.125$, $p = .014$) on the brief symptom inventory (Derogatis & Melisaratos, 1983) than did people who were not above the treatment threshold for cannabis use. No significant differences were found between above and below threshold cannabis users on the subscales of depression (*"feeling no interest in things"*), hostility (*"urges to break or smash things"*), or anxiety (*"feeling tense or keyed up"*). Together, these differences in people using cannabis at thresholds requiring treatment suggest a unique set of interpersonal challenges that may affect their ability to engage with and follow through on a program of psychological treatment with a therapist relative to users of alcohol or other drugs and may result in them feeling disconnected from the treatment process. As further evidence of this, people who were above threshold for cannabis use attended significantly fewer treatment sessions than did those who were below threshold (4.95 sessions vs 6.10 sessions, $F(1,206) = 4.361$, $p = .038$). This emphasizes the particular need to focus on better engaging cannabis users in psychological treatments.

Motivation

Controversially, *"amotivational syndrome"* has also been suggested to be associated with chronic cannabis use, generally defined *"as the diminished or absent drive to engage in typically rewarding activitie"* (NIDA, 2010, p. 7). The syndrome is typically described as an inability to concentrate and carry out long-term plans, and a loss of desire to work or be productive (Cherek et al., 2002). Although there is limited research to support *"amotivational syndrome"* in cannabis use, the impact of cannabis use on decreased motivation is documented throughout the available literature (eg, Hall et al., 1994; NIDA, 2010). By way of example, in a sample of 274 people with depression and alcohol or cannabis use problems

(Kay-Lambkin et al., 2011), baseline data on readiness to change revealed differences between people using alcohol at above threshold levels, and those using cannabis at above threshold levels. Average readiness and motivation to change alcohol use was significantly higher (and closer toward the action stage of change) than it was for cannabis use [67.91 vs 40.95, t(117) = –23.31, p = 0.000]. This is despite people presenting for the research program for help with alcohol or cannabis use and depression. These results suggest that ambivalence to change cannabis use most likely needs to be considered in the early stages of engaging and managing cannabis use.

Risk Perceptions

Risk perceptions play a strong role in decisions to stop using substances (Romer & Jamieson, 2001). Behavioral theories highlight the role of perceived harms in predicting initiation and continuation of substance use. For example, in a 30-year longitudinal study of US adolescents, higher levels of substance use were observed in participants with lower perceptions of risks for that substance (Johnston, O'Malley, Backman, & Schulenberg, 2005). This has also been demonstrated in Australia, where higher levels of cannabis use in particular, was associated with lower perceived risk of harms related to the drug, and continued use (Thornton et al., 2013).

Cannabis has often been viewed as a relatively benign illicit drug, with the majority considering their use sporadic, of limited duration and without major consequences (Thornton et al., 2012a). A key barrier to treatment engagement is the widespread perception that cannabis is a *"safe, harmless, natural substance"* and few cannabis users want to quit or cut down (Akre et al., 2009) (Box e20.1).

A large scale comparison of cannabis users in the United States explored a range of presenting characteristics among treatment seeking versus nontreatment-seeking cannabis users (Pacek & Vandrey, 2014). Across both samples, cannabis users did not endorse reasons for initiating a quit attempt that involved concerns around the deleterious health effects of cannabis use (eg, knew others who had suffered with health problems due to cannabis, worried about reduced life expectancies; Pacek & Vandrey, 2014). Hence, treatment seeking in cannabis users may be more related, for example, to the impact of use on a person's ability to perform their desired roles, rather than to concerns about the health impacts of the drug.

In a qualitative study involving cannabis, tobacco and alcohol users, participants reported that cannabis was a drug to be used and enjoyed without an impact on functioning (Thornton et al., 2012b). On the other hand, tobacco use was considered to be a drug associated with a range of significant negative physical consequences, and was unanimously nominated by participants as the most harmful substance of cannabis, alcohol, and tobacco (Thornton et al., 2012b).

Despite their attitudes, cannabis users frequently report use patterns that increase the likelihood of long-term use, polydrug use, and exposure to cannabis-related harms (Swift & Copeland, 2012). Ambivalence about the negative effects of cannabis use, the multiple perceived positive effects, and relatively low cost, all contribute to the documented difficulties in encouraging cannabis users to modify their consumption of the drug (Budney & Stanger, 2012).

BOX e20.1

RISK PERCEPTIONS ASSOCIATED WITH CANNABIS USE ARE LOW

"Most blokes who go home from work and have a couple of cones or a joint, they tinker in their shed, or play the guitar, or whatever and next they get up and go to work and perform as necessary with absolutely no problems."

(Thornton et al., under review)

Therapeutic Alliance

The importance of the therapeutic alliance as a component of engagement in substance use treatment is well established. Therapeutic alliance refers to the collaborative relationship between a healthcare professional and a client or patient (Bordin, 1979). Alliance is the most studied process factor in psychotherapy research, because of its positive influence on treatment outcomes (Shelef & Diamond, 2008). The importance of engaging clients in treatment and establishing a strong therapeutic alliance is highlighted throughout the substance abuse treatment literature, and is found to positively influence treatment outcomes (Miller et al., 2005; Tetzlaff et al., 2005). Miller and Wilbourne (2002) suggest that 50–66% of outcome in alcohol treatment is attributable to the therapeutic alliance. In particular, the client's experience of the quality of alliance early in treatment is thought to impact on substance use outcomes (Diamond et al., 2006).

Therapeutic alliance consists of three core components: bond, tasks, and goals (Bordin, 1979, see Table e20.1). It is argued that all three components need to be present, and in agreement between client and therapist in order to maximize engagement and treatment outcomes.

One core dimension of therapeutic alliance, *bond*, describes the personal feelings a client has toward a therapist, characterized by acceptance, support, and

TABLE e20.1 The Three Core Components of the Therapeutic Alliance; the Collaborative Relationship Between a Client and Therapist (Bordin, 1979)

Therapeutic alliance domain	Interpretation
Bond	Mutual liking, trust, and attachment between client and therapist
Tasks	Agreement between client and therapist about the strategies and activities of therapy
Goals	Agreement between client and therapist about the targeted areas of change for therapy (including the order in which targets should be addressed)

understanding in the relationship. In a study of 77 clients presenting to a public drug and alcohol service in Australia, Healey et al. (2013) reported that cannabis users reported significantly poorer perceptions of bond, relative to users of other drugs. This was supported by their therapists, who also rated the bond with their cannabis-using clients significantly lower than they did clients using other drugs. There was evidence for the client's perception of the bond to worsen as the severity of cannabis use increased, and cannabis use remained a significant independent predictor of client-related bond, when age and gender were taken into account (Healey et al., 2013). Given that the bond dimension incorporates the emotional attachment between the client and therapist, perhaps a combination of lower interpersonal sensitivity, heightened paranoia, phobic anxiety, and psychoticism that have been associated with cannabis use (NIDA, 2010; Healey et al., 2013) led to clients feeling emotionally numbed or disconnected from their therapist during treatment. These factors are suggestive of the potential difficulties cannabis users face in engaging in substance use treatment—leading to poor treatment seeking and premature treatment dropout (Fig. e20.1).

WHAT CAN BE DONE TO MINIMIZE THE IMPACT OF THESE CHALLENGES ASSOCIATED WITH CANNABIS USE?

Internet/Computerized Treatments—the "Tasks" of Therapy

One of the most promising new areas of intervention research is the development of innovative models of intervention delivery to reduce the barriers to treatment provision. One way of improving engagement and the therapeutic alliance in cannabis users, given their heightened paranoia and interpersonal sensitivity relative to users of other drugs, may be the use of non-face-to-face (non-F2F) treatments. In addition, a desire for self-reliance is the most important treatment barrier reported by the majority of cannabis users, followed by a preference for informal help seeking (van der Pol et al., 2013). Thus, non-F2F approaches may be an ideal treatment-client match for this group of illicit drug users. Such treatments include bibliotherapy, computer-delivered, Internet-delivered, and phone-based modalities.

In recent years, as the demand for drug and alcohol services has remained strong, leading to the integration of non-F2F treatments into the substance abuse literature and practice as a potentially cost-efficient strategy that can be available to a large number of people (Copeland, 2011). In a comparison of computer-based interventions with traditional psychotherapy, similar

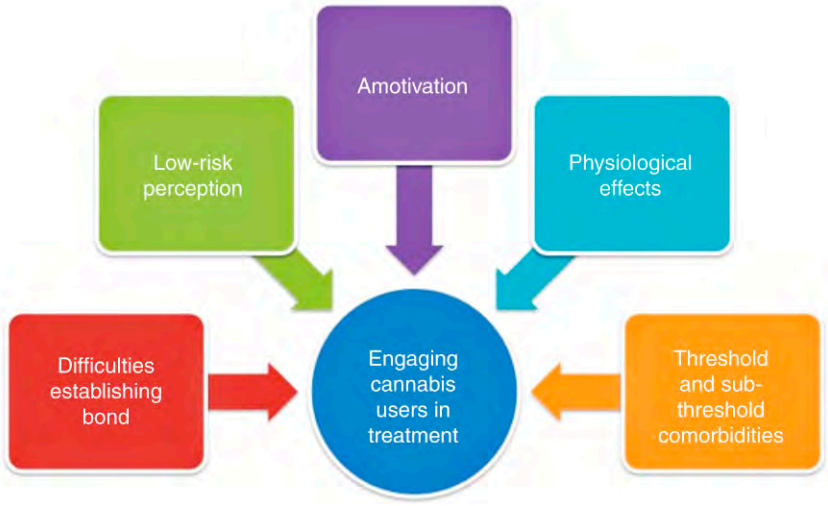

FIGURE e20.1 **Potential threats to the engagement of cannabis users in treatment.**

improvements in substance use outcomes were reported, lending weight to the idea that a computer-assisted treatment model could augment the treatment provided by clinicians working in substance use services (Carroll et al., 2008).

Research is emerging regarding the efficacy of non-F2F interventions in cannabis use disorders. For example, in a synthesis of data across two randomized trials of online self-guided versus telephone delivered interventions for cannabis use, Rooke et al. (2014) reported stronger treatment effects in telephone-delivered treatment than for web-based treatment, along with higher rates of treatment engagement.

With the widespread availability of the Internet, there are many benefits to Internet-delivered treatments for substance use, such as the absence of waiting lists and appointment times, and the freedom of the location and timing of treatment. Moore et al. (2011) conducted a systematic review into computer-based interventions for drug use disorders. Results across five randomized controlled trials revealed that computer-based treatments are associated with high client satisfaction, and were no different in terms of client retention and engagement when compared to therapist-delivered interventions (Moore et al., 2011).

Previous research has indicated that cannabis users are less anxious than people using other drugs about the idea of integrating computers or the Internet into their treatment (Healey et al., 2013). In addition, the same study reported that a higher proportion of cannabis users had previously used the Internet to access treatment or information about cannabis use; a level higher than users of any other drug (Healey et al., 2013). This perhaps points to a potential advantage of this treatment modality for cannabis users in that they may be willing to at least try alternative modes of delivery of cannabis use treatment.

A recent metaanalysis conducted across 10 randomized trials of Internet or computer-based interventions for cannabis use indicated the efficacy of these treatment modalities, at least over the short term, in terms of reduced cannabis use (Tait et al., 2013). For example, in a trial of a 6-session web-based treatment program for cannabis use disorder, 225 treatment seeking cannabis users were randomized to receive web-based treatment versus an attentional control (web-based; Rooke et al., 2013). Results at 3-month follow-up indicated those in the web-based cannabis intervention reported significantly fewer days of cannabis use in the past month, lower quantity of cannabis use and significantly fewer symptoms of cannabis abuse relative to controls (Rooke et al., 2013).

There is also emerging evidence that computerized treatments for cannabis use are at least as effective, if not more so, than are F2F treatments. For example, the clinical efficacy of the SHADE (self-help for alcohol and other drug use and depression) computer treatment program has been examined in two trials among people with depression and comorbid alcohol or cannabis use, relative to therapist-delivered treatment (Kay-Lambkin et al., 2009, 2011). Both SHADE computerized and therapist-delivered treatments yielded similar improvements in substance use and depression, at posttreatment and at 12-month follow-up. SHADE was most efficacious for people with cannabis use, with cannabis users exposed to SHADE computerized treatment reporting large effect size changes from baseline to 12-month follow-up assessment (Kay-Lambkin et al., 2009). An examination of therapeutic alliance for participants in the SHADE trial revealed no significant differences for those above and below threshold for cannabis use on the therapeutic alliance dimension of bond overall [$F(1,178) = 0.700$, $p = .404$], and for participants in the SHADE computerized treatment condition [$F(1,63) = 0.009$, $p = .925$].

These findings generally highlight the potential of non-F2F treatments, particularly those involving computer/the Internet in supporting treatments for cannabis users. These modalities can potentially increase the reach of therapy outside an individual treatment session, and can overcome logistical and emotional barriers to attending regular treatment appointments with a therapist that have been previously reported by cannabis users. Given cannabis users might additionally find it difficult building an emotional bond with their therapist, report paranoid ideation and interpersonal sensitivity, Internet/computer based treatments may be one potential way to engage, transition, or retain this growing population in treatment.

Target Issues of Concern/Risk—the "Goals" of Therapy

Pacek and Vandrey (2014) have previously reported that the biggest disparity between treatment seekers and nontreatment seekers for cannabis use were related to self-image and positive life change (like myself better, control of life, increase energy). Cannabis users in their sample who sought treatment endorsed reasons for treatment seeking that favored improved self-image. Other research has indicated that the majority of cannabis users (up to 91%) also smoke tobacco (Norberg et al., 2012), which they universally perceive as a toxic and addictive substance (Akre et al., 2009). Importantly, the majority of cannabis users report a clear intent to stop tobacco use (Akre et al., 2009), providing an opportunity for engaging them in broad discussions about their current lifestyle.

Preliminary evidence suggests the potential benefit of a lifestyle-focused intervention in cannabis users. For example, a recent "Healthy Lifestyle" trial among 252 tobacco smokers with psychosis (Baker et al., 2011; Baker et al., 2015), engaged a sample who were, on average,

daily cannabis users at baseline. Cannabis users in this study who received a telephone-delivered tobacco intervention reported an average reduction in cannabis use of daily to weekly use from baseline to follow-up assessment ($p = 0.033$). This is despite cannabis not being specifically targeted in the treatment.

A second study is underway using an online lifestyle intervention in the general community. Of the 92 participants engaged to date, 14 (15%) are daily cannabis users. Initial data analyses indicate the potential benefit of the online intervention in reducing tobacco use, cannabis use, depressive symptoms, and improving quality of life in both users and nonusers of cannabis. In particular, at baseline, 6 (43%) of the cannabis users reported mixing tobacco with cannabis, and all of these participants had stopped this practice at 6-month follow-up. The reduction in cannabis by the small sample of users might be indicative of the benefits of capitalizing on the high motivation to quit tobacco in cannabis users, and previous work suggesting the serendipitous benefits of multicomponent Internet-delivered treatments (Kay-Lambkin et al., 2013).

By focusing cannabis treatment in the early stages on issues of perceived harm and risk, there is a real potential to encourage cannabis users to consider other aspects of their lifestyle that might impact on these risky behaviors (eg, cannabis use). This approach is consistent with a nonconfrontational, motivational approach, which may also assist with higher engagement and retention in treatment, and a "foot-in-the-door" to cannabis users addressing their cannabis use down the track. For example, when addressed first, tobacco cessation treatment enhances engagement in substance use treatment. The important secondary prevention opportunity to minimize tobacco- and other lifestyle-related harms in this treatment strategy cannot be overstated.

Specialized Cannabis Clinics—the "Bond" in Therapy

The success of cannabis interventions is still largely dependent on client engagement, retention and adherence to treatment long enough to produce positive change (Baker et al., 2009; Gibbons et al., 2010). Evidence suggests that cannabis users do not identify with users of other substances, and accordingly are reluctant to engage with traditional substance use treatment services for fear of stigmatization. In response to this, in Australia, some publicly funded substance use agencies have established specialized cannabis clinics, for exclusive engagement of cannabis users, and located separately from the mainstream drug services.

Initial research conducted with the population seeking treatment for cannabis use via specialized cannabis clinics indicates the benefits of this approach, with these clinics attracting and engaging a greater proportion of treatment naïve cannabis users than nonspecialized drug and alcohol clinics (Copeland & Allsop, 2014). Importantly, clients who engaged with the specialized cannabis clinic attended an average of 10 weeks of treatment (10.95 weeks).

Research conducted among a drug and alcohol service incorporating a specialized cannabis clinic revealed that the differential perceptions of bond by cannabis users versus users of other drugs is not evident in clients attending the specialized clinic (Healey et al., 2013). Perhaps this provides initial support for the idea of specialized cannabis clinics, engaging clients specifically interested in managing their cannabis use, which allows the therapist to focus more on the establishment of a collaborative partnership with the client in therapy as opposed to a focusing on working toward agreeing on a primary focus of treatment. Staff in these specialized clinics receive additional training and supervision around engaging and managing people with current cannabis use problems; attesting to the importance of these support packages for therapists working exclusively with cannabis using clients. This is particularly true, given reports by cannabis clinic therapists in the study by Healey et al. (2013), who reported significantly lower confidence and optimism in therapy than did therapists in the traditional drug and alcohol services.

MINI-DICTIONARY

Cannabis users In this chapter, the term "cannabis users" refers to people who use cannabis, and is not meant to convey prejudice or offense toward people engaging in this form of drug use.
Comorbid/comorbidity Refers to the concurrent occurrence of more than one disorder within the one person, for example, a substance use problem and a mental health problem. Includes subthreshold presence of symptoms related to multiple disorders.
Engagement Refers to the factors associated with increased attendance and participation in treatment, including therapeutic alliance, individual client factors, and individual therapist factors.
Psychological and behavioral treatment Refers to treatment that is nonpharmacological in nature, and includes a focus on changing behaviors, psychological responses to key events, thoughts, feelings, and social factors. Types of treatment include, but are not limited to, motivation enhancement training, and cognitive behavior therapy.
Therapeutic alliance Refers to the relationship between a client and a therapist who are engaged in a program of treatment. The core components of therapeutic alliance are bond, tasks and goals.

Handbook of
Cannabis and Related Pathologies

EDITED BY
VICTOR R. PREEDY

Handbook of Cannabis and Related Pathologies: Biology, Pharmacology, Diagnosis, and Treatment is the first book to take an interdisciplinary approach to the understanding of cannabis use and misuse. Recent worldwide trends toward decriminalizing marijuana for medical use have increased legal use of the drug and recreational use remains high, making cannabis one of the most commonly used drugs. Cannabis has a wide range of adverse neurological effects, and use and abuse can lead to physical, social, and psychopathological issues that are multifarious and complex. Effective understanding and treatment requires knowledge of the drug's effects from across scientific disciplines.

This book provides an overview of the biological and pharmacological components of the cannabis plant; outlines its neurological, social, and psychopathological effects; assists in diagnosis and screening for use and dependency; and aids researchers in developing effective treatments for cannabis-related issues and disorders. Fully illustrated, with contributions from internationally recognized experts, *Handbook of Cannabis and Related Pathologies* is the go-to resource for neuroscientists, pharmacologists, pathologists, public-health workers, and any other researcher who needs an in-depth and cross-disciplinary understanding of cannabis and its effects.

Key Features
- Each chapter includes an abstract, key facts, mini-dictionary of terms, and summary points
- Comprehensively illustrated with numerous figures, tables, and diagrams per chapter
- The only publication to provide a "one-stop-shopping" synopsis of everything to do with cannabis and its related pathology, from chemicals and cells, to individuals and communities, to diagnosis and treatment
- The interdisciplinary approach offers an integrated and informed synopsis of the complex issues surrounding cannabis as a substance, its use, and its misuse

About the Editor
Victor R. Preedy, BSc, PhD, DSc, FRSB, FRSH, FRIPHH, FRSPH, FRCPath, FRSC is a senior member of King's College London. He is also director of the Genomics Centre and a member of the Faculty of Life Sciences and Medicine.

Professor Preedy has longstanding academic interests in substance misuse, especially in relation to health and well being. He was a member of the editorial board of *Drug and Alcohol Dependence* and was a founding member of the editorial board of *Addiction Biology*. In his career, Professor Preedy was Reader at the Addictive Behaviour Centre at the University of Roehampton, and also Reader at the School of Pharmacy (now part of University College London). Professor Preedy is editor of the multivolume seminal works *Comprehensive Handbook of Alcohol Related Pathology* and *The Neuropathology of Drug Addictions and Substance Misuse* (both published by Academic Press-Elsevier).

To his credit, Professor Preedy has published over 600 articles, which include peer-reviewed manuscripts based on original research, abstracts and symposium presentations, reviews, and numerous books and volumes.
