Contributors ix
Foreword xvii
Preface xix
Editors xxiii

SECTION I

FUNGAL BRANCHES ON THE EUKARYOTIC TREE OF LIFE / 1

1 The Fungal Tree of Life: From Molecular Systematics to Genome-Scale Phylogenies / 3
Joseph W. Spatafora, M. Catherine Aime, Igor V. Grigoriev, Francis Martin, Jason E. Stajich, and Meredith Blackwell

2 Six Key Traits of Fungi: Their Evolutionary Origins and Genetic Bases / 35
László G. Nagy, Renáta Tóth, Enikő Kiss, Jason Slot, Attila Gácser, and Gábor M. Kovács

3 What Defines the "Kingdom" Fungi? / 57
Thomas A. Richards, Guy Leonard, and Jeremy G. Wideman

4 Fungal Diversity Revisited: 2.2 to 3.8 Million Species / 79
David L. Hawksworth, and Robert Lücking

5 Microsporidia: Obligate Intracellular Pathogens within the Fungal Kingdom / 97
Bing Han and Louis M. Weiss

SECTION II

LIFE OF FUNGI / 115

6 Fungal Sex: The *Ascomycota* / 117
Richard J. Bennett and B. Gillian Turgeon

7 Fungal Sex: The Basidiomycota / 147
Marco A. Coelho, Guus Bakkeren, Sheng Sun, Michael E. Hood, and Tatiana Giraud

8 Fungal Sex: The Mucoromycota / 177
Soo Chan Lee and Alexander Idnurm

9 Sex and the Imperfect Fungi / 193
Paul S. Dyer and Ulrich Kück

10 Molecular Mechanisms Regulating Cell Fusion and Heterokaryon Formation in Filamentous Fungi / 215
Asen Daskalov, Jens Heller, Stephanie Herzog, André Fleißner, and N. Louise Glass

11 Cell Biology of Hyphal Growth / 231
Gero Steinberg, Miguel A. Peñalva, Meritxell Riquelme, Han A. Wösten, and Steven D. Harris

12 The Fungal Cell Wall: Structure, Biosynthesis, and Function / 267
Neil A. R. Gow, Jean-Paul Latge, and Carol A. Munro

13 Fungal Ecology: Principles and Mechanisms of Colonization and Competition by Saprotrophic Fungi / 293
Lynne Boddy and Jennifer Hiscox

14 Long-Distance Dispersal of Fungi / 309
Jacob J. Golan and Anne Pringle

15 The Mycelium as a Network / 335
Mark D. Fricker, Luke L. M. Heaton, Nick S. Jones, and Lynne Boddy

SECTION III

FUNGAL ECOLOGY / 369

16 The Geomycology of Elemental Cycling and Transformations in the Environment / 371
Geoffrey Michael Gadd

17 Ecology of Fungal Plant Pathogens / 387
Aad J. Termorshuizen

18 Key Ecological Roles for Zoosporic True Fungi in Aquatic Habitats / 399
Frank H. Gleason, Bettina Scholz, Thomas G. Jephcott, Floris F. van Ogtrop, Linda Henderson, Osu Lilje, Sandra Kittelmann, and Deborah J. Macarthur

SECTION IV

HOW FUNGI SENSE THEIR ENVIRONMENT / 417

19 Nutrient Sensing at the Plasma Membrane of Fungal Cells / 419
Patrick van Dijck, Neil Andrew Brown, Gustavo H. Goldman, Julian Rutherford, Chaoyang Xue, and Griet van Zeebroeck

20 The Complexity of Fungal Vision / 441
Reinhard Fischer, Jesus Aguirre, Alfredo Herrera-Estrella, and Luis M. Corrochano

21 Stress Adaptation / 463
Alistair J. P. Brown, Leah E. Cowen, Antonio Di Pietro, and Janet Quinn

22 Thigmo Responses: The Fungal Sense of Touch / 487
Mariana Cruz Almeida and Alexandra C. Brand

23 Melanin, Radiation, and Energy Transduction in Fungi / 509
Arturo Casadevall, Radames J. B. Cordero, Ruth Bryan, Joshua Nosanchuk, and Ekaterina Dadachova

24 Making Time: Conservation of Biological Clocks from Fungi to Animals / 515
Jay C. Dunlap and Jennifer J. Loros

25 Target of Rapamycin (TOR) Regulates Growth in Response to Nutritional Signals / 535
Ronit Weisman

SECTION V

FUNGAL GENETICS AND GENOMICS AS MODELS FOR BIOLOGY / 549

26 Fungal Cell Cycle: A Unicellular versus Multicellular Comparison / 551
Ilkay Dörter and Michelle Momany

27 A Matter of Scale and Dimensions: Chromatin of Chromosome Landmarks in the Fungi / 571
Allyson A. Erlendson, Steven Friedman, and Michael Freitag

28 Ploidy Variation in Fungi: Polyploidy, Aneuploidy, and Genome Evolution / 599
Robert T. Todd, Anja Forche, and Anna Selmecki

29 Fungal Genomes and Insights into the Evolution of the Kingdom / 619
Jason E. Stajich

30 Sources of Fungal Genetic Variation and Associating It with Phenotypic Diversity / 635
John W. Taylor, Sara Branco, Cheng Gao, Chris Hann-Soden, Liliam Montoya, Iman Sylvain, and Pierre Gladieux

31 RNA Interference in Fungi: Retention and Loss / 657
Francisco E. Nicolás and Victoriano Garre

32 **Amyloid Prions in Fungi / 673**
SVEN J. SAUPE, DANIEL F. JAROSZ, AND HEATHER L. TRUE

33 **Repeat-Induced Point Mutation and Other Genome Defense Mechanisms in Fungi / 687**
EUGENE GLADYSHEV

SECTION VI

FUNGAL INTERACTIONS WITH PLANTS: IMPACT ON AGRICULTURE AND THE BIOSPHERE / 701

34 **Plant Pathogenic Fungi / 703**
GUNTHER DOEHLEMANN, BILAL ÖKMEN, WENJUN ZHU, AND AMIR SHARON

35 **The Mutualistic Interaction between Plants and Arbuscular Mycorrhizal Fungi / 727**
LUISA LANFRANCO, PAOLA BONFANTE, AND ANDREA GENRE

36 **Lichenized Fungi and the Evolution of Symbiotic Organization / 749**
MARTIN GRUBE AND MATS WEDIN

37 **Fungal Plant Pathogenesis Mediated by Effectors / 767**
PIERRE J.G.M. DE WIT, ALISON C. TESTA, AND RICHARD P. OLIVER

38 **Emerging Fungal Threats to Plants and Animals Challenge Agriculture and Ecosystem Resilience / 787**
HELEN N. FONES, MATTHEW C. FISHER, AND SARAH J. GURR

SECTION VII

FUNGI AND THE HUMAN HOST / 811

39 **Fungi that Infect Humans / 813**
JULIA R. KÖHLER, BERNHARD HUBE, ROSANA PUCCIA, ARTURO CASADEVALL, AND JOHN R. PERFECT

40 **The Mycobiome: Impact on Health and Disease States / 845**
NAJLA EL-JURDI AND MAHMOUD GHANNOUM

41 **Skin Fungi from Colonization to Infection / 855**
SYBREN DE HOOG, MICHEL MONOD, TOM DAWSON, TEUN BOEKHOUT, PETER MAYSER, AND YVONNE GRÄSER

42 **Fungal Biofilms: Inside Out / 873**
KATHERINE LAGREE AND AARON P. MITCHELL

43 **Fungal Recognition and Host Defense Mechanisms / 887**
I. M. DAMBUZA, S. M. LEVITZ, M. G. NETEA, AND G. D. BROWN

44 **Antifungal Drugs: The Current Armamentarium and Development of New Agents / 903**
NICOLE ROBBINS, GERARD D. WRIGHT, AND LEAH E. COWEN

SECTION VIII

FUNGAL INTERACTIONS WITH ANIMALS (FUNGI, INSECTS, AND NEMATODES) AND OTHER MICROBES / 923

45 **The Insect Pathogens / 925**
BRIAN LOVETT AND RAYMOND J. ST. LEGER

46 **Made for Each Other: Ascomycete Yeasts and Insects / 945**
MEREDITH BLACKWELL

47 **Nematode-Trapping Fungi / 963**
XIANGZHI JIANG, MEICHUN XIANG, AND XINGZHONG LIU

48 **Host-Microsporidia Interactions in *Caenorhabiditis elegans*, a Model Nematode Host / 975**
EMILY R. TROEMEL

49 **Bacterial Endosymbionts: Master Modulators of Fungal Phenotypes / 981**
SARAH J. ARALDI-BRONDOLO, JOSEPH SPRAKER, JUSTIN P. SHAFFER, EMMA H. WOYTENKO, DAVID A. BALTRUS, RACHEL E. GALLERY, AND A. ELIZABETH ARNOLD

50 **Necrotrophic Mycoparasites and Their Genomes / 1005**
MAGNUS KARLSSON, LEA ATANASOVA, DAN FUNCK JENSEN, AND SUSANNE ZEILINGER

SECTION **IX**

FUNGI: TECHNOLOGY AND NATURAL PRODUCTS / 1027

51 Fungal Enzymes and Yeasts for Conversion of Plant Biomass to Bioenergy and High-Value Products / 1029
LENE LANGE

52 Fungal Ligninolytic Enzymes and Their Applications / 1049
MIIA R. MÄKELÄ, ERIN L. BREDEWEG, JON K. MAGNUSON, SCOTT E. BAKER, RONALD P. DE VRIES, AND KRISTIINA HILDÉN

53 Fungi as a Source of Food / 1063
JOËLLE DUPONT, SYLVIE DEQUIN, TATIANA GIRAUD, FRANÇOIS LE TACON, SOUHIR MARSIT, JEANNE ROPARS, FRANCK RICHARD, AND MARC-ANDRÉ SELOSSE

54 Biologically Active Secondary Metabolites from the Fungi / 1087
GERALD F. BILLS AND JAMES B. GLOER

Index / 1121

Contributors

Jesus Aguirre
Departamento de Biología Celular y del Desarrollo, Instituto de Fisiología Celular, Universidad Nacional Autónoma de México, Mexico City, D.F., Mexico

M. Catherine Aime
Department of Botany and Plant Pathology, Purdue University, West Lafayette, Indiana

Mariana Cruz Almeida
MRC Centre for Medical Mycology, University of Aberdeen, School of Medicine, Medical Sciences & Nutrition, Institute of Medical Sciences, Foresterhill, Aberdeen, Aberdeenshire, United Kingdom

Sarah J. Araldi-Brondolo
School of Plant Sciences, University of Arizona, Tucson, Arizona

A. Elizabeth Arnold
School of Plant Sciences and Department of Ecology and Evolutionary Biology, University of Arizona, Tucson, Arizona

Lea Atanasova
Institute of Microbiology, University of Innsbruck, Innsbruck, Austria

Scott E. Baker
Earth and Biological Sciences Directorate, Pacific Northwest National Laboratory, Richland, WA 99352, and Joint BioEnergy Institute, Emeryville, California

Guus Bakkeren
Agriculture and Agri-Food Canada, Summerland Research and Development Centre, Summerland, BC, Canada

David A. Baltrus
School of Plant Sciences, University of Arizona, Tucson, Arizona

Richard J. Bennett
Molecular Microbiology and Immunology, Brown University, 171 Meeting St., Providence, Rhode Island

Gerald F. Bills
Texas Therapeutics Institute, The Brown Foundation Institute of Molecular Medicine, The University of Texas Health Science Center at Houston, 1881 East Road, Houston, Texas

Meredith Blackwell
Department of Biological Sciences, Louisiana State University, Baton Rouge, LA 70803, and Department of Biological Sciences, University of South Carolina, Columbia, South Carolina

Lynne Boddy
Cardiff School of Biosciences, Cardiff University, Cardiff, United Kingdom

Teun Boekhout
Westerdijk Fungal Biodiversity Institute, Utrecht, The Netherlands

Paola Bonfante
Department of Life Sciences and Systems Biology, University of Torino, Torino, Italy

Sara Branco
Département Génétique et Ecologie Evolutives Laboratoire Ecologie, Systématique et Evolution, CNRS-UPS-AgroParisTech, Université de Paris-Sud, Orsay, France, and Dept. of Microbiology and Immunology, Montana State University, Bozeman, Montana

Alexandra C. Brand
MRC Centre for Medical Mycology, University of Aberdeen, School of Medicine, Medical Sciences & Nutrition, Institute of Medical Sciences, Foresterhill, Aberdeen, Aberdeenshire, United Kingdom

Erin L. Bredeweg
Earth and Biological Sciences Directorate, Pacific Northwest National Laboratory, Richland, Washington

Alistair J. P. Brown
Medical Research Council Centre for Medical Mycology at the University of Aberdeen, Aberdeen Fungal Group, University of Aberdeen, Institute of Medical Sciences, Foresterhill, Aberdeen, United Kingdom

Gordon D. Brown
MRC Centre for Medical Mycology, Aberdeen Fungal Group, Institute of Medical Sciences, University of Aberdeen, Aberdeen, United Kingdom

Neil Andrew Brown
Plant Biology and Crop Science, Rothamsted Research, Harpenden, United Kingdom

Ruth Bryan
Departments of Medicine and Microbiology & Immunology, Albert Einstein College of Medicine, Bronx, New York

Arturo Casadevall
Department of Molecular Microbiology and Immunology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD 21205

Marco A. Coelho
UCIBIO-REQUIMTE, Departamento de Ciências da Vida, Faculdade de Ciências e Tecnologia, Universidade NOVA de Lisboa, Caparica, Portugal

Radames J. B. Cordero
Department of Molecular Microbiology and Immunology, Johns Hopkins Bloomberg School of Public Health, Baltimore, Maryland

Luis M. Corrochano
Department of Genetics, University of Seville, Seville, Spain

Leah E. Cowen
Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada

Ekaterina Dadachova
Fedoruk Center for Nuclear Innovation, University of Saskatchewan, Saskatoon, Saskatchewan, Canada

Ivy M. Dambuza
MRC Centre for Medical Mycology, Aberdeen Fungal Group, Institute of Medical Sciences, University of Aberdeen, Aberdeen, United Kingdom

Asen Daskalov
Department of Plant and Microbial Biology, The University of California, Berkeley, California

Tom Dawson
Institute of Medical Biology, Agency for Science, Technology, and Research, Singapore

Sybren de Hoog
Westerdijk Fungal Biodiversity Institute, Utrecht, The Netherlands

Ronald P. De Vries
Dept. of Food and Environmental Sciences, Univ. of Helsinki, Helsinki, Finland, and CBS-KNAW Fungal Biodiversity Center and Fungal Molecular Physiology, Utrecht University, Utrecht, The Netherlands

Pierre J. G. M. de Wit
Laboratory of Phytopathology, Wageningen University, Wageningen, The Netherlands

Sylvie Dequin
SPO, INRA, SupAgro, Université Montpellier, Montpellier, France

Antonio di Pietro
Departamento de Genética, Universidad de Córdoba, Campus de Rabanales, Edificio Gregor Mendel C5, Córdoba, Spain

Gunther Doehlemann
Botanical Institute and Center of Excellence on Plant Sciences (CEPLAS), University of Cologne, BioCenter, Cologne, Germany

Ilkay Dörter
Fungal Biology Group and Plant Biology Department, University of Georgia, Athens, Georgia

Jay C. Dunlap
Department of Molecular and Systems Biology, Geisel School of Medicine at Dartmouth, Hanover, New Hampshire

Joëlle Dupont
Institut de Systématique, Evolution et Biodiversité, ISYEB - UMR 7205 – CNRS, MNHN, UPMC, EPHE, Muséum National d'Histoire Naturelle, Sorbonne Universités, CP39, Paris, France

Paul S. Dyer
School of Life Sciences, University Park, University of Nottingham, Nottingham, United Kingdom

Najla El-Jurdi
Department of Medicine, Division of Hematology-Oncology, University Hospitals Cleveland Medical Center, Case Western Reserve University, Cleveland, Ohio

Allyson A. Erlendson
Department of Biochemistry and Biophysics, Oregon State University, Corvallis, Oregon

Reinhard Fischer
Karlsruhe Institute of Technology (KIT), Institute of Applied Biosciences, Department of Microbiology, Karlsruhe, Germany

Matthew C. Fisher
Department of Infectious Disease Epidemiology, School of Public Health, Imperial College, London, St Mary's Hospital, London, United Kingdom

André Fleißner
Institut für Genetik, Technische Universität Braunschweig, Braunschweig, Germany

Helen N. Fones
Department of Biosciences, University of Exeter, Exeter, United Kingdom

Anja Forche
Bowdoin College, Brunswick, Maine

Michael Freitag
Department of Biochemistry and Biophysics, Oregon State University, Corvallis, Oregon

Department of Forest Mycology and Plant Pathology, Uppsala BioCenter, Swedish University of Agricultural Sciences, Uppsala, Sweden

Enikő Kiss
Synthetic and Systems Biology Unit, Institute of Biochemistry, HAS, Szeged, Hungary

Sandra Kittelmann
AgResearch Ltd., Grasslands Research Centre, Palmerston North, New Zealand

Julia R. Köhler
Division of Infectious Disease, Boston Children's Hospital, Boston, Massachusetts

Gábor M. Kovács
Department of Plant Anatomy, Institute of Biology, Eötvös Loránd University, and Plant Protection Institute, Center for Agricultural Research, Hungarian Academy of Sciences, Budapest, Hungary

Ulrich Kück
Lehrstuhl für Allgemeine und Molekulare Botanik, Ruhr-University Bochum, Bochum, Germany

Katherine Lagree
Department of Biological Sciences, Carnegie Mellon University, Pittsburgh, Pennsylvania

Luisa Lanfranco
Department of Life Sciences and Systems Biology, University of Torino, Torino, Italy

Lene Lange
Technical University of Denmark, Department of Chemical and Biochemical Engineering, Center for Bioprocess Engineering, Kgs. Lyngby, Denmark

Jean-Paul Latge
Unité des Aspergillus, Institut Pasteur, Paris, France

François Le Tacon
INRA, Université de Lorraine, UMR1136 Interactions Arbres-Microorganismes, Laboratoire d'Excellence ARBRE, Champenoux, France

Soo Chan Lee
South Texas Center for Emerging Infectious Diseases (STCEID), Department of Biology, University of Texas at San Antonio, San Antonio, Texas

Guy Leonard
Biosciences, College of Life and Environmental Sciences, University of Exeter, Exeter, United Kingdom

Stuart M. Levitz
Department of Medicine, University of Massachusetts Medical School, Worcester, Massachuseetts

Osu Lilje
School of Life and Environmental Sciences, Faculty of Science, University of Sydney, NSW, Australia

Xingzhong Liu
State Key Laboratory of Mycology, Institute of Microbiology, Chinese Academy of Sciences, Chaoyang District, Beijing, China

Jennifer J. Loros
Department of Molecular and Systems Biology and Department of Biochemistry and Cell Biology, Geisel School of Medicine at Dartmouth, Hanover, New Hampshire

Brian Lovett
Department of Entomology, University of Maryland, College Park, Maryland

Robert Lücking
Botanischer Garten und Botanisches Museum, Freie Universität Berlin, Berlin, Germany

Deborah J. Macarthur
School of Science, Faculty of Health Sciences, Australian Catholic University, NSW, Australia

Jon K. Magnuson
Joint BioEnergy Institute, Emeryville, California, and Energy and Environment Directorate, Pacific Northwest National Laboratory, Richland, Washington

Miia R. Mäkelä
Division of Microbiology and Biotechnology, Department of Food and Environmental Sciences, University of Helsinki, Helsinki, Finland

Souhir Marsit
SPO, INRA, SupAgro, Université Montpellier, Montpellier, France

Francis Martin
INRA, Unité Mixte de Recherche 1136 Interactions Arbres/Microorganismes, Laboratoire d'Excellence Recherches Avancés sur la Biologie de l'Arbre et les Ecosystèmes Forestiers (ARBRE), Centre INRA-Lorraine, Champenoux, France

Peter Mayser
Universitätsklinikum Giessen Hautklinik, Giessen, Germany

Aaron P. Mitchell
Department of Biological Sciences, Carnegie Mellon University, Pittsburgh, Pennsylvania

Michelle Momany
Fungal Biology Group and Plant Biology Department, University of Georgia, Athens, Georgia

Michel Monod
Department of Dermatology, Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland

Liliam Montoya
Department of Plant and Microbial Biology, University of California, Berkeley, California

Carol A. Munro
Aberdeen Fungal Group, Institute of Medical Sciences, University of Aberdeen, Aberdeen, United Kingdom

László G. Nagy
Synthetic and Systems Biology Unit, Institute of Biochemistry, HAS, Szeged, Hungary

Mihai G. Netea
Department of Internal Medicine and Radboud Center for Infectious Diseases (RCI), Radboud University Medical Center, Nijmegen, The Netherlands

Francisco E. Nicolás
Department of Genetics and Microbiology, Faculty of Biology, University of Murcia, Murcia, Spain

Joshua Nosanchuk
Departments of Medicine and Microbiology & Immunology, Albert Einstein College of Medicine, Bronx, New York

Bilal Ökmen
Botanical Institute and Center of Excellence on Plant Sciences (CEPLAS), University of Cologne, BioCenter, Cologne, Germany

Richard P. Oliver
Centre for Crop and Disease Management, Department of Environment and Agriculture, Curtin University, Perth, Western Australia 6102, Australia

Miguel A. Peñalva
Department of Cellular and Molecular Biology, Centro de Investigaciones Biológicas CSIC, Madrid, 28040, Spain

John R. Perfect
Division of Infectious Diseases, Duke University Medical Center, Durham, North Carolina

Anne Pringle
Department of Botany, Department of Bacteriology, University of Wisconsin–Madison, Madison, Wisconsin

Rosana Puccia
Disciplina de Biologia Celular, Departamento de Microbiologia, Imunologia e Parasitologia, Escola Paulista de Medicina-Universidade Federal de São Paulo, São Paulo, Brazil

Janet Quinn
Institute for Cell and Molecular Biosciences, Newcastle University, Newcastle upon Tyne, United Kingdom

Franck Richard
CEFE-CNRS, UMR 5175, Equipe Interactions Biotiques, Montpellier Cedex 5, France

Thomas A. Richards
Biosciences, College of Life and Environmental Sciences, University of Exeter, Exeter, United Kingdom, and Integrated Microbial Biodiversity Program, Canadian Institute for Advanced Research (CIFAR), Toronto, Canada

Meritxell Riquelme
Department of Microbiology, Center for Scientific Research and Higher Education of Ensenada, CICESE, Ensenada, Baja California C.P. 22860, Mexico

Nicole Robbins
Michael G. DeGroote Institute for Infectious Disease Research and the Department of Biochemistry and Biomedical Sciences, McMaster University, Hamilton, Ontario, Canada

Jeanne Ropars
Institut Pasteur, INRA, Unité Biologie et Pathogénicité Fongiques, Paris, France

Julian Rutherford
Institute for Cell and Molecular Biosciences, Medical School, Newcastle University, Newcastle upon Tyne, United Kingdom

Sven J. Saupe
Institut de Biochimie et de Génétique Cellulaire, UMR 5095, CNRS, Université de Bordeaux, Bordeaux, France

Bettina Scholz
Faculty of Natural Resource Sciences, University of Akureyri, Borgir v. Nordurslod, IS 600 Akureyri, and BioPol ehf., Skagaströnd, Iceland

Anna Selmecki
Creighton University, Department of Medical Microbiology and Immunology, Omaha, Nebraska

Marc-Andre Selosse
Dept. of Plant Taxonomy and Nature Conservation, University of Gdansk, 80-308 Gdansk, Poland, and Institut de Systématique, Evolution et Biodiversité, ISYEB - UMR 7205 – CNRS, MNHN, UPMC, EPHE, Paris, France

Justin Park Shaffer
School of Plant Sciences, University of Arizona, Tucson, Arizona

Amir Sharon
Department of Molecular Biology and Ecology of Plants, Tel Aviv University, Tel Aviv, Israel

Jason Slot
Department of Plant Pathology, Ohio State University, Columbus, Ohio

Joseph W. Spatafora
Department of Botany and Plant Pathology, Oregon State University, Corvallis, Oregon

Joseph Spraker
School of Plant Sciences, University of Arizona, Tucson, Arizona

Raymond J. St. Leger
Department of Entomology, University of Maryland, College Park, Maryland

Jason E. Stajich
Department of Plant Pathology & Microbiology and Institute for Integrative Genome Biology, University of California–Riverside, Riverside, California

Gero Steinberg
Department of Biosciences, College of Live and Environmental Sciences, University of Exeter, Exeter EX1 1TE, United Kingdom, and Department of Biology, University of Utrecht, Utrecht, The Netherlands

Sheng Sun
Department of Molecular Genetics and Microbiology, Duke University Medical Center, Durham, North Carolina

Iman Sylvain
Department of Plant and Microbial Biology, University of California, Berkeley, California

John W. Taylor
Department of Plant and Microbial Biology, University of California, Berkeley, California

Aad Termorshuizen
Soil Cares Research, Wageningen, The Netherlands

Alison C. Testa
Centre for Crop and Disease Management, Department of Environment and Agriculture, Curtin University, Perth, Western Australia, Australia

Robert T. Todd
Creighton University, Department of Medical Microbiology and Immunology, Omaha, Nebraska

Renáta Tóth
Department of Microbiology, University of Szeged, Szeged, Hungary

Emily R. Troemel
Division of Biological Sciences, Section of Cell and Developmental Biology, University of California, San Diego, 9500 Gilman Drive, La Jolla, California

Heather True
Department of Cell Biology and Physiology, Washington University School of Medicine, St. Louis, Missouri

B. Gillian Turgeon

Foreword

Studies attempting to estimate fungal biodiversity mainly serve to underscore the limitations of our current awareness of the likely total number of species—currently estimated to be around 5 million. As environmental organisms, fungi influence the global ecology and the recycling of nutrients in the biosphere and also, both positively and negatively, the viability of many plants and animals. As simple eukaryotes that can be facilely studied and experimentally manipulated, fungi serve as important models that have profoundly influenced our understanding of life by enabling the identification and analysis of conserved mechanisms underpinning the growth, cell division, and death of all eukaryotic cells.

Fungal research is a vibrant and exciting area, but it is often dispersed among distinct scientific communities with different cultures and traditions. The objective of bringing together this broad research portfolio into a book and collection of contemporary reviews is therefore a useful, important, but challenging objective. This ASM-sponsored volume is unusual in uniting a community of mycologists and cell biologists with the common objective of illustrating the state of our understanding of both model fungi and organisms with specific environmental, pathogenic, or biological relevance. The book includes chapters where the focus is at the molecular, cellular, or organismal levels of spatial organization and includes fungi from all the major phylogenetic groupings. The result is an anthology of articles that defines the current trajectory of current research and questions for the next generation of investigators. The authors are leaders in their respective fields, and the editorial style is such that the work has achieved an overview of the field as a whole in a form that is useful both for the specialist and for those seeking understanding in areas in which they may be unfamiliar.

Some of the most profoundly important questions in biology have been explored using fungi, yeasts, and molds—and it is likely that this paradigm will continue into the future. This book should serve to stimulate a new generation of mycologically inclined scientists to investigate the extraordinary diversity and experimental accessibility of members of the mycobiota.

Sir Paul Nurse
The Francis Crick Institute,
London, United Kingdom

Preface

Our fascination with the Fungal Kingdom is a natural and ancient one and based on (i) the roles of fungi in the production of a variety of foods and beverages, and even as a source of food themselves; (ii) their global ecological impact, especially as the cause of devastating infections of humans and other animals and of plants, including many crops grown around the world; and (iii) their roles as fundamental model systems in genetics and biological research.

The earliest fascination with fungi likely began with humans across the globe foraging for food sources, often in the context of forests, and the prominent role of mushroom fruiting bodies associated with trees, either as mycorrhizal species on roots of living trees or as wood-degrading fungi on dead plant materials. These mushroom species include popular and delicious edible ones such as porcini, chanterelles, and truffles as well as shiitake, oyster, portobello, and more. In aggregate, the global commercial mushroom market was ~$35 billion US in 2015 and is anticipated to grow to as much as ~$60 billion by 2021. The species named are representatives of just one phylum (the Basidiomycota) within the broader Fungal Kingdom, which is now estimated to include as many as 2.2 to 3.8 million or more distinct species and at least seven phyla (Ascomycota, Basidiomycota, Mucoromycota, Zoopagomycota, Blastocladiomycota, Chytridiomycota, and the Cryptomycota/Rozellomycota).

Interest in fungi also derives from their key roles in the production of other foods and beverages, including the prominent role of the yeast *Saccharomyces cerevisiae* (Ascomycota) in production of beer, wine, Champagne, and bread. Yet other fungi such as *Penicillium chrysogenum* produce natural products like the antibiotic penicillin, which revolutionized medicine and health care and contributed to dramatically prolong the human lifespan by enabling effective treatment of infectious diseases. Finally, pathogenic fungi cause (i) devastating, life-threatening systemic infections of humans and also other diseases including allergies, blindness, vaginitis, and common skin infections including dandruff and athlete's foot; (ii) widespread infections of animals including the ones that are devastating bat populations in North America and causing extinctions in frog species around the world; and (iii) the majority of infections that occur in plants, including many crop species, which lead to famines and disruptions of food supply with billions of dollars lost in agriculture annually. Whatever your vantage point, the impact of fungi on the biology of our planet, the development of human civilization, and our daily lives and health is writ large.

A few decades ago the position of the Fungal Kingdom within the broader eukaryotic tree of life was unclear, and in many instances it was thought and even taught that the fungi were more closely related to plants than to animals. The overt morphological features of mushrooms likely contributed to this view, along with uncertainty about where to place unicellular microbes within the context of complex multicellular organisms such as animals. But with the advent of molecular phylogenetic studies, the placement of fungi within the eukaryotic tree of life came into sharper focus, and we now appreciate that fungi are much more closely related to animals than they are to plants. This evolutionary kinship is in fact so certain that the Animal Kingdom and the Fungal Kingdom are now appreciated to be sister groups within the broader Opisthokonta supergroup of eukaryotes. This revised phylogenetic placement reveals much about the con-

servation of molecular mechanisms of life and contributes to making fungi exceptional models to understand the form and function of other eukaryotes, including the Animal Kingdom.

In concert with these advances in molecular phylogenetics and taxonomy, two other fields have revolutionized our understanding of the Fungal Kingdom. First, advances in genetics of fungi have contributed to illuminate their unique and conserved biological properties. Studies on fungi have contributed profound insights as models for all of biology, such as the discovery of RNA interference (RNAi) pathways and how they operate to silence transgenes and protect genome integrity; the detailed mechanisms and operation of a biological clock and the key concept that this involves a molecular oscillator; the first experimental demonstration of DNA sequences that can function as telomeres, centromeres, and eukaryotic origins of replication; the discovery of the first components of the nuclear pore; the description of the secretory pathway and discovery of autophagy; the elucidation of how the cell cycle is orchestrated; the understanding of the impact of both ploidy and aneuploidy on cell functions; insights into how species evolve and species boundaries operate; and the discovery that the mismatch repair system is required for the stability of DNA repeats, leading to insights into how similar mutations lead to colon cancer in humans. Taken together, genetic, genomic, and cell biological studies have brought representatives of the entire Fungal Kingdom of life into focus and thereby made an invaluable contribution to our understanding of how eukaryotic organisms evolved and function. Indeed, seven Nobel prizes have been awarded to scientists studying yeasts and molds as model organisms that explain fundamental aspects of cell biology. These were awarded to Alexander Fleming, Ernst Chain, and Howard Florey in 1945 for the discovery of penicillin by *Penicillium notatum*; to George Beadle and Edward Tatum in 1958 for their One Gene = One Enzyme hypothesis in *Neurospora crassa*; to Paul Nurse and Leland Hartwell in 2001 for cell division and cancer in *Schizosaccharomyces pombe* and *Saccharomyces cerevisiae*; to Roger Kornberg in 2006 for eukaryotic gene transcription in *S. cerevisiae*; to Jack W. Szostak (shared) in 2009 for chromosome telomeres in *S. cerevisiae*; to Randy Schekman in 2013 (shared) for machinery regulating vesicle traffic in *S. cerevisiae*; and to Yoshinori Ohsumi in 2016 for autophagy in S. cerevisiae.

In concert with advances in genetics, subsequent advances in genome sciences have provided the complete genome sequences for an increasing number of fungal species, now >1,000, and in some species a staggering number of individual representative genomes (500 or more). In fact, a fungal species was the first eukaryotic organism to have its genome completely sequenced (the model budding yeast S. cerevisiae). Second, advances in genetics and cell biology have contributed to provide a detailed view of how the genome contributes to the functions of the cell and of the organism. Together, these advances in genomics and genetics provide a "blueprint" for how these species operate and have evolved at a cellular level, and consequently they offer a wealth of knowledge about how representative species in the fungal kingdom function and the diversity that lies within. This diversity spans from the most basic way that a fungal cell is organized, either as a yeast or as a filamentous hypha, to the myriad ways these species interact with their environment, from the aquatic basal fungi (Chytridiomycota, Cryptomycota), to fungi that are associated with plants and were critical for their emergence from the oceans and colonization of the planet, to fungi that are pathogens of plants or animals. This diversity also extends to the biological behavior and cell biology of fungi, including for example fungi that can sense light and those that have evolved to be insensitive to light (blind), the modes of sexual reproduction including heterothallism and homothallism, the loss and retention of RNAi pathways, the replacement of regional centromeres by point centromeres, and the retention of flagella in basal fungi versus their loss in fungal branches that evolved the ability to be aerially dispersed.

Given the rapidly advancing fields of fungal genetics and genomics, and mycology more generally, we increasingly found ourselves in need of a compendium to organize this information and to serve as a reference to guide both our own efforts and those of others whose research focuses on or interfaces with fungi. We have assembled a team of six editors with complementary and diverse interests and enlisted a cadre of 170 experts in the field who as authors have contributed the 54 chapters that comprise *The Fungal Kingdom*. We have organized the book into nine different sections to present related material together and provide a framework for organization. Each chapter is designed to be self-contained, such that any reader may choose to read any given chapter in isolation or a series of related chapters from one section. At the same time, the book has a coherent theme of focusing on the diversity, importance, impact, dangers, and beauty of the fungi and could therefore be read as a continuous text. As modes of publication have advanced, this book is also an experiment in that it is available as a hard copy printed volume, as an electronic book, and as individual chapters available electronically or in their published form as part of the *Microbiology Spectrum* journal from ASM Press.

It is our hope, and our goal and intention, that this book both takes stock of the current state of knowledge in the field and also spurs further investigations into topics of interest that stem from the information contained herein. We invite you to peruse the current state of knowledge here and hope these musings spur you to join us in further advancing the field. We also invite you to communicate to us your experiences with the book. It is our fervent hope that advances over the next several decades will ultimately render this book out of date, and therefore in need of revision or replacement, as the field advances.

In closing, we would like to thank the numerous individuals who have contributed to advance our understanding of the Fungal Kingdom and, by extension, to the stimulation and realization of this text. We wish to dedicate this effort to the scientific mentors who trained and inspired us, and also to our significant others, children, and families, without whose forbearance and tolerance this effort would not have been possible. Finally, we thank our tireless ASM editors, Greg Payne, Lauren Luethy, and Ellie Tupper, who with administrative assistance from Melissa Palmer made this text possible through their indefatigable and enthusiastic efforts.

Joseph Heitman, M.D., Ph.D., is James B. Duke Professor and Chair, Department of Molecular Genetics and Microbiology, Duke University. His research focuses on model and pathogenic fungi, including mating-type locus evolution, transitions in sexual reproduction modes, fungal virulence, and genome evolution. His work discovered FKBP12 and TOR as the targets of rapamycin and unisexual reproduction. He is fellow of the American Society for Clinical Investigation, American Academy of Microbiology, AAAS, and Association of American Physicians and received Burroughs Wellcome, AMGEN, Squibb, and NIH MERIT awards. He is an editor or board member for numerous journals and has edited seven textbooks.

Barbara Howlett, Ph.D., is an Honorary Professor in the School of BioSciences, the University of Melbourne. She studies blackleg, a fungal disease of canola. She has exploited a "genome to paddock" approach: identifying fungal genes and genetic mechanisms crucial for disease, and developing disease management strategies that are now implemented by Australian canola growers. She also has discovered biosynthetic pathways for fungal toxins involved in diseases of both plants and animals. Howlett is a Fellow of the American Academy of Microbiology, the Australian Academy of Science, and the Australasian Plant Pathology Society and an Honorary Member of the American Mycological Society.

Pedro W. Crous, Ph.D., D.Sc., is professor in evolutionary phytopathology at the Universities Wageningen and Utrecht, the Netherlands, where he is presently the Director of the Westerdijk Fungal Biodiversity Institute. His main research interests are fungal systematics and the characterization of fungal plant pathogens. To coordinate global research on fungal biodiversity, he launched MycoBank, is the author of several thousand fungal taxa, and is a key role player in DNA barcoding of fungi. He is an editor or board member for numerous journals and has authored or edited several textbooks.

Eva H. Stukenbrock, Ph.D., is a Max Planck professor at the Christian-Albrechts University of Kiel and the Max Planck Institute for Evolutionary Biology, Plön, Germany. Her research focuses on population biology and evolution of plant-associated fungi. Work in her group integrates evolutionary genomics with experimental and molecular approaches. She received her Ph.D. from the ETH Zurich, Switzerland, and established her independent line of research at Aarhus University, Denmark. Since 2010 she has been affiliated with the Max Planck Society in Germany, first as a research group leader and since 2014 as Max Planck fellow.

Timothy Yong James, Ph.D., is an Associate Professor in the Department of Ecology and Evolutionary Biology at the University of Michigan and the Lewis E. Wehmeyer and Elaine Prince Wehmeyer Chair in Fungal Taxonomy. His research interests include resolving the fungal tree of life and the structure of genetic variation within genomes, individuals, and populations. His research organisms span the fungal tree, with emphasis on the zoosporic fungi or chytrids. He is an Associate Editor of the journal *Mycologia* and recipient of the Alexopoulos Prize from the Mycological Society of America.

Professor Neil A. R. Gow, Ph.D., has research interests in medical mycology and in particular the structure and function of the fungal cell wall in relation to host-pathogen interactions. He is a founding member of the Aberdeen Fungal Group (AFG), which was established as the MRC Centre for Medical Mycology at the University of Aberdeen, United Kingdom. He has served as president of the British Mycological Society, the International Society for Human and Animal Mycology, and the Microbiology Society and has been elected as a FAAM, FRS, FRSE, and FMedSci.

Fungal Branches on the Eukaryotic Tree of Life

The Fungal Tree of Life: From Molecular Systematics to Genome-Scale Phylogenies

1

Joseph W. Spatafora,[1] M. Catherine Aime,[2] Igor V. Grigoriev,[3] Francis Martin,[4] Jason E. Stajich,[5] and Meredith Blackwell[6]

INTRODUCTION

In 1996 the genome of *Saccharomyces cerevisiae* was published and marked the beginning of a new era in fungal biology (1). Since then, rapid advancements in both sequencing technologies and computational biology have resulted in the sequencing of genomes for more than 800 species (e.g., http://genome.jgi.doe.gov/fungi/). These genomes represent a windfall of data that are informing evolutionary studies of fungi and the search for biological solutions to alternative fuels, bioremediation, carbon sequestration, and sustainable agriculture and forestry (2). Indeed, the marriage between genomics and phylogenetics occurred early, both in the use of phylogenetic techniques to study genome evolution and in the use of genome-scale data to infer evolutionary relationships. In this article we will review the impact of genomic-scale phylogenies, along with standard molecular phylogenies, on our understanding of the evolution of the fungal tree of life and the classification that communicates it.

Genomic data provide the maximum amount of discrete genetic information available for phylogenetic analyses, and hundreds to thousands of genes have been identified as useful phylogenetic markers (3). Markov clustering algorithms have been proven powerful tools to identify orthologous clusters of proteins that can be filtered for single-copy clusters that are useful in phylogenetic analyses (4). This approach has transformed phylogenetics by no longer requiring selection of an *a priori* set of markers (e.g., rDNA, RPB2, etc.), but rather promotes the mining of a data set of genomes for the largest set of appropriate markers. Furthermore, hidden Markov models have proven to be valuable tools for identifying and retrieving these markers in newly sequenced genomes and rapidly growing genome-scale phylogenetic data sets (5).

The estimation of species trees from genome-scale data sets is not without challenges, however. Phylogenetic analyses of genomic data have revealed that different genes within a genome can have different evolutionary histories, i.e., phylogenetic conflict (6). Sources of conflict include incomplete lineage sorting (or deep coalescence), hybridization, and horizontal gene transfer, and the detection and characterization of this conflict in the context of phylogenetic inference are still in their infancy (7). The application of standard measures of topological support, such as the bootstrap partition, can also be difficult to interpret, due to the observation that nodes that resolve differently in different gene data sets can have high or maximum bootstrap partition values in a subset of analyses (e.g., 8, 9). At the time of the writing of this manuscript the majority of genome-scale phylogenetic analyses focus on the analysis of concatenated superalignments, but development and use of supertree methods, gene tree-species tree reconciliations, and alternative measures of nodal sup-

port are increasing (e.g., 8, 10) and will be developed further over the coming years.

Despite the challenges mentioned above, phylogenetic analyses of genome-scale data sets, and more traditional multigene data sets, have greatly advanced our understanding of fungal evolution. Historically, the fungi were divided into more or less four groups—chytridiomycetes, zygomycetes, ascomycetes, and basidiomycetes—defined by morphological traits associated with reproduction. (Note: The suffix "-mycetes" is used to denote a class-level taxonomic group in fungal nomenclature, e.g., Agaricomycetes. Its use as a lowercase noun, however, signifies an informal name and not an explicit taxonomic rank.) The chytridiomycetes, or zoosporic fungi, were recognized based on their production of zoospores, characterized by a single posterior, smooth flagellum. The zygomycetes were characterized by gametangial conjugation and the production of zygospores, coenocytic hyphae, and typically asexual reproduction by sporangia. The ascomycetes and basidiomycetes were identified by the production of asci and basidia, respectively, possession of regularly septate hyphae, and a dikaryotic nuclear phase in their life cycle. The classification of the kingdom Fungi used here recognizes eight phyla (Fig. 1, Table 1), with the zoosporic fungi comprising the first three lineages of the kingdom—Cryptomycota/Microsporidia, Chytridiomycota, and Blastocladiomycota—since the divergence from the last universal common ancestor (LUCA) of Fungi.

The resolution of zoosporic fungi as paraphyletic rejects the flagellum as a diagnostic trait (synapomorphy) for a monophyletic group of flagellated fungi. Rather, it is an ancestral (symplesiomorphic) trait inherited from the LUCA of the kingdom Fungi. Most extant species of fungi are nonflagellated and are the result of multiple losses of the flagellum during fungal evolution. Two losses of the flagellum have occurred, giving rise to the Microsporidia and the most recent common ancestor (MRCA) of the remaining phyla of zygomycetes, ascomycetes, and basidiomycetes. Inferences of additional losses of the flagellum are required for the placement of nonflagellated species among the Chytridiomycota (11) and possibly for the placement of the enigmatic zoosporic genus *Olpidium* among zygomycetes (12), but the absolute number of losses is unclear. The zygomycetes are also paraphyletic and are classified in two phyla: Zoopagomycota and Mucoromycota (13). This classification rejects the zygospore as a synapomorphy for the zygomycetes; rather, it was inherited from the MRCA of terrestrial fungi and lost in the MRCA of ascomycetes and basidiomycetes. The monophyly of ascomycetes and basidiomycetes has been confirmed, and they are classified as the phyla Ascomycota and Basidiomycota, respectively, of the subkingdom Dikarya (14). More information on character evolution will be highlighted throughout this article.

One of the greatest challenges in evolutionary biology of fungi is accurately estimating geologic dates of the origin of the kingdom Fungi, emergence of the major phyla, and diversification of extant lineages (15). Our knowledge of the fossil record of fungi is less than that of plants and animals, but there does exist an increasing number of fossils that can be assigned to major groups of fungi based on their morphological similarity to extant taxa (16). An important observation is that morphologies associated with Blastocladiomycota, Chytridiomycota, Mucoromycota, and Ascomycota are present in the early Devonian and are associated with the earliest known land plant flora of the Rhynie chert. This observation, in combination with relaxed molecular clock analyses (e.g., 17, 18), suggests that the common ancestors of the phyla of Fungi are in fact old and may have been among the first terrestrial organisms. The interpretation of fungus-like fossils can be challenging, however, as it is difficult to interpret some morphologies that are not present among extant lineages as definitive representatives of the kingdom Fungi (19).

In this article we will highlight the major phyla of fungi based on the current understanding of the fungal tree of life. In doing so, we will outline their phylogenetic diversity and classification, provide examples of important taxa for each group, and discuss advancements in our understanding of morphological and ecological evolution through the analysis of genomic and molecular data. There are many specialized terms used in this article, and we are unable to fully define all of them here. However, Fig. 2 to 5 provide examples of taxa and morphologies discussed herein, but the reader is directed to more traditional textbooks in mycology for more detailed discussions.

ZOOSPORIC FUNGI (Fig. 2)

Before we consider zoosporic fungi, a brief discussion of some unique aspects of their development and morphology is necessary. The morphology of zoosporic fungi varies depending on the extent of their thallus development, number and position of reproductive structures, and position in the substrate. Thalli may exist as single cells with sparse rhizoidal systems to more extensive networks of rhizoids (rhizomycelia) and mycelial thalli. Endobiotic chytrids are partially or completely

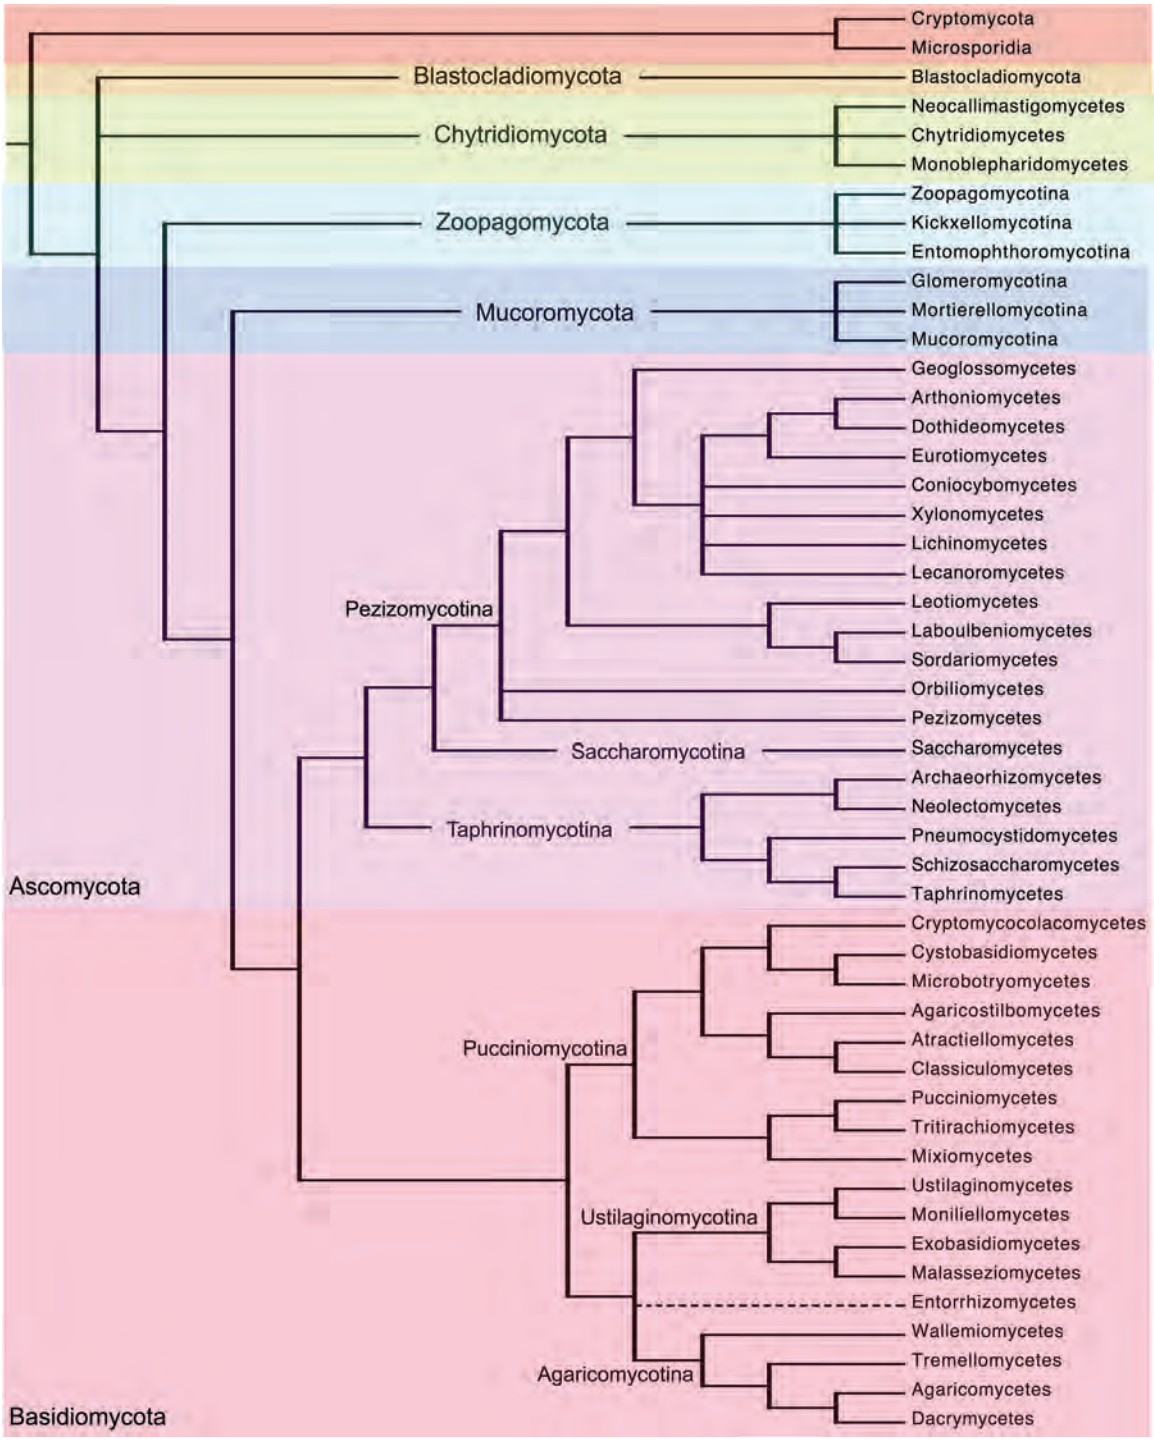

Figure 1 Fungal tree of life. Cladogram of the kingdom Fungi based on published multi-gene and genome-scale phylogenies (11–14, 17, 18, 32, 33, 83, 98, 109, 112, 167, 168). Polytomies represent regions of the tree currently unresolved by molecular and genomic data.

  Incertae sedis
    Entorrhizomycetes Begerow, Stoll & R. Bauer (2007)

immersed in their substrate, while only the rhizoids of epibiotic chytrids are immersed. Often, the thalli of single-celled chytrids are converted entirely to thin-walled zoosporangia or thick-walled resting sporangia (holocarpic condition), and others have thalli that are only partially converted to reproductive structures (eucarpic condition). Other terms describe the number of reproductive structures produced by an individual: a single sporangium on a thallus is a monocentric thallus, and multiple sporangia on a rhizomycelium or mycelium are termed polycentric. Zoosporangia, in which zoospores are produced, are asexual reproductive structures; resting sporangia that germinate by release of flagellated cells and resting spores that germinate by germ tubes may be asexual or sexual structures.

Cryptomycota/Microsporidia

Cryptomycota plus Microsporidia are sister to the remaining lineages of Kingdom Fungi. (Note: Rozellomycota [20] is another name for Cryptomycota [21] based on the genus *Rozella* and the principle of autotypification [14]. *Cryptomyces* is a genus in Ascomycota and cannot be used to typify Cryptomycota.) Cryptomycota consists of a handful of described taxa and taxa that are known only from environmental samples. One described taxon is *Rozella* (Fig. 2a), a biotrophic intracellular parasite of other zoosporic fungi

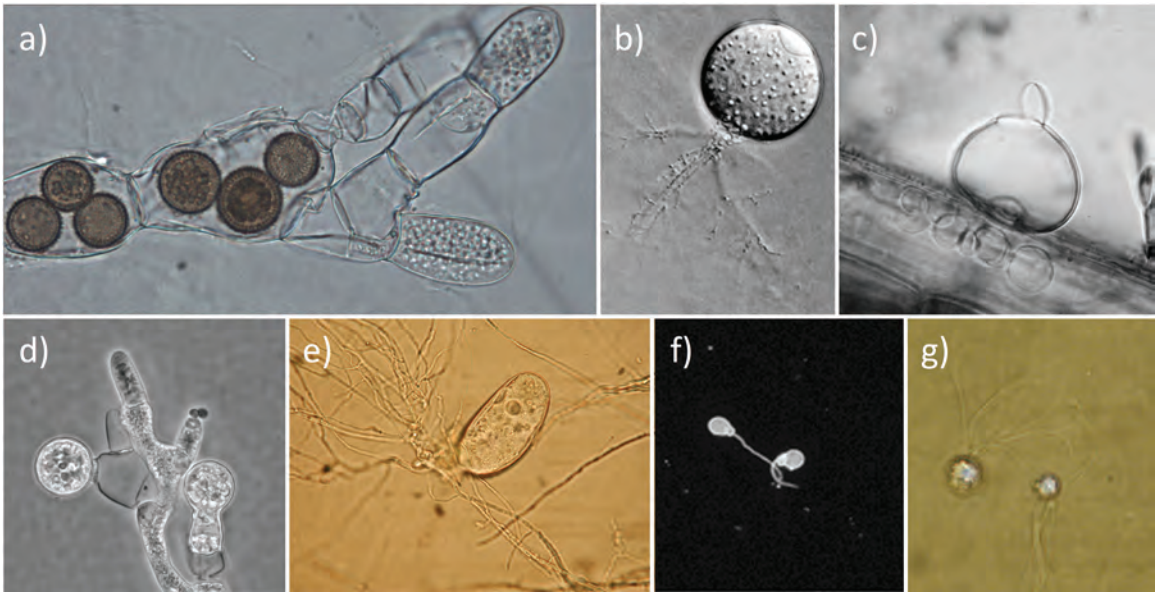

Figure 2 Examples of zoosporic fungal diversity. (**a**) *Rozella allomycis* (Cryptomycota) parasitizing hyphae of *Allomyces* (Blastocladiomycota). Chytridiomycota: (**b**) *C. hyalinus* (Chytridiomycetes) monocentric, operculate zoosporangium with rhizoids; (**c**) *Catenochytridium* sp. of Chytridiomycota and Blastocladiomycota and oomycetes of the kingdom Stramenopila (22). There are few additional described genera and species of Cryptomycota, but environmental sampling using molecular markers has revealed a phylogenetically diverse assemblage of fungi detected in soils, marine and freshwater sediments, and oxygen-depleted environments (23, 24). Some environmental Cryptomycota produce zoospores with a single, smooth flagellum, but chitin, a cell wall carbohydrate produced by most fungi, was not originally detected in the life history stages first observed (25). A more recent study detected chitin restricted to the cyst phase that attaches to the *Allomyces* hyphae and in the inner wall of the resting sporangia (26). The ecology of the environmental Cryptomycota is largely conjecture at this time, because they have not been cultured, an observation frequently invoked in fungal systems to infer an obligate biotroph. Recently, molecular data have determined that *Paramicrosporidium* (20), nonflagellated parasites of amoebae, and *Amoeboaphelidium*, an algal parasite, are members of Cryptomycota (27), lending support to parasitism as an ecological signature of the phylum.

Microsporidia are intracellular parasites of all major groups of animals. They are particularly well known from insects, crustaceans, and fish but are also known to occur in mammals, including humans (28). Microsporidia produce unique spores that infect host cells through a harpoon-like organelle that pierces the host cell membrane and provides a conduit for the injection of the parasite's cytoplasm (29). Once inside the host cell, a spore, which includes an inner chitin-containing wall, is ultimately formed. The phylogenetic affinity of Microsporidia has been difficult to determine, with past classifications placing it among the polyphyletic protists, and early multigene phylogenies placing it in different parts of the kingdom Fungi (reviewed in reference 30). Genome-scale phylogenies have also proven problematic due to highly reduced genomes and fast rates of nucleotide substitution (31), but multiple analyses have garnered increasing support for its close relationship to Cryptomycota (32, 33). Comparative genomic analyses have demonstrated that both groups share genomic traits including a nucleotide transporter that Microsporidia use for obtaining ATP from their hosts (33). This phylogenetic placement of Microspo-

ridia provides further evidence for the early origins of parasitism and more than one loss of the flagellum within the kingdom Fungi.

Blastocladiomycota

The remaining two phyla of zoosporic fungi are Blastocladiomycota and Chytridiomycota. The branching order of these two lineages is unresolved (Fig. 1), and both have been inferred as the sister lineage to the terrestrial, nonflagellated fungi in large multigene and genome-scale phylogenetic analyses (11, 13, 18). The failure to resolve this branching order appears to be attributed to low phylogenetic signal, rather than strong conflict among competing individual gene trees (18), although only two species of Blastocladiales have been sequenced at this time. Resolution of this branching is central to accurately understanding the changes in life cycles and morphology, especially the loss of flagellum that accompanied the transition onto land. Additional taxon sampling and analysis of changes associated with genome content (e.g., phylogenetic mapping of gene birth events, rare genomic changes, etc.) will be required.

Blastocladiomycota contains a single class and order, Blastocladiomycetes and Blastocladiales, respectively. Fossils of both sporothalli and gametothalli have been described from the Lower Devonian (Rhynie chert) as *Paleoblastocladia* (34), supporting it as an ancient lineage, but current molecular data are consistent with extant species sharing a recent MRCA as compared to other phyla of fungi. Blastocladiomycota exhibit a range of growth morphologies from monocentric with limited thallus development to polycentric with the production of robust, coenocytic hyphae. Furthermore, most known species exhibit a true alternation of generation with free-living haploid and diploid life stages. In *Allomyces*, for example, free-living haploid thalli produce male and female gametangia that can usually be differentiated through color and size; the male gametangia are typically pigmented with carotenoids and are smaller in size than female gametangia. Both male and female gametangia produce motile gametes (planogametes) that fuse to form a diploid zygote, which germinates to form a free-living diploid thallus. This thallus produces sporangia that yield diploid zoospores that are released into the environment and germinate to form other diploid thalli. The diploid thallus ultimately matures and produces resistant sporangia that are the sites of meiosis and production of haploid zoospores, which when released into the environment germinate into haploid thalli, completing the life cycle. Meiosis associated with spore formation (sporic) is unknown in any other fungi.

Well-studied genera within Blastocladiales include *Allomyces*, *Blastocladiella*, *Coelomomyces*, and *Physoderma*, which exhibit saprobic and parasitic ecologies associated with animals and plants. *Allomyces* is frequently isolated from soil and serves as an excellent instructional model of polycentric development (mycelial development with multiple sporangia) and alternation of generations. Its ease of growth on synthetic media with simple sugar sources is consistent with a saprobic life history. *Blastocladiella* is another saprobic species isolated from soil, but it displays monocentric development, with a simple thallus consisting of a single sporangium anchored to its substrate by rhizoidal elements. *Coelomomyces* is a parasite of mosquitoes and copepods, with alternate generations produced in different hosts. Haploid zoospores infect copepods and produce one- to two-celled wall-less hyphal bodies within the host. These hyphal bodies give rise to flagellated gametes that fuse inside or outside of the copepod host, resulting in a diploid flagellated zygote that infects mosquito larvae. Inside the mosquito, the fungus develops a limited diploid thallus that produces resting sporangia, which are the site of meiosis and production of haploid zoospores. *Physoderma* includes stem and foliar pathogens of plants (e.g., corn, alfalfa, etc.), which is relatively rare for zoosporic species of the kingdom Fungi. Species of *Physoderma* produce monocentric epibiotic sporangia that infect a single host cell, but as the infection progresses, polycentric growth develops, producing large endobiotic sporangia that occupy much of the host cell.

Chytridiomycota

Chytridiomycota includes three classes of fungi: Chytridiomycetes, Monoblepharidomycetes, and Neocallimastigomycetes. Although some classifications recognize the latter two classes as phyla (e.g., 14), the three taxa collectively form a well-supported monophyletic clade in genome-scale analyses, but their relationship to each other is uncertain (18). Chytridiomycota may have been the earliest fungi in terrestrial environments, but it is not clear if certain Precambrian microfossils actually represent species of the phylum. Spherules and flask-shaped fossils from chert lenses of the Early Devonian Rhynie chert formation have been interpreted as thalli and zoosporangia of Chytridiomycota. The study of plants and plant parts, including pollen, has been a productive means of discovering and identifying increasing numbers of Chytridiomycota fossils and the presumptive reactions of their hosts 412 million years ago (16).

Chytridiomycetes

Chytridiomycetes are water-inhabiting fungi, often parasitic on algae and oomycetes, or soil inhabitants, some of which are parasitic on vascular plants. A few chytrids parasitize animal eggs and protozoa, while others are saprobic on the decaying remains of plants. Multigene phylogenetic analyses, new culture techniques, and additional collections of Chytridiomycetes have revealed greater diversity and led to increased numbers of orders in which to classify about 700 species in under 90 genera (e.g., 11, 14). Today there are 10 described orders of Chytridiomycetes: Chytridiales, Spizellomycetales, Cladochytriales, Rhizophydiales, Polychytriales, Rhizophlyctidales, Lobulomycetales, Synchytriales, Gromochytriales, and Mesochytriales (e.g., 35–39).

An exemplar life cycle is that of *Chytriomyces hyalinus*, which forms a well-developed rhizoidal system within its substrate (Fig. 2b). The sporangium that develops from the encysted zoospore has a saucer-shaped operculum from which zoospores escape into a fibrous vesicle of overlapping filaments where the cells complete their maturation and then escape (40). The zoospores encyst and germinate to form new sporangia and rhizoids (asexual thalli) or to function as sexual thalli. This is one of the few members of the Chytridiomycetes in which sexual reproduction has been well documented. The rhizoids of the two thalli come into contact and fuse, and a resting spore forms at the junction of the rhizoidal anastomosis. The resting sporangium develops a thick wall and eventually germinates by production of zoospores, apparently after meiosis (41). Other well-studied members of Chytridiomycetes include *Synchytrium endobioticum*, a pathogen that causes potato wart disease, and *Nowakowskiella*, an operculate, polycentric genus of aquatic saprobes of decaying plant materials. Species of *Nowakowskiella* are often isolated from pond water by using cellulosic baits. The most widely studied chytrid is *Batrachochytrium dendrobatidis*, the fungus associated with amphibian declines (42, 43). The disease was first detected in Australia and Panama, but it now has been found on all continents except Antarctica. Estimates predict that 30% of the world's amphibian species will be affected by severe population decline or extinction (44–47). Zoospores attack the keratinized parts of the amphibian, such as larval mouthparts and the first two layers of adult skin, to cause the infection. The flagella are resorbed, and the *B. dendrobatidis* cells enlarge within the infected host cells. Growth of the somatic cells and their conversion to zoosporangia cause the hyperplasia and hyperkeratosis that are symptomatic of the disease. Severe infections reduce the efficiency of cutaneous respiration and osmoregulation. Evolutionary analyses of the *B. dendrobatidis* genome revealed that it has evolved from saprobic ancestors and that its unique ecology of being a vertebrate pathogen is correlated with lineage-specific expansion of multiple gene families of proteases (48).

Monoblepharidomycetes

Monoblepharidomycetes consists of only about 30 species in 6 genera, most of which are saprobes that grow in fresh water on submerged twigs and fruits. The fungi can be isolated by baiting soil samples in water with hemp or sesame seeds. Genera are distinguished in part by a polycentric mycelial thallus (*Gonapodya*, *Monoblepharella*, and *Monoblepharis*) or a uniaxial thallus (*Oedogoniomyces*, *Harpochytrium*, and *Hyaloraphidium*). When hyphae are present in Monoblepharidales, they appear foamy or reticulate because the protoplasm is highly vacuolated. Monoblepharidales is of special interest because of its unique method of sexual reproduction using a nonmotile female gametangium and a flagellated male gamete, unlike any other fungus.

Monoblepharis polymorpha has a well-developed branched thallus consisting of hyphae with a foamy appearance. Elongated zoosporangia are borne singly at the hyphal tips subtended by a septum. Zoospores are released from the tip of the sporangium, swim for a time, become rounded, and germinate by a germ tube to form a new mycelium. The same thallus that bears sporangia also produces gametangia when subjected to higher temperatures. The elongated male gametangium is borne on the large, rounded egg-like female gametangium (Fig. 2d). Uniflagellate gametes formed within the male gametangium mature and are released. A single male gamete fertilizes the enlarged female gamete, resulting in cytoplasmic fusion and production of a diploid zygote. The zygote functions as a resting spore and germinates by producing a hypha to initiate a new thallus. The site of meiosis has not been demonstrated but probably occurs in early divisions of the zygote nucleus (49, 50).

Neocallimastigomycetes

The zoospores of members of Neocallimastigomycetes were once considered to be flagellated protozoa, but DNA sequences placed them in a distinct group of the core chytrids (11). The class consists of about 20 species placed in 6 genera, including *Neocallimastix*, *Orpinomyces*, and *Piromyces* (Fig. 2e). All species inhabit anaerobic regions of the rumen and hindgut of

herbivores, and they produce cellulases and xylanases that help to degrade the dietary fibers from plant cell walls (51, 52). Phylogenomic analyses revealed that many of these plant cell wall-degrading enzymes are of bacterial origin and represent a horizontal gene transfer from bacteria that presumably co-occur with Neocallimastigales in the herbivore digestive tract (53). All species are obligate anaerobes, and although a few other fungi (e.g., *Blastocladia* and certain yeasts in Saccharomycetales) are facultatively anaerobic, among fungi only members of Neocallimastigales require completely anaerobic environments. As a group, these fungi grow on a range of simple and complex carbohydrates and exhibit mixed acid fermentation (54), and renewed attention is aimed at their potential in applied industrial mycology (55).

ZYGOMYCETE FUNGI (Fig. 3)

As mentioned previously, genome-scale phylogenies do not support the monophyly of zygomycetes and reject the zygospore as a synapomorphy for them (13).

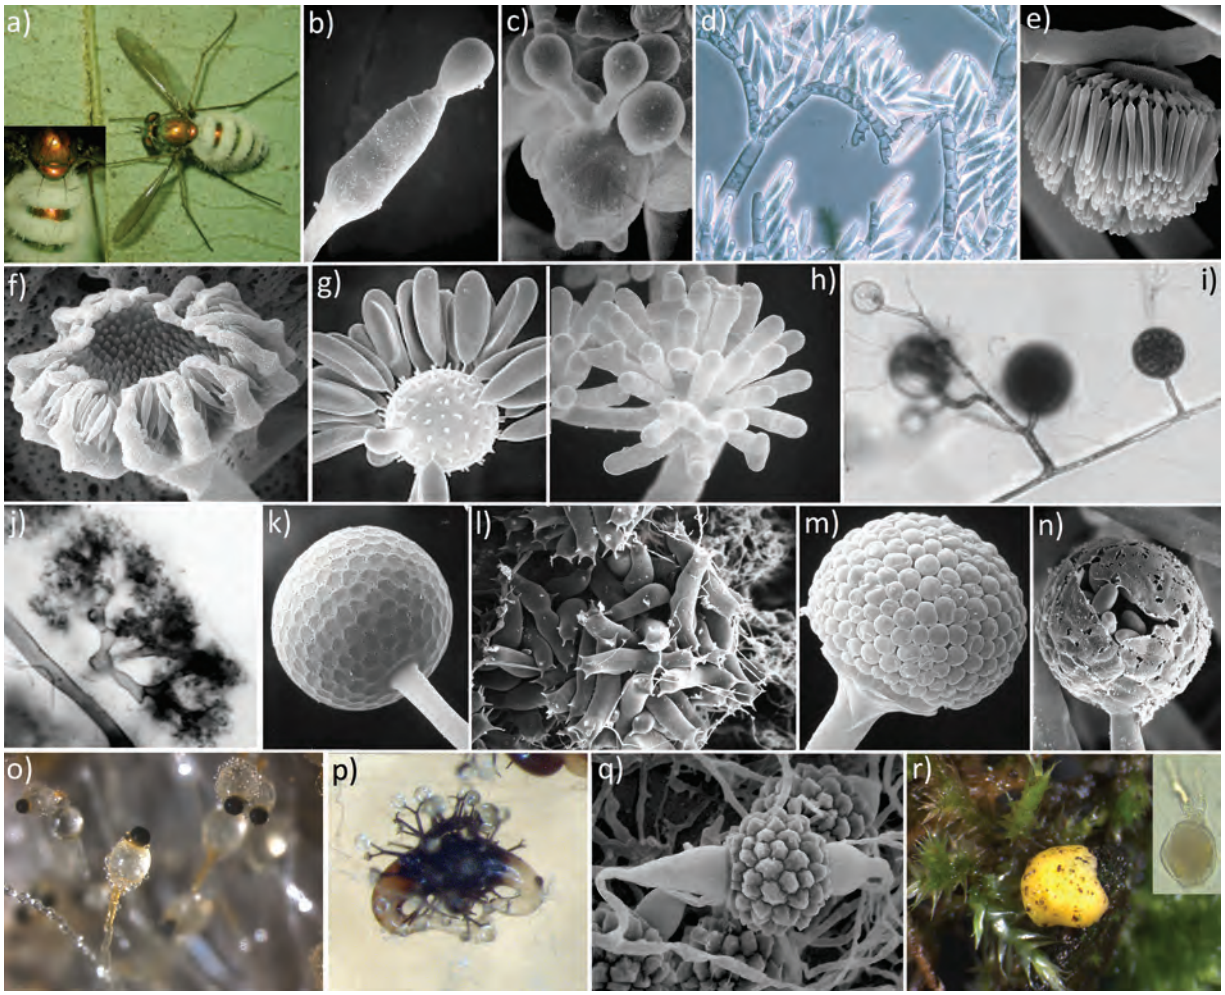

Figure 3 Examples of zygomycete fungal diversity. Zoopagomycota: (**a**) adult fly infected by a species of Entomophthorales; (**b**) *Basidiobolus* conidium; (**c**) *Conidiobolus* conidia; (**d**) *Zygopolaris* thallus with trichospores (photo by R.W. Lichtwardt); (**e**) *Linderina* sporangium; (**f**) *Kickxella* sporangium; (**g**) *Rhopalomyces* sporangium; (**h**) *Piptocephalis* sporangium. Mucoromycota: (**i**) *Glomus* spore (photo from American Society for the Advancement of Science); (**j**) *G. sinuosum* sporocarp (photo by D. Redeker); (**k**) *G. mosseae* arbuscule (photo by K. Rather, the zygospore is best interpreted as arising in the MRCA of Zoopagomycota, Mucoromycota, Ascomycota, and Basidiomycota and lost in the MRCA of Dikarya (Ascomycota + Basidiomycota). Most zygomycetes are characterized by coenocytic hyphae and sporangial asexual reproduction, but lineages characterized by septate or compartmentalized hyphae and/or asexual reproduction by formation of conidia exist. Importantly, it is with the emergence of the zygomycete fungi that we observe a loss of the fungal flagellum and the rise of the terrestrial, filamentous fungi. It is generally assumed that this loss of the flagellum in the kingdom Fungi corresponds to the transition to a terrestrial environment and the dawn of early terrestrial ecosystems. As such, zygomycetes represent an important group of fungi for ecological studies of host association and diversification of nutritional modes and cell biology studies regarding the evolution of centrosomes, organelles associated with hyphal growth and differentiation, and multicellularity.

Zoopagomycota

Zoopagomycota is the sister to Mucoromycota+ Dikarya. It comprises three subphyla: Zoopagomycotina, Kickxellomycotina, and Entomophthoromycotina. The primary ecologies of members of the phylum include pathogens and commensals of animals, parasites of other fungi and amoebae, and rarely, as plant associates. The phylogenetic placement of Zoopagomycota as sister to the remainder of nonflagellated fungi is important for numerous reasons, but two are highlighted here. First, diversification with animals and nonplant hosts occurred at least as early as diversification with terrestrial plants. This suggests that fungi were among the first terrestrial organisms and that fossils of the first land animals should be examined with greater scrutiny for fungal associations, potentially providing a more complete picture of early terrestrial fungi. Second, the loss of the flagellum in fungi corresponds to other modifications, including the loss of the centriole. Most nonflagellated fungi of Mucoromycota, Basidiomycota, and Ascomycota possess an organelle unique to fungi, the spindle pole body, which serves as the microtubule attachment necessary for chromosome segregation during nuclear division. It has been hypothesized that the spindle pole body is derived from centrioles through the loss of the 9+2 microtubular system, though there is no support for this homology based on detectable sequence similarity. In contrast, Zoopagomycota lineages retain a functional centrosome that possesses a degenerate 9+2 microtubular system (56). Furthermore, there is some evidence that the genus *Olpidium*, a zoosporic fungus that retains its flagellum and infects nematodes and plant roots of Brassicaceae, may be a member of—or closely related to—Zoopagomycota (12). Collectively, these observations suggest that Zoopagomycota is critical to understanding the evolution of fungi as they transitioned to terrestrial ecosystems.

Zoopagomycotina contains a single order, Zoopagales. Species in this order include predators of nematodes (e.g., *Stylopage*) and nematode eggs (e.g., *Rhopalomyces* [Fig. 3g]), predators of amoebae (e.g., *Stylopage*, *Zoopage*), and mycoparasites of mucoralean fungi (e.g., *Syncephalis*). Hyphae are small in diameter, coenocytic, and they form haustoria on or within their hosts. Asexual reproduction is by conidia or sporangia according to species, and where known, sexual reproduction is by production of zygospores. Many of these fungi are obligate symbionts and thus are difficult to obtain in axenic culture, and for this reason there is a paucity of molecular and genomic data. Furthermore, these fungi are underrepresented in environmental sequence data (57), presumably due to the inadequacy of existing environmental sampling techniques (e.g., primer bias, insufficient reference data, etc.), and their internal transcribed spacer sequences are longer than most fungi, contributing to underrepresentation (58).

Kickxellomycotina comprises four orders: Asellariales, Dimargaritales, Harpellales, and Kickxellales. Species of Kickxellomycotina possess hyphae that are regularly compartmentalized by bifurcate septa that are occluded by a lenticular plug. Asellariales and Harpellales are associated with digestive tracts of aquatic stages of arthropods and comprise two of the four orders that have been treated previously as Trichomycetes (59); the other two orders, Amoebidiales and Eccrinales, are members of Mesomycetozoea, not the kingdom Fungi (60, 61). Asellariales has filamentous, branched thalli and reproduces asexually by disarticulation of the thalli into arthrospores. They occur in the digestive tracts of marine, aquatic, and terrestrial species of isopods and Collembola, where they are thought to function as commensals (62). Harpellales has branched or unbranched filamentous thalli, and they reproduce by trichospores, which are asexual spores with hair-like appendages (Fig. 3d). They attach to the hindgut of aquatic stages of arthropods via a holdfast and are generally considered to be in a commensal relationship with their host (59). Dimargaritales species are haustorial parasites of other fungi, with the best-known species occurring on mucoralean hosts (63), and Kickxellales includes mycoparasites and saprobes isolated from soil (64). Dimargaritales and Kickxellales, as well as Zoopagales, produce unique

sporangia called merosporangia. These are cylindrical sporangia that arise from a bulbous structure, and one or more sporangiospores may occur in chains within the sporangium (Fig. 3e–h).

Entomophthoromycotina contains three classes, each with a single order: Basidiobolomycetes and Basidiobolales, Entomophthoromycetes and Entomophthorales, and Neozygitomycetes and Neozygitales (13, 65, 66). These fungi are associated with animals as either commensals isolated from animal dung or as pathogens and parasites of insects. Many species are commonly isolated from soil and maintained in pure culture, which is consistent with a saprobic life cycle phase. Basidiobolales is commonly isolated from amphibian dung, although species are known to occur on the dung of many vertebrates. They produce primary conidia that forcibly eject a single spore which if it lands on an appropriate substrate will germinate to form a mycelium or otherwise will undergo repetitive germination, producing a secondary conidium (Fig. 3b). Under some conditions nonforcibly discharged capilliconidia are produced from forcibly discharged conidia. These adhere to the outer surface of insects (67). Dispersal is then achieved when the insects are ingested by insectivorous animals, and after surviving gut passage, the fungus is excreted with the feces. In a few cases gut infections are known in various marine and terrestrial vertebrates, and human gut infections have been mistaken for Crohn's disease (68). The ecological function of Basidiobolales is speculative at this time because no definitive functional experiments have been performed, but its specificity to animal dung and placement in Zoopagomycota support an interaction with animal hosts in the digestive system. The phylogenetic placement of Basidiobolales with molecular- and genome-scale data is problematic. In all current data sets, it is characterized by long and unstable branches, and its relationship to other Entomophthoromycotina is unambiguous at this time (69).

Entomophthorales, or literally, insect destroyers, comprises pathogens of insects (Fig. 3a). They infect their hosts via spores and multiply within the host as one- to two-celled hyphal bodies, which also can function as gametangia. Upon the host's death, the fungus ruptures through the cuticle segments, producing forcibly discharged primary conidia (Fig. 3a). Frequently, infected hosts alight in perched or elevated positions, a phenomenon known as summit disease, which is thought to be an induced behavior or adaptation for spore dispersal of the pathogen (20, 70, 71). Neozygitales are pathogens of insects and mites. They were classified as a family within Entomophthorales but were distinguished from Entomophthorales based on the shape and size of chromosomes (65), although inadequate molecular data currently exist to test this hypothesis. *Neozygites* produces adhesive capilliconidia similar to those of *Basidiobolus* (72).

Mucoromycota

Mucoromycota consists of the subphyla Glomeromycotina, Mortierellomycotina, and Mucoromycotina. Unlike Zoopagomycota, Mucoromycota is characterized by plant associations and plant-based ecologies (e.g., mycorrhizae, root endophytes, decomposers, etc.). Some exist as parasites of animals and other fungi, but these all represent opportunistic infections of hosts with compromised immune systems or relatively recent derivations from saprobic ecologies (73). Mucoromycota is the sister group to Dikarya, which is also characterized by dominant plant-associated life styles, suggesting that the MRCA of Mucoromycota and Dikarya corresponds to the origin of modern fungus-plant associations, or at least the evolutionary potential for such relationships.

Glomeromycotina consists of the arbuscular mycorrhizae and *Geosiphon*, a symbiont of cyanobacteria (74). Arbuscular mycorrhizae (Fig. 3i–k) are the most common form of mycorrhizae on the planet, and arbuscule fossils are present among the first land plant fossils (75–77), confirming an ancient symbiosis. As such, they are a central taxon in the development of hypotheses concerning the evolution of early land plants and terrestrial ecosystems (78–80). Despite this importance, they have been an enigma with respect to phylogenetics of the kingdom Fungi. Morphologically, they resemble zygomycetes in the production of coenocytic hyphae and terminal or subterminal spores that resemble azygospores (Fig. 3i), asexually formed zygospore-like structures produced terminally on a single hypha or suspensor cell (81). Sexual reproduction has never been observed for the group, preventing analysis of morphological characters traditionally used in classifications. Early molecular phylogenies based on the small subunit ribosomal DNA resolved the arbuscular mycorrhizae—with varying statistical support depending on the analysis—as separate from the zygomycetes and sister to Dikarya (40, 82). However, genome-scale phylogenies and genome content analyses strongly support the arbuscular mycorrhizae as members of Mucoromycota (13, 83). Recently, mating type genes have been identified in the Glomeromycotina genomes, and their structure and diversity are consistent with a functional sexual reproductive cycle without morphological evidence of sex. Interestingly, the *MAT* genes are more similar to those of basidiomycetes than those in other fungal groups, although this is still

a topic of debate (84). So while we have learned much about Glomeromycotina from genomic data, where and when these fungi undergo sexual reproduction remains a mystery. Currently, there are four orders of Glomeromycotina, Archaeosporales, Diversisporales, Glomerales, and Paraglomerales, with *Geosiphon* being classified in Archaeosporales (74).

The relationship of Glomeromycotina to the other subphyla of Mucoromycota is unresolved, with some analyses resolving it as sister to Mortierellomycotina and Mucoromycotina, while others resolved it as the sister group to Mortierellomycotina. The taxon sampling for both Glomeromycotina and Mortierellomycotina is sparse, and expanded taxon sampling is needed to fully test these rival hypotheses. Mortierellomycotina, and its sole order Mortierellales, are commonly isolated soil fungi. They produce zygospores and sporangia similar to some species of Mucorales (Fig. 3l and 3m), the order in which they were previously classified, but molecular phylogenetics (85) and genome-scale (13) phylogenies both strongly support the taxon as representing a distinct subphylum. Interestingly, even earlier studies of sterols separated the two orders because Mortierellales contain membrane sterols other than ergosterol (86). These fungi have been demonstrated as root endophytes of plants (87, 88), but their effect on the host fitness remains unknown. Some species are reported to have distinctive odors, perhaps associated with animal dispersal. Mortierellales are also prolific producers of fatty acids, in particular arachidonic acid, and *Mortierella* species are used in its industrial production (89). Both Glomeromycotina and Mortierellomycotina possess intimate relationships with bacteria, and while facultative, show high levels of specificity and cospeciation (90, 91), and the fungus tends to grow better when cleared of the bacterium (92). Because of their relationship to Glomeromycotina, demonstrated plant associations, and industrial applications including potential alternative fuels, Mortierellomycotina are the subject of significant genomic inquiries.

Mucoromycotina contains the remainder of known zygomycete species and is classified in three orders: Mucorales, Umbelopsidales, and Endogonales (13). Mucorales is one of the more commonly isolated groups of fungi, because many are fast-growing, early colonizers of carbon-rich substrates. Because many species culture relatively easily, Mucorales are well represented in culture collections, and their zygospores and sporangia (Fig. 3n–r) are well documented (93). They include taxa that cause economically significant pre- and post-harvest diseases of fruits (e.g., *Gilbertella*, *Mucor*, *Rhizopus*). They also significantly impact humans both beneficially through their use in industrial production of food (e.g., tempeh, *Rhizopus*) and compounds used as food supplements (e.g., beta-carotene, *Blakeslea*), and antagonistically as rare but increasingly diagnosed human mycoses (e.g., *Mucor*, *Apophysomyces* [94]). It is among Mucorales that sexual reproduction in fungi was first demonstrated (95), and numerous species of Mucorales exhibit phototropic responses to light (96), making them important eukaryotic model organisms (e.g., *Mucor mucedo*, *Phycomyces blakesleeanus*). Umbelopsidales was recently described for *Umbelopsis* (13), a genus of soil-inhabiting fungi that also occurs as root endophytes (87). Like *Mortierella*, it was formerly classified in Mucorales, but genomic and molecular analyses support it as a distinct taxon (85). Endogonales are saprobic or ectomycorrhizal depending on the species (81). Saprobic species occur in heavily decayed woody substrates, while mycorrhizal species associate with both nonvascular and vascular plants (78). They have been argued as important organisms in the colonization of land by green plants (79) and represent an independent origin of mycorrhizae relative to both Glomeromycotina and Dikarya. It is within Mucoromycota that the first multicellular sporocarps were produced. These include independent origins in *Endogone* (Mucoromycotina [78]) (Fig. 3s) and *Modicella* (Mortierellomycotina [97]), and as aggregations of spore-producing hyphae and spores in species of Glomeromycotina (Fig. 3j) (74). Multicellular sporocarps are not produced by Zoopagomycota, suggesting that the genetic potential for complex thallus development did not arise until the MRCA of Mucoromycota and Dikarya and then resulted in multiple independent inventions of complex spore-producing structures in Mucoromycota, Ascomycota, and Basidiomycota (98).

DIKARYA

Dikarya is the only described subkingdom of Fungi and comprises the phyla Ascomycota and Basidiomycota. The name is based on the nuclear condition of possessing two genotypically distinct nuclei within the thallus at some point in the life cycle. The hyphae of Dikarya are regularly septate, and if a hyphal compartment contains one nucleus or more than one nucleus but all of the same genotype, it is referred to as monokaryotic or homokaryotic, respectively. If a hyphal compartment contains two nuclei of different genotypes, it is referred to as dikaryotic or heterokaryotic. In Basidiomycota, basidiospores typically possess one type of nucleus and germinate to form a mono-

karyon. Monokaryons fuse (plasmogamy) with other compatible monokaryons, producing the dikaryotic state that is maintained by the products of the mating type genes. The dikaryon constitutes the major vegetative phase of the life cycle for most Basidiomycota, and it is as a dikaryon that most Basidiomycota function in nature (e.g., wood decay, mycorrhizae, pathogens, etc.). Karyogamy occurs in unique cells, termed basidia, resulting in a short-lived diploid zygote that immediately undergoes meiosis to produce haploid nuclei that are incorporated into basidiospores. Importantly, plasmogamy is separated from karyogamy and meiosis both temporally and spatially. In Ascomycota the dikaryotic state is restricted to the sexual reproductive cells, with the vegetative mycelium being homokaryotic. Female gametangia (ascogonia) are fertilized by male gametangia (antheridia) or gametes (spermatia), resulting in a dikaryotic state (ascogenous hyphae). A number of rounds of conjugate nuclear divisions occur prior to karyogamy. Karyogamy and meiosis follow shortly afterward in the young ascus cell, resulting in homokaryotic ascospores. Thus, although both phyla of Dikarya have inherited the dikaryotic state from a common ancestor, they are expressed differently in the life cycles of Ascomycota and Basidiomycota. For more on life cycles of Ascomycota and Basidiomycota, the reader is directed to general mycology textbooks (e.g., 41).

More genomes have been sequenced for species of Ascomycota and Basidiomycota than other phyla of the kingdom Fungi (http://genome.jgi.doe.gov/fungi/), resulting in an increased resolution of phylogenetic relationships and evolutionary processes that have shaped phylogenetic and ecological diversity in Dikarya. Ascomycota consists of three subphyla—Taphrinomycotina, Saccharomycotina, and Pezizomycotina—as does Basidiomycota: Pucciniomycotina, Ustilaginomycotina, and Agaricomycotina. These subphyla include the majority of described species of fungi, and most are associated with plants as symbionts or decomposers of plant materials, although there are numerous independent transitions to other hosts and materials (e.g., animals). It is within Dikarya that we see the apex of multicellular sporocarp production, complex multicellularity, yet sporocarps are distributed sporadically across separate subphyla. Major innovations in sporocarp formation can be found primarily in Pezizomycotina and Agaricomycotina (98), but also within a single genus of Taphrinomycotina (*Neolecta* [99]) and scattered within Pucciniomycotina (e.g., *Septobasidium* [100], *Eocronartium*, and *Jola* [101]). When considering the diversity across the kingdom Fungi, there are a minimum of seven clades of sporocarp-forming fungi: three in Mucoromycota (discussed above), two in Ascomycota, and two in Basidiomycota. Genomic analyses of evolutionary development, or EvoDevo, of sporocarp formation are in their infancy, but a recent study involving Ascomycota paints a complex picture (102). Genes hypothesized to function in complex multicellularity were present in the MRCA of Ascomycota and diversified in Pezizomycotina but were lost in parallel in Saccharomycotina, the budding yeasts, and the yeast lineages of Taphrinomycotina. While present, genes that may be necessary for complex multicellularity did not expand in copy number or show substantial diversification within *Neolecta*, thus complicating a simple explanation of gains and losses of sporocarps.

Ascomycota (Fig. 4)

Ascomycota is a diverse phylum of fungi that includes decomposers associated with a myriad of substrates (e.g., dung, wood, soil), symbionts and associates of plants and animals, and inhabitants of marine and terrestrial ecosystems. Plant-associated species range from antagonistic pathogens to beneficial symbionts (e.g., mycorrhizae) to foliar, root, and wood endophytes whose true functions remain unknown. They have impacted our civilization since the dawn of humans with both positive and negative outcomes. Some ascomycetes were among the first organisms domesticated by humans and have been used in fermentation of foods and beverages for over 9,000 years (103). They are the source of numerous lifesaving drugs including antibiotics, statins, and immunosuppressants. Unfortunately, they are also the causal agents of disease, especially of plants, that have changed continents by removing entire species from the landscape after introduction by humans (e.g., chestnut blight [104]) or have resulted in billions of dollars of loss in modern agriculture (e.g., *Fusarium* head blight [105]). Indeed, our relationship with Ascomycota is one that has profound effects on our planet and our species.

Taphrinomycotina

The subphylum Taphrinomycotina includes about 140 species with both yeast and filamentous growth forms and is a sister group to the remaining Ascomycota. Taphrinomycotina is classified into five classes —Taphrinomycetes, Schizosaccharomycetes, Pneumocystidiomycetes, Neolectomycetes, and Archaeorhizomycetes—each with a single order. Taphrinomycetes includes plant pathogens such as *Taphrina* and *Protomyces*, which are characterized by saprobic, monokaryotic yeast and pathogenic, dikaryotic filamentous life stages. Taphrinales has played an important role in

Figure 4 Examples of Ascomycota diversity. (**A**) Apothecia (yellow) of *Orbilia*, Orbiliomycetes (J. H. Petersen/MycoKey). (**B**) Apothecia of *Aleuria*, Pezizomycetes (J. H. Petertsen/MycoKey). (**C**) Thallus of *Ophioparma* with apothecia, Lecanoromycetes (B. McCune, Oregon State University). (**D**) Thallus of *Lichinella*, Lichinomycetes (B. McCune, Oregon State University). (**E**) Bitunicate asci of *Thaxteriella*, Dothideomycetes (S. Huhndorf, Field Museum). (**F**) Thallus of *Arthonia* with apothecia, Arthoniomycetes (B. McCune, Oregon State University). (**G**) Thallus of *Prolixandromyces*, Laboulbeniomycetes (A. Weir, SUNY-ESF). (**H**) Perithecia of *Neurospora*, Sordariomycetes (N. B. Raju, Stanford University). (**I**) Earth-tongue apothecia of *Cudonia*, Leotiomycetes (Z. Wang, Iowa State University). (**J**) Cleistothecia of *Eupenicillium*, Eurotiomycetes (D. Geiser, Penn State University). (**K**) Operculate ascus of *Peziza* (J. H. Petersen/MycoKey). (**L**) Ascostroma of *Venturia*, Dothideomycetes (T. Volk, University of Wisconsin at La Crosse). (**M**) Unitunicate asci *Neurospora* (N. B. Raju, Stanford University). (**N**) Prototunicate ascus of *Eurotium* (D. Geiser, Penn State University).

the development of evolutionary hypotheses of the kingdom Fungi and has been considered a possible evolutionary link between Ascomycota and Basidiomycota, due to the life cycle described above, which is similar to that of some smut and other microfungal basidiomycetes of Ustilaginomycotina and Pucciniomycotina. Based on numerous molecular phylogenetic studies, however, it is strongly supported as a member of Ascomycota, and it is unclear if the similarity in life cycles with some Basidiomycota is homologous or not.

Schizosaccharomycetes includes the fission yeasts, which display an unusual form of cell division for fungi. Rather than dividing by budding, as is true for all other yeast forms, cells of Schizosaccharomycetales elongate and divide into equal cells through the formation of a fission plate. *Schizosaccharomyces pombe* is the best-studied species and was originally isolated from millet beer in East Africa (106). Pneumocystidiomycetes comprises pulmonary pathogens of mammals, including humans. Species of *Pneumocystis* are found in soils associated with rodent dens. *Pneumocystis jirovecii* is an opportunistic pathogen of humans and is the causal agent of pneumocystic pneumonia in people with compromised immune systems. Neolectomycetes includes the only sporocarp-producing species of Taphrinomycotina. The genus *Neolecta* forms earth tongue-like sporocarps with a hymenium of asci produced from uniquely branched hyphae (107). The ecology of the group is unknown, but the inability to maintain it in axenic culture suggests a symbiotic association in nature (108). Ancestral character state reconstruction analyses resolved *Neolecta* as an independent origin of sporocarp formation in Ascomycota, unique to that of Pezizomycotina (98, 109), but comparative genomic analyses support the possession of common genetic multicellular machinery between *Neolecta* and Pezizomycotina (102). Archaeorhizomycetes is the most recently described class of Taphrinomycotina. It is commonly detected in environmental sampling of soil and was initially known informally as Soil Clone Group 1 (110, 111). One species was serendipitously described from a culture collection of root-associated fungi; it and a second recently described species are associated with the surfaces of tree roots (112, 113).

Saccharomycotina

The subphylum Saccharomycotina includes about 1,000 species in a single order, Saccharomycetales, and 10 major families and several undescribed clades (114). Saccharomycetales include the majority of the ascomycete yeasts and are characterized by budding in asexual reproduction (115). Yeasts, however, have evolved multiple times in the kingdom Fungi, most likely through parallel diversification of novel transcription factors (116). In Saccharomycotina, somatic cells and hyphae may be haploid or diploid, and diploid cells undergo meiosis to convert to gametes, which fuse to form a zygote and develop into asci to produce one to eight ascospores. Ascogenous hyphae are not produced as in Pezizomycotina. Two other traits that distinguish Saccharomycetales yeasts from other ascomycetes occur during ascosporogenesis. These are meiotic divisions with perpendicular spindles developing within the nuclear envelope and formation of ascospores within a common ascus vesicle instead of ascospores developing in individual ascus vesicles as in Pezizomycotina (41). Although they are relatively similar in morphology, Saccharomycotina yeasts are metabolically diverse. In common with Taphrinomycotina, Saccharomycotina lack the septal pore-blocking Woronin bodies characteristic of Pezizomycotina. Earlier yeast taxa were distinguished by the application of about 100 physiological tests. Previously, hypotheses of relationships were difficult to address because of the lack of distinctive morphological characteristics. Now DNA analysis distinguishes yeast species rapidly, as well as providing phylogenetic hypotheses (114, 115). To expand our knowledge of biotechnologically important yeasts, a variety of additional species were sequenced across the known phylogeny, especially from outside of the better-known *S. cerevisiae* clade. This study revealed several transitions in the early evolution of the ascomycetes, the synteny of the *MAT* loci across Ascomycota, and a genetic code change from CUG-Ser to CUG-Ala in one lineage (117, 118). Phylogenomic analyses have also revealed that *S. cerevisiae* and its relatives are the product of a whole-genome duplication (119, 120) that is the result of an ancient hybridization event between two ancestral species (121).

Yeasts occupy a wide variety of natural (e.g., desert and forest plants, insect guts, and environments) and human-provided (e.g., pickle vats, breweries) habitats. *S. cerevisiae* is the most widely known yeast in the world due to its role in bread making and brewing of alcoholic beverages and as a model organism. This was the first eukaryotic species to have its entire genome sequenced, which was justified by its industrial and biological importance. *S. cerevisiae* and many other yeasts are closely associated with insects, including bees, dipterans, and beetles. Certain yeasts display specific associations with insects and plants, including dipterans and cacti in American deserts (122), nitidulid beetles and ephemeral flowers around the world (123), and widely distributed wood-feeding beetles (124). A dis-

tinctive group of previously unknown yeasts related to *Suhomyces tanzawaensis* are associated with fungus-feeding beetles and drosophilids (125). Sexual reproduction and overwintering of *S. cerevisiae* and its hybrids are promoted in the gut of social wasps (126). The bodies of human beings and many mammals are substrates for animal pathogenic yeasts. *Candida albicans* and relatives inhabit the digestive tracts of healthy individuals but may become invasive in those with suppressed immune systems. Infections can be localized (esophageal candidiasis, or thrush; genital candidiasis, or "yeast infection") or invasive in the brain, heart, bones, and eyes. *Candida* can be spread in the blood, a fairly common infection in hospitals where candidemia has been estimated to be fatal in as many as 19 to 24% of cases (127). *Candida auris*, recently recognized as an emerging fungal disease in the United States, is multidrug-resistant (https://www.cdc.gov/fungal/diseases/candidiasis/candida-auris.html). Few yeasts are plant pathogens, but *Ashbya gossypii* is well known to be destructive to fruit development in cotton (128). This species is also industrially important because it overproduces riboflavin (129). Interestingly, *A. gossypii*, and occasionally *S. cerevisiae*, are insect-associated.

Pezizomycotina

The subphylum Pezizomycotina contains many more species than the two other ascomycete subphyla combined; the 63,000 or so species are placed in 13 classes and 67 orders. Pezizomycotina are mostly filamentous (130), although many are capable of dimorphic growth. With the exception of *Neolecta* (Taphrinomycotina), they include all of the sporocarp-forming Ascomycota, but the life cycles of many are only known from their hyphal and asexual reproductive states. Past classifications of the group have emphasized sporocarp morphology and development and ascus morphology and dehiscence. Ascomycete sporocarps, or ascomata, were categorized into four basic types. Apothecia have an exposed hymenium of asci and are typically cup-shaped or spathulate (Fig. 4a–d). Perithecia enclose the hymenium in a flask-shaped ascoma, and the ascospores are released through an opening called an ostiole (Fig. 4h). Cleistothecia completely enclose an ill-defined hymenium of scattered asci, and no pore or opening is present (Fig. 4j). (Note: Chasmothecia are another form of completely enclosed ascomata, but the hymenium exists as a single basal fascicle of asci.) All three forms of these ascomata are assumed to be formed after fertilization of the ascogonium, a form of development called ascohymenial. The fourth major group of ascomata is ascostromata (Fig. 4l). In these fungi, ascogonia are fertilized in preformed locules, which mature into ascostromata containing asci and ascospores, a form of development called ascolocular.

Asci of Pezizomycotina may be operculate or inoperculate. The apex of operculate asci contains a preformed lid, like a manhole cover, that is opened for ascospore release (Fig. 4k), while inoperculate asci lack an operculum. Inoperculate asci can be further categorized based on the nature of the ascus walls. Bitunicate or fissitunicate asci possess more than one functional wall layer, an ectoascus and an endoascus (Fig. 4e). Ascospores are released by the endoascus rupturing through and extending beyond the ectoascus in a manner reminiscent of a jack-in-the-box. Unitunicate asci possess a single functional wall layer, and the ascus apex usually possesses a pore or canal through which ascospores are released (Fig. 4m). Prototunicate asci are typically globose and possess a thin ascus wall that breaks down, or deliquesces, at ascospore maturity (Fig. 4n). Species that produce prototunicate asci do not forcibly eject their ascospores. The combinations of ascomatal and ascal characters can be informative in describing the overall morphology of a species, but most traits have been gained and lost multiple times during the evolution of Pezizomycotina, with a few notable exceptions (e.g., the operculate ascus of Pezizomycetes).

In addition to the sexual morphs, Pezizomycotina reproduce prolifically through asexual reproduction in which the nuclei of spores are products of mitotic divisions. A species can only have one sexual state but may have many asexual states, a phenomenon called pleomorphy. Many Pezizomycotina are only known from their asexual morphs, and it is common for a species to reproduce asexually throughout the growing season but reproduce sexually only once. Historically, unique Latin binomials were given to asexual and sexual states, a system referred to as the dual system of nomenclature, and thus a single species could have several names. The reason for this was manifold, but the main argument was that the sexual and asexual states of Pezizomycotina could be separated in space and time, so when one observed an asexual state, it could be difficult to link it to a sexual state. Perhaps the fungus was only observed in its asexual form by chance; perhaps the sexual form occurs on a different host or in a different geographic region; perhaps the fungus only reproduces asexually in axenic culture; or perhaps the fungus is truly asexual. The advent of molecular data and phylogenetic analyses provided a mechanism to link sexual and asexual morphs and to identify them as conspecific. For this reason, the dual system of nomen-

clature was abolished recently (131), and all fungi must now be called by only one name. Needless to say, determining what name to call a fungus that has many names is no trivial task and is the subject of much debate, but today students only need to learn one name for a single species.

Nonlichenized apothecial fungi are classified into four classes of Pezizomycotina: Orbiliomycetes, Pezizomycetes, Leotiomycetes, and Geoglossomycetes. Orbiliomycetes and Pezizomycetes are sister to the remainder of the subphylum, but their branching order is unresolved (132). Orbiliomycetes produce small apothecia with inoperculate asci. Apothecia typically fruit on wood or soil, and the asci are small and release ascospores through an apical slit. The group is best known for its asexual states of *Arthrobotrys*, which are predators of nematodes. These fungi form hyphal rings or loops that constrict and capture nematodes as they crawl through the rings. Pezizomycetes produce a diversity of ascomatal types with operculate asci. Apothecia may be minute, as in the coprophilous *Ascobolus*, or large, as in the type genus *Peziza*. Some taxa produce apothecia elevated on a stipe, as in *Helvella*, or below ground, as in the prized culinary truffles of *Tuber*. The asci of all these taxa are operculate and have a positive amyloid reaction, with the exception of species that form truffles, which have lost their ability to forcibly discharge their spores. Leotiomycetes is the largest class of inoperculate apothecial fungi (133). They produce a myriad of apothecial morphologies ranging from cup fungi to stipitate earth tongues to hysteriate apothecia that are resupinate and expose the hymenium as a long and slender slit. At one time all fungi that produce apothecia with inoperculate asci were classified in Leotiomycetes. Species of the class include important plant pathogens (*Sclerotinia*), foliar (*Rhytisma*) and root (*Phialocephala*) endophytes, and mycorrhizae of ericaceous plants (*Rhizoscyphus*), to name a few. Animal pathogens are also known, including the recently emerged white nose syndrome of bats (*Pseudogymnoascus destructans*), which is devastating brown bat populations of North America (134). Geoglossomycetes comprise a subset of earth tongue species (Fig. 4i). These fungi were classified in Leotiomycetes along with other earth tongue genera *Leotia* and *Spathularia*. Molecular systematic analyses revealed that *Geoglossum* and its relatives represent a separate origin of the earth tongue morphology, however, and a unique class of fungi (135).

Sordariomycetes includes nonlichenized, perithecial species with inoperculate, unitunicate asci, but species possessing cleistothecia and/or prototunicate asci are known to be derived from within perithecial lineages (133). Perithecia may be produced on well-developed, stipitate stromata (e.g., as in *Xylaria* and *Cordyceps*), embedded in resupinate (e.g., *Hypoxylon*) or cushion-shaped stromata (e.g., *Hypocrea*), or superficially in an aggregated or scattered manner (e.g., *Neurospora*, Fig. 4h). Species of the class include some of the most devastating plant pathogens known. Chestnut blight, *Cryphonectria parasitica*, essentially eliminated the American chestnut from the forests of eastern North America and contributed to the development of the Plant Quarantine Act of 1912. Dutch elm disease, *Ophiostoma ulmi*, devastated the American elm and significantly impacted its presence and abundance on the landscape and its use as an important urban tree (136). *Fusarium graminearum*, head scab of wheat, is a global pathogen of wheat, one of the most important grains in human agriculture, and results in losses of billions of dollars in crop production (105). In addition to plant pathogens, Sordariomycetes are frequently identified as endophytes through culture and amplicon-based environmental sampling studies (137). Sordariomycetes also includes insect pathogens of *Beauveria* and *Metarhizium*, which are some of the most promising biological control agents of insect pests in agricultural ecosystems (138). Some species have recently been identified as having the potential to grow as an endophyte, suggesting a role in plant protection against insect pests and a nutritional role of transferring nitrogen to the plant host (e.g., 72, 139).

Eurotiomycetes are cleistothecial species that produce prototunicate asci and ascostromatic species that produce bitunicate or fissitunicate asci (140). Cleistothecial taxa include important industrial and medical species of *Aspergillus* and *Penicillium* (Eurotiales) and human pathogens of *Coccidioides* (Onygenales) that cause valley fever. These fungi produce both some of the most potent mycotoxins known to science (aflatoxins of *Aspergillus*) and lifesaving antibiotics that changed the course of history (penicillin of *Penicillium*). There even exists an independent origin of ectomycorrhizae among Eurotiomycetes, the genera *Elaphomyces* and *Pseudotulostoma*, which form large truffle-like or stipitate-capitate fruiting bodies, respectively (141). Although *Pseudoulostoma* and *Elaphomyces* are members of Eurotiales, the carbohydrate metabolism of *Elaphomyces granulatus* has been shown to be more similar to animal pathogens in Onygenales than to other members of its order (142). Ascostromatic species include the black yeasts (Chaetothyriales) that result in opportunistic cutaneous and subcutaneous infections. Lichenized species are also represented among the Eurotiomycetes by the order Verrucariales.

These lichens produce perithecioid ascostromata with bitunicate to fissitunicate asci, representing one of the rare combinations of reported ascohymenial development and bitunicate asci. A third and unique clade of Eurotiomycetes is Mycocaliciales, which are saprobes or commensals on lichens (143).

Dothideomycetes is a large and ecologically diverse class and represents the core of ascostromatic fungi with bitunicate asci (144). Ascostromata are frequently perithecioid in appearance and are referred to as pseudothecia (Fig. 4l), but there are apothecioid and cleistothecioid morphologies, as well. The majority of species are associated with terrestrial plants, and they are commonly identified as endophytes in environmental sampling studies based on cultures and DNA barcodes (e.g., 137, 145, 146). Numerous taxa diverged from this ecology, however, including marine fungi of mangroves, insect pathogens (e.g., *Myriangium*), mycoparasites (e.g., *Ampelomyces*), lichens (e.g., *Trypethelium*), and ectomycorrhizae (147). *Cenococcum geophilum* is one of the most abundant ectomycorrhizae-formers on the planet and represents another independent origin of ectomycorrhizae within the kingdom Fungi (148). Functional genomic studies have demonstrated that *C. geophilum* plays a role in drought tolerance of host trees, where it manipulates the host's response to water stress (149). The class is best known, however, for its large number of virulent plant pathogens including *Bipolaris maydis* (the causal agent of southern corn blight), *Zymoseptoria tritici* (Septoria wheat blotch), and *Mycosphaerella fijiensis* (black sigatoka of banana), to name a few. Species and races of these fungi frequently produce host-selective toxins that function as pathogenicity factors for selective host species and genotypes (150, 151).

Because of their importance in agriculture and relative ease of culturing, more than 100 Dothideomycetes genomes have been sequenced (http://genome.jgi.doe.gov/programs/fungi/). Published analyses of Dothideomycetes genomes revealed that the structural evolution of chromosomes is mostly a product of intrachromosomal rearrangements, a phenomenon called mesosynteny (152). Furthermore, disposable chromosomes, which may be present or absent within an isolate, are common, but their function is mostly unknown. Comparative analyses of multiple genomes across a phylogenetic and ecological diversity of Dothideomycetes support the idea that the plant pathogen "play book" is particularly rich in enzymes for secondary metabolite production, carbohydrate-active enzymes, small secreted proteins (SSPs), peptidases, and lipases (153). In addition, genes that encode for effector proteins, which have a role in pathogenicity, occur often in close proximity to transposable elements (154), suggesting that transposable elements may play a role in their evolutionary diversification.

The remaining two classes of nonlichenized Pezizomycotina are Laboulbeniomycetes and Xylonomycetes. Laboulbeniomycetes is an enigmatic class that is primarily composed of ectoparasites of insects (155–157). In Laboulbeniales, minute thalli develop from an ascospore through a definitive number of cell divisions and adhere to the exoskeleton through the production of a holdfast cell (Fig. 4g). Certain species tend to be host- and position-specific, with some species being transmitted through behaviors associated with sexual reproduction (158). Members of the second order, Pyxidiophorales, are mostly mycelial mycoparasites with ascospore dispersal by arthropods (159). Xylonomycetes is one of the more recently described classes of Pezizomycetes and contains wood endophytes in *Xylona* (160) and endosymbionts of beetles in *Symbiotaphrina*, the latter of which may benefit the insect by detoxifying noxious plant compounds (161).

The remaining four classes of Pezizomycotina are Arthoniomycetes, Coniocybomycetes, Lecanoromycetes, and Lichinomycetes and consist almost entirely of lichenized species (144, 162). Lichens are stable symbioses between a fungus (mycobiont) and photosynthetic green alga and/or cyanobacterium (photobiont) that result in the formation of a thallus unique to the symbiosis. Lichens are some of the more successful fungal symbioses on the planet and are conspicuous members of terrestrial ecosystems, where they play important roles in carbon and nitrogen cycles. The classic definition of a lichen being formed by one fungus has been challenged recently, however, by environmental sampling and microscopy data (163) which demonstrated that basidiomycete yeasts of Cystobasidiomycetes (Pucciniomycotina) were embedded in the cortex. Furthermore, the presence and abundance of the yeasts correlated with variations in phenotype. Although there are fewer genomic studies of lichenized than nonlichenized fungi, current comparative genomic analyses have shed some light on the formation and maintenance of lichen symbiosis. For example, species of lichenized Pezizomycotina possess an ammonium transporter/ammonia permease family that was horizontally transferred from Archaea but is absent in nonlichenized species (164). Functional analyses using the lichen-forming fungus *Endocarpon pusillum* and its algal partner identified genes involved in the nitrogen and carbon transfer between symbionts and lectins required for symbiotic recognition (165).

Lecanoromycetes is the largest and best-studied class of lichens (162). It includes most of the common forest lichens and such growth forms as foliose, fruticose, and crustose lichens. Lichinomycetes and Coniocybomycetes are two smaller classes that form a monophyletic group. Lichinomycetes form gelatinous thalli in which the cyanobacterial photobiont is not sequestered in a defined layer of the lichen. Coniocybomycetes form mazedia, which are stalked ascospore-producing structures. Mazedial lichens are also known from Caliciales of Lecanoromycetes, and mazedia are known from several groups of nonlichenized Pezizomycotina (166). Arthoniomycetes is the second-largest class of lichens, and they possess bitunicate asci, although their ascomata have been interpreted as ascohymenial (144).

Molecular systematics has provided great clarity to the phylogenetic relationships of the classes of lichenized and nonlichenized Pezizomycotina (109, 167), but genomic sampling of lichens is still sparse and is heavily biased toward nonlichenized fungi. Orbiliomycetes and Pezizomycetes are sister to the other classes of Pezizomycotina, with the remaining classes informally referred to as Leotiomyceta to designate their monophyly. Within Leotiomyceta, Sordariomycetes, Laboulbeniomycetes, and Leotiomycetes form a clade, as do Arthoniomycetes and Dothideomycetes. Eurotiomycetes is sister to Arthoniomycetes+Dothideomycetes, and the three classes may form a more inclusive clade with Lecanoromycetes, Coniocybomycetes, Lichinomycetes, and Xylonomycetes, but the relationships are not unequivocally supported by current data (109, 167). Finally, Geoglossomycetes appears to represent an isolated lineage of Pezizomycotina (135), but genomic data are lacking.

Basidiomycota (Fig. 5)

The phylum Basidiomycota is defined by the synapomorphies of basidium and basidiospore. Basidia are modified terminal hyphal cells that are the site of karyogamy and meiosis. They are typically produced in hymenial tissues such as gills or pores. Basidiospores are, with few exceptions, formed on sterigmata, outgrowths of basidia, and typically contain a single haploid nucleus. Basidiospores can either be forcibly ejected from the sterigma (ballistospores) or passively dispersed (statismospores) by water, wind, or animals. Most Basidiomycota have a filamentous thallus that is compartmentalized by regularly distributed septations. Basidiomycota consists of three subphyla: Pucciniomycotina, Ustilaginomycotina, and Agaricomycotina. Although reconstruction of the earliest nodes of Basidiomycota has been problematic, genomic studies tend to support Ustilaginomycotina (smuts and relatives) and Agaricomycotina (fleshy basidiomycetes) as a monophyletic group that shares an MRCA relative of Pucciniomycotina (e.g., 168). Pucciniomycotina includes yeasts and filamentous taxa, with the best-known species being the plant-pathogenic rusts of Pucciniales. Pucciniomycotina and Ustilaginomycotina were formerly classified in the obsolete class Teliomycetes based on the production of teliospores, which germinate to produce basidia (as promycelia) and basidiospores, rather than the production of a hymenium.

Former higher-level classifications of Basidiomycota emphasized the morphology of the basidia and the nature of basidiospore germination. Phragmobasidia were described as basidia with some form of septation, whereas holobasidia lacked septations (169). Heterobasidiomycetes produced basidiospores that could germinate either directly via a germ tube or indirectly via secondary spore production or repetitive germination. Homobasidiomycetes produced basidiospores that germinated directly through germ tube formation only (170). There is considerable positive correlation between the two systems in that most taxa that produce phragmobasidia are heterobasidiomycetes, and most taxa that produce holobasidia are homobasidiomycetes, but with exceptions. When considered in light of current phylogenetic classifications, heterobasidiomycetes are found in all three subphyla of Basidiomycota, and homobasidiomycetes are predominantly found in Agaricomycotina. Interestingly, the current phylogenetic classification of subphyla is most consistent with septum morphology (171, 172). Pucciniomycotina possess a simple septum. Agaricomycotina possess a dolipore septum characterized by a septum wall that swells near the septal pore and is bounded by a septal pore cap that is derived from the endoplasmic reticulum. Ustilaginomycotina possess a range of septum types from simple pores coupled with membranous pore caps to swollen pore margins that lack a septal pore cap.

One final important trait in Basidiomycota taxonomy that we will emphasize here is the clamp connection. Most basidiomycetes possess a vegetative mycelium that is dikaryotic, meaning that each hyphal compartment contains two nuclei. Clamp connections occur in the dikaryon and function in maintenance of the dikaryotic nuclear state. Clamp connections are short, modified hyphal branches that grow away from the hyphal tip and undergo self-fusion with the main hyphae from which they branched. Clamp connection formation involves synchronized nuclear divisions and septum formation and results in a clamp-like morphology at the septum of the main hypha. Clamp connections are found only in

Figure 5 Examples of Basidiomycota diversity. Pucciniomycotina: (**a**) uredinia of *Puccinia iridis*; (**b**) fruiting body of *Phleogena faginea*; (**c**) aecia of *Coleosporium*; (**d**) yeast state of *Symmetrospora oryzicola*. Ustilaginomycotina: (**e**) smut galls of *Ustilago maydis*; (**f**) gall of *Exobasidium*; (**g**) culture of *Moniliella* sp. Agaricomycotina: (**h**) culture of *Wallemia*; (**i**) stinkhorn fruiting body of *Phallus* (photo by Nu Nguyen). (**j**) coral fruiting body of *Clavaria*; (**k**) crust fruiting body of *Amylostereum*; (**l**) club fruiting body of *Clavariadelphis*; (**m**) polypore, conk fruiting body of *Pycnoporus*; (**n**) gilled mushroom fruiting body of *Russula*; (**o**) pored mushroom fruiting body of *Boletus*; (**p**) puffball fruiting body of *Lycoperdon*.

Basidiomycota but are not found in all species or all tissue types (e.g., monokaryon versus dikaryon, vegetative hyphae versus sporocarps, etc.).

Molecular phylogenetic and phylogenomic analyses find greater support for the relationship of Pucciniomycotina as the sister to Ustilaginomycotina and Agaricomycotina than for other arrangements and are consistent with phragmobasidia and repetitive spore germination being symplesiomorphic characters inherited from the MRCA of Basidiomycota. As is also true of Ascomycota, sporocarp formation may have evolved multiple times within Basidiomycota, being rare

but scattered throughout Pucciniomycotina and common among most lineages of Agaricomycotina (e.g., jelly fungi, mushrooms, polypores, etc.). The oldest definitive fossil data for Basidiomycota are septate hyphae with clamp connections from the Pennsylvanian (300 to 360 million years ago) that occur associated with gymnosperms and ferns (173, 174). There also exist fossils of mushrooms from the Cretaceous through the Tertiary (reviewed in reference 16).

Pucciniomycotina

One significant outcome of molecular phylogenetics is the discovery of the true phylogenetic, morphological, and ecological diversity of Pucciniomycotina (101, 175). Currently there are 9 classes and over 8,000 species in which yeast and dimorphic growth forms are common. Basidiocarp formation is rare, but fleshy clavarioid or crust-like forms occur in Pucciniomycetes (e.g., *Eocronartium*, *Septobasidium*), and smaller stilboid and pulvinate basidiocarps are formed in some Atractiellomycetes (e.g., *Phleogena*, *Hobsonia*; Fig. 5b), Agaricostilbomycetes (e.g., *Agaricostilbum*), and Microbotryomycetes (e.g., *Pycnopulvinus*), which presumably represents an independent origin of sporocarps from that of Agaricomycotina. Basidia are almost always phragmobasidia, but unicellular forms (holobasidia) are known. The unifying character of the subphylum is the simple septum, which is morphologically similar to the simple septum of Ascomycota that lacks any septal pore cap. The majority of species are plant-associated as pathogens, endophytes, and phylloplane fungi, but there also exist insect pathogens, orchid mycorrhizae, mycoparasites, and freshwater and marine yeasts. Environmental sequencing studies have revealed unknown Pucciniomycotina diversity in anoxic deep sea habitats, Arctic ice, and other extreme environments including niches characterized by extreme osmotic pressures (reviewed in reference 176). Indeed, the modern concept of Pucciniomycotina comprises fungi that occupy a diversity of ecological niches comparable to Agaricomycotina and Pezizomycotina.

The largest class in Pucciniomycotina is Pucciniomycetes, and the best-studied species are plant pathogens in the order Pucciniales, the "rust" fungi, which collectively attack a wide range of plants from grasses to trees (Fig. 5a and 5c). These fungi exhibit the most complex life cycles among the kingdom Fungi, which include multiple (up to five) spore stages that can occur on more than one host. For example, *Puccinia graminis*, rust of wheat and other grasses, produces monokaryotic spermatia and dikaryotic aeciospores on the alternate host *Berberis*. Aeciospores infect the primary host, *Triticum*, resulting in the production of dikaryotic urediniospores and teliospores. Karyogamy and meiosis occur in teliospores, which overwinter in wheat stubble and germinate in the spring to produce basidia and basidiospores, which reinfect the alternate host. Eradication of the alternate host has been applied as one control method for serious disease caused by rust fungi, the most famous example being the Barberry Eradication Program for stem rust of wheat that was in effect in the United States from 1918 to 1980. This program had a positive impact by reducing the amount of inoculum available for infecting wheat in the United States during its implementation (177). This life cycle of occurring on two hosts is referred to as heteroecious, and the production of all five spore stages is termed macrocyclic. Not all Pucciniales life cycles are this complex, however; some only occur on one host (autoecious), and some have lost certain spore stages (demicyclic and microcyclic). Septobasidiales, also in Pucciniomycetes, represents one of the more divergent ecologies of Pucciniomycotina in that its members parasitize scale insects (100, 178). The fungus parasitizes adults of the insect colony, sterilizing them but not killing them, at least initially. The insect continues to feed on the host plant, providing nutrients to the fungus, which in turn provides shelter to other free-living members of the insect colony.

In addition to Pucciniomycetes, Pucciniomycotina includes eight other classes that exhibit a range of ecologies and morphologies (175). Members of Agaricostilbomycetes were originally described as ascomycetes but are now known to be Pucciniomycotina and include plant saprobes and mycoparasites. Atractiellomycetes display diverse ecological strategies including mycorrhizae of neotropical orchids. Classiculomycetes include hyphal species that associate with leaf litter in freshwater environments but may be capable of mycoparasitism, as well. Cryptomycocolacomycetes are mycoparasites and have been isolated from bark beetle galleries. Cystobasidiomycetes are predominantly mycoparasitic yeasts and include some commonly isolated basidiomycete red yeasts formerly placed in the anamorphic genera *Rhodotorula* and *Sporobolomyces* (Fig. 5d), as well as Cyphobasidiales—a yeast lineage recently identified as comprising a third symbiotic partner in many common lichen species (163).

Microbotryomycetes, the second-largest class, contains primarily plant pathogens and saprobic phylloplane fungi. The plant pathogens include the "anther smuts," *Microbotryum violaceum* and relatives, which were originally classified in Ustilaginomycotina because of the smut-like appearance of the teliospores, a con-

vergent habit of infecting host reproductive tissues. Most orders of the class contain yeast species that are common in environmental sampling and represent a large and poorly characterized diversity (reviewed in reference 179), including the ubiquitous red yeasts of the genera *Rhodotorula*, *Sporobolomyces*, and *Sporidiobolus*. Mixiomycetes are an enigmatic monotypic class that was originally classified in ascomycetes based on the production of a sac-like spore-producing structure, although it appears that these spores are mitotic in origin. *Mixia osmundae* is an intracellular parasite of ferns but has also been detected in environmental sequencing of angiosperms, including bamboo and beach (180). Finally, Tritirachiomycetes are another group that was originally classified as ascomycete molds. No sexual state has been observed for the group. It is isolated from dead plant material and indoor environments and is suspected of being a mycoparasite of ascomycete molds, such as *Penicillium* (181).

Genomic sequencing of Pucciniomycotina is rapidly advancing and includes some of the largest (*Melampsora allii-populina*, 335 Mb; http://genome.jgi.doe.gov/) and some of the smallest (*Mixia*, 13.6 Mb [180]) filamentous fungal genomes sequenced to date. Comparison of pathogenic species of Pucciniomycetes revealed genomic features related to their biotrophic ecology including a large number of SSPs, diminished nitrogen and sulfur assimilation pathways, and expanded families of membrane transporters (182). SSPs along with secreted hydrolytic enzymes and membrane transporters are upregulated *in planta*, consistent with functions in host infection and nutrient acquisition.

Ustilaginomycotina

The subphylum Ustilaginomycotina includes the smut fungi and relatives. The majority of species are plant pathogens, and the term "smut fungi" refers to the black and powdery masses of teliospores produced on the host plant. The smut morphology has been derived convergently in Ustilaginomycotina and Pucciniomycotina (see Microbotryomycetes, Pucciniomycotina) and also occurs in Entorrhizomycetes. This last class contains a small cohort of sedge- and rush-associated smut fungi that cause spore-filled galls to form on host roots. Traditionally placed within Ustilaginomycotina, this group has recently been elevated to phylum status (183), although robust phylogenetic and genomic data are needed to definitively resolve their relationship to other Dikarya. In Entorrhizomycetes, the septal pore is of the dolipore type and lacks a septal pore cap, similar to that of the smut *Tilletia* (Ustilaginomycotina, Exobasidiomycetes [184]).

The cell walls of Ustilaginomycotina are unique in that they contain high proportions of glucose and an absence of xylose, distinguishing them from the rest of the Basidiomycota (185). Their hyphal septa can be swollen near the septal pore, reminiscent of dolipores, and although they lack a septal pore cap, they may possess a membranous pore cap associated with the septal pore (reviewed in 186). They also possess a characteristic host-parasite interaction zone defined by fungal exocytosis of interaction vesicles (179). The genomes of Ustilaginomycotina are some of the smallest among the Basidiomycota, ranging from ~8 Mb and 4,000 genes in animal-associated yeasts of *Malassezia* (187) to 24 Mb and 8,400 genes in phylloplane species of *Tilletiopsis* (http://genome.jgi.doe.gov/programs/fungi/).

The subphylum includes important plant-pathogenic fungi that occur on angiosperms, especially grasses and sedges, with some exceptions. The majority of Ustilaginomycotina species exhibit a dimorphic life cycle that includes a haploid, saprobic yeast phase and a dikaryotic, filamentous biotrophic or pathogenic phase. Yeast phases can be found on numerous plant substrates, and the filamentous phase is initiated by the mating event. Young basidia become thick-walled and darkly pigmented and develop into teliospores. Teliospores germinate promycelia that may be septate (e.g., phragmobasidia of *Ustilago*) or not (e.g., holobasidia of *Tilletia*), depending on the species. The majority of smut fungi produce basidiospores that are capable of repetitive germination, giving rise to secondary spores called sporidia. Sporidia grow and divide as yeasts until mating between two sporidia reconstitutes the filamentous phase.

Ustilaginomycotina consists of four classes: Exobasidiomycetes, Malasseziomycetes, Moniliellomycetes, and Ustilaginomycetes. Most species of Exobasidiomycetes produce holobasidia, and teliospores may be present or absent according to group. *Exobasidium* species (Exobasidiales) are biotrophic primarily on members of Ericaceae (Fig. 5f); they lack a teliospore and sporulate by producing long holobasidia through stomata or from the epidermis (188). *Tilletia* (Tilletiales) is a particularly notorious plant pathogen responsible for karnal bunt of wheat and diseases of other grasses including barley and rice. It is not known to be dimorphic, and basidiospores often conjugate on the basidium, directly giving rise to filamentous dikaryotic growth. Infections can cause large losses in production, and contamination of grains with *Tilletia* teliospores has had a profound impact on agricultural trade due to plant quarantine regulations (189).

Malasseziomycetes are lipophilic yeasts. They are unusual among Ustilaginomycotina in that they are not

plant associated but are found on the skins of mammals including humans. *Malassezia* species are sometimes referred to as dandruff fungi, and the genomes of multiple species have been sequenced with the first, *M. globosa*, sequenced by Procter & Gamble, the manufacturers of Head & Shoulders shampoo (187). Comparative genomics of multiple species have revealed that these fungi are incapable of fatty acid biosynthesis and are dependent upon a lipid-rich diet. To compensate for its inability to synthesize fatty acids, *Malassezia* possesses numerous secreted lipases and other hydrolases for securing host lipids (187, 190). And while *Malassezia* species are only known as asexual yeasts, their genomes do possess the genes necessary for mating. Recently, environmental sampling studies have identified *Malassezia* as a commonly encountered marine fungus, although its function in these ecosystems is unknown (191). Moniliellomycetes also consists of lipophilic yeasts (Fig. 5g) that were traditionally classified with other fungi now placed in Agaricomycotina. However, recent molecular phylogenies suggest it is a distinct class-level taxon in Ustilaginomycotina (192). Most species are known from industrial settings, foods, fats, oils, or substrates with low water activity. The septal pore apparatus of *Moniliella oedocephalis* is of the dolipore type but without pore caps (193), which may further support the current placement within Ustilaginomycotina.

Most Ustilaginomycetes species are dimorphic plant pathogens and usually produce teliospores in the reproductive organs of their host. *Ustilago maydis*, corn smut, is the best-studied species due to corn's importance in agriculture as food and biofuel feedstock. The fungus infects the plant through the developing ovaries but can colonize all parts of the host, resulting in chlorosis, anthocyanin formation, and reduced growth. The production of teliospores occurs in kernels of corn that have been infected by the fungus and coopted for spore production. The result is that a kernel is transformed into a large gasteroid "tumor" or gall filled with teliospores (Fig. 5e). Teliospores are darkly pigmented and produce four-celled phragmobasidia with basidiospores. Basidiospores divide by budding, producing a haploid and saprobic yeast phase. Two yeasts of opposite mating types conjugate to initiate the dikaryotic and pathogenic filamentous phase of the life cycle. Although the pathogens can be quite destructive on grains, some, such as the galls of *U. maydis*, which are a delicacy in Mesoamerica called huitlacoche, are edible and have gained increasing popularity in adventure eating in other parts of the world (194).

Genome analyses of *Ustilago* revealed a small genome of approximately 20 Mb encoding less than 7,000 genes with no known pathogenicity factors (195). Rather, SSPs, which exist in small gene families, were demonstrated to function in pathogenicity. These SSPs are coregulated and expressed in infected tissue, and SSP mutants exhibited a range of phenotypes from reduced to increased virulence. The discovery of SSPs and demonstration of their role in infection and pathogenicity have since transformed the study of biotrophic fungi including pathogens and beneficial symbionts (196).

Agaricomycotina

Agaricomycotina is currently divided into four classes: Wallemiomycetes, Tremellomycetes, Dacrymycetes, and Agaricomycetes. Wallemiomycetes is sister to the remainder of Agaricomycotina and consists of ascomycete-like molds that do not produce sporocarps and are capable of withstanding conditions of high osmotic stress (Fig. 5h) (168). Tremellomycetes and Dacrymycetes include the majority of fungi with gelatinous sporocarps, or jelly fungi, while Agaricomycetes includes some jelly fungi and the remainder of fleshy, sporocarp-producing species (e.g., mushrooms). Tremellomycetes is sister to Dacrymycetes and Agaricomycetes and contains three orders: Cystofilobasidiales, Filobasidiales, and Tremellales. Cystofilobasidiales and Filobasidiales comprise species that are yeasts or are dimorphic, with sporocarp production being unknown. Tremellales includes many of the well-known jelly fungi (e.g., *Tremella mesenterica*, witches butter) and important human pathogens such as *Cryptococcus*. Species of *Tremella* fruit from wood and produce phragmobasidia with longitudinal septations dividing the basidium into four equal compartments with long, slender sterigmata. Many species in the class are either known or suspected to be mycoparasites and likely play a role in parasitizing wood-inhabiting fungi. *Cryptococcus* is a common inhabitant of soils, plant material (e.g., bark), and bird guano. It grows primarily as yeast in host tissue but is dimorphic, producing holobasidia with long chains of basidiospores. *Cryptococcus neoformans* is an important human pathogen, especially of people with compromised immune systems, but *Cryptococcus gattii* is known to infect immunocompetent people who were otherwise healthy (197). Dacrymycetes includes a single order, Dacrymycetales, and is the sister group to Agaricomycetes. Species of this class produce Y-shaped basidia in gelatinous sporocarps that fruit from wood. Dacrymycetales are characterized as brown rot fungi in which wood decay involves the breakdown of cellulose and hemicellose, but not lignin.

Agaricomycetes comprise the majority of fleshy, sporocarp-producing basidiomycetes. The diversity of fruiting bodies includes mushrooms and boletes, polypores and conks, crusts, coral fungi, puffballs and truffle-like fungi, and stinkhorns. Historically, these fungi were classified as hymenomycetes and gasteromycetes in a system attributed to Elias Fries in what is frequently referred to as the Friesian system (198). Hymenomycetes (hymenial fungi) produce basidia and basidiospores on a basidia-producing tissue called the hymenium that is exposed to the environment and forcibly eject their basidiospores. These fungi include the mushrooms, boletes, corals, crusts, polypores, and conks. Gasteromycetes (stomach fungi) produce basidia in an enclosed region of the sporocarp, the gleba, and do not forcibly eject their basidiospores. Spores may be dispersed by wind and rain, as in the puffballs (Fig. 5p), or by animal mycophagy or phoresis, as in truffles and stinkhorns (Fig. 5i), respectively. We now understand that hymenomycetes and gasteromycetes are artificial taxa and that these forms are intermixed through the phylogeny of Agaricomycetes. Molecular phylogenetic analyses resolve the evolutionary transition in spore dispersal from forcibly discharged to passively discharged basidiospores, with gasteromycetes being derived from hymenomycetes on multiple occasions (199, 200). Moreover, most sporocarp morphologies have been derived multiple times, including the mushroom morphology characterized by a stipe, a gilled or pored hymenium, and a cap (Fig. 5n). The evolutionary plasticity of the sporocarp is likely a result of strong evolutionary selection pressures on production and dispersal of basidiospores.

The modern understanding of Agaricomycetes evolution is the result of numerous studies of molecular phylogenetics (e.g., 201) and evolutionary genomics (e.g., 17, 202), with the outcome being significant revisions to the premolecular taxonomy of the class. Currently, there are 21 orders of Agaricomycetes, with 6 orders classified in the subclass Agaricomycetidae, 4 in Phallomycetidae, and the remaining 11 treated as *incertae sedis*. Auriculariales, Sebacinales, and Cantharellales represent some of the first orders to diverge since the MRCA of Agaricomycetes, but the branching order of these taxa is unresolved. Auriculariales and Sebacinales include species that produce gelatinous sporocarps and, in some species, phragmobasidia, providing further evidence that these traits are ancestral for Agaricomycetes. Cantharellales is best known for prized edible forest mushrooms of *Cantharellus*, but the order includes numerous morphologies including toothed fungi (e.g., *Hydnum*), coral fungi (e.g., *Clavulina*), and crusts (e.g., *Botryosphaeria*). Phallomycetidae is one of the more morphologically diverse clades and contains four orders: Phallales (the stinkhorns; Fig. 5i), Geastrales (earthstars), Gomphales (coral fungi of *Ramaria* and cantherelloid fungi of *Gomphus*; Fig. 5j and 5l), and Hysterangiales (basidiomycete truffles). Agaricomycetidae contains many of the best-known mushroom-forming taxa, including Agaricales and Boletales, but the modern definition of these orders includes numerous other morphologies. For example, Agaricales also includes bird's nests of *Nidularia*, puffballs of *Lycoperdon* (Fig. 5p), coral fungi of *Clavaria* (Fig. 5j), truffles of *Hydnangium*, and oyster mushrooms of *Pleurotus*. Likewise, in addition to the pored mushrooms of boletes (Fig. 5o), Boletales includes truffles of *Rhizopogon*, earthballs of *Scleroderma*, and resupinate fungi of *Serpula*.

Other orders of Agaricomycetidae include crust-forming fungi (Atheliales and Jaapiales) and clavarioid basidiolichens (Lepidostromatales).

The remaining orders of Agaricomycetes mostly include nongilled fungi that were once accommodated in the concept of Aphyllophorales, an old order name meaning "without gills" (203). These include the polypores (Fig. 5m), conks, and shelf fungi (Gloeophyllales, Hymenochaetales, Polyporales, Stereopsidales, Thelephorales, Trechisporales) and the crust or parchment fungi (Corticiales). Perhaps the most remarkable order of Agaricomycetes is Russulales. This order of fungi contains all known major morphologies of fleshy sporocarps, including mushrooms (*Russula* and *Lactarius*), polypores (*Bondarzewia*), tooth fungi (*Auriscaplium*), crusts (*Aleurodiscus*), coral fungi (*Clavicorona*), and truffles (*Gymnomyces*), and it demonstrates the "tricks" that evolution has played on fungal taxonomists. Interestingly, most of the fungi of Russulales form basidiospores with wall ornamentation that stain blue to black in iodine solution, the positive amyloid reaction. For a more complete review of Agaricomycetes systematics and taxonomy see Hibbett et al. (204).

Agaricomycetes are dominant forest fungi, where they function as ectomycorrhizal symbionts, tree pathogens, and agents of wood and litter decay. Comparative and evolutionary genomics have provided significant insight into the evolution of these ecologies. Saprobic, or plant-decomposing, Agaricomycetes appear to be the ancestral ecology, with symbiotic lifestyles such as ectomycorrhizae being more derived. Wood-decay Agaricomycetes are categorized into two major groups, white rot and brown rot, although comparative genomic analyses of wood-decay species reveal the inadequacy of a simple two-category system (205). White rot fungi

are capable of breaking down cellulose, hemicellulose, and lignin at roughly equal rates. Brown rot fungi do not break down lignin to any appreciable degree. The ability to efficiently break down lignin is attributed to major innovations of wood- and lignin-degrading enzymes, the fungal class II peroxidases (PODs), in the common ancestor of Agaricomycetes (17). Phylogenomic analyses support a diversification of PODs in the late Permian, leading to the hypothesis that the rise of wood-decay fungi and the diversification of their enzymatic machinery resulted in dramatic decreases in lignified coal deposits at the end of the Permian (17). Brown rot fungi have been derived multiple times through the loss of fungal PODs and the ability to degrade lignin. Major white rot orders include Auriculariales, Hymenochaetales, Corticiales, Polyporales, Russulales, and Agaricales, while brown rot has evolved independently in Gloeophyllales, Polyporales, and Boletales.

Ectomycorrhizae ("outer" + "fungus" + "root") are fungi that form symbioses with forest trees, especially species of Pinaceae and Fagaceae. They associate with the fine roots of the plant, but they do not penetrate the cells of the plant—thus the term "ecto." Rather, they form a sheath around the cortex cells of the fine roots. The symbiosis is based on an exchange of common goods, with the fungus providing water and mineral nutrients (e.g., phosphorus, nitrogen, etc.) to the plant and the plant providing sugars (e.g., glucose) to the fungus. Ectomycorrhizae have been derived numerous times during the evolution of Agaricomycetes, including within Agaricales, Boletales, Russulales, Hymenochaetales, and Cantharellales, and from both white rot and brown rot ancestors. Comparative genomics have revealed some consistent themes that allow a fungus to adopt an ectomycorrhizal lifestyle (197). First, these fungi lose much of the enzymatic machinery (carbohydrate active enzymes), especially cellulases, associated with the breakdown of plant cell walls. Second, they have evolved SSPs that interact with the plant's host defense system. Together these attributes allow the fungus to colonize plant roots and not be identified by the plant as a hostile intruder. Also, many ectomycorrhizal fungi exhibit significant genome expansions, but not in gene content. These genome expansions are due to an increase in the abundance of transposable elements. The function of these transposable elements is unknown, but it hypothesized that they may promote genomic adaptations.

SUMMARY

Molecular and genomic analyses of the fungal tree of life have shown that numerous morphologies emphasized in premolecular classification (e.g., zoospores, zygospores, fruiting body morphology, etc.) are not diagnostic of monophyletic groups. Rather, the taxa that possess these traits experienced more complicated patterns of diversification and are frequently paraphyletic. The first three lineages to diverge since the LUCA of kingdom Fungi comprise mostly zoosporic fungi, Cryptomycota, Blastocladiomycota, and Chytridiomycota. While losses of flagellum are known within the zoosporic clades and presumably in the MRCA of the remaining phyla of nonflagellated fungi, the definitive number and placement of flagellum losses are currently disputed due to insufficient taxon and data sampling (e.g., the genus *Olpidium*). Zygomycete fungi comprise two separate phyla of nonflagellated fungi: Zoopagomycota and Mucoromycota. They display differences in host and substrate associations—Zoopagomycota with animals and fungi, Mucoromycota with plants and plant substrates—and may represent morphologies and lifestyles of the first terrestrial fungi. Ascomycota and Basidiomycota form the Dikarya and possess the most derived traits, representing the apex of morphological complexity among the fungi.

Our understanding of fungal evolution has been significantly influenced by molecular and genome technologies, in both unraveling the aforementioned phylogenetic relationships and illuminating processes of adaptation and diversification. The sequencing of fungal genomes is quickly becoming routine, representing the starting point for an increasing number and types of studies. This is resulting in a rapid increase in the number of species that can be incorporated into genome-scale phylogenies, as evidenced by MycoCosm, with more than 800 fungal genomes (http://genome.jgi.doe.gov/fungi/). Continued taxon sampling should exploit existing resources of biological culture collections to continue populating the fungal tree of life with genome data from unsampled species and lineages. Doing so will not only incorporate the global collecting effort of mycologists across generations, but it will also add significant value to existing isolates, making them more amenable to inclusion in a wider range of research. The next wave of genome sampling must also incorporate a greater diversity of fungi that cannot be maintained in culture. This will require sampling of sporocarps and spores and will in most cases represent metagenomes with resident populations of bacteria and other eukaryotes. While this approach is more computationally intensive, extraction of phylogenetically informative markers is tractable (139). Furthermore, significant progress has been made in grouping sequences by organism to achieve accurate assemblies

of the composite of individuals within a metagenome (206, 207), and increased sporocarp sampling will provide more data examples for refinement of algorithms and computational pipelines. Continued advancements in genome-scale phylogenies of fungi are not completely dependent upon sampling alone, however. Advancements in models of evolution are needed to understand conflict among data partitions more accurately and better discern between complicated processes such as incomplete lineage sorting and insufficient phylogenetic signal (6).

All phylogenetic analyses are inherently biased by what has been called the "invisible dimension of fungal diversity" (208). Environmental sampling of ecosystems and niches is consistent with the existence of numerous unknown higher-level lineages (209). While some of these have been brought into culture and expanded our knowledge of sparsely populated lineages (e.g., 25, 111), an urgent need to culture more of these fungi exists, resulting in biological resources necessary for functional analyses. Currently, the incorporation of unknown fungi into phylogenetic analyses is limited to a few loci of limited phylogenetic informativeness that can be obtained through amplicon-based sampling approaches. The holy grail of metagenomic sampling would be the sequencing of, and access to, the complete genomes of all or most of the organisms in a sample. Such data would have considerably more explanatory power within and beyond phylogenetics (e.g., ecological genomics, EvoDevo, etc.).

Finally, a greater need for integration of other types of data (e.g., fossils, ecology, physiology, etc.) with genomic data and genome-scale phylogenies exists. Fossils of fungi are more rarely reported than those of plants and animals, but the number of researchers studying paleomycology is as much of a limiting factor as the fossilization rate of fungi. As more fossils are described, greater effort should be given to integration of these data in phylogenies and the development of relaxed clock methods so that major events in fungal evolution can be incorporated more accurately into other biological and geological events of the Earth's history. Fungal ecology and ecological genomics are rapidly growing, and significant advancements have been made in understanding evolutionary transitions to mycorrhizal symbioses, wood decay, and plant pathogenesis. Systematic integration of metagenomic (e.g., short sequence read libraries, metatranscriptomes, etc.) with genome-derived phylogenies is needed, however, to better understand the distribution of fungi and fungal metabolic traits across ecosystems and ecological niches.

Six Key Traits of Fungi: Their Evolutionary Origins and Genetic Bases

2

László G. Nagy,[1] Renáta Tóth,[2] Enikő Kiss,[1] Jason Slot,[3] Attila Gácser,[2] and Gábor M. Kovács[4,5]

INTRODUCTION

The fungal lineage is one of the three large eukaryotic lineages that dominate terrestrial ecosystems. They share a common ancestor with animals in the eukaryotic supergroup Opisthokonta and have a deeper common ancestry with plants, yet several phenotypes such as morphological, physiological, or nutritional traits make them unique among all living organisms. This article provides an overview of some of the most important fungal traits, how they evolve, and what major genes and gene families contribute to their development. The traits highlighted here represent just a sample of the characteristics that have evolved in fungi, including polarized multicellular growth, fruiting body development, dimorphism, secondary metabolism, wood decay, and mycorrhizae. However, a great deal of other important traits also underlie the evolution of the taxonomically and phenotypically hyperdiverse fungal kingdom, which could fill up a volume on its own. After reviewing the evolution of these six well-studied traits in fungi, we discuss how the recurrent evolution of phenotypic similarity, that is, convergent evolution in the broad sense, has shaped their phylogenetic distribution in extant species.

THE EVOLUTION AND DE-EVOLUTION OF MULTICELLULARITY

Multicellular life dominates most ecosystems on Earth, and its evolution is considered to be one of the major transitions in the history of life. Multicellularity confers several competitive advantages. Among others, it allows the division of labor between cells, increased size and complexity, a longer life span, or an advantage in avoiding predation. It has been estimated that multicellularity evolved in some form 25 to 30 times both in the prokaryotes and the eukaryotes, but most of those lineages are simple aggregates or colonies of cells that show little phenotypic or functional differentiation. Fungi represent one of the few lineages that have achieved higher levels of multicellular complexity. Like animals and plants, fungi evolved integrated multicellular structures that enable them to adapt to diverse ecological niches. However, unlike animals and plants, fungi evolved complex multicellularity through filamentous intermediate stages. Fungal filaments (hyphae), unlike filamentous forms in other lineages, develop by polarized apical growth, and individual cells are divided from the elongating hypha by developing cross-walls (septa), a unique solution for filamentous growth seen mostly in higher fungi (1). Hyphae have been hypothesized to have emerged through gradual elongation of substrate-anchoring rhizoids of ancestral unicellular fungi such as chytrids (2).

Similar, apically growing hyphae have evolved in the Oomycetes (Stramenopila), but oomycete hyphae are not septate, allowing the transport of compounds and organelles along the hyphae. Such aseptate hyphae are a multinucleate, coenocytic architecture, similar to hyphae of early-diverging fungal groups (e.g., Mucoromycota). Within fungi, hyphae evolved convergently

in multiple groups (Fig. 1A,B), one of them comprising most of the well-known filamentous fungi. Other hyphal groups include the Monoblepharidomycetes, an early-diverging lineage of aquatic fungi in which several species have switched to filamentous growth (3), and certain chytrid-like fungi.

Fungal mycelia—intricate branching networks of hyphae—are adapted to efficiently explore the available space in the substrate. Foraging for nutrients may have driven the emergence of multicellularity in fungi, although transition to terrestrial habitats and exploitation of prokaryotic biofilms have also been proposed as the necessary selection pressures for their emergence (4). The first multicellular hyphae evolved in the common ancestor of the Zoopagomycota, Mucoromycota, and the Dikarya and were probably similar to those of extant Mucoromycota mucoralean fungi such as the bread mold *Rhizopus stolonifer*. Early filamentous species have relatively simple, little-differentiated mycelia of tube-like cells that are not (or are minimally) compartmentalized by septa. More derived fungi evolved various solutions to block the free diffusion of materials in hyphae, which would also minimize the risk of the free passage of external invaders (5). Specialized structures around septa, including Woronin bodies and the dolipore septum among others, serve to regulate transport between cells in the hyphae of Asco- and Basidiomycota, respectively, although exceptions to this rule exist. *Neolecta vitellina*, a basal ascomycete (Taphrinomycotina), produces crystalline bodies analogous to Woronin bodies but which are of vacuolar origin and only loosely bound to the membrane (6). Although structurally different, all three solutions provide the means to finely coordinate the transport of goods and to block the diffusion of organelles from one cell to the other.

Polarized Growth and the Underlying Cellular Components

Polarized hyphal growth of fungi is a unique innovation in the history of life, with similar solutions seen only in a few other groups such as Oomycota and the pollen tubes of seed plants and axons of some neurons. The orchestration of hyphal growth involves several cellular pathways and entailed the evolution of several novel traits, including the establishment of polarity, apical extension, the coordinated transport of material to the sites of active growth, the establishment of branching, and septation patterns. In hyphae, growth occurs in the apical zone, coincident with a strong gradient of cell wall material deposition toward the tip. Apical growth is achieved by the expansion of the hyphal tip, which is predominantly driven by turgor pressure within the cell that, in turn, is regulated by the osmotic mitogen-activated protein kinase cascade (7). Cell wall materials are transported by secretory vesicles to the growing tip along cytoskeletal structures (7). One of the core signal transduction pathways connected to polarity establishment is the Ras/Rho GTPase pathway described in *Saccharomyces cerevisiae*, which is also conserved in filamentous fungi. This pathway is responsible for polarity establishment and maintenance by the formation of a stable polarity axis that specifies the site of germ tube emergence. This positional information is generated by the recruitment of cell polarity proteins (Bud4, Axl2, swoC in *Aspergillus nidulans*) at the site of polarized growth (8) and then is transduced via regulatory Rho GTPases (RacA *A. nidulans*, CDC42 *S. cerevisiae*) toward the morphogenetic machinery, which is the main organizer of tipward secretion, cell wall expansion, and tip growth (1, 9).

The key contributor to the hyphal morphogenetic machinery is the Spitzenkörper (10). It is hypothesized to serve as a vesicular distributor between the microtubular vesicular transport system and the actin patches accumulated at the apex, and therefore it is responsible for the growth directionality of hyphae. These vesicles transport structural and landmark proteins, proteins that facilitate membrane docking and fusion, different enzymes (chitin synthase), and Ca^{2+}, components that are essential for hypha elongation. The microtubule network connected to the Spitzenkörper has an indirect role in polarity maintenance and hyphal growth and is responsible for the long-range vesicular transport to the apex (11).

In addition to the microtubular network, the actin cytoskeleton is also connected to the Spitzenkörper. It has a crucial role in taking vesicles delivered to the apex via myosin-based transport and guiding them to polarization/secretion sites serving as a bridge between the Spitzenkörper and the extension site of the hyphal apex. The actin cytoskeleton is regulated by different polarity-establishing and -maintaining factors: the polarisome and the Arp2/3 protein complex. Both of these complexes have a role in actin polarization; the polarisome is responsible for the organization of the actin cytoskeleton to the expansion site by formin-dependent actin polarization (SepA and MesA in *A. nidulans*; Spa2, Bud6, and Bni1 in *Neurospora crassa*). The Arp2/3 complex in turn controls the building of cortical actin patches at the apex which have a crucial role in endocytosis (12).

Precise coordination of vesicle delivery to the expansion site is essential for polarized growth. The key

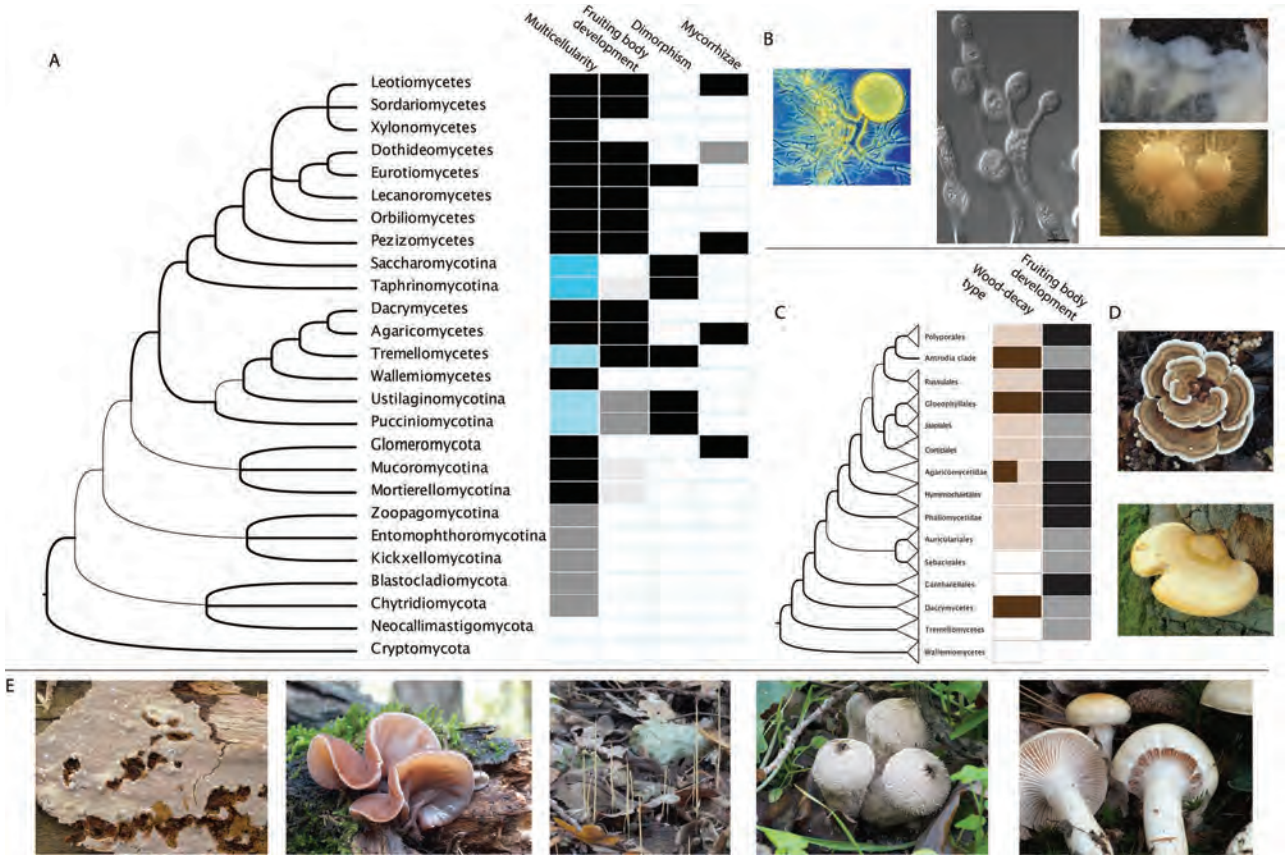

Figure 1 Overview of the phylogenetic distribution of the traits presented in this article. (**A**) Phylogeny of the major fungal groups and the phylogenetic distribution of the traits discussed in this article. Tree modified and redrawn from MycoCosm (http://genome.jgi.doe.gov/programs/fungi/index.jsf). Thick branches denote well-known relationships, while thin branches mark uncertainties in our understanding of fungal relationships. Presence or absence of a given trait is highlighted by black or white shading, respectively. Gray shading denotes rare or not fully developed states of the given trait, while blue denotes the secondary partial loss of multicellular growth in yeasts. (**B**) The evolution of hyphae from unicellular ancestors (left, *Spizellomyces punctatus*; photo courtesy of Don Barr, http://www.bsu.edu/classes/ruch/msa/barr/4-15.jpg). Hyphae evolved in several groups, including the Monoblepharidomycetes (middle, *Monoblepharella* sp.; [from reference 3]) and the crown fungi (top right, *Psathyrella spadiceogrisea* mycelium growing on sawdust). Also shown are hyphal and yeast-like colonies of the dimorphic fungus *Aureobasidium pullulans* (bottom right). (**C**) Detailed view of the major orders, their wood-rotting characteristics, and the distribution of agaricoid fruiting body morphologies of the Agaricomycetes. Brown and beige represent brown and white rot lineages, respectively, whereas empty rectangles denote groups that do not degrade wood (Wallemiomycetes, Tremellomycetes) or cause an uncharacterized type of wood decay or mycorrhiza (Sebacinales and Cantharellales). (**D**) Examples of typical white (*Trametes versicolor*, top) and brown (*Piptoporus quercinus*, bottom) rot Basidiomycota. (**E**) Examples of the diversity of fruiting body morphologies in the Agaricomycetes, including from left to right, resupinate (*Cylindrobasidium evolvens*); auricularioid, jelly fungi (*Auricularia auricula-judae*); club and coral fungi (*Typhula phacorrhiza*); puffballs (*Lycoperdon perlatum*); and agaricoid morphologies (*Hygrophorus* sp). Photos: L. Nagy unless stated otherwise.

regulators of this process are the Coatomer complex that mediates vesicle formation (SEC proteins, Sec21 in *N. crassa*), the exocyst complex (SEC proteins, Exo-70, and Exo-84 in *S. cerevisiae*; RabA/B in *A. nidulans*), which is a conserved multiprotein complex with a role in vesicle targeting and vesicle distribution from the Spitzenkörper, and finally, the SNARE complex (nsyn1 and nsyn2 SNAREs in *N. crassa*), which facilitates vesicle fusion with specific membrane types (13).

The rapid rate of hyphal extension requires a large amount of cell wall components deposited at the extension site. According to the steady state theory of hyphal wall growth, the plastic wall material (chitin, 1-3beta glucan) has to be synthesized and delivered continuously to the apex to elongate the hypha. After deposition, cross-linking mechanisms rigidify the proto cell wall material, and only the hyphal apex is plastic enough to grow continuously. This process is coordinated by various cell wall-synthesizing enzymes: glucanases and different types of chitin synthases (chsB/D/E in *A. nidulans* and chs1 in *N. crassa*).

Along with the elongated morphology, septation and branching patterns are also characteristic morphological features of filamentous fungi. Mitotic signals and cortical markers are the inducers of septation, and the morphogenetic machinery behind this process is composed of actin cytoskeleton, septins (aspA-E in *A. nidulans*), and formins (sepA/D/G/H) (14). Septation and branching are two morphogenetically connected events. In septum-forming fungi, the branching event occurs just after septation and starts with the generation of a new polarity axis, followed by the recruitment of the morphogenetic machinery to induce branch emergence. In *N. crassa*, the characteristic pod proteins (pod4/5/8) are required for branch formation, but interestingly, they have no obvious role in the morphogenesis of primary hyphae (8).

The De-Evolution of the Multicellular Life Stage

Many fungal groups seem to have secondarily lost multicellularity. These are collectively known as yeasts, and they are some of the best-studied and economically most important eukaryotic organisms such as S. *cerevisiae* and *Schizosaccharomyces pombe*. The term "yeast" covers a polyphyletic assemblage of phenotypically similar fungi, many of which are only distantly related to each other. It usually refers to species that are unicellular through most of their life cycle and divide through budding or fission. Such species evolved in many major groups, including the Asco- and Basidiomycota and certain Mucoromycota, and can be found in large clades such as the Saccharomycotina or derived as smaller groups within diverse clades of filamentous fungi. The most widely known ascomycete yeasts include the genera *Saccharomyces*, *Candida*, *Pichia*, and *Yarrowia* in the Saccharomycotina subphylum; *Schizosaccharomyces* in the Taphrinomycotina; as well as several species in phylogenetically dispersed clades (for details see reference 15). Basidiomycete yeasts occur in two large clades: the Pucciniomycotina (e.g., *Rhodotorula* and *Sporobolomyces*) and the Tremellomycetes (e.g., *Cryptococcus* and *Xanthophyllomyces* [formerly *Phaffia*]). Yeasts evolved from multicellular filamentous ancestors; the independent origin of similar cellular morphologies in diverse groups is a fascinating example of convergent evolution and probably reflects adaptation to similar niches. With their unicellular habit, morphology, and limited dispersal abilities, yeasts are adapted to liquid environments and to the absorption of simple sugars, in contrast to filamentous fungi, which can forage for nutrients over larger distances and drier environments. In nature, yeasts are mostly found in aquatic habitats or moist, sugar-rich environments such as fruits, floral nectars, and other plant exudates or as members of the intestinal microbial flora of animals.

Most people view yeasts as unicellular eukaryotes that have greatly contributed to our understanding of several conserved cellular processes of eukaryotes. Because of this, yeasts are often viewed as the de-evolution of multicellularity in fungi. However, most yeasts, even those that grow as single-celled organisms during most of their life cycle, are able to switch to filamentous growth as a response to changing environmental conditions (for details see the section on dimorphic fungi). Some of them produce only pseudohyphae, elongate to cylindrical cells that are more similar to elongated yeast cells than to real hyphae. However, many species can grow typical hyphae too. Thus, most yeasts are not unicellular in the traditional sense (16).

The mostly unicellular Saccharomycotina group contains *Eremothecium gossypii* (*Ashbya gossypii*), a species that produces elongate, unseptate hypha-like cells that resemble the true hyphae of filamentous fungi. The phylogenetic position of *E. gossypii* within yeasts suggests that its filamentous cells represent a step toward the re-evolution of hyphal growth, although molecular studies suggest that the filaments of *E. gossypii* are more similar to elongated yeast cells than to true hyphae (9).

Yeasts have small, streamlined genomes compared to filamentous fungi, containing 6,000 to 8,000 genes, on average. Their evolution from filamentous ancestors

represents a classic example of convergent evolution and has been marked by extensive gene losses, on average, 3,000 to 5,000 lost genes per lineage, which affected a wide array of genes related to complex polysaccharide metabolism such as genes coding for plant cell wall-degrading enzymes (PCWDEs), secondary metabolism, oxidoreductases, cyclophilins, or hydrophobins (17). Their highly streamlined genomes, however, contain many genes required for hyphal morphogenesis, suggesting a close relationship between multicellular hyphal growth and yeast divisions and/or pseudohyphal growth. Recent results suggest that the convergent evolution of yeast-like fungi is a result of parallel deployment of dormant developmental potentials, rather than the result of the independent evolution of similar genetic toolkits. Convergent diversification of conserved (Zn-cluster) transcription factor families might have led to the potential for yeast-like growth to become dominant in the life cycle at the cost of partial or complete loss of hyphal growth (17). It has also been shown that the genes required for yeast-like growth, including chitin and glucan synthases, as well as chitinases and glucanases involved in separating mother and daughter cells, evolved early in fungi and are shared by most—both filamentous and yeast-like—fungi, which raises the question of what function these genes are responsible for in nonyeast fungi. Because of the similarity between yeast budding and fission and conidium and arthrospore generation, it is tempting to speculate that the cradle for yeast-like growth could have been the morphogenetic machinery of asexual reproduction, although this needs to be tested.

FUNGAL DIMORPHISM

Dimorphic fungal species have the ability to reversibly switch between hyphal and yeast or yeast-like morphologies in response to different stimuli (Fig. 1B), particularly shifts in environmental conditions. Dimorphism is a frequent characteristic of pathogenic fungal species of plants, insects, and humans and other mammalian hosts, and it contributes to their capacity to cause tens of millions of infections annually worldwide. Generally, in dimorphic pathogens of insects and humans and other mammals, the yeast phase is considered to be more pathogenic because this form is able to spread throughout the body, resulting in systemic infection. The role of filamentous growth is also fundamental: besides promoting host tissue adhesion, this form also contributes to transmission to new hosts, maintains survival in the environment, and is required for mating and thus for genetic diversity.

In phytopathogenic fungi, the role of yeast forms in pathogenicity is species specific. Usually it is the mycelial phase that infects plant tissues. In both morphological states one can distinguish between yeast-phase-specific and hyphal-phase-specific gene expressions, while most of the housekeeping genes remain constitutively expressed regardless of the cell type. The expression of phase-specific genes depends on the morphotype and might be associated with virulence.

The six primary pathogens in the Ascomycota that are traditionally classified as dimorphic fungi and cause systemic disease in humans are *Blastomyces dermatitidis* (blastomycosis), *Coccidioides immitis* (coccidioidomycosis, or valley fever), *Histoplasma capsulatum* (histoplasmosis), *Paracoccidioides brasiliensis* (paracoccidioidomycosis), *Sporothrix schenckii* (sporotrichosis), and *Penicillium marneffei* (penicilliosis) (18).

Molecular Mechanisms of Switching Between Yeast and Hyphal Stages

A common mnemonic used for thermally dimorphic fungi is "mold in the cold, yeast (yeast-like) in the heat." In general, the majority of these species are environmental saprobes of the soil, water, etc. and grow as molds at 20 to 25°C. Once the environmental milieu is disrupted and the conidia (e.g., spores) or hyphal fragments are inhaled by or inoculated into humans or other mammalian hosts, dimorphic transition from hyphal growth to yeast or spherule (*Coccidioides* spp.) occurs at 37°C (19, 20).

Following uptake by alveolar macrophages, a large number of fungal transcripts appear that promote adaptation to the new restrictive environment (21). These transcripts induce hyphae to yeast dimorphic transition, cell wall rearrangement, sporulation, and the expression of other possible virulence-effecting genes that alter metabolic pathways. All are required for successful immune evasion, intracellular survival, and systemic dissemination (18). Dimorphic transition is mainly temperature dependent, although other nonthermal signals such as increased CO_2 tension, oxidative stress, and mammalian hormones such as estradiol or L-DOPA could contribute (22–24).

Inside the host, the yeast-like phase is fundamental for successful invasion. During the transition, besides changes in cell size and shape, a large number of yeast-phase- or spherule-phase-specific genes are activated, resulting in cell wall reassembly and alterations in certain signaling pathways (18, 20). For example, β-glucans are one of the most relevant pathogen-associated molecular patterns in the fungal cell wall that are recognized quickly by the host immune cells and enhance efficient

clearance (25). However, in the yeast phase of certain dimorphic fungi, the amount of α-glucan in the cell wall is elevated, which may conceal the immune recognizable β-glucans from the host (26, 27).

Because pathogenicity of these fungi is possibly a consequence of adaptation to the host environment, most signaling pathways associated with virulence are suggested to be sensors of environmental stress. These pathways can include, for example, the protein kinase C cell wall integrity, the cyclic AMP protein kinase A (PKA), calcium-calcineurin, and other two-component pathways. The two main intracellular signaling pathways associated with morphology transition are the cyclic AMP-PKA and the mitogen-activated protein kinase (MAPK) cascade pathways (22). Detection of changes in the amount of the available carbon or nitrogen sources leads to elevated cyclic AMP levels intracellularly, which stimulates PKA. PKA then activates the transcription of factors needed for the dimorphic switch. MAPK cascades consist of several kinases responding to various environmental stimuli and induce a wide variety of response mechanisms. Such kinases include mainly serine, threonine, and tyrosine kinases but also kinases that phosphorylate histidine residues of proteins. A hybrid dimorphism-regulating histidine kinase (*DRK1*) in *B. dermatitidis* was identified and considered to be a global regulator of morphology switch (18). *DRK1* is highly conserved among three dimorphic fungi species and plays a key role in sporulation, hyphae-to-yeast transition, cell wall integrity, and virulence.

Recent studies and observations cumulatively suggest that mammal-infecting dimorphic fungi have evolved several strategies to evade the host immune responses. Such strategies include masking their pathogen-associated danger signals, altering fungal signaling pathways, and promoting intracellular survival. An additional example is the oxidative stress-evading strategy of *H. capsulatum* and *P. brasiliensis* (28–30). Both species evolved their own nitric oxide reductase and several catalase enzymes to overcome the effect of reactive oxygen and nitrogen species produced by host cells.

Dimorphism Is Widespread among Fungi

Another mnemonic that refers to dimorphic fungal pathogens is "Body heat probably changes shape." This phrase allows the inclusion of certain *Candida* spp. in the group of dimorphic species because of the ability of switching morphology in the opposite direction, from yeast to filamentous growth (Fig. 1A). Of these species, *Candida albicans* is known as polymorphic because it is able to exist in yeast, hyphal, or pseudohyphal forms and is the primary species responsible for candidiasis of the oral mucosa, skin, and genitalia. Despite being a human commensal, *C. albicans* and other non-*albicans Candida* spp. are able to cause severe disease in immunosuppressed patients (31–34). Filamentous growth is required for host tissue adhesion and penetration. Although by definition, pseudohyphae are considered to be elongated blastospores, their contribution to tissue damage and penetration along with true hyphae has also been confirmed by numerous studies.

Commonly occurring *Candida* spp. that are able to exist in all three forms, in addition to *C. albicans*, include *Candida dubliniensis* and possibly *Candida tropicalis*, while species capable of switching between only yeast and pseudohypae are *Candida parapsilosis*, *Candida guilliermondii*, and *Candida lusitaniae* (35).

Other examples of ascomycetes reported to be dimorphic and frequently associated with pathogenic behavior are *Exophiala dermatitidis* (Chaetothyriomycetes), *Lacazia loboi* (Eurotiomycetes), and *Aureobasidium pullulans* (Dothideomycetes). All of these species are associated with subcutaneous infections. Besides ascomycetes, morphotype-associated pathogenicity is also observed among basidiomycetes that infect mammalian hosts. Although *Cryptococcus neoformans* is not considered to be a dimorphic fungus, this species has a unique property of forming "giant," or "titan," cells in the host. Further studies have also described morphotype-associated pathogenicity among certain Zygomycota and dermatophyte species (36, 37).

Plant Pathogenic Dimorphic Fungi

Dimorphic fungi are also common pathogens of important crops. In contrast to pathogenic fungi of mammals, phytopathogens are usually considered saprobic in the unicellular yeast phase but parasitic in the filamentous stage inside the plant. The role of the yeast form in pathogenicity is species specific and may contribute to dissemination (38). In the majority of cases, to penetrate the structural barrier of plant cells, hyphal growth is needed. Examples include *Taphrina deformans*, a common phytopathogen responsible for peach leaf curl, and *Ustilago maydis*, which is associated with corn smut disease. Once reaching the plant surface, both *U. maydis* and *T. deformans* switch from budding yeast to filamentous growth (21). The phenomenon is induced by mating in *U. maydis*, although not in *T. deformans* (39, 40). *Ophiostoma ulmi* and *Ophiostoma novo-ulmi* are the main causative species of Dutch elm disease. Additional factors that promote morphology change in *Ophiostoma* spp. include lipoxygenases, cyclooxygenases, nitrogen sources, and quorum sensing molecules (41). Filamentous forms of *Ophiostoma* spp.

invade between the vascular structures, while blastospores disseminate in the xylem network of the infected elm trees.

Current scientific research is concerned about exploring the underlying conditions and exact altered signaling mechanisms that help dimorphic fungi to adapt to the host environment. Several mechanisms for yeast-hyphal switches have already been revealed, although our full understanding of morphotype-associated pathogenicity and thus the origin of virulence is still incomplete.

FRUITING BODIES

Fruiting bodies are some of the most spectacular morphological structures of fungi. Compared to indeterminately growing vegetative mycelia, sexual fruiting bodies result from temporally and spatially integrated developmental programs. In this regard, they resemble multicellular animals and plants, but their role in the species' life cycle is different. Whereas for plants and animals the complex multicellular phase of the life cycle comprises the reproducing individual, the role of fungal fruiting bodies is restricted to sexual reproduction. Therefore, unlike vegetative mycelia, fruiting bodies are quite ephemeral; their life span usually ranges from a few hours to a few days (except highly resistant bracket fungi, which can be perennial). They support the development and dispersal of meiospores in terrestrial environments by providing protection and a skeleton on which spore-producing basidia or asci develop.

Fruiting bodies of some sort evolved in most clades of terrestrial fungi (Fig. 1A,C), but it is the Dikarya in which the most typical manifestations and >99% of the fruiting body-forming species are found, with the two largest groups being the Agaricomycetes and the Pezizomycotina. It is less well known that fruiting bodies have evolved in several other clades as well, such as the Taphrinomycotina, the Pucciniomycotina, and the "Zygomycota." The earliest diverging clades in which fruiting bodies developed are the Mucoromycotina and the Mortierellomycotina, to which *Endogone* spp. and *Modicella* spp. belong, respectively. These species form small irregularly lobed or truffle-like structures that contain zygospores (42). Fruiting body-forming members of the Pucciniomycotina (rusts and allies) usually form up to a few millimeters-tall cylindrical or capitate structures (e.g., Phleogena, Gymnosporangium) or crust-like, corticioid layers on the substrate (e.g., Septobasidium). The Taphrinomycotina contain the genus *Neolecta*, one of the most enigmatic fungi, which forms vividly colored, tongue-like ascocarps (6, 43).

Although fruiting bodies can be found in most clades in the Dikarya and even in earlier-diverging clades, the evolutionary origins of their development are not well known. The patchy phylogenetic distribution of fruiting body-forming fungi suggests multiple independent origins, which is further supported by the apparent lack of homologies between fruiting bodies in separate clades. Given the widespread occurrence of fruiting body-producing lineages, however, the alternative hypothesis that the last common ancestor of all Dikarya species was able to produce fruiting bodies cannot be ruled out.

Diversity and Evolution of Fruiting Body Types

Fruiting bodies serve two major goals: the protection of developing reproductive organs and the promotion of spore dispersal either by providing an enlarged supporting surface for the sporogenous tissue (e.g., hymenium) and/or by lifting it above ground level. Several alternative solutions have evolved for these tasks during evolution, ranging from simple aggregations of basidia or asci on a hyphal mat (subiculum) to highly integrated complex types that consist of several (>10) distinct cell types (44). The simplest such solutions in the Basidiomycota comprise crust-like, flat fruiting bodies that enclose basidia into a sporogeneous tissue (resupinate type [45–47], e.g., *Phanerochaete*, *Peniophora*), whereas in the Ascomycota, cleisthothecia (closed sac-like structures) are the simplest fruiting body types (43, 48). Relative to these simple types, a graded series of increasingly more complex morphologies have evolved in several clades (Fig. 1C-E), which will be detailed in the next paragraphs.

The evolution of fruiting body types has followed different principles in the Asco- and Basidiomycota. In the Basidiomycota a clear trend exists from crust-like, resupinate, to more complex morphologies (45–47). A great diversity of morphological types derived from the ancestral resupinate types, including coral-like (coralloid), pileate-stipitate (those with cap and stipe), console-shaped (polyporoid and bracket fungi), puffball-like (gasteroid), or reduced cup-shaped (cyphelloid), among others. The pileate-stipitate, typical "mushroom-like" morphologies evolved several times from resupinate ancestors (45–47, 49), possibly through coral-like intermediates (50). The pileate-stipitate morphology appears to be a (sub)terminal state, dominating the largest Basidiomycete orders (Agaricales, Boletales, Russulales), possibly due to an optimized surface enlargement of the spore-producing tissue and to efficient protection from precipitation. Pileate-stipitate fruiting bodies show

few evolutionary transformations, with the exception of gastromycetation and sequestrization, two related processes denoting the origins of puffball-like fruiting bodies from agaricoid ancestors (46, 49, 51). These evolve by the gradual sequestration of the hymenium and often evolve toward an underground, truffle-like lifestyle, probably as an adaptation to dry environments and to zoochory (dispersal by animals). Gasteroid forms in the broad sense (including secotioid and sequestrate) evolved several times from pileate-stipitate ancestors, although they rarely dominate their clades in terms of species diversity, suggesting an internal genetic tendency for their evolution that is coupled with mechanisms that limit their diversification. Another widespread type derived from pileate-stipitate ancestors is the cyphelloid morphology (52). These are cup- or tube-shaped pendant fruiting bodies that most likely evolved via the loss of the stipe and gills of agaricoid species. They are found in several, mostly white-spored clades of the Agaricales.

Ascomycete fruiting bodies evolve from open morphologies toward closed fruiting body types (53). The major morphological types found in the Ascomycota are cleistothecium, perithecium, apothecium, and pseudothecium. The simplest of these is the cleistothecium, a completely closed, usually globose structure that often bears characteristic hyphal appendages. Cleistothecia are characteristic of the Eurotiomycetes (*Eurotium*, *Talaromyces*, and allies). Perithecia are globose or flask-shaped structures that open to the outside through the ostiolum, a channel through which spores exit the fruiting body. Perithecia are rarely bigger than a millimeter but can develop in large numbers and can congregate on a common supporting stroma (e.g., in *Xylaria* species). They are characteristic of the Sordariomycetes and the Laboulbeniomycetes (derived perithecia). Pseudothecia are morphologically similar to perithecia, but they often incorporate tissues from the substrate, and asci are not regularly organized within them. They are found in the Dothideomycetes. Apothecia are completely open, plesiomorphically cup- or disc-shaped fruiting bodies that can reach several centimeters in size. They are found in species of the Pezizomycetes, Leotiomycetes, Orbiliomycetes, Lecanoromycetes, and Lichinomycetes. Several modified and highly derived complex versions of apothecia have evolved, such as morels (*Morchella* spp.) and truffles (e.g., *Tuber* spp.). Like gasteroid fruiting bodies of basidiomycetes, truffle-like species evolved several times from apothecial ancestors, probably in response to some widespread selection pressure such as dry climate (54).

Development of Fungal Fruiting Bodies

The development of fruiting bodies on vegetative mycelia is a major transition in the life of a fungus. It involves a complete reprogramming of hyphal branching patterns and the initiation of a spatially and temporally organized developmental program. Initiation of fruiting body development is part of the sexual reproductive cycle and is thus regulated by genes located in the mating type loci and involves the recognition of compatible nuclei, which happens in basidiomycetes when dikaryotic hyphae develop (48, 55).

Both ascomycete and basidiomycete fruiting bodies develop from aggregated hyphae. In the basidiomycete *Coprinopsis cinerea*, which has been used extensively to study fruiting body development, the first hyphal aggregates are primary hyphal knots, which differentiate primarily in response to light and nutritional signals. Secondary hyphal knots derive from primary hyphal knots, and their differentiation is controlled by both environmental factors and the activity of mating type genes (55, 56). Secondary hyphal knots develop into stage 1 primordia (0.5 to 1 mm diameter), which already have cap, stipe, and gill rudiments and develop further into stage 2 primordia (2 to 3 mm tall), then to young and mature fruiting bodies. A characteristic of *Coprinopsis* spp. is an autolytic phase at the end of development, during which endogenously produced chitinase and glucanase enzymes digest the tissues into a black inky liquid, which might facilitate spore dispersal but may also have other roles (57). In the ascomycete *N. crassa*, the development of fruiting bodies starts from protoperithecia. Female protoperithecia are induced by nitrogen starvation, fertilized by a compatible male cell (hyphal fragments, micro- or macroconidia), and develop into mature perithecia that contain asci and eight ascospores (48). Variations of these developmental scenarios in various species exist, but the general principles of the early development seem to be conserved across the Asco- and Basidiomycota.

In pileate-stipitate species of the Basidiomycota, a number of developmental types have evolved, differing in the spatial and temporal patterns of tissue differentiation and the extent to which primordia are covered by protective tissues (veils and blemas), among other factors. Based on where in the fruiting body initial primordial cap tissues emerge, epi- and endonodular development can be distinguished (58). In epinodular species, cap rudiments develop on top of the nodulus (globose structures derived from hyphal knots), whereas in endonodular species, the cap is formed within the nodular context. Epinodular development is further divided into exocarpic, where cap and hymenium rudi-

ments are open to the environment, and endocarpic, where the developing hymenial tissues are covered by various hyphal layers. In traditional terms, endonodular and endocarpic types correspond to angiocarpic, whereas exocarpic corresponds to gymnocarpic development, although a strict correspondence is difficult to draw. These protective hyphal sheaths can later vanish or give rise to universal and partial veils, leaving the characteristic patches and rings on mature mushrooms, respectively (58).

Fruiting body morphologies and developmental patterns formed the basis for mushroom classification for a long time. For example, gasteroid basidiomycetes have been classified in the Gasteromycetes on the basis of their shared gross morphology and closed development, although several anatomical, biochemical, or ultrastructural characteristics pointed at a potentially polyphyletic origin (59, 60). Fungal classification has been revolutionized by molecular phylogenetic studies, yet developmental characteristics are still useful for species identification and for defining monophyletic groups.

The Genetic Bases of Fruiting Body Development

Fruiting body development is realized by intricate networks of regulatory and structural genes. A large number of signal transduction pathways and gene regulatory networks orchestrate responses to external (e.g., nutrient availability, light, temperature) and internal (e.g., pheromones) cues (for reviews see references 48, 56) that ultimately lead to the reorganization of the expression patterns of structural and effector genes. Among the environmental stimuli, light is central to the development of fruiting bodies. Light responses are orchestrated to a large extent by blue light receptors, primarily by the photosensor white-collar genes (WC1-2) first identified in *N. crassa* (56, 61, 62). One of the key regulatory pathways of fruiting body development is the velvet complex (VelB, VeA, and LaeA in *A. nidulans*), which controls secondary metabolism and sexual reproduction in response to light stimuli (63, 64). The striatin-interacting phosphatases and kinases complex has recently been characterized in *Sordaria macrospora* as a significant component of internal signaling pathways involved in fruiting body development (65, 66). Several transcription factors impact fruiting body development, morphology, and morphogenesis (for more details see references 67–70). Structural and effector genes are recruited from the cellular morphogenesis toolkit, among other genes for cell wall modifications, cytoskeletal proteins, and genes involved in protein and cell wall component biosynthesis or coding for cell wall-associated proteins. A number of fruiting body-specific proteins have also been identified, in particular, cell wall proteins such as lectins (71, 72), various lectin domain-containing proteins, and hydrophobins (73). The roles of several developmentally regulated, but as of now poorly characterized, genes await more thorough understanding. For example, the PriA and Fve proteins were found to be overexpressed in primordia and young fruiting bodies of *Lentinula edodes* and fruiting bodies of *Flammulina velutipes*, but their exact role in the developmental process remains an enigma.

PLANT CELL WALL DECOMPOSITION BY FUNGI

Most fungi obtain their nutrients from plants, either as saprobes, parasites, or mycorrhizal mutualists. They evolved a wide array of extracellular enzyme systems to attack and decompose complex plant materials and are the most efficient decomposers of lignocellulosic plant cell walls among all microbes. Thus, fungi play an important role in reintroducing fixed carbon into the carbon cycle by degrading dead plant debris and contribute to the functioning of ecosystems all over the world. Several symbiotic interactions also rely on the ability of fungi to decompose plant cell walls. For example, fungus-growing termites and ants use the lignocellulose-degrading ability of various *Leucoagaricus*, *Termitomyces*, and *Pterula* spp. (Agaricales), whereas ruminants harbor large populations of anaerobic Neocallimastigomycota fungi in their rumen. Fungal lignocellulose decomposition is achieved by a variety of mechanisms, including both enzymatic and nonenzymatic systems. The extracellular enzymes of wood-decay fungi received intense industrial interest because of their potential to facilitate the bioconversion of lignocellulosic materials for biofuel production and other industrial applications (e.g., paper industry).

The Diversity of Wood-Decay Types

Wood decay strategies have been classified in three broad categories in the past: white rot, brown rot, and soft rot (Fig. 1A,C). White rot fungi degrade cellulose, hemicellulose, and lignin components of plant cell walls (74), whereas in soft and brown rot only cellulosic substances are removed and lignin is not appreciably degraded. White and brown rot are typical of Basidiomycetes, whereas soft rot is mainly produced by ascomycetes. This broad classification of decay types has been contested recently based partially on comparative

genomics of Basidiomycota (74–76), suggesting that the functional diversity of wood-decay fungi and their role in ecosystems could be better described by a continuum. Several species traditionally classified as white rot fungi lack the enzyme systems to degrade lignin. Among others, *Schizophyllum commune*, *Botryobasidium* spp., and *Jaapia* spp. belong to this category, and although they are usually found on white-rotted wood, their nutritional strategy is unclear. Because of this uncertainty in decay mode and the diversity of nutritional strategies, the definition of white rot is now restricted to species that achieve lignin degradation through the action of class II peroxidases (76) (see below). In general, it is likely that a wide array of strategies for attacking lignocellulose-containing plant cell walls have evolved in various fungi and that these capabilities will support diverse industrial applications when it is known how to leverage them.

The capacity for white rot presumably evolved in the most recent common ancestor of the Auriculariales and more-derived Agaricomycetes (74, 75). Species associated with white rot (e.g., *Botryobasidium* spp., *Tulasnella* spp.) can be found in earlier-diverging clades too (Cantharellales), but they lack the hallmark enzymes of white rot (76). The symptoms they produce on rotten wood might reflect an ancestral, soft-rot-like wood decomposition strategy (75). White rot has a single evolutionary origin but has been lost several times. Brown rot fungi, which evolved by the loss of much of the white-rot-specific enzyme complements, originated several times in the Agaricomycetes, among others in the Polyporales, Hymenochaetales, Boletales, and Agaricales (74). Their convergent evolution is underpinned by the loss of several lignocellulose-degrading enzymes, in some cases the loss of complete enzyme/protein families.

The Evolution of Decay-Related Enzyme Families

Enzyme families involved in lignin decomposition are overrepresented in the genomes of white rot fungi (74–79) compared to brown rot and mutualistic fungi. Phylogenetic analyses of these gene families revealed an intricate evolutionary history formed by gene duplications and losses throughout the Basidiomycetes. Numerous gene duplications have been reconstructed in lineages containing white rot fungi, generating the raw material for the evolutionary diversification and potentially for adaptations to various substrates and environmental conditions. However, whether the enormous diversity of these enzymes within the same genome (e.g., up to 40 copies of peroxidases in a genome) reflects a diversity in the expression, activity, or substrate specificity across multiple similar copies is not well understood.

The ability to decay wood components was probably already present in the most recent common ancestor of the Dikarya (Ascomycota plus Basidiomycota), some 700 to 750 million years ago (74, 80–82), and maybe even earlier. However, it was not until the end of the Carboniferous when high redox-potential enzymes and thus white rot fungi evolved and started to degrade woody substrates on Earth (74). Although molecular clock dating of fungal divergences is notoriously difficult, recent genome-based analyses support the origin of the Agaricomycetes around 290 million years ago. The diversification of white rot fungi at the end of the Carboniferous has been linked to the decline in organic carbon accumulation in this era (74, 83).

In contrast to white rot fungi, brown rotters degrade the cellulosic materials through nonenzymatic action involving H_2O_2 produced by the Fenton reaction. Brown rot fungi possess very few or no ligninolytic enzymes due to extensive gene losses in these gene families, which might be driven by selection for the loss of energetically expensive ligninolytic mechanisms of white rot species (84). Although not able to utilize lignin for energy production, brown rot fungi evolved mechanisms to modify lignin so that cellulose fibrils among lignin polymers become more accessible (85). Brown rot fungi are also adapted better to coniferous tree hosts, in contrast to white rot fungi, which are more often found on angiosperm wood (86, 87).

Beyond lignocellulose-active enzymes, other cellular pathways are at least as important for the utilization of plant cell wall materials, such as detoxification and membrane transport pathways for neutralizing toxic decomposition intermediates and importing monomers into the cells. These pathways, however, received less attention than the front-end enzyme systems and will require greater scrutiny in future studies.

The Cellular and Genetic Bases of Wood Decay

Extracellular enzymes play a major role in the degradation of lignocellulosic compounds of plant cell walls by wood-rotting fungi. Plant cell walls are complex and highly diverse composites of various polysaccharides. Fungi evolved a similarly diverse suite of enzymes, mostly glycoside hydrolyses for degrading these components, the most important of which are cellulases, hemicellulases, pectinases that act on main chains of polysaccharides, and accessory "debranching enzymes" that digest polysaccharide side chains. Ligninolytic en-

zymes (87–89) decompose highly recalcitrant lignin polymers. Enzyme families acting on cellulose chains include endoglucanases, exoglucanases, and beta-glucanases. The oxidoreductive cleavage of cellulose chains by lytic polysaccharide monooxigenases has only recently been discovered as an additional synergistic mechanism of cellulose degradation (90, 91). The decomposition of hemicellulose and pectin, due to their complex structure, involves a more diverse set of enzymes: xylanases, mannanases, galactosidases, endoglucanases, cellobiohydrolases, beta-glycosidases, endo- and exopolygalacturonases, pectin and pectate lyases, etc (92). Cellulose, hemicellulose, and pectin degradation have evolved in both the Asco- and Basidiomycota, but there are large differences in the individual species' ability to decompose these compounds. Pectinases, for example, were probably present in the genomes of ca. 750-million-year-old aquatic ancestors of the Dikarya and Chytridiomycota, indicating an ancient adaptation to obtain nutrients from pectin-containing cell walls of early green plants (82).

Lignin, one of the most recalcitrant biopolymers found in nature, is composed of cross-linked aromatic phenol-polymers. The most efficient decomposers of lignin are white rot fungi belonging to the Agaricomycetes, wherein members of the order Polyporales contain the best-characterized white rot species (e.g., *Trametes versicolor*, *Phanerochaete chrysosporium*). Less well known but important lignin decomposers are also found in the Agaricales, Boletales, and Russulales. Lignin degradation by white rot fungi is achieved through the generation of oxidative radicals by extracellular enzyme systems. The most important ligninolytic enzymes are class II peroxidases, laccases, and dye decolorizing peroxidases. Based on structural and functional considerations, class II peroxidases are further subdivided into four subfamilies: lignin peroxidases, versatile peroxidases, manganese-peroxidases, and generic peroxidases (74, 89, 93). These high-redox-potential peroxidases catalyze the oxidation of lignin polymers by hydrogen-peroxide generated by glyoxal oxidases, pyranose oxidases, and aryl-alcohol oxidases (93, 94).

SECONDARY METABOLISM

Secondary (or specialized) metabolites (SMs) are small molecules whose primary roles involve ecological or environmental interactions as opposed to basic growth, development, and reproduction. For example, SMs secreted by fungi may act as antibiotics or signals to other organisms or alter the availability of nutrients in soil or host tissues. Fungal SMs can be quite diverse, similar to plants, and are in part distributed among fungi according to ecological traits rather than species relationships. The origin and evolution of secondary metabolic pathways in fungi reflect broader patterns of genome remodeling in a biochemical arms race with competitors and hosts.

Only a small proportion of the adaptive biological functions of SMs are characterized (it is sometimes argued that most have no current functions [95]), but a subset of these is known to have important ecological roles (96). As with plants, the most obvious roles for SMs are defense and competition (Fig. 2). Although most classes of antibiotic pharmaceuticals are bacterial in origin, antibiotics are nonetheless important products of fungi (97). Beta-lactams, including penicillin and cephalosporins, are among the few fungus-derived antibiotics that are suitable for human use. The existence of a large number of SMs is suggested by homologs of known SM genes found in the growing database of whole-genome sequences, but they have not yet been observed to be expressed (98). Cryptic antifungal and antibiotic fungal SMs can be uncovered via dual-plating experiments, in which fungi paired with other microorganisms secrete compounds that inhibit growth of the competitor or via inducing the expression of "silent" SM genes (99). However, specific SM-mediated ecological interactions are not usually documented in their natural context.

Among the main exceptions to this lack of tested functionality are SMs produced by fungi that act as pathogens of plants. For example, plant pathogens often secrete SM toxins to directly induce plant cell death during necrotrophic growth (100). *Cochliobolus carbonum* secretes the host-selective HC toxin, which prevents induction of normal defenses in maize (101). Other plant pathogens manipulate the host's internal signals involved in growth and programmed cell death. For example, *Botrytis cinerea* and other fungi secrete the plant hormones abscisic acid and ethylene during necrotrophic pathogenesis (102).

Some fungal SMs appear to be involved in fungus-animal interactions. Nematodes and arthropods are the main predators of fungi, so it is likely that they are often the targets of SMs that affect animal neurotransmitter signaling pathways. For example, psilocin and muscarine are produced by a number of mushroom-forming basidiomycetes and bind to serotonin and acetylcholine receptors, respectively (103). Ascomycete molds also produce larvicidal compounds, and a mutant *Aspergillus* that produces few SMs due to deletion of a global regulator of SM pathways is preferred by fungivorous arthropods (104).

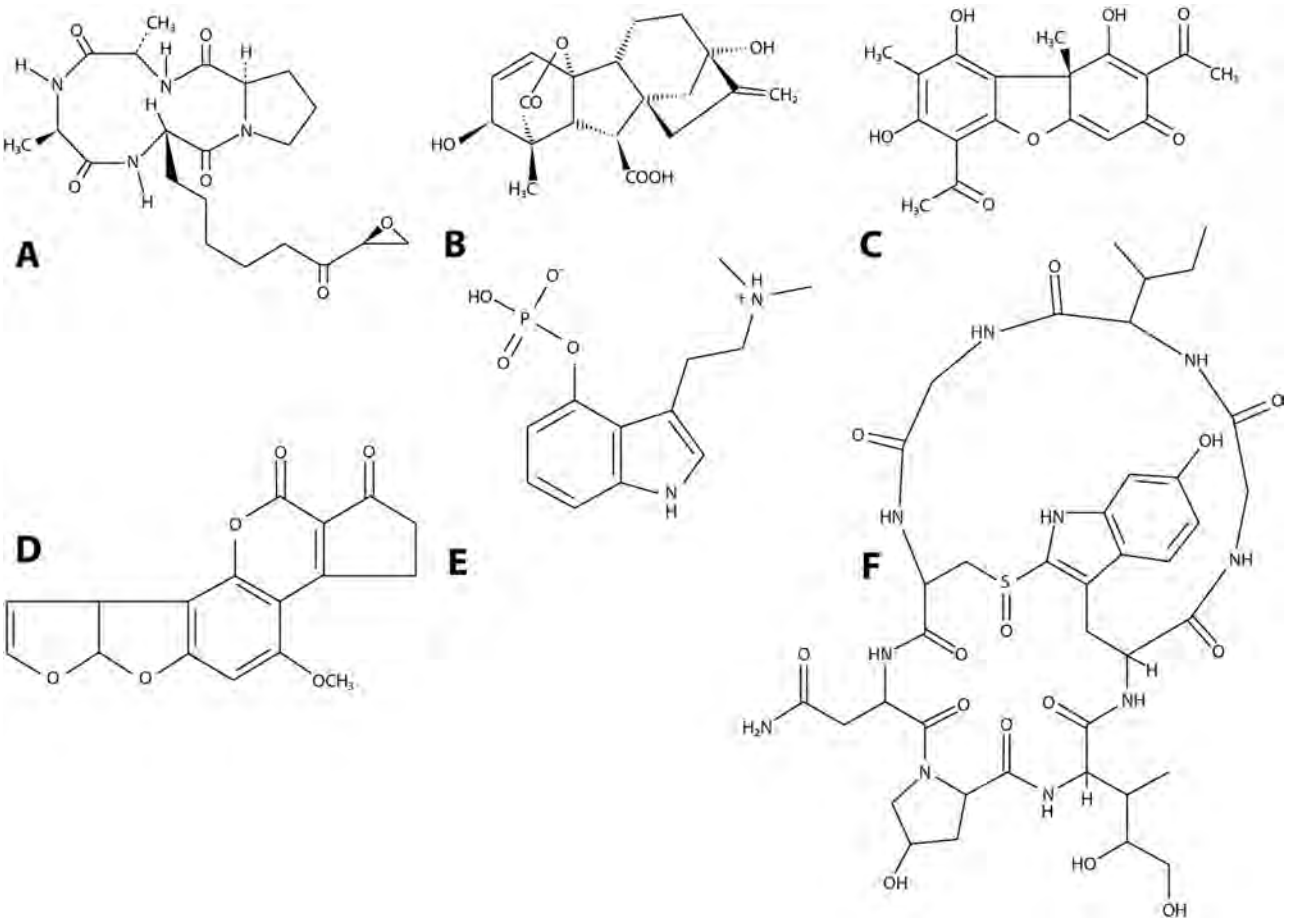

Figure 2 Secondary metabolites produced by fungi. (**A**) HC toxin is a nonribosomal peptide virulence factor produced by plant pathogens such as the Northern corn leaf spot fungus, *Cochliobolus carbonum*. (**B**) Gibberellic acid is a diterpene-derived plant growth hormone produced by some *Fusarium* spp. (e.g., *Fusarium moniliforme* = *Gibberella fujikuroi*), which leads to growth defects in grass seedlings. (**C**) Usnic acid is a common polyketide secondary metabolite thought to protect against biotic and abiotic stress in many lichens. (**D**) Aflatoxin B1 is a highly carcinogenic polyketide produced by *Aspergillus* molds that spoils grain and peanut harvests. (**E**) Psilocybin is a hallucinogenic indole alkaloid produced by a variety of mushrooms. (**F**) Alpha amanitin is a deadly peptide alkaloid that inhibits RNA polymerase II, produced by diverse mushroom-forming fungi.

These same antimicrobial and competitive functions can also be of benefit to plant hosts of symbiotic fungi. Grass endophytes of Clavicipitaceae have long been studied for their antiherbivory toxins, which can increase fitness and dominance of infected plants (105). Surprisingly, some endophytes have been recently shown to produce the same SMs as their hosts and may compensate for reduced production of these SMs by the plants when they are allocating resources to, for example, reproduction (106). In general, endophytes are prolific producers of diverse metabolites and are considered "acquired immune systems" of the plants that benefit from them (107).

Because fungi are absorptive-feeding organisms, fungal growth is constrained by environmental conditions and competition that affect the availability of nutrients. SMs play a role in increasing access to limiting elements such as iron. Siderophores are molecules with especially high affinity for binding iron (108). There are a number of independently evolved siderophores in fungi. Siderophores are particularly important to animal-pathogenic fungi that compete with both hosts and their commensal microorganisms for limited iron (109, 110).

SMs are also important for protection from environmental stresses such as desiccation and radiation.

Melanins are amorphous SM polymers synthesized from various precursors, which absorb radiation and create a resistant barrier to dehydration and mechanical damage (111). For example, the melanized rhizomorphs of *Armillaria* spp. allow the fungus to cross long distances in exposed, low-moisture environments to access new substrates (112), and melanized sclerotia enable pathogens and symbionts of annual plants to survive and overwinter in detritus and soil. The tendency of melanins to neutralize radical molecules may also protect melanized yeasts against similar molecules used by immune macrophages and soil predators such as amoeba (113). Lichenized fungi, on the other hand, endure chronic environmental exposure and consequently utilize numerous SMs to reduce the damaging effect of light exposure (114).

Major Types of Secondary Metabolites

Five main classes of fungal SMs have been studied in depth: peptides, polyketides, peptide-polyketide hybrids, terpenes, and alkaloids. Peptide SMs are usually synthesized by special polymerizing enzymes called nonribosomal peptide synthetases but are occasionally produced from repetitive DNA templates by cleavage of the resulting polypeptide sequences. Examples of nonribosomal peptide synthetase-produced SMs include the beta-lactam antibiotics such as penicillin and cephalosporin and the immunosuppressant cyclosporin (115). Amatoxins, the deadly RNA transcription inhibitors produced by death angel mushrooms such as *Amanita bisporigera*, are produced by cleaving 35 amino acid proteins into octopeptides, which are then cyclized by a mechanism that is not fully understood (116). Polyketide synthetases, the most abundant SM-producing enzymes in fungi, polymerize fatty acid subunits rather than amino acid subunits like the nonribosomal peptide synthetases (115). A basic polyketide chain can be modified with functional group "decorations" and formed in rings by other enzymes in these pathways to produce a wide range of compounds. Among these are the aflatoxins from *Aspergillus* spp., which are toxic and costly contaminants of maize, peanut, and other crops (117), and statins from diverse species, originally targeted as pharmaceuticals to reduce cholesterol synthesis (118).

Terpenes are volatile or nonvolatile compounds produced from isoprenoid subunits and include both the trichothecene mycotoxins from *Fusarium* spp. and desirable flavor compounds in edible mushrooms (119, 120). Gibberellic acids are terpenoid hormones first characterized in *Gibberella* (*Fusarium*) *fujikuroi*-infected rice as the cause of hypertrophy symptoms leading to extensive crop losses. Alkaloids are diverse nitrogen-containing SMs that are often associated with toxicity and feeding deterrence against herbivores and fungivores. Vertically transmitted fungal endophytes of grasses, for example, produce from amino acid precursors four classes of alkaloids that are toxic to mammals and invertebrates. Among these, insecticidal loline alkaloids are derived from L-proline and L-homoserine, and livestock/human-intoxicating indole and indole diterpene alkaloids, which interfere with neural and vascular processes, are derived from L-tryptophan (121). Notable toxicoses caused by indole-based alkaloids include "ryegrass staggers" in livestock caused by lolitrem B, and ergotism and related syndromes in humans and animals caused by ergot alkaloids produced by *Claviceps purpurea* (ergot) and clavicipitaceous grass endophytes. Psilocin from "magic" mushrooms and lysergic acid diethylamide (LSD) are indole alkaloids that have additionally influenced human culture and religion through their hallucinogenic activity (122). Due to their high potential for bioactivity, fungal alkaloids have contributed a number of therapeutic drugs such as ergometrine, an ergot alkaloid that revolutionized medical control over postpartum hemorrhage, and a number of promising anticancer drugs.

The Evolution of Secondary Metabolism in Fungi

The roles and extent of secondary metabolism in fungi vary widely by lineage. Filamentous Ascomycota contain by far the majority of known SM genes, while ascomycete yeasts, Basidiomycetes, Zygomycetes, and chytrids have few or none of the classes described above (123). Fungal metabolic pathways involved in ecological processes are often encoded in "gene clusters" (124). For example, most enzymes, regulators, and transporters required for production and delivery of SMs are the products of genes in close physical proximity on chromosomes. The evolution of such gene clusters is highly dynamic; specific gene clusters are usually distributed among only a fraction of fungal taxa but can be found in taxa that are distantly related (125). This distribution of gene clusters reflects a history of horizontal gene transfer, along with rapid degeneration, loss, and remodeling of metabolic pathways. Numerous SM gene clusters appear to have been horizontally transferred between distantly related fungi (126, 127). For example, the 24-gene sterigmatocystin cluster in *Podospora anserina* (Sordariomycetes) is highly similar to that in *A. nidulans* (Eurotiomycetes) both in gene order and nucleotide sequence (128). However, within *Aspergillus*, homologous clusters are variable in their

presence and composition. Rapid rearrangement and degeneration of these clusters resulted in a diversity of producers and nonproducers of aflatoxins among *Aspergillus* species and the virulence factor dothistromin in the pine pathogen *Dothistroma septosporum* (129). Secondary metabolism gene clusters in fungi will continue to be an important topic of evolutionary, ecological, and pharmacological studies in the coming years.

MYCORRHIZAE

One of the major traits of fungi is their ability to form symbiotic interactions with plants. These interactions can be either parasitic or mutually beneficial, and many of them probably evolved in parallel with the colonization of the land by plants. It has been long suggested that the colonization of land by plants has been aided by early mutualistic fungi (130). There are several types of mutualistic interactions between plants and fungi, among which mycorrhizae formed by land plants and fungi are the most frequent. Although plant-fungal symbioses played a crucial role and were a driving force in the evolution of both partners, here we focus on the evolution, physiology, and anatomy of mycorrhizae from a fungal perspective.

There are several possible definitions of "mycorrhizae," and while there might be debates about them, the main types of mycorrhizal interactions are relatively well defined. The term itself means "fungus-root" and was coined by Frank (1885) in his landmark work in which he also posited the importance and mutual benefits of reciprocal nutrient exchange through mycorrhizae (131, 132). According to Trappe's definition (179), mycorrhizae are "dual organs of absorption formed when symbiotic fungi inhabit healthy absorbing organs (roots, rhizomes, or thalli) of most terrestrial plants and many aquatics and epiphytes." The use of the phrase "most terrestrial plants" is not exaggeration at all: the majority of land plants form mycorrhizae: 90% of the plant families are mycorrhizal, as are 70 to 80% of known plants on the species level (133–137). The main function of mycorrhizae is reciprocal nutrient exchange between the partners: using their extraradical hyphae, fungi mobilize and/or uptake nutrients from the soil, transport them into the roots, and thus to the plants, while the plants transfer assimilated sugars to the fungal partner (133, 138). The most important nutrients mobilized and transported from the soil are phosphate, nitrogen, and water. Nutrient mobilization, however, depends on the type of mycorrhiza, the fungal partner, the habitat, and the environment. Hence, there is a fine balance in the dominance and importance of different processes, mycorrhizal partners, and the main nutrients exchanged between them in different habitats and ecosystems (133, 138, 139).

Diversity of Mycorrhizal Types

Coining a generic definition of mycorrhizae is complicated by the functional and anatomical diversity of mycorrhizal interactions. The wide range of morphological types of mycorrhizae can be classified as two main forms of fungal colonization: in endomycorrhizae the fungal hyphae penetrate the root cells, whereas in ectomycorrhizae (ECM) the fungi colonize the intercellular spaces only. There are clear differences between these two types, not only in gross anatomy, but also in characteristic enzyme sets used by the fungi. Endomycorrhizae can be further subdivided into arbuscular mycorrhizae (AM), orchid mycorrhizae, and ericoid mycorrhizae (ERM), each characteristic of certain plant lineages (133, 134). Many other types characteristic of smaller plant groups exist (134). For example, arbutoid and monotropid mycorrhizae are ectendomycorrhizae showing main structural characteristics of ECM but also hyphal colonization of plant cells (133). The plants forming these mycorrhizae are mycotrophic: they are not or are not completely autotrophic and gain assimilates from other plants mostly through connections with ECM fungi.

ERM are endomycorrhizae formed by plants in the Ericales and various asco- and basidiomycetes (133, 134). The best-known fungal taxa are found in the ascomycete genera *Hymenoscyphus*, *Cadophora*, and *Oidiodendron*, but *Sebacina* spp. and other basidiomycetes have also been identified as ERM fungi (140). Some Ericales have specialized, extremely thin, simple roots (133, 141) and grow in habitats with a very slow organic turnover, which makes them dependent on mycorrhizal partners with good saprobic capacities.

Orchid mycorrhiza (ORM) is also an endomycorrhizal interaction, with characteristic intracellular hyphal forms such as the pelotons (densely coiling intracellular hyphal mass) and the moniliform hyphae (133, 141). Orchids depend obligately on their symbiotic fungal partners. They require the presence of fungi for the germination of their seeds and the development of the protocorm stage (133). Some orchids are mycoheterotrophic due to the complete or incomplete loss of photosynthetic capacity in the adult stage or the insufficient amount of light in their habitats. These mycoheterotrophic species fully or partly rely nutritionally on fungi that form mycorrhizae with autotrophic plants (133). The decomposition processes driven by fungal partners with strong saprobic capacities also play a role

in the carbon supply to the plants in ORM. Although the association between orchids and fungi had been known for a long time, the mutualistic reciprocal transport was proven only 10 years ago: in addition to the fungal N transport to the plant, a reciprocal C exchange between the two partners has also been observed (142). The most widespread orchid mycorrhizal fungi are found in the Cantharellales (Basidiomycota), e.g., *Rhizoctonia*, *Tulasnella*, and *Ceratobasidium*. However, a huge diversity of other, mostly basidiomycete fungi can also be detected in orchid roots. Even members of the Atractelliomycetes (Pucciniomycotina) were proven to colonize and form an intracellular interface in terrestrial orchid roots (143).

Arbuscular Mycorrhiza (AM)

AM is the most widespread mycorrhiza type and probably the most frequent symbiosis on Earth (144, 145). AM is exclusively formed by obligate biotrophic fungi of the Glomeromycota, while high numbers of plant species from almost all mainland plant groups form this mycorrhizal type (133, 136). The Glomeromycota is a relatively small group with approximately 230 known species (146). One of the main benefits for the plants in this symbiosis is the phosphate transferred by AM fungi to the plants (133). Although these fungi harbor genes related to sexual reproduction (147, 148) no sexual stage is known. AM is an endomycorrhiza named after the tree-like arbuscules formed in the plant cells (133). Plant cells completely reorganize themselves during colonization by the AM hyphae, and the colonization itself depends highly on the plant, among other factors, because PCWDEs are missing from the genome of *Rhizophagus irregularis* (147). Precolonization recognition processes of plant and fungal partners in mycorrhizal interactions are best known in the case of the AM. Here, fungi release diffusible factors, e.g., lipochitooligosaccharides (the "myc-factors"), acting as elicitors and signals recognized by the plant, while the plants secrete diverse compounds such as strigolactons, which influence the fungus before colonization (149). The plant membrane around the arbuscules has many special characteristics; e.g., specific plant phosphate transporters are located on the periarbuscular membrane. The arbuscule and the perisymbiotic membrane share many similar features with haustoria of intracellular biotrophic pathogens such as downy mildews, powdery mildews, and rust fungi (150). Nevertheless, beneficial mycorrhizal and parasitic interactions have clearly different functional and regulatory features (150, 151).

Fossilized spores and arbuscular structures and the capability of the basal green plants to form AM (152–158) suggest that AM fungi helped plants to conquer land (159). The clade of AM fungi, Glomeromycotina (160), branched off approximately 400 to 450 million years ago in the phylogeny of fungi (161), and the Glomeromycotina groups with Mucoromycotina (160, 162, 163). This is especially interesting considering that Mucoromycotina fungi were recently shown to be mutualistic symbionts of basal plant groups (123, 164–166) and that hyphal structures resembling mucoralean fungi were also reported from plant fossils (167). These findings seem to change the paradigm that the Glomeromycotina was the only ancient mycorrhizal lineage. Nevertheless, it seems that the capacity to form AM evolved only once in fungal evolution, in the ancestor of the Glomeromycotina clade.

Although we have detailed data on the molecular mechanisms of AM symbiosis, ranging from the presymbiotic phase through root colonization and arbuscule development, and there is information about the shared genomic toolkits of AM-forming plants (168), our knowledge of the genomic backgrounds of AM formation is limited. For several reasons, including the relatively big (~140 to 150 Mb) genomes with a high number of repetitive elements, the genome of only a single species, *R. irregularis* (once known as *Glomus intraradices*), has been completely sequenced (147, 163).

Ectomycorrhiza (ECM)

ECM is the most dominant type in temperate forest ecosystems (133, 137, 169), although it can be abundant in tropical areas too (170). Interestingly, only around 2% of plant species, mostly woody plants (e.g., *Fagaceae*, *Pinaceae*), form ECM (133, 137). In ECM the fungal partner forms a mantle on the surface of the colonized root tips, and the exchange of nutrients takes place in an intercellular interface between the plant and fungus, called the Hartig-net. The Hartig-net is a coenocytic structure (171) formed around the epidermal and/or cortical cell layers of the roots (133). Based on the diversity in ECM morphology, including characteristics of emanating elements and rhizomorph structures, ECM have been assigned to different exploration types (172), which probably reflect functional differences among ECM fungi.

Several ECM fungal lineages appeared during the evolution of the Dikarya, to which the majority of ECM fungi belong. The capacity to form ECM evolved independently in the Basidiomycota (e.g., *Amanita muscaria*) and the Ascomycota (e.g., *Tuber melanosporum*), according to some estimates 78 to 82 times (137). Compared to AM, the ECM association is evolutionarily younger, around 100 to 170 million years old.

ECM groups have evolved from nutritionally diverse ancestors, including white rot and brown rot fungi and plant pathogens (173). The comparative analyses of the first two genome sequences of ECM fungi, the basidiomycete *Laccaria bicolor* and the ascomycete truffle *T. melanosporum*, revealed striking differences between the two ECM species (174, 175). This heterogeneity was further supported by the comparative analysis of 49 fungal genomes representing 11 ECM, 3 ORM, and 1 ERM species of fungi, alongside several saprobes and plant pathogens (173) and the genome of *Cenococcum geophilum*, one of the most widespread ECM-forming Ascomycota.

Consistent with the independent origins of ECM fungi, the genetic toolkits underlying the mycorrhizal interaction have also evolved independently. Thus, identifying the genetic bases of mycorrhiza formation is challenging, which is further complicated by the high proportion (7 to 38%) of orphan genes (i.e., genes showing no homology with any other known genes) induced during mycorrhiza formation. Their abundance might be explained either by the recent origins of the lifestyle and the underlying genes or by the high rate of the evolution of interaction-related genes. One conserved pattern across ECM lineages is the lower diversity of PCWDEs compared to related wood-decaying or parasitic species. Many lineages have lost most of their PCWDE complement, which indicates reduced saprotrophic capabilities of these fungi. Nevertheless, PCWDEs play a crucial role in root colonization and in nutrient mobilization in the soil, and their presence suggests that many lineages of ECM fungi retain some saprotrophic potential. In contrast to ECM, ERM and ORM fungi possess high numbers of PCWDE genes and have strong saprobic capacities (173). The genetic bases of mycorrhiza formation comprise complex pathways of secreted proteins, effectors, regulators, PCWDEs, and several hitherto unknown components. Small secreted proteins are particularly abundant in ECM species and are upregulated during mycorrhiza formation in high numbers (176). These might be involved in controlling host defense mechanisms during the establishment of the mycorrhizal interaction. For example, MiSSP7 of *L. bicolor* interacts with jasmonic acid signaling repressors of the host plant (this pathway modulates plant-microbe interactions in plants), which promotes symbiosis (177). The wide array of mycorrhiza-induced effector-like secreted small proteins suggests that several other aspects of regulating the interaction and maintaining the fine balance between mutualism and parasitism exist and remain to be identified (177, 178).

EVOLUTIONARY CONVERGENCE IN FUNGI

Fungi show evolutionary convergence at multiple levels. All of the traits considered here result from convergent evolution at various taxonomic levels. For example, fruiting bodies evolved in the Asco-, Basidio-, and Mucoromycota, but also show convergence at finer scales in the Basidiomycota, where the agaricoid morphology has evolved in at least seven orders independently. Convergence can be observed both in trait gains and losses, the latter being naturally more common and including the repeated evolution of brown rot lineages from white rot ancestors through losses of PCWDE genes or the parallel reduction of the multicellular phase in the life cycles of yeasts. On the other hand, surprisingly similar phenotypic solutions for polarized hyphal growth and fruiting body formation evolved several times independently. The evolution of ECM associations is marked by both gains and losses: many PCWDE genes have been lost, whereas genes involved in ECM formation have been gained in a lineage-specific manner in ECM clades (169, 173). It is therefore important to consider the genetic mechanisms of phenotypic convergence in fungi. Parallel losses of conserved genetic toolkits provide a straightforward explanation for the repeated evolution of similar phenotypes. For instance, the loss of ligninolyic and other PCWDE genes resulted in selective nonenzymatic degradation of cellulosic plant cell wall components by brown rot fungi, which presumably, combined with the parallel elaboration of as yet unknown compensatory biochemical activities, resulted in similar wood-degrading strategies in multiple clades of these fungi.

Similarly, the evolution of major yeast lineages has been marked primarily by gene loss and limited genetic novelty associated with the morphological transition. However, phylogenetic patterns suggest that phenotypic similarity evolved independently in multiple yeast-like clades, fruiting body-forming groups, or hyphae, which prefigures mechanisms for gaining similar phenotypes independently in a convergent or parallel manner. Consistent with the predictions of convergent evolutionary theory, independently evolved ECM lineages share little of the known genetic innovations involved in ECM formation (169, 173). On the other hand, classical convergence fails to explain the convergent evolution of polarized hyphal growth or fruiting body formation. For these cases, a continuum of mechanisms for convergent evolution needs to be considered, ranging from the parallel cooption of orthologous genes and pathways for similar functions to underlying latent homologies or the evolution of divergent genetic toolkits.

What Defines the "Kingdom" Fungi?

3

Thomas A. Richards,[1,2] Guy Leonard,[1] and Jeremy G. Wideman[1]

It is a certainty that the tree of life can be broken up into large units of biodiversity that span such great evolutionary distances that one could call them kingdoms. However, if these units are to have any meaning, they must represent radiations of diverse groups underpinned by unique shared derived adaptations that drove the evolutionary success of each group. Without such evolutionary characters, these classifications are merely abstract concepts or arbitrarily demarcated lineages. Even the five kingdoms (commonly called plants, animals, fungi, protists, and prokaryotes) that gained popular acceptance from Whittaker (1) were abstractly defined and nonmonophyletic. These kingdoms were defined based on cellular organization (prokaryote or eukaryote), multicellularity (protist or "higher" eukaryote), and trophic level (producer [plants], consumer [animals], or decomposer [fungi]). Somewhat more phylogenetically sound definitions (2) have replaced these classifications, but the names, defining characters, and number of kingdoms are still not settled (e.g., 3, 4).

When different authors classify higher units of biodiversity, there are few rules and many differing interpretations of what is important and what is not (see 1–3, 5–9); some authors have even abandoned the need for formal terms such as "kingdom" (10). Furthermore, mapping trait evolution onto the tree of life is difficult, and even more so when these determinations are subject to constant revision (i.e., characters mapped onto trees need to be repositioned because the tree is constantly being redrawn and the characters are found in additional taxa). The combination of these factors means that classifications such as kingdoms are temporary, and "noisy," especially with respect to placement of taxa that branch close to the border of a kingdom on a phylogenetic tree. Take, for example, the three primary monophyletic eukaryotic kingdoms: plants (Archaeplastida [10]), animals (Metazoa), and Fungi. It can be argued that, of the three, only the Archaeplastida have a known defining evolutionary trait that underpins their evolutionary success and diversification. This defining trait is the endosymbiotically acquired primary plastid organelle derived from a cyanobacterium (e.g., 11). However, even this trait is not unique, because the protist *Paulinella* (Rhizaria) also has a cyanobacterially derived endosymbiont with some characteristics of an organelle (12). For the Metazoa and Fungi, the distinction is much less clear between members of these kingdoms and their protist sisters, and historically, some authors did not separate fungi from protists (6). In the case of Metazoa, many of the cellular systems thought to define animal multicellularity have now been identified in their protist relatives (e.g., 13, 14), leading to a reevaluation of the cellular systems that define membership in the animal kingdom. In the following section, we discuss this conundrum with regard to defining the boundaries of the Fungi. We argue that, irrespective of where taxonomic boundaries are drawn or how we define the Fungi, understanding the changes that underpinned the evolution and diversification of this group is the most important and interesting aspect of this research area.

IN SEARCH OF A SYNAPOMORPHY FOR FUNGI

There have been numerous attempts to identify a genetic, molecular, or cellular character that defines the kingdom Fungi, specifically a synapomorphy that separates them from other groups. To formally qualify as a diagnostic synapomorphy, such a character must clearly define the clade (i.e., be held by the majority of the taxa that branch within the clade), in this case fungi. Secondary loss of a trait within the circum-

[1]Biosciences, College of Life and Environmental Sciences, University of Exeter, Exeter, United Kingdom; [2]Integrated Microbial Biodiversity Program, Canadian Institute for Advanced Research (CIFAR), Toronto, Canada.

scribed clade is formally permitted, but patterns of loss complicate the use of the trait as a synapomorphy. Importantly, the trait must be absent everywhere else in the tree of life. Historically, attempts to identify such characters have been met with limited success. Here, we summarize the several lines of evidence that have been put forward but ultimately refuted as characters used to define the Fungi.

Amino Acid Biosynthesis

For over 30 years, the synthesis of the amino acid lysine via the α-aminoadipate pathway was discussed as a putative diagnostic character for the Fungi, even though the presence of the pathway in *Euglena*, a photosynthetic protist, was also reported (15, 16). Access to eukaryotic and prokaryotic genomic data, and in some cases physiological experiments, has demonstrated that the genes encoding this pathway are present throughout the eukaryotes (17, 18) and, indeed, also present in a number of prokaryotic genomes (e.g., 19). These results indicate that synthesis of the amino acid lysine via the α-aminoadipate pathway is not a useful diagnostic character for the Fungi.

Ergosterol

One of the key genes for the α-aminoadipate lysine pathway encodes the enzyme α-aminoadipate reductase. This gene is involved in the synthesis of both lysine and ergosterol (18). The presence of ergosterol within the cell, and specifically the cell membrane, has also been claimed to be diagnostic for fungi (e.g., 20). Some authors have used this biomarker for tracing fungi from environmental samples (e.g., 21–23). Unfortunately, a large number of groups classified as Fungi, which are placed in phylogenetic trees within the fungal radiation, lack either the pathways to synthesize ergosterol or the presence of ergosterol as a detectable sterol (24). Critically, numerous protists that do not group on phylogenetic trees with fungi also synthesize ergosterol (25). These include trypanosomatid flagellates and *Euglena* (of the protist phylum *Euglenozoa*) (26–28), *Chlorella* and *Chlamydomonas* (Archaeplastida) (29, 30), and *Acanthamoeba* (Amoebozoa) (31). The taxon distribution (10) of this biochemical characteristic therefore suggests that utilization of ergosterol is at least as old as the major diversification of the eukaryotes, and consequently ergosterol cannot be used as a synapomorphy for fungi. It is therefore important that we no longer consider ergosterol as a useful biomarker for tracing fungi in environmental samples because this is not a reliable indicator of fungal presence/abundance (24). Even in most of the situations in which this biomarker has been used to detect fungi, i.e., plant and soil environments, nonfungal eukaryotes that produce ergosterol are found. As such, ergosterol detection should not be used as a biomarker specifically to quantify fungi without further checks on community composition such as environmental DNA diversity and abundance approaches, methods that essentially make the use of ergosterol detection as a proxy for fungal presence/biomass redundant.

The Fungal Cell Wall

Another trait thought useful for diagnosing fungi was the carbohydrate chemical composition of the cell wall. "Perhaps one of the most mutually satisfying by-products of fungal cell wall research, to taxonomists and biochemists alike, is the close correlation that can be established between chemical composition of the cell wall and major taxonomic groupings elaborated on morphological criteria," wrote Bartnicki-Garcia in 1968 (32). This work showed that many major taxonomic groups within the Fungi had different cell wall carbohydrate chemical compositions. This was cutting-edge research at the time and clearly demonstrated that the cell wall diversified in composition across the major fungal groups (see Table 1 in reference 32). As such, it was thought that these chemical characteristics were therefore diagnostic for higher taxonomic groups within the Fungi and not for the Fungi as a single group. Later work demonstrated that the chitin synthesis pathway has been lost in several fungal groups, for example, in *Pneumocystis* (33), an ascomycete fungus (34), therefore showing a clear example of secondary loss of a chitin cell wall. Indeed, numerous fungal groups have different cell wall compositions, while some fungi lose their wall (e.g., many fungal zoospores) or modify its components dependent on the life cycle stage (see reference 35 and Fig. 3 in reference 36).

Further work has shown that several groups initially classified as Fungi and thought not to have a chitinous cell wall (i.e., oomycetes and hyphochytriomycetes), but which were later shown to be members of the stramenopiles (37), do produce chitin in their cell walls (38, 39). Indeed, the ability to lay down chitin on the cell surface is present across numerous eukaryotic groups. These include, for example, *Entamoeba* (of the protist phylum Amoebozoa) (40, 41), *Trichomonas* (Excavata) (42, 43), Diatom and Pseudofungi (stramenopiles) (38, 44–46), *Plasmodiophora* (Rhizaria) (47), and *Chlorella* (Archaeplastida) (48). We note that in the case of the green alga *Chlorella* it has been suggested that the presence of a chitin synthesis pathway and a chitin cell wall is the result of horizontal gene

transfer (48). Yet even with this caveat, the taxon distribution of the production of chitin as a cell surface material suggests that this feature is older than the major radiations of the eukaryotes (47).

Considering the distribution of genes that encode chitin cell wall synthesis enzymes, it is clear that many of the features of chitin synthesis predate the radiation of fungi and are found across a wide diversity of eukaryotes. These include both chitin synthase (divisions 1, 2, and 3), chitinase (I and II), and chitin deacetylase enzymes (Fig. 1). These are collectively required to synthesize and remodel chitin polysaccharide. It is possible that horizontal gene transfer has led to this taxon distribution, but it is unlikely to have occurred on such a scale and across so many major divisions of the eukaryotes. As such, chitin as a metabolic trait and a feature of cell wall composition must have predated the radiation of fungi, therefore invalidating chitin synthesis and/or the chitin cell wall as a useful character for Fungi or any groups within.

β-Glucans are also key components of some fungal cell walls (e.g., 32, 35, 36). However, a range of β-glucans are found associated with cell wall structures in a number of protist groups, for example, associated with encystment of *Acanthamoeba* (Amoebozoa) (49, 50), the oocyst of *Toxoplasma* (50), and filamentous growth in the oomycetes (Stramenopiles) (39). Furthermore, the β-glucan paramylon can be produced at high quantities by *Euglena* (Euglenozoa) (51). Taken together, this demonstrates that β-glucan biosynthesis and utilization as a cell wall component predate the origin and diversification of fungi.

Both the β-glucan and chitin data demonstrate that the term "fungal cell wall" is a misleading concept and that it is actually a group of highly heterogeneous and dynamic traits (32, 35). These traits are found in many taxonomic groups that do not branch with or within the fungi; thus, it is important that we abandon this concept as a diagnostic feature.

NO SYNAPOMORPHY FOR THE FUNGI

The historical record of cellular and biochemical traits used as fungal synapomorphies summarized above demonstrates that the search for a diagnostic unifying character for the Fungi has failed. To paraphrase Tom

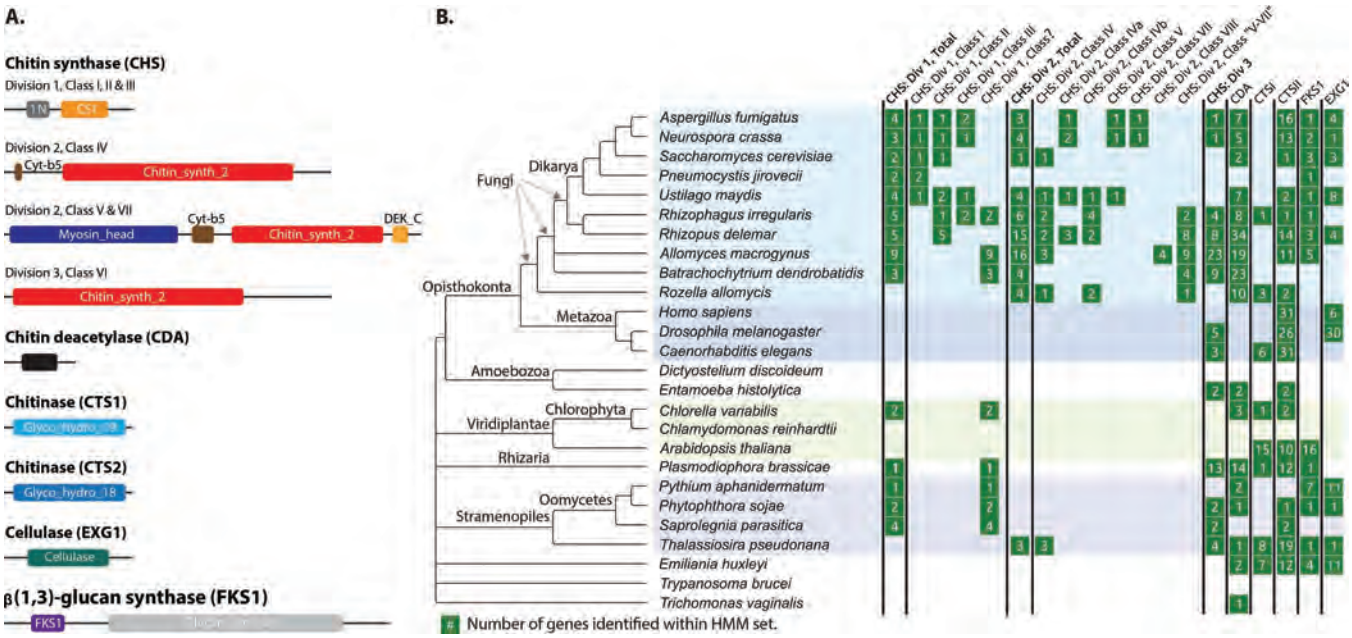

Figure 1 Diversity and distribution of gene families known to function in chitin cell wall synthesis or remodeling. (**A**) The diversity of domain architectures (as identified using PFAM [184]) for chitin cell wall synthesis or remodeling gene families. Note the gene fusion between a myosin head domain motor protein and a chitin synthase which was previously suggested to be fungus-specific (92). (**B**) The taxonomic distribution of putative homologues across a subset of eukaryotic taxa identified using a custom-built set of domain-specific hidden Markov models kindly provided by Jason Stajich and Divya Sain (185). The fungal component of the phylogenetic tree is based on Spatafora et al. (186).

Bruns, there is no fungal synapomorphy; get used to it (personal and public communication). And indeed, this is a state of affairs eloquently outlined by others (52), who coined the phrase "Bruns' law" to describe the situation of dissolving fungal synapomorphies. Yet the taxa that are indisputably fungal (e.g., Dikarya) form a coherent monophyletic group (e.g., 53–55) that undoubtedly represents a highly successful group of organisms both in terms of evolutionary diversity (e.g. 56) and ecological biomass. A more important question therefore is to ask what evolutionary transitions at or near the basal radiation of fungi tell us about the evolution, diversification, and success of this group.

EVOLUTION AT THE DAWN OF FUNGI AND THE RISE OF FUNGAL PHENOTYPES

Cavalier-Smith has set out a scenario for the origin of fungi from a protistan ancestor involving the loss of phagotrophy and the coupling of absorptive trophic function (also called osmotrophy) with cell wall development (often in the form of polarized hyphal growth) (57). Using phylogenetic reconstructions to infer characters deep within the fungal radiation, Cavalier-Smith also inferred that the ancestral fungus had an alternate nonflagellated trophic phase and a zoosporic phase (spore with a flagellum) (57). Later work involving phylogenetic reconstruction of the fungi with improved taxon and gene sampling provided data consistent with this hypothesis (53). Therefore, loss of a flagellum represents one or more derived transitions within the fungal radiation (53, 58). The loss of a flagellum is, for example, linked to radiation of terrestrial fungi, including the diversification of the Dikarya, which encompasses the majority of sampled fungal forms (53).

Interestingly, Cavalier-Smith's hypothesis for the origin of fungi involves changes in four linked biological/cellular functions, suggesting that these characteristic changes were synergistic. Specifically, these changes involved:

1. Loss of phagotrophy, which removed the requirement for a flexible cell surface membrane, allowing fungal cells to develop rigid and structurally reinforced cellular surfaces
2. Rigid reinforcement of the cell surface, which protects the cell against high turgor pressures, allowing cell function to flood the cytoplasm with high concentrations of solutes, which (i) allows for a very fast metabolic rate and (ii) allows a cell to assert high force to penetrate and ramify into robust structures as part of their feeding process
3. Evolution of rigid cells, allowing for polarized growth at the hyphal tip
4. A shift to external processing (digestion) of complex chemical compounds coupled to active transport of processed metabolites into the cell (osmotrophy or absorptive feeding [57])

Several emergent properties arise from the evolution of polarized, reinforced, osmotrophic functions. Fungi can essentially feed as they grow; i.e., they can couple the act of growth with nutrient sensing and metabolite processing, allowing for improved economy. These characters have made fungi very effective feeders, especially in environments composed of complex biological structures where fixed carbon, phosphorus, and nitrogen are packaged into recalcitrant materials which need to be broken down for utilization. This function is reflected by the observations that environments showing these characteristics, such as plant hosts, animal hosts, soil, sediments, and "litter," are often associated with high fungal biomass and diversity (4, 53, 56, 59–62). Although this pattern of evolution certainly occurred early in the radiation of the fungi, it is important to recognize that an evolutionary transition that included these four synergistic cellular/metabolic changes occurred on multiple occasions throughout the eukaryotic tree of life. For example, similar independent transitions occurred in the lineages that gave rise to the Pseudofungi (i.e., oomycetes and hyphochytriomycetes) and *Corallochytrium* (37, 63). These features are therefore not unique to fungi, yet we believe that studying how these features evolved in fungi and comparing them to other eukaryotes represents a fruitful path for understanding how fungi came to be and why they became such a successful and highly diverse group.

OSMOTROPHY RESULTS IN PUBLIC GOODS INTERACTIONS AND SYMBIOTIC ASSOCIATIONS

As a consequence of the fungal osmotrophic function, nutrients are processed in the extracellular environment, a function that underpins how some fungi operate both as parasitic and/or mutualistic symbionts of other organisms. This function has been especially important in how fungi form diverse and critical associations with land plants (64–68). As a result of the loss of phagotrophy and diversification of osmotrophic functions, fungi must also engage in public goods interactions (e.g., 64, 69–71). This is because metabolites processed by secreted enzymes outside the cell are essentially rendered accessible to any other organism that

occupies the same environment and can take up and make use of the metabolites released (discussed in references 72, 73). As such, communities where fungi function are also the sites of public goods competitions.

Microbes evolved many strategies to maximize public goods competitions. In fungi, two common biological features are predicted to function to maximize osmotrophic public goods functions. First, growth as multicellular hyphal networks allows the colonization of three-dimensional space, which hypothetically acts to minimize loss of metabolites to competitors. Indeed, comparative experiments have demonstrated that public goods functions drive the evolution of multicellularity in yeast to maximize utilization of hexose sugars released by the function of secreted enzymes (70). It has also been shown that hyphal networks allow fungi to explore wider environments, accessing additional nutrient sources where such sources are patchy, i.e., separated by zones where nutrients are absent. Fungal networks therefore demonstrate the properties of high transport capacity. Importantly, these features are also enhanced by larger networks, where the relative cost of such development is reduced by increase in the size of the network formed (74). It remains to be tested if the development of a hyphal network provides adaptive advantages over nonnetworked competitors in terms of maximizing specific osmotrophic function and public goods competitions (such as breakdown of recalcitrant material). However, as Bebber et al. (74) demonstrate, hyphal networks do maximize the economics of growth in many environments in which fungi are both diverse and abundant.

Second, fungi have hugely diversified secondary metabolism (e.g., 75). Many of the products of this metabolic function act as antimicrobial toxins (76), and many of these secondary metabolic properties are encoded by clusters of genes (e.g., 77–81). Examples of these clusters encode both metabolic pathway components and transporters (e.g., 82) to tightly couple expression (e.g., 83) and chromosomal linkage (and therefore coinheritance) of the genes encoding biosynthesis, export, and detoxification. The role of these metabolic functions is often unclear. Yet synthesis and secretion of many toxins is likely to function to exclude microbes that do not possess a cognate gene cluster encoding detoxification phenotypes from an environment where a public good is present and the toxin is produced. Such traits, often described as "spiteful" in the evolutionary ecological literature, therefore act to police access to the public goods released by osmotrophic functions (72, 73).

Even though filamentous growth, construction of a robust cell wall, loss of phagotrophy, and osmotrophic feeding make up the fungal lifestyle, and underpinned the success of fungi, it is important to note that none of these features are diagnostic for the kingdom. This is because they are all found together elsewhere on the tree of life (e.g., 37, 63). Our current understanding of both fungal diversity and biomass in terrestrial environments, however, tells us that fungi are particularly good at performing these functions. In the next section, we seek to understand what underpinned the success of this lifestyle.

WHY ARE FUNGI ECOLOGICALLY SUCCESSFUL?

Older than Their Competitors

As argued by other authors (e.g., 57), the relative age of the fungi compared to other fungus-like groups, e.g., oomycetes (Pseudofungi), hyphochytriomycetes (Pseudofungi), and *Corallochytrium* (Holozoa, Opisthokonts), may explain why they dominate many environments compared to other eukaryotic groups that grow and feed in a similar manner. Put simply, the fungi "got there first" and have successfully retained such niches by further adaptation that underpins the competitive exclusion of others. Molecular clock data suggest that the Dikarya, one of the major radiations of the terrestrial fungi, seem to date to ~500 million years ago (84). In contrast, the major radiation of the oomycetes, a group that also successfully couples a rigid cell wall, polarized cell growth, and osmotrophic feeding, seems to have occurred ~250 million years ago. The largely plant-associated Peronosporales are estimated to date from ~150 million years ago (85), some considerable time after fungal forms colonized similar plant-associated habitats. Such hypotheses (57) are difficult to test, but it is likely that fungi have had an extended time frame in which to evolve capabilities to maximize retention of terrestrial niches such as plant-associated environments.

Economic Coupling of Growth and Feeding

One other possibility is that fungi are just better at coupling rigid cell wall synthesis, polarized cell growth, and osmotrophic feeding (i.e., feeding as they grow) than their nonfungal competitors. By "better," we mean they can perform this function at a higher rate and/or with greater metabolic efficiency, allowing them to outcompete others. If this is the case, then it is likely due to adaptations in cytoskeletal functions that allow high-speed trafficking and efficient ordering of vesicles and other cellular machinery which drive rapid/efficient hyphal tip growth and feeding (such machinery

is discussed below). Indeed, some data suggest that filamentous ascomycetes can achieve very fast rates of vesicle transportation to growing hyphal tips (86). Furthermore, many fungi possess a range of unique endomembrane/cytoskeletal systems associated with the center of tip growth. These include, for example, the cytological characteristic of a vesicle organizing center called the Spitzenkörper and/or the apical vesical crescent, found at the hyphal tip of many fungi, which identifies the main area of growth in filamentous Dikarya and zygomycetes, respectively (e.g., 87, 88). Other non-Dikarya fungi have also been shown to have hyphal tip structures similar to the Spitzenkörper, specifically *Allomyces*, that branch among the deepest phylogenetic branches within the fungi (89). Yet these systems are absent in many fungi, and where present, the Spitzenkörper is highly variable in cellular structure (e.g., 87, 88). As such, it is hard to identify a cellular trait that specifically defines polarized cell growth across the Fungi.

Investigating how fungal and nonfungal microbes couple rigid cell wall synthesis, polarized cell growth, and osmotrophic feeding, however, is likely to be important for understanding the evolution of characters that underpinned the success of the Fungi. For example, a gene fusion between the actin cytoskeleton myosin motor head domain and a division 2 chitin synthase domain (e.g., 90, 91) was proposed to be a "unifying" character for the Fungi (92). This gene is localized to both vesicles and the hyphal tip and is involved in tip growth in *Ustilago* (93, 94). The myosin-chitin synthase gene fusion seemed like a good candidate for a fungal synapomorphy because the function of these protein domains involves cytoskeletal trafficking and cell wall synthesis and thus is directly implicated in polarized cell growth and rigid cell wall development. However, it is important to note that this character is absent in many established fungal groups (e.g., *Saccharomyces* and *Schizosaccharomyces* [90]) (Fig. 1), though likely due to secondary loss. Furthermore, since gene fusions are often unstable characters undergoing both fission, horizontal gene transfer, and domain rearrangement (95–97) (which has also been demonstrated in fungi [98]), it is unclear if synapomorphies of these types can be trusted. Indeed, there is some evidence that the myosin-chitin synthase gene fusion may not be specific to fungi and is present in other opisthokont lineages (63, 91) and therefore is invalid as a synapomorphy for the Fungi. However, even though it is not a unifying feature, the acquisition of the myosin-chitin synthase gene fusion undoubtedly contributed to filamentous growth functions within the Fungi.

Looking elsewhere in fungal growth and feeding may also prove fruitful for understanding what functions underpinned the success of fungi. Cellular growth in fungal filamentous structures occurs almost exclusively from the tip (99); this is part of the function that allows them to grow as they feed. This feeding process occurs at a high rate in Pezizomycotina that specialize in filamentous growth (86). However, these endomembrane and cytoskeletal systems were co-opted to control bud growth in *Saccharomyces cerevisiae*. Subsequently, *S. cerevisiae* has been developed as a model system for studying protein function associated with polarized growth (99, 100) (Fig. 2).

Briefly, polarized growth occurs by delivery of secretory vesicles from the Golgi (Fig. 2A, see step i) along cytoskeletal tracks to predetermined areas of the cell membrane (in filamentous fungi this would be at the hyphal tip). This process is initiated by Cdc42, which is activated by its guanine-nucleotide exchange factor Cdc24 (Fig. 2A-ii), which leads to the development of a network of physically interacting proteins (99, 100) known as the polarisome (Fig. 2A-iii). The polarisome, and specifically the formin Bni1, radiates actin cables (101) which play a key role in exocytosis (102). Msb3 and Msb4 interact with Spa2, a scaffold protein of the polarisome (Fig. 2A-iv), and are hypothesized to recruit Cdc42 from the cytosol at the site of tip growth (103). Post-Golgi secretory vesicles are transported along the actin cables using a type V myosin (Myo2) motor protein (104, 105) (Fig. 2A-v) to dock with another multiprotein complex called the exocyst in a process that is dependent on Sec4 and its guanine-nucleotide exchange factor Sec2 (106, 107) (Fig. 2A-vi). This process therefore enables the vesicle to be guided to its target site on the plasma membrane (108). Cdc42, along with Rho1, is required for localization of Sec3, which acts as a spatial marker for the formation of the exocyst (Fig. 2A-vii), while Rho3 and Cdc42 mediate docking of the Golgi-derived vesicle (Fig. 2A-viii). In filamentous fungi, homologous sets of proteins function similarly; however, an even more complex set of polarity factors are present; e.g., in addition to Cdc42, another RhoGTPase, Rac1, and an expanded set of effectors (guanine-nucleotide exchange factors and GTPase-activating proteins) play key roles in regulating these processes (109–111).

The polarisome and the exocyst, and proteins associated with these complexes, are very important for establishing the temporal and spatial control of polarized cell growth. They also fit the criteria of key functional adaptations that underpin the success of fungi as microbes because their function is linked to rigid cell wall

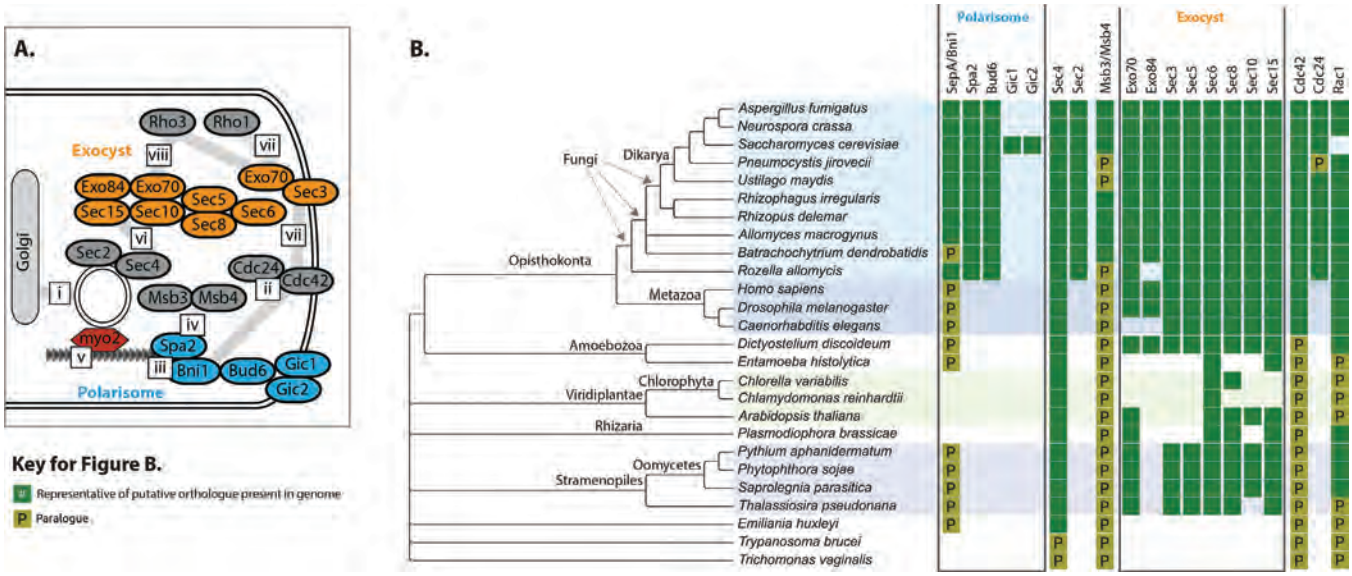

Figure 2 Diversity and distribution of gene families known to function in hyphal growth. (**A**) A cartoon illustrating how proteins interact relating to subprocesses which govern vesicle trafficking associated with hyphal growth. Functions are briefly discussed in the main body of this manuscript and are marked i to viii. (**B**) The taxonomic distribution of putative orthologues identified using reciprocal BLAST searches and phylogenetic methods across a subset of eukaryotic taxa (data not shown). The fungal component of the phylogenetic tree is based on Spatafora et al. (186).

development, polarized cell growth, and osmotrophic feeding. As such, these are examples of the systems we should investigate from the perspective of fungal cellular function and GTPase-activating protein evolution.

Comparative genome analysis shows that the exocyst system and Sec4 orthologues are conserved across a diversity of eukaryotes (112, 113), suggesting a broad function in directing the interaction between vesicle, membrane, and cytoskeleton (Fig. 2B). Given current genome sampling, polarisome components seem to be unique to fungi. However, preliminary genomic data suggest that these components could be present in unpublished but publicly available opisthokont protists (data not shown), thus demonstrating further evidence that many functions and gene networks associated with fungal growth are not specific to fungi.

INCREASED SAMPLING FURTHER CHALLENGES OUR UNDERSTANDING OF THE TREE OF LIFE

So far, we have reviewed the data demonstrating that, to date, no cellular or genomic characters have been identified that represent a synapomorphy for the Fungi. As a consequence, it may be argued that the best definition of fungi is a phylogenetic definition. Specifically, our best approximation of defining the kingdom is declaring, "Phylogenetic cluster X incorporating known taxa A, B, C, etc., represents the Fungi." This is a challenging state of affairs because where one draws the line on a phylogenetic tree to define the kingdom is also problematic. This is because the phylogenetic tree is incomplete in terms of genetic data and the diversity of groups sampled. Several discoveries over the past 20 years have repeatedly challenged how and where we mark the Fungi on a phylogenetic tree. In the next section we will briefly outline these discoveries.

Protistan Relatives of Fungi

Multigene phylogenetic analyses have demonstrated that the opisthokont radiation is composed of two major evolutionary branches: (i) the Holozoa, which comprise Metazoa, Choanoflagellata, Filasterea, *Corallochytrium*, and Ichthyosporea, and (ii) the Holomycota, which comprise fungi, *Fonticula*, and *Nuclearia*, with *Fonticula* and *Nuclearia* forming a robustly supported clade sister to fungi (63, 114, 115). This branching relationship suggests that *Fonticula* and *Nuclearia* should have characteristics similar to fungi and to the exclusion of others including the Holozoa. In reality, however, what we see is a diverse mosaic of characters, initially attributed to fungi and now identified to be

present across the opisthokonts, specifically in Holozoa protists.

Holozoa comprise a wide diversity of biological forms, which are not possible to discuss at length here. However, for the purposes of this article, it is important to mention that representatives of the nonmetazoan Holozoa show many of the characteristics thought to typify fungi. These include *Corallochytrium limacisporum*, a free-living protist which appears to have lost phagotrophy and feeds via osmotrophic function, a pattern of convergent evolution mirroring that which occurred within or at the base of the Fungi (63). Similarly, during host-associated stages, holozoan parasites *Dermocystidium salmonis*, *Ichthyophonus hoferi*, *Psorospermium haeckii*, and *Rhinosporidium seeberi* absorb nutrients through their cell wall structures (for review, see reference 116). Members of the Ichthyosporea (e.g., *A. parasiticum* and *I. hoferi*) develop polar growth similar to that seen in fungal hyphae (63, 117). Representatives of the Ichthyosporea also showed diversified sets of chitin synthase genes (63) presumably used as cell wall components. *I. hoferi*, for example, has chitin in its cell wall (118), and the Dermocystida *R. seeberi* appears to encode a class 2 chitin synthase (119). *C. limacisporum* putatively encodes a division II class IV/V/VII chitin synthase-myosin fusion (63) previously thought to "unify" the Fungi (92). Furthermore, *Corallochytrium* and members of the Ichthyosporea have a developmental cycle that involves a single-celled flagellated zoospore (e.g., *Sphaerothecum destructans*) and a multinucleated (coenocyte) feeding structure, a developmental cycle that has similarities to that of "chytrids" (i.e., fungi that form spores with a flagellum [zoospores] and which were at one stage classified as Chytridiomycota but were later divided into three phyla: Chytridiomycota, Blastocladiomycota, and Neocallimastigomycota [63, 116, 120, 121]). Both Ichthyosporea and *Corallochytrium* branch on the Holozoa side of the opisthokont tree, but current phylogenetic analysis does not confirm with strong support whether these groups are monophyletic (63), making it difficult to reconstruct the evolution of these "fungal-like" characteristics in the Holozoa as either multiple cases of convergent evolution or retention of ancestral traits.

Nuclearia are a group of pseudopodia/filipodia-forming "obligate" amoebae and were first identified as a separate protist lineage within the Opisthokonta by small-subunit (SSU) rDNA sequencing and phylogeny (122). The related *Fonticula alba* is a cellular slime mold and an amoeboid protist which can form multicellular fruiting bodies (115, 123). Both of these taxa are phagotrophic and lack a trophic phase typified by absorptive/osmotrophic feeding and a chitin cell wall (115); as expected, they fail many definitions of fungi (e.g., 57). The phylogenetic placement of *Fonticula*/*Nuclearia* as a close relative of fungi (e.g., 63, 115) separates the Fungi from many holozoan protists which also have fungus-like characteristics (discussed above). Furthermore, this placement suggests that a close ancestor of fungi was a pseudopodia/filipodia-forming phagotrophic cell with an alternative flagellated life cycle stage.

Interestingly, environmental sequencing has also suggested a large diversity of phylogenetic branches associated with *Fonticula* in both freshwater and marine environments. These results suggest a wealth of unexplored biodiversity associated with this branch (124, 125), which could potentially further confuse evolutionary trait reconstruction at or near the origin of fungi.

New Branches Near the Origin of Fungi

The history of our understanding of fungal diversity has been dominated by what can be cultured on selective solid media (e.g., 126). Such methods have proved very effective at recovering some fungal groups, especially Dikarya, but are less effective at recovering other groups such as the chytrids and non-Mucorales zygomycetes. Microbes that take part in complex symbiotic associations with other organisms or are propagated in liquid environments are often excluded by culture plate sampling techniques, meaning that our understanding of biodiversity is largely incomplete. Culture plate methods also act to select for certain fungal groups that grow quickly on solid media with abundant nutrients. This means that many fungal groups can readily be recovered from natural environments even though these microbes were not active or abundant in the initial environment sampled. Their rapid growth on culture plates means they competitively exclude those microbes that were actually active and dominant in the environment sampled. Therefore, such sampling can be positively misleading regarding the true diversity of fungi, and indeed other eukaryotic microbes, present in an environment. As such, our understanding of the tree of life is partial and biased (as discussed in references 127, 128).

Our understanding of how extant biodiversity maps onto the tree of life, specifically at the base of major groups such as fungi, has been challenged by two lines of research. First, environmental DNA analysis has revealed that uncultured groups, which are both diverse and abundant in natural environments, represent substantial additions to the tree of life in terms of both branch placement and molecular diversity (e.g., 128–130). These include, for example, a group formally

known as soil clone group 1 (131), which has been detected in numerous soil environments (132) and which was later classified as Archaeorhizomycetes within the ascomycete subphylum Taphrinomycotina (133). Second, molecular sequencing combined with phylogenetic analysis of groups once thought to be distant relatives of fungi has shown that such groups branch within, or at the base of, the fungal radiation (e.g., microsporidia, discussed below).

There are now examples of both types of these newly discovered and placed groups that collectively challenge where we draw the line that defines fungi and consequently which characters are used for this definition. In the following section we shall briefly introduce some of these groups and what data are available pertinent to our understanding of the origins and classification of fungi. In many cases the phylogenetic placement of these groups relies on (partial) 18S SSU rDNA gene phylogenetic analysis and also includes rDNA sequences that form long branches in phylogenetic trees. Phylogenetic analysis of such datasets provides very inconsistent and often misleading results (134–136), meaning that the placement of these groups relative to each other and the boundary that defines fungi is largely unresolved and requires comprehensive multigene phylogenetic analysis.

Aquatic Environmental Sequencing and the Expansion of the Chytrid Branches

The use of environmental DNA methods (127) for sampling aquatic environments, including both freshwater and marine environments, has revealed a diversity of novel SSU rDNA sequences that cluster among the deepest branches of the Fungi closest to known chytrid taxa (e.g., 137). The phylogenetic placement of these sequences often involves relatively long branches, and the bootstrap support is often weak; for this reason, the phylogenetic relationships reported should be treated with caution. Nonetheless, these data suggest a diversity of undescribed and uncultured chytrid-like forms that exist in aquatic environments (e.g., 137–141). Strikingly, these sequences show a trend of low levels of sequence similarity to taxonomically described fungi compared to environmental sequences that cluster with the Dikarya (142), suggesting there is a wealth of unexplored phylogenetic diversity present in aquatic environments and branching within or close to known chytrid groups. However, it is possible that this pattern is exaggerated by a slower rate of rDNA variation in Dikarya as compared to the chytrids.

It has been hypothesized that this chytrid diversity is an important component of the heterotrophic flagellate community in water column communities, playing a key role in the microbial loop as either parasites and/or saprotrophs (143–145). However, the nature of the detection of these groups (environmental sequencing) means that understanding their biology and ecology is difficult. However, clear examples of chytrid groups (146, 147) and their affiliates (145) have been identified associated with diatoms, suggesting trophic interactions with primary producers in both marine and freshwater environments. Their phylogenetic placement as allies to the Chytridiomycota and other chytrids would, however, suggest that they have a life cycle with alternating nonflagellated trophic and zoosporic phases and can form feeding structures reinforced with a chitin cell wall. However, work is needed to investigate the biology of these groups to confirm the presence of these life cycle characteristics.

Possible Fungal/Chytrid-Like Group Known as Basal Clone Group 1

Among the diversity of SSU rDNA sequences sampled from aquatic environments, one distinct group has consistently been identified. This group of sequences was initially detected in marine sediments (148) and deep-sea environments (139, 149, 150) using PCR targeting a wide diversity of eukaryotic SSU rDNA combined with clone library selection and sequencing (see GenBank sequence KD14-BASS [GenBank accession: EU154992] or DSGM-63 [AB275063] for exemplar representatives of this group). This clade has subsequently been detected in RNA and DNA samples from a range of marine environments (e.g., 141, 142), including both sediments and water-column samples, and is associated with both large and small filtration fractions, suggesting that this group has a complex life cycle in which it forms different cellular morphotypes or interacts with second-party cells (141). Phylogenetic analysis of the SSU rDNA sequences gives a mixed picture of the placement of this group, forming a relatively long and distinct branch that in some analyses is placed among the Fungi (e.g., 149), while others show it as a branching sister to Ichthyosporea (e.g., 139). Work is needed to assess the ecological roles and evolutionary position of this diverse and divergent group. Such analyses will likely have implications for understanding the evolutionary patterns within the Opisthokonta independent of whether or not this group branches within Fungi.

Microsporidia

Microsporidia have historically been placed at numerous branching points in the tree of life, and their lack of many eukaryotic cellular structures (e.g., flagella,

mitochondria, and typical stacked Golgi) has made it difficult to assign them to a higher taxonomic group based on ultrastructural data (57). SSU rDNA phylogenetic trees initially placed the microsporidia at the base of the eukaryotic radiation. This result, along with the absence of these cellular structures and the characteristic of short prokaryotic-like SSU rDNA genes, had been used to argue that they were derived from an early—premitochondrial—phase of eukaryotic evolution (151). This hypothesis has been refuted with the demonstration that microsporidia possess highly reduced mitochondria-like organelles (152) and that microsporidian nuclear-encoded proteins are of mitochondrial ancestry (153, 154). Additionally, phylogenetic analysis of nuclear-encoded protein coding genes with appropriate correction for site rate variation has shown that the microsporidia branch with fungi (e.g., 155, 156). Gene synteny analysis of the *sex*-related locus demonstrated that fungi and microsporidia share a unique syntenic pairing of the RPS9 and RPL21 encoding genes, supporting the close phylogenetic association of fungi and microsporidia (157). The placement of microsporidia with fungi therefore demonstrates that the microsporidia are a striking example of genomic and cellular reduction when compared to their fungal and protist relatives (158).

The microsporidia encompass over 1,500 described species, which are all intracellular parasites that infect other eukaryotes. The defining feature of microsporidia is the development of long polar tubes coiled within the parasite's cell, which are used to infect the host cell (158) as part of their life cycle, although some microsporidia can invade host cells via host phagocytosis (159). Microsporidia do not form a walled trophic form and they do not form filamentous structures similar to hyphal cells (57), which are characteristics argued to underpin the successful radiation of the fungi discussed above. The majority of microsporidia do form a chitin cell wall around their spore (57). Because microsporidia lack flagella, they do not form an alternate nonflagellated trophic phase and a zoosporic phase as part of their life cycle. Such characteristics are thought to typify the ancestral fungus (discussed above) and are found in *Rozella* (discussed below). As such, independent of where the microsporidia are placed relative to the origin of the fungi, they have secondarily lost these characteristics.

The pattern of genomic and cellular evolutionary reduction that is evident in the microsporidian lineage makes it difficult to identify characters that can be putatively assigned as shared synapomorphies with established fungal taxa, which in turn further complicates how we define the kingdom. Specifically, it makes it very difficult to support either of these statements: "Microsporidia belong in fungi," or alternatively, "Microsporidia belong as a sister group to fungi," even though improved multigene phylogenies suggest that they branch with *Rozella* (55) and *Rozella* has historically been classified as a fungus (e.g., 160).

Cryptomycota-Rozellomycota-Rozellida-Rozellosporidia

A range of phylogenetic analyses suggest that *Rozella* represents the first phylogenetic branch among fungi (53, 55). This conclusion is based on the premise that *Rozella* has historically been classified as a fungus (e.g., 53, 121, 160), although the treatment of *Rozella* as a fungus is now debated (161, 162). As such, the biology of *Rozella* and associated groups is very important for understanding the evolutionary transitions at, or near, the base of fungi. Concatenated multigene phylogenetic analysis suggests that *Rozella* branches with the microsporidia, although alternative branch placement with statistical comparisons could not reject microsporidia branching separately from *Rozella* as the next branch below the fungi (55). Shared derived horizontal gene transfers (HGTs) were also identified that support the sisterhood of *Rozella* and the microsporidia (55, 163), but again the taxon distribution of these characters could potentially be amended by additional genome sequencing demonstrating a wider distribution of the HGTs.

Rozella has also been shown to be part of a large and diverse group of uncultured microbes, primarily identified through environmental DNA techniques (and which also seem to form associations with diatoms [147, 164, 165]). This environmental group, along with *Rozella*, has been given a range of different names, i.e., Cryptomycota, Rozellomycota, Rozellida, and Rozellosporidia. *Rozella* (unlike microsporidia) has a life cycle composed of alternating nonflagellated trophic and zoosporic phases (166). Fluorescent *in situ* environmental DNA methods combined with antibody staining of microtubules demonstrated that some subgroups within the environmental clade related to *Rozella* also develop alternative nonflagellated and zoosporic phases (165). These results are consistent with this biphasic life cycle being present in the earliest diverging groups of the Fungi.

Like microsporidia, *Rozella* and its uncultured relatives were thought to lack a cell wall during trophic growth within the host (160). Indeed, *Rozella* grows within its host as naked unicellular thalli (160). Furthermore, *Rozella* is thought to feed phagotrophically on host cellular structures because it was shown

to form pseudopod-like projections surrounding host cytoplasm (167) during infection. Fluorescent *in situ* RNA labeling combined with cell wall staining of cells captured using environmental sampling allowed analysis of only fragments of the life cycle of additional representatives of this group but suggested that a chitin cell wall is absent from a subset of life cycle stages, although it should be noted that such sampling is incomplete either for the life cycle of an individual species or across the wider group (165). Follow-up work has since demonstrated that *Rozella* does indeed produce a chitin cell wall as a resting spore as well as during the invasion process, where the production of a cell wall is specifically linked to host penetration (55, 92), but it does not seem to use a cell wall during trophic growth. This pattern of development has similarities with how microsporidia use their chitin cell wall. Consequently, *Rozella*, like some true fungal groups (discussed above), fails the definition of fungi that requires a developmental stage composed of a trophic form with a chitin cell wall (57).

Recent exciting work has shown a number of established cultures of intracellular microbes branching within the radiation of environmental sequences that branch with *Rozella* (168). This allows us to further investigate the phylogeny and cellular characteristics present in this otherwise cryptic environmental group. One of the striking results of this work is the demonstration that subgroups within this radiation possess cellular structures similar to the microsporidia. Specifically, *Paramicrosporidium* was shown to produce unflagellated chitin and/or cellulose-walled spores (as indicated by calcofluor white staining) and grow within the host as unwalled nonphagotrophic meronts (168)—again like microsporidia. *Nucleophaga amoebae*, a microbe initially described in 1895 (169; see 170) as a "chytrid" fungus, was also shown to branch within the radiation of environmental sequences that branches with *Rozella* and, also like *Paramicrosporidium*, produces unflagellated chitin and/or cellulose walled spores (168, 170). Interestingly, *Nucleophaga* (see Fig. 1C and D in reference 170) and *Paramicrosporidium* (see Fig. 1C–E from reference 168) also develop putative anchoring disks and an atypical polar filament like microsporidia.

Haag et al. (171) identified a novel gut microbe of *Daphnia* named *Mitosporidium daphnia*. Genome sequencing combined with phylogenetic analysis showed that this taxon branched at the root of the microsporidia in a phylogeny of 53 gene families. However, rDNA phylogenetic analysis encompassing much wider taxon sampling shows that *Mitosporidium* branches within the radiation of environmental sequences that branch with *Rozella* (170). Cytological analysis shows that *Mitosporidium* possesses a microsporidia-like polar tube and lacks a flagellum for spore dispersal. Collectively, these results show, in comparison to what we know about *Rozella*, that this group seems to be a mosaic of fungal chytrid and microsporidian cellular features. This mosaic pattern of features is further complicated by evidence that representatives of this group (e.g., *Nucleophaga* and *Rozella*) can form pseudopodia-like cytoplasmic projections and possibly perform phagotrophy (167, 172), a feature that, under some definitions, must be absent for a group to be classified as fungi (57).

Aphelids

Aphelids are amoeboflagellate parasites of microalgae (173, 174) classified as protists. They form zoospores resembling those of chytrids, yet in contrast to known chytrids, aphelids feed via phagotrophy when inside their host (e.g., 173). *Amoebaphelidium protococcarum* (173), like other aphelids (175, 176), attaches to host cells, produces a cyst cell wall, and penetrates the host via a germ tube, a process that is similar to how *Rozella* and microsporidia enter the host. Once inside the host, they form pseudopods and feed on host-derived cytoplasm via phagotrophy, unlike microsporidia but possibly in a manner similar to the intracellular pseudopodia development observed for *Rozella* (167). Phylogenetic analysis based on three rDNA encoding genes and two protein encoding genes demonstrates strong support for the monophyly of microsporidia, *Rozella*, and the aphelids, which together are argued to form a sister clade to the fungi (173). These results were used, along with similarities in germ/infection tube apparatuses and a posterior vacuole, to suggest that these groups form a distinct monophyletic group (named aphelid-*Rozella*-microsporidia) (173) now formally classified by some as Opisthosporidia (162).

The data discussed in this section cover numerous groups newly and/or only partially sampled and demonstrate collectively that we are some distance from achieving an accurate census of the diversity of microbial forms that branch within, or close to, the Fungi. Furthermore, these data also show that we still know relatively little about the diversity of cellular and genomic features that are evident within groups that branch close to the Fungi. This state of affairs makes it very difficult to understand the evolution of traits such as cell wall development, hyphal growth, flagellum formation, phagotrophy, and pseudopodia formation across the deep branches of the Fungi. However, further investigation into these deep-diverging lineages

of fungi/protists will undoubtedly aid our understanding of the traits present in early fungi and help to explain the general ecological and evolutionary success of the fungal lineage.

PSEUDOPODIA FORMATION ACROSS THE DEEP BRANCHES OF THE FUNGI FURTHER CONFUSES THE FUNGI-PROTIST DISTINCTION

One current suggestion is to go against the historical classification of *Rozella* and *Nucleophaga* as fungi and exclude *Rozella* and its phylogenetic allies from the Fungi because they are thought to be phagotrophic (161). *Rozella* and related groups have been shown to form pseudopodia-like projections (167, 170), cellular features linked to phagotrophic function (172). Phagotrophy is argued as necessarily absent in taxa within the Fungi (161). However, it has been known for some time that chytrid zoospores from groups unambiguously classified as fungi also form short pseudopodia and develop amoeboid stages, e.g., *Amoebochytrium*, *Caulochytrium*, *Catenaria*, and *Paraphysoderma* (see 172). However, in these cases, pseudopodia appear to be used to crawl, and true phagocytosis, to our knowledge, has never been reported.

Pseudopodia (and the similar cellular structures of filopodia) are fine actin-based membrane-cytoplasmic cell surface projections used for both environmental sensing and cell motility and form structures necessary for phagotrophy. This cellular characteristic is found throughout the eukaryotes and is thought to have evolved early in their evolution (177), long before the emergence of the fungal lineage. In recent work, phylogenomic comparisons of genes encoding actin-based cellular protrusion proteins showed these gene families to be present in fungi (178). These include, for example, the Arp2/3 complex involved in actin-remodeling (179), which in metazoans is regulated by WASP and cortactin function (180). The seven subunits of this complex are present in all major eukaryote groups and almost all eukaryotes surveyed which make pseudopodia/filipodia, consistent with the idea that pseudopodia/filopodia development has a deep origin within the eukaryotes (178). In contrast, Ena/VASP, an actin-regulation protein which functions in pseudopodia/filopodia formation (181), is exclusive to Amorphea/Unikonta and appears to have been secondarily lost in the Fungi (178), although genome sampling in this study only included Dikarya and two chytrid genomes.

Recent and exciting work by Fritz-Laylin and colleagues has investigated the evolution of the genes encoding proteins with what they define as "α-motility" (motion driven by actin-filled pseudopods at the leading edge of the cell and involving fast migration and weak nonspecific adhesion to external surfaces [182]). Using comparative genomics, they showed that lineages with both WASP and SCAR/WAVE, activators of branched actin assembly, make the three-dimensional pseudopods needed for α-motility. These genes encode proteins responsible for "nucleation promoting factors" that drive assembly of branched actin by the Arp2/3 complex and are distributed throughout the eukaryotic tree, suggesting an ancient origin and function (178, 182). The distribution pattern of WASP and SCAR/WAVE encoding genes was then used to identify pseudopod function in the chytrid fungus *Batrachochytrium dendrobatidis*. Specifically, they demonstrated that zoospores, which naturally lack a cell wall, form *bona fide* dynamic pseudopod-like protrusions, and staining of these structures demonstrated a "shell of cortical actin surrounding the cell body and a dense network of filamentous actin filling the pseudopod" (182). To test this observation further, drug treatment with an actin nucleation inhibitor significantly reduced the number of cells with identifiable pseudopodia-like structures (182). These data confirm that species of established fungal taxonomic groups form pseudopodia-like structures.

It is therefore clear that the cytoskeletal systems associated with pseudopodia, a cellular function that overlaps with phagotrophic function, were not cleanly lost at the base of the Fungi and that elements of these cellular systems are retained within some fungal branches. As such, the hypothesis that loss of phagocytosis is the defining trait for the Fungi requires further work to understand the evolution of the cellular systems that drive this function. We suspect that even with a clear set of data identifying cell/molecular traits associated with phagotrophy, and a full understanding of how the genes that encode this function are distributed in fungi and protists, no clean separation between fungi and protists will be evident for this trait. This is partly because phagotrophic function, as we currently understand it, is defined by few specific protein families (e.g., 183). Furthermore, if such phagotrophic genes can be found, they are likely to have also been lost in other eukaryotic groups that have lost phagotrophy, for example, plants and oomycetes, making the loss of such traits an unreliable demarcation for the Fungi.

CONCLUSION

This review has discussed how the definition of the Fungi, and the list of taxa that are included within this

kingdom, have been in a continual state of flux. An additional purpose of this historical review of failed fungal synapomorphies is to demonstrate that cellular, molecular, and genetic characters are hostages to fortune; i.e., they are very likely to be shown by further sampling to have complex evolutionary histories which invalidate them as diagnostic characters. This is because the features that have been argued to define the kingdom are either only partially present in the Fungi or, more importantly, are present elsewhere in the tree of life (summarized in Fig. 3). In most cases, for features used to identify the kingdom Fungi, both situations are true. It can be argued that the loss of a trait within a monophyletic group, for example, the loss of ergosterol within the Fungi, does not invalidate the use of such a character as a defining synapomorphy

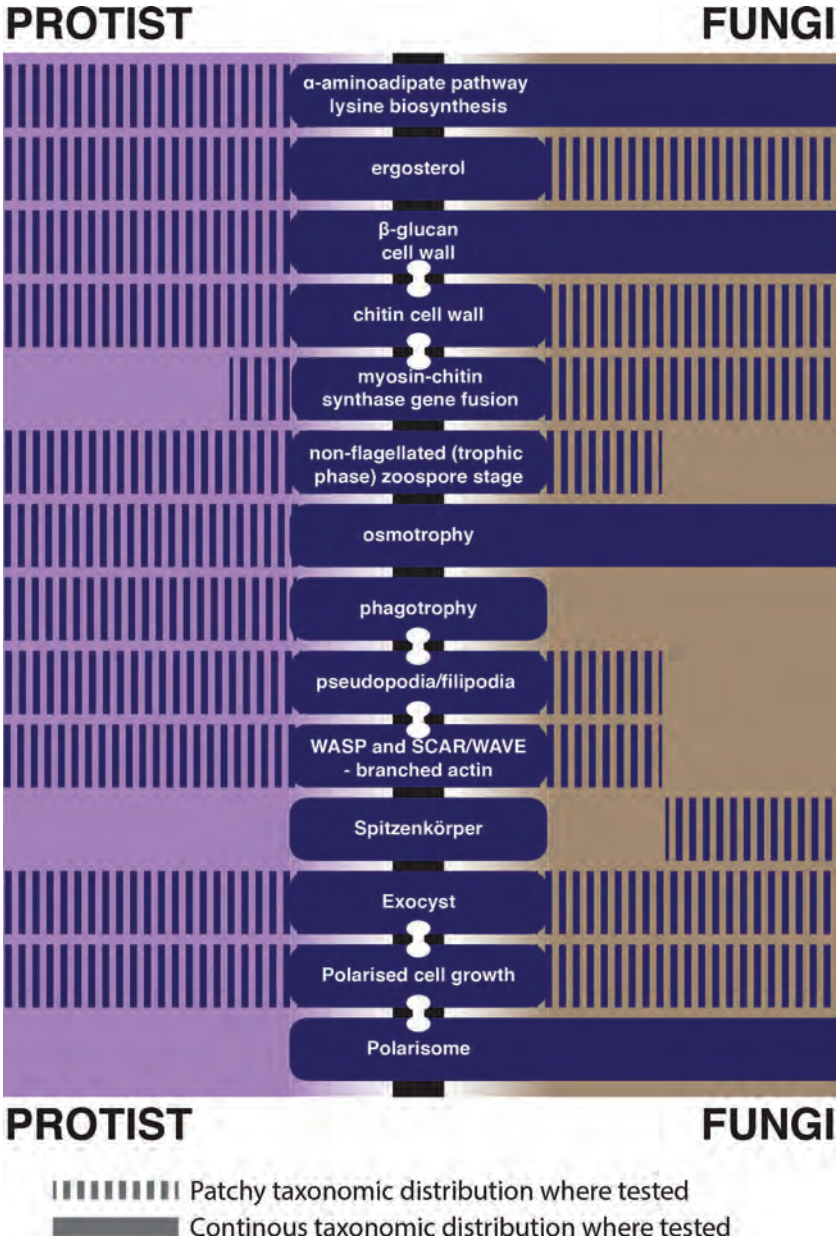

Figure 3 Cartoon illustration summarizing how features previously discussed as defining the protist-fungal transition have been shown to have a mosaic distribution within the Fungi and/or outside the Fungi among other eukaryotes. White connecting nodes illustrate linked characters/traits.

because loss represents a secondary modification. Yet the demonstration that a trait is not exclusive to the group it is said to define, and instead is present throughout the tree of life, is a knockout blow. This means that such characters cannot be used as a synapomorphy for the evolutionary group intended, unless a unique aspect of the trait can be identified which is specific to the group it is claimed to define. Likewise, we find the use of trait loss, such as the loss of phagotrophy, as a defining synapomorphy problematic because the loss of such traits has occurred on numerous occasions, which makes it difficult to see how loss can uniquely identify a group. This is further complicated by the observation that multiple chytrid lineages build pseudopodia/filipodia. Pseudopodia/filopodia are cellular systems that are prerequisites for phagotrophy, suggesting that the molecular characteristics that define the trait "phagotrophy" were not cleanly lost prior to the diversification of taxa currently unambiguously defined as fungi.

This debate is further complicated by the large number of highly diverse phylogenetic branches which are very difficult to place with or within the Fungi (summarized in Fig. 4). This confuses our understanding of character evolution. It remains a point of contention (e.g., 92, 161, 162) whether many of these groups and the associated uncultured environmentally detected diversity should be classified as fungi (such definitions are of course dependent on what characters are used to define fungi).

We do not deny that there is a unit of biodiversity that can be classified as fungi, but we argue that the line between fungi and protists is, at this point, a hostage to fortune and therefore will change given further sampling of taxa, genomes, and traits. As such, we prefer to see the transition from protist to fungi as gradual, with no clear demarcation. It therefore largely becomes a matter of emphasis where one draws the line which marks the border of the kingdom. We do not see this as a negative statement. Nor should this point be confused with philosophical arguments that can be summarized as a disagreement between the "lumpers" and the "splitters." Rather, we hope to encourage the field

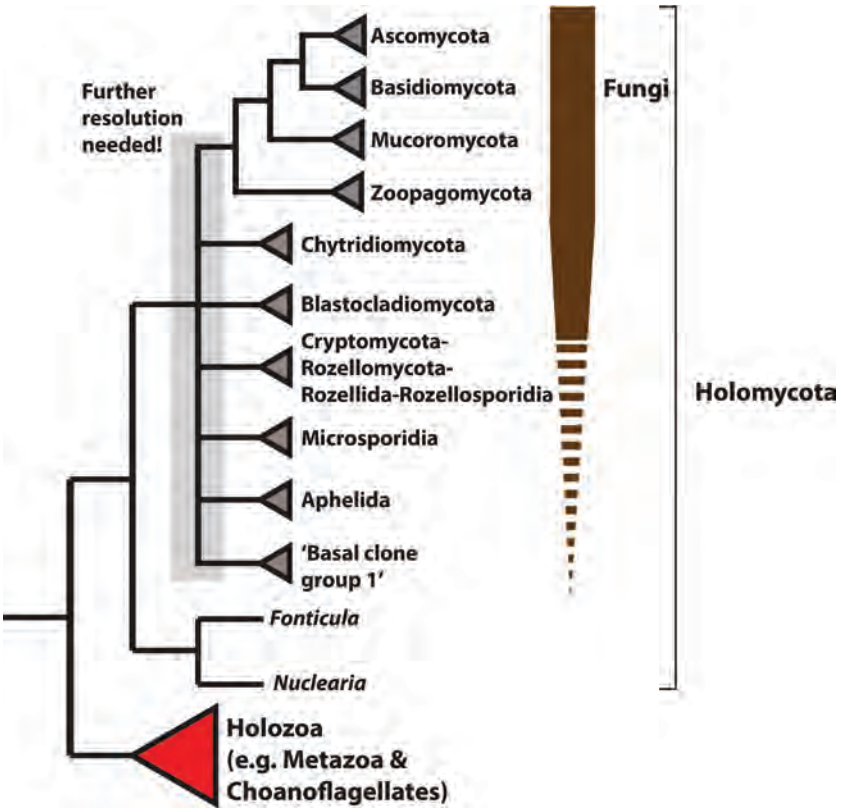

Figure 4 Schematic phylogenetic tree illustrating additional groups branching proximate to the origin of the fungal clade and the phylogenetic uncertainty among the deep branches of the Fungi and associated groups. Basal clone group 1 is composed of environmental sequences, which in some analyses is placed close to fungi (149).

to focus less on constructing categories unlikely to stand the test of time and focus more on seeking explanations for major transitions in the clade. This being said, it is perfectly possible that, with the growth of comparative data sets, a clear line can be established that separates protists and fungi. However, it would not surprise us, given what we are learning about groups historically classified as chytrids (e.g., 182), if many of these groups end up resembling protists more than fungi, which would lead to much taxonomic revision if strict naming conventions are to be imposed. This leaves us in a confusing state of affairs because we currently lack a consensus on the definition and composition of the kingdom Fungi such that it could be argued that the definition of fungi (or protist) does not matter at all. However, on an optimistic note, the investigation of the boundary between fungi and protists is going to tell us a lot about what drove the success of this evolutionarily diverse group, and this understanding, we believe, is the real prize.

Fungal Diversity Revisited: 2.2 to 3.8 Million Species

4

David L. Hawksworth[1] and Robert Lücking[2]

BACKGROUND

In 1825, Elias Magnus Fries (1794–1878) predicted that the fungi would prove to be the largest group in the vegetable kingdom, analogous to the insects in the animal kingdom. Notwithstanding that fungi are not actually part of the plant kingdom, how right he has proved to be as the bicentenary of his prediction approaches. By the 1960s a few mycologists were speculating that there might be as many fungal as plant species, but almost no attempts to calculate estimates from the available data were made. As concern over the conservation of biodiversity in general grew in the subsequent decades, culminating in the signing of the Convention on Biological Diversity in 1992, more precise figures on species numbers of all kinds of organisms were required. A series of estimates of the number of fungi settled on figures ranging from 500,000 to almost 10 million species, with 1.5 to perhaps 5 million receiving most support among mycologists. A recent study even predicts up to a trillion species of microorganisms globally (1); how many of these are supposed to be fungi is not specified, but if this estimate holds true and only 1% of these were fungi, the global estimate of fungal diversity would be a thousand times higher than the current highest estimate of 10 million species.

Different extrapolation techniques have been used to arrive at global fungal species richness estimates, including publication rates of new taxa (2), plant:fungus ratios (3, 4) similar to plant:insect ratios first used in Erwin's famous study (5), quantitative macroecological grid-based approaches (6–8), methods based on environmental sequence data including plant:fungus ratios (9, 10), and ecological scaling laws (1).

This article provides updated background information on the number of described species and explores new evidence obtained from rates of species discovery, extrapolations from fungus:plant ratios, and molecular sequence data from environmental samples. We conclude by indicating where undescribed species are likely to be found and recommend a working number suitable for general use in estimates of global and regional species richness.

We focus here on the numbers of species in the kingdom *Fungi*, that is, inclusive of the *Cryptomycota* and *Microsporidia*, and also including lichen-forming fungi. We do not, however, consider other organisms that mycologists study as fungi, such as the fungal analogues *Mycetozoa* (as an unranked supergroup or in the kingdom *Protozoa*, phylum *Amoebozoa*) and *Oomycota* and *Hyphochytriomycota* (in the kingdom *Heterokonta* = *Straminipila*). However, we caution that some data sets and papers discussed in the following sections are based on fungi in the broad sense and thus include information from the analogue phyla. While readers should bear this in mind, the numbers of known taxa in these groups are relatively modest, so their occasional unavoidable inclusion will not materially affect the interpretations presented here.

EVIDENCE FROM PUBLICATION RATES OF NEW TAXA

Numbers of Described Species

The number of new species described in each decade, as recorded in the Index Fungorum database (http://www.indexfungorum.org), shows three distinct phases (Fig. 1): an ascending phase in which progress was fast in the 1750s to 1860s, a steep phase as microscopy came into general use and there was intensive collecting

[1]Department of Life Sciences, The Natural History Museum, London SW7 5BD, United Kingdom, and Comparative Plant and Fungal Biology, Royal Botanic Gardens, Kew, Richmond, Surrey TW9 3DS, United Kingdom; [2]Botanischer Garten und Botanisches Museum, Freie Universität Berlin, 14195 Berlin, Germany.

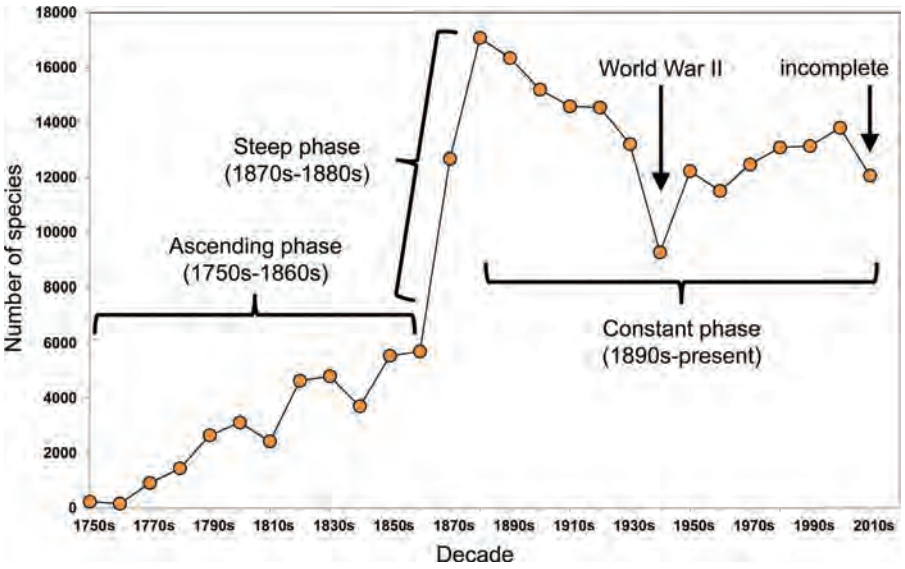

Figure 1 Numbers of newly introduced species names of fungi for each decade from 1750 to 2010. Based on data from the Index Fungorum database provided by P. M. Kirk.

in hitherto barely explored parts of the world in the 1870s to 1880s, and then a relatively constant phase from the 1890s to the present day. The partially higher figures in the first decades of the "constant phase" reflect continuing exploration and a number of prolific individual mycologists. The rate of description over the past 40 years has, however, remained fairly constant at around 1,300 per year (Fig. 2), with peaks generally relating to particular major monographic works.

Of special note is the somewhat steep increase in the rate since 2010 to around 1,800 per year. This resurgence in species description is largely attributed to the increasing use of molecular techniques for species delimitation and is of particular note because this increase followed, and even accelerated after, the ending of the separate naming of morphs of the same species in 2011 (when the provision for a Latin diagnosis or description was also eliminated). Prior to that date, the totals for

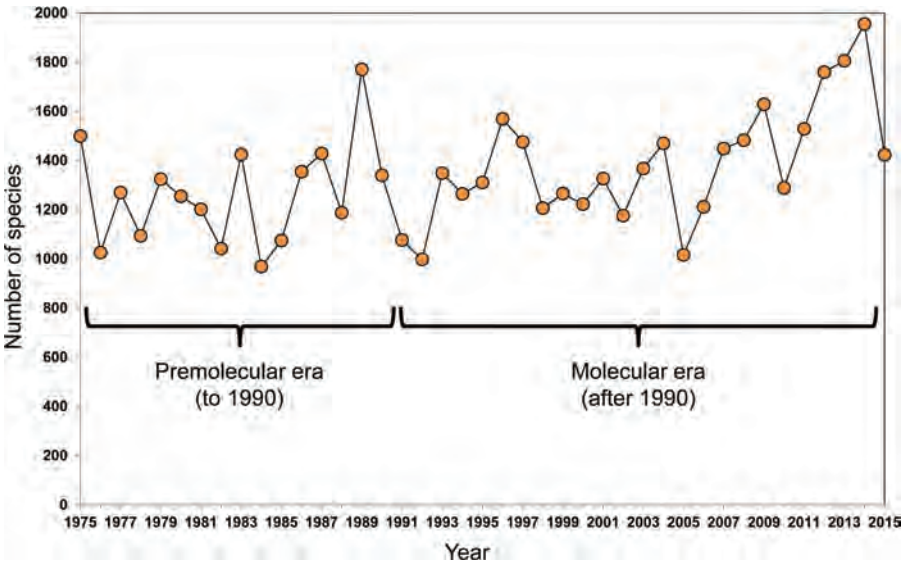

Figure 2 Numbers of newly introduced species names of fungi for each year from 1975 to 2015. Note that the data for 2015 were incomplete when this work went to press. Based on data from the Index Fungorum database provided by P. M. Kirk.

annually described "species" included separate names given to different morphs of the same species.

The number of newly named species does not, however, equal the number that have been truly described for the first time. It is much easier to name a fungus as new to science rather than to ascertain that it has previously been named. This is not simply a matter of comparing material to that of previously recognized species in the same genus but requires meticulous detective work, because not uncommonly, species were described in genera they do not belong to. Further, species concepts change, for example, in genera where morphologically identical fungi were regarded as different species if they occurred on different plant species. The number of accepted fungi can only be obtained by counting those recognized as "good" in each genus. This has been done since 1943 through the 10 editions of *Ainsworth & Bisby's Dictionary of the Fungi* and now annually through Species Fungorum inputs to the Catalogue of Life (http://www.catalogueoflife.org/annual-checklist/). An analysis of these data shows that the total number of existing species names runs at around 2 to 3 times that of currently accepted species (Fig. 3), a figure consistent with the ratio of 2.6 derived from an analysis of names in monographic works (11). The number of described good fungal species currently stands at around 120,000.

Unlike the situation in many other groups of organisms (12), the number of good fungal species continues to rise steeply decade by decade, with no indication of leveling off. The steepness of the curve would be even greater if there were more mycologists actively involved in species discovery, using either morphological or molecular approaches.

The number of species being recognized is necessarily impacted by the species concepts used. While in the premolecular era, species circumscriptions were based almost entirely on morphological and sometimes biochemical and cultural features, the incorporation of molecular information has led to a refining of species concepts. There is, however, a plethora of species concepts in biology (13, 14) and no single objective criterion that can be applied universally. Because the purpose of names is to provide a means of communication, a pragmatic species concept is essential, which may be defined as the following: "a species is what it is useful to give a species name to." (15). There have been numerous attempts to apply mechanistic systems for species recognition in phylogenetic trees, but the consolidated species concept has much to commend it and ultimately provides a broad consensus on how to recognize fungal species. The consolidated species concept adopts a polyphasic approach combining morphological, ecological, and phylogenetic species concepts (16) and is being increasingly taken up by mycologists. While in some situations this may lead to more species being recognized than otherwise would have been the case, in others it results in formerly separately distinguished

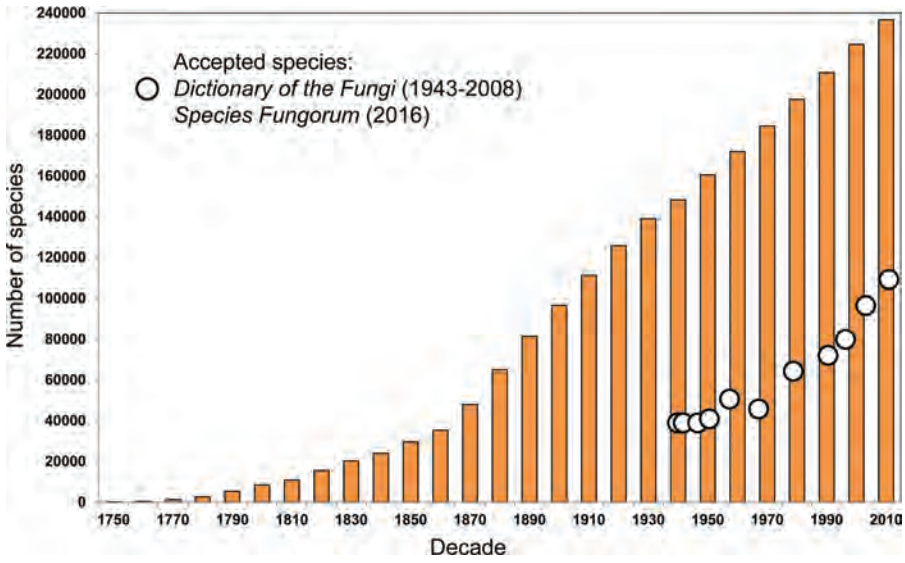

Figure 3 Growth in the total catalogued number of species names of fungi by decade from 1750 compared with the global number of accepted species. Based on figures adopted in the 10 editions of *Ainsworth & Bisby's Dictionary of the Fungi* for 1943–2008 and data in the Index Fungorum and Species Fungorum (Catalogue of Life) databases provided by P. M. Kirk.

species being united. Therefore, over- and underestimations in particular cases are usually balanced out. A rarely considered notion is the time scale: a proportion of "species" is in active speciation, with incomplete lineage sorting, yielding it difficult to resolve good species (17); in such cases, determining the number of species is philosophical, since that number is in active flux. A large number of new fungal species continue to be described with no molecular data, either due to the age of the underlying material (e.g., unveiled in older collections) or by taxonomists who do not have access to molecular techniques; assessing the proportion of good species in such taxa is therefore difficult.

Patterns in Taxon Discovery

Some predictable patterns in the recognition of published taxa in the rank of genus and above have been recognized and applied to a broad set of organisms, including fungi (2). By combining the full classifications of around 1.2 million species of all groups of organisms, these authors found, as might have been expected, that accumulation curves of higher taxa over time showed that these were more completely described and in many cases approached an asymptote. The use of the higher taxon approach was then validated by comparing the actual number of known species with that predicted from the accumulation curves. The authors then fitted asymptotic regression models to the actual curves for different groups to provide estimates of undiscovered species numbers. In the case of fungi, this led to a total number of expected fungal species of 611,000 (standard error ± 297,000). This conclusion was, however, misleading, because the analysis was based on the assumption that there were only 43,271 catalogued fungal species, rather than the nearly 100,000 accepted at that time (18). Intriguingly, a recalculation using their method with the latter species number generates a figure of around 1,400,000—not far out of line with estimates derived from extrapolations based on plant:fungus ratios (see below).

EVIDENCE FROM SPECIES RECOGNITION STUDIES

Unknown fungi are now considered to come mostly from two sources: (i) newly discovered species by means of traditional inventory methods in little-studied areas and habitats and (ii) newly discovered lineages through environmental sequencing. A further, neglected but significant source of unrecognized fungal diversity is the restudy of known taxa, applying species recognition techniques to molecular data, using either the fungal barcoding locus ITS (19) or multilocus approaches. Exemplar taxa are the fly agaric, *Amanita muscaria*, and the golden chanterelle, *Cantharellus cibarius*, which contain numerous, often regionally distributed species (20, 21). The record is currently set by the basidiolichen fungus *Cora glabrata*, which has been shown to contain at least 189 species (6, 22). We surveyed 45 such studies published between 1998 and 2016, including studies of non-lichenized and lichenized forms, and computed the ratio of species recognized in the target group before and after the study (Table 1). Most studies started out with a single or few species, whereas two looked at complexes of up to 18 species—*Protoparmelia* (23) and *Usnea* (24)—and one revised a complex of 71 species accepted prior to the study, in the genus *Coprinellus* (25). The posterior:prior ratios in the number of species recognized ranged from 0.67 (from 18 to 12 species in a group of *Usnea* [24]) to 189 (from 1 to 189 species in the basidiolichen *Cora glabrata*) (6, 22). Other high ratios were found for *Dictyonema* with 59 (26), *Cladosporium cladosporioides* with 22 (27), *Sticta weigelii* with 15 (28), *Microbotryum violaceum* with 11 (29), and *Fusarium graminearum* with 7 (30). Environmental sequence and genomic data revealed high ratios for the genera *Archaeorhizomyces*, with 145 (31), and *Cyphobasidium* with 26 (32), as well as for the still barely explored *Cryptomycota*, with 138 (33, 34), in which the true figure could be much higher. The median ratio over all evaluated studies was 3.0, and the arithmetic mean was 14.5 (Table 1).

To obtain a more reliable picture, we adjusted these ratios by geographic area covered. If a species complex had a global distribution prior to the study, and if based on material from a single geographic area, it was found to represent several species with presumably restricted distribution, the detected ratio was adjusted by the factor 2 (expanding to both hemispheres in cases in which one hemisphere was covered), the factor 3 (for tropical fungi for which a single tropical region was covered), and up to the factor 6 (for cosmopolitan fungi for which a single region within a single continent was studied). These factors were derived from selected global studies, for example, in the genera *Cladosporium* (27), *Cora* (6, 22), *Fusarium* (30), and *Sticta* (28). In some cases, we added unpublished data to the adjusted values; thus, for *Archaeorhizomyces* we currently recognize at least 500 species (B. E. Smith and R. Lücking, unpublished data), and for *Cyphobasidium*, we recognize about 100 species from deposited GenBank sequences (32). The thus adjusted ratios ranged from 0.7 (*Usnea*) to 435 (*Archaeorhizomyces*), with a median value of 10.5 and an arithmetic mean of 39.3.

To predict the global species richness of *Fungi* using these raw and adjusted ratios, we employed two further adjustments. First, we weighted the ratios according to the number of species recognized in a genus in the 2008 *Dictionary of the Fungi* (18). For instance, a genus in which a single species had been recognized received a low weight (1.0), since even a high number of newly recognized species will only contribute minimally to global fungal species richness. This adjustment avoided a high impact of extraordinary ratios such as in the previously monotypic genus *Cora*. In contrast, for groups in which a large number of species had already been recognized, the ratios based on a study of one or a few species were upweighted, e.g., in the genus *Puccinia* (35), with 4,000 accepted species. In addition, to account for ecological bias in the evaluated studies, we applied a group weight according to the major lifestyle attributed to each genus; to that end, we divided the approximately 100,000 known fungi in 2008 as follows: 40,000 saprotrophic (weight 4.0), 20,000 phytopathogenic (weight 2.0), 20,000 lichenized (weight 2.0), 8,000 ectomycorrhizal (weight 0.8), 5,000 endophytic (weight 0.5), 3,000 entomopathogenic (weight 0.2), 2,000 aquatic (weight 0.2), 500 endomycorrhizal (weight 0.05), 500 marine (weight 0.05), 400 soil (weight 0.04), and 100 human pathogenic (weight 0.01). The categories aquatic, marine, and soil are used here for cases where the habitat is known but not the biology. These proportions denote estimates based on known fungi in 2008, not estimated proportions of extrapolated global species richness, in which, presumably, categories such as plant pathogens and soil fungi will have much higher values. Using these weights, the overall arithmetic mean of the posterior:prior ratio for all evaluated studies amounted to 11.3. This suggests that even without including important sources of new species discoveries, the already accepted *Fungi* may contain up to 10 times as many species as currently recognized, resulting in more than 1 million estimated species. Remarkably, this is about 4 times higher than the currently estimated synonymy ratio of 2.6, suggesting that a large proportion of these unrecognized species have no names available.

EVIDENCE FROM EXTRAPOLATIONS BASED ON PLANT:FUNGUS RATIOS

The widely cited and accepted plant:fungus ratio-derived global estimate of 1.5 million species of fungi was based on information from several independent sources (3): (i) the numbers of fungi reported from all habitats in the United Kingdom and sites within the United Kingdom compared with the number of plant species present, (ii) the numbers of host-specific fungi on particular plant species, (iii) percentages of new species being discovered, and (iv) extrapolations to the global level based on conservative estimates for the number of plant species, making allowances to discount separately named morphs of the same species. The 1.5 million figure was considered conservative because, while numbers of fungi from all sources, including organisms other than plants and soil, were included in the species totals for particular places, no allowances were made for undiscovered fungi in and on the millions of insects predicted to exist.

Some figures used in these early extrapolations have subsequently been revised upward. Ten years later, it was pointed out that the number of plant species and the fungus:plant ratio were too conservative and the vast number of insect fungi had not been considered. As a consequence, some revised estimates ranged between 2.7 and 9.9 million fungal species (4).

The total inventory of fungal species found in field surveys in a particular site continues to increase year by year, even with regular visits spanning several decades, while the number of plant species remains more or less unchanged. Esher Common (Surrey, United Kingdom) is by far the most investigated site by field mycologists in the world, and to date about 3,400 species have been found (B. M. Spooner, personal communication). Because the number of vascular plant species remains at 420, this now gives a fungus:plant ratio of 8:1.

Some preliminary results from next-generation sequencing of soil samples from a wood within the second most field-surveyed site in the world, the Slapton Ley National Nature Reserve in southwest England, are illuminating in relation to the fungus:plant ratios (G. W. Griffith, B. S. Dentinger, and D. L. Hawksworth, unpublished). The wood studied has 1,136 species of fungi and 88 vascular plant species recorded during field surveys, a ratio of 12.9:1. However, just 686 sequence-based species (accounting only for taxa represented by five or more sequences) were recovered from soil samples (and a further 153 taxa were represented by one to four sequences). What is intriguing is that of the 164 named genera represented in the next-generation sequencing data set, only 32 were among the 549 genera collected in the fieldwork, which included fungi on plant parts and plant litter, not just sporophores emerging from the soil. The actual ratio in a site may therefore be substantially higher than indicated by traditional inventory techniques.

The interpretation of some data sets needs to be considered in the light of such long-term investigations. Ratios comparing fungal sequences recovered

from environmental samples with plants growing on the sample sites have given some surprising ratios. For example, data from a forest in North Carolina gave fungus:plant ratios of 19:1 (491 fungi and 26 plants) and 13:1 (616 fungi and 48 plants), leading to a suggestion that there may be 3.5 to 5.1 million fungal species worldwide (9). A more modest ratio of 7.5:1 (1,500 fungi and <200 plants) was obtained from boreal forest soils in Alaska (36). In contrast, Tedersoo et al.'s (37) impressive study of 365 globally distributed soil samples using metabarcoding molecular methods (see below) led the authors to conclude that fungal species richness had actually been overestimated by 1.5 to 2.5 times from that based on plant:fungus species ratios. Any such extrapolation from soil samples alone to the total fungal biota at a site is, however, unsound as evidenced by the above data from the Slapton reserve. Much of the actual fungal species diversity in a site will inevitably be missed in soil sampling, because most is above ground, on and in plants and animals of all kinds, in water, in lichens, on rocks, etc.

Collections made in brief smash-and-grab collecting trips or even extending over several years will only start to reveal what fungi may actually be present at a site. Studies such as that of Piepenbring and collaborators (38), in which 567 species of fungi and 311 species of plants were found along a 500-m pathway in Panama over 2 years, giving a ratio of just 1.8:1, have to be interpreted in this context. The ratio resulting from that study would be expected to rise significantly if the period over which it was conducted had been 2 decades rather than 2 years, and with increased attention to microscopic fungi.

When considering fungi of all biologies and in all ecological niches in a site, the ratio can be expected to vary depending on the geographical location, as recognized some 25 years ago (3). It is not surprising, therefore, that the studies of fungus:plant ratios in a site, obtained by field survey and molecular approaches, have generated ranges from 1.8 to 19.1:1. The mean of the figures cited in this section yields a ratio of 9.8:1, suggesting that the ratio of around 6:1 arrived at in 1991 may be conservative. With the currently accepted number of approximately 380,000 vascular plant species (39), this adjusted ratio would predict a number of nearly 3.8 million fungal species.

EVIDENCE FROM ENVIRONMENTAL SEQUENCING TECHNIQUES

The advent of obtaining taxon-specific, molecular sequence data from environmental samples, most commonly soils but also water and plant tissues, has generated a new source of data for estimating global species numbers. It is commonly found that numerous sequences thus obtained do not have any matches with those from named fungi in GenBank (see below), and this has led to speculations that previous estimates have been too low.

Generalizing data from environmental samples is problematic for several reasons, including that the broader geographic context of detected operational taxonomic units (OTUs) is usually unknown. For example, using 454-sequencing technology, two 0.25-g soil samples from an Alaskan forest collected just 1 m apart had only 14% of fungal species in common (36). In a pyrosequencing study in the Andes, 1,839 species-like taxa were found, of which 25% were most similar to other unidentified environmental samples, with significant differences between forests at different altitudes (40). The most comprehensive study of soil samples to date is that of Tedersoo et al. (37), who analyzed 2-g soil samples from pooled soil in 5-cm deep cores taken from 365 global sites. They obtained 80,486 fungal OTUs, used a 98% sequence similarity for species recognition, and did not consider almost half in further analyses because they were singletons and potentially artifacts; in that study, plant:fungus richness declined toward the poles. However, in concluding that extrapolations from plant:fungus ratios were unjustified (see above), the authors did not take into account fungi other than those in soil, such as those in and on aerial parts of plants, in decaying vegetation, lichen-fungi, and entomogenous fungi.

Especially instructive is a study of 928 swabs of dust samples across the continental United States by direct PCR and using high-throughput sequencing (HTS) to analyze them (41); not only were 38,473 fungal taxa detected, but there were clear geographic patterns with a predictive value of placing a sample within 230 km. Of the 38,473 taxa, however, sequences of about 40% could not be matched with any named species (R. R. Dunn, personal communication).

Just how many unidentified sequences generated from environmental samples represent undescribed species is uncertain. Compared with the 120,000 formally recognized species (see above), as of 25 November 2016, there were only 34,878 named fungal species in GenBank, but there were a further 94,059 species-level OTUs with no names (C. L. Schoch, personal communication); these figures have increased by 68% and a staggering 117%, respectively, in the past 5 years. However, only a minute fraction of environmental sequences are deposited individually in GenBank; the vast

majority is placed in the Sequence Read Archive (SRA) (42). Currently, the SRA, on the query "(fungal OR Fungi) AND (internal transcribed spacer [or, ITS] OR ITS1 OR ITS2)," returns 179 studies, 1,822 biosamples (i.e., environmental samples), and 14,334 experiments or HTS runs, containing 928 million fungal ITS reads, with an average length of 353 bases (SRA: https://trace.ncbi.nlm.nih.gov/Traces/sra/sra.cgi?view=search_obj; accessed 12 March 2017). In contrast, using the same query, GenBank (43) returns 993,987 sequences obtained predominantly through Sanger sequencing (GenBank: https://www.ncbi.nlm.nih.gov/genbank; accessed 12 March 2017). Thus, at present there are almost 1,000 times more HTS reads than Sanger sequences. Only 3 years ago, this ratio was 18:1, which means it has increased by a factor of more than 50 in this short period.

Obviously, a proportion of the unidentified sequences can be expected to represent known but as yet unsequenced species, especially considering that about 85,000 of the currently accepted fungal species have no sequence data available. In the case of *Mortierella*, a reference set of type and other strains was sequenced and then compared with unnamed sequences in GenBank (44); the authors modeled the effects of increasing type strain sequencing and found a linear relationship with the number of strains that could be identified, and they predicted a number close to that of the already described species.

One of the most significant problems with using environmental sequence data to extrapolate global fungal species richness is the approach to define OTUs. Due to the volume of data generated and the usual broad taxonomic range detected, alignment-based methods that would allow us to critically define species as phylogenetic lineages are impossible to use as routine techniques. Thus, environmental sequence data are analyzed using clustering techniques, and OTUs as equivalents to species are defined on thresholds, ranging between 95 and 99% depending on the study. This approach has several shortcomings. First, species do not exhibit fixed sequence thresholds; in contrast, sequence divergence and hence the barcoding gap depend on the evolutionary age of the species complex. Second, commonly used thresholds of 95 to 97% are unrealistic. Assuming that the ITS barcoding locus has a length of, e.g., 500 to 600 bases, 5% divergence would correspond to 25 to 30 bases. In most studied species, infraspecific ITS variation is much lower, with an average of about 1%. Theoretically, a more realistic threshold of 99% would greatly increase the number of OTUs detected in a data set. However, this effect is more than outweighed by the sensitivity of clustering methods to variation in the data, including the common CAFIE (carry-forward-incomplete-extension) sequencing error common to all base flow technologies (45) (see below).

This error and other problems with clustering techniques can lead to an overestimation of the number of OTUs at several orders of magnitude, which may result in serious bias when using such estimates for global extrapolations. We tested this effect with SRA data of the soil fungus *Archaeorhizomyces* (Smith and Lücking, unpublished). Through a blast script, we obtained 106,563 ITS reads from the SRA that were reasonably close to the type species, *Archaeorhizomyces finlayi*. Clustering analysis using USEARCH (46) resulted in the following numbers of OTUs depending on the set threshold: 2,658 at 95%, 5,793 at 97%, 10,630 at 98%, and 28,435 at 99%. Thus, the difference between the 95% and the 99% threshold is an order of magnitude. Alignment-based phylogenetic analysis suggests the presence of approximately 500 species-level lineages in this data set. Thus, depending on the threshold level used for species-level separations, clustering could overestimate the actual species richness in this case by a factor of between 5 and 50.

Lücking and colleagues (45) showed that severe problems with estimating OTUs through clustering emerge from even minor sequencing errors. The CAFIE error is common to all next-generation sequencing technologies, because it represents a statistical error of the distribution of bases among wells on a plate through a given base flow. Through careful adjustment, this error can be held to a minimum of less than one erroneously phased insertion per read, i.e., about 0.3% assuming an ITS1 or ITS2 read length of approximately 300 bases. This proportion is well within the expected infraspecific variation even at a high level of 99% similarity and thus theoretically should disappear as background signal. However, the random distribution of this error across the entire sequence, which cannot be recognized by quality filtering methods, especially not in environmental samples where no expected sequence patterns exist for comparison, causes clustering methods to interpret these differences as taxonomic, leading to serious overestimations by distribution sequences of the same taxon, but with different minor errors, into separate clusters. This is because clustering methods work with local alignments of small, highly similar sequences, whereas phylogenetic methods require alignment of sequences of a data set to template sequences obtained from Sanger sequencing. As a consequence, in a broad alignment including Sanger reference sequences, erroneous and phased indels will be located

in mostly gapped columns, which have practically no influence on the resulting topology, whereas in clustering methods, they will frequently be aligned with nonhomologous base calls and falsely interpreted as substitutions (45).

In the above (45), a proportion of less than 1% erroneously phased indels caused by CAFIE errors in the ITS of a single species caused overestimation of the number of taxa by a factor of 35 at a 95% threshold level, 137 at 97%, and 980 at 99%. Thus, instead of disappearing as background signal, the sequencing error had a tremendous effect on OTU evaluation when in that case it was known that all sequence data came from a single target species. Even after removing all erroneous indels, clustering continued to overestimate species richness by a factor of 4 at a 95% threshold level, 8 at 97%, and 116 at 99%, due to minor remaining infragenomic variation and other sequencing errors. In contrast, alignment-based phylogenetic analysis of a broad set of nearly 2,000 reads recovered a single species, even with all sequence errors included. Thus, while environmental sequencing continues to accumulate a vast amount of important data on unrecognized fungi, extrapolations from these data must be taken with great care when based on clustering methods. An extreme example is a recent study which predicts up to a trillion species of microorganisms globally based on OTUs derived from environmental sequence data (1), using ecological scaling laws which, put in simple terms, predict how the global, limited number of *N* individuals would divide into *S* species, taking into account resource competition based on body size and other factors. This number, while certainly intriguing, appears to be exaggerated, and it would be interesting to see what alternative prediction would be obtained when defining the underlying taxonomic entities in this analysis through alignment-based phylogenetic methods.

In spite of these shortcomings, it is clear that environmental sequencing is now the major source of discovering novel fungal taxa, at least in the same order of magnitude as taxa recovered in species recognition studies or perhaps much higher. It follows that to properly catalog these fungi, a naming system for voucherless sequences must be developed, and proposals on how to do that are currently under consideration (47–51).

In addition to discovering new species, environmental sequencing may reveal unknown higher fungal taxa up to the class level. The best-known example is the recently discovered class *Archaeorhizomycetes* (31, 52). In Tedersoo and colleagues' study (37), ~6% of all fungal OTUs below the phylum level could not be assigned to any known class. Further clustering of unidentified fungal sequences at 70% sequence similarity revealed 14 distinct taxonomic groups comprising >7 OTUs, suggesting that there are several deeply divergent class-level fungal lineages that have not yet been described or previously sequenced. A follow-up study by the same group (53) also revealed numerous new lineages at least at the order level.

WHERE ARE THE UNDESCRIBED FUNGI?

If there are at least 1.5 million or more fungi on Earth, and we know of just 120,000, where can the missing 1.38 million species be? As outlined, three major sources for unrecognized fungal diversity seem to emerge: (i) geographic areas and ecological habitats that are largely understudied, particularly in tropical regions and biodiversity hot spots, (ii) ecologically cryptic fungi that occur in the environment but usually do not manifest themselves via discernible structures other than microscopic hyphae and mycelia, and (iii) so-called cryptic species hidden under well-established names.

Biodiversity Hot Spots

It is generally recognized that missing species of all groups of organisms will be found in biodiversity hot spots (54). A novel quantitative method to identify hot spots of unrecognized species richness is the grid approach (6–8), which relies on linear interpolation and hence gives more reliable estimates than nonlinear extrapolation. The area in question is divided into grids, and observed richness per grid is linearly correlated with predictive macroenvironmental parameters and sampling effort, using at least one well-sampled grid for calibration. This method can be applied to both traditional inventories and data based on environmental sequencing, as long as species are reliably delimited and macroenvironmental predictors can be reasonably derived from the data. Thus far, the method has been employed for lichen-forming fungi in the families *Graphidaceae* and *Trypetheliaceae* and the genus *Cora*, resulting in estimates ranging between 1.5 and 4 times the number of known species.

South America is generally recognized as having major hot spots, and various studies point to high levels of novelty there. By combining data from basidiomes and sequence data from ectomycorrhizal roots in a *Dicymbe corymbosa* forest in Guyana, Henkel and collaborators (55) estimated that over 250 species were associated with this one tree species in this single site. López-Quintero and colleagues (56) found that of 632 macromycete species in Colombian Amazonian forests, 52%

could not be identified to the species level, a significant proportion likely representing undescribed species. Truong and coworkers (57) collected 1,430 basidiomes during just four collecting expeditions in southern South American *Nothofagaceae*-dominated forests; they generated 439 OTUs out of 957 specimens, of which 308 (ca. 70%) did not match any in the UNITE dynamic database at 97 to 99% similarity and thus did not correspond to any "species hypothesis" currently in the database.

Little-Explored Habitats

There are an enormous number of potential sites for fungi in any locality, and in the case of the tropics at least 31 ecological niches meriting study can be recognized, many requiring different techniques and specialists to explore (58). While no site on Earth can yet be considered to have a complete inventory of the fungi present, some habitats stand out as particularly underexplored.

The situation can be exemplified by the fungi which obligately grow on lichens, the lichenicolous fungi. With a few notable exceptions, this niche was largely overlooked by lichenologists and other mycologists until the mid-1970s. In 1976, there were just 457 species known worldwide (59), but by 2016 that number exceeded 1,800 (http://www.lichenicolous.net/); that represents a 394% increase over 40 years, or 98.5% per decade. This growth is reflected at the more local level, where in Great Britain and Ireland the number known rose from just 218 species in 1983 to 403 in 2003, an increase of 85% over 20 years (60); the number has now passed 500 and continues to rise (D. L. Hawksworth, unpublished). That figure compares with around 1,900 lichenized species in the same region, implying by extrapolation to the global scale that there may be as many as 25% as many lichenicolous fungi as lichenized species, i.e., around 5,000 species. This hypothesis is supported by studies of these fungi in areas where they have not previously been investigated; for example, of 189 species reported from Isla Navarino in Chile on the basis primarily of collections made in just 1 year, 6 genera and 60 species (32%) were new to science (61). And these figures do not include the so-called endolichenic fungi that can be cultured from lichen thalli or are only known from sequence data (e.g., 62, 63). In addition, emerging studies suggest the presence of highly specific, yet morphologically cryptic, basidiomycete yeasts and other basidiomycetes in the cortex of lichen thalli, which add yet another dimension to unknown fungal diversity (32, 51).

The experience with lichenicolous fungi appears or can be expected to be paralleled in other little-explored habitats, including bryophytes (64–66), algae (67, 68), endophytic fungi inside vascular plants (69–71), tropical foliicolous and fungicolous fungi (72), mammal guts (73), insect guts (74–77) and exoskeletons (78, 79), on and in rocks (80, 81), and in deep sea and ocean sediments (82), to name just a few.

Cryptic Species

Biologically distinct species which are morphologically indistinguishable, so-called cryptic species, were recognized 2 decades ago as one place where some of the predicted "missing fungi" might be discovered, since physiological and other biological divergence evidently often precedes morphological divergence in the evolution of fungal species. Based on studies of selected complexes then available, it was suggested that the number of known fungi might rise by a factor of 5 or more for this single reason (83). Molecular studies reveal that cryptic speciation is widespread through diverse groups of fungi, including plant pathogens, clinically important fungi, lichen-forming fungi, and mushrooms. Recognition of such cryptic speciation is indeed playing an increasingly important role in species discovery, as outlined above, and the ratio derived from current studies, 11.3:1, is about twice as high as estimated by Hawksworth and Rossman (83).

Existing Reference Collections

It has been estimated that over half of the projected 70,000 undiscovered plant species have already been collected and await description (84). Similarly, most reference collections of fungi, whether of dried specimens (fungaria) or living cultures (culture or microbial resource collections), include material that is not named to the species level, and in some cases not even to the genus level. Further, some collections and isolates referred to named fungi not uncommonly prove, on critical examination, to be different species. It has been suggested that around 20,000 fungal species have been collected but are as yet undescribed (83), but that is likely to be an underestimate because many mycologists have large backlogs of material awaiting formal description.

One of the challenges in the linking of newly obtained sequence data with named material in collections, particularly those that are type material, is fixing the application of the species name. Currently, the 34,878 species with sequences in GenBank (see above) represent just 29% of the 120,000 known species. Obtaining sequences for the missing 71% of named accepted species is essential to determine the novelty of recovered sequences from the environment, specimens,

or isolates. While some researchers have had considerable success in recovering DNA from dried specimens (85), even from a dried *Hygrophorus* basidiome collected as far back as 1794 (86), this is not always possible (87). Aged dried material generally exhibits high levels of DNA degradation, making access through conventional extraction and PCR methods difficult (88, 89). In view of the serendipity of obtaining satisfactory results, collection curators are often unwilling to allow parts of often scant, irreplaceable type specimens to be destroyed for DNA extraction. Several attempts are now being made at using high-throughput sequencing technologies to obtain sequence data from highly fragmented DNA (88). One of the main problems in this respect is contamination, since even for highly variable loci, it will be a challenge to piece small fragments together without the risk of generating artificial chimeras. Therefore, efforts should be made to identify highly diagnostic regions in the ITS or other loci that allow the identification of a taxon even when only short fragments are at hand (89), as exemplified by comparing the ITS1 and ITS2 subregions (90).

There is a particular problem regarding the type species of generic names. An impressive 5,317 generic names of fungi are represented in GenBank (C. L. Schoch, personal communication), but in many cases the sequences are not from the name-fixing type species. A concerted attempt has been initiated to sequence the type species of genera currently not represented in DNA databases. This involves recollection and/or isolation from the geographical area of the original material and from the same host or substrate when no DNA has been recovered from the type material (91). Sequenced material of species can then in some cases be designated as an interpretive type—an epitype (92). Such an effort involves global collaboration of sequencing laboratories with colleagues in countries where high unknown diversity is located.

TOWARD A WORKING NUMBER OF GLOBAL FUNGAL SPECIES RICHNESS

There is general acceptance among mycologists that the global number of fungal species is a seven-digit figure, in the range 1 to 5 million (10), with "at least" 1.5 million now predominating, though a possible order of magnitude higher has been hinted at (93) and a minimum figure of 611,000 to 712,000 was arrived at (2, 94), leaving aside the figure of potentially billions of fungi extrapolated by Locey and Lennon (1). A recalculation of the number computed via Mora and colleagues' approach (2) gives a figure of about 1.4 million (see above), close to the 1.5 million estimate which has come to be widely accepted by other biologists (54, 95–97), notwithstanding a few estimates that fail to appreciate the difficulty of inventorying fungi (98) or that equate numbers detected in soil alone as indicative of the total number at a site (37).

Unfortunately, the different techniques used to estimate global species richness are in part additive and in part overlapping or redundant, so that a combination of estimates from these studies is difficult. Thus, the revised estimate of nearly 3.8 million fungal species based on an updated fungus:plant ratio of 9.8:1 and 380,000 vascular plant species should include fungal species of all sorts with all types of ecologies and detected by different methodologies, including environmental sequencing and species delimitation methods. This number should then be congruent with approaches such as publication rates or scaling methods, but these approaches result in widely disparate estimates. Alternatively, an additive approach would be based on the three major sources of unrecognized fungal species richness, which can be reasonably sorted in descending order into (i) environmental sequencing, (ii) cryptic speciation, and (iii) other novel discoveries through traditional field work. For cryptic speciation, the above survey of established literature results in a weighted ratio of about an order of magnitude, i.e., more than 1 million additional species if based on 120,000 previously known species. If novel species from environmental sequencing are at least as high in number, this would add at least another million.

We conservatively assume that other novel discoveries (excluding species delimitation methods and environmental sequencing) will occur at a proportion of at best 10% of the latter two approaches. This assumption is based on the rate of 1,300 newly described species per year until about 2010, before the onset of rigorous species delimitation methods and environmental sequencing (see above). At this rate, it would take nearly 100 years to double the number of known species. Thus, while environmental sequencing and species delimitation methods would contribute about 2 million new taxa, other novel discoveries would add at best another 120,000 taxa within a reasonable time frame, for a total of a little over 2.2 million. This would give a range of between 2.2 (additive approach) and 3.8 million (global ratio approach), very much in line with the previously updated estimates of between 2.3 and 3 million (4, 99) and precisely narrowing down the range of 1 to 5.1 million given by Blackwell (10) by 1.2 to 1.3 million on either side.

We therefore propose to replace previous estimates of global fungal species richness with this updated range

of 2.2 to 3.8 million. This estimate is likely to be further improved on when reliable statistical approaches to analyze the huge amount of environmental sequence data become available. An interesting approach would be to combine the following techniques: (i) a geographically and ecologically broad sample of environmental sequence data, (ii) alignment-based species recognition methods to properly estimate OTU diversity, (iii) species-based niche modeling to establish macro- and microecological patterns, and (iv) a grid-based interpolation of global species richness, taking into account sampling effort. We predict that such an analysis will result in estimates that might lie well above the revised conservative estimate of 2.2 million species and likely even beyond 3.8 million species. But even if continuing to adopt the previous, now appearing highly conservative number of 1.5 million species, the discovery and formal description of the missing fungi remain a daunting task.

Acknowledgments. *We thank Robert R. Dunn, Gareth W. Griffiths, Conrad L. Schoch, and Brian M. Spooner for providing previously unpublished data. We are especially indebted to Paul M. Kirk for providing the raw data from Index Fungorum, on which Figs. 1 to 3 were based.*

Microsporidia: Obligate Intracellular Pathogens Within the Fungal Kingdom

5

Bing Han[1] and Louis M. Weiss[1,2]

INTRODUCTION

Microsporidia were initially described about 150 years ago with the identification of *Nosema bombycis* as the organism responsible for the disease pébrine in silkworms (1). Microsporidia are ubiquitous in the environment and infect almost all invertebrates and vertebrates, as well as some protists (2). Spores from microsporidia are commonly found in surface water (3). These organisms are eukaryotes that have a nucleus with a nuclear envelope, an intracytoplasmic membrane system, chromosome separation on mitotic spindles, vesicular Golgi, and a mitochondrial remnant organelle lacking a genome termed a mitosome (4). For insects, fish, laboratory rodents, and rabbits microsporidia are important pathogens, and they have been investigated as biological control agents for destructive species of insects (2). Several species of microsporidia have caused significant agricultural economic losses including *Nosema apis* and *Nosema ceranae* in honeybees (5), *Loma salmonae* in salmonid fish (6), and *Thelohania* species in shrimp (7). Franzen (8) published an excellent review of the history of research on these pathogens, and a recent textbook by Weiss and Becnel (2) provides a comprehensive examination of what is known about these organisms. In 1977 Sprague elevated the class or order Microsporidia to the phylum Microspora (9), and a decade later Sprague and Becnel (10) suggested that the term Microsporidia should instead be used for the phylum name. These organisms were previously considered "primitive" protozoa (11), but molecular phylogenetic analysis has resulted in the insight that these organisms are not primitive but instead are degenerate, and that Microsporidia are related to the Fungi, either as a basal branch of the Fungi or as a sister group (12–16).

The majority of microsporidia initially infect their hosts via the gastrointestinal tract, and they have evolved an infection apparatus, the polar tube, which allows them to infect host cells at a distance, enabling them to traverse the space between the lumen of the gastrointestinal tract and the host cells lining the digestive system (2). Many of the microsporidia disseminate following initial infection, and there are descriptions of microsporidian infections in almost every organ system, with human cases of encephalitis, ocular infection, sinusitis, myositis, and disseminated infection being well documented in published literature (2, 17). Microsporidia can have significant effects on their hosts and host cells, with infection resulting in juvenilization, feminization, or other changes to host physiology, as well as the formation of xenomas or other multinucleate cellular structures (2). Recent work to investigate microsporidia-host interactions has demonstrated the complexity of this interaction and the effects of microsporidia on the host cell transcriptional response in model systems of this interaction, including insects and *Caenorhabditis elegans* (18–20).

Human infection with microsporidia causing encephalitis was initially described in 1959. The species of microsporidia described to date in human infection suggest that most infections in humans are zoonotic and/or waterborne. Microsporidiosis has been a particular problem in immune suppressed hosts, such as those with advanced human immunodeficiency virus infection (AIDS) (21) and patients on immune suppressive drugs such as patients with organ transplantation or those receiving immune modulatory antibodies such as anti-tumor necrosis factor alpha (21, 22). Microsporidian infections in immunocompetent mammals are often chronic and asymptomatic, while immunocom-

[1]Department of Pathology, Division of Tropical Medicine and Parasitology; [2]Department of Medicine, Division of Infectious Diseases, Albert Einstein College of Medicine, Bronx, NY 10461.

promised hosts often develop lethal infections (23). Diarrhea due to microsporidiosis from *Enterocytozoon bieneusi* was initially reported in patients with AIDS in 1985 (24), and the number of articles describing human disease increased dramatically after 1990 with improvements in diagnostic techniques (2, 21, 25). The development of effective combination antiretroviral therapy has resulted in a decline in the cases of microsporidiosis in patients with HIV infection (2, 26). As noted above, however, infection can also occur in immunocompetent individuals, and in particular, diarrhea (often self-limited) and keratitis have been important manifestations in patients with intact immune systems (2).

Microsporidian infection in many mammals leads to a chronic infection with persistently high antibody titers and ongoing inflammation that can reactivate, leading to acute infection when immune suppression is administered (27, 28). Studies using *Encephalitozoon* species in mice have helped define the protective mammalian immune response to microsporidiosis (29, 30). Immunity to infection is mediated by T cells and is dependent on interferon-gamma and interleukin-12 (31–34). Evidence for this is provided by the protection against lethal microsporidiosis (*Encephalitozoon cuniculi* infection) afforded by adoptive transfer of sensitized syngenic T-enriched spleen cells into athymic or SCID mice (35, 36). In intraperitoneal *E. cuniculi* infection models, mice deficient in CD8+ cells or perforin-deficient mice have a lethal infection, but there is no lethality in CD4+-deficient mice (32, 37). Oral *E. cuniculi* infection murine models have shown that CD4+ cells are also involved in the protective immune response for this natural route of infection (33, 38). The most important subset for protective immunity in oral infection models was CD8+αβ T cells, and dendritic cell interferon-gamma protection was critical for priming the gut intraepithelial lymphocyte response (39). The ability to trigger a robust T cell response against microsporidian infection is age-dependent (40). Adoptive transfer of immune B lymphocytes into athymic BALB/c (nu/nu) or SCID mice or passive transfer of hyperimmune serum is not sufficient to protect athymic mice from lethal microsporidiosis (41, 42). Antibodies do, however, provide some protection as evidenced by observations that maternal antibodies protect newborn rabbits from infection with *E. cuniculi* during the first 2 weeks of life and that antibodies to the polar tube can prevent infection of host cells (43).

There are approximately 1,400 described species of microsporidia, which are distributed into about 200 genera (2), of which the following have been demonstrated to cause infections in humans (Table 1): *Nosema* (*Nosema corneum*, renamed *Vittaforma corneae* [44]; *Nosema algerae*, reclassified initially as *Brachiola algerae* [45] and now as *Anncaliia algerae* [46]), *Pleistophora* (47), *Encephalitozoon* (48, 49), *Enterocytozoon* (24), *Septata* (50) (reclassified as *Encephalitozoon* [51]), *Trachipleistophora* (52–54), *Brachiola* (45), *Anncaliia* (46), *Tubulonosema* (55, 56), *Endoreticulatus* (57), and *Microsporidium* (48).

Costa et al. (58) have reviewed drugs that are used for the treatment of microsporidiosis in various hosts. In humans with AIDS, there is reasonable evidence from case reports that treatment with antiretroviral therapy allows the patient's immune system to control and eradicate microsporidiosis (59, 60). Albendazole, a benzimidazole that binds to β-tubulin, has activity against many species of microsporidia and is used for therapy of microsporidiosis; however, albendazole is not effective for infections due to *E. bieneusi* or *V. corneae*. The tubulin genes of both *E. bieneusi* and *V. corneae* have amino acid residues that are known to be associated with albendazole resistance (61, 62). Studies suggest that *E. bieneusi* and many other microsporidian infections are responsive to fumagillin, a water-insoluble antibiotic made by *Aspergillus fumigatus* that inhibits methionine aminiopeptidase type 2, or to synthetic analogs of fumagillin, such as TNP-470 (63, 64). Ocular infections caused by microsporidia have been treated with fumagillin bicylohexylammonium in saline. Itraconazole combined with albendazole has been used as a therapy in cases of disseminated infections caused by *Trachipleistophora* or *Anncaliia*. Nitazoxinide therapy has been effective in stopping diarrhea caused by *E. bieneusi* in patients with organ transplantation (unpublished data); however, this effect may be dependent on the immune status of the patient, because this drug had minimal efficacy in patients with AIDS with low CD4 counts (65).

MORPHOLOGY AND LIFE CYCLES

The microsporidian life cycle consists of a proliferative phase (merogony), the spore production phase (sporogony), and the mature spore or infective phase (2, 66, 67) (Fig. 1). The general features of the life cycle are as follows: (i) spores are ingested or inhaled and then germinate, resulting in extension of the polar tube and injection of the sporoplasm into the host cell cytoplasm; (ii) merogony ensues as injected sporoplasm develops into meronts (the proliferative stage), which multiply, depending on the species, by binary fission or multiple fission, forming multinucleate plasmodial forms; (iii) sporogony follows merogony, and the meront cell

Table 1 Species of microsporidia infecting humans

Species	Synonym(s)	Common sites of infection in humans	Other mammalian hosts	Reported nonmammalian hosts	Disease manifestations reported
Anncaliia algerae	*Brachiola algerae* *Nosema algerae*	Eye Muscle		Mosquitoes	Myositis, keratoconjunctivitis, cellulitis
Anncaliia connori	*Brachiola connori* *Nosema connori*	Systemic			Disseminated disease
Anncaliia vesicularum	*Brachiola vesicularum*	Muscle			Myositis
Encephalitozoon cuniculi	*Nosema cuniculi*	Systemic	Wide host range	Birds	Hepatitis, encephalitis, peritonitis, urethritis, prostatitis, nephritis, sinusitis, keratoconjunctivitis, cystitis, diarrhea, disseminated infection
Encephalitozoon hellem		Eyes	Bats	Birds	Superficial keratoconjunctivitis, sinusitis, pneumonitis, nephritis, prostatitis, urethritis, cystitis, diarrhea, disseminated infection
Encephalitozoon intestinalis	*Septata intestinalis*	Small intestine	Wide host range	Geese	Diarrhea, intestinal perforation, cholangitis, nephritis, superficial keratoconjunctivitis, disseminated infection
Enterocytozoon bieneusi		Small intestine Biliary tract	Wide host range	Birds	Diarrhea, malabsorption with wasting syndrome, cholangitis, rhinitis, bronchitis
Microsporidium africanum		Eyes			Stromal keratitis
Microsporidium ceylonensis		Eyes			Stromal keratitis
Microsporium CU (Endoreticulatus-like)		Muscle			Myositis
Nosema ocularum		Eyes			Stromal keratitis
Pleistophora ronneafiei		Muscle		Fish[a]	Myositis
Trachipleistophora anthropopthera		Eyes Systemic		Insects[a]	Encephalitis, keratitis, disseminated infection

[a]Putative host(s) based on phylogeny or host relationships of other species within the genus.

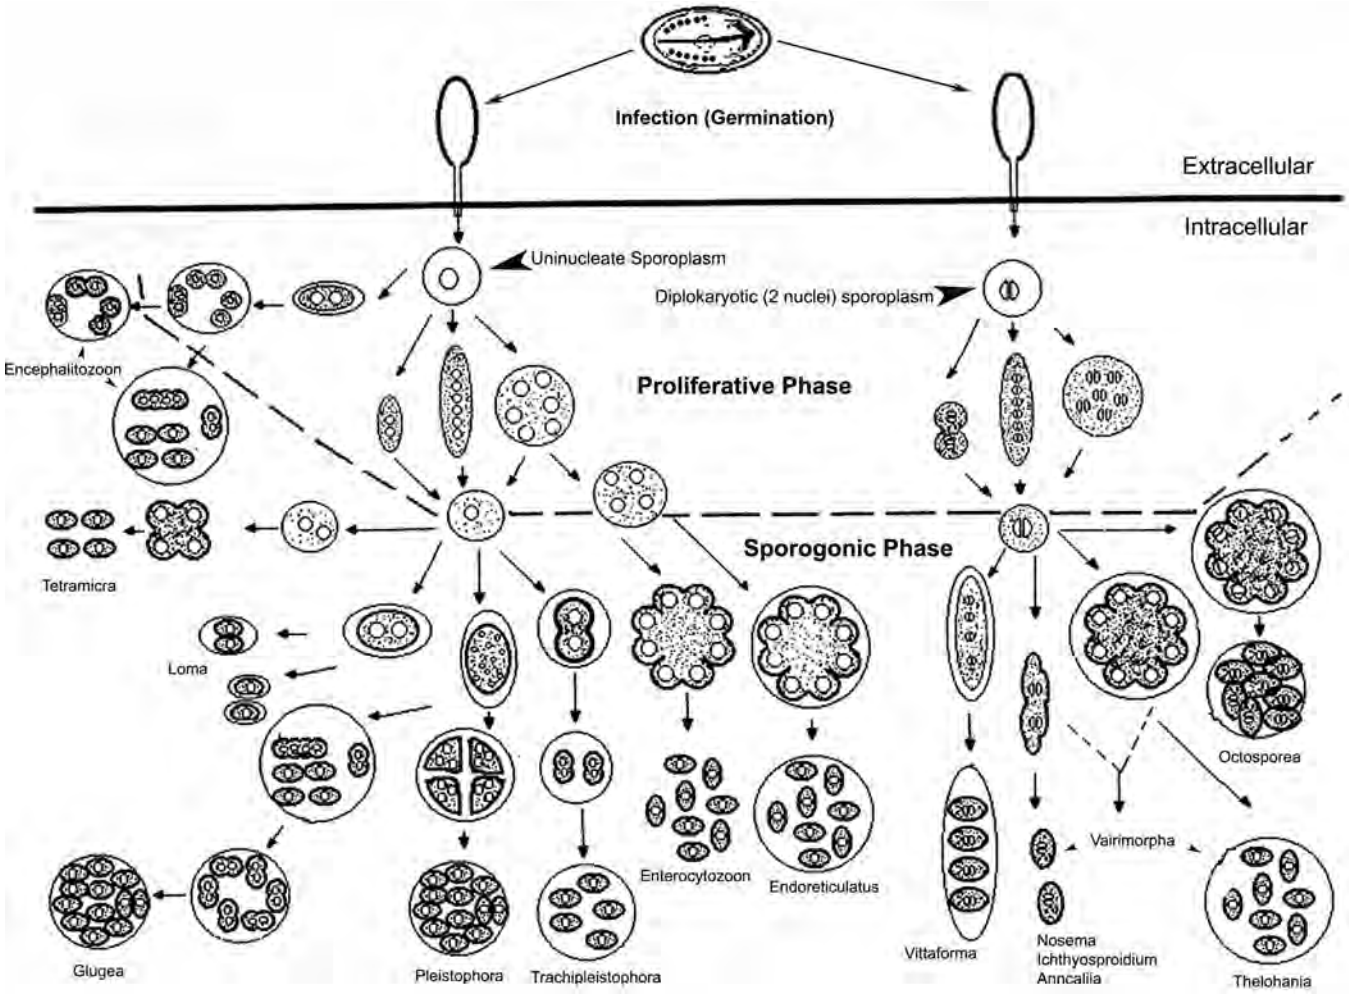

Figure 1 Microsporidian life cycles. The initial phase of infection involves spores being exposed to the proper environmental conditions that cause germination of the spores and polar tube extrusion. The polar tube pierces the plasma membrane (solid black line) of the host cell, and the sporoplasm travels through the polar tube into the host cell. The sporoplasm then divides during the proliferative phase, and the morphology of this division is used for determination of microsporidian genera. The sporoplasm on the left is uninucleate, and the cells that are produced from it represent the developmental patterns of several microsporidia with isolated nuclei. The sporoplasm on the right is diplokaryotic, and it similarly produces the various diplokaryotic developmental patterns. Cells containing either type of nucleation will produce one of three basic developmental forms. Some cycles have cells that divide immediately after karyokinesis by binary fission (e.g., *Anncaliia*). A second type forms elongated moniliform multinucleate cells that divide by multiple fission (e.g., some *Nosema* species). The third type forms rounded plasmodial multinucleate cells that divide by plasmotomy (e.g., *Endoreticulatus* species). Cells may repeat their division cycles one to several times in the proliferative phase. The intracellular stages in this phase are usually in direct contact with the host cell cytoplasm or closely abutted to the host endoplasmic reticulum; however, the proliferative cells of *Encephalitozoon* (and probably *Tetramicra*) are surrounded by a host-formed parasitophorous vacuole throughout their development, and the proliferative plasmodium of the genus *Pleistophora* is surrounded by a thick layer of parasite secretions that becomes the sporophorous vesicle in the sporogonic phase. The sporogonic phase is illustrated below the dashed line. Some of the microsporidian genera maintain direct contact with the host cell cytoplasm during sporogony, i.e., *Nosema*, *Ichthyosporidium*, *Anncaliia*, *Enterocyotozoon*, and probably *Tetramicra*. The remaining genera form a sporophorous vesicle as illustrated by the circles around developing sporogonial stages. It should be noted that in the *Thelohania* cycle and the *Thelohania*-like part of the *Vairimorpha* cycle, the diplokarya separate and continue their development as cells with isolated nuclei. Adapted with permission from reference 70.

membranes thicken, forming sporonts; (iv) after dividing, sporonts give rise to sporoblasts that develop into mature spores without additional multiplication; and (v) the host cell becomes distended with mature spores, ruptures, and releases spores into the environment. The combination of multiplication during both merogony and sporogony results in a very large number of spores being produced from a single infection and is the basis of the enormous reproductive potential of these pathogens.

Microsporidia form characteristic unicellular spores (Fig. 2) that are environmentally resistant, enabling their transmission in food and water (68). Spore structure is characteristic of the phylum, and spores can vary in size and shape depending on the species (9, 69). The spore coat consists of an electron-dense, proteinaceous exospore, an electron-lucent endospore, and an inner membrane or plasmalemma. A defining characteristic of these pathogenic protists is the presence of an invasion organelle that consists of the polar tube that is attached to the inside of the anterior end of the spore by an anchoring disk, and a series of associated membranes. The polar tube coils around the nucleus and there can be up to 30 coils depending on the species of microsporidium (2, 9, 70). During germination, the polar tube rapidly everts, forming a hollow tube that brings the sporoplasm into intimate contact with the host cell and acting as a conduit to deliver the sporoplasm to the host cell, essentially functioning like a hypodermic needle (71–73) (Fig. 3). When a spore is phagocytosed by a host cell, germination can occur, allowing the polar tube to pierce the phagocytic vacuole and permitting the sporoplasm to escape the phagosome and to be delivered into the host cell cytoplasm (74).

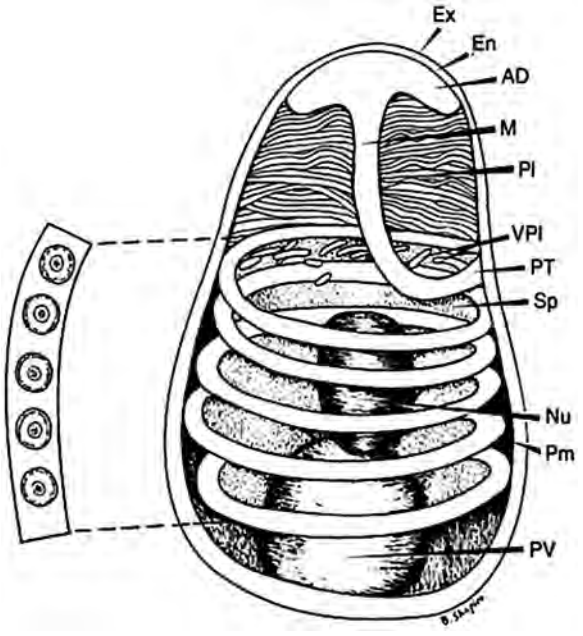

Figure 2 Diagram of a microsporidian spore. Spores range in size from 1 to 10 μm. The spore coat consists of an electron-dense exospore (Ex), an electron-lucent endospore (En), and a plasma membrane (Pm). It is thinner at the anterior end of the spore. The sporoplasm (Sp) contains a single nucleus (Nu), the posterior vacuole (PV), and ribosomes. The polar filament is attached to the anterior end of the spore by an anchoring disc (AD) and is divided into two regions: the manubroid, or straight portion (M), and the posterior region forming five coils (PT) around the sporoplasm. The manubroid polar filament is surrounded by the lamellar polaroplast (Pl) and vesicular polaroplast (VPl). The insert depicts a cross section of the polar tube coils (five coils in this spore), demonstrating the various concentric layers of different electron density and electron-dense core present in such cross sections. Reprinted with permission from reference 70.

Polar tube discharge from the anterior pole of the spore is a rapid event, and the conditions that promote germination vary widely among different microsporidia and probably reflect the adaptation of a particular microsporidium to a specific host and external environment during transmission of these pathogens (reviewed by Keohane and Weiss [75]). Conditions that promote spore discharge include pH shifts, dehydration followed by rehydration, various cations and anions, mucin or polyanions, hydrogen peroxide, ultraviolet irradiation, and calcium flux (75). In response to their particular activation signal, microsporidia have an increase in intrasporal osmotic pressure, resulting in an influx of water into the spore, which is accompanied by swelling of the polaroplasts and posterior vacuole prior to spore discharge (76, 77). In *A.* (*N.*) *algerae*, it has been suggested that this is mediated by the breakdown of trehalose by trehalase (76, 78).

PHYLOGENETIC ANALYSIS OF THE MICROSPORIDIA

Microsporidia have several apomorphic characteristics including the polar tube, the posterior vacuole, the polaroplast, and the diplokaryon (in some species) that distinguish them as a taxon. These ultrastructural features and phenotypic, developmental, and ecological characteristics have been the basis of the classical classification of these organisms. Tuzet et al. (79), Sprague (9), Larsson (80), Issi (81), Weiser (82), Sprague et al. (83), and Weiss and Becnel (2) have all provided useful overviews of the history, ultrastructural and structural characteristics, and life cycle differences of the various microsporidian taxa. Microsporidia can be divided into three main groups: (i) the "primitive" (Metchniko-

Figure 3 Scanning electron micrograph of microsporidia infection of a host cell shows the extruded polar tube of a spore of *Encephalitozoon intestinalis* piercing and infecting Vero E6 green monkey kidney cells in tissue culture. Reprinted with permission from reference 70 and with the kind permission of N. P. Kock, C. Schmetz, and J. Schottelius, Bernhard Nocht Institute for Tropical Medicine, Hamburg, Germany; published in Kock NP. 1998. Diagnosis of human pathogen microsporidia (dissertation).

vellidae) hyperparasites of gregarines in annelids that have a rudimentary polar filament and a spore without a polaroplast; (ii) the Chytridiopsidae, Hesseidsae, and Burkeidae, which have a short polar filament and minimal development of the polaroplast and endospore; and (c) the "higher" Microsporidia that have a well-developed polar filament, polaroplast, and posterior vacuole. The various modern classification systems for the microsporidia focus on the characteristics used to divide the third group into subgroups. These systems, however, have problems, because many of these characteristics may be convergent. For example, the characteristics of being diplokaryotic during the microsporidian life cycle and the presence of a pansporoblastic membrane are not defining characteristics, because the genus *Nosema*, defined as being diplokaryotic throughout its life cycle, is actually a polyphyletic assemblage of unrelated taxa. To this end, *Nosema locustae* has been redefined as both *Paranosema* (Sokolova et al., 2003; Sokolova et al., 2005) and *Antonospora*, (Slamovits et al., 2004); *Nosema kingi* is now *Tubulinosema kingi* (Franzen et al., 2005); *Nosema algerae* has been redefined as *A. algerae* (Franzen et al., 2006); and *Nosema cristatella* (Canning et al., 1997) is now *Pseudonosema cristatella* (Canning, 2002).

Currently over 3,000 partial and complete small subunit ribosomal RNA (ssrRNA) genes of various microsporidia species and isolates are accessible on Genbank (http://www.ncbi.nlm.nih.gov/genbank/) and MicrosporidiaDB (http://microsporidiadb.org/micro/). This ssrRNA sequence data has been useful in the development of diagnostic PCR primers as well as for investigations into phylogenetic relationships (84, 85) (reviewed by Weiss and Vossbrinck [25]). The ssrRNA sequence of microsporidia diverges greatly from that of other eukaryotes, it is significantly shorter than other eukaryotic ssRNAs, and microsporidian ssRNA lacks loops that are present in either eukaryotic and/or prokaryotic ssrRNA (11, 86–88). This divergence of ssRNA sequence structure, while once thought to be evidence of microsporidia being an early branch in evolution, instead is due to the specialization and extremely reduced genome size reduction of these obligate intracellular pathogens (11). The genome size of the microsporidia varies from 2.3 to 51.3 Mb (89, 90). The genome sizes of microsporidia in the family *Encephalitizoonidae* (all of which are human pathogens) are all under 3.0 Mb, making these genomes among the smallest eukaryotic nuclear genomes (91–96). There are almost no introns in these compact genomes, gene density is high, proteins are shorter than the corresponding genes in *Saccharomyces cerevisiae*, and there is a high degree of gene composition conservation among the various microsporidia (91–96). Chromosomal analysis of *E. cuniculi* (97, 98) and studies of the heterogeneity of gene loci in both *E. cuniculi* (99) and *Nematocida parisii* (100) indicate that microsporidia are probably diploid. Data on *N. ceranae* have further suggested that this microsporidium is tetraploid (101). Several microsporidian genomes have been sequenced and annotated, and these data are available on MicrosporidiaDB (http://microsporidiadb.org/micro/) (102).

The development of molecular data, e.g., ssrRNA and now genomic sequencing, has resulted in the reassignment of many genera as well as the erection of new genera. It is clear that descriptions of new microsporidian species should now include detailed microscopic and ultrastructural images along with supporting molecular data, e.g., ssrRNA sequence (2, 89, 103). Studies using ssRNA have demonstrated that some microsporidia thought to be separate species are synonymous, e.g., *N. bombycis* and *Nosema tichoplusiae* (104), and confirmed that other microsporidia, e.g.,

Encephalitozoon hellem and *Encephalitozoon intestinalis*, are indeed separate species (105). A reasonable approach for integration of molecular data and other characteristics used for microsporidian classification is to create molecular phylogenies of the microsporidia and then to place the nonmolecular data on the tree (84). This type of analysis should facilitate studies that seek to understand the evolution of these organisms, including features such as the loss and gain of alternative hosts, host switching, loss and gain of sexual recombination, use of the pansporoblastic membrane, changes in the numbers of coils in the polar filament versus tissues infected, strategies of generalist versus specialist parasites, and changes in genome size and composition (103). Studies using this technique have demonstrated a significant degree of homoplasy (convergence, parallelism, and reversal) among the microsporidia, which probably reflects an effect of the reduced genome size seen in these pathogenic protists. Host-parasite cospeciation may have occurred with microsporidia and has been examined in *Nosema* species from bees (106, 107) and in the *Amblyosporidae* from mosquitoes (108, 109). Several other studies have examined the phylogeny of microsporidia isolated from various host types including fish (110, 111), insects (2, 112–114), and crustaceans (115, 116). It should be noted that discrepancies exist between phylogenies based on traditional characteristics and those based on molecular analysis and that these types of discrepancies have not been fully resolved (103).

Molecular phylogenetic data provide several lines of strong evidence that microsporidia are related to the Fungi as either a basal branch of the Fungi or a sister group (12, 13, 117). Analysis of α-tubulin, β-tubulin, glutamyl-tRNA synthetase, seryl-tRNA synthetase, vacuolar ATPase, TATA box binding protein, transcription initiation factor IIB, subunit A of vacuolar ATPase, guanosine triphosphate-binding protein, heat shock protein gene (*hsp70*), the largest subunit of RNA polymerase II (*RPB1*), and transcription factor IIB sequences demonstrates that microsporidia are not primitive eukaryotes but instead are related to fungi (117–127). Microsporidian ssrRNA genes lack a paromomycin binding site, similar to fungi (128). Microsporidian genomes display two syntenic ribosomal genes (RPL21 and RPS9) that are also syntenic throughout the fungi but are linked in other eukaryotic lineages (129, 130). The microsporidian EF-1α gene has an insertion that is found only in fungi and animals—not in protozoa (12, 128, 131, 132). Analysis of the *E. cuniculi* genome and other microsporidian genomes demonstrates that most microsporidian proteins are most similar to fungal homologs (13, 14, 91, 95, 96, 133). Biological evidence also supports the relationship of microsporidia to fungi. Microsporidia have chitin in their spore wall and store trehalose, as do fungi (69, 78). Microsporidia display similarities to the fungi during mitosis (e.g., closed mitosis and spindle pole bodies [134]) and meiosis (135). Data suggest that trehalose is probably the major sugar reserve in microsporidia, as is seen in many fungi (2). *O*-mannosylation, as seen in fungi, occurs in microsporidia as demonstrated by studies of major polar tube protein PTP1 (136).

Keeling (137), in an analysis of β-tubulin data that included microsporidia and representatives of many fungal phyla, found evidence that microsporidia were a sister group to the Zygomycota. Comparative analysis utilizing the complete genomes of several microsporidia also supports a similar relationship of microsporidia with the Fungi (13, 92, 130) Analysis of a six-gene dataset (16) that included a large diversity of Fungi suggested that microsporidia branched deeply, forming a sister clade to the Fungi with *Rozella*, a hyperparasitic chytrid that infects other chytrids. Analyses of individual gene trees, supertrees, and trees based on concatenation of hundreds of genes also supported a deep-branching position as a sister group to the Fungi (13, 138). However, these data, while suggestive, do not definitively determine if the microsporidia (and *Rozella*) are within the Fungi or sisters to the Fungi. Environmental microbiome studies have defined a previously unrecognized group of organisms termed the Cryptomycota (139–143), which are a large and diverse lineage, including aphelids and *Rozella*, of Fungi or fungal relatives that are poorly described at the biological level but that are closely related to the microsporidia. The most recent genome-scale phylogenies place microsporidia together with Cryptomycota as the basal branch of the fungal kingdom (or alternatively as a sister phylum). These, and other, recently described microsporidia-like organisms, e.g., *Mitosporidium daphniae* (144), *Nucleophaga terricolae*, and *Paramicrosporidium* (15, 145, 146), illustrate that more environmental sampling and genome sequencing will be needed to fully resolve the relationship of microsporidia and the Fungi, as well as to provide a better understanding of the Cryptomycota and reveal what this group has to teach us about the origin and diversification of the microsporidia.

STRUCTURE AND COMPOSITON OF THE MICROSPORIDIAN SPORE

The spore is the infectious stage of the microsporidian life cycle and the only stage that can survive outside the

host cell. The shape of the microsporidian spore is usually pyriform or oval, and the spores vary in size from approximately 1 to 12 μm, although some needle-like spores can be as long as 20 μm (9). The spore has three general features: the spore coat, the sporoplasm, and the invasion apparatus (147). The spore coat contains three layers: an electron-dense outer exospore layer, an electron-lucent inner endospore layer, and the plasma membrane (147). The endospore layer is composed predominantly of chitin and glycoproteins, and it is thinnest in the region of the anterior anchoring disk complex where rupture occurs during extrusion of the polar tube. Chitin, a major component of the endospore, forms bridges across the endospore and is part of the fibrillar system of the exospore (69). The presence of chitin in the endospore enables microsporidian spores to be stained by fluorescent brighteners such as calcofluor white or Uvitex 2B (148). Both chitin deactylase, in several microsporidia (149), and a *N. bombycis* GH19 chitinase were found to localize to the spore wall (150).

The spore wall protects the organism from harsh environmental conditions, permitting transmission of the organism via water or food. It is probable that proteins in the spore wall are involved in processes such as spore adherence, signaling, or other interactions with host cells (151). Increased hydrostatic pressure in the spore has been demonstrated to cause discharge of the polar tube (152). Several spore wall proteins have been identified using proteomic techniques, and the localization of these proteins has been validated by immunofluorescence (indirect fluorescent-antibody assay) and ultrastructural (immunoEM) studies. The first spore wall protein (SWP) to be identified was *E. cuniculi* spore wall protein 1 (EcSWP1) (153). Ultrastructural analysis has demonstrated that this protein is found in the exospore. During spore development EcSWP1 was absent in meronts and was first seen in early sporonts, and the amount of this protein increased in the exospore during spore maturation (153). Homologs of SWP1 have been identified in *E. intestinalis* and *E. hellem* (154, 155). In *E. hellem* two SWP1 proteins (EhSWP1a, EhSWP1b) were identified. Using monoclonal antibodies to various SWP1 proteins, EiSWP1, EhSWP1a, and EhSWP1b were all found to localize to the exospore in mature spores (154, 155). A second SWP protein (SWP2) was identified in *E. intestinalis* along with EiSWP1. This 150-kDa protein shared a high similarity with the N-terminal region of EiSWP1; immuno-EM demonstrated that EiSWP2 localized to the spore surface and that EiSWP2 became much more abundant as spores continued development into sporoblasts and mature spores. Homologs of EiSWP2 have not been found in *E. hellem* or *E. cuniculi*, suggesting that this protein may have a unique role in *E. intestinalis*. A third spore wall protein (SWP3/EnP2) was identified from *E. cuniculi* using a proteomic strategy (156, 157). EcSWP3, also called endospore protein 2 (EnP2), has been demonstrated to localize to the endospore adjacent to the plasma membrane (156). Another endospore protein (EnP1) was identified at the same time as SWP3/EnP2 in *E. cuniculi* (156). EnP1, which is also called SWP4, is a cysteine-rich protein and contains disulfide linkages that may facilitate its binding in the endospore.

It has been found that host cell surface sulfated glycosaminoglycans play an important role in the adherence of *E. intestinalis* and *E. cuniculi* to host cell surfaces (158). EnP1 has been found to be involved in host cell adherence by its interacting with host cell membrane glycosaminoglycans through the heparin binding motifs found in EnP1 (151). Homologs of these proteins have been found in other microsporidia. These SWP adhesion domains may facilitate the binding of microsporidian spores to either the cell surface or mucus of the gastrointestinal tract prior to germination. Many of the SWPs that have been identified in various microsporidia have posttranslational glycosylation, often involving mannosylation, which is likely important for spore wall adherence to host cells during invasion. Using various proteomic techniques, additional SWPs such as SWP5 (159), SWP6, and SWP7 (L. M. Weiss, unpublished data) have also been identified in the *Encephalitozoonidae*, and other putative SWPs have been identified in *N. bombycis* (160–164). Some *N. bombycis* SWPs have been suggested to function as scaffolding proteins that support other proteins to form the integrated spore wall of microsporidia (162). Many of these newly identified *N. bombycis* SWPs have not been found in the *Encephalitozoonidae*, suggesting (not surprisingly) that some SWPs may be species (or genus) specific and related to the environment and the specific interactions that are needed for infection between different hosts (e.g., insects versus mammalian hosts). SWPs appear to be specific to microsporidia, because homologs of these various SWPs have not been found in other organisms.

STRUCTURE AND COMPOSITION OF THE POLAR TUBE

It has been almost 125 years since the initial description of polar tubes and their discharge from spores (165, 166). The polar tube is an invasion organelle that is unique to the microsporidia. While the polar

tube superficially resembles the structures seen in Myxosporea (which are related to cnidarians), the microsporidian polar tube has a distinct function, acting as a tube rather than as a nematocyst. During infection this highly specialized structure is discharged from the spore, forming a hollow tube that delivers the infectious sporoplasm into its host cell's cytoplasm. The polar tube in different species of microsporidia is variable in diameter, length, and arrangement in the spore. The number of coils in a spore can range from 3 to 50 depending on the species of microsporidia (167). Polar tubes can be from 50 to 500 μm in length, and the length can be two to three times longer after the polar tube has completely discharged from the spore (73). The diameter of the tube is 0.1 to 0.2 μm, and during sporoplasm passage the diameter can increase significantly, illustrating the flexibility of this structure (73, 168, 169).

The mechanism of spore germination still remains to be definitively determined. It is generally believed that spore germination occurs in several phases that may overlap: (i) activation, (ii) an increase in intrasporal osmotic pressure, (iii) eversion of the polar tube, and (iv) passage of the sporoplasm through the everted polar tube (2). Before germination, the polar tube is coiled inside the mature spores and filled with material when visualized by transmission electron microscopy. After activation, the conditions of which are often specific to a particular species of microsporidia, the polar tube bursts through the anterior pole of spore at the location of the anchoring disk (73, 170) and forms a hollow tube (170, 171). This discharge process occurs rapidly, with full eversion occurring within 2 s (71). Different species of microsporidia require different conditions for germination, and this probably depends on the host species target as well as environmental conditions related to transmission of a particular organism. While a universal stimulant for spore activation is not known, many species can be induced to germinate in distilled water containing 1 to 5% hydrogen peroxide (75). Various reports using *A.* (*N.*) *algerae* have demonstrated that successful germination is associated with an increase in intrasporal osmotic pressure and that this osmotic pressure is the force that drives polar tube extrusion, rather than this requiring ATP or another energy source (152). These studies of *A. algerae* found that the increase in osmotic pressure was related to a decrease in trehalose levels in germinating spores. This suggests that upon activation of spores, the breakdown in compartmentalization brings trehalose in contact with the enzyme trehalase, resulting in its digestion into simple sugars increasing spore osmotic pressure (172).

Proteomic studies of the polar tube have begun to define the full complement of proteins that make up this structure, which should lead to a better understanding of how the polar tube is formed and how it functions during invasion (136, 173–188). Polar tube proteins (PTPs) are highly immunogenic in both experimental and natural infections. In a large serosurvey, antibodies reacting to *E. cuniculi* were present in 5% of pregnant French women and 8% of Dutch blood donors (189). Polar tubes have been found to be insoluble in 1% SDS and 9 M urea and soluble in 2% dithiothreitol (DTT), allowing the purification of potential PTPs. Weidner used these solubility properties to isolate potential PTPs from *Ameson michaelis* and demonstrated that this protein mixture could self-polymerize (169). Using a similar extraction procedure and reverse-phase high-performance liquid chromatography, a 43-kDa PTP was identified and designated PTP1, based on its being the major protein by mass in the *Glugea americanus* DTT solubilized material (174). Subsequently, additional PTP1s were purified from several microsporidia of the genus *Encephalitozoonidae* using the same purification protocol (175, 177, 190).

PTP1 is a proline-rich protein that contains many cysteine residues in its N-terminal and C-terminal domains. Based on the solubilization of the polar tube by DTT, disulfide bridges probably play an essential role in maintaining this structure. The abundance of proline in PTP1 is consistent with properties seen in the intact polar tube because this amino acid has been reported to increase the tensile strength and elasticity of proteins. Analysis of the glycosylation of PTP1 demonstrated that there are a significant number of O-linked mannosylation sites in this protein (136, 183, 186). Mannose pretreatment of host cells was found to decrease *E. hellem* infection, which was consistent with an interaction between mannosylated PTP1 and some unknown host cell mannose-binding receptor protein (136, 184, 185, 191, 192). Examination of published microsporidian genomes (www.MicrosporidiaDB.org) has demonstrated that PTP1 homologs are not easily identified in all genomes, which may reflect the high evolution rates in microsporidia that often make the identification of orthologous proteins difficult. For example, the putative PTP1 of *Antonospora locustae*, *Paranosema grylli*, and *N. ceranae* were identified based on a combination of features including the presence of a predicted signal peptide, their similar length, conserved acidic pI, and predicted amino acid compositions along with their close physical juxtaposition to another PTP, named PTP2 (180); but it would not have been identified by a simple BLAST search of the genomes (2, 193–195).

PTP2 was also identified using proteomic and antibody-based approaches (180, 184, 196). Interestingly, PTP2 is found at the same genomic locus as PTP1. Preservation of gene order may be due to constraints of evolution on these small eukaryotic genomes (197). PTP2 is more conserved in size than PTP1, and the identified PTP2s from various microsporidia share common characteristics, despite a high degree of sequence divergence; e.g., they have a basic pI, high lysine content, and a conservation of cysteine residues that are most likely involved in intra- and/or inter-protein disulfide bridges (180, 184, 196). PTP2 has been identified in the genome of many microsporidia including *A.* (*Paranosema*) *locustae*, *Trachipleistophora hominis*, *E. cuniculi*, *E. hellem*, *E. intestinalis*, *P. grylli*, *N. cerana*, *N. bombycis*, *E. bieneusi*, *A. algerae*, *Tubulinosema ratisbonensis*, *N. parisii*, *V. cornea*, and *Edhazardia aedis* (2, 184, 194, 196).

Immunoscreening of a cDNA library of *E. cuniculi* led to the identification of a third polar tube protein, PTP3 (182). Unlike PTP1 and PTP2, it was found that PTP3 is solubilized in the presence of SDS alone without the need for a reducing agent such as DTT (180), which explains why it was not seen in standard polar tube preparations. PTP3 along with PTP1 and PTP2 was, however, found in studies examining cross-linked polar tube complexes, and these three PTPs were also demonstrated to interact in yeast two-hybrid assays (182, 185). It has been suggested that PTP3 may act as a scaffolding protein for the assembly of other PTPs in the formation of the polar tube during development. Genome analysis has confirmed the presence of PTP3 orthologs in the genomes of *E. intestinalis*, *E. hellem*, *Encephalitozoon romalae*, *N. ceranae*, *N. bombycis, A. locustae, P. grylli, T. hominis*, *E. bieneusi*, *A. algerae*, *N. parisii*, *Octosporea bayeri*, *T. ratisbonensis*, and *Vavria culicis floridensis* (2). The sequence of these PTP3 orthologs is more conserved than the sequences of the PTP1 and PTP2 orthologs.

Two new PTPs (PTP4 and PTP5) have been identified in the polar tube using proteomic and antibody-based approaches (198). Orthologous PTP4 and PTP5 are present in many microsporidian genomes including *E. cuniculi*, *E. hellem*, *E. intestinalis*, *P. grylli*, *N. ceranae*, *N. bombycis*, *A. algerae*, *O. bayeri*, *E. aedis*, *V. cornea*, and *T. ratisbonensis* (2). Similar to PTP1 and PTP2, the genes for PTP4 and PTP5 usually are in a cluster in the genome (2). Monoclonal antibody to PTP4 stains the extruded tip of the polar tube, whereas the other PTPs (i.e., PTP1, PTP2, PTP3, PTP5) are located uniformly along the entire polar tube (B. Han and L. M. Weiss, submitted) (2, 196). This specialized location of PTP4 suggests that this protein is probably involved in the interaction of the polar tube and host cell at the invasion synapse. Recently, by employing PTP4 for an immunoprecipitation assay followed by proteomic analysis, we were able to identify a potential host cell receptor for PTP4, and mutant host cells without this receptor have a markedly reduced infection rate (Han and Weiss, submitted). The mechanism by which the polar tube interacts with the host cell membrane resulting in penetration is currently unknown; however, there is some evidence that host cell actin may be involved in microsporidian penetration of the host cell within the invasion synapse (199). Furthermore, ongoing proteomic studies of the polar tube suggest that additional PTPs remain to be characterized in this structure (L. M. Weiss, unpublished data).

SUMMARY

Microsporidia are unicellular eukaryotes that develop as obligate intracellular parasites. They have a unique invasion organelle, the polar tube, which upon appropriate environmental stimulation rapidly discharges out of the spore, pierces a cell membrane, and serves as a conduit for sporoplasm passage into a host cell. Phylogenetic analysis suggests that microsporidia are related to the Fungi, being either a basal branch or sister group. Despite the description of microsporidia over 150 years ago, we still lack an understanding of the mechanism of invasion, including the role of various PTPs and SWPs as well as host cell proteins in the formation and function of the invasion synapse. Over the past 2 decades, proteomic approaches have helped define PTPs and SWPs as well as the importance of post-translational modifications such as glycosylation in the functioning of these proteins, but the absence of genetic techniques for the manipulation of microsporidia has hampered research on the function of these various proteins. Recent advances in ultrastructural techniques are, however, helping to better define the role of various PTPs and SWPs in the formation and functioning of the invasion synapse. The study of the mechanism of invasion should provide fundamental insights into the biology of these ubiquitous intracellular pathogens that can be integrated into studies aimed at treating or controlling microsporidiosis.

Fungal Sex: The *Ascomycota*

6

Richard J. Bennett[1] and B. Gillian Turgeon[2]

PHYLOGENY OF THE ASCOMYCETES

There are ~64,000 known species within the *Ascomycota*, making it the largest phylum of Fungi. Major subphyla include the *Taphrinomycotina* (e.g., *Schizosaccharomyces pombe*), the *Saccharomycotina* (including *Candida* and *Saccharomyces* clades), and the *Pezizomycotina* (the largest subphylum, which includes the *Eurotiomycetes*, *Dothideomycetes*, *Sordariomycetes*, and *Leotiomycetes*) (see Fig. 1). Most *Saccharomycotina* grow as budding yeast or are dimorphic (can grow as yeast or filaments), whereas most *Pezizomycotina* are predominantly filamentous, although some are also dimorphic.

SEX IN THE MODEL YEASTS

Sexual reproduction is thought to have evolved early in the eukaryotic lineage and to have been retained by the majority of extant species. The unicellular yeasts *Saccharomyces cerevisiae* and *S. pombe* have been invaluable in defining fundamental aspects of sexual reproduction, as well as addressing the benefits of sex for adaptive evolution (1, 2). Despite often being grouped together, *S. cerevisiae* (a budding yeast) and *S. pombe* (a fission yeast) last shared a common ancestor more than 330 million years ago (3). The *Schizosaccharomyces* genus forms a deep branch from the base of the *Ascomycota* tree (the *Taphrinomycotina*) and is considered to be representative of "ancient" ascomycetes (4) (Fig. 1). *S. cerevisiae* has undergone faster evolution than *S. pombe* since their split from a common ancestor, so that the latter may display attributes closer to the common roots of fungi and animals (4). The two yeasts exhibit both similarities and important differences in mating (gamete fusion) and meiosis (gametogenesis). Mating in these species involves pheromone-based communication and fusion between cells of opposite mating types. In *S. cerevisiae*, signaling between **a** and α cell types leads to the formation of diploid **a**/α cells, whereas in *S. pombe*, mating of P (plus or h+) and M (minus or h–) cells generates diploid P/M (h+/h–) cells (Fig. 2).

Regulation of Cell Type Identity

Genes encoded at the mating-type (or *MAT*) locus define cell type identity. In *S. cerevisiae*, haploid *MAT***a** cells express the *MAT**a**1* gene, haploid *MAT*α cells express *MAT1* and *MAT2* genes, and diploid *MAT***a**/α cells express all three *MAT* genes (*5*, 6). Both *MAT**a**1* and *MAT2* encode homeodomain proteins (**a**1 and α2, respectively), whereas *MAT1* encodes an α-domain protein (α1). These activities cooperate to ensure that haploid **a** and α cells express sex-specific pheromones and pheromone receptors. Furthermore, they allow **a** and α cells to express "haploid-specific" genes, which include several components of the pheromone-signaling mitogen-activated protein kinase (MAPK) cascade.

In *S. cerevisiae* α cells, α-specific genes are expressed due to α1 and Mcm1 activity, and the expression of **a**-specific genes is repressed by α2/Mcm1. In **a** cells, **a**-specific genes are constitutively expressed due to the presence of Mcm1 (a constitutive MADS-box transcription factor), while α-specific genes are off due to the absence of α1. In diploid **a**/α cells, both **a**- and α-specific genes are turned off, because a complex between **a**1 and α2 represses expression of α1 (and hence α-specific genes), while **a**-specific genes are repressed by α2/Mcm1. Critically, the **a**1/α2 complex also represses "haploid-specific" genes; because these genes include inhibitors of meiosis, the requirement for the **a**1/α2 complex ensures that only diploid **a**/α cells can initiate meiosis.

In *S. pombe*, a similar mechanism regulates cell type identity, with cells expressing the *mat1-P* locus mating as P cells and *mat1-M*-expressing cells mating as M cells. The *mat1-P* locus encodes Pc and Pi proteins,

[1]Molecular Microbiology and Immunology, Brown University, Providence, RI 02912; [2]Plant Pathology and Plant-Microbe Biology, Cornell University, Ithaca, NY 14853.

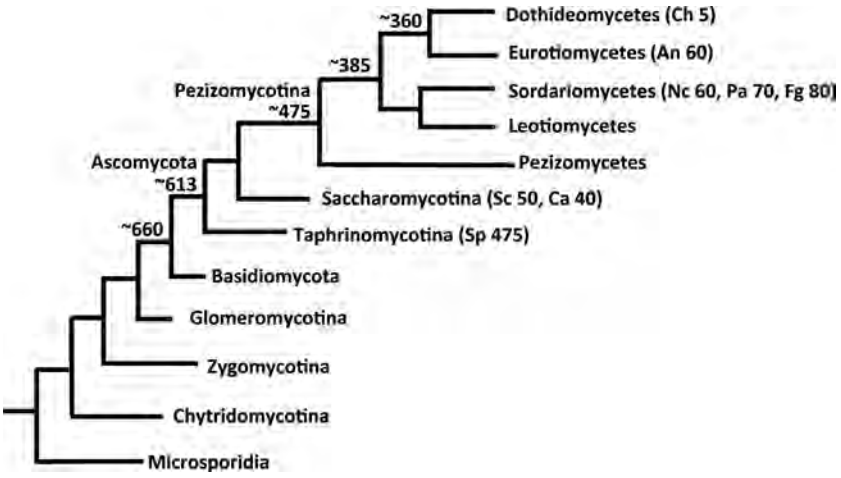

Figure 1 Phylogenetic relationships of major groups of fungi. Synthesis from references 280–282. Numbers at the nodes indicate estimated age, in millions of years, at which an ancestral group arose. Abbreviations: An, *Aspergillus nidulans*; Ca, *Candida albicans*; Ch, *Cochliobolus heterostrophus*; Fg, *Fusarium graminearum*; Pa, *Podospora anserina*; Nc, *Neurospora crassa*; Sc, *Saccharomyces cerevisiae*; Sp, *Schizosaccharomyces pombe*. Numbers in parentheses indicate the approximate age of that group in millions of years.

whereas the *mat1-M* locus encodes Mc and Mi proteins. For successful mating, the *mat1-Pc* gene is required for expression of P-specific genes, whereas the *mat1-Mc* gene drives expression of M-specific genes (7). As in *S. cerevisiae*, cell-type-specific expression includes that of pheromone and pheromone receptor genes (8–11). While *mat1-Pc* and *mat1-Mc* genes are sufficient for conjugation, expression of all four *mat1*-encoded proteins is necessary for *S. pombe* meiosis.

Pheromone Signaling in *S. cerevisiae*

Pheromone signaling in fungi is transduced via a conserved MAPK pathway (see Fig. 3) (for detailed reviews see references 12–15). In *S. cerevisiae*, pheromone binding to its cell surface receptor activates a heterotrimeric G protein complex, which dissociates into separate Gα (Gpa1) and Gβγ (Ste4–Ste18) components. The activated Gβγ complex directly contacts several components: (i) Ste20, a p21-activated protein kinase, (ii) Ste5,

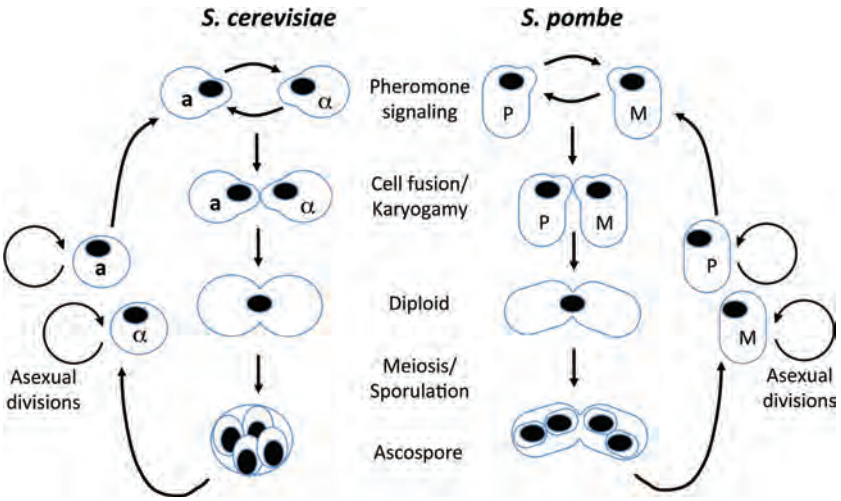

Figure 2 Life cycles of *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*. Both species can divide asexually or can undergo opposite sex mating. Meiosis and sporulation is used to complete the life cycle and regenerate haploid forms of the species.

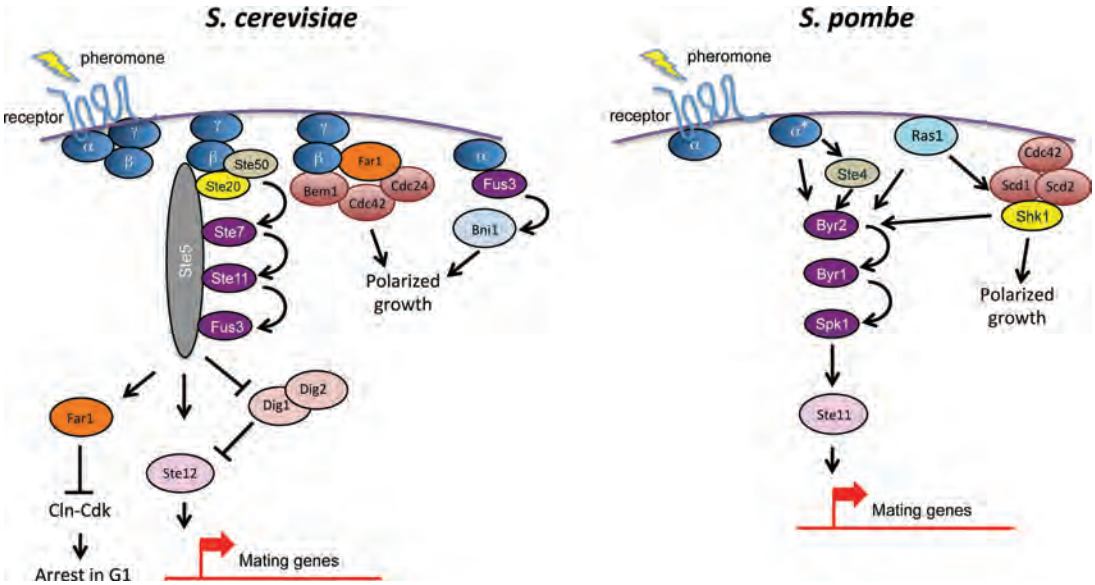

Figure 3 Pheromone signaling in *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*. Pheromone signaling is transduced from a G-protein coupled receptor via a mitogen-activated protein kinase (MAPK) cascade into a transcriptional response in the nucleus. In *S. cerevisiae*, pheromone-receptor interactions cause dissociation of the G protein complex, and Gβγ subunits promote pheromone signaling via two scaffold proteins. The Ste5 scaffold mediates MAPK signaling and the transcriptional response to pheromone, whereas the Far1 scaffold interacts with Cdc42 to mediate shmoo formation and also leads to cell cycle arrest. In *S. pombe*, no scaffold protein has been identified for pheromone signaling. Here, the Gα subunit transduces the pheromone signal to the MAPK cascade and does so in concert with Ste4 and Ras1 activities.

a scaffold protein for MAPK proteins, (iii) Far1, a second scaffold protein involved in cell cycle arrest and cell polarization (16–19), and (iv) the Cdc42-guanine-nucleotide exchange factor, Cdc24.

Ste20 acts upstream of the MAPK cascade and is activated by the GTP-bound form of the G protein Cdc42. Because Cdc42 is membrane localized, this step recruits Ste20 to the membrane and promotes its interaction with the membrane-bound Gβγ complex (20). Cdc42 is itself activated by pheromone signaling; the Gβγ complex recruits Far1 together with Cdc24, a guanine-nucleotide exchange factor that increases the exchange of GDP for GTP on Cdc42 (16, 18). Cdc24 also functions in a Far1-independent manner by binding directly to the Gβγ complex (21). Notably, loss of Far1 affects shmoo formation and cell cycle arrest, but not the transcriptional response to pheromone (22, 23).

At the heart of the pheromone-signaling cascade is the scaffold protein Ste5, which interacts with the MAPKKK Ste11, the MAPKK Ste7, and the terminal MAPK Fus3 (24–26). Ste5 also binds the Gβ subunit, Ste4, and the guanine-nucleotide exchange factor protein, Cdc24 (19, 26). Shuttling of Ste5 between the nucleus and the cytoplasm occurs in vegetative cells, but increased export of the nuclear pool follows pheromone exposure, and Ste5 accumulates at the membrane via interactions with Gβ and Cdc24 (21, 27). The Ste5 scaffold promotes Ste11-Ste7-Fus3 interactions, and an additional contact with Gβγ brings these proteins into close proximity with the upstream kinase, Ste20. Membrane localization of Ste5 is critical for pheromone signaling; tethering of Ste5 to the membrane activates signaling even in the absence of pheromone and independently of Gβγ (28). However, signaling is still dependent on Ste20, indicating that recruitment of Ste5 to the membrane brings the Ste20 kinase into close proximity with its target, the MAPKKK Ste11 (28). Ste11 activation is also promoted by Ste50, which may promote a conformational change in Ste11 that enhances its phosphorylation by Ste20 (29). The Ste5 scaffold binds to the three kinases (Ste11, Ste7, and Fus3) via distinct interaction domains (24) and also is a direct coactivator of Fus3 phosphorylation by Ste7 (30).

Phosphorylated Fus3 protein is released from the Ste5 scaffold and enters the nucleus, where it activates the transcription factor Ste12. Fus3 directly stimulates Ste12 activity by phosphorylation and also targets the Ste12 regulators Dig1/Dig2 (31, 32). Ste12 binds DNA

as a homodimer (33, 34), as a heterodimer with Mcm1 or α1 (35–37), and as a complex with Dig1/Dig2 or Dig1/Tec1 (38). Activated Fus3 also phosphorylates and activates the Far1 scaffold protein (39). Far1 mediates cell cycle arrest by interfering with cyclin-Cdk activity, potentially by disrupting docking interactions between cyclins and their substrates (40). Far1 also acts as a scaffold for Gβγ and Cdc24, thereby establishing the site for formation of the mating projection (or shmoo) and recruiting Cdc42 and Bem1 proteins away from bud sites (23, 41). In addition to Far1, activated Fus3 also contributes to polarized growth by interacting with the free Gα subunit and promoting phosphorylation of Bni1 (42, 43). The latter results in activation of Bni1, facilitating local actin assembly and polarized growth.

Pheromone Signaling in *S. pombe*

In *S. pombe*, pheromones secreted by P and M cells bind to the cell surface receptors Mam2 and Map3, respectively. However, whereas Gβγ is responsible for MAPK signaling in *S. cerevisiae*, the Gα protein mediates MAPK signaling in *S. pombe*, and a corresponding Gβγ complex has not been identified (44). In *Kluyveromyces lactis*, the Gα subunit alone is also sufficient for signal transduction (45), whereas in *Candida albicans*, both Gα and Gβγ components make positive contributions to MAPK signaling (46).

The *S. pombe* MAPK cascade involves sequential activation of a MAPKKK (Byr2), a MAPKK (Byr1), and a MAPK (Spk1) (47, 48), and expression of these kinases can substitute for their *S. cerevisiae* counterparts and vice versa (49). MAPK signaling activates the Ste11 transcription factor, which is responsible for mating gene expression (50). Unlike *S. cerevisiae*, however, there is apparently no equivalent of the scaffold protein, Ste5, and it is not clear how the *S. pombe* Gα protein passes its signal to the MAPKKK, Byr2. One possible candidate is Ste4 (homologous to *Sc*Ste50), which interacts with both Gα and Byr2 (51, 52). The GTPase Ras1 is also necessary for *S. pombe* mating and may promote activation of the Byr2 kinase (48, 53, 54). Mating in *S. pombe* is closely integrated with nutritional cues, with nitrogen starvation leading to repression of TORC1 and cAMP pathways, and promoting basal activation of the Ste11 transcription factor (55). *S. pombe* also undergoes polarized growth in response to pheromone and, similar to *S. cerevisiae*, Cdc42 is a major regulator of cell polarity. However, it is not known how *S. pombe* Cdc42 is recruited to pheromone receptors. Ras1 could potentially link the polarization machinery to the pheromone-sensing pathway (15).

Why does *S. pombe* apparently lack the protein scaffolds central to pheromone signaling in other yeast species? One possibility is that scaffold proteins remain to be identified in *S. pombe*. Alternatively, it is possible that scaffolds evolved to limit cross talk between different signaling pathways (56–58), and this is not necessary in *S. pombe* because pheromone MAPK components are not shared with other programs. Furthermore, a major function of Far1 is to mediate cell cycle arrest in *S. cerevisiae*, whereas mating in *S. pombe* occurs in nutritionally poor conditions that may naturally arrest cells in G1. Far1 and Ste5 could therefore have become redundant in the *Schizosaccharomyces* lineage, whereas at least one of these scaffolds has been retained by other ascomycetes and basidiomycetes (15).

Meiosis in *S. cerevisiae*

Diploid **a**/α cells of *S. cerevisiae* stably propagate in the diploid state unless induced by nutrient-poor environments to enter meiosis, resulting in the formation of four haploid ascospores (see tetrads in Fig. 4). The master regulator of meiosis is the transcription factor Ime1 (inducer of meiosis 1) (59), whose expression is regulated by multiple environmental cues (60). *IME1* is also regulated by a long noncoding RNA (lncRNA), *IRT1*. This lncRNA is the result of Rme1 (repressor of Ime1) binding to the *IME1* promoter, and it induces a repressive chromatin state over the *IME1* promoter (61). In diploid cells, the **a**1/α2 complex represses *RME1* so that its gene product no longer produces the inhibitory *IRT1* and expression of *IME1* is permitted. Interestingly, a second lncRNA, *RME2*, controls expression of the *IME4* gene, which also promotes entry into meiosis (62, 63). In haploid **a** or α cells, *RME2* is an antisense transcript that blocks *IME4* expression, and inhibition is relieved in diploid cells due to **a**1/α2 blocking formation of the *RME2* transcript (64, 65). Thus, two lncRNAs, *IRT1* and *RME2*, combine to provide precise regulation over entry into meiosis (Fig. 5A).

Meiosis is accompanied by synchronous waves of gene expression involving ~1,600 genes (66–68). Ime1 may induce early meiosis genes by acting with a transcriptional cofactor, Ume6 (69–71), although a recent study suggests that Ime1 promotes Ume6 degradation to promote progression into meiosis (72). *IME2* is an early meiosis gene that encodes a serine-threonine kinase critical for downstream signaling. This kinase also targets Ime1 for destruction, thereby ensuring that Ime1 is only active in a narrow temporal window (73, 74). The Ndt80 transcription factor is the key regulator of middle meiosis genes, binding to middle sporulation

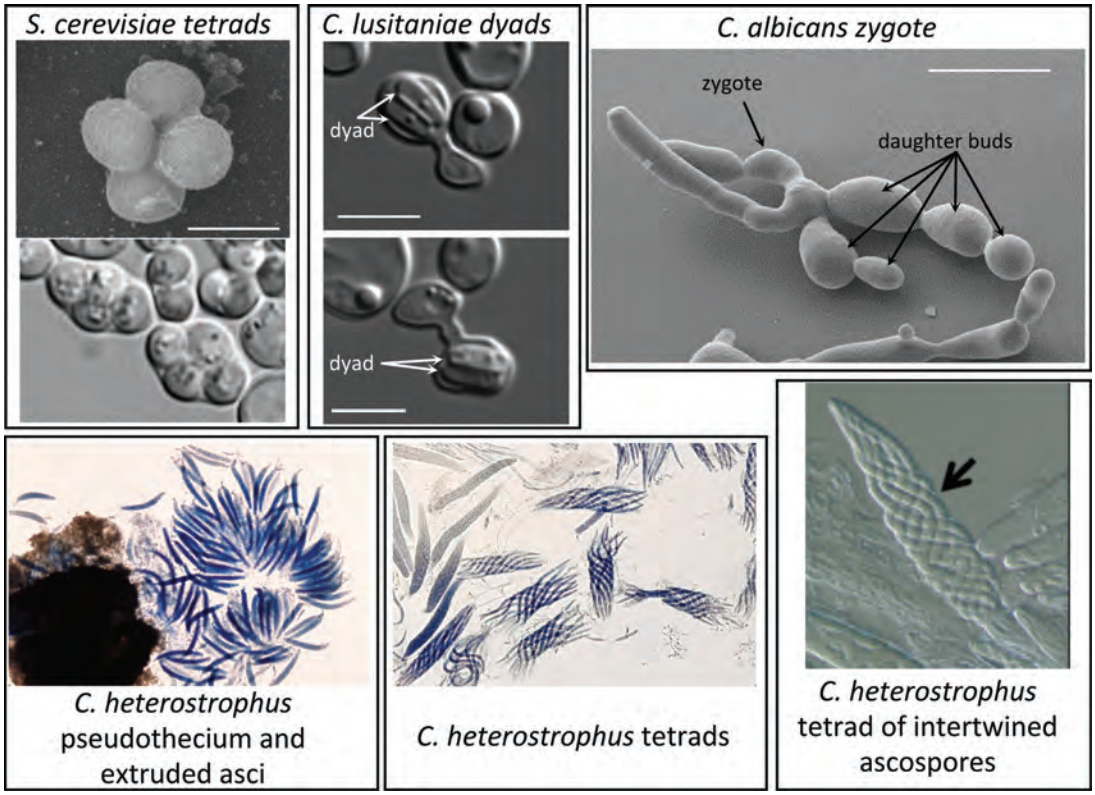

Figure 4 Images of ascomycetes undergoing sexual reproduction. The top row of images shows *Saccharomyces cerevisiae* tetrads (four ascospores) produced by meiosis, *Candida lusitaniae* dyads (two cell ascospores) produced by meiosis within the mating zygote, and a *Candida albicans* mating zygote with attached daughter cell buds. The bottom row of images shows a pseudothecium with extruded asci from the self-incompatible species *Cochliobolus heterostrophus*, *C. heterostrophus* tetrads, and *C. heterostrophus* asci containing filamentous ascospores. Scale bars in the top three panels are 3.4 m, 5 m, and 8.5 m, respectively. We acknowledge Aaron Neiman (Stony Brook University) and Matthew Hirakawa (Brown University) for the images of *S. cerevisiae* and *C. albicans* cells, respectively.

elements and removing the repressor Sum1 from middle sporulation element sequences (75). High-level expression of Ndt80 ensures commitment to the meiotic program (76).

Meiosis in *S. pombe*

S. cerevisiae cells stably propagate in the diploid state, whereas *S. pombe* cells often enter meiosis immediately after mating. Constitutive pheromone signaling is sufficient to drive *S. pombe* cells into meiosis (50). The MAPK target, Ste11, is a key transcriptional regulator of both mating and meiosis; it induces *mat1-Pc* and *mat1-Mc*, which in turn activate expression of *mat1-Pm* and *mat1-Mm* genes (77). Mat1-Pm and Mat1-Mm act synergistically to drive expression of the *mei3* gene that initiates the meiotic cascade (78, 79).

lncRNAs play a central role in regulating meiosis in *S. pombe* as in *S. cerevisiae* (Fig. 5B). Here, Mei2 recognizes an lncRNA (meiRNA) produced at the *sme2* locus and acts to sequester a key meiosis silencing factor, the RNA-binding protein Mmi1. In vegetative cells, Mmi1 silences the expression of ~20 meiosis genes by targeting their mRNAs for degradation (80–82). Sequestration of Mmi1 by Mei2 (and meiRNA) therefore allows meiotic gene expression to take place. Target genes include *mei4*, whose gene product is a transcription factor responsible for the induction of more than 500 meiosis genes (83).

Mei2 is itself regulated by the serine-threonine kinase Pat1 and the MAPK transcription factor Ste11 (Fig. 5B). Pat1 is an inhibitor of Mei2, but in diploid P/M cells the pseudo-substrate Mei3 is produced, which inhibits Pat1 kinase activity, thereby releasing Mei2 (77, 78, 84, 85). In addition, nitrogen starvation facilitates Ste11 expression, which induces the expression of Mei2 (86). As a result of these mechanisms, Mei2 is

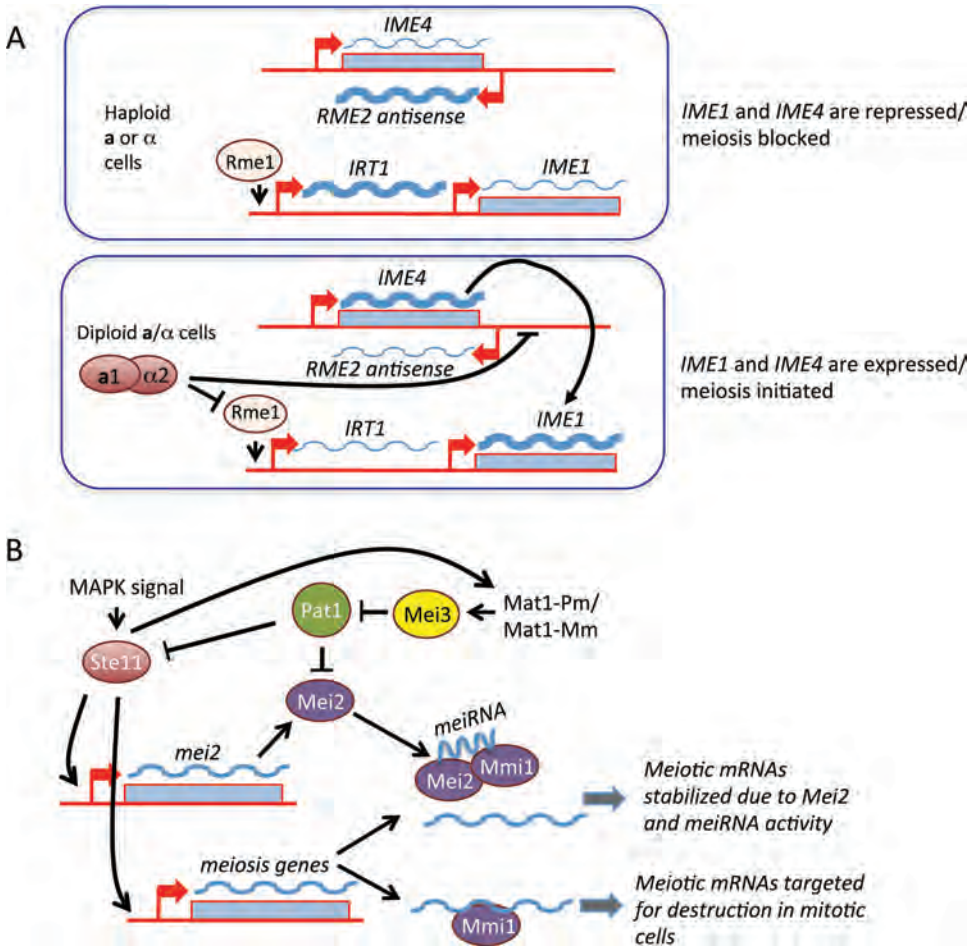

Figure 5 Regulation of meiosis in *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*. (**A**) In *S. cerevisiae*, two long noncoding RNAs, *IRT1* and *RME2*, regulate the expression of *IME1* and *IME4*, respectively, thereby controlling entry into meiosis. (**B**) In *S. pombe*, Mei2 and the long noncoding RNA meiRNA play a central role in meiotic regulation by suppressing Mmi1 and thereby stabilizing mRNAs necessary for entry into meiosis.

produced in an active form only in diploid P/M cells under starvation conditions. As in *S. cerevisiae*, waves of meiotic gene expression regulate progression through this developmental program (83).

Mating Type Switching in Yeasts

Both *S. cerevisiae* and *S. pombe* exhibit mating-type switching, allowing cells in a colony of one mating type to switch to the opposite mating type and then mate and produce sexual spores. Switching involves the copying of genetic information from a silent cassette to an active transcriptional locus. Notably, switching evolved independently in the lineages leading to *S. cerevisiae* and *S. pombe*, as discussed below.

In *S. cerevisiae*, cell type identity is defined by genes encoded at the *MAT* locus, with two additional silent cassettes present at the *HML*α and *HMR***a** loci (Fig. 6). Silent cassettes are kept inactive by flanking silencer sequences in tandem with trans-acting factors (e.g., the silent information regulator proteins, Sir1/2/3/4) to keep these DNA regions in a heterochromatic state (87). Mating-type switching occurs when the HO endonuclease makes a double-strand DNA break (DSB) at the *MAT* locus, and DNA from one of the silent cassettes is copied via a synthesis-dependent strand-annealing mechanism (87). The HO enzyme is only expressed in mother cells that have undergone cell division due to asymmetric localization of Ash1, a transcriptional inhibitor of *HO* expression, to the daughter cell (88–91). The HO protein evolved from homing endonucleases that replicate by a mechanism related to mating-type switching (92).

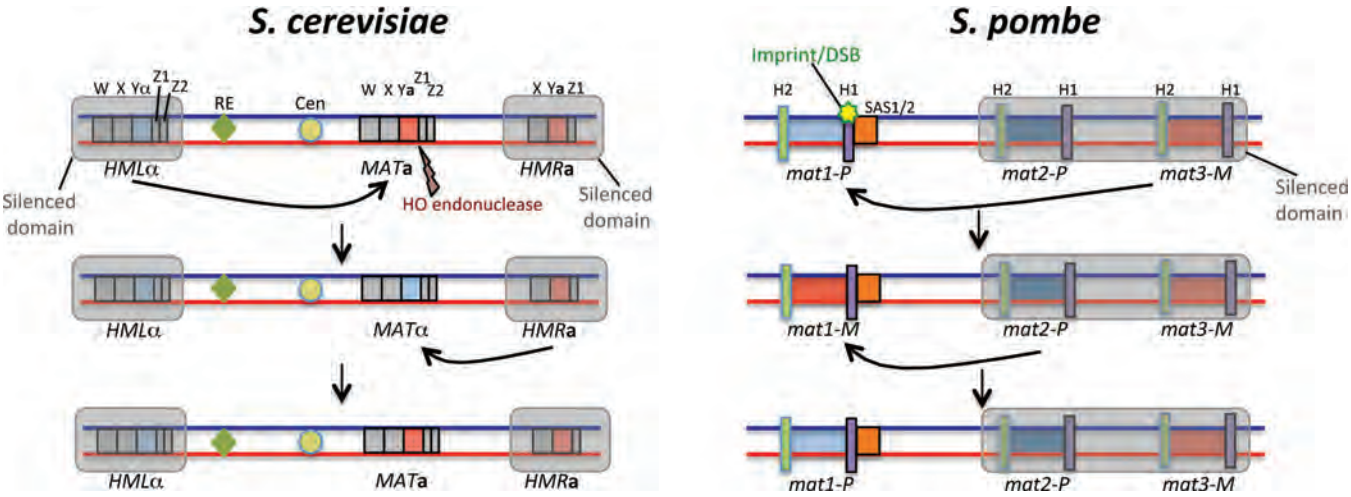

Figure 6 Mating type cassettes in *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*. In both yeasts, mating type switching occurs by copying genetic information from a silent cassette into the transcriptionally active locus. In *S. cerevisiae*, silent cassettes are present at *HML*α and *HMR***a** and are copied into the active *MAT* locus. Recombination is activated by a DNA double-strand break introduced by the HO endonuclease at *MAT*. A recombination enhancer (RE) promotes recombination between *MAT***a** and *HML*α. In *S. pombe*, silent cassettes are present at *mat2-P* and *mat3-M* and are copied into the active *mat1* locus. Each cassette is flanked by homology regions (H1 and H2), and an imprinting event at H1 leads to recombinational repair of the damage using DNA from a silent cassette.

Mating-type switching exhibits donor preference, so that *MAT***a** strongly favors recombination with *HML*α, while *MAT*α favors recombination with *HMR***a** (93–96). Donor preference occurs because a recombination enhancer is present between *HML*α and the centromere (97, 98). In *MAT***a** cells, the recombination enhancer is active and, together with protein cofactors, promotes a conformational change in the chromosome structure so that the DSB at *MAT***a** is brought into close proximity with *HML*α (99, 100). The recombination enhancer is inactivated in *MAT*α cells by binding of Mcm1-α2, so that *MAT*α now preferentially recombines with *HMR***a**.

In *S. pombe*, pedigree analysis revealed that only one in four granddaughter cells undergoes a mating-type switch and that the sister of the switched cell is now also competent for mating-type switching (101, 102). To explain these findings it was proposed that a strand-specific imprinting event occurs at the *mat1* locus during DNA synthesis. DNA replication proceeds unidirectionally through the *mat1* locus due to a replication fork barrier at *RTS1*, and it was envisaged that imprinting occurs at *mat1* during lagging strand DNA synthesis (see Fig. 7). In the next round of DNA replication, leading-strand replication results in a transient DSB at the site of the imprint and initiates recombination with one of two silent cassettes, *mat2-P* or *mat3-M* (102–104). The nature of the imprint is unclear, although it could be an RNA primer left from lagging strand DNA synthesis that has been ligated to form a DNA-RNA-DNA hybrid (103, 105).

Similar to mating-type switching in *S. cerevisiae*, switching in *S. pombe* is biased so that the *mat1-P* cassette preferentially recombines with *mat3-M*, and *mat1-M* preferentially recombines with *mat2-P* (106). Recombination enhancers close to *mat2-P* and *mat3-M* contribute to these switching events (107). In addition, the *mat1-Mc* protein is important for directionality by promoting the expression of a truncated *swi2* transcript (108). The truncated Swi2 protein mediates differences in heterochromatin structure at *mat2-P* and *mat3-M*, thereby changing the bias of donor cassette choice (108).

Evolution of Mating-Type Switching

Mating-type switching arose independently in the lineages leading to *S. cerevisiae* and *S. pombe*, yet the mechanisms in both species involve three *MAT*-like loci (including two silenced loci), a DSB-initiated recombination event, a donor bias in cassette exchange, and a cell lineage tracking system (mediated by Ash1 in *S. cerevisiae* and genomic imprinting in *S. pombe*). In addition to promoting sexual reproduction, mating-type switching may provide a selective advantage by

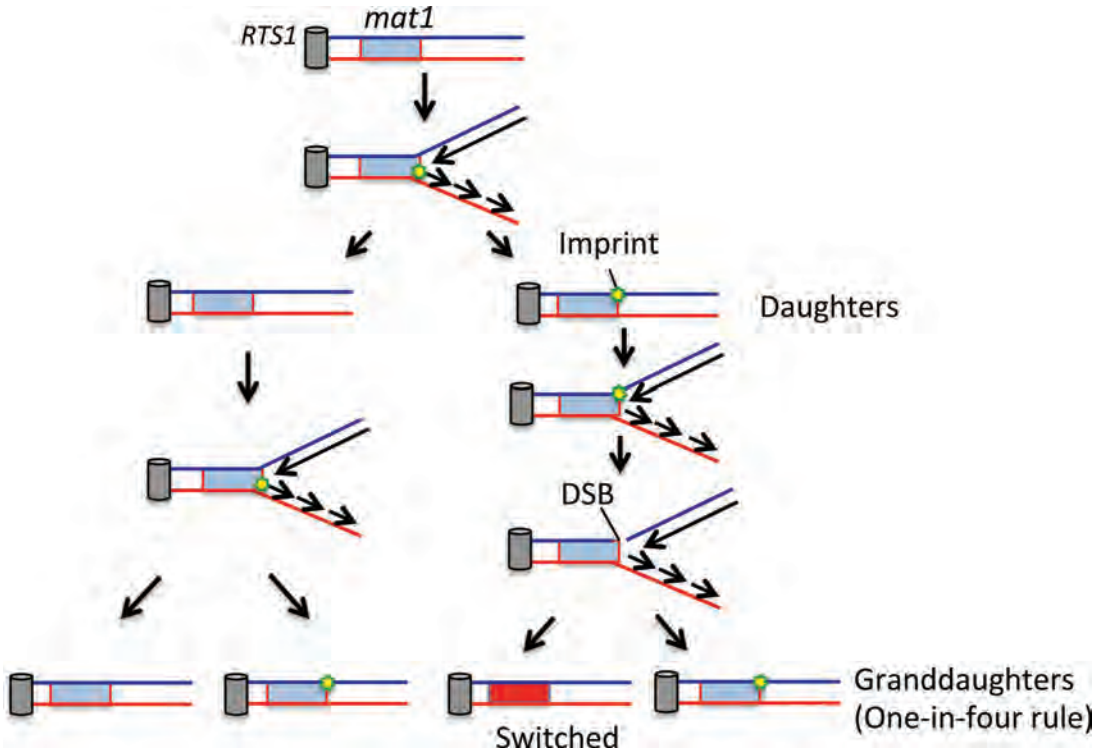

Figure 7 Mechanism of mating-type switching in *S. pombe*. During mating-type switching, a DNA imprint is first introduced during lagging strand DNA replication at the *mat1* locus. During the next round of DNA replication, the imprint is converted into a DNA double-strand break by leading strand synthesis. The DNA break initiates recombinational repair with one of the silent *mat* cassettes (*mat2-P* or *mat3-M*), resulting in switching of the cassette at the active locus.

allowing isolated cells to generate sexual spores that can subsequently survive nutrient-poor environments (109, 110). This could be important for yeasts such as *S. cerevisiae* and *S. pombe*, because unlike many other fungal species they are unable to make asexual spores by conidiation.

Recently, novel switching mechanisms were discovered in two methylotrophs, *Hansenula polymorpha* and *Pichia pastoris*, that shed light on how switching may have evolved in the ascomycetes (111, 112). In both species there are two linked *MAT*-like loci, one representing *MAT***a** and the other, *MAT*α. However, only one of these loci is actively expressed, whereas the other is silenced or expressed only at a reduced level. Mating-type switching occurs by recombination between inverted-repeat sequences and results in expression of the opposite mating type (Fig. 8A). Interestingly, these findings suggest that mating-type switching evolved in the ancestor to the lineage leading to the *Saccharomycetaceae* and the methylotrophs and was subsequently lost in the lineage leading to the *Candida* clade (Fig. 8B). The more primitive mating-type switching found in modern-day methylotrophs could have evolved into the three-*MAT* loci system present in *Saccharomycetaceae*, because this more efficient switching mechanism yields a higher spore yield (111). Conversely, loss of switching in some lineages could indicate that these species do not require frequent spore formation for either survival or dispersal (111).

SEXUAL REPRODUCTION IN *CANDIDA* SPECIES

Within the *Saccharomycotina* is a monophyletic group of species referred to as the *Candida* clade that includes significant human pathogens such as *C. albicans* (113–115). Historically, *Candida* referred to asexual or imperfect yeasts, but it is now known that many *Candida* species are competent for sexual or parasexual reproduction. The *Candida* clade can be further subdivided into haploid and diploid subclades, and several haploid *Candida* species are competent to undergo full sexual cycles (113). The best-studied haploid species is *Candida lusitaniae*, which undergoes meiosis despite

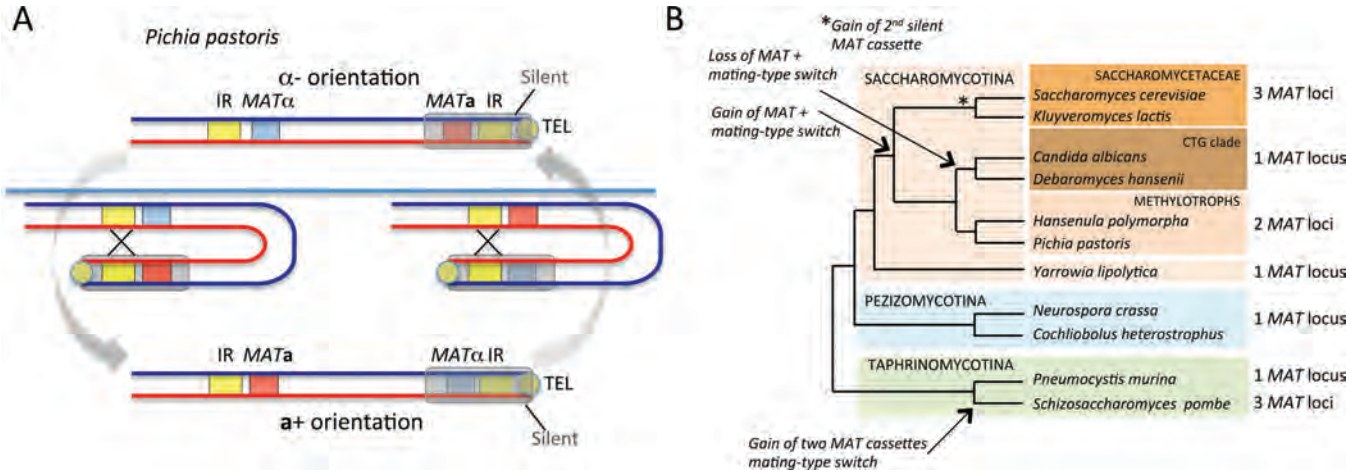

Figure 8 Evolution of mating type-switching mechanisms. (**A**) In *Pichia pastoris*, mating-type switching occurs by a flip-flop inversion mechanism. Inverted repeat (IR) regions flank a transcriptionally active *MAT* locus and a silenced *MAT* locus, the latter being located close to the telomere (TEL). Recombination events between IR regions lead to a change in mating type. (**B**) Model for how mating type switching evolved in the *Ascomycota*. Note that both *Hanenula polymorpha* and *P. pastoris* exhibit a similar inversion mechanism for mating-type switching. Adapted from reference 111.

lacking the meiotic recombinase Rad51, synaptonemal complex proteins, and the crossover interference pathway (see dyads formed by meiosis in Fig. 4) (113, 116). The MAPK transcription factor Ste12 is essential for both mating and meiosis in *C. lusitaniae* (117, 118). This resembles the scenario in *S. pombe*, where the same transcription factor drives both developmental programs. Other species in the haploid subclade include *Candida guilliermondii*, which exhibits heterothallic mating, as well as the homothallic (self-mating) species *Debaryomyces hansenii* and *Lodderomyces elongisporus* (113, 116).

Diploid *Candida* clade species include *C. albicans*, the most common cause of nosocomial fungal infections (119, 120). A mating-type-like (*MTL*) locus was identified in *C. albicans* and led to the demonstration that mating can take place between **a** and α cells, both *in vitro* and in a mammalian host (see image of mating zygote, Fig. 4) (121–123). Miller and Johnson showed that efficient mating requires cells to undergo a phenotypic switch from the default white state to the mating-competent opaque state (124). This regulatory mechanism has also been observed in two closely related *Candida* species (125–127). White-opaque switching involves a complex interplay between multiple transcriptional feedback loops, as well as regulation by chromatin modifications (for reviews see 128–131). In addition to regulating mating, the white-opaque switch influences many other traits, including filamentation, interactions with host cells, and virulence (132–135).

Why did the white-opaque switch evolve in a subset of *Candida* species? It is possible that the switch emerged to limit sexual reproduction to specific niches in the mammalian host (136). In support of this hypothesis, white and opaque cells exhibit different tissue trophisms (137, 138). Mating in the host could also facilitate the formation of specialized "sexual biofilms," because opaque **a** and α cells secrete pheromones that cause white cells of the opposite mating type to become adherent and form biofilms (139). Sexual biofilms stabilize pheromone gradients between opaque **a** and α cells, thereby stimulating conjugation between these cell types (139, 140).

Pheromone signaling between *C. albicans* opaque cells proceeds by a mechanism similar to that in *S. cerevisiae*, although some notable differences exist. For example, the *C. albicans* Ste5 (Cst5) scaffold coordinates MAPK signaling even though it lacks the von Willebrand A domain present in *S. cerevisiae* Ste5, which mediates binding to Ste7 (30, 141). Despite lacking this domain, *C. albicans* Ste5/Cst5 still binds to the MAPKKK, the MAPKK, and the MAPK to direct pheromone signaling (141). *C. albicans* also contains a Far1 ortholog, and in contrast to *S. cerevisiae*, loss of this scaffold blocks transcriptional responses to pheromone, as well as cell cycle arrest and polarized growth (142).

Some diploid *Candida* clade species, including *Candida parapsilosis* and its sister species *Candida metapsilosis* and *Candida orthopsilosis*, have not been observed to undergo sexual reproduction in the labora-

tory (143). *C. parapsilosis* isolates are all of the *MTL***a**/**a** mating type and contain a disrupting mutation in the *MTLa1* gene, suggesting that the *MTL* locus has degenerated and the ability to undergo sex has been lost (143). However, analysis of natural variation in *C. parapsilosis* isolates found evidence for interstrain recombination, suggestive of a population that has undergone sexual mating (144). Furthermore, a comparative analysis of *C. orthopsilosis* and *C. metapsilosis* genomes provides evidence for hybridization events due to mating between parental lineages (145, 146). Questions therefore remain concerning the extent to which various *Candida* species undergo sexual reproduction, both in the laboratory and in nature.

REWIRING CELL IDENTITY IN YEASTS

The ability to compare cell identity mechanisms across multiple *Saccharomycotina* species has revealed striking differences between species. Thus, whereas **a**-specific genes are constitutively expressed in *S. cerevisiae*, their expression in *C. albicans* requires the *MTL***a**-encoded factor **a**2, which is absent from *S. cerevisiae* (147, 148). Furthermore, *S. cerevisiae* represses **a**-specific genes in α cells by means of the α2 protein, whereas this mechanism does not operate in *C. albicans*. By comparative analysis of multiple *Saccharomycotina*, it is inferred that *C. albicans* has retained the ancestral mechanism for regulation of cell identity, whereas *S. cerevisiae* exhibits a derived circuit.

Examination of additional species has revealed a hybrid form of regulation in some *Kluyveromyces* species, with **a**-specific genes being both positively regulated by **a**2 and negatively regulated by α2 (149). This hybrid state was resolved by different routes during evolution; some species reverted to the ancestral regulatory circuit (e.g., *C. albicans*), whereas others, such as *S. cerevisiae*, retained only the new regulatory circuit (149). Hybrid circuits represent high potential states for evolution: they can be resolved by alternative routes without disruption to the overall circuit logic. The hybrid form of regulation could have provided a fitness advantage to the ancestor of *Kluyveromyces* and *Saccharomyces* species, because it would have arisen around the same time as the emergence of silent mating cassettes (149, 150). The ability to repress **a**-specific genes could have been advantageous in cases where leaky expression of **a**2 from silent cassettes would have inappropriately activated **a**-specific gene expression (149). These studies demonstrate how the comparative analysis of genetic circuits from multiple species can provide insights into the rewiring of transcriptional pathways during evolution.

PARASEXUAL REPRODUCTION IN *CANDIDA*

In most fungal species, a meiotic program is used to complete sexual reproduction. However, a conventional meiosis has not been observed in *C. albicans*, and instead, tetraploid cells (the products of diploid **a** and α mating) undergo a parasexual program of concerted chromosome loss (CCL) (151–153). Parasex is thought to involve chromosome nondisjunction events during mitotic divisions, and the products of parasex are therefore aneuploid cells that exhibit a wide variety of ploidies (151–153). A subset of progeny undergoes genetic recombination during the parasexual process, and the "meiosis-specific" recombinase Spo11 is implicated in this process (151).

Recent experiments demonstrate that haploid forms of *C. albicans* also can be generated by CCL (154). Haploid forms were originally thought to be inviable due to the presence of recessive lethal alleles in the diploid *C. albicans* genome. However, rare haploid forms were produced both *in vitro* and in a mammalian model of oral candidiasis. Haploid cells exhibit many of the attributes of diploid cells, including white-to-opaque switching and mating (154). However, although haploid cells represent an exciting breakthrough for genetic studies of *C. albicans*, they are currently limited in use due to their low fitness and tendency to spontaneously rediploidize (154).

HOMOTHALLIC MATING IN *CANDIDA*

As mentioned above, *Candida* clade species do not contain silent mating-type cassettes or undergo mating-type switching, yet several species are capable of homothallic mating. In *C. albicans*, **a** cells secrete both **a** and α pheromones, with α pheromone normally degraded by an aspartyl protease, Bar1, that is secreted only by **a** cells. However, in *bar1/bar1* mutants, **a** cells experience autocrine α pheromone signaling, resulting in activation of mating responses and productive unisexual **a**-**a** mating events (155). Same-sex **a**-**a** and α-α mating products (as well as conventional **a**-α products) are also observed in experiments in which **a** and α cells are mixed with one another (155). Additional experiments established that pheromone signaling alone is sufficient to induce same-sex mating in *C. albicans* (156). It is therefore possible that mating could be induced by pheromone-like peptides encountered in the mammalian host (156).

As noted above, there are also haploid *Candida* clade species that are homothallic, including *L. elongisporus* and *D. hansenii* (113). In *D. hansenii*, the two

MTL loci have become fused into one locus containing *MTLa1*, *MTLa2*, and *MTL2* genes (157). Presumably, the expression of these transcription factors enables the expression of both "**a**-specific" and "α-specific" genes in one cell to enable self-fertility. In contrast, all of the mating-type genes are missing from *L. elongisporus*, as well as the genes for **a**-factor and the receptor for **a**-factor (113). One possibility is that *L. elongisporus* uses autocrine α pheromone signaling to activate self-mating, similar to the mechanism described for *C. albicans*.

SEXUAL DEVELOPMENT IN FILAMENTOUS ASCOMYCETES

Sexual reproduction in filamentous ascomycetes (*Pezizomycotina*) is a more complex developmental process than that in unicellular yeasts (see Fig. 9), and requires self/nonself recognition between cells of opposite mating types, as well as between nuclei in a common cytoplasm (158). Most filamentous fungi are hermaphroditic, meaning an individual strain can behave as male or female. The female partner is a specialized hypha, the trichogyne, which develops from a protoperithecium formed at the beginning of the sexual phase, whereas the male partner is a conidium, or hyphal cell. Fertilization is accomplished when a male cell nucleus enters the trichogyne. Nuclei of opposite mating types do not fuse immediately after fertilization but divide in the female cytoplasm until a fruiting body (variously called a pseudothecium, perithecium, cleistothecium, apothecium, or gymnothecium) is erected (Fig. 4). A second recognition phase occurs when nuclei of opposite mating types discriminate self from nonself and enter specialized ascogenous hyphae. The apical cell of the dikaryotic ascogenous hypha typically differentiates into a hook-like crozier composed of several cells. Karyogamy ensues between two nuclei of opposite mating types compartmentalized in the penultimate cell; the antepenultimate and the apical cells contain one nucleus each, and these can subsequently fuse and reconstitute a dikaryotic cell that usually forms another crozier. The fused nucleus is in the only diploid cell in the life cycle and is diploid only briefly before the cell differentiates into a meiocyte and meiosis occurs. The meiocyte subsequently differentiates into the ascus mother cell. In filamentous ascomycetes, a mitosis usually follows meiosis, and the mature ascus

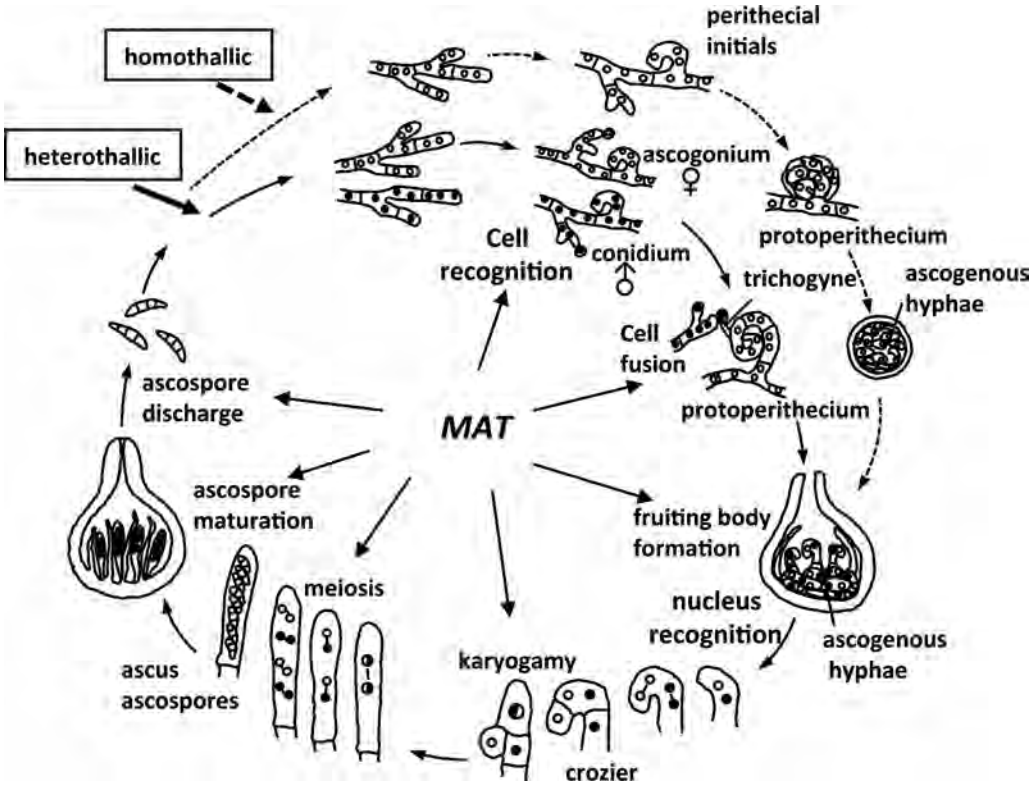

Figure 9 Generalized life cycle of filamentous *Pezizomycotina*. *MAT* impacts all stages indicated (see text). Heterothallic species, inner ring (solid); homothallic species, outer ring (dashed).

therefore contains eight spores (four pairs of twins), twice the number typical in yeasts (see *Cochliobolus heterostrophus* in Fig. 4).

In contrast to filamentous ascomycetes, unicellular yeasts do not bear reproductive spores inside developmentally complex fruiting bodies. The differentiation events within the female organs also constitute essential differences with ascomycete yeasts. In both filamentous and unicellular species, the mating-type proteins control fertilization and meiosis. However, in filamentous fungi, they also control internuclear recognition and the formation of dikaryotic hyphae (159). Ultimately, this complex cycle yields genetically variable progeny from a single fertilization event. Cytologically, the program of ascus development is similar in heterothallic and homothallic species (159–161), but the early cell-cell recognition events differ (Fig. 9).

Heterothallic Mating-Type Loci in *Pezizomycotina*

As for many ascomycetous yeasts, the mating-type locus in *Pezizomycotina* is a single *MAT* locus consisting of genes encoding key transcription factors (158, 159, 162, 163). *MAT* nomenclature is not uniform, in part because these loci were initially discovered genetically (164, 165) or sorted into mating types according to mating interactions before the molecular nature of the corresponding genes was known. Furthermore, nomenclature rules tend to be species-specific (as exemplified by the *S. cerevisiae* and *S. pombe MAT* loci described earlier). Upon molecular characterization (164–167) of *MAT*-encoded genes, Turgeon and Yoder (168) proposed that the locus be called *MAT1* and the alternate idiomorphs (169, 170) be called *MAT1-1* and *MAT1-2*. For ease of cross-species comparisons, it was suggested that these designations should be adopted as new heterothallic *MAT* loci were identified. The genes encoded at *MAT1-1* would be *MAT1-1-1*, *MAT1-1-2*, etc., and those encoded at *MAT1-2* would be *MAT1-2-1*, *MAT1-2-2*, etc., as needed. Fungi for which there was already a rich mating-type literature, such as *N. crassa* and *P. anserina*, would continue to be referred to by their original terminology (171, 172).

The *MAT1-2* idiomorph of most *Pezizomycotina* carries a single gene, *MAT1-2-1*, encoding a high mobility group (HMG) protein (173), whereas the *MAT1-1* idiomorph harbors a gene, *MAT1-1-1*, encoding an α1 box-containing protein (174) and may or may not harbor additional genes (Fig. 10) (159, 164, 172, 175–180). Notably, both *MAT* idiomorphs in an early diverging fungal lineage, the *Zygomycotina*, encode HMG-type proteins (181). *MAT*-like genes encoding HMG-type proteins also have been identified in the most basal class of fungi, the *Microsporidia* (182, 183). In tracing *MAT* gene evolutionary history, Martin et al. (184) determined that the α1 protein is a member of the HMG protein family, and thus the apparently unrelated *MAT1-2-1* and *MAT1-1-1* genes both encode HMG proteins (184). This discovery, together with the evidence that HMG proteins are present at the *MAT* locus in both mating types in early diverging lineages, supports the hypothesis that the ancestral fungal *MAT* alleles encoded HMG protein transcription factors that subsequently diverged (Fig. 11).

In the *Sordariomycetes*, *MAT1-1-1* encodes the α1 box (HMG) protein, *MAT1-1-2* encodes a protein with an HPG (also termed PPF) domain, and *MAT1-1-3* encodes another HMG-type protein (185, 186) (Fig. 10). Note that there are many genes that encode HMG-type proteins in fungal genomes (187). Deletion analysis of these genes in *P. anserina* demonstrated that 11 out of 12 HMG proteins are involved in regulation of the sexual cycle and highlighted their central importance in this developmental program. Several comprehensive reviews are available that describe the discovery, structural features, and function of *MAT* loci in *Pezizomycotina* (158, 159, 163, 169, 188–191).

Homothallic Mating in *Pezizomycotina*

A number of mechanisms allow single individuals to undergo sexual reproduction, including primary homothallism, pseudohomothallism, homothallism arising from mating-type switching (either bidirectional or unidirectional), and unisexual reproduction. The reader is referred to an excellent overview of these reproductive mechanisms by Wilson et al. (192).

Primary homothallism

In homothallic *Pezizomycotina*, a single individual can complete the sexual cycle because each nucleus in a genetically homogeneous strain carries both *MAT* genes. In an early seminal publication, Metzenberg and Glass (169) proposed that "homothallic species may be functionally heterothallic at the level of nuclei in the ascogenous hyphae" perhaps by an epigenetic mechanism, such as silencing of one of the two mating types. Other studies have proposed the same mechanism (193–195). We still do not have definitive proof of such a mechanism, but the net result would be as for yeasts that switch; functional heterothallism is achieved, and a diploid nucleus is formed from haploid nuclei.

Homothallic *Pezizomycotina MAT* loci can be very diverse compared to heterothallic *MAT* loci, which are generally conserved both within and across species

(159, 196–199). All heterothallic *Cochliobolus* species, for example, have the same *MAT* topology (197). In contrast, homothallic species carry *MAT1-1* and *MAT1-2* in a single nucleus but with strikingly different rearrangements and polyphyletic evolutionary origins (197). In two species, *Cochliobolus luttrellii* and *Cochliobolus homomorphus*, the *MAT* genes have become fused into a single open reading frame, and the corresponding proteins are truncated at the fusion junction. In two other examples, *MAT1-1* and *MAT1-2* are not fused. In *Cochliobolus kusanoi*, the organization is an inverted *MAT1-1-1* gene linked to a hybrid gene containing a truncated *MAT-1-1-1* fused to the full *MAT1-2-1* sequence. Fragments of genes known to be on the flanks of heterothallic relatives are interspersed, suggestive of accompanying, or additional, recombination events. In *Cochliobolus cymbopogonis*, homologs of both of the heterothallic idiomorphs are present but are not closely linked.

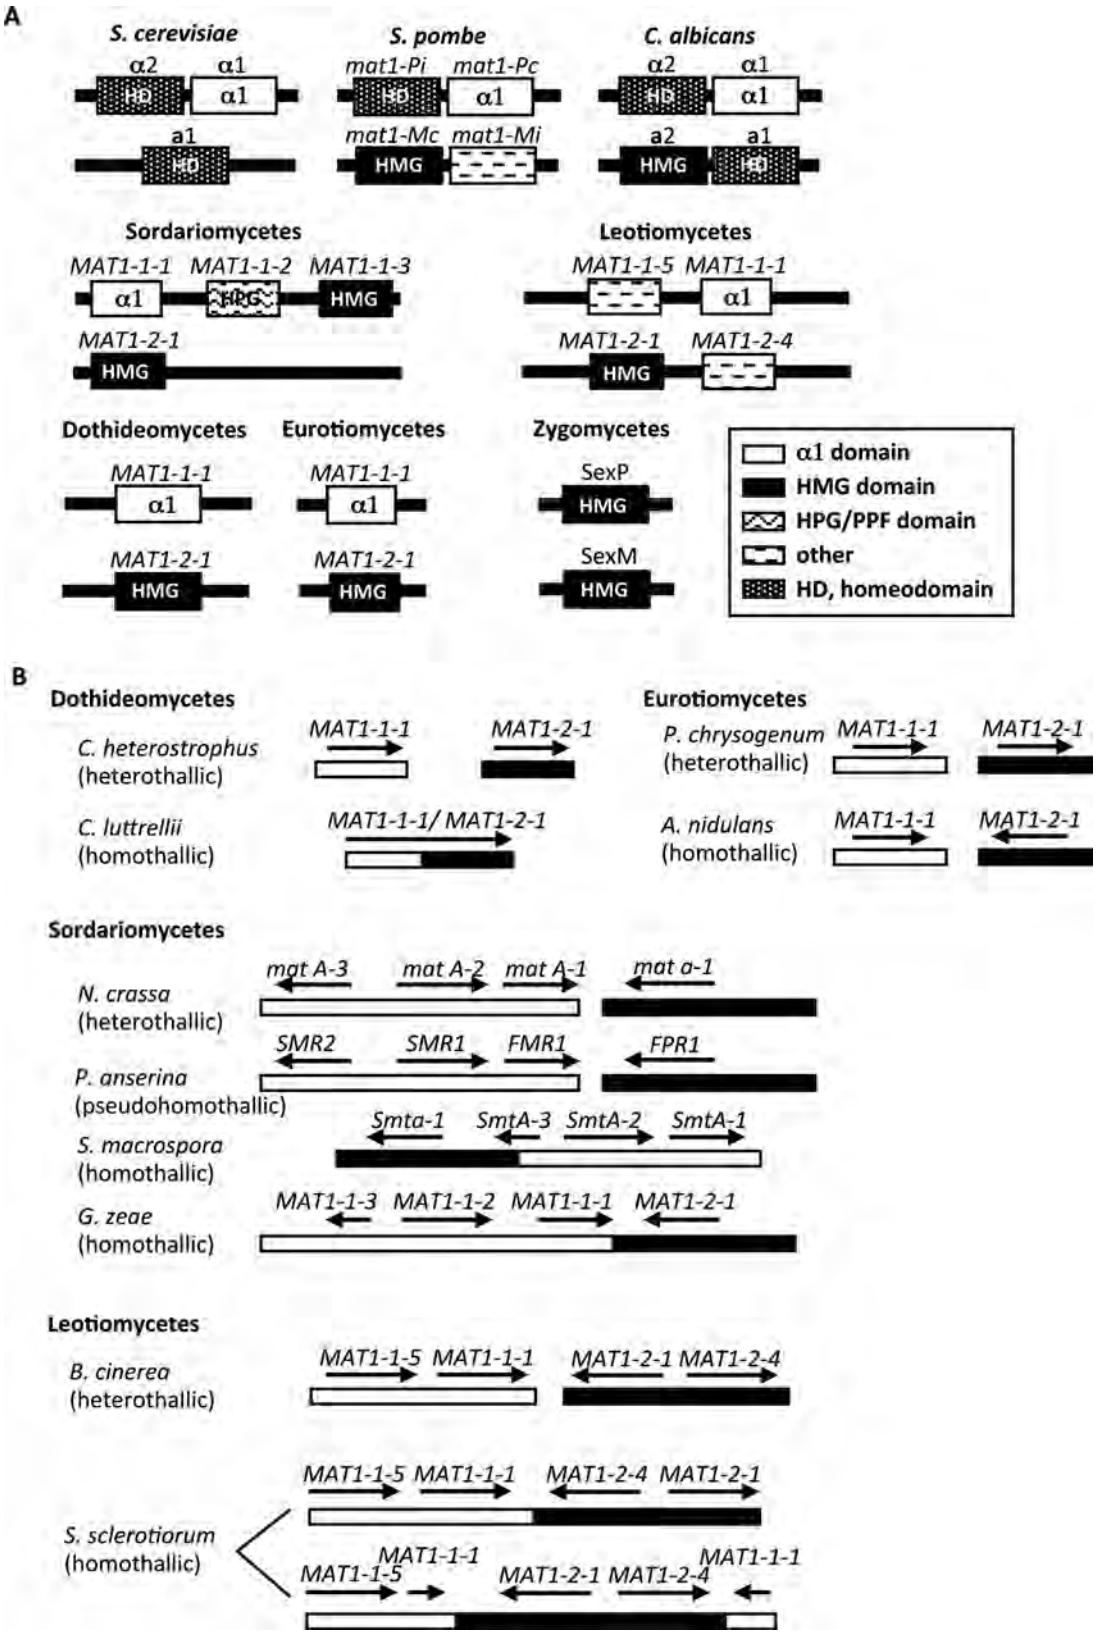
Both *MAT1-1* and *MAT1-2* are found in the same genome in members of other taxonomic groups. These include the *Sordariomycetes Fusarium graminearum* (196), *Sordaria macrospora* (200), and *Chaetomium globosum* (159); the *Eurotiomycete Aspergillus nidulans* (177, 201–203); and the *Leotiomycete Sclerotinia sclerotiorum* (180, 204). The latter carries both *MAT* idiomorphs fused end to end (180). The *MAT1-1* region has *MAT1-1-1* and *MAT1-1-5* genes, while the *MAT1-2* region harbors *MAT1-2-1* and *MAT1-2-4* genes, as it does in the close heterothallic relative *Botrytis cinerea* (Fig. 10). Two versions of the *MAT* region that differ by a 3.6-kb inversion are found in selfing populations. The inversion is likely promoted by a 250-bp repeat within the *MAT1-1-1* and *MAT1-2-1* genes, which changes orientation of the genes, truncates one gene, and is correlated with altered gene expression.

Heterothallic *B. cinerea* itself has an unusual *MAT* structure, with a truncated copy of *MAT1-1-1* in the *MAT1-2* mating region and a truncated copy of *MAT1-2-1* in the *MAT1-1* region. Comparisons of heterothallic *B. cinerea* with homothallic *S. sclerotiorum* suggest that inversions and deletions in the latter *MAT* region led to the present-day structures in heterothallic *B. cinerea*. Some *B. cinerea* isolates are also homothallic (205, 206) and yet can still outcross to *MAT1-1* and *MAT1-2* strains. Analysis of several homothallic strains revealed that they do not carry both *MAT* regions and therefore are analogous to species that exhibit unisexual mating (see section below).

As noted, several other species such as *S. sclerotiorum*, *F. graminearum*, and *A. nidulans* (180, 207–209) can also both self- and outcross, i.e., exhibit both self-compatible and self-incompatible behavior, although this is relatively rare (210–213). Often, homothallic strains do not produce asexual spores (e.g., *Neurospora* species), which may underlie the inability to outcross.

Bidirectional mating-type switching

As discussed above, several yeast species contain silent mating-type cassettes that can be inserted into the active *MAT* locus, leading to switching of cell type, and thus appear homothallic. Silent mating-type cassettes have not been reported in *Pezizomycotina* genomes, however, and there is no evidence that these species can undergo switching by this mechanism.



Unidirectional mating-type switching

An unusual case of unidirectional switching has been described for the *Sordariomycete Chromocrea spinulosa* (*Hypocrea spinulosa*). This species is found as two cell types that are capable of mating with each other, but only one of these can undergo self-mating (214). When the two cell types are mated with one another or when self-compatible progeny undergo sexual reproduction, the resulting progeny segregate 1:1 self-compatible: self-incompatible. Molecular characterization reveals that self-incompatible strains are all *MAT1-1* and have the three-gene structure typical of the *Sordariomycete MAT* locus (215). In contrast, self-compatible strains have *MAT1-1* plus a second copy of *MAT1-1* linked to a *MAT1-2-1* gene. The presence of a repeated sequence hints at an intramolecular, unidirectional switching mechanism whereby the *MAT1-2-1* gene is eliminated, resulting in a strain with *MAT1-1* that can only undergo outcrossing.

Recent studies of unidirectional mating-type switching in species of *Ceratocystidaceae* have shown that self-fertile isolates of *Ceratocystis fimbriata* and *Ceratocystis albifundus* have three genes at the *MAT1* locus (*MAT1-1-1*, *MAT1-1-2*, and *MAT1-2-1*) (192). Ascospore progeny are either self-fertile or self-sterile as for *C. spinulosa*, and it has been shown that elimination of the *MAT1-2-1* gene is responsible for the self-sterile phenotype (216, 217). The mechanism by which this occurs is unknown but could be promoted by homologous recombination within repeats that flank the *MAT1-2-1* gene, similar to the mechanism envisaged for *C. spinulosa*.

Pseudohomothallism (secondary homothallism)

Pseudohomothallism refers to species that are self-fertile because nuclei representing each mating type are separately maintained in parental cells and progeny.

P. anserina and *Neurospora tetrasperma* have served as models for this lifestyle and can both self- and outcross (218–221). Both species can resolve naturally into homokaryotic strains differing in mating type by loss of one of the two nuclei or by inefficient recombination mechanisms.

How do pseudohomothallic fungi generate dikaryotic cells during sexual reproduction? Both *P. anserina* and *N. tetrasperma* undergo defined nuclear divisions during meiosis that result in two nonsister nuclei being packaged together into ascospores. The precise meiotic divisions are different in the two species (for a recent review see 222), but both species rely on limiting recombination around the mating-type locus. In *N. tetrasperma*, the mating region is on a 9.4-Mb chromosome, with ~7 Mb of this chromosome repressed for recombination (~1,500 genes). There are several large inversions which may account for recombination suppression (223). The *P. anserina mat* region extends for ~0.8 Mb and is similarly suppressed for recombination over this length. In this species, however, it is unknown how recombination is prevented in the suppressed region. For both *N. tetrasperma* and *P. anserina* the regulation of recombination events close to *mat* are necessary for the correct packaging of dikaryons during meiosis (222).

Samils et al. (224) recently tracked differential gene expression in homokaryotic *N. tetrasperma* strains and in heterothallic *N. crassa* strains containing different mating types. These analyses revealed a mating-type bias and preferential enrichment for differentially expressed genes on the *mat* chromosome. Thus, *mat A* target genes were associated with sexual and female development, while *mat a* target genes were associated with vegetative and male development, indicative of sexual dimorphism. In subsequent work, analysis of *mat*-linked single nucleotide polymorphisms in three different heterokaryons examined the ratio of *mat A* to *mat a* nuclei during development; *mat A* nuclei were present at higher levels than *mat a* nuclei during mycelial growth (87% *mat A*), whereas during sexual development the nuclear ratio became more even (40 to 57% *mat A*) and there was an expression bias toward *mat a*-linked genes. In short, both the nuclear ratio and biases in *mat A/mat a* target gene expression may contribute to the fitness of heterokaryons throughout the life cycle (225).

Unisexual mating

In primary and secondary homothallism, fungal species either display the presence of both mating-type genes in a single genome or have two opposite mating-type nuclei in a single cell, respectively. However, some species are capable of unisexual mating (selfing), in which all nuclei contain a single mating-type idiomorph only. Unisexual mating was discovered in homothallic *Neurospora* species (198, 226, 227) and was recently described for *Huntiella moniliformis*, which carries the *MAT1-2-1* gene, in contrast to *Neurospora africana*, which carries the *MAT1-1-1* gene (228). As discussed earlier, unisexual mating is also observed in some *Candida* clade species, as well as in the basidiomycetes (229, 230).

Nonbipolar homothallism

Mating behavior by the sordariomycete *Glomerella cingulata*, first described in 1914, has remained "atypical" since the initial publication (231–233). Two types of self-fertile strains (plus and minus) exist, and these strains can also outcross. Cisar and TeBeest (233) came to the conclusion, after exhaustive crossing experiments, that *G. cingulata* does not have a simple bipolar mating system but rather involves a single locus with multiple idiomorphs. To our knowledge there has been no follow-up work with this species.

Heterologous Expression of *MAT* Genes

The cross-species expression of *MAT* genes has been examined in only a handful of fungal species (178, 234–237). It has been demonstrated, for example, that self-fertility does not transfer to heterothallic *N. crassa* from a closely related homothallic *Neurospora* species (226). In contrast, manipulation of *MAT* loci in heterothallic and homothallic *Cochliobolus* species has been informative regarding *MAT* protein contributions to sexual development. These studies have established that heterothallism preceded homothallism in this genus (197), and this evolutionary trend has since been confirmed for a number of additional fungal groups (198). Yun et al. (197) examined whether the transfer of a ho-

mothallic *MAT* region into a heterothallic *mat*-deletion strain, or vice versa, could alter the reproductive lifestyle. These studies demonstrated that:

1. A *mat*-deletion strain of heterothallic *C. heterostrophus* could be made functionally homothallic upon transfer of the fused *MAT* gene from homothallic *C. luttrellii*. Transgenic strains could self and produce both fruiting structures (pseudothecia) and viable asci and ascospores. Thus, the homothallic *MAT* gene alone is able to mediate the switch from heterothallism to homothallism (197). This is in direct contrast to results obtained when both *C. heterostrophus* heterothallic *MAT* genes are added to the same *C. heterostrophus* *mat*-deletion strain; pseudothecia form, but these are not fertile (no asci or ascospores) (238).
2. The fused *MAT* locus from a more distantly related homothallic species, *C. homomorphus*, was able to initiate the sexual developmental process in the same *mat*-deletion strain of heterothallic *C. heterostrophus*, but pseudothecia that formed were barren (no asci). This experiment establishes that structural differences between *C. luttrellii* and

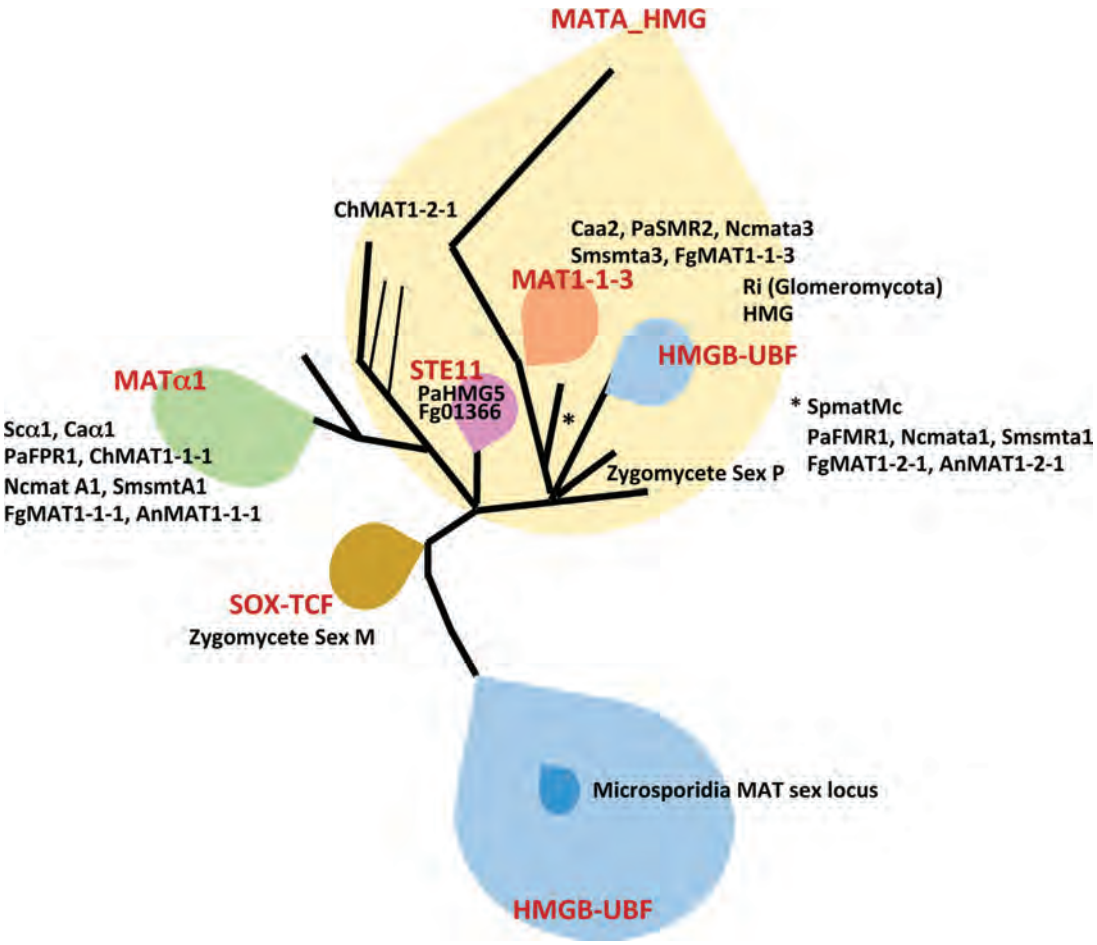

Figure 11 Phylogenetic relationships among members of the HMG-box superfamily. Adapted from Fig. 3 of reference 184 and Fig. 2 of reference 187. Note that the alpha 1 domain (α1) is an HMG protein. C. homomorphus MAT genes hold the key to homothallic fertility.

3. A *mat*-deletion strain of homothallic *C. luttrellii* was made heterothallic by expression of *C. heterostrophus MAT1-1-1* and *MAT1-2-1*; the two transgenic strains, differing in heterothallic mating type, could mate and produce both pseudothecia and viable ascospores, indicating that *MAT* alone is able to induce the switch from homothallism to heterothallism (238). Interestingly, homothallic *C. luttrellii MAT*-deletion strains carrying only a single heterologous *MAT* gene from heterothallic *C. heterostrophus* were also capable of producing fertile pseudothecia. These were much smaller in size than those produced by an outcross and were only about 10% as fertile (but asci contained full tetrads) and can be considered unisexual mating events, as described above.

The contributions of *MAT* genes to mating also have been examined using the homothallic *Dothideomycete*, *Didymella zeae-maydis*. This species contains linked *MAT1-1-1* and *MAT1-2-1* genes (207). Strains deleted for *MAT1-2-1* were completely sterile when selfed, suggesting that the function of the MAT1-2-1 HMG protein is essential for mating. In contrast, selfing of strains deleted for *MAT1-1-1* produced some ascospores, although the fertility was much lower than in wild type self-mating. This suggests that the function of MAT1-1-1 (α1 domain) might be redundant with one or more of the other HMG proteins in the genome (187, 239). The ability of a strain with only a single *MAT* gene to self is reminiscent of the finding that homothallic *C. luttrellii mat*-deletion strains can also self if carrying a single *MAT* gene from heterothallic *C. heterostrophus* and is yet another example of unisexual mating.

The Search for Sex in "Asexual" Filamentous Ascomycetes

Sharon et al. (240) first demonstrated that fungi for which there was no evidence of sexual reproduction (apparently asexual species) carried mating-type genes. Both mating types of *Bipolaris sacchari*, an asexual relative of sexual *Cochliobolus*, could be found in *B. sacchari* populations. Furthermore, heterologous expression of *B. sacchari MAT* genes in a *mat*-deleted strain of heterothallic *C. heterostrophus* demonstrated that the *B. sacchari MAT* genes were fully functional. The reverse heterologous expression experiment (expression of *C. heterostrophus MAT1-1* and *MAT1-2* in *B. sacchari*) did not change the asexual phenotype. These data, together with phylogenic evidence, support the argument that asexual fungi arise from sexual ones and that defects in mating in asexual species could be attributable to mutations in any one of the suite of genes in the mating pathway.

In the human pathogen *A. fumigatus*, considerable effort was required before successful mating was observed in this species (241). Losada et al. (242) capitalized on this finding, making a highly fertile isogenic pair of strains that mate in a heterothallic manner, and showed that mating type is not associated with virulence. Swilaiman et al. recently demonstrated the same phenomenon for the human pathogen *Aspergillus lentulus* (243).

Mating-type genes have also been identified in two supposedly asexual dicot phytopathogens, *Fusarium oxysporum* (196) and *Alternaria alternata* (244). The *F. oxysporum* genes were shown to be expressed and highly similar to *MAT* genes in sexual *Fusarium* species. The *Alternaria* genes were functional in *mat*-deleted strains of *C. heterostrophus*, but under no condition could *Alternaria* strains of different mating types be shown to mate. More recently, population genetic analysis has provided support for cryptic sex in *A. alternata* populations, which could complicate eradication of this phytopathogen (245).

A debate surrounds the issue of how asexual lineages can persist without an invigorating sexual cycle (246, 247), with one idea being that there is elevated intragenomic diversity in asexual genomes. Notably, genome mining of the asexual mycorrhizal fungus *Rhizophagus irregularis* (a member of the *Glomeromycota*) identified genes for HMG proteins as found in all ascomycete lineages, as well as in the early diverging *Zygomycete* and *Microsporidial* fungi (248). Riley et al. (249) examined three isolates and extracted 76 HMG homologs, none of which was flanked by genes known to be on *MAT* flanks in other fungi. Intriguingly, a 9-kb-long region containing four tandem-repeated MATA-HMGs (Fig. 11) was identified which supports the notion that frequent gene duplications generate intragenomic diversity, which may save supposedly asexual *Glomeromycota* from extinction. Alternatively, cryptic sexual cycles may yet be discovered in many asexual fungal species.

MATING SIGNALING IN FILAMENTOUS ASCOMYCETES

MAT Gene Functions

In heterothallic ascomycetes, the *MAT* genes are required for recognition of strains of opposite mating type, as

well as for recognition of nuclei of opposite mating-type, fertilization, formation of the biparental ascogenous hyphae, and meiosis (see Fig. 9). *MAT* genes have been determined to play important roles in many homothallic species as well. For example, in homothallic *F. graminearum*, studies indicate that both *MAT* genes are required for production of fertile perithecia (185). In contrast, in *S. macrospora*, only one of the three *MAT1-1* genes (*SmtA-2/MAT1-1-2*) was found to be essential for sexual reproduction (250). An intriguing report on *P. anserina* (251) documented that mutations in the same gene (*SMR1/MAT1-1-2*) led to barren perithecia. Fifteen suppressor mutations of this phenotype were found; all were mutations in *MAT* genes, and all rendered mutants weakly self-fertile. This suggests that regulation of self-compatible/incompatible mating targets is determined by specific sequences in *MAT* itself.

Pheromones and Receptors

Genes encoding pheromones and their cognate receptors are essential for sexual development of heterothallic *Pezizomycotina* (252–254). In contrast, the roles of pheromones/pheromone receptors are less obvious in some homothallic species because mate recognition and attraction may be unnecessary (255). For example, although *F. graminearum* encodes genes for pheromones and receptors, neither the pheromones nor their cognate receptors are required for sexual development (256). Homothallic *S. macrospora* encodes, but does not strictly need, pheromones for mating (mutants exhibit reduced numbers of pseudothecia), but it does require products of the corresponding receptor genes for sexual development (250, 257). For *A. nidulans*, expression of the gene encoding the α pheromone precursor and the two receptor genes is increased during sexual development; however, expression of these genes is not under *MAT* control (203). For homothallic *Neurospora* species, one or more pheromone receptor genes are important for sexual development (258, 259).

Transcriptional Analysis of Mating

The genes regulated by *MAT* in filamentous ascomycetes have been described for several species, including *S. macrospora* (250, 257, 260), *F. graminearum* (261–264), *Aspergillus* species (265), *N. crassa* (224, 266, 267), and *P. anserina* (268). The studies with *N. crassa* demonstrated that there is rapid evolution of sex-associated genes and differential expression associated with mating type. The *P. anserina* study demonstrated that even conserved target genes could have different transcriptional profiles when multiple species are compared.

A recent transcriptional study of sexual development in *F. graminearum* by Kim et al. (185) brings the contributions of *MAT* genes and signaling elements in a homothallic species into sharper focus. It also highlights a common theme in this article: sexual reproductive pathways are plastic, and a component's function in one species is often repurposed in another. Previous work demonstrated that all four *MAT* genes are essential for sexual development (254, 269–271). Kim et al. (185) uncovered 1,245 differentially expressed genes by comparing different *MAT* mutants or comparing mutants with wild type strains. They identified 50 transcription factor-encoding genes; those with a specific and essential function in sexual development were enriched only among downregulated genes. Deletion of 106 of the differentially expressed genes pinpointed 25 genes specifically required for sexual development, with most regulated by both *MAT1-1* and *MAT1-2*. Among the sex-specific transcription factors is an ortholog (FGSG_01366) of PaHMG5, an upstream regulator of the *P. anserina MAT* genes *FMR1* and *FPR1* (187) and the pheromone/receptor system. In *F. graminearum*, however, FGSG_01366 appears to be a direct downstream target of *MAT*.

Sexual and asexual development in filamentous ascomycetes is also known to involve velvet complex regulation (272) and G protein signaling (273, 274). Mutants deleted for *VelB*, encoding a velvet complex component, or *GPA1*, encoding the α subunit of the tripartite G protein, are self-sterile, similar to *mat*-deletion strains (275, 276). Of the four *F. graminearum MAT* genes, three are downregulated in the *velB* mutant, while only one is downregulated in the *GPA1* mutant. More than half of the genes downregulated in the *mat*-deletion strains overlapped with genes downregulated in *velB*-deletion strains, while less than 20% overlapped with genes downregulated in the *gpa1*-deletion strain (250).

At this point, models of *MAT* circuitry in *Pezizomycotina* have largely relied on transcriptional profiling data, and few are supported by comprehensive functional analyses. However, robust genome-wide techniques, such as ChIP-seq, are beginning to shed light on transcriptional programs. One example is a study of *Penicillium chrysogenum* that reports direct binding targets of MAT1-1-1 and provides evidence for a conserved MAT1-1-1 (α1) DNA-binding motif (277). Known targets such as *ppg1*, the homolog of the *S. cerevisiae* gene α-factor pheromone-producing gene, and *pre1*, the homolog of *ScSTE3*, were confirmed in this study. Moreover, genes were identified that support the notion that *MAT* pathway components can be repurposed, as described in the following section.

ADDITIONAL ROLES FOR SEXUAL SIGNALING IN THE *ASCOMYCETES*

Recent studies have revealed that the fungal sexual machinery has been repurposed for alternative functions in some *Ascomycetes*. A prime example is provided by *Fusarium oxysporum*, a plant pathogen that can sense and grow toward chemicals produced by its tomato host. Experiments by Turrà et al. demonstrated that chemotrophic growth was due to secreted class III peroxidases produced by the plant, while *F. oxysporum* utilized components of a MAPK signaling pathway to respond to these environmental cues (278, 279). Key signaling components included *F. oxysporum* Ste2, a functional homolog of the *S. cerevisiae* α pheromone-sensing receptor. No sexual cycle has been observed in *F. oxysporum*, but the addition of synthetic α pheromone analogs (either *S. cerevisiae* or *F. oxysporum* pheromones) induced polarized growth in *F. oxysporum* cells. Loss of Ste2 blocked both the response to α pheromone analogs and the ability to respond to root peroxidases and also reduced the virulence on tomato plants. These results demonstrate a role for Ste2 and MAPK signaling in responding to environmental cues but generate additional questions, including how the same pheromone receptor can respond both to pheromone peptides and to plant peroxidases. This is particularly true given that peroxidases have to be catalytically active to elicit a chemotropic response in *F. oxysporum* (279). Further experiments will be needed to address these questions, but it appears clear that the pheromone-signaling machinery has been adapted for novel signaling purposes in select species.

Adaptation of the pheromone-sensing pathway is also represented by pheromone-induced biofilm formation in *C. albicans*. As discussed earlier, pheromone signaling not only induces polarized growth in responding cells, but also increases adherence of cells to inert surfaces and leads to the establishment of biofilms. These biofilms may have evolved to enhance mating of *C. albicans* cells in the mammalian host, or they could act to seed infections independent of their role in promoting the parasexual cycle.

It is also true that the transcriptional targets of *MAT* genes can include genes that are involved with processes other than sexual reproduction. In *C. albicans*, the white-opaque switch is directly regulated by the mating-type locus, but this switch regulates pleiotropic attributes in addition to sexual mating and biofilm formation. Similarly, in *P. chrysogenum*, the targets of MAT1-1-1 include genes with functions in asexual development; morphogenesis; and amino acid, iron, and secondary metabolism (277).

CONCLUSIONS

Given the breadth of *Ascomycetes*, the diversity of mating programs present in this phylum is perhaps not surprising. From the relatively simple programs in the model yeasts to the more complex programs in filamentous species, studies continue to highlight the variety of techniques used to support sexual reproduction. Furthermore, given recent exciting examples, it seems likely that other novel functions for pheromone-signaling pathways will be uncovered in fungal species and that these will similarly take advantage of the existing cellular machinery to enable adaptation during evolution.

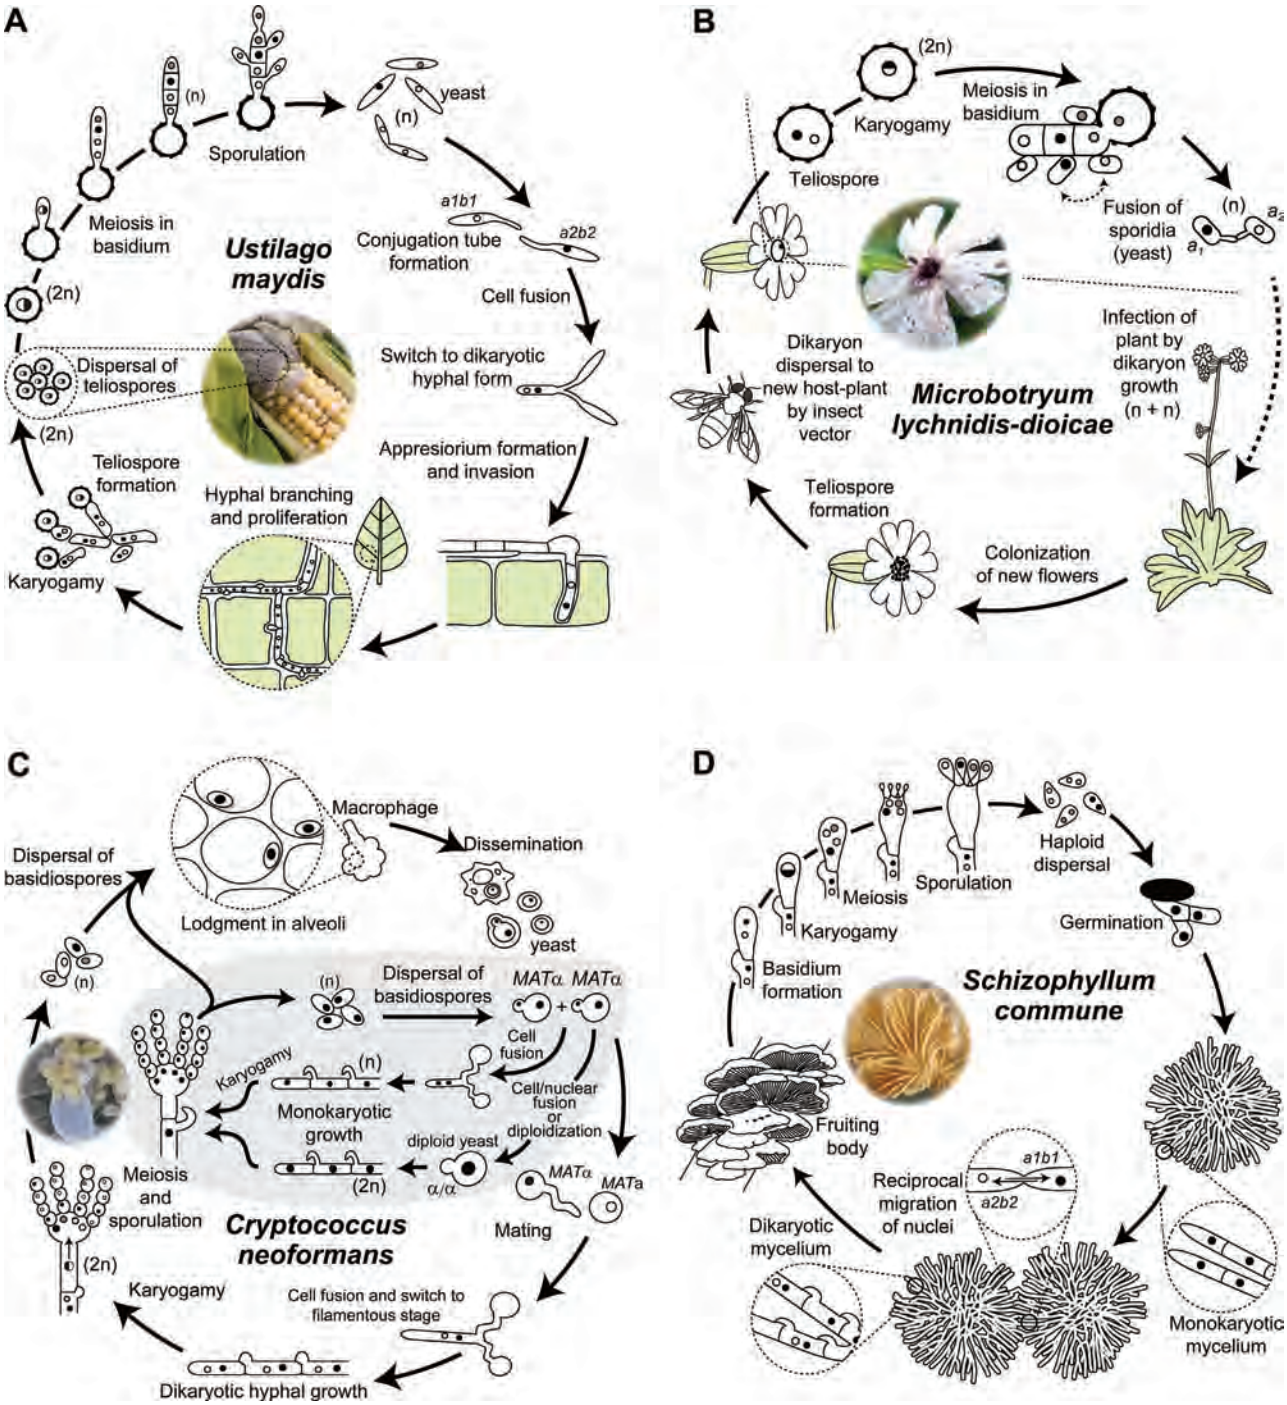
Fungal Sex: The Basidiomycota

7

Marco A. Coelho,[1] Guus Bakkeren,[2] Sheng Sun,[3]
Michael E. Hood,[4] and Tatiana Giraud[5]

BREEDING SYSTEMS AND LIFESTYLES IN THE BASIDIOMYCOTA

In the phylum Basidiomycota, a wide variety of lifestyles are represented. These range from well-known and conspicuous wood-decaying mushrooms, plant growth-promoting and mutualistic mycorrhizae, and crop-destroying smut and rust fungi, to yeast-like human pathogens. Lifestyle differences have consequences for the mating and breeding systems of these fungi (see "Glossary," below, for definitions of specialist terms used in this article), which are reflected in the genetic evolution of mating-type determination. For over a century fungi have been recognized as having diverse breeding systems, from homothallism (i.e., universal compatibility among gametes, including among clonemates) to heterothallism (i.e., mating among haploid gametes carrying different mating-type alleles). The study of breeding systems, for example, led to the discovery of the astounding variability in mating-type alleles among mushrooms, with thousands of different mating types in some species (1), and to the realization that in many fungal pathogens the process of sexual reproduction is closely linked to infection and pathogenicity (2) (Fig. 1). The importance of basidiomycete fungi and their great research tractability, from ecology to genomics, have brought major insights into the diversification of genetic mechanisms used to achieve sexual reproduction.



Diversity and Phylogenetic Relationships: Phylum Basidiomycota

From a phylogenetic perspective, the phylum Basidiomycota is the sister group to the phylum Ascomycota, forming together the subkingdom Dikarya. Three independently evolving lineages are strongly within the Basidiomycota (Fig. 2) (3). The subphylum Agaricomycotina contains most of the described species (ca. 21,000), including many mushrooms as saprophytes or mycorrhizal symbionts of plants, the jelly fungi, and a large diversity of yeasts, some of which are important pathogens of humans (*viz.*, *Cryptococcus neoformans*) (4, 5). The subphylum Ustilaginomycotina comprises more than 1,700 species, and while many species are pathogens of graminaceous plants (such as the maize smut *Ustilago maydis*), others are commonly associated with human and animal infections and are known from their asexual (anamorphic) states only (*viz.*, *Malassezia* spp.) (4, 6, 7). The subphylum Pucciniomycotina is a sister group of the clade containing Ustilaginomycotina and Agaricomycotina and consists of more than 8,400 described species (8). Besides the array of saprobic yeast species usually recovered from soils, aquatic habitats, or the phylloplane (e.g., *Rhodotorula* spp. and *Sporobolomyces* spp.) (9), most of the Pucciniomycotina species are plant parasites, such as the obligate pathogenic rust fungi (e.g., *Puccinia* spp.) or anther-smut fungi (*Microbotryum* spp.). Through the diversification of mating and dispersal stages, this huge variety of fungal lifestyles is highly integrated with equally diverse sexual cycles and breeding systems, a theme that has long been the subject of study by influential mycologists (1, 10–13).

Sexual Development and Determination of Cell Type Identity

Most fungi are able to undergo both asexual and sexual reproduction and have evolved tightly controlled mechanisms to regulate the process of mating, with respect

to timing, and gamete dispersal, recognition, and fusion. In basidiomycetes, the sexual cycle typically involves fusion of genetically distinct homokaryotic hyphae or haploid yeast cells to produce a dikaryon, in which the two haploid parental nuclei are replicated in a coordinated fashion without fusion during hyphal elongation, usually involving the formation of clamp connections (i.e., a hook-like structure formed by hyphal cells to ensure proper distribution of the two genetically distinct nuclei during mitotic cell divisions; see below) (14). Nuclear fusion (karyogamy) then takes place in the basidia or in other specialized structures (e.g., teliospores), after which the diploid nucleus undergoes meiosis to generate haploid basidiospores (meiospores) and complete the life cycle (see Fig. 1 for representative life cycles).

Despite the wide variation of sexual cycles in nature, one common underlying feature shared by most fungi is the lack of genetically determined anisogamy: many fungi are isogamous (i.e., where all gametes have the same sizes), and even in anisogamous species, all haploid genotypes produce both types of gamete sizes. This means that there are not individuals of different sexes in fungi (15). Furthermore, many fungi are heterothallic, meaning that syngamy can only occur between gametes of different genetically determined mating types (15–17).

In members of the sister phylum Ascomycota, mating-type identity is governed at a single genetic mating type (*MAT*) locus (see reference 197). In that case, only two mating types segregate in meiosis, defining what is termed a bipolar system. By contrast, basidiomycetes have evolved a breeding system that relies on two genetic *MAT* loci. One locus encodes tightly linked pheromones and pheromone receptors (hereafter referred to as the *P/R* locus), and the other encodes homeodomain-type transcription factors (hereafter, *HD* locus), determining viability following syngamy. For successful mating and completion of the sexual cycle, haploid cells that conjugate must differ at both *MAT* loci (18, 19). When the two *MAT* loci are unlinked, four mating types can be generated by meiosis among the haploid progeny, defining this as a tetrapolar breeding system. Other basidiomycetes have instead a bipolar system controlled by a single *MAT* locus, either because the *P/R* and *HD* loci are linked or because one has lost its function in mating-type determinism. In mushroom-forming species (Agaricomycetes), there has been a generalized diversification of alleles at both *MAT* loci, in some cases yielding species with hundreds or thousands of possible mating types (1, 20–22). Data compiled from early studies indicate that as many as 65% of the species in the Agaricomycotina are tetrapolar (13, 23), whereas classical mating studies indicate a predominance of bipolar systems in the majority of the Ustilaginomycotina (24) and the Pucciniomycotina (25). In the following sections we summarize current knowledge of the

Figure 1 General life cycles of dimorphic and mushroom-forming basidiomycetes. Three basidiomycetes are pictured where sexual reproduction and a dimorphic switch between a yeast cell and a hyphal form are crucial to infection of plant (A, B) or animal (C) hosts. The haploid yeast forms of the maize smut *Ustilago maydis* (A) and the anther smut *Microbotryum* spp. (B) are nonpathogenic and can undergo asexual mitotic vegetative growth. In *Microbotryum*, the yeast stage is, however, short-lived because mating occurs mostly between cells within the same tetrad. Upon mating with a compatible partner, both fungi switch to an enduring infection hyphal form (dikaryon; n + n) that can invade the host plant. Proliferation and differentiation of *U. maydis* (**A**) in the plant culminates with the production of masses of wind-dispersing diploid spores (teliospores; 2n) in large tumor-like tissues, whereas in *Microbotryum* (**B**), teliospores are formed in the anthers of infected flowers and transmitted by pollinators onto healthy plants. In the case of *Cryptococcus neoformans* (**C**), the single-celled yeast form may be free-living or mycoparasitic. A similar dimorphic switch occurs upon mating of yeast cells of opposite mating type (**α** or α), ultimately resulting in the infectious propagules (basidiospores) that potentially infect an animal host after dispersal. These infectious structures may also be generated by haploid selfing (depicted with gray background), where fusion occurs between homothallic cells carrying identical *MAT* alleles (α/α diploid is depicted) and form monokaryotic hyphae with unfused clamp connections (see text for details). In mushroom-forming fungi such as *Schizophyllum commune* (**D**), germination of haploid spores yields haploid monokaryons capable of independent growth. When two compatible monokaryons meet, a fertile clamped dikaryon is formed which develops into fruiting bodies (mushrooms) triggered upon suitable environmental cues, where basidia arise. In all these and other basidiomycetes, nuclear fusion (karyogamy) is usually delayed until the formation of basidia (or teliospores). Meiosis ensues, generating four haploid nuclei, which give rise to basidiospores to complete the cycle. Adapted from Morrow and Fraser (2) and Nieuwenhuis et al. molecular basis of mating-type determination in basidiomycetes and discuss transitions in breeding systems, using examples from throughout the Basidiomycota phylogenetic diversity.

MOLECULAR DETERMINANTS OF MATING TYPE

The Pheromone/Receptor Sensing System

In the Basidiomycota, syngamy is governed by, in its simplest form, small 10- to 15-amino acid-lipopeptide pheromones derived from 35 to 40 amino acid precursors through posttranslation modifications at both the N- and C-termini (26–28). These diffusible pheromones are received by seven transmembrane-domain pheromone receptors, coupled to a G-protein for downstream signal transduction (28, 29). This molecular determination of mating fusion is similar in part to the **a**- and α-factor P/R system in the ascomycetes and is thought to predate the separation of Asco- and Basidiomycota lineages. There is, however, one remarkable difference between the phyla: only homologues of genes encoding the pair of the **a**-factor pheromone and Ste3 pheromone receptor of the ascomycete system appear to exist in basidiomycetes. Therefore, instead of the **a**-factor/Ste3 and α-factor/Ste2 coupled sensing system characteristic of the ascomycetes (described in reference 197), "chemo-sensing" specificity in basidiomycetes is mediated by allelic variants of the same type of genes (18). Mating is often initiated by a reciprocal exchange of pheromones recognized by matching pheromone receptor variants in both mating types, and thus two strains need to carry different alleles of the pheromone and receptor genes at the *P/R* locus.

All active basidiomycete mating pheromones isolated so far are hydrophobic diffusible lipopeptides that undergo farnesylation at the C-terminal cysteine residue of the CAAX motif (where "C" is cysteine, "A" is often an aliphatic amino acid, and "X" is any residue) and amino-terminal processing. This was first demonstrated in the secreted pheromone (rhodotorucine A) of the red-pigmented yeast *Rhodosporidium toruloides* (recently renamed *Rhodotorula toruloides*) (30, 31) and later extended to many other basidiomycetes (26, 32–36), and also for the **a**-factor of the ascomycete yeast *Saccharomyces cerevisiae* that now stands as the model paradigm for the fungal kingdom (37, 38).

Among the basidiomycetes, exceptional pheromone gene structures were revealed in members of the Pucciniomycotina. Where investigated, the pheromone precursor genes each encode tandem copies of the mature peptide moiety (39–43), and an initial step of processing of a spacer region is required to reveal C-terminal CAAX motifs for each repeat (37, 44). In species where pheromones of opposite mating types have been clearly identified (namely, in *R. toruloides*, *Sporidiobolus salmonicolor*, *Leucosporidium scottii*, and *Microbotryum* spp.), the *MAT A1* pheromone precursor typically presents a greater number of repeats of the peptide moiety (up to six copies in some species), whereas the *MAT A2* pheromone gene appears to encode only one or two copies of the mature pheromone (39, 42, 43, 45). Interestingly, this increased production of pheromone per mole of precursor in *MAT A1* cells, possibly allowing communication with *A2* cells at longer distances, is consistent with the observed asymmetric growth of conjugation tubes in both *R. toruloides* (46) and *Microbotryum* spp. (43, 47), which occurs earlier and to a greater extent from *MAT A2* cells. These

Figure 2 Phylogeny of the Basidiomycota indicating the breeding system and the number of *MAT* genes across representative species of the three subphyla. The breeding system and the different taxonomic lineages are color-coded as given in the key and are kept consistent in all figures. Gene numbers shown for each species were obtained either from previous reports (20, 41, 100) or from newly surveyed genome data (marked with a hash sign after the species name). In the Agaricomycetes, values shown in parentheses are putative nonmating-type pheromone receptors. A question mark indicates cases where information on the breeding system is not available or is uncertain (e.g., because the sexual stage of a species is unknown). A schematic representation of the *P/R* and *HD* loci is given in Fig. 3 for representative species of each lineage marked with numbers enclosed in white circles. Letters in superscript next to the number of pheromone precursor genes indicate that (a) all genes encode the same mature pheromone peptide or that (b) no CAAX motif was detected in one of the putative pheromone precursors. The species phylogenetic tree was constructed in IQ-TREE (193) using a previously described approach (194). Branch support values are shown in the tree nodes as given in the key and were assessed with the ultrafast bootstrap approximation (UFBoot) and the approximate likelihood ratio test (SH-aLRT), each with 1,000 replicates. The basidiomycete clade is rooted with sequences from Ascomycete fungi.

findings suggest that the two mating types may have distinct signaling roles during conjugation, despite the absence of morphologically differentiated cells.

In response to the interaction of the pheromone ligand with a suitable pheromone receptor, mating and sexual development are initiated through a heterotrimeric G protein located at the plasma membrane that triggers a variety of downstream signaling processes. In *U. maydis*, where this has been investigated in greater detail, this signaling is attributed to two interconnected pathways involving a cAMP-dependent protein kinase A and a mitogen-activated protein kinase (28, 48–50). The point of convergence of the two pathways is the pheromone response factor (Prf1), which is an HMG-box transcription factor that recognizes and binds to pheromone response elements located in the regulatory regions of pheromone-induced genes (51, 52). Interestingly, whereas most of the core components of the mitogen-activated protein kinase cascade pathway (e.g., Ste11, Ste7, Fus3) are conserved over wide evolutionary distances, the key downstream transcription factors that ultimately activate or repress their target genes are often not conserved among species and thus are difficult to reveal through candidate gene approaches or sequence comparison.

Homeodomain Transcription Factors: The Second Compatibility Checkpoint

While the *P/R* system controls syngamy, the production of viable mating products requires compatibility at additional genetic components in the basidiomycetes, which is mediated by genes at the *HD* locus. In its most basic configuration, the *HD* locus encodes a pair of proteins of dissimilar homeodomain classes, having protein domains HD1 or HD2, and their coding genes are normally adjacent and divergently transcribed. Development following syngamy depends upon the formation of functional heterodimeric transcription factors where dimerization is restricted to HD1 and HD2 proteins that originate from haploid mates bearing different alleles of the *HD* locus. This requirement ensures that active heterodimers are only formed in the dikaryotic stage and do not arise in haploid cells. Failure to form heterodimers in the haploid is explained by interfering amino acids at HD1 and HD2 proteins from the same allele that disturb their general cohesiveness (53–55). Studies have shown that the relevant interfaces for discriminating HD1-HD2 interactions and determining allele specificity seem to be located N-terminally to the DNA binding motifs and that this region is usually highly variable between different alleles of both *HD1* and *HD2* genes (53, 54, 56). Analyses in *U. maydis* of chimeric and mutant alleles and protein-protein interaction studies using the yeast two-hybrid system revealed that dimerization between HD1 and HD2 proteins involves polar-hydrophobic interactions with variable cohesive contact sites contributing to binding affinity (54, 57, 58). Once formed, the functional heterodimers will bind to gene promoter elements, leading to the induction of the specific sets of genes involved in subsequent differentiation, which can include a morphological switch from yeast-like cells to filamentous growth and pathogenicity, as in the smuts, or fruiting body formation in the mushrooms (28, 41, 58–60).

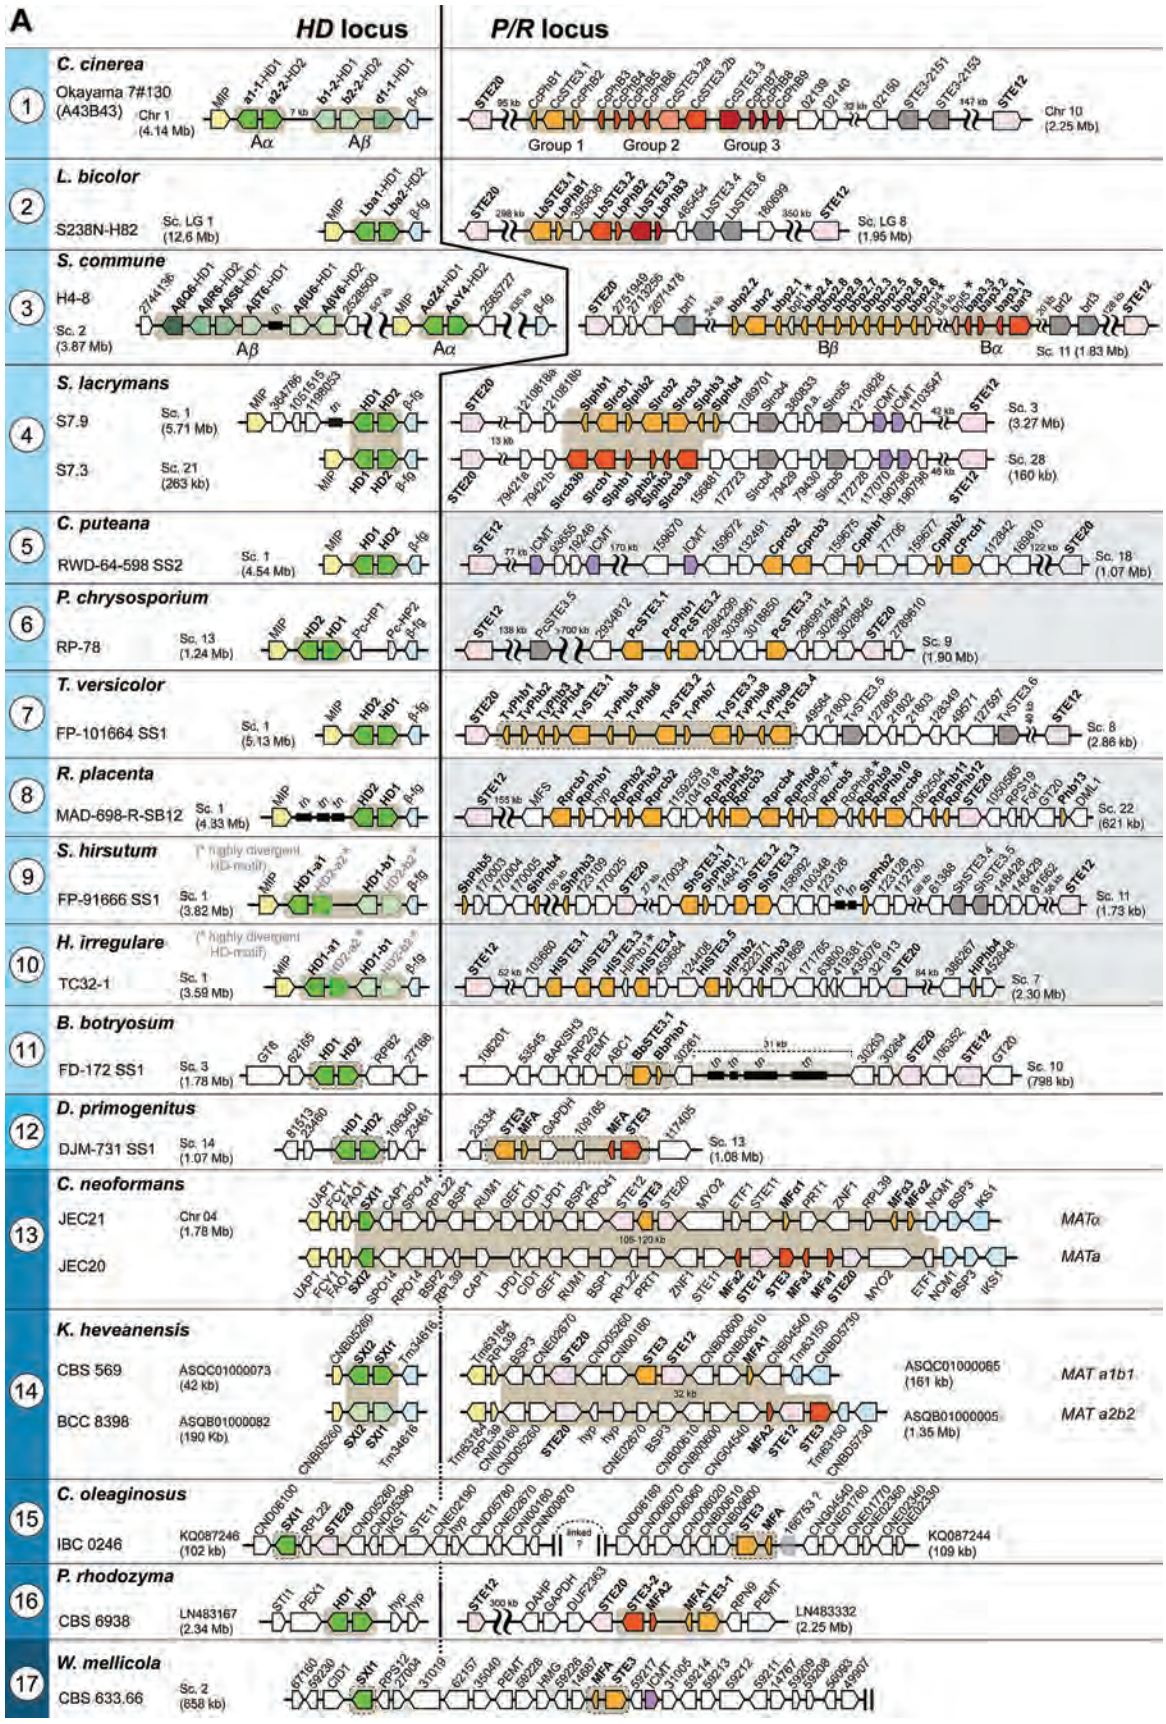
BREEDING SYSTEMS IN THE BASIDIOMYCOTA

The distinction between heterothallic and homothallic compatibility represents a fundamental breeding system classification in fungi, and both systems are found across the Basidiomycota. In heterothallic basidiomycete species, sexual reproduction is only possible between gametes carrying different alleles at both *MAT* loci, preventing intrahaploid mating (i.e., selfing at the haploid level) (61). On the other hand, homothallic species produce universally compatible gametes, each being able to undergo intrahaploid mating with their clonemates. We have summarized in Fig. 2 and Fig. 3 data regarding the breeding system and the genomic organization of the mating-type genes in representative species of the three major subphyla of the Basidiomycota, some of which will be highlighted in the following sections.

Tetrapolar Systems: *U. maydis* and Other Smut Relatives

The maize smut *U. maydis* (order Ustilaginales; Fig. 2) is one of the most intensively studied basidiomycete models with respect to the organization and function of mating-type genes (62). The fungus has a dimorphic life cycle with a yeast-like haploid saprophytic phase switching to filamentous pathogenic growth in the dikaryotic stage following syngamy (Fig. 1A). In this species, the process of mating and completion of the sexual cycle is regulated by a tetrapolar breeding system, i.e., with the *P/R* (or *a*) locus unlinked from the *HD* (or *b*) locus. The *P/R* locus exists in two allelic forms (*a1* and *a2*), which are defined by structurally dissimilar DNA regions of 4.5 kb for the *a1* and 8 kb for the *a2*, each comprising one pheromone receptor gene (*PRA1* or *PRA2*) and one pheromone precursor gene (*MFA1* or *MFA2*) (Fig. 3B). The Pra1 receptor only responds to the Mfa2 pheromone, while Pra2 can

only recognize Mfa1. The observed size difference between the two allelic forms of the *P/R* locus is due to the presence in the *a2* allele of two additional genes (*lga2* and *rga2*) that direct uniparental mitochondrial DNA inheritance, as well as a third, nonfunctional pheromone-encoding gene (26, 33, 52, 63).



Interestingly, the presence of this pseudogene led to early speculations about the existence of a complex scenario ancestral to the Ustilaginales in which the *P/R* locus occurred in more than two allelic forms, with this additional cryptic pheromone gene being recognized by a distinct receptor encoded by a third unidentified *P/R* allele (52). This hypothesis was substantiated upon characterization of the breeding system of the closely related head smut fungus *Sporisorium reilianum*. Compared to *U. maydis*, the *P/R* locus of *S. reilianum* exists in three alleles, each containing two distinct pheromone genes and one pheromone receptor (64) (Fig. 3B). Importantly, each of the mature pheromones in one allele interacts specifically with only one of the receptors encoded by the other two alleles. For instance, the pheromones encoded by the *MFA1.2* and *MFA1.3* genes at the *a1* locus interact with the Pra2 and the Pra3 receptors encoded by the *a2* and *a3* alleles, respectively (Fig. 3B). This leads to a scenario in which each mating type can detect (and be detected by) the other two, but not itself. Additional support for this ancestral triallelic *P/R* system model was more recently attained in a study where the complete *P/R* loci of additional smut species spanning about 100 million years of evolution in the order Ustilaginales were sequenced and compared (65). Interestingly, the three *P/R* alleles previously described in *S. reilianum* were conserved and generally syntenic among members of the same order. This supports a potential scenario in which the biallelic *P/R* system as observed in *U. maydis* resulted from the loss of the *a3* allele and loss of one of the two pheromone genes, which is now lacking in extant *a1* and *a2* alleles. Accordingly, a phylogenetic analysis using pheromone receptor sequences from a wider taxonomic range (Fig. 4) shows that all Ustilaginomycotina receptors group together and within one of the three allelic classes previously defined (*PRA1*, *PRA2*, *PRA3*) (65). This result denotes that the triallelic *P/R* system is probably as old as the stem age of the Ustilaginomycotina, about 450 million years (66).

Following fusion of compatible partners, heterozygosity at the *HD* locus is required for dikaryon maintenance and filamentous growth in *U. maydis* (54, 67). The two divergently transcribed *HD* genes encode homeodomain proteins known as bE (for *bEast*; HD1-type) and bW (for *bWest*; HD2-type). However, in contrast to the biallelic and triallelic *P/R* locus of *U. maydis* and *S. reilianum*, respectively, the *HD* locus is highly multiallelic: in *U. maydis* more than 30 intercompatible allelic versions were found in nature (68; DeVay, cited in 69), while in *S. reilianum* five alleles have been identified so far (64). The homeodomains and C-terminal regions of the allelic HD1 and HD2 proteins are highly conserved, whereas the sequences N-terminal to the homeodomain regions are highly variable and required for the interaction of nonallelic HD1 and HD2 proteins (54).

Variation in Tetrapolar Systems beyond *Ustilago/Sporisorium*

Outside the Ustilaginomycotina, the number of tetrapolar species characterized for molecular polymorphisms at the *MAT* loci has increased in recent years (42, 45, 70–74). *Kwoniella heveanensis* (70) and *Cryptococcus amylolentus* (71) in the Agaricomycotina and *L. scottii* (42) in the Pucciniomycotina are examples where the *P/R* locus is biallelic, while the *HD* locus displays greater polymorphism (Fig. 2 and 3). In all three, the *P/R* and *HD* loci localize to different chromosomes. Sequencing of the *P/R* locus in each species showed their biallelic nature but, in comparison to *U. maydis* and *S. reilianum*, the *P/R* locus in *K. heveanensis* and *L. scottii* covers a relatively larger genomic region (about 32 kb and 50 kb, respectively; Fig. 3A and 3B), which is highly rearranged between mating types. Included here are the genes encoding *MAT*-specific pheromones (*MFA* or *RHA*) and receptors (*STE3*), as well as genes previously shown to be required for the onset of filamentation in dimorphic species (e.g., *STE20*, *STE12*) (75–77) and lineage-specific genes not obviously involved in mating (Fig. 3). The *HD* locus in *K. heveanensis* and *C. amylolentus* contains only the divergently transcribed homeodomain genes, *HD1* and *HD2* (named *SXI1* and *SXI2*) (70, 71). In *L. scottii*, in contrast to *K. heveanensis* and *C. amylolentus*, the boundaries of the *HD* locus may have extended further outside from the *HD1/HD2* gene module, given the evidence of increased sequence divergence in a region spanning about ~80 kb that encompasses the *HD1/HD2* genes (42). Sequence analysis of this variable region from different *K. heveanensis* isolates provided evidence that the locus is multiallelic with at least six different *HD1/HD2* alleles (70). The same holds true for *L. scottii*, but with 28 *HD* alleles being revealed upon inspection of 43 isolates (42).

From an evolutionary standpoint, it is noteworthy that extant tetrapolar dimorphic basidiomycetes have more commonly a biallelic *P/R* locus (26, 70–72, 74,

78). For these, the proportion of compatible mates in the population cannot exceed 50%, irrespective of the number of alleles at the *HD* locus. However, given that compatibility at the *HD* locus can only be assessed after syngamy, increased *HD* allele diversity should be naturally selected when outcrossing is the rule, to allow more frequent dikaryon viability after syngamy and, in this way, limit the amount of wasted mating opportunities.

Tetrapolar Systems with Multiple Alleles in the Agaricomycetes

A vast repertoire of mating types has been found in most members of the class Agaricomycetes (Fig. 2), such as the wood-rotting mushroom *Schizophyllum commune* (Fig. 1D) with more than 15,000 intercompatible mating types, and the ink cap mushroom *Coprinopsis cinerea* with an estimated 12,000 distinct mating types (1). Such diversity is likely due to selection for rare alleles under outcrossing: any new specificity will be compatible with all extant mating types and therefore may increase in frequency under this selective advantage (15, 79). Studies have shown that two hallmarks of the *MAT* loci of these and other heterothallic Agaricomycetes account for such astonishing numbers of mating types within a single species. First, a single locus may itself be extremely polymorphic, in some cases with hundreds of specificities (1, 13, 16); second, for some species, multiallelism in both *P/R* and *HD* loci is generated by rounds of segmental duplication and diversification of *MAT* genes, resulting in independent but functionally redundant subloci, upon which recombination can act to give rise to novel allele specificities and, by definition, new mating types (80).

Recent advances in genome sequencing are now allowing detailed comparisons of *MAT* loci among diverse species, and a comparative overview of these genomic regions in several Agaricomycetes is presented in Fig. 3A. A great body of literature exists on the mating-type systems and distribution in Agaricomycetes, preventing a full discussion, and the reader is referred to some exceptional and recent reviews (16, 20). Here, we shall concentrate mainly on the model mushroom *C. cinerea*, which has long served as an invaluable model to understand the molecular underpinnings of multiple mating types and multiallelic *MAT* loci in the Agaricomycetes. Where relevant, reference will be made to other mushroom species, but many of the principles that govern the evolution of multiple mating types in *C. cinerea* seem also to hold in other species.

Initial studies in *C. cinerea* using classical genetics determined that the *HD* locus is multiallelic and composed of two subloci (*A* and *A*; Fig. 3A) that can recombine at detectable frequencies despite their close proximity in the genome (81, 82). Molecular genetic studies and genome sequencing later revealed that, whereas the *A* sublocus encodes one *HD1/HD2* gene pair, the *A* sublocus encodes up to three pairs and is located at a distance of ~7 kb from the *Aα* sublocus (Fig. 3A) (83–86). Recombination between the two subloci is possible through the ~7 kb-long intergenic

Figure 3 Schematic showing the genomic structure and diversity of *MAT* loci in representative basidiomycete lineages. The genomic organization of the homeodomain (*HD*) and pheromone/receptor (*P/R*) *MAT* loci is shown for selected species of (**A**) the Agaricomycotina and (**B**) the Ustilaginomycotina and Pucciniomycotina. Arrows indicate genes and their direction of transcription. Putative *MAT* loci are shaded in light brown, and *MAT* genes are colored as indicated in the key with different color grades representing different alleles (or paralogs). When known, conserved genes flanking *MAT* loci (colored light yellow or light blue) are shown within each lineage. Genes that encode components of the pheromone response pathway are shown in pink and are in many cases within the *MAT* locus. Putative homologs of a protein required for posttranslational modification of pheromone precursors (isoprenyl cysteine methyltransferase [ICMT]) are colored purple and appear near the *P/R* locus in some species. *P/R* loci no longer determining mating-type specificity in bipolar Agaricomycetes are depicted with a gray background. In *M. lychnidis-dioicae*, the two mating-type chromosomes are highly rearranged and enriched in transposable elements, so that only a small number of genes is depicted. Of note, whereas in *M. nashicola P/R* and *HD* genes are far apart on the same chromosome, in *E. vaccinii* and *M. endogenum* the two sets of genes are closer together. Other genes or genomic features are colored or represented as given in the key. For citations and additional details, see text. Gene names or their associated protein accession numbers are shown as they appear in their respective genome databases, except in species of Ustilaginomycotina and Tremellomycetes, where names were given based on sequence identity to the closest homolog in *U. maydis* and *C. neoformans*, respectively.

Figure 3 *continues on next page*

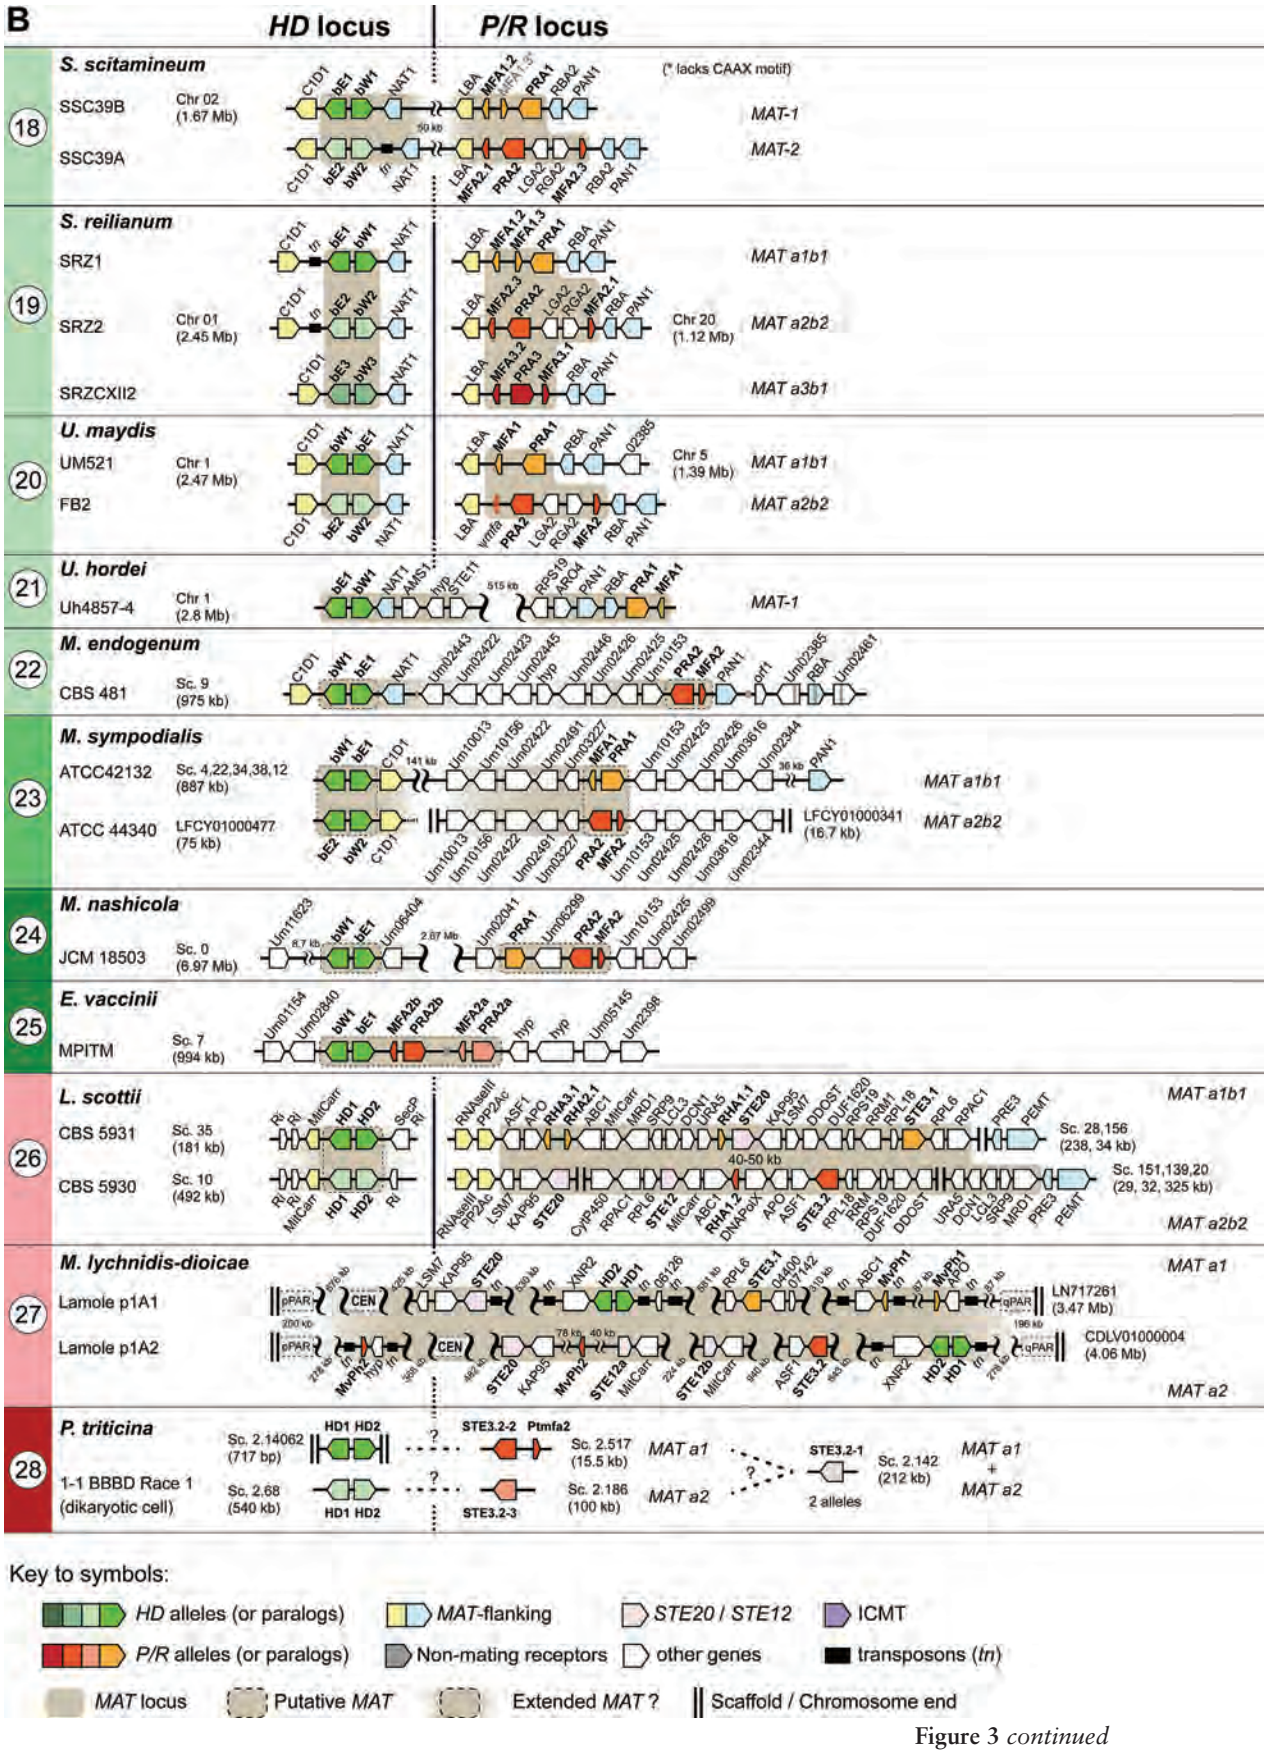

Figure 3 *continued*

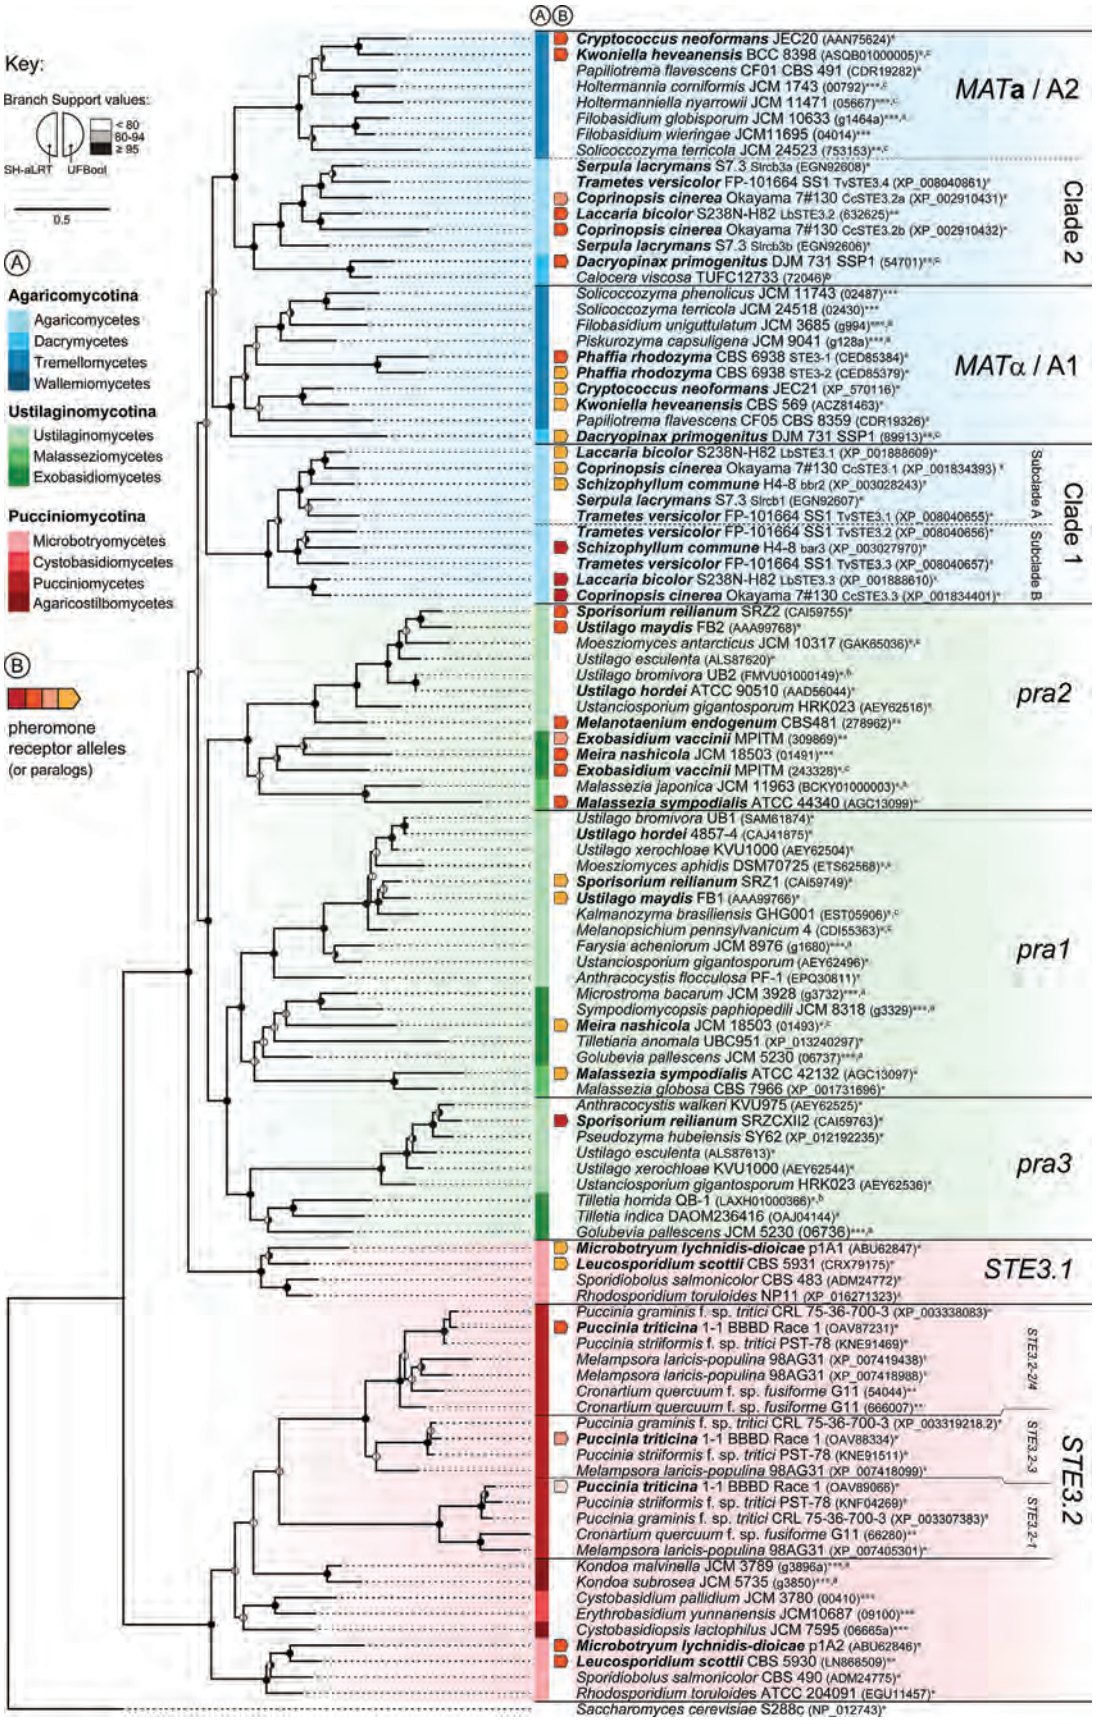

region that is highly conserved between alleles. Sequence and functional analysis of five *HD* alleles led to a theoretical archetypal structure for the *C. cinerea HD* locus with three paralogous *HD1/HD2* gene pairs (known as the *a*, *b*, and *d* pairs). This implies that molecular mechanisms akin to gene deletion have been at work during evolution of the *HD* locus, because the extant alleles have fewer than the six *HD1/HD2* genes postulated in the model (exemplified by allele *A43* in Fig. 3A) (83–85). At present, four, seven, and three distinct alleles have been identified for the *a, b*, and *d* pairs, respectively (56, 85), generating 84 *HD* alleles considering all possible permutations. Although this is about half the number estimated by John Raper, 160 *HD* alleles in nature (1), the identification of one additional allele per group would be sufficient to reach Raper's estimates. However, the actual numbers of alleles in nature are of course unknown.

Similarly, the *P/R* locus in *C. cinerea* is multiallelic and consists of three tandemly arranged but independent groups of paralogous genes (groups or subloci 1 to 3). The sequencing of several alleles revealed that each group contains multiallelic and functionally redundant genes encoding at least one pheromone receptor and up to four pheromone genes (Fig. 3A) (20). In any given group of paralogous genes, the relative order, direction of transcription, and number of genes may vary and, importantly, each group has freely interchangeable alleles (80). In *C. cinerea*, from 13 sequenced *P/R* alleles, two, five, and seven alleles were identified for groups 1, 2, and 3, respectively. Together, this gives rise to 70 possible combinations, approaching the number of 79 *P/R* alleles estimated to exist in nature (1). Phylogenetic analyses of *C. cinerea* receptors of the three paralogous gene groups and from different alleles added yet another layer of complexity in the evolutionary history. Strikingly, the different allelic versions of the pheromone receptors as defined by their position within the *P/R* locus do not always fall into the same clade (20, 80), an observation that led some authors to conclude that gene shuffling occurred within the locus during evolution (80). This pattern has also been observed in *S. commune* (87) and in *Ganoderma lucidum* (88). Such relocations may have restricted intralocus recombination at some point during evolution, thereby contributing to the fixation of some of the alleles in the populations.

With additional pheromone receptors from other Agaricomycetes added to the phylogenetic analysis, the origin of the paralogous groups of genes within the *P/R* locus can be traced back to an early stage of the evolution of this taxonomic lineage, with a duplication event initially separating these genes into two distinct evolutionary groups (clades 1 and 2 in Fig. 4). More recent duplications (e.g., *CcSTE3.1* and *CcSTE3.3* in *C. cinerea* or *LbSTE3.1* and *LbSTE3.3* in *Laccaria bicolor*) (Fig. 4) followed by sequence diversification and recombination (80) are suggested to have led to the high numbers of alleles presently estimated from natural populations of several mushroom species (16, 20, 41, and references therein).

In *C. cinerea* and other Agaricomycetes, each encounter of two monokaryotic hyphae results in promiscuous cell-cell fusion irrespective of whether or not they are compatible at *MAT* (18, 89). However, for the development and maintenance of the dikaryon, nuclei of interacting partners must harbor different allelic versions of genes in at least one sublocus of both *P/R* and *HD* loci (18, 89–91). Classical genetic analyses of these semicompatible interactions in *C. cinerea* and *S. commune* have shown that the *P/R* system is involved in events that follow hyphal fusion, namely in the reciprocal exchange and migration of nuclei and clamp cell fusion (Fig. 5). On the other hand, genes encoded at the *HD* locus repress asexual sporulation (92), regulate pairing of nuclei within the dikaryotic tip cell, and coordinate nuclear division, clamp cell formation, and septation from the subapical cell (1, 18, 93) (Fig. 5). If the two mates share identical alleles at *P/R* and *HD* loci, no nuclear exchange occurs and the fungal individuals resume monokaryotic growth.

Additional pheromone receptor-like genes (i.e., *STE3*-like) have been identified from numerous Agaricomycetes using sequence similarity-based approaches (Fig. 3A), and many fall within one of the three clades of Agaricomycete mating-type receptors (subclades A and B of clade 1 as well as clade 2) (Fig. 4). However, their function remains largely elusive, because reports suggest that these are non-mating-type-specific receptors (94, 95), and experimental evidence from *S. commune* suggests that they are not sufficient *per se* to induce mating-specific development (96). Many of these non-mating-type-specific receptors are located in the close neighborhood of the *P/R* locus, while others are unlinked (Fig. 3A). Three distinctive features of these Ste3-like receptors are seen in comparison to the mating-type-specific receptors: (i) they present longer C-terminal cytoplasmic regions, (ii) lack pheromone genes in close association, and (iii) show lower levels of intraspecific polymorphism. Non-mating-type-specific receptors have been documented in *C. cinerea* (41), *Phanerochaete chrysosporium* (97), *L. bicolor* (98), *Postia placenta* (99), and several species of the order Polyporales (100), and many more can be expected to be identified from whole-genome sequence data. example, up to 29 Ste3-like receptors were identified in the genome of *Serpula lacrymans* (Fig. 2). A few theoretical possibilities have been proposed for their function (41). One such possibility considers that they may play a role during monokaryotic fruiting, in a way similar to that described for the *C. neoformans* non-mating-type receptor gene *CPR2*, whose overexpression elicits homothallic reproduction (101). Another hypothesis suggests that these genes may function in vegetative communication within a species or in conspecific recognition avoiding hybridization (41). Experimental studies addressing the function of these non-mating-type-specific receptors are thus critically needed.

Comparative genomics revealed that gene content and organization (synteny) are generally conserved around the *HD* locus in Agaricomycetes. Two genes usually border this locus: one encodes a mitochondrial intermediate peptidase (*MIP*), which has served as a valuable marker for the isolation of *HD* loci from nonmodel species, and the other is known as a beta-flanking gene (*-fg*) for an unknown protein (Fig. 3A) (94, 100, 102). Although this configuration is found in most species analyzed, exceptions have been reported. In *S. commune*, for example, two large rearrangements at the *HD* locus have taken place causing the separation of the *HD* locus into two clearly distinct subloci that now lie more than 500 kb apart and frequently recombine during meiosis (Fig. 3A) (103, 104). A similar situation is observed in *Flammulina velutipes* (winter mushroom or enoki), but the distance between the two *HD* subloci is about 70 kb. Interestingly, whereas synteny analysis of the surrounding regions indicates that the separation of the two *HD* subloci in *S. commune* emerged via transposition of the two gene clusters, the extant arrangement in *F. velutipes* was driven by two large inversions (95). Other exceptions to the typical *MIP–HD1/HD2–-fg* gene arrangement were observed in the cacao pathogen *Moniliophthora roreri*, where both *MIP* and *-fg* are located 40 and 60 kb upstream of *HD1/HD2* (105), respectively, and in the Shiitake mushroom, *Lentinula edodes*, where *MIP* is distant from the *HD* locus (106). Gene order conservation at the *P/R* locus is also observed among Agaricomycetes, although to a lesser extent compared to the *HD* locus. The *P/R* locus in *L. bicolor* was shown to be in a chromosomal region more prone to gene duplication, translocations, and accumulation of transposable elements (98), and in the wood-decay basidiomycete *Botryobasidium botryosum* (order Cantharelalles; Fig. 2), genome inspection revealed the presence of transposons in the immediate vicinity of pheromone and receptor genes (Fig. 3A; this report). Another illustrative example is the position of *STE20* and *STE12* genes, which varies among the species shown in Fig. 3A.

Tetrapolarity with multiple alleles at both *MAT* loci is often suggested to promote outcrossing (107, 108). It is true that tetrapolarity is less favorable to selfing than to outcrossing, because the chances that any two haploid siblings from the same diploid parent are compatible is at most 25% for tetrapolarity, compared to 50% from a bipolar cross (107). However, tetrapolarity also yields only 25% compatibility under outcrossing when both mating-type genes are biallelic, so that tetrapolarity in itself does not favor outcrossing compared to selfing under biallelism. It is multiallelism that may restrict inbreeding, however, and the evolution of high numbers of mating types is suspected to be primarily driven by selection for increased compatibility at syngamy under an already established outcrossing mating system. An evolutionary scenario could be one with ancestral mating-type determinism being biallelic at the *HD* locus and where the high level of gamete dispersal evolves, leading to widespread outcrossing, which in turn selects for rare alleles, yielding multiallelism at the

Figure 4 Phylogeny of Basidiomycota pheromone receptor proteins. Amino acid sequences identified by BLAST from publicly available databases or from genome projects were retrieved for representative species of the tree subphyla of the Basidiomycota. A total of 106 sequences were manually inspected, amended where necessary, and aligned with MAFFT (195), and poorly aligned regions were trimmed with trimAl (196). The phylogenetic tree and branch support were obtained as in Fig. 2, and the tree was rooted with *S. cerevisiae* Ste3p. GenBank accession numbers (*), Joint Genome Institute protein identifiers (**), and RIKEN/NBRP identifiers (***) are given after the strain name, with letters in superscript indicating (a) genomes assembled from available raw sequencing data and inspected locally, (b) genomic contigs/scaffolds lacking gene annotation, and (c) genes whose annotation was corrected. Species highlighted in boldface are shown in Fig. 3, with arrows before their names indicating the allelic version (or paralog) of the pheromone receptor as colored in Fig. 3. Of note, the *STE3.1* and *STE3.2* alleles in the Microbotryomycetes (Pucciniomycotina) displayed the deepest allelic divergence and trans-specific polymorphism, with the *STE3.1* alleles of the different species branching together rather than each of these alleles clustering with the *STE3.2* allele from the same species (42, 45, 137).

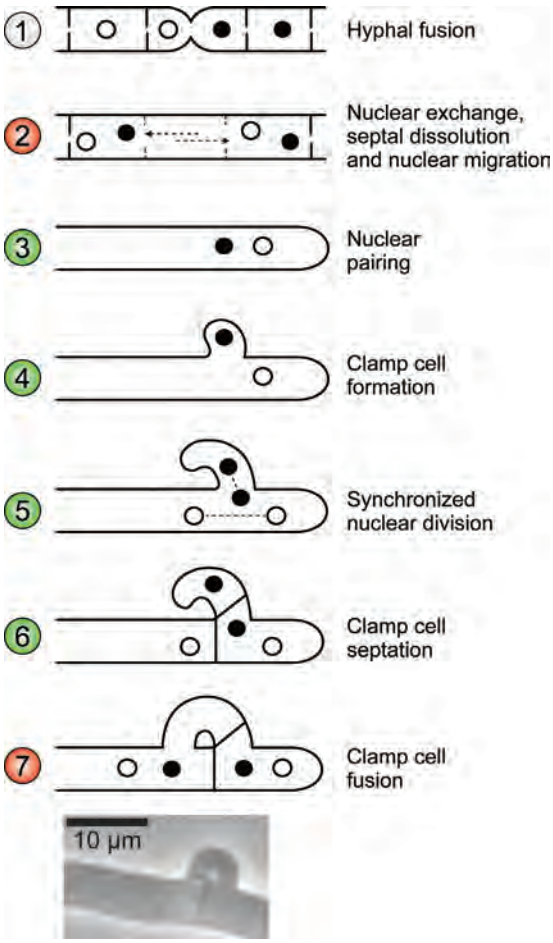

Figure 5 Roles of *P/R* and *HD* genes on the formation and maintenance of the dikaryon in *C. cinerea*. Pheromone signaling is not required to attract mates, and hyphal fusion is mating-type independent (diagram 1). Upon fusion, nuclei enter the mycelium of the other mate and migrate until they reach a hyphal tip cell (diagram 2). During hyphal tip elongation, the two types of haploid nuclei (depicted in white and black, representing different *MAT* genotypes) pair at the tip cell (diagram 3), and at the place where mitosis will take place, a hook-like structure (called a clamp connection) is formed (diagram 4). The two nuclei divide synchronously: one of the nuclei divides in the direction of the clamp cell that is growing backward toward the main hyphae, while the other divides along the main hyphal axis (diagram 5). Septa are generated between the dividing nuclei. This way one nucleus stays temporarily entrapped in the clamp cell, one nucleus of the other type is enclosed in the newly formed subapical cell, and a nucleus of each type is maintained in the emerging hyphal tip cell (diagram 6). The clamp cell fuses with the subapical cell and releases the entrapped nucleus from the clamp cell, restoring the dikaryotic state of the subapical cell (diagram 7). In *C. cinerea*, steps controlled by *P/R* (diagrams 2 and 7) and *HD* (diagrams 3 to 6) genes are colored red and green, respectively. See Casselton et al. (18) and Kües (90) for details. The micrograph at the bottom was obtained from Stajich et al. (86), with permission.

HD locus. Recruiting a biallelic *P/R* locus in mating-type determinism would not favor outcrossing, because again, compatibility odds will be similar under outcrossing compared to selfing. Different scenarios for explaining the incorporation of the *P/R* locus in the mating-type determinism system are possible, such as its role in syngamy or mate attraction, or again, evolution first of multiallelism (e.g., due to population differentiation). Studies addressing the pattern of mating in nature, depending on gamete dispersal rates and polymorphism levels at the mating-type genes, will be fundamental to test some of these predictions.

Bipolar Breeding Systems: Genomic Changes and Evolutionary Considerations

Early studies indicated that, although the tetrapolar mating system predominates in the Basidiomycota, a considerable number of species are bipolar. For example, roughly a quarter of the mushroom species are bipolar (1, 13) and, significantly, they occur phylogenetically interspersed with tetrapolar relatives (100). Owing to the occurrence of multiple bipolar species within the basidiomycetes, the origin of tetrapolarity as the ancestral state to this clade is still debatable. However, several lines of evidence argue strongly in favor of this hypothesis. First, the tetrapolar system is architecturally complex, making it unlikely to have arisen multiple times (23, 109). Second, the same mating-type-determining genes (at both *P/R* and *HD* loci) are involved in mating-type determinism in species of the three major basidiomycete lineages, suggesting a common origin (41, 42, 108). Third, all bipolar species investigated so far display genomic signatures, suggesting that they derived secondarily from a tetrapolar system (detailed below). Based on these observations, the prevailing hypothesis is that the tetrapolar system evolved in a basidiomycete ancestor following the acquisition of a separate locus (the *P/R* locus) for *MAT* determination that segregated independently of the *HD* locus, and with multiallelism evolving in many lineages (17, 41).

As initially envisaged by John Raper (1), and more recently supported by solid molecular evidence (detailed below), bipolarity in the Basidiomycota appears to be the result of simple genetic changes. There are two general ways this can be achieved: (i) by linkage of the *P/R* and *HD* loci into a single, nonrecombining *MAT* region with often only two alleles of each locus being retained or (ii) by loss of function of the *P/R* locus in mating-type specificity, conceivably through mutations that cause constitutive expression of the *P/R*-regulated pathway or that produce a self-compatible allele at the *P/R* locus.

Transition to bipolarity in smuts and *Malassezia* through linkage of *P/R* and *HD* loci

There are now several direct examples that support the formation of a bipolar system through a chromosomal translocation that places both *P/R* and *HD* loci in tight linkage. In the Ustilaginomycotina, a prime example is provided by *Ustilago hordei*, a bipolar smut pathogen closely related to tetrapolar *U. maydis* (Fig. 2) (110). With the molecular analysis of the *MAT* loci, initially in *U. maydis* (26, 59, 111, 112), the genomic basis of the bipolar mating behavior of *U. hordei* was subsequently revealed: both *P/R* and *HD* complexes were physically linked on the same chromosome, 430 and 500 kb apart on the largest chromosome representing the respective *MAT-2* and *MAT-1* loci (Fig. 3B), and the presence of inversions in between these complexes was proposed to cause the almost complete lack of recombination of the complexes (113–115), likely resulting in a subsequent accumulation of transposable elements. Detailed analyses have since then been published on mating types in several Ustilaginomycotina spp.

Complete genomes of five species of closely related genera varying in mating-type organization are available: tetrapolar *U. maydis* (116) and *S. reilianum* (117) and the bipolar species *U. hordei*, with the *HD* and *P/R* loci 430 to 500 kb apart (118), *Sporisorium scitamineum*, with the *HD* and *P/R* loci 59 kb apart (119, 120) (Fig. 3B), and *Ustilago bromivora*, with the *HD* and *P/R* loci 183 kb apart (121). Based on comparison of chromosomal rearrangements between *U. maydis*, *U. hordei*, and *S. reilianum*, it was suggested that the tetrapolar organization in the *S. reilianum* lineage was ancestral and that part of *S. reilianum* chromosome 1 harboring the *HD* locus was translocated to its chromosome 20 harboring the *P/R* locus, to generate the bipolar organization in *U. hordei* (118). This potential scenario was strengthened in the recently published bipolar *S. scitamineum* genome: homologous parts of *S. reilianum* chromosomes 1 and 2 seem rearranged to give chromosome 2 in *S. scitamineum* (120). In all these cases, the presence of many repetitive and transposable elements at the breakpoints suggested they may be functionally involved (122). As stated above, the resulting spacing between the *HD* and *P/R* loci in these species varied between 59 and 500 kb, and this was likely a consequence of increasing numbers of such elements due to decreased recombination.

A similar *MAT* loci configuration has also been recently identified in the human skin commensal yeast *Malassezia* spp. complex that is responsible for dandruff and other skin pathologies. These include *Malassezia sympodialis*, *Malassezia globosa*, and *Malassezia yamatoensis* (123, 124) (Fig. 2). Similar to *U. hordei*, the *P/R* and *HD* loci in these three *Malassezia* spp. are also located on the same chromosome and are separated by large chromosomal regions that are >100 kb in size. Interestingly, comparison of the chromosomal regions encompassing the *P/R* and *HD* loci in these species also suggests that the linkage between the two *MAT* loci are the result of two independent events, with one giving rise to the linkage between the two *MAT* loci in *M. sympodialis* and *M. globosa*, while the other rearrangement led to the *P/R* and *HD* linkage in *M. yamatoensis*. Additionally, analyses of natural isolates of *M. sympodialis* suggest that recombination is still occurring between the *P/R* and *HD* loci in natural populations, indicating that linkage between the two *MAT* loci is not tight. In agreement with this, the 170-kb *MAT* region of *M. globosa* does not contain accumulations of repetitive elements as found at the *MAT-1* locus of *U. hordei* (125), as is expected in regions of suppressed recombination. Moreover, a preliminary examination of the *P/R*-containing region in the genomes of two *M. sympodialis* strains of opposite mating types revealed conserved gene order in the immediate vicinities of the *P/R* gene pair, which are found adjacent but inverted in both mating types (Fig. 3B; this report). The breeding system in *Malassezia* species is thus considered "pseudo-bipolar," a term initially proposed for the breeding system of the red-pigmented yeast *S. salmonicolor* to reflect a situation where multiallelism might occur despite the apparent loose linkage of the two *MAT* regions (45); linkage is expected to be selected for in selfing mating systems, in which rare alleles have no advantage, leading to gradual loss of alleles but two by genetic drift.

Bipolarity in pathogenic *Cryptococcus* spp. complex and in *Trichosporon*

Outside the Ustilaginomycotina, deviations from the classic tetrapolar system have also been observed in a variety of species. For example, all the species within the human pathogenic *Cryptococcus* spp. complex (Tremellomycetes, Agaricomycotina; Fig 2) (126) have bipolar mating systems. In these species, there are two mating types, *MAT***a** and *MAT*α, defined by two alleles (**a** and α) at a single large *MAT* locus (Fig. 3A). The *MAT* locus in pathogenic *Cryptococcus* spp. is ~120 kb in size and contains about 20 genes, including those encoding mating pheromones and their cognate receptors and homeodomain transcription factors (*HD1* or *SXI1* and *HD2* or *SXI2*). There is, however, a distinctive feature regarding the normally two-gene homeo-

domain function in this group of species: the *HD1* (or *SXI1*) gene is unique to *MAT*α strains, whereas *HD2* (or *SXI2*) is specific to the *MAT***a** strains (Fig. 3A). This is in contrast to other basidiomycetes in which a divergently transcribed *HD1/HD2* gene pair is present in each mating type.

Accordingly, each mating type in pathogenic *Cryptococcus* spp. has been reduced to the minimal number of *HD* genes required to function upon fusion of compatible cells (127). Recessive losses of genes from one mating type could likely occur because each is sheltered in a permanent hemizygous state due to recombination suppression within the *MAT* locus, associated with extensive chromosomal rearrangements. However, gene conversion does occur within these regions and at a frequency that is at least comparable to the crossover frequencies in other chromosomal regions (71). Additionally, it has been shown that recombination hotspots associated with the presence of GC-rich motifs are located at the regions that flank the *MAT* locus in *Cryptococcus* (128, 129), which could potentially function as repressors of crossover within the *MAT* locus. Comparison of the *MAT* loci of closely related tetrapolar species such as *C. amylolentus* (71) and *Cryptococcus heveanensis* (70) suggests that the single *MAT* locus in the pathogenic *Cryptococcus* spp. is the result of fusion of ancestral *P/R* and *HD* loci, possibly mediated by repetitive sequences and transposable elements that may act as substrates for nonhomologous recombination (130, 131).

A recent genomic study found that in the oil-accumulating yeast *Trichosporon oleaginosus* (recently renamed *Cutaneotrichosporon oleaginosus*) (Fig. 2 and Fig. 3A), as well as in some of its sister species, the mating-type regions show significant structural differences from those of other Tremellomycetes that possess tetrapolar breeding systems. Specifically, no homologs of the *HD2* transcription factor could be identified in the genomes of *T. oleaginosus* and *Trichosporon asahii*, suggesting that this transcription factor might have been lost during the evolution of the *Trichosporon* spp. complex (132). Alternatively, this gene is absent from only one mating type like the situation in the *Cryptococcus* spp. complex, a possibility which cannot be ruled out since the three sequenced strains carried the same alleles of *P/R* and *HD* genes. However, if the latter hypothesis ends up being true, then such gene loss would represent a case of parallel evolution in *Trichosporon* and the human pathogenic *Cryptococcus* spp. complex given that the last common ancestor of the two lineages most likely contained the standard *HD1/HD2* gene arrangement. It would be of interest in this scenario to test whether the *HD* gene loss is associated with established genetic linkage between the genomic regions that contain the *P/R* and *HD* genes (Fig. 3A). Unfortunately, the fragmented nature of the available genome assembly of *T. oleaginosus* (132) and the lack of descriptions of a sexual cycle for any *Trichosporon* species prevent a more definitive answer at this time.

Expansion of the mating-type locus in *Microbotryum* following linkage of *P/R* and *HD* loci

The findings in the aforementioned bipolar species support the hypothesis of a tendency toward expansion of the regions of recombination suppression in mating-type regions in fungi (133), although it is not yet clear what underlying factors have been driving this trend, e.g., whether it is simply the linkage of the two mating-type loci. In line with this, a more extreme case of the evolution of bipolarity from tetrapolarity by linkage between the two *MAT* loci is observed in the anther-smut fungus *Microbotryum lychnidis-dioicae*. All species belonging to the genus *Microbotryum* are castrating floral smut pathogens that parasitize plants in the Caryophyllaceae family (Fig. 1B), forming a complex of sibling species highly specialized on different plant species (61, 134, 135). The most studied species is *M. lychnidis-dioicae*, which parasitizes *Silene latifolia* (136). This fungal species is bipolar, with only one *MAT* locus and two alleles, called a_1 and a_2 (137). This is among the first fungal species for which bipolar mating types have been described (138) and also the first fungal species for which size-dimorphic mating-type chromosomes were revealed (139). A sex event is required before each new plant infection, and *M. lychnidis-dioicae* displays a highly selfing mating system under heterothallism, performing mostly intratetrad mating (a.k.a. automixis) (140–142). The populations are therefore highly homozygous throughout much of the genome (143, 144).

A recent high-quality assembly of the genome of *M. lychnidis-dioicae* has revealed that bipolarity and mating-type chromosome dimorphism are due to the linkage of the *P/R* and *HD* loci in a very large region of suppressed recombination (145, 146). The centromere is also located in the nonrecombining region (145), which leads to the segregation of mating types in the first meiotic division. The mating-type chromosomes of *M. lychnidis-dioicae* thus do not recombine across 90% of their lengths (a_1, 3.5 mega-base pairs [Mbp]; a_2, 4.0 Mbp), with only small pseudo-autosomal regions at both edges that recombine. The nonrecombining

region is highly rearranged, with at least 210 inversion events. As expected due to the less efficient selection in genomic regions without recombination (147), the cessation of recombination has led to genomic degeneration, with accumulation of transposable elements, nonsynonymous substitutions, biased gene expression, and the hemizygous loss of hundreds of genes (145, 148).

Most other anther-smut fungi are bipolar with dimorphic mating-type chromosomes that also show degeneration (148); one clade has recently been found to have a tetrapolar breeding system: in particular, *Microbotryum saponariae* and *Microbotryum lagerheimii*, which parasitize, respectively, *Saponaria officinalis* and *Silene vulgaris* (73). In these closely related species, the two *MAT* loci segregate independently, being located on different chromosomes, but are linked to their respective centromeres (73). This situation may have resulted from a reversion from bipolarity to tetrapolarity or from the independent evolution of the linkage of *MAT* loci under automixis in the other lineages. Indeed, both bipolarity with linkage to the centromere, as in *M. lychnidis-dioicae*, and linkage of both *MAT* loci to their respective centromeres on different chromosomes, as in *M. saponariae*, are equally favorable under automixis in anther-smut fungi (73, 145).

Transition to bipolarity through loss of function of the *P/R* genes in mating-type determination

It is not surprising that changes in the configuration of the *MAT* loci can alter the mating behavior of individuals, sometimes resulting in transitions between different breeding systems. For example, in tetrapolar heterothallic species, the *HD* locus encodes genes that heterodimerize during mating to form active transcription regulators, ensuring the proper development following syngamy. However, the heterodimer can only form between HD1 and HD2 proteins derived from different alleles. Thus, if recombination occurs between the *HD1* and *HD2* genes resulting in bringing together compatible *HD1* and *HD2* alleles on the same chromosome, a haploid individual bearing this novel *HD* genotype pair would transition from compatibility determined by two sequential compatibility checkpoints (*P/R* and *HD*) to a single mechanism (*P/R*) inherited in a bipolar manner. This newly formed *HD* allele could also be the first step in a transition from heterothallism to homothallism provided that compatible pheromones and receptors are brought together at the *P/R* locus in a subsequent event. Examples of these types of transition have been reported in *C. cinerea*, where fusion of the *HD1* and *HD2* genes from different subunits results in self-compatibility and constitutive sexual development (149). Alternatively, mutations in a pheromone receptor gene in *C. cinerea* resulted in a receptor that was either constitutively activated (150) or that responded erroneously to a normally incompatible pheromone encoded within the same allele (151), removing its function in mating-type determination.

Studies of several other Agaricomycetes, including *Coprinellus disseminatus* (152), *Pholiota microspora* (153, 154), *P. chrysosporium* (94), and *Heterobasidion irregulare* (155), have shown that a transition from a tetrapolar to a bipolar breeding system was indeed due to the uncoupling of the *P/R* from mating-type-determining functions. These bipolar species retained nonetheless a multiallelic *HD* locus, with the number of alleles defining the number of mating types (e.g., ~123 mating types are estimated for *C. disseminatus*) (16, 152). Therefore, a new mating type will arise as soon as a novel *HD* allele is generated. However, evolving novel *HD* alleles that are still able to heterodimerize with extant alleles, while restricting self-activation, will become increasingly challenging (156). Compared to tetrapolar multiallelic species such as *C. cinerea* and *S. commune*, and assuming that *HD* alleles are found at equal frequency in the population, the probability of randomly chosen individuals being compatible in an outcrossing event is theoretically greater in bipolar multiallelic species: only a single locus needs to be compatible, rather than two in the tetrapolar situation (16). Furthermore, considering that mating in mushroom-forming fungi is preceded by basidiospore (meiospore) dispersal, outcrossing rather than selfing is more likely to occur (16, 61). Therefore, and because mating-type compatibility is not discriminated prior to syngamy, the costs of landing on an incompatible mate are in this case very high. It can thus be easily envisaged that mutations at the *P/R* locus causing loss of function in mating-type determination may have been selected for, in some circumstances, because the chance of compatibility would be greatly increased, and there is no selective pressure anymore to restrict inbreeding, which is already avoided by gamete dispersal.

Homothallism in the Basidiomycota

In some fungal species, haploid cells are universally compatible for mating, including among clonemates (a.k.a. intrahaploid mating, same-clone mating, or haploid selfing) (15, 79, 156). We call these species homothallic, and several proximal mechanisms have been proposed to account for such mating behavior: (i) the presence of compatible sets of *MAT* genes, either fused or unlinked, in one haploid genome (primary homothal-

lism), (ii) mating-type switching (either bidirectional or unidirectional), and (iii) the lack of any gene-based mating-type discrimination (also known as the ability for unisexual reproduction or same-sex mating) (reviewed in 157, 158). Some other fungal species, referred to as pseudohomothallic, also have the ability to complete the sexual cycle without the apparent need for syngamy (159–161). However, pseudohomothallism is achieved by packaging two nuclei of compatible mating types derived from the same meiosis into a single spore. This process is thus more similar to diploid selfing via automixis or intratetrad mating and has different genetic consequences compared to intrahaploid mating (79, 162).

Homothallism is present in three main fungal lineages (the phyla Mucoromycota, Ascomycota, and Basidiomycota), indicating that this form of sexual behavior may provide a selective advantage under certain conditions, for instance, by promoting universal compatibility (79, 162). Compared to other phyla, however, homothallic basidiomycete species are less common. Whether this relates to the complex genetic underpinnings of the mating system in this phylum, as described above, or is because they can more easily evolve multiple alleles, allowing high frequencies of mating compatibility, is still an unresolved matter. Primary homothallism has been proposed for a handful of species in the Basidiomycota, most notably *Sistotrema brinkmannii* (163), in which homothallic and bipolar heterothallic individuals are found in the same population, and for the cacao pathogen *Moniliophtora perniciosa* (164). A partial genome sequence is only available for the latter species, which upon examination revealed various genes for putative pheromones and receptors and one or possibly two *HD1* genes (165), but their genomic organization as well as their function during the sexual cycle remain undetermined. We present below details of two basidiomycete species for which there has been progress in understanding the genetic basis of homothallism.

Homothallic breeding system of *Phaffia rhodozyma*

Recently, inspection of the genomes of three strains of the homothallic yeast *P. rhodozyma*, belonging to the order Cystofilobasidiales (Fig. 2) (166), revealed the presence of pheromone precursor and receptor genes organized in two gene clusters, located ~5 kb apart. Each cluster was composed of one pheromone and one pheromone receptor gene (either *MFA1/STE3-1* or *MFA2/STE3-2*; Fig. 3A) (167). In contrast, a single *HD1/HD2* gene pair was found in the genome that was not linked to the *P/R* locus (Fig. 2) (167). In elucidating the molecular interactions involved in mating compatibility in *P. rhodozyma*, David-Palma et al. (168) pursued targeted gene replacement of the *MAT* genes and genetic crosses using single, double, and triple mutants (168). They determined that both *P/R* gene clusters produced intercompatible gene products, enabling self-signaling, and each pheromone only interacted with the receptor of the other cluster (i.e., Mfa1 activates Ste3-2 and Mfa2 activates Ste3-1; Fig. 3A). Additionally, the single pair of HD1 and HD2 homeodomain proteins was also shown to be required and apparently cooperated for normal completion of the sexual cycle (168).

Even though the genetic makeup of *MAT* loci in *P. rhodozyma* is suggestive of primary homothallism, David-Palma et al. (168) pointed out why this configuration departs in several aspects from what would be expected from simply gathering in a haploid genome the intercompatible alleles of *MAT* genes. First, although the two pheromone receptor genes exhibited considerable sequence similarity (~50% amino acid identity), phylogenetic analyses indicated that they were more closely related to each other than to receptor genes in other species, and both seemed to derive from the *MATα/A1*-related allele lineage (Fig. 4). This indicates that the two pheromone receptor genes in *Phaffia* have diverged much more recently than in most basidiomycetes (possibly coalescing within the genus) (M. David-Palma, personal communication), and the extant arrangement may be the result of fusion of two mating-type variants. The second aspect concerns the *HD* genes, in that only one *HD1/HD2* pair is present, but both proteins are required for sexual development. Based on evidence of a very weak interaction between the two *HD* proteins in a yeast two-hybrid assay (168), it was proposed that at the generation of a compatible HD1/HD2 pair within the haploid genome there would need to be one or more mutations relaxing the structural hindrance that normally prevents interactions between HD proteins encoded by the same locus in heterothallic species (168). Similar investigations are currently under way in other species of the Cystofilobasidiales to reconstruct the evolutionary transitions in breeding systems in this lineage (M. David-Palma, personal communication).

Homothallism in *C. neoformans*

While most homothallic species can initiate sexual reproduction through fusion with any other haploid cell, including clonemates, they do so through the presence of two intercompatible mating alleles within a haploid genome. In the human pathogenic fungus *C. neoformans*, the proximal mechanism for homothallism is

different because it concerns haploid cells with a single mating-type allele in their genome (169). Specifically, while *C. neoformans* has a bipolar breeding system in which mating typically occurs between *MAT***a** and *MAT*α cells, it has been found that, in response to nutrient limitation, *MAT*α cells can also complete the sexual cycle in the absence of *MAT***a** cells (169). The α-α diploid state can be established through either (i) cellular and nuclear fusion of two clonemates, (ii) nuclear fusion between mother and daughter nuclei, (iii) endoreplication of the entire genome of a single cell resulting in a diploid nucleus, or (iv) fusion of cells of the same mating type but of different genetic lineages (169). While the first three pathways represent different ways to achieve same-clone mating (haploid selfing), the latter enables outcrossing and thus the possibility to admix genetic diversity despite identical cell-type identity of the mating partners. In all cases, the resulting diploid cell undergoes monokaryotic filamentation and subsequent basidium formation, where meiosis takes place to produce the haploid spores as in the heterothallic mating cycle (Fig. 1C).

Importantly, recent studies using this model basidiomycete have shown that α-α mating between genetically identical cells can generate phenotypic and genotypic diversity *de novo*, including single-nucleotide polymorphisms (less frequently), chromosomal translocations, and aneuploidy (more frequently) which, although usually likely deleterious, may rarely provide a beneficial novelty (170). Moreover, crossovers have also been detected within the *MAT* locus during meiosis of genotypes resulting from α-α mating (129), presumably because the two *MAT*α alleles are colinear, unlike **a**-α combinations (130). It should be pointed out that among the *C. neoformans* natural isolates, the vast majority (up to >99%) are of the α mating type (171). Thus, α-α mating could be beneficial when a compatible mating partner for a heterothallic cross is hard to find in nature. In turn, it is also possible that α-α mating played a role in generating the highly imbalanced mating-type ratio observed among natural isolates. Recently, this type of homothallism determinism has also been identified in the human pathogen *Candida albicans* (172, 173) as well as in the tree wound-infecting fungus *Huntiella moniliformis* (174), suggesting that it could be more prevalent among fungal species than is currently appreciated.

Evolutionary considerations on the costs of homothallism

Although it has been traditionally accepted among mycologists that homothallism evolved to promote same-clone mating (170, 175), it is important to point out that the potential for same-clone mating of a species as assessed in a laboratory setting does not imply that this is the prevalent mating system of the species in nature. Moreover, the sexual cycle involving clonemates does not result in actual recombination, the supposedly main advantage of sexual reproduction (176), while still incurring some costs (e.g., slower reproduction and maintenance of the meiotic machinery). Same-clone mating is less efficient at purging deleterious mutations: homologous chromosomes carrying different deleterious mutations that occurred in a given large clonal lineage can of course be recombined and produce a chromosome free of deleterious mutations (177), but this constitutes more outcrossing (i.e., mating between two different genotypes) than same-clone mating *per se*. Besides, in a population undergoing only same-clone mating, different deleterious mutations that are fixed by genetic drift in distinct clonal lineages cannot be eliminated from the populations, and Muller's ratchet will inexorably lower population fitness (133). Furthermore, same-clone mating cannot bring together different beneficial mutations that evolved in distinct clonal lineages (Hill-Robertson interference). A transition to asexuality would bypass some of the costs of sex while producing haploid progeny that are genetically the same as the participants in same-clone mating.

Homothallism has been suggested instead to have evolved due to the selective advantage of increasing the number of available mates, because it can be seen as a universal compatibility (15, 79). The frequency of outcrossing in homothallic species under experimental conditions of mate choice has rarely been explored, but outcrossing has still been shown to occur in some homothallic fungi (178, 179). Homothallism would therefore be advantageous through universal compatibility under outcrossing. However, given that same-clone mating incurs costs of sex without some of the major benefits of recombination, heterothallism may be favored by selection for increasing the chance to produce recombinant offspring when there is limited haploid dispersal (15, 79). Nevertheless, same-clone mating may allow a benefit from indirect advantages of the sexual cycle without breaking apart beneficial allelic combinations (180, 181). Such advantages include the production of resistant sexual spores as a life history constraint, changes in ploidy level and physiology, virus elimination, and genome defenses that depend on the sexual cycle, such as repeat-induced point mutation (182) or meiotic silencing of unpaired DNA (183). Recent studies also showed that same-clone mating can generate *de novo* mutations and new beneficial phenotypes (170).

New Genome Sequencing Projects: What Can They Tell Us about *MAT* Gene Structure and Evolution?

With the exponential growth of data resulting from several large-scale genomics initiatives, such as the 1000 Fungal Genomes Project at the Joint Genome Institute (184) and the Fungal Genome Initiative at the Broad Institute (185), it is now possible to identify and compare the genomic organization of *MAT* genes across many fungal species. For example, genome surveys allowed the detection of *P/R* and *HD* genes in important plant pathogens with complex life cycles, such as the rust fungi (Pucciniales, Pucciniomycotina; Fig. 3B) (40, 186). Indeed, because many rust species are macrocyclic (i.e., completing their sexual stage on a different and sometimes obscure or unknown alternative host plant) and sometimes unculturable, sexual compatibility has been very difficult to study. Some reports have shed light on possible breeding systems: several *Puccinia* and *Uromyces* spp. may have a simple bipolar system (187), whereas a more complicated tetrapolar system with multiple allelic specificities may be present in *Melampsora lini* (188) and the related oat crown rust pathogen, *Puccinia coronata* (189). Whether these and other species have bi- or multiallelic *MAT* loci remains unknown, but new insight is now arising from different fungal genome sequencing initiatives.

In a recent study, several new wheat rust *Puccinia* spp. genomes were analyzed for the presence of mating-type genes (186). In three cereal-infecting rust fungi (*Puccinia triticina* [*Pt*], *Puccinia graminis* f.sp. *tritici*, and *Puccinia striiformis* f.sp. *tritici*), one divergently transcribed *HD1/HD2* gene pair was found, reminiscent of the organization in other basidiomycetes; two alleles of each were present in the dikaryotic urediniospores, which is the cell type produced upon mating. Preliminary analyses of multiple genome sequences allude to the presence of more than two alleles in nature (G. B., unpublished). Three homologs for the pheromone receptor (Ste3) were identified in the dikaryotic urediniospores. Phylogenetic analysis, comparing Ste3 proteins from various rusts and other basidiomycetes, revealed that one *STE3* gene (*PtSTE3.2-1*) was present in two allelic forms, whereas the other two (*PtSTE3.2-2* and *PtSTE3.2-3*) likely represented the two mating specificities, one in each haplotype genome (186) (Fig. 3B and Fig. 4). This was substantiated by revealing many more single-nucleotide polymorphisms in *STE3.2-1* homologs in *P. triticina*, *P. graminis* f.sp. *tritici*, and *P. striiformis* f.sp. *tritici* among several sequenced genomes; the conclusion, also based on differential expression in various life cycle stages, is that this gene may represent a novel function (186), suggesting that *MAT* pathway components may be repurposed. In further support, a pheromone precursor gene (*PtMFA2*) was identified 650 bp from *PtSTE3.2-2*, divergently transcribed as found, e.g., in the *P/R a2* locus of *U. maydis*. However, the current rather fragmented *Puccinia* genomes did not allow for further conclusions about the possible physical linkage of the *HD* and *P/R* gene complexes to constitute a bipolar arrangement, but based on the current assembly and some mapping data in *P. triticina*, these loci are at least 216 kb apart (186). Current developments of single-molecule sequencing by Pacific Biosciences, focusing on generating very long kb-sized reads, are expected to improve these genome assemblies in the near future.

CONCLUSIONS

The basidiomycete fungi have been found to undertake nearly every permutation of reproductive compatibility mechanisms, and the recent literature reviewed here illustrates that the high diversity at mating compatibility loci has remained for several decades "the most challenging problem in the control of [their] sexuality" (190). The advent of inexpensive molecular tools now provides access to genetic information in a broader range of nonmodel species, including at the population-genomic level, so that more comprehensive databases are being assembled. Such surveys shed light on the generalities of what *does* happen in nature, beyond our glimpses and speculations into what *can* happen in exceptional cases (vis-à-vis reference 191). Just as importantly, the large-scale comparative approaches that derive from improved resolution of phylogenomic techniques (192) may provide new understanding of the ecological and evolutionary forces responsible for transitions in breeding systems and underlying genetic determinants. Fungi thus provide rich opportunities for the match of tractable study systems with questions pertaining to sexual life histories as a defining characteristic retained among diverse eukaryotic lineages.

GLOSSARY OF TERMS

Anisogamy: Situation in a species with two classes of gamete sizes—one class of large gametes (female function) and one class of small gametes (male function); a single genotype can produce both types of gametes in most anisogamous fungi, so that there are no different sexes.

Automixis: A form of diploid selfing resulting from the fusion among products of a single meiosis (i.e., intratetrad mating).

Bipolarity: Breeding system with a single locus controlling mating type; it is often associated with only two alleles in fungi.

Breeding system: Mechanism determining reproductive compatibility, i.e., with no mating type (homothallism) or mating types determined by one locus (bipolar) or with two independent loci (tetrapolar); it is important to distinguish the breeding system from the mating system, because, even if they likely coevolved, the understanding of their relationships and their evolutionary implications can only be precisely achieved by recognizing that they refer to different concepts (15, 17).

Clonemates: Cells with identical genotypes resulting from clonal division of a mother cell.

Diploid selfing: Mating among meiotic products from a single diploid individual.

Haploid selfing (or same-clone mating, intrahaploid mating): Mating among haploid clonemates.

Heterothallism: Situation in which a given haploid genotype can only mate with another haploid genotype carrying a different allele at the mating-type locus (loci). It is important to distinguish the terms "heterothallism" and "self-sterility," the latter usually being used to refer to the inability of diploid selfing rather than haploid selfing in the scientific literature, which have very different evolutionary consequences. Even in fungi, many heterothallic species can undergo selfing (e.g., *Microbotryum* anther smuts; Fig. 1).

Hill-Robertson interference (named after the two scientists who first proposed the concept): A phenomenon referring to less efficient selection because of linkage disequilibria (generated either by drift or in a clonal population); for example, in the case of beneficial mutations appearing in different individuals at two different genes in linkage disequilibrium, selection can only fix one of the two.

Homeodomain protein: Protein that harbors a characteristic approximately 60-amino acid helical protein-folding structure, highly conserved among eukaryotes, that binds DNA at so-called conserved homeobox sequences of about 180 bp and often regulates transcription of other sets of genes; in basidiomycetes, these transcription factors control a set of genes involved in the mating process, including morphological changes. The term "homeo" refers to the term "homeosis designing," the replacement of a body part by another body part in animals, as can occur when transcription factors are affected by mutations.

Homothallism: Situation in which a haploid genotype can mate with any other haploid genotype in the population, including its clonemates; homothallism is typically assessed by the ability of a haploid genotype to produce sexual structures alone in a petri dish; however, it is important to recognize that it does not inform on the mating system actually occurring in natural populations. It is also important to distinguish the terms "homothallism" and "self-fertility," the latter usually being used in the scientific literature to refer to the ability of diploid selfing rather than haploid selfing, which have very different evolutionary consequences. Using "self-fertility" for "homothallism" can only lead to confusion in the actual phenomenon that is referred to and therefore in the understanding of concepts and evolution and breeding and mating systems.

Inbreeding: Mating occurring among related individuals.

Isogamy: Situation in a species in which all gametes have similar sizes.

Karyogamy: Fusion of haploid nuclei following mating.

Mating system: The pairing of mating participants in nature, considering their genetic relatedness, i.e., outcrossing versus inbreeding or selfing (and either haploid or diploid selfing).

Mating types: Different types of individuals or gametes in the population, with gametes of similar sizes, but mating compatibility being usually determined by the exchange of molecular signals and being possible only between different mating types. It is important to distinguish sexes from mating types because the evolutionary causes of their evolution and their evolutionary consequences are very different (15).

Muller's ratchet (proposed by Hermann Joseph Muller): A process in which the chromosomes of asexual populations accumulate inexorably deleterious mutations where the lack of recombination prevents regenerating chromosomes free of deleterious mutation from two homologous chromosomes carrying different deleterious mutations.

Outcrossing: Mating among different genotypes, usually unrelated individuals.

Selfing: Mating among meiotic products from the individual; used in the broader literature to mean "diploid selfing." See Diploid selfing, Haploid selfing.

Sexes: Different types of individuals in the population, one type producing large gametes (females) and the other type producing small gametes (males).

Syngamy: Haploid cell fusion during mating.

Tetrapolarity: Breeding system with two unlinked loci controlling mating type; it is often associated with multiple alleles in fungi.

Fungal Sex: The Mucoromycota

8

Soo Chan Lee[1] and Alexander Idnurm[2]

INTRODUCTION TO THE MUCOROMYCOTA

The Mucoromycota is a newly formalized phylum of fungi that are one of what are sometimes considered the basal lineages in the fungi (1). These species have undergone a different evolutionary trajectory than the Ascomycetes and Basidiomycetes. Generally, the species are difficult to develop into experimental models, but despite this our understanding of mating and sex in the fungi overall has been punctuated with major discoveries being made in this lineage.

In the conventional four-phylum classification, the fungal kingdom included Ascomycota, Basidiomycota, Zygomycota, and Chytridiomycota. The two dikaryon lineages, Ascomycota and Basidiomycota, are monophyletic; on the other hand, the early-diverged and basal fungal lineages Zygomycota and Chytridiomycota (2, 3) were found to be polyphyletic (4, 5). Recent further classification appreciates that within the previous Zygomycota clade, there are two distinct phyla, Mucoromycota and Zoopagomycota (Fig. 1). The class Glomeromycotina—which, judging from the arbuscular mycorrhizal interactions with plants, had been considered an independent phylum—now has been placed within the phylum Mucoromycota, which further includes the classes of Mucoromycotina and Mortierellomycotina (1). The Zoopagomycota include the classes of Entomophthoromycotina, Kickxellomycotina, and Zoopagomycotina. Our current knowledge of sexual development is largely limited to the fungi belonging to the order Mucorales. This chapter, therefore, mainly covers sexual development in Mucorales (13 families, 56 genera, 300 species [6]) (Fig. 2), with a focus on the research from the past decade.

The Mucorales species have been important for a number of reasons, as has been pointed out in previous reviews (7–9). First, it was from research into this group that the first proposal that sex occurred in fungal species was made, for the species *Syzygites megalocarpus* (10). The name "zygospore," hence the common use of the terms "zygomycete" or "Zygomycota," was chosen by de Bary to describe these sexual spores from *S. megalocarpus* (11). Zygospores are the sexual spores formed in these species, and they range up to several millimeters in diameter such that they are visible to the naked eye (Fig. 2). However, higher resolution using scanning electron microscopy reveals that they often have intricate decorations on their surfaces. The second major contribution from the Mucorales was the concepts of heterothallism and homothallism, which were developed based on these species (12). Despite these contributions, mating in these species was not studied as well as it was in the Dikarya, and in some cases was almost forgotten. For instance, the revision of the International Code of Botanical Nomenclature into the International Code of Nomenclature in Melbourne in 2011 aimed to remove the dual naming system for the anamorphic and teleomorphic forms of fungi; however, the new article 59 is specific only to the Ascomycetes and Basidiomycetes. The anamorph of *S. megalocarpus* is named *Sporodinia grandis* (13), so it is ironic that the first teleomorphic fungus still has two names.

STRUCTURE AND GENE CONTENT OF THE *sex/MAT* LOCUS

Sexual reproduction is orchestrated by the mating type (*MAT*) or *sex* locus that is a small region of the fungal genome. Approaches using genetic linkage maps for *Phycomyces blakesleeanus* demonstrated that the sex trait was linked to the *madE* gene and the *lysA* gene (14, 15). This suggested that the sex determination system was encoded by a single, and likely small, part of the genome.

[1]South Texas Center for Emerging Infectious Diseases (STCEID), Department of Biology, University of Texas at San Antonio, San Antonio, TX 78249; [2]School of BioSciences, University of Melbourne, Parkville 3010 VIC, Australia.

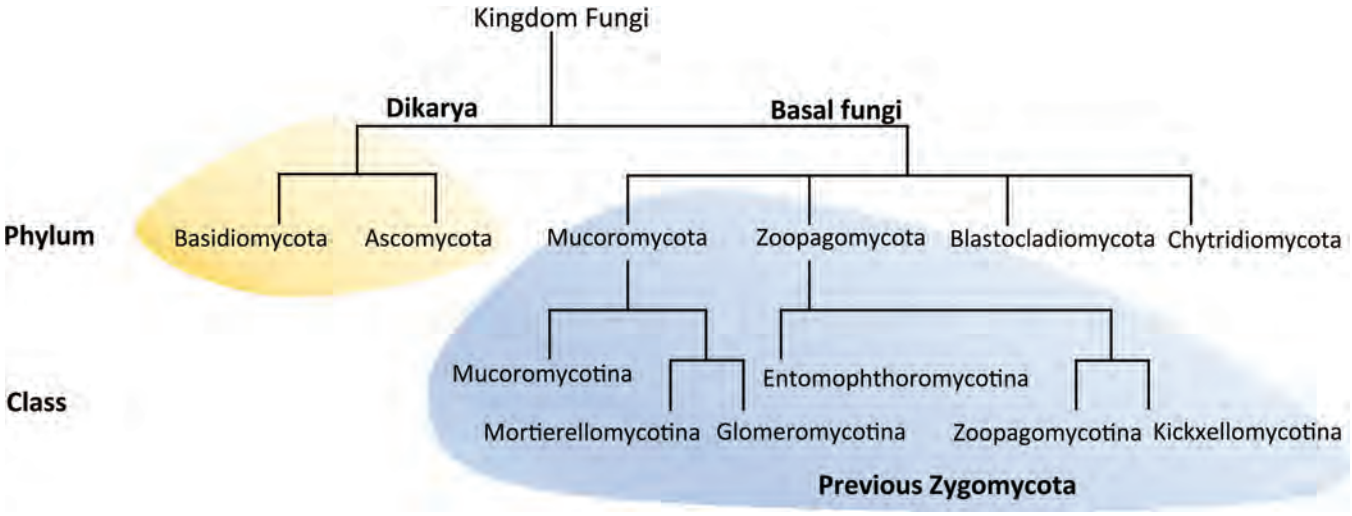

Figure 1 A tree of the fungal kingdom. The previous phylum Zygomycota is polyphyletic and further classified into two phyla, according to Spatafora et al. (1). The phylum Mucoromycota includes the classes Mucoromycotina, Mortierellomycotina, and Glomeromycotina, and the phylum Zoopagomycota includes the classes Entomophthoromycotina, Zoopagomycotina, and Kickxellomycotina.

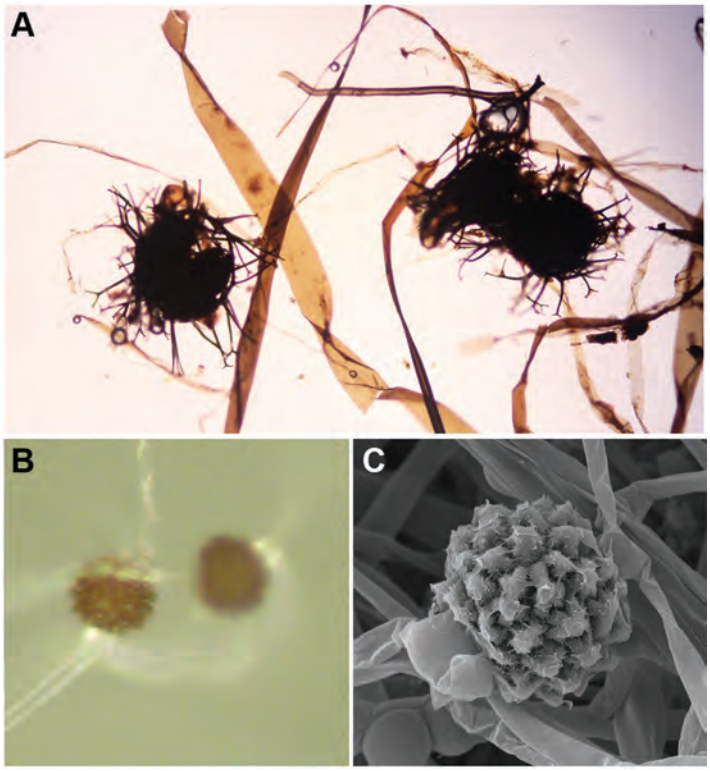

Figure 2 Images of the sexual zygospores produced by species in the order Mucorales. (**A**) Three remnants of zygospores of *P. blakesleeanus* isolated from an environmental sample from Florida, 2014. The long ribbon structures are desiccated asexual sporangiophores. When two mating types of *M. circinelloides* are cocultured in dark conditions, zygospores are formed. (**B**) Light microscopy of two zygospores of *M. circinelloides* and (**C**) scanning electron micrograph of an *M. circinelloides* zygospore.

A seminal study identified the *sex* locus in *P. blakesleeanus* by searching genome sequencing information for possible candidates that may encode either homeodomain or high-mobility group (HMG) types of transcription factors, because these are encoded within the *MAT* loci in the Dikarya (16). The genes discovered encode putative HMG transcription factors, SexP and SexM in (+) and (–) mating types, respectively. The *sexP* and *sexM* genes are idiomorphic, and the sequences of the genes diverge, yet both encode an HMG transcription factor. In both mating types, the *sexP*/*sexM* genes are flanked by conserved genes that encode a putative triose phosphate transporter (TptA) and an RNA helicase (RnhA) (Fig. 3).

Several lines of evidence indicate that this region is a bona fide *sex* locus that represents sexual identity (mating type) and controls sexual development in *P. blakesleeanus* (16). First, any haploid strain contains either the *sexP* or *sexM* gene in the genome, and only mating conditions (cocultures of two mating types) induce the expression of both *sexP* and *sexM* genes and then formation of zygospores. Second, strains containing the *sexP* gene only mate with (–) mating types and strains with the *sexM* gene only mate with (+) mating types, the progeny from crosses with *sexP* or *sexM* segregate 1:1, and no mating occurs between two strains with the same mating type. Third, aneuploid strains that are disomic for the *sexP* and *sexM* genes appear to be self-fertile and produce the initial structures for mating. Finding similar regions that are associated with sexual identity and mating in the genomes of two other Mucorales species, *Mucor circinelloides* and *Rhizopus delemar*, provides additional support that *sexP* and *sexM* are the key regulators of sexual development (17, 18). *P. blakesleeanus* cannot be stably transformed with DNA constructs (19), and thus the roles of *sexM* and *sexP* in mating could not be tested by gene disruption. The disruption of the *sexM* gene in *M. circinelloides* results in loss of fertility in the mutants in mating with (+) mating type cells (and no mating was observed with [–] mating type cells), providing gene functional evidence for the role of the *sex* genes in sexual development in Mucorales (20). Taken together, an arrangement of idiomorphic DNA with either the *sexP* or *sexM* gene, flanked by the *tptA* and *rnhA* genes, clearly represents the *sex* locus in at least three species of Mucorales.

The two *sex* genes differ in sequence and in size between the two mating types; for example, the *sexP* genes of Mucorales are 958 ± 24 bp, and the *sexM* genes are 668 ± 69 bp (the average size of the *sex* genes in *Phycomyces nitens*, *P. blakesleeanus*, *M. circinelloides*, and *Blakeslea trispora*) (21). Currently known *sexM* genes from Mucorales fungi are convergently transcribed with the flanking *rnhA* gene, and the *sexP* genes are also transcribed in a similar way with an exception in the two *Phycomyces* species, where the *sexP* gene is transcribed in an opposite way with the *rnhA* gene (Fig. 3). This observation may indicate that a gene inversion in the *sexM* gene, the *sexP* gene, or both occurred during species evolution in Mucorales. The consensus sequence of a transcription factor binding site, GATCxxxxAxCCAAT, where x is any nucleotide, is observed in the upstream of all known *sexP* genes (21, 22), but what that hypothetical factor might be is unknown.

Although the gene arrangement (*tptA*/*sex*/*rnhA*) associated with the *sex* locus is common in the Mucorales, notable differences have been observed. As mentioned above, the *sexP* gene in *P. blakesleeanus* is divergently transcribed to the *rnhA* gene, unlike other Mucorales, in which the *sexP* genes are convergently transcribed. In addition, the (+) *sex* locus of *P. blakesleeanus* contains a repetitive element in the intergenic space between the *sexP* and *rnhA* genes. The locus in *P. nitens* appears to either have expanded in size or undergone some rearrangement, likely through addition of repetitive element DNA, and it was not possible to join the two *tptA* and *rnhA* regions together by sequencing (21), although they are linked in genetic crosses (A. Idnurm, unpublished data). The (+) *sex* loci of *R. delemar* and *Rhizopus oryzae* additionally contain a gene (*arbA*) encoding a BTB/ankyrin/RCC1 domain protein between the *tptA* and *sexP* genes. Interestingly, in the homothallic species *S. megalocarpus*, the equivalent of the original (–) *sex* locus contains the additional *arbA* gene between *tptA* and *rnhA*. The *S. megalocarpus sex* locus expands to the 5′ part of the *rnhA* gene, while the *rnhA* genes in the other Mucorales species are not part of the idiomorphic *sex* locus. In the *sex* loci of both mating types in *R. oryzae*, *R. delemar*, and *S. megalocarpus*, the direction of transcription of the *tptA* gene is opposite to that of the *tptA* gene in *M. circinelloides*, *B. trispora*, and *Phycomyces* species, suggesting a possibility of another gene inversion in the *tptA* locus during species evolution in Mucorales. Exploring the synteny around the *sex* locus further than *tptA* and *rnhA* reveals additional genes that are conserved between some species. These include the *algL* and *glrA* genes, which encode a predicted alginate lyase and glutathione reductase, respectively. These genes may be valuable additional starting points to identify candidate *sex* loci in the genomes of other Mucorales species.

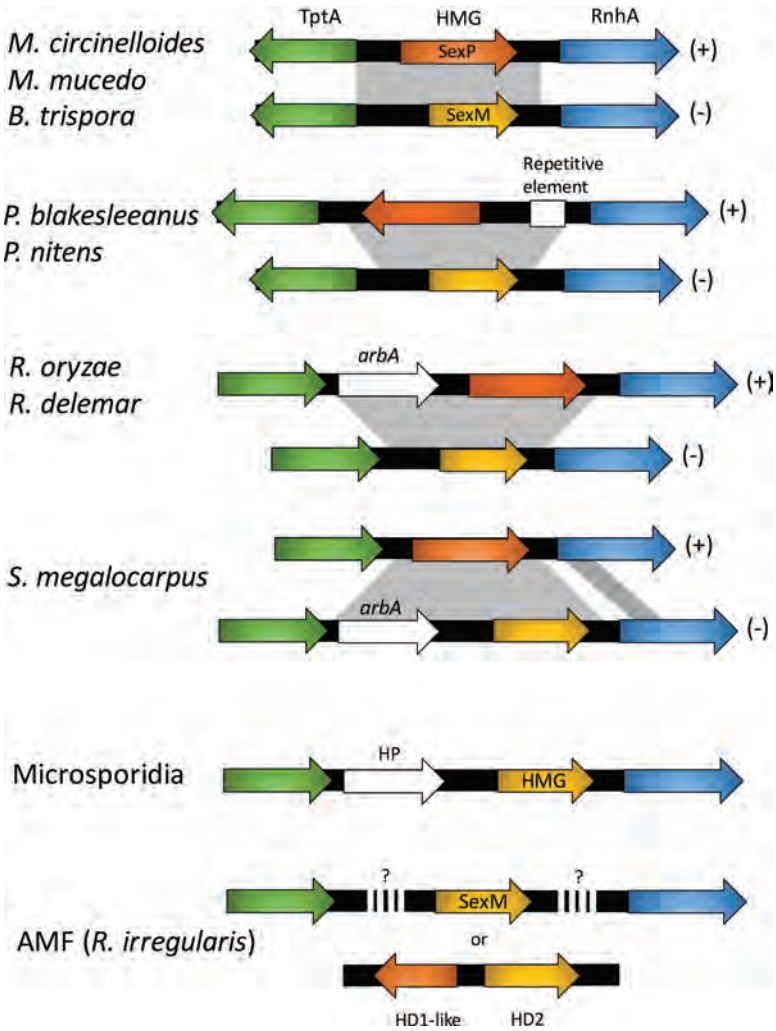

Figure 3 Alignments of genes within or adjacent to the *MAT*/*sex* loci in species of Mucorales, arbuscular mycorrhizal fungi, and microsporidia. Genes encoding allelic or idiomorphic HMG transcription factors, SexP and SexM in (+) and (–) mating types, are flanked by genes encoding a putative triose phosphate transporter (TptA) and RNA helicase (RnhA). This gene cluster is commonly found in the *sex* locus of Mucorales. Although the gene synteny for TptA-SexP/M-RnhA is conserved, notable differences exist. Examples include differences in the direction of the *sexP* and/or *tptA* genes and in the integration of an additional open reading frame or repetitive element, and a level of expansion of the idiomorphic region, which implies expansion of the *sex* locus. Interestingly, microsporidian genomes contain a similar gene cluster for TptA/HMG/RnhA, which might be involved in sexual reproduction of these obligate intracellular eukaryotic pathogens. In the AMF *R. irregularis*, the homologous genes encoding TptA, HMG, and RNA helicase are found, although they are less likely to be linked as is seen in the *sex* locus of Mucorales. In addition, an HD1-like/HD2 gene cluster is encoded in the *R. irregularis* genome, and the two genes are divergently transcribed, which may represent a basidiomycete *MAT* locus-like *sex* locus, with divergently transcribed HD1/HD2 gene pairs.

ROLES OF THE SexM AND SexP HMG DOMAIN PROTEINS IN MATING

How SexM and SexP control the sexual process is currently unknown. Some clues may be available based upon the properties thus far elucidated for the genes and proteins that they encode. The *sexP* gene is expressed during vegetative growth and mating; on the other hand, the *sexM* transcripts are expressed during mating, as observed in *P. blakesleeanus*, *Mucor mucedo*, and *M. circinelloides* (16, 23, 22; S. C. Lee and J. Heitman, unpublished data). Supplementation of trisporic acid to the growing media during vegetative growth also induces the expression of *sexM* (22; Lee and Heitman, unpublished data). Mutation of the *car* genes that are required for the synthesis of the pheromones blocks the induction of the *sexM* and *sexP* genes (23). These observations suggest a connection between the *sex* genes and the pheromone trisporic acid (see below), although the direct connection has yet to be revealed.

There is the potential for an interaction between SexP and SexM to govern sexual development. It is possible that SexP and SexM may control the same set of genes required for mating, for instance, in which the two HMG proteins may form a heterodimer analogous to the homeodomain heterodimers observed in some Dikarya species. However, analysis of the *P. blakesleeanus* proteins in yeast two-hybrid assays failed to find evidence for heterodimerization (23). Alternatively, each SexP or SexM transcription factor may have its own separate target genes that are specific for mating. This would also be consistent with the specialization in functions between the (+) and (–) strains, which are discussed later. Further analysis is needed to define the mode of function of the SexP and SexM proteins.

An HMG transcription factor is also a sole sex determinant in multicellular eukaryotes including humans, in which the Sry HMG factor defines sexual identity (24). This observation supports the hypothesis that the early-diverged group of fungi shares a common ancestor with the metazoans, which is not shared with the Dikarya (2, 25). Mucorales, therefore, might represent an ancestral sexual recognition system that could shed light to help us understand the evolution of sex in metazoans as well as fungi. Indeed, the similarity along with characteristic differences in the *sex* loci in different Mucorales species, including gene inversions, additional gene integrations, and an integration of a repetitive element within the *sex* locus, is in accord with the hypothesis for the earliest steps in the evolution of sex chromosomes posited by Ohno (26).

Heterothallic fungi produce progeny of each mating type in a 1:1 ratio. However, in pathogenic fungi a skew in mating types in isolates from hosts is often observed, suggesting that mating loci may be involved in virulence and pathogenicity. For example, when *Mucor amphibiorum* infection spread among native Australian platypus and nonnative cane toads, an interestingly higher prevalence of (+) mating type was observed (27). The fact that the (+) mating type is more virulent in the toad mucormycosis model than the (–) mating type explains the biased mating types in *M. amphibiorum* isolates (27). Similarly, in the plant pathogenic *Mucor piriformis*, more (–) mating type isolates than (+) mating type isolates were observed in infected plants. Infections of host plants by (–) mating types resulted in larger lesions than did infections by (+) mating types under laboratory conditions (28). In the human pathogenic species *M. circinelloides*, (–) mating type isolates that produce larger spores were found to be more virulent than (+) mating type isolates that produce smaller spores in two different heterologous host models involving larvae of *Galleria mellonella* and zebra fish (20, 29). However, the (–) specific *sexM* mutants did not display a difference in spore size or virulence, suggesting that further investigation is needed to address the connection between mating type, spore size, and virulence in this fungus.

A discovery about the inheritance of organelle genomes and the role of sex determination was made in *P. blakesleeanus* through the analysis of the inheritance of the mitochondrial organelle (30). In *P. blakesleeanus*, strains of both mating type are identical in size and appearance and contribute equal amounts of cytoplasmic material into the equivalent of their gametes (isogamy). Despite this, the organelle genome is only inherited from the (+) mating partner. Other studies that have aimed to link uniparental inheritance of organelles to specific genes on sex chromosomes or mating type loci have been hampered by either large sex determining regions (e.g., the sex chromosomes in humans or the large *MAT* locus in the green alga *Chlamydomonas*) or dissimilar-sized gametes wherein one provides the bulk of the cytoplasm (anisogamy). In the case of *P. blakesleeanus*, the *sex* locus encodes a single gene. In addition, inheritance information from crosses between isogenic strains, identical except for mating type, provided the first definitive evidence that a gene that confers mating type (or gender) also controls cytoplasmic inheritance. Like other aspects of mating in the Mucorales, how mitochondrial inheritance is controlled by SexM or SexP (or both proteins) remains to be elucidated.

A second discovery of sex-specific functions is that the (+) *sex* senses light to inhibit mating, while light has

no effect on the (–) *sex* (23). From these two observations, it appears that the two sexes of *P. blakesleeanus* are specialized in their functions. There has been a long debate over the terms "mating type" or "sex" for fungi, with the argument being made that mating type is more suitable because few differences have been observed between mating types. However, these studies in *P. blakesleeanus* indicate that this argument would be worth reconsidering.

THE EVOLUTION OF HOMOTHALLISM FROM HETEROTHALLIC ANCESTORS VIA REARRANGEMENTS OF THE *sex* LOCUS

A fundamental concept of fungal sexual reproduction is the potential for a single genotype to be able to undergo sexual reproduction by itself versus the requirement of two genotypes, the latter system enforcing outcrossing. Species in which two parents are needed for mating to occur are termed "heterothallic," and those requiring only a single genotype are termed "homothallic." Defining these two mating systems was done with experiments on different members of the Mucorales (12).

One Mucorales species noted for its impact on understanding sexual reproduction in the fungi is *S. megalocarpus*. The mating type loci in this species were sequenced, starting from amplifying fragments with degenerate oligonucleotide primers designed to conserve regions in the *rnhA* and *tptA* genes on either side of *sexM* or *sexP*. Two regions of 20 and 25 kb were sequenced, revealing that this species contains copies of the homologs of both *sexM* and *sexP* within a single hypha (31). The nature of the adjacent genes, i.e., duplicated and then having undergone degradation into pseudogenes, suggests that the mechanism by which homothallism evolved in *S. megalocarpus* was through a duplication event of the *sex* locus in an ancestral heterothallic species. Perhaps most remarkable about the observations made of *S. megalocarpus* is that the equivalent type of arrangement of *MAT* locus genes had been observed to explain homothallism from heterothallic ancestors in ascomycete species, thus providing an example of convergent evolution impacting mating lifestyles in the fungi.

Other Mucorales species are homothallic, but at present the genes required for this process that could potentially explain why they have this reproductive lifestyle have not been characterized. There is an active ZyGoLife project involving the Joint Genome Institute to sequence the genomes of Mucorales species. Future characterization of the *sex* loci in these species should provide additional insight into the connection of evolution between heterothallic and homothallic reproductive strategies.

THE TRISPORIC ACID MATING PHEROMONES

"Sex pheromone" (Greek, *pherein*, meaning to convey, and English, *hormone*) refers to chemicals that are secreted from cells to trigger responses for sexual development in fungi, insects, and even some vertebrates and plants (32–35). In most ascomycetes and basidiomycetes, peptide pheromones, such as α factor or **a** factor mating pheromone for *Saccharomyces cerevisiae* or MF**a**1 or MFα1 pheromone in *Cryptococcus neoformans*, respectively, are involved in sexual recognition between two type cells (36, 37). The Mucorales fungi, unlike the Dikarya species, utilize a volatile organic molecule, trisporic acid, as their sex pheromone (38–40). The synthesis of trisporic acid is initiated from β-carotene in both mating types. To achieve higher amounts of trisporic acid production, both mating types of fungal cells should be in proximity. Sutter et al. revealed that a higher amount of trisporic acid was synthesized by the (+) mating type of *B. trispora* cells in the presence of M-factor that is specifically synthesized by the (–) mating type; similarly, when stimulated by P-factor from (+) mating type cells, (–) mating type cells produce more trisporic acid (41). The authors therefore proposed that the M-factor and P-factor serve as precursors of trisporic acid synthesis (41).

In heterothallic Mucorales, cooperation between two different mating type cells is required to produce trisporic acid (Fig. 4). Cleavage of β-carotene by an oxygenase (42–44) is an initial step in both mating types that results in production of 4-dihydrotrisporin. In the (–) mating type, the resulting 4-dihydrotrisporin is converted into trisporin and trisporol, and these two intermediate compounds need to be delivered into the opposite (+) mating type cells to complete synthesis of trisporic acid. On the other hand, in (+) mating type cells, 4-dihydromethyl trisporate is produced from 4-dihydrotrisporin that results from cleavage of β-carotene. Subsequently, 4-dihydromethyl trisporate is oxidized, producing methyltrisporate (45, 46). It is suggested that the conversion of 4-dihydromethyl trisporate into methyltrisporate is a (–) mating type-specific reaction (40). The enzyme 4-dihydromethyltrisporate dehydrogenase (TDH), encoded by the *tsp1* gene, mediates the conversion of 4-dihydromethyl trisporate into methyltrisporate, and this enzyme activity is differentially regulated in (+) and (–) mating types in *M. mucedo*

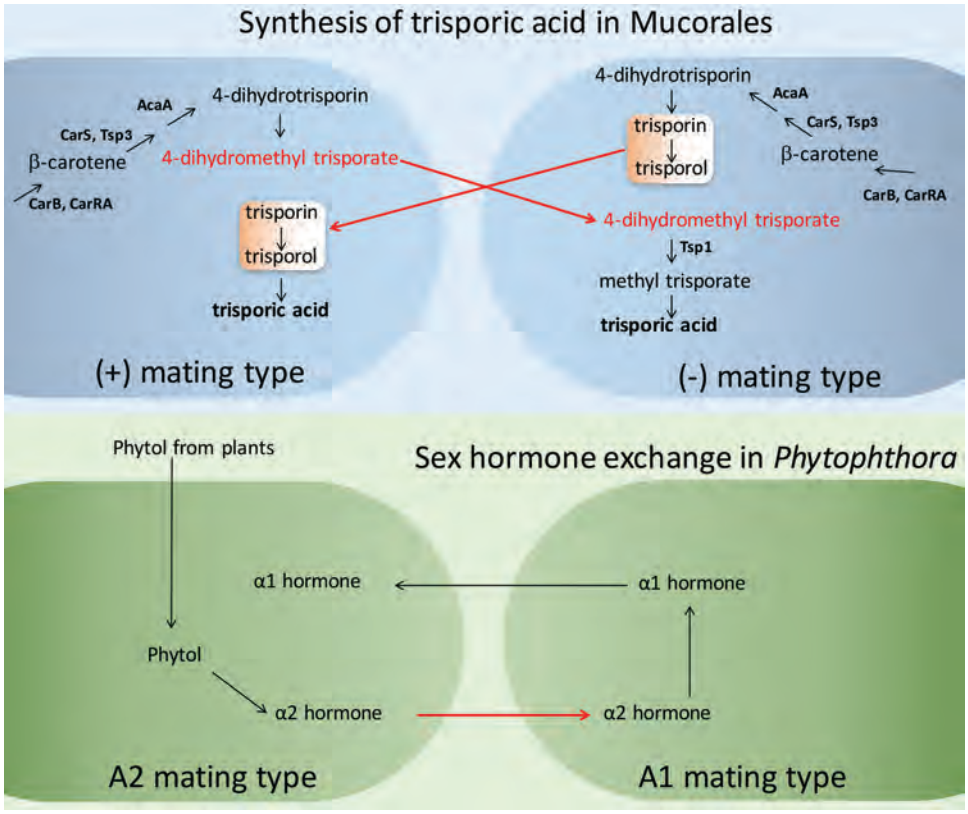

Figure 4 Diagram comparing pheromone processing steps in the Mucorales and the Oomycetes. Synthesis of β-carotene is an important step for production of trisporic acid, and two enzymes, CarB and CarRA, are among the enzymes known to be involved in this process. Synthesis of trisporic acid is initiated by enzymatic cleavage of β-carotene, which involves enzymes such as CarS, Tsp3, and AcaA. Remarkably, the intermediate products after β-carotene cleavage must be exchanged between cells of the two mating types to complete trisporic acid synthesis. For example, the 4-dihydromethyl trisporate in (+) mating type cells is delivered into (–) mating type cells and is converted by Tsp1 into methyl trisporate, and this is then further converted into trisporic acid. Two intermediate compounds, trisporin and trisporol in (–) mating type cells, are transferred into (+) mating cells and are finally converted into trisporic acid. Sex hormone synthesis in the Oomycete *Phytophthora* species is analogous to the inter-mating type collaboration to produce sexual pheromone trisporic acid in Mucorales. The α2 hormone is a sex hormone in the A2 mating type, and it is produced from phytol provided by plants. The α2 hormone, then, must be delivered into A1 mating type cells, where it serves as a precursor of α1 hormone synthesis.

(47). For example, TDH is only activated in sexually stimulated (–) mating type cells but not in nonstimulated (–) or (+) mating type hyphae, indicating that the conversion of 4-dihydromethyl trisporate into methyltrisporate only occurs in (–) mating type cells. Therefore, it is apparent that 4-dihydromethyl trisporate should be transferred from the (+) mating type cells into the (–) mating type cells to complete the synthesis of trisporic acid. Finally, trisporin and trisporol are converted into trisporic acid in (+) mating type cells, and methyltrisporate is converted into trisporic acid in (–) mating type cells.

Interestingly, the intercellular cooperation between two opposite mating types to produce sex pheromones is also observed in the evolutionarily distinct Oomycete lineage (48) (Fig. 4). Heterothallic *Phytophthora* species have two mating types, called A1 and A2, and mating occurs when both mating type cells are cocultured. The A1 mating type produces α1 hormone, and the A2 mating type produces α2 hormone during sexual development (49). The plant hormone phytol triggers the production of α2 hormone in the A2 mating type, and remarkably then the α2 hormone is transferred to A1 mating type cells and eventually converted into α1

hormone (50). Thus, the Mucorales belonging to the fungal kingdom in the Opisthokonts clade exhibit a convergent evolutionary trajectory in the cooperative synthesis of sex pheromone shared with *Phytophthora* species in the Oomycota in the Stramenopiles clade.

P. blakesleeanus mutants that are unable to synthesize β-carotene lack trisporic acid production and exhibit defects in sexual development (51). The β-carotene-deficient mutants, *carB*, *carR*, and *carA*, displayed abnormal sexual development even in unilateral crosses with wild-type opposite mating type cells, where the mating progress is not initiated or arrested in the early stage of zygophore formation without plasmogamy (cell fusion) between two opposite mating type cells (52). *carB* encodes a phytoene dehydrogenase that converts phytoene into lycopene, and *carR* encodes a lycopene cyclase that converts lycopene into β-carotene (53, 54). On the other hand, the *carA* mutant is leaky and has residual phytoene synthase activity that can still generate β-carotene, albeit in reduced amounts, and undergoes complete sexual development when unilaterally crossed with wild type to produce intact zygospores. However, the unilateral cross between *carA* and wild type still displays a biased formation of early sexual structures (52).

Oxidative cleavage of β-carotene is an essential first step to synthesize the pheromone trisporic acid. Gessler et al. demonstrated that degradation of β-carotene by enzymes extracted from the hyphae of *B. trispora* resulted in the production of β-apo-13-carotene. The resulting intermediate induces production of a larger amount of trisporic acid (55). This reaction is mediated by a carotene oxygenase, encoded by the *tsp3* gene, which was first identified in the *R. delemar* genome (25, 56). The *P. blakesleeanus* genome encodes five putative carotene cleavage oxygenase genes, two of which, designated *carS* and *acaA*, were found to be involved in β-carotene catalysis (43). The *carS* gene product cleaves β-carotene into β-apo-12-carotinal, and the AcaA protein further cleaves β-apo-12-carotinal into β-apo-13-carotenone. The *P. blakesleeanus carS* mutant therefore accumulated large amounts of uncatalyzed β-carotene and lacks apocarotenoids, resulting in both bright yellow pigmentation and defects in sexual development (44). The position of these cleavage steps with their origin in the β-carotene molecule is also supported by the isolation of breakdown products from β-carotene of lengths of 7, 15, and 18 carbons in mated cultures of *P. blakesleeanus* (57–59).

The *carRA* gene encodes an enzyme that has a dual activity of phytoene synthase and lycopene cyclase, and the CarRA enzyme is involved in biosynthesis of β-carotene (60, 61). The *B. trispora carRA* gene is constitutively expressed in the (+) mating type; however, the level of *carRA* mRNA is increased in the (–) mating type as vegetative growth progresses (160-fold increase at 144-hour pi). The *carRA* gene is also upregulated at an early stage of sexual development (25-fold at 48-hour coculture of both mating types); however, the expression of the gene is no longer elevated as coculture progresses. Thus, at the 144-hour point, in a (–) mating type mono-culture, the expression of the *carRA* gene is even higher than in (+) and (–) mating type coculture, indicating an even higher accumulation of β-carotene during vegetative growth.

The enzyme TDH is activated only in sexually stimulated (–) mating type hyphae, although the *tsp1* gene encoding TDH is constitutively expressed regardless of mating type and sexual or asexual development in *M. mucedo* (47). The regulation of TDH activity remains unknown; additional complexities include the presence of multiple copies in the genomes of some Mucorales and predicted differences in substrate binding sites and capabilities of dimerization (62). In *B. trispora*, the *tsp1* gene is downregulated as mating progresses, and there is no difference in the level of expression of the gene between mating and vegetative conditions (63). However, the *tsp3* gene, which encodes the carotenoid cleavage dioxygenase and is involved in the initial cleavage of β-carotene, is highly expressed, and its expression remains elevated during the coculture of two mating type cells of *B. trispora*. During vegetative growth, supplementation of the intermediates during production of trisporic acid from β-carotene induces the higher expression of *tsp3* in the (+) mating type compared to in the (–) mating type. Interestingly, there were differences in β-carotene production in the two Mucorales species, *B. trispora* and *M. mucedo*, in response to the supplementation of trisporic acid and its intermediates, indicating that species-specific regulation of trisporic synthesis likely exists (63).

As mentioned above, there is convergent evolution in terms of pheromone processing between the Mucorales and Oomycetes. More broadly, the processing of the pheromones in the Mucorales shares some striking similarities to the processing of the Dikarya peptide-based mating pheromones. Both chemicals are synthesized as longer molecules and then processed and modified multiple times to produce the mature product. However, the chemicals themselves are different, and it is also interesting that the first two steps for processing from β-carotene, at least in some Mucorales, appear to be a result of likely subfunctionalization of the carotenoid oxygenase after the genome duplication reported in

some species (64). The effect of this is that one copy in *P. blakesleeanus*, CarS, recognizes β-carotene to synthesize β-apo-12-carotinal. The second copy, AcaA, has no activity on β-carotene and instead cleaves β-apo-12-carotinal as its substrate.

MENDELIAN AND CLASSICAL GENETICS

The first genetic map in the Mucorales was produced in *P. blakesleeanus*. In this species, the isolation of mutants was made by chemical means, and through the painstaking method of first crossing the mutation into the opposite mating type, and then combinations of crosses were performed to measure genetic linkages based on the phenotypes of mutants (14, 15). This genetic analysis was able to generate a map with 29 genes and the positions of 11 centromeres.

More recently, another genetic map was made that used molecular markers, based on PCR restriction fragment length polymorphisms, in 121 progeny from a cross between two wild-type parents (65). This 1,583-centiMorgan map generated between 9 and 12 linkage groups (depending on the stringency of cut-off for linkage between the markers) and an estimated 33 kb between centiMorgans. As part of the mapping process, a number of genes known from classical mutagenesis were predicted and point mutations identified in the corresponding mutants. This map provided physical linkage for genetic markers onto the genome sequence and indicated strong congruence between the original mutant phenotype segregation and molecular marker maps. It also revealed regions in which the current genome sequencing assembly could potentially be refined in the future.

In the absence of reliable systems for genetic transformation in *P. blakesleeanus* (19), positional cloning has been the only option to identify genes. In these cases, mutations were induced by chemicals such as nitrosoguanidine.

In the first reported example of positional cloning that used molecular markers spaced across the genome, the genetic basis behind the *madI* mutation causing reduced phototropism was identified. Unknowingly, this was a difficult genetics task because the *madI* strains turned out to be heterozygous wild-type/*madA* mutants (64). MadA is a blue-light sensor homologous to the white collar 1 protein of *Neurospora crassa* (66). Hence, the segregation analysis could only poorly define the best linkage for *madI* within the genome to markers near *madA*. It is not clear why the *madI* strains are maintained as wild-type/*madA* heterozygotes. One hypothesis is that the strains are heterokaryons, with two nuclei that each have a deleterious mutation such that in isolation the strain would not survive, but in the heterokaryon there is cross-complementation of these mutations.

Similarly, the *madC* gene that is required for phototropism has been identified by positional cloning (67). A genetic linkage between the genes for carotene biosynthesis and *madC* had first been made based on analysis of just seven zygospores (68). Positional cloning linked the *madC* mutations to markers near three genes impacting carotene synthesis, and the *madC* gene was identified as carrying loss-of-function mutations in a putative Ras GTPase activating protein. How this gene or Ras impacts phototropism is unknown; however, mutation of the homolog in the ascomycete *N. crassa* defined a role for this gene in the circadian banding of the asexual spores (67).

POPULATION GENETICS

Little work has been performed to understand the population structures of members of the Mucorales (reviewed in 69). This is an important area for future investigation, for instance, in the context of the potential population skews in distribution of mating types seen in pathogenic members. Work with *Phycomyces* species has demonstrated that both mating types coinhabit some locations (21) and that zygospores can be isolated from the environment, indicating that mating occurs in nature (Fig. 2A). Curiously, a sample from one location in Michigan in 2012 contained both *P. blakesleeanus* and *P. nitens*, i.e., a sympatric distribution (21). Given that members of the Mucorales are often found in similar locations (e.g., dung of animals) and use similar sex pheromones, how Mucorales species compete for similar resources also warrants future investigation.

SIMILARITIES AND DIFFERENCES BETWEEN THE MUCORALES AND OTHER BASAL FUNGI

Microsporidia are obligate intracellular pathogens, and their hosts range from single-celled protists to nematodes to humans (70). Microsporidia were once considered early-diverged eukaryotes and are now considered to be a sister group of fungi (71). Interestingly, their genomes contain a locus that exhibits a high similarity to the *sex* locus of Mucorales (18) (see Fig. 3). Two human pathogenic microsporidia, *Encephalitozoon cuniculi* and *Enterocytozoon bieneusi*, have a microsynteny of genes encoding TptA, an HMG-domain protein, and

RNA helicase in their genomes. An additional open reading frame for a hypothetical protein exists in the intergenic areas between the genes for TptA and the HMG-domain protein in both microsporidial species. Some other microsporidia species also share loci with a similar architecture in their genomes. The gene cluster of *tptA/sex/rnhA* is unique to the Mucorales and microsporidian lineages; i.e., the cluster has not been observed in any additional branch of fungi. Microsporidian genomes retain genes that function in meiosis, including the core components needed for meiosis (18, 72). Therefore, these observations suggest that microsporidia evolved from ancestral sexual basal fungi and may retain extant sexual cycles (73).

Heterozygous diploids of microsporidia may be indicative of extant sexual cycles. An *E. cuniculi* genome survey found that multiple loci exhibit heterozygosity, indicating that the species is diploid and may undergo sexual development (74–76). *E. bieneusi* and *Vairimorpha* species show alternation of karyotype during the infection cycle from the diplokaryotic phase to monokaryotic, which might be associated with sexual cycle (77, 78). A few microsporidian species that exhibit a transition between monokaryotic to diplokaryotic phases display evidence of gametogenesis and syngamy (79–81). For example, uninucleate mosquito microsporidia infect the host cells and then undergo repeated binary fissions to form enlarged multinucleated plasmodia. The plasmodia then break into uninucleate cells, which is called gametogony and is analogous to gametogenesis (80). A similar infection cycle was also observed in the ant microsporidian *Kneallhazia solenopsae*. However, a bona fide sexual cycle in microsporidia has not been observed in nature or under laboratory conditions, and associations of the *sex*-like locus in mating need to be further investigated.

The Glomeromycota is another basal fungal lineage and has been considered an independent phylum but was most recently placed within the new Mucoromycota phylum (1). The arbuscular mycorrhizal fungi (AMF) in this clade have been considered ancient asexual fungi. This long-standing view has been challenged by evidence of recombination in natural populations of AMF and conservation of meiotic machinery in the AMF genomes (82), which might imply ongoing sexual reproduction (83–85). A recent study by Riley et al. revealed that there are significant numbers of mating-type-A (MATA)-HMG homologs in the genome of *Glomus intraradices* (*Rhizophagus irregularis*) (86). In *R. irregularis*, the genes encoding homologs of TptA, SexM, and RNA helicase are not likely syntenic as seen in Mucorales and microsporidia (87) (see Fig. 3). In the Mucorales and metazoans, HMG proteins such as SexP/M and Sry, respectively, are key sex determinants. In some basidiomycetes, HMGs are not part of the mating locus; however, they are major regulators of sexual reproduction, and examples include Rop1 and Prf1 in *Ustilago maydis*, Pcc1 in *Coprinus cinereus*, and Mat2 in *C. neoformans* (88–90). It is therefore possible that some of the MATA-HMG encoded by the AMF may play roles in sexual development.

However, another study recently proposed that a pair of divergently transcribed homeodomain (HD) genes may represent a locus that governs sexual cycle in *R. irregularis* (91). The authors revealed that the fungus encodes HD1-like and HD2 proteins in a single locus and that sequences of the locus vary among 24 *Rhizophagus* species isolates (see Fig. 3). The syntenic HD1/HD2 gene locus represents a *MAT* locus in some basidiomycetes, and the sequences of the loci vary based on mating types. Thus, the diverged HD1-like/HD2 locus can be a *MAT* locus, and there are extant sexual cycles in *R. irregularis*. If the HD1-like/HD2 is the *MAT* locus in Glomeromycota, the hypothesis that HMG protein is an ancestral sex determinant in the fungal kingdom is challenged. An alternative hypothesis can be proposed that both HMG and HD1/HD2 are ancestral sex determinants and that during evolution of the fungal kingdom, a random loss of one or the other occurred. There is no direct evidence that the AMF's HD1-like/HD2 is the *MAT* locus. Therefore, it is as yet premature to support one hypothesis over the other. Further investigations incorporating more basal fungal lineages would provide robust information to elucidate the evolution of the *sex/MAT* locus in fungi.

CONCLUSIONS AND AREAS FOR FUTURE RESEARCH

A decade ago we reviewed the knowns and unknowns of the mating systems in fungi outside of the Dikarya lineage (7). Since then, some of the mysteries surrounding sexual reproduction in at least the Mucorales species have been resolved, including the discoveries of the genes within the mating type (*sex*) locus and some of the genes controlling pheromone biosynthesis. We would argue that the Mucorales have once again contributed to our understanding of reproductive systems in the fungi. However, it is worth reflecting that the same time separates the evolution of mating type systems in the Mucoromycota and the Dikarya lineage as other early fungal lineages. Mating systems in these other lineages still remain to be determined. The ambiguity of the possibility of a *MAT/sex* locus in the

Glomeromycota could be better clarified with information on other lineages. How well conserved is the pheromone system or the HMG-domain determinants of sex type, as seen in the Mucorales in the genera *Phycomyces*, *Mucor*, and *Rhizopus*? For instance, species in the genus *Mortierella* have been proposed to use the same pheromones as the Mucorales (92), yet the genome sequences that are available for this genus lack the genes for synthesis of β-carotene. The possibility of there being a conserved and common *sex* locus in all of the Mucorales is also not yet clear: candidate loci are present in the draft genomes of many of these species, including the earliest Umbelopsidaceae lineage, yet clear *sex* loci are absent from some genome sequences (93). A better set of genome sequences in these fungi based on current knowledge of their evolution (94) holds the promise of exciting new discoveries.

GLOSSARY

Anamorphic: A growth form in fungi that features only asexual reproductive structures (*cf*. teleomorphic).

CentiMorgan: A unit of genetic distance between markers, which may be genes, traits, or molecules. One CentiMorgan represents one recombination event per 100 progeny between two markers. The term honors the American geneticist Thomas Hunt Morgan.

Dikarya: A subkingdom within the fungi that includes the Ascomycota and Basidiomycota phyla. The name derives from stages in the life cycle of species that have two haploid nuclei per cell or cellular compartment prior to their fusion to initiate the meiotic cycle.

Gametogenesis: The formation of gametes, which are haploid cells dedicated to fusion during the sexual cycle.

Gametogony: In the microsporidia, a process in which a cell containing multiple nuclei divides into cells that can be used as gametes.

Genetic linkage: A state in which one or more genes or other markers, DNA polymorphisms or phenotypic, are close to each other based on genetic crosses, implying physical proximity on the same chromosome.

Heterokaryon: A hypha or other cell type in which more than one type of nucleus is present.

Heterothallism: A sexual reproductive system that requires the contribution of two different isolates of fungi (*cf*. homothallism).

Heterozygosity: A situation in which an organism contains two alleles (copies) of a gene that are different in sequence.

High-mobility group (HMG): A domain within proteins that binds to DNA. HMG-domain proteins are involved in conferring the sex or mating type in animals and some fungi.

Homeodomain: A domain within proteins that binds to DNA. Homeodomain proteins are involved in conferring the mating type in some fungi.

Homothallism: A sexual reproductive system requiring only a single isolate of fungus (*cf*. heterothallism).

Idiomorphic: Regions of DNA that do not share sequence similarity yet occupy the same site in the genome.

***MAT* locus/*sex* locus**: A region or regions within a fungal genome that are required for the sexual process. To date, these all include transcription factors with homeodomain or HMG domains, and in some cases in basidiomycete species, genes for pheromone synthesis and pheromone receptors.

Physical linkage: The presence of genes or other genetic elements on the same piece of DNA.

Plasmodia: A growth form in which the cytoplasm contains multiple nuclei.

Plasmogamy: The step in mating in fungi where fusion between two parents results in a mixture of cytoplasmic material, but prior to fusion of the nuclei.

Syngamy: The fusion of two cells.

Teleomorphic: Referring to a growth form in fungi that features sexual reproduction (*cf*. anamorphic).

Trisporic acid: An 18-carbon terpenoid molecule that is formed during the production of pheromones in members of the Mucoromycota.

Zygophore: A specialized hypha produced by Mucorales species that initiates fusion for the formation of the zygospores; equivalent to a gamete.

Zygospore: The sexual spore produced by species in the phylum Mucoromycota.

Sex and the Imperfect Fungi

9

Paul S. Dyer[1] and Ulrich Kück[2]

INTRODUCTION

Sexual reproduction is a ubiquitous feature of the eukaryotic kingdom with the many benefits of sex in generating genetic diversity as substrates for evolutionary selection being well known. When two different partners come together, there is the generation of genetic variation in the offspring, through the processes of crossover and recombination during meiosis, enabling response of future generations to environmental selection pressures (1–4). Sexual reproduction also allows the repair of random epigenetic or conventional genetic damage by recombination with homologous chromosomes and can mask lethal mutations (4, 5). In addition, sexual recombination alleviates clonal interference and prevents deleterious mutations hitchhiking to fixation (6). Indeed, there are so many benefits to sexual reproduction that exceptions that are purely asexual have been termed "evolutionary scandals" (7). As a result, supposed ancient asexual species such as the bdelloid rotifers (an exclusively female class of over 460 rotifer species thought to date back several million years) and darwinulid ostracods (a family of around 30 crustacean species thought to have been exclusively female and asexual for over 200 million years, but for which very rare living males have recently been described) have gained notoriety (8–10). It therefore comes as a great surprise that, until recently, approximately 20% of all fungal species were considered to reproduce only by asexual means, with no recognized sexual cycle, based on knowledge of described fungal species (11, 12). Indeed, in some phylogenetic groupings such as the Ascomycotina, up to 40% of taxa surveyed were deemed to be asexual (13). This is despite the fact that sexual reproduction in fungi can have additional benefits such as the production of fruit bodies and sexual spores that are resistant to adverse environmental conditions, thereby promoting survival of sexual offspring; it can provide a transient diploid arena for selection of genes; and sex can favorably impact genome evolution (14–17). Asexual species are also proposed to be short-lived evolutionary "dead ends" subject to rapid extinction (12, 18). Fungal species lacking a known sexual cycle have been referred to as "imperfect" or "mitosporic" fungi and have been grouped into the "Fungi Imperfecti" or "Deuteromycota," although phylogenetic analysis has shown that these are artificial groupings not based on taxonomic relationship (19). The terms "asexual" and "imperfect" are used synonymously in this review.

Therefore, the imperfect fungi appear to present an evolutionary paradox. However, in the past few decades, there has been accumulating evidence that many of these supposedly asexual species might actually have the potential for sexual reproduction and thus exhibit what has been termed "cryptic" (20, 21), "clandestine" (22), or "covert" (23) sexuality, i.e., having the presence of a sexual cycle that has not yet been directly observed. There are various lines of evidence to support this assertion such as analysis of population genetic markers and the recent, fast-growing number of sequencing data sets from asexual yeasts and filamentous fungi indicating that they harbor mating-type loci, and thus have the potential for a sexual life cycle (see further details below). Indeed, the suggestion of cryptic sexuality has been fulfilled or "consummated" recently for several previously considered asexual fungal species when mating and sexual cycles were conclusively demonstrated for the first time. Prominent examples include the discovery of mating in the opportunistic yeast pathogen *Candida albicans* (24, 25), and both mating and complete sexual cycles in the opportunistic filamentous fungal pathogens *Aspergillus flavus*, *Aspergillus fumigatus*, and *Aspergillus parasiticus* (26–28), as well as the biotechnologically relevant species *Penicillium*

[1]School of Life Sciences, University Park, University of Nottingham, Nottingham, NG7 2RD, United Kingdom; [2]Lehrstuhl für Allgemeine und Molekulare Botanik, Ruhr-University Bochum, 44780 Bochum, Germany.

chrysogenum, *Penicillium roqueforti*, and *Trichoderma reesei* (29–32; S. S. Swilaiman, H. Darbyshir, J. Houbraken, R. Samson, and P. S. Dyer, unpublished results).

This article will review how these recent advances were made. It will also speculate on the evolution of asexuality in fungi, including consideration of whether there are any truly imperfect fungi, what characteristics they might have, and the factors that could favor their appearance. Special attention is given to the ascomycete group of fungi from which most discoveries have been made.

EVIDENCE FOR SEXUAL POTENTIAL

Various complementary approaches or "sex tests" (33) have been used to provide evidence of the potential for sexual reproduction in asexual species as will now be described.

Population Genetics

One of the first indirect lines of evidence for sexual recombination in supposed asexual species came from population genetic studies. It would be expected that the genetic diversity, both in terms of genotype and phenotype, is higher in sexually propagating populations than in exclusively asexually propagating clonal species. Various molecular and physiological markers have been used in such population genetic analyses. For example, sequencing with arbitrary primer pairs (SWAPP) provides a molecular method to find and characterize genetic markers with nucleotide-level resolution. In the human pathogen *Coccidioides immitis* this technique provided molecular evidence for recombination in a fungus for which no sexual stage has so far been described (34). Alternatively, the distribution of alleles of unlinked loci or microsatellite markers has been analyzed in field populations. It would be expected that if a species were freely sexually recombining, then this would result in most unlinked loci being associated randomly in populations, whereas if there were a predominantly clonal and asexual reproduction, then nonrandom association of alleles ("linkage disequilibrium") would be observed. Thus, evidence of recombination through random association can be taken as an indication of a sexual life cycle. For example, a total of 236 isolates from *Diplodia pinea*, a haploid opportunistic plant pathogen, were characterized using 13 microsatellite markers. Analysis of these markers confirmed previous results that *D. pinea* has a high level of gene and genotypic diversity (35). In parallel, sequencing of seven molecular markers from 31 isolates of the animal-associated asexual *Penicillium dipodomyis* provided evidence of genetic diversity and recombination suggesting cryptic promiscuity (36). In previous work, evidence of recombination had also been observed in populations of *A. flavus*, *A. parasiticus*, and *A. fumigatus* based on DNA fingerprinting and the large number of vegetative compatibility groups present within populations (reviewed in reference 37), and in *P. chrysogenum* based on microsatellite analysis (38)—all species that were, at the time, considered purely asexual. However, it is cautioned that there are possibly other explanations for genetic diversity in populations such as parasexual reproduction (see Daskalov et al. [176]).

Mating-Type Genes

Mating-type (*MAT*) genes have provided fundamental insights into the reproductive status of asexual fungi through studies both of their distribution and also functional activity. By way of background, two main types of fungal sexual breeding systems can be distinguished: (i) heterothallism, involving two individuals of opposing mating type, and (ii) homothallism, which refers to sexual reproduction by selfing of an individual strain. Heterothallic sex maintains genetic variation due to mixing of genotypes, whereas homothallic sex can lead to clonality, similar to that observed in asexual reproduction (12). In heterothallic species, sexual recombination occurs between morphologically identical partners containing opposite *MAT* loci, which, in the case of ascomycetes, consist of dissimilar sequences occupying the same locus on the chromosome. In contrast, homothallic species normally contain genes for both *MAT* loci, which can either be located at a single *MAT* locus or on different chromosomes (21, 39). In most fungi, the mating-type locus represents a relatively small region of the genome, less than a few thousand base pairs, expressing transcription factors that determine both the haploid cell type specificity and/or the diploid zygote fate. Only very few fungi possess larger dimorphic sex chromosomes analogous to those of animals (reviewed by Heitman [40]).

For the most part, our general understanding of mating-related processes in ascomycetes is based on knowledge obtained from studies with the hemiascomycete baker's yeast *Saccharomyces cerevisiae* and the filamentous euascomycete (Pezizomycotina) *Neurospora crassa* (39). In *S. cerevisiae*, two alternative mating-type (*MAT*) loci, namely *MAT*α and *MAT***a**, determine the sex of individual strains (41). These loci are termed idiomorphs to indicate that they do not represent alleles of a single gene (42). In addition, each yeast strain carries silent mating-type loci of both

*MAT*α and *MAT***a**, thus allowing infrequent switching of the mating-type identity. In *N. crassa*, *MAT* loci are designated *mata* and *matA*, whereas in most other euascomycetes the terms *MAT1-1* and *MAT1-2* are used (21, 43–45). *MAT* loci from euascomycetes harbor one or more open reading frames (ORFs), of which at least one codes for a *MAT* transcription factor (TF) (21, 46). In contrast to yeasts, euascomycetes normally have only one active mating-type locus, with no extra silent mating-type loci. *MAT* loci have been characterized from a broad range of homo- and heterothallic euascomycetes (21, 39, 43, 47). Mating-type loci in sordariomycetes seem to be more complex with more than one open reading frame per mating-type locus. Heterothallic members of the Eurotiales are usually less complex and normally contain only a single functional open reading frame as depicted for various *Aspergillus* and *Penicillium* species in Fig. 1. This latter group can be considered to provide ideal experimental systems for gaining mechanistic and functional insights into *MAT* TFs and their various cellular functions as will be focused on below (48–51).

As a rule, the *MAT1-1* locus encodes an α-domain TF, and the alternative idiomorph, *MAT1-2*, is characterized by a gene coding for a TF with a high-mobility group (HMG) domain. The corresponding genes are generally referred to as *MAT1-1-1* and *MAT1-2-1* (45, 47). While DNA-binding HMG proteins are ubiquitous and found in a wide range of eukaryotes, α1-domain proteins seem to be limited to the fungal kingdom. The prototype of an α-domain protein is Matα1p from *S. cerevisiae*, whose function has been studied by genetic dissection (52). From this study the α domain was shown to act as a degradation signal for a pathway defined by the SUMO-targeted ligase Slx5–Slx8, which suggested a coordinated regulation in the turnover of regulatory transcription factors to ensure rapid mating-type switch in yeast. Extensive sequence comparisons,

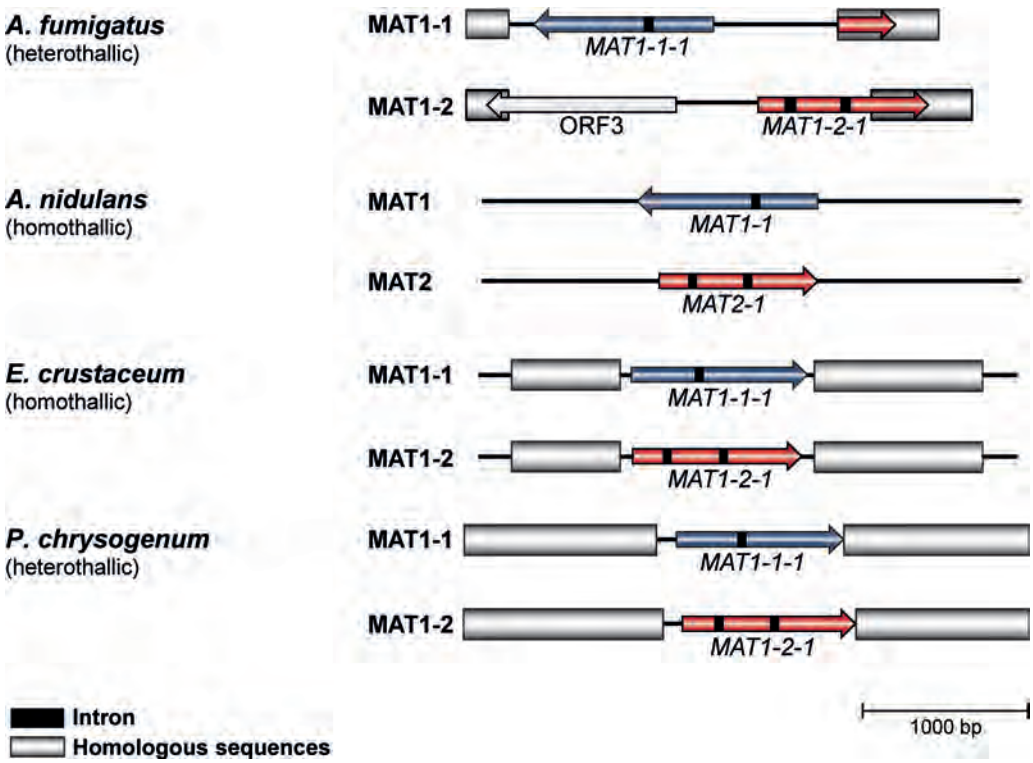

Figure 1 Comparison of *MAT* loci from homo- and heterothallic members of the Eurotiales. Blue arrows indicate a *MAT*α-domain gene, red arrows indicate a *MAT* high-mobility group gene, black bars indicate intronic sequences, gray bars homologous sequences (48, 49, 51, 173). For *A. nidulans*, the gene designation is as previously published by Paoletti et al. (49). Note that, whereas isolates of heterothallic species contain only one *MAT* idiomorph (either *MAT1-1* or *MAT1-2*), isolates of homothallic species contain both types of *MAT* gene in the same genome (i.e., both *MAT1-1* and *MAT1-2*).

phylogenetic analyses, and *in silico* predictions of secondary and tertiary structures of α and HMG transcription factors supported the hypothesis that the α1 domain is related to the HMG domain (53). This study concluded that fungal α1-box genes originated from an ancestral HMG gene.

Distribution of mating-type genes

First, mating-type genes have provided insights into the nature of asexual fungi through a population genetics approach investigating the distribution of *MAT* genes in natural populations of supposedly asexual fungi. It might be predicted that truly asexual species would be composed of near-clonal populations consisting of isolates of only one mating type as a result of speciation from a founder of a single mating type. Alternatively, genetic drift could lead to loss of a complementary mating type because there would be no selection pressure to maintain both mating types within a species. And rarely, some fungal species have been found in which isolates of only one mating type have been found (reviewed by Dyer et al. [21]). For example, all isolates of the plant pathogens *Rhynchosporium lolii* and *Rhynchosporium orthosporum* from a diverse range of geographical locations and plant hosts throughout Europe were exclusively of the *MAT1-1* genotype (54), whereas all individuals of the lichen-forming fungus *Thamnolia vermicularis* sampled from the Northern, and parts of the Southern, Hemisphere were entirely of the *MAT1-2* genotype (55). However, almost always, when studies of *MAT* distribution have been made in asexual fungal species, it has been found that isolates of both mating types can be found (i.e., the presence of both *MAT1-1* and *MAT1-2* idiomorphs), and often these are present in a near 1:1 distribution (reviewed in reference 21). This is consistent with a heterothallic sexual breeding system and has been used as strong evidence for the potential for sexual reproduction in the respective asexual species. Such studies have been made with a wide taxonomic diversity of fungi including *Aspergillus*, *Cochliobolus*, *Fusarium*, *Penicillium*, *Rhynchosporium*, and *Trichoderma* species as listed in Table 1. As an example, both *MAT1-1* and *MAT1-2* isolates of *P. chrysogenum* have been found worldwide in near equal distribution (Fig. 2). It is noted that the term heterothallic should only strictly be used for outcrossing species where a sexual state has been observed, and the term "proto-heterothallic" has been suggested to describe such asexual species where genetic evidence (e.g., the presence of complementary *MAT* loci) indicates the presence of a sexual cycle (56).

Function and regulatory impact of mating-type locus encoded transcription factors

Second, mating-type genes have provided insights into the nature of asexual fungi through an investigation of their expression and functional activity. The majority of studies have been limited to examining whether or not *MAT* genes are expressed at the mRNA level as an indication of activity. In almost all cases, *MAT* gene expression has indeed been demonstrated in imperfect fungi where assayed, which has been interpreted as providing evidence of sexual potential because the *MAT* genes would appear to be conferring sexual identity in the respective species under examination (see examples listed in Table 1). There have been some rare exceptions. For instance, it was not possible to detect *MAT1-1-1* gene expression in *R. lolii* and *R. orthosporum*, although *MAT* gene expression was detected in other supposed asexual *Rhynchosporium* species (54), but such cases are highly unusual, so far.

However, more in-depth research over recent years has revealed a rather more complex scenario, with expression analysis, providing evidence for a regulatory impact of *MAT*-encoded TFs beyond specifically sexual reproduction. Therefore, it has become clear that *MAT* gene expression alone does not necessarily indicate sexual potential, and caution should be exercised in interpreting such data, because *MAT* genes are likely to have other important functions in asexual fungi beyond mating and sexual development. This was demonstrated by pioneering *MAT*-locus-dependent expression analysis in the asexual *Aspergillusoryzae*, which showed that *MAT1-1* and *MAT1-2* specifically regulated over a thousand genes, including many of unknown function, with 33 genes differentially regulated over 10-fold between the different mating types (57). This was interpreted, in part, as evidence for *MAT* gene functional activity and therefore sexual potential, but this study also indicated that *MAT* loci are involved in the regulation of genes beyond those strictly involved in a putative sexual cycle. Similarly, gene manipulation of the *MAT1-1-1* gene from the then considered asexual *P. chrysogenum* revealed that the MAT1-1 α-domain TF impacted developmental processes of biotechnological relevance such as penicillin biosynthesis, light-dependent asexual sporulation, and hyphal morphology, in addition to any role in sex (30). This work was extended, when the *MAT1-1-1* gene from *P. chrysogenum* was analyzed by ChIP-seq analysis. This investigation led to the identification of 254 putative direct MAT1-1-1 target genes and a highly specific MAT1-1-1 DNA-binding sequence (58). Interestingly, some of the most highly bound regions in ChIP experiments

occurred near homologs of known functional targets of the *S. cerevisiae* MATα1 protein, such as Pcppg1, a homolog of MFα1, encoding the α-pheromone, and Pcpre1, a homolog of STE3, coding for the a-factor receptor (59, 60). In addition, this analysis confirmed a large number of new MAT1-1-1 target genes, which had never been related to any MAT TF before and were assigned to functional categories beyond mating, such as asexual development, morphogenesis, amino acid metabolism, secondary metabolism, and iron metabolism (58). A summary of MAT1-1-1 target genes is depicted in Fig. 3. In parallel work, it was later shown that the MAT1-2 HMG domain TF from *P. chrysogenum* also impacted a variety of developmental processes, including light-dependent asexual sporulation, conidiospore germination, and surface properties, again in addition to any role in sex (61). A summary of MAT-controlled processes in *P. chrysogenum* is shown in Fig. 4. Comparable results were obtained with the homothallic cereal pathogen *Fusarium graminearum* which contains both *MAT1-1* and *MAT1-2* loci in the same genome. Unlike *Sordaria macrospora*, another well-studied homothallic euascomycete (62), *F. graminearum* requires all the transcripts from both *MAT* loci

Figure 2 Occurrence of both *MAT* idiomorphs in wild-type isolates from *Penicillium chrysogenum*. Blue and red dots represent strains with the *MAT1-1* or *MAT1-2* locus, respectively (C. M. O'Gorman and U. Kück, unpublished data).

for sexual development. The regulatory mechanisms controlled by *MAT* genes in *F. graminearum* were explored by several strategies, including genome-wide transcriptional profiling in various genetic backgrounds, and high-throughput gene deletions (63). Genome-wide microarray with total RNAs from *F. graminearum* mutants that lacked each *MAT* locus individually or together revealed 1,245 differentially expressed genes, including those involved in metabolism, cell wall organization, cellular response to stimuli, cell adhesion, fertilization, development, chromatin silencing, and signal transduction.

Another example of *MAT* genes regulating nonsexual processes comes from *Fusarium verticillioides*, where deletion of the *MAT1-2-1* gene led to a drastic reduction in carotenoid production in parallel with a severe decrease in photo-induced expression of genes encoding key enzymes of the carotenoid biosynthesis pathway (64). Moreover, *F. graminearum MAT1-1-1* and *MAT1-2-1* deletion mutants were shown to be reduced in virulence, although none of the *MAT* locus genes was important for plant infection, indicating that the MAT proteins may play a host-specific role in colonization of corn stalks (65). Another interesting demonstration of MAT TFs acting outside the sexual life cycle was found for the human pathogenic basidiomycete *Cryptococcus neoformans*, where the heterodimers of MAT TFs Sxi2a and Sxi1α were shown to be involved in regulation of several well-studied virulence genes (66). Based on these observations, it can be proposed that MAT TF target genes in hemiascomycetes are restricted to genes relevant for mating, whereas MAT-mediated regulation beyond sexual development might be a common feature in euascomycetes. It is conceivable that comprehensive rewiring of gene regulatory networks controlled by MAT TFs has occurred since the division of these two subclasses.

Genome Studies

Whole-genome sequencing projects have been completed for several asexual fungi over the past decade. This has allowed the genomes to be screened for the presence of genes known to be required for sexual reproduction as a way to evaluate whether the species are truly asexual. The rationale for this work is that, if a species is genuinely asexual, then it would be predicted that genes required for sexual reproduction would either accumulate deleterious mutations, or even be lost, in asexual species due to random mutation and lack of selective pressure to maintain the functional forms of the gene. Furthermore, those genes involved with the earliest stages of mating might be the most obvious candidates for mutation and/or loss to avoid unnecessary downstream metabolic investment in sex. This is

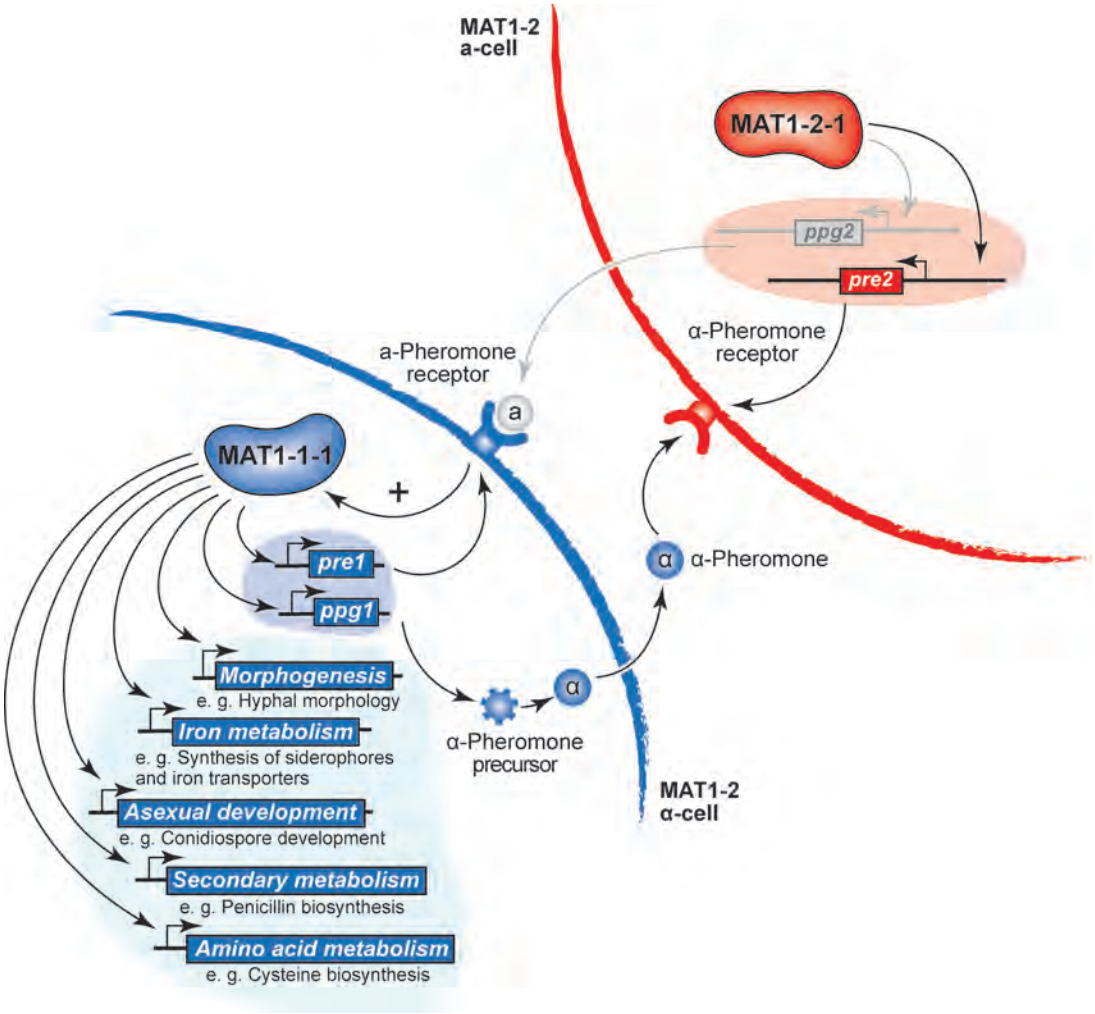

Figure 3 Target genes of the *MAT1-1-1* locus encoded transcription factors from *Penicillium chrysogenum*, deduced from functional genomics experiments (58, 61). In particular, ChIP-seq analysis has shown that MAT1-1-1 regulates gene expression far beyond their described function as regulator of sexual development (modified from reference 174).

based on the understanding that asexual species have evolved from sexual ancestors (e.g., reference 67), sex being a basal characteristic of the fungal kingdom (68).

Perhaps surprisingly, almost all genome projects to date have revealed that supposedly asexual fungi do have apparently intact sets of genes known to be required for sexual reproduction, with no evidence of gene mutation or loss. In the first study for the Pezizomycotina, the genomes of the then considered asexual *A. fumigatus* and *A. oryzae* were screened for the presence of over 200 genes linked to sex (from mating through to meiosis), and it was found that all genes were present. Furthermore, a heterothallic mating system was indicated based on the presence of a characteristic *MAT* idiomorph (69). Soon afterward, genome sequencing of the asexual *Aspergillus niger*, used widely in the biotechnological industries, again revealed the presence of a suite of genes linked to mating and sexual development (70). An apparent mutation in the *pro1* gene was found in the latter study, but this was later discounted because of an incorrect annotation of an intron. Concurrent genome screening of the then asexual *A. flavus* also revealed a full complement of apparently functional genes required for sexual reproduction (C. E. Eagle and P. S. Dyer, unpublished results). Furthermore, BLAST analysis of the genome sequence of the basidiomycete yeast *Malassezia globosa*, a causal organism of dandruff, revealed the presence of a *MAT* locus containing pheromone, pheromone receptor, and sex-linked homeodomain genes, together with

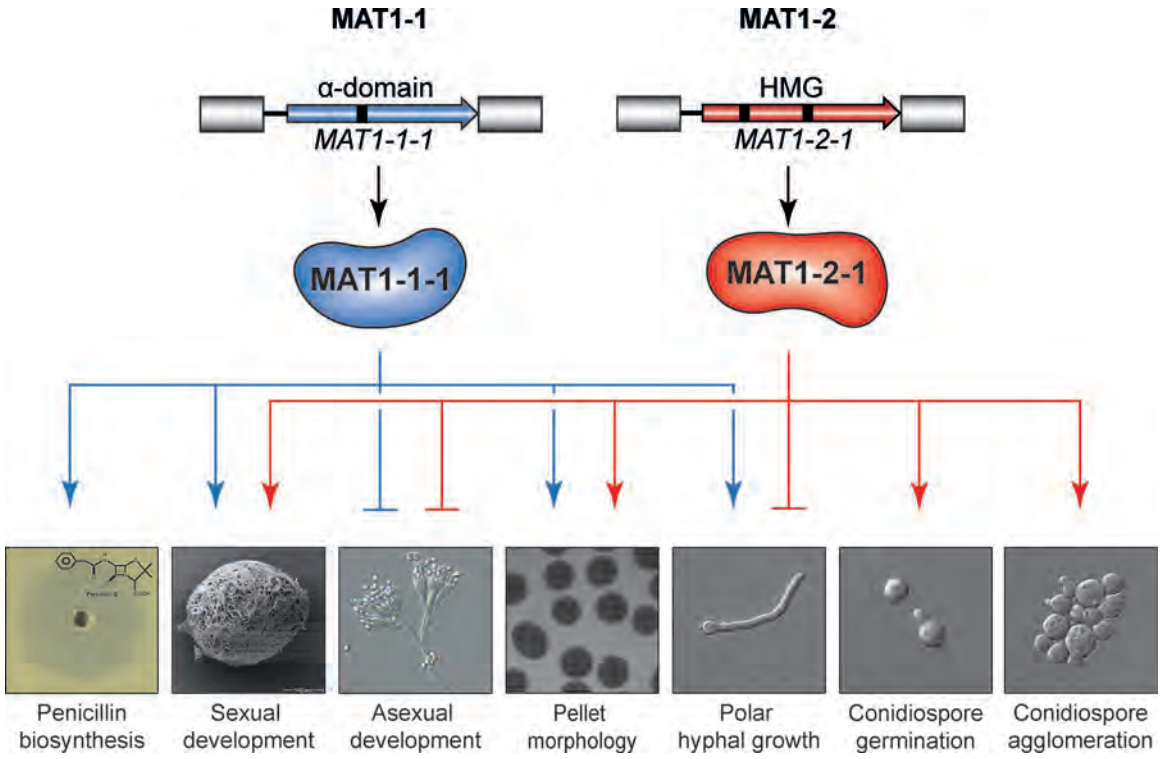

Figure 4 Summary of the regulatory functions of *MAT* locus encoded transcription factors MAT1-1-1 and MAT1-2-1 in *Penicillium chrysogenum* (modified according to reference 175).

other pheromone signaling pathway genes elsewhere in the genome of this presumed asexual species (71). Most recently, genome analysis of asexual *Rhynchosporium* species has again failed to detect any loss or mutation in genes related to sexual reproduction (54; International Rhynchosporium Genome Project, unpublished results). A further revelation from genome analysis of *P. chrysogenum* was the discovery of mutations apparently caused by a RIP-like (repeat-induced point mutation) process, again linked to sexual reproduction (72).

However, some caution must again be exercised in interpreting such evidence. Genome analysis of eight *Candida* genomes revealed that certain species with known sexual states were missing some orthodox components of mating and meiotic pathways. For example, the homothallic *Lelongisporus elongisporus* lacked any known *MAT* gene, having a syntenic *MAT* locus but which only contained noncoding DNA, and also lacked a pheromone precursor and receptor (73). Similarly, evidence of a degenerated *MAT1-1-1* pseudogene has been reported for the heterothallic *Cordyceps takaomontana* (74). Therefore, the lack of sex-related genes is not conclusive proof of asexuality, whereas the presence of such genes is arguably circumstantial evidence for sexual potential.

Functionality of Sex-Related Genes

Further evidence that imperfect fungi have the potential for sexual reproduction has come from studies where sex-related genes from certain asexual species have been expressed heterologously in model fungal species known to be sexual, and have been shown to be functionally active. This provides evidence of a conserved sexual function in the respective asexual host species. Genes assayed in this way include *MAT* genes and members of pheromone signaling pathways as will now be described.

Cross-species mating-type gene exchange provides a powerful method to demonstrate the functionality of mating-type locus-encoded proteins. Different approaches are feasible. For example, mating-type loci of the α domain or HMG type can be introduced into isolates of a heterothallic species carrying the opposite mating-type locus. In this case, the triggering of sexual development leading to formation of fruiting bodies (although not necessarily sexual spore formation) provides good evidence of *MAT* gene functionality. This

approach was successfully demonstrated in pioneering studies of known sexual species when *MAT* loci from the homothallic fungus *S. macrospora* were shown to induce sexual development (although not ascospore formation) in the heterothallic fungus *Podospora anserina* (75). An alternative approach is to use deletion mutants, lacking a mating-type locus. Complementation of the deletion mutant may be performed with a DNA fragment carrying the *MAT* locus from a heterologous host. For example, *MAT1-2-1* from *A. fumigatus*, encoding a HMG box mating transcriptional factor, was introduced into a mating-type deletion mutant of the homothallic fungus *A. nidulans* (76). Using a *MAT1-2-1* gene under the expressional control of the *Aspergillus nidulans MAT2* (*matA*) promoter, it was demonstrated that the *MAT1-2-1* gene from *A. fumigatus*, at that point only known to be asexual, was able to drive sexual reproduction in *A. nidulans*. In parallel studies, it was shown that the *MAT1-1-1* gene from *A. fumigatus* was able to complement an *A. nidulans MAT1* (*matB*) deletion mutant and restore sexual fertility (50). Comparable results were reported for *Acremonium chrysogenum*, the fungal producer of the pharmaceutically relevant β-lactam antibiotic cephalosporin C. This filamentous fungus is classified as asexual, because no direct observation of mating or meiosis has yet been reported. The investigated strains were shown to carry a *MAT1-1* mating-type locus with a *MAT1-1-1* α-domain gene and a *MAT1-1-2* gene, encoding an HPG domain protein, defined by the presence of the three invariant amino acids histidine, proline, and glycine. In addition, a *MAT1-1-3* gene was detected, encoding a high-mobility group (HMG) domain protein (77). So far, only a single wild-type isolate has been characterized, and no reports are available that strains with opposite mating-type loci exist. To assess the potential of *A. chrysogenum* for sexual reproduction, the entire *A. chrysogenum MAT* locus was transferred into a *MAT1-1* deletion strain of the heterothallic ascomycete *P. anserina*. After fertilization with a *P. anserina MAT1-2* (*MAT2*) strain, the corresponding transformants developed fruiting bodies with mature ascospores. These results demonstrated that the *MAT* genes of *A. chrysogenum* were functional and supported the hypothesis of an extant sexual cycle in this species.

Other evidence for a sexual cycle stems from functional studies of pheromone and pheromone receptor genes, using the heterologous *S. cerevisiae* system as a genetic tool. Successful pheromone binding and signaling would be expected to result in cell cycle arrest and change in cell morphology and lead to formation of a halo in lawns of *S. cerevisiae* (78). Based on similarity to the *S. cerevisiae* MFα proteins, the *P. chrysogenum* Pcppg1 gene was predicted to produce a decapeptide pheromone of sequence KWCGHIGQGC, expected to bind to the cognate PcPRE2 receptor protein. And indeed, *S. cerevisiae* wild-type cells (ScSTE2p) or yeasts heterologously expressing PcPRE2 exhibited polarized growth, leading to pear-shaped forms (shmoos, originally named after a cartoon character of this shape drawn by Al Capp) of unconjugated haploid cells, in response to either the native *S. cerevisiae* α factors or the synthetic decapeptide pheromone PcPPG1, respectively (30). This result was complemented by bioassays in which adding synthetic PcPPG1 pheromone to lawns of yeast cell, expressing PcPRE2, resulted in halo formation. Thus, PcPRE2 and PcPPG1 represent a functional pheromone-receptor pair likely involved in the mating of *P. chrysogenum*, which was later observed by Böhm et al. (30). These data were consistent with microarray analyses demonstrating the expression of the genes for a pheromone precursor (Pcppg1) and two pheromone receptors (Pcpre1, Pcpre2) in *P. chrysogenum* (30).

As well as the examples above, a STE12 homolog from the asexual *Penicillium marneffei* (renamed *Talaromyces marneffei*) was able to complement a *steA* gene deletion mutation of *A. nidulans* and restore sexual fertility (79). Meanwhile, overexpression of the *A. fumigatus nsdD* gene led to increased development of sexual structures (cleistothecia) in *A. nidulans* (50). Finally, before the identification of any sexual stage, pheromone precursor and receptor genes were shown to be expressed in *A. fumigatus*, *A. flavus*, *A. parasiticus*, *A. oryzae*, and *P. chrysogenum* in what was termed "sexual posturing" (22, 48, 51, 57, 80). Most recently, similar expression of pheromone signaling genes has been demonstrated in several other asexual aspergilli including *Aspergillus aculeatus*, *A. brasiliensis*, *A. clavatus, A. niger, A. sydowii, A. wentii*, and *A. zonatus* (178). However, as above, some caution must be used when interpreting such results because it appears that some aspects of the cellular sexual machinery can be subverted for other purposes in fungi. For example, the STE2 pheromone receptor of the asexual *Fusarium oxysporum* has been shown to play a role in detection of plant exudates (81). Therefore, detecting expression of sex-related genes is not necessarily a sign of cryptic sexuality.

Formation of Sex-Related Structures and Lichen Species Pairs

One final line of evidence that imperfect fungi have the potential for sexual reproduction comes from the observation that certain asexual species have been

observed to form developmental structures representing the initial stages of sexual reproduction. This suggests that they might have the potential for sexual fertility if correct conditions can be identified to induce the complete sexual cycle (56). For example, several asexual *Aspergillus* and *Penicillium* species are known to form sclerotia, a necessary prerequisite for sexual reproduction in closely related species (82, 83). This phenomenon was recently observed for certain isolates of *A. niger* which were able to form sclerotia when they were incubated on certain organic substrates including raisins (Fig. 5) (84) (G. Ashton and P. S. Dyer, unpublished results).

A particularly intriguing phenomenon related to this is the occurrence of so-called "species pairs" in lichen biology. This refers to the situation where two morphologically and phylogenetically very closely related pairs of lichen species have been described which differ solely in the fact that one species bears sexual structures on the thallus, whereas the sister species lacks any sexual structures (85–87). It is tempting to speculate that the reason for asexuality in the sterile partner species might be principally because of the lack of a suitable mating partner to induce sex, rather than these being genuinely separate species as per received orthodoxy. In related examples from lichen-forming fungi, Seymour et al. (86) reported finding the first fertile example of *Usnea sphacelata* (as evidenced by formation of sexual fruiting bodies [ascomata] on the thalli), and Greenaway (88) described the first fertile thalli of *Normandina pulchella*; both species had previously been considered to reproduce only by asexual means.

DISCOVERY OF MATING AND SEXUAL REPRODUCTION—AND IMPLICATIONS

The above lines of evidence have provided, and these continue to give, an indication of the potential for sexual reproduction in the imperfect fungi, although such evidence has at best been circumstantial because the elusive sexual states were still missing. However, a series of major breakthroughs have been reported since 2000 for yeasts and 2009 for filamentous fungi, where modern molecular approaches combined with classical microbiology laboratory culture have been used to demonstrate the existence of either mating and/or a complete functional sexual reproductive cycle in a series of supposed asexual species from different genera. In most cases, a key first step was the use of molecular diagnostic tools to identify potential sexual mating partners and then the setting up of directed crosses between parental isolates of complementary mating type under a range of incubation conditions (56). Some notable examples are described below.

Mating in *C. albicans*

There had been strong indications that the opportunistic human pathogen *C. albicans* might have sexual potential following the identification of a mating-type locus similar to that seen in the model sexual yeast

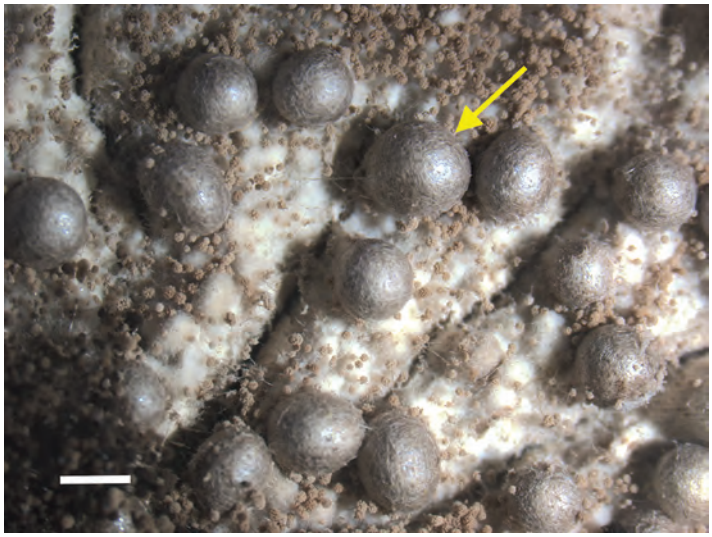

Figure 5 Sclerotia formation (arrowed large gray-brown spheres) in *Aspergillus niger*, an indication of the potential for sex in this biotechnologically important species? Scale bar indicates 500 μm. Note that this species is predominantly of the *MAT1-1-1* genotype (H. Darbyshir, G. Ashton, and P. S. Dyer, unpublished data).

S. cerevisiae, together with the detection of other genes that had high homology to sexual pathway genes in *S. cerevisiae* (89) (see also Bennett and Turgeon [177]). These indications were confirmed when two different groups were able to induce mating between **a** or α strains of *C. albicans* to produce a tetraploid state. Hull et al. (24) made artificial **a** or α strains by deletion of the alternative MTL α or **a** locus, respectively, and crossed these under selective conditions in mice, while Magee and Magee (25) induced chromosome loss to produce **a** or α strains by deletion of one of the MTL loci and then crossed auxotrophic strains on agar media using selective conditions. Although both groups therefore reported the first success in mating strains of *C. albicans*, the rates of mating were rather low and led to a tetraploid state without any meiotic division. A second major advance then followed, being the discovery that homozygous **a/a** or α/α *C. albicans* cells must undergo a phenotypic transition from a "white" traditional yeast-like morphology to an "opaque" morphology to achieve mating competency (90–92). However, even under these conditions, meiosis has still not yet been observed in *C. albicans*. Instead, tetraploids appear to undergo stochastic concerted chromosome loss to return to a diploid or near-diploid state, particularly under stressful conditions (93, 94). Furthermore, even when mating-competent haploid strains of *C. albicans* were produced under *in vitro* and *in vivo* conditions, it was still not possible to induce meiosis (95). Therefore, true sex involving meiotic nuclear recombination has still not yet been observed in *C. albicans*; instead, this is best described as mating and a parasexual process. It is also noted that the intriguing phenomenon of same-sex mating has also been observed in *C. albicans*, but again with no evidence of meiosis (96).

Sex in *Aspergillus* Species

The genus *Aspergillus* comprises over 340 species (97) and includes a series of species of great economic, medical, and scientific importance. Members of the genus share the common feature of an "aspergillum," a branching head conidiogenous structure for the production of asexual spores. In addition, about one-third of species (36% according to reference 33) are known to reproduce sexually. All the latter species produce fruiting bodies known as cleistothecia, but a variety of cleistothecial forms are evident, meaning that under traditional taxonomic classification, different teleomorphic genera have been assigned according to morphological features such as whether cleistothecia are enclosed, the color of cleistothecia, and whether they are surrounded by accessory cells (33, 37, 97). The fact that the remaining majority of *Aspergillus* species (64% according to reference 33) are only known as imperfect fungi has attracted research interest both from an applied and fundamental perspective, because many species of biotechnological and pathological interest were only known as asexual organisms. If it were possible to induce sexual cycles in such species, then this would provide a valuable tool for strain improvement and classical genetic analysis, as well as providing insights into the population biology and evolutionary potential of species. Research into this area has been reviewed (see reference 37), with a summary and updates provided below.

Initial investigations involved the use of population genetic approaches, which revealed evidence of high levels of genetic diversity and recombination in nature for the spoilage and aflatoxin producing *A. flavus* and *A. parasiticus* (98, 99), and the opportunistic pathogen *A. fumigatus* (28, 48, 100, 101). Mating-type genes were then identified for the first time from the aspergilli (102, 103), which allowed PCR diagnostics to be developed. This led to the identification of alternative *MAT1-1* and *MAT1-2* idiomorphs and the discovery of a near 1:1 distribution of compatible mating types both within global and regional populations of *A. fumigatus* (28, 48). Similar results were later reported for both *A. flavus* and *A. parasiticus* for a local field population from the United States (80). All these observations provided evidence of cryptic sexuality in these species.

A major breakthrough then came when laboratory work led to a sexual stage being induced for the first time in *A. fumigatus*. This was achieved by crossing known *MAT1-1* and *MAT1-2* isolates from a population in Ireland (which had shown evidence of recombination) on oatmeal agar in a barrage formation under specific environmental conditions. Cleistothecia characteristic of the teleomorph genus *Neosartorya* were produced after 6 to 12 months, and the sexual stage named *Neosartorya fumigata* under existing taxonomic rules. Recombination was demonstrated in the ascospore offspring using molecular markers (28). Soon afterward, similar crossing efforts were rewarded with *A. flavus* and *A. parasiticus*, when incubation of strains of opposite mating type for between 6 and 12 months led to the production of hardened sclerotia found to contain sexual ascospores, although recombination was not assayed. The two sexual stages were assigned to the teleomorph genus *Petromyces* (26, 27).

The studies with *A. fumigatus, A. flavus*, and *A. parasiticus* provided a precedent for ensuing research in which attempts were made to cross *MAT1-1* and *MAT1-2* isolates of other asexual *Aspergillus* species

under conditions conducive to sex in the aspergilli. A sexual cycle was subsequently induced in *A. nomius* (104), *A. lentulus* (105), *A. terreus* (106; A. E. Ahmed and P. S. Dyer, unpublished results), *A. tubingensis* (107), *A. sclerotiicarbonarius* (108), and *A. clavatus* (S. Swilaiman and P. S. Dyer, unpublished results). The discovery of sexual reproduction in *A. tubingensis* and *A. sclerotiicarbonarius* is particularly notable, because these are members of the black aspergilli and therefore related to the economically important species *A. niger*, which is much used in the biotechnology sectors. However, all efforts to induce sexual reproduction have so far failed in this species, although the ability to induce sclerotial production in certain strains, together with identification of a TF linked to this process, is a promising sign (Fig. 5) (84; T. R. Jørgensen, J. Frisvad, K. F. Nielsen, P. S. Dyer, and A. F. J. Ram, unpublished results).

Sex in *Penicillium* Species

The genus *Penicillium* comprises over 360 species that have a ubiquitous distribution (83). Morphologically, they are characterized by the production of an asexual reproductive structure, called the penicillius (83, 109). Together with species of the genus *Aspergillus*, penicillia belong to the order *Eurotiales* (97) and are among the most prevalent fungi on earth. Taxonomically, *Penicillium* species are the asexual (anamorphic) forms of sexual (teleomorphic) species from the genera *Eupenicillium* and *Talaromyces* (83, 97). However, the majority of *Penicillium* species (73% according to reference 33) have no known sexual state.

Because of their widespread beneficial usage in food production and biotechnology, penicillia are of outstanding economic and medical importance. For example, *P. camemberti* and *P. roqueforti* are used in the making of white mold (e.g., Brie and Camembert) and blue mold-ripened cheeses (e.g., Roquefort and Stilton) (110). In the pharmaceutical industry, *P. brevicompactum* is used for large-scale production of the immunosuppressant mycophenolic acid, *P. griseofulvum* for the industrial production of the broad-spectrum antibiotic griseofulvin, and *P. citrinum* for production of the cholesterol-lowering drug compactin (111–113). Last but not least, *P. chrysogenum*, perhaps the most renowned representative of the genus *Penicillium*, constitutes the only industrial producer of the β-lactam antibiotic penicillin. Today, penicillin is the most commonly used drug in the treatment of bacterial infections and one of the most valued products in the global anti-infective market. As with the aspergilli, the economic importance of certain asexual *Penicillium* species has meant that they have attracted research interest regarding the possibility of inducing sexual reproduction for strain improvement and classical genetic applications as will now be described for *P. chrysogenum* and *P. roqueforti*.

Initial investigations of the sexual potential of *P. chrysogenum* (reclassified recently as *P. rubens* by Houbraken et al. [97, 114]) were made using DNA and genome-sequencing approaches (51, 115). Interestingly, the strain originally discovered by Sir Alexander Fleming (116) was found to contain a *MAT1-2* locus, while later, industrially used strains were found to carry the *MAT1-1* locus. The latter observation can be explained by the fact that they all are derivatives of a wild-type isolate, obtained in the late 1940s in Peoria, Illinois. Hoff and coworkers showed that these strains retained transcriptionally expressed pheromone and pheromone receptor genes required for sexual reproduction (51). A further survey showed that *P. chrysogenum* isolates from diverse global locations contain either the *MAT1-1* or the *MAT1-2* locus with an almost equal distribution (Fig. 1).

In order to induce the sexual life cycle in *P. chrysogenum*, 17 *MAT1-1* wild-type or mutant strains were crossed in various combinations with 10 *MAT1-2* wild-type isolates using a range of different growth media and conditions. Finally, a *MAT1-1* strain derived from a strain development program in the 1950s was found to generate cleistothecia in crosses with a *MAT1-2* wild-type strain (30). The culture conditions were similar to those described for *A. fumigatus* (28), but the oatmeal agar had to be supplemented with biotin, which accelerated the formation of mature cleistothecia, which appeared after 5 weeks. Measurement of the penicillin titer on plate test and examination of restriction fragment length polymorphism of 11 genes, which differed between the two parental strains, proved that genetic recombination has occurred in all ascospore isolates investigated. In a subsequent analysis, the chromosome constitution of selected ascospore isolates was determined by whole genome sequencing (61). Included in these studies were the functional analyses of deletion strains, lacking either the *MAT1-1* or the *MAT1-2* locus. From these studies, it became evident that both mating-type loci have functions beyond sexual development (see discussion above).

Meanwhile the sexual potential of *P. roqueforti* has also been investigated. *P. roqueforti* is widespread in the natural environment and is a common spoilage agent in stored foods and meat products. In food production, this ascomycete is used as a starter culture for blue-veined cheese production. A survey of several

world isolates from *P. roqueforti* revealed the presence of both mating types, and the detection of repeat-induced point mutation (RIP) within repeated sequences and transposable elements indicated strongly that sexual recombination had occurred or was ongoing in *P. roqueforti* (31, 117). This indirect evidence for a sexual cycle was recently confirmed when a sexual cycle was induced under laboratory conditions (31, 117; Swilaiman et al., unpublished). In one study, four *MAT-1-1* and *MAT1-2* strains were tested in eight possible mating combinations. Although many combinations were not fully fertile (only empty fruiting bodies were produced), typical sexual structures such as cleistothecia, asci, and ascospores were detected in some crosses (32). In a parallel study, sexual reproduction was induced in a higher number of crosses, including when crossing isolates from different types of blue cheese (31; Swilaiman et al., unpublished). Interestingly, the conditions developed for *P. chrysogenum* (30) to induce sex were identical, indicating that these conditions are valid for a wide range of *Penicillium* species. Recombination of ascospore progeny from *P. roqueforti* was demonstrated with either microsatellite or DNA fingerprint markers (31, 32; Swilaiman et al., unpublished). The sexual cycle of *P. roqueforti* offers the exciting potential to select for progeny with altered flavor and mycotoxin characteristics for novel blue cheese strains (H. Darbyshir, J. Frisvad, and P. S. Dyer, unpublished results).

Sex in *Trichoderma* and Other Genera

The ascomycete *T. reesei* is used in the biotechnology industry for applications such as the decomposition of diverse substrates through to the production of second-generation biofuels from cellulosic waste. Moreover, efficient biocontrol strains have been developed as biological fungicides (118). *T. reesei*, the anamorph of the ascomycete *Hypocrea jecorina*, was believed for more than 50 years to propagate strictly asexually. However, Seibel and coworkers succeeded in inducing sexual development in the industrial production strain QM6a (29). This strain contains the *MAT1-2* mating-type locus, but was found to be female sterile, i.e., unable to produce the specialized hyphal tissues needed for fruit body development (in this case, perithecia). Thus, in mating, this strain was only able to act as a male fertilizing partner, but was then able to undergo a heterothallic reproductive cycle with wild-type isolates carrying the *MAT1-1* locus. Perithecia embedded in stroma were generated under different light conditions. Interestingly, visible light is dispensable for stroma formation, and constant light even inhibited stroma formation. Further studies indicated that the light-regulatory protein Envoy 1, a homolog of the light-oxygen-voltage (LOV) domain-containing protein vivid from *N. crassa*, is essential for female fertility (119). In follow-up studies, further parental strains were crossed with *T. reesei*. The analysis of unusual 16-spore asci, which were produced when parental strains showed chromosomal heterogeneities, revealed the formation of a considerable number of inviable ascospores. This indicated that chromosomal homogeneity is crucial for highest sexual fertility (120). These results correspond well with the sequencing data of ascospore progeny of *P. chrysogenum* that were derived after crossing of parental strains that exhibited heterogeneous chromosomal configurations (121).

There are further reports of sex being induced in other genera such as *Fusarium* (122) and *Trichophyton* (123) species by utilizing *MAT* diagnostic tools and particular crossing conditions, but a full discussion is beyond the scope of the present review.

Implications of the Discovery of Fungal Sex

The presence of a sexual cycle offers many potential benefits. First, the discovery of a sexual cycle in biotechnologically relevant species provides an exciting new tool in addition to conventional breeding approaches to genetically engineer industrial production strains in the laboratory. Thus, fungal mating systems may be appropriate for the improvement of industrial production strains similar to established animal and plant-breeding programs (124). This strategy was recently implemented for *T. reesei*, when a female sterile strain was engineered to female fertility (125). By introduction of the *ham5* gene, it was possible to restore female fertility of the QM6a *T. reesei* wild-type strain, which is the progenitor strain of all industrially used derivatives. The generation of this strain, which may serve as male as well as female partner in mating experiments, provides the basis for further breeding of this cellulose-producing fungus. As an indication of the potential for this work, a crossing experiment with different wild-type mating partners of *T. reesei* showed that ascospore isolates were obtained that produced a higher level of xylanases than either parental strain, despite chromosomal heterogeneity (120). In comparable work, low-penicillin-producing strains could be crossed with *P. chrysogenum* wild-type isolates to give rise to ascospore isolates with an increased penicillin titer (61). By crossing different isolates of *P. chrysogenum* it was also possible to select for ascospore progeny with minimal production of a secondary metabolite chrysogenin, which can interfere with penicillin purification (30).

However, it might prove to be a general problem in future mating experiments to obtain mating partners with compatible karyotypes. Previous crossing experiments with isolates from different locations of the pseudohomothallic ascomycete *Neurospora tetrasperma* resulted frequently in sexual dysfunction, with abnormalities ranging from reduced ascospore viability to complete sterility (126). Pulsed-field gel electrophoresis analysis and mating of different geographic strains from the homothallic fungus *S. macrospora* showed a correlation between karyotype heterogeneity and reduced sexual fertility (127). Similarly, one investigation of mating with *P. roqueforti* strains from noncheese and cheese habitats belonging to different genetic clusters found that highest fertility was only achieved when strains from the same genetic cluster were crossed. Fertility was significantly reduced when strains isolated from cheese were crossed with those from noncheese habitats, possibly as a result of domestication and clonal selection (128). However, parallel studies found comparable levels of fertility when crossing different isolates of *P. roqueforti* used in blue cheese production, so this might be a strain-specific effect (31; Swilaiman et al., unpublished). In future strain improvement programs, the combination of conventional mating experiments and contemporary molecular tools, such as ChIP-Seq or forward genetic analysis, will generate novel approaches to engineer genetically industrial producer strains. One prerequisite for the success of these breeding experiments might therefore be to select or design mating partners with compatible karyotypes to ensure breeding success.

Second, the discovery of a sexual cycle provides a very valuable tool for classical genetic analysis. By crossing of partners showing different traits and analysis of the sexual progeny, it is possible to determine whether a trait is mono- or polygenic in basis. The sexual cycle can also be used for gene mapping, verification of gene function, and identification of genes of interest through techniques such as bulk segregant analysis (124).

Finally, the discovery of a sexual cycle provides important insights into the evolutionary potential of species. Species undergoing sexual recombination are likely to generate and maintain considerable genetic diversity within populations. This is predicted to lead to more rapid breakdown of control measures for fungal pathogens (129). Therefore, having knowledge about the reproductive mode of a species can inform disease management strategies. This might, for example, involve removal of suitable substrates to reduce the risk of occurrence of the sexual cycle—as can be achieved by removal of straw stubble after harvest to prevent the sexual cycle of plant pathogenic *Tapesia* species (130), and melon debris infected with *Monosporascus cannoballus* after crop termination (131).

POTENTIAL FOR SEX IN OTHER ASEXUAL SPECIES—CONSIDERATIONS

As will be apparent from the examples given above, in almost all cases where asexual fungal species have been studied in depth, evidence can be obtained of cryptic sexuality, and, in many instances, a fully functional sexual cycle can be induced. This raises the question of whether there are any truly imperfect fungi. We offer some considerations about this topic below.

First, we contend that there are some genuinely long-lived asexual fungal species, which is made possible by the genetic flexibility that is an especial characteristic of the fungal kingdom (132). Fungi exist in nature in a variety of ploidy states, from haploid to diploid to tetraploid, they can exhibit accessory chromosomes, and some species can even manipulate the genome to duplicate localized chromosome regions in the face of environmental pressures (132, 133). In tandem with this, fungi have developed alternative methods to heterothallic sex to allow gene flow both within and between species. Fungi are able to undergo vegetative fusion with hyphae of partners of the same heterokaryon compatibility group, thereby allowing nuclear exchange, and this can even lead to nuclear fusion and gene recombination via the parasexual cycle (see Daskalov et al. [176]). In recent years there have been reports of same-sex mating in human pathogenic fungi (92, 96). Also, there is accumulating evidence of horizontal gene transfer in the fungal kingdom both from fungi and also prokaryotic organisms (134). In early reports, transfer of low-molecular extrachromosomal DNA was reported between *Neurospora* species, between the distantly related ascomycetes *Ascobolus immersus* and *P. anserina*, and from the zygomycete mycoparasite *Parasitella parasitica* to its host *Absidia glauca* (135–137). Therefore, there is arguably less pressure on fungi to be sexually "perfect" to provide new sources of genetic variation than in many other eukaryotic organisms where there is an obligate requirement for sex.

What characteristics might such long-lived imperfect fungal species have? We would suggest factors such as the lack of any observed sexual cycle or developmental structures despite sustained investigative studies; a high degree of clonality in populations; loss of genes normally associated with sexual development or their

subversion to other cellular functions; dominance of one mating type (if *MAT* loci could even be detected); and development of alternative methods for generating or sustaining genetic variation as an adaptation to asexuality. The predicted long-term genomic effects of the loss of sex have even been classified and include possible congruent divergence of nuclear loci (the "Meselson effect" in asexual diploids), decrease in mutation rate, and loss of transposable element activity (see Table 1 in Normak et al. [4]). As a prime example in the fungal kingdom, we propose the group of fungi involved with vesicular-arbuscular mycorrhizal (VAM) symbioses from the phylum Glomeromycota (138). No morphological evidence of sexual structures has ever been observed in this group, which, combined with clonal population structures and conservation of asexual spore morphology, has led to the suggestion that they have been asexual for over 400 million years, even though some core meiotic genes have been detected (7, 139–141). Instead, it appears that individuals can arise from heterokaryotic spores composed of a mosaic of nuclei, which can maintain and promote genetic variation that helps explain occasional signs of recombination seen in the VAM fungi (142, 143). Such nuclear variation might provide a useful way to buffer these apparently asexual organisms against the effects of accumulating mutations (144) and maintain genetic diversity in the absence of sex. Most recently, a putative mating-type locus has been identified from genome sequencing of the model species *Rhizophagus irregularis*, suggesting a sexual origin for the observed heterokaryosis (145).

Second, we suggest that certain human activities have resulted in an increased likelihood of the evolution of asexual fungal species. Despite the many benefits of sexual reproduction, there are also costs to sexual reproduction leading to fungal "sexual hangups" (15). In outcrossing sex for every good, enhanced individual in the sexual offspring, there will be a corresponding poorly adapted one with less favorable sets of genes compared with the parents. Indeed, there is some evidence from comparing offspring of outcrossing and selfing in *A. nidulans* that outcrossing can result in progeny with an overall mean reduction in fitness, albeit that some offspring have significantly increased fitness (146). Thus, sex involving outcrossing has the risk of breaking up favorable sets of genes, a factor that can provide strong selection pressure for either the evolution of asexuality and/or homothallism in organisms well adapted to their environment (147). Human activities can exacerbate this phenomenon by establishing large, relatively uniform environments in which well-adapted organisms might evolve away from sex to avoid the risk of dilution of favorable genomes. There are also increased metabolic costs to sexual reproduction compared with asexual reproduction as a result of the investment needed for mating and development of fruiting bodies. In addition, the number of sexual spores produced is normally far less than can be produced by an equivalent investment in asexual reproduction, and development of such sexual spores needs a longer time period because of the complexity of sexual morphogenesis, all further reasons for the evolution of asexuality. Thus, there can be benefits to an asexual lifestyle. As Ross (148) wryly commented, the thought that the absence of sex is an imperfection, and that sex is perfection, might be an assumption of the human observer, rather than the fungus!

An example of such human activity perhaps favoring the evolution of asexuality is the deployment over wide geographic regions of crop plants with a narrow genetic base that has provided the opportunity for the clonal spread of fungal plant pathogens, which if well adapted to their host have an incentive to lose sex for all the factors listed above. And, indeed, there is evidence of what has been termed a "slow decline" in sexual fertility in populations of some fungal phytopathogens (149). *F. oxysporum* has evolved to be pathogenic on a wide variety of plant hosts and exhibits clonal spread on some crops such as banana. Despite concerted efforts, it has not been possible to induce a sexual cycle in this species complex, and pheromone-signaling sex-related genes now appear to be involved with pathogenicity processes detecting a plant host (81). A similar evolution away from sex is apparent for several other *Fusarium* species (122, 150). Similarly, different *Rhynchosporium* species (causing leaf blotch disease) are thought to have evolved on various graminaceous hosts as a result of human agricultural activities linked to crop selection, cultivation, and then dispersal over recent millennia (151, 152). These host-specialized species are only known to reproduce asexually, and sampling of *R. lolii* and *R. orthosporum* has so far only detected isolates of a single mating type (54). Finally, the rice pathogen *Magnaoporthe oryzae* is considered to be a heterothallic sexual species. However, there are reports of extensive loss of sexual potential in field populations worldwide, both due to loss of female fertility (i.e., the ability to produce maternal fruit body tissues, while rudimentary male ability to donate nuclei is retained) or total loss of any mating ability (153, 154). The slow decline in sexual ability might be attributable to various factors, as previously discussed (149), and the loss of sexual fertility seen in the field mirrors that seen

under laboratory conditions when isolates are subcultured long-term by asexual means (149, 155). The long-term future of such asexual species is unclear; it may be speculated that they are still likely to be relatively short-lived evolutionary dead ends (18) because they are dependent on human activity.

Third, we suggest that although some asexual species do exist and others are currently evolving, overall such species are still likely to be very rare. Therefore there is likely to be the occurrence of a sexual cycle in the majority of 20% of all fungi that are currently only known in the imperfect state. We suggest that there are various reasons for the failure to detect sex in such species. Many might need very specific conditions to induce a sexual cycle, requiring much painstaking work to identify (56). A further obstacle is that almost all are likely to exhibit heterothallic breeding systems, requiring the identification of a possibly rare compatible mating type as is the case for *C. neoformans* and *Cryptococcus gattii* (92), whereas it will be much easier to induce sex in homothallic species where no mating partner is needed. For some species, many isolates might have low sexual fertility as a result of a slow decline in sexual potential in the species overall (149). Therefore, it might take dedicated sampling to find rare isolates of a species that are a remnant that maintain sexual potential. But such isolates would be important in evolutionary terms to generate variation episodically within populations. Indeed, given the argument that "a little sex goes a long way," (7) it may only be necessary to retain a low proportion of isolates that retain the ability to reproduce sexually, i.e., that a very low rate of sexual recombination is sufficient to overcome evolutionary problems associated with asexuality.

CONCLUSIONS

With the advent of the "one species, one name" ruling in fungal biology (156), whether a species is perfect or imperfect has less taxonomic relevance than the past, because only one Latin binomial is needed for a species regardless of sexuality. But a knowledge of the reproductive mode remains a critical feature for an understanding of the biology of a species. There has been a sexual revolution in the understanding of asexuality over recent years, with a number of studies revealing sexual cycles in species that were previously considered imperfect. This implies that the majority of asexual fungal species will be shown to exhibit cryptic sexuality with the potential for sexual reproduction. However, there is a danger of simply thinking of fungi as either "perfect" sexual or "imperfect" asexual species. Indeed, we finish by echoing the comments of Dyer and Paoletti (149) that species should not be viewed as either sexual OR asexual, but, rather, they should be thought of as consisting of isolates on a continuum of sexual fertility, with the potential presence of isolates within a species with a range of abilities to undergo sexual reproduction from high to low fertility to even apparent asexuality. A thought to ponder over a cup of coffee, appropriate given that caffeine can induce sex in some fungal species (157).

INTRODUCTION

Cell-cell fusion is an essential biological process that occurs in organisms throughout the tree of life. It is involved in both sexual and asexual developmental processes in most species and has been shown to occur in multicellular and in unicellular organisms. Somatic cell fusion events are widespread in eukaryotic organisms, including animals, where they are important for muscle differentiation, placental development, and formation of multinucleate giant cells in the immune system (1–4).

Somatic cell fusion is a highly regulated event that requires reciprocal recognition as well as coordinated molecular processes in fusion partners. However, indiscriminate cell fusion comes with risks, including fusion with infected, impaired, or genetically different fusion partners, which can result in a disadvantaged heterokaryon. Thus, cells have evolved mechanisms to discriminate genetically identical from genetically nonidentical (nonself) cells. There are diverse types of genetic recognition mechanisms that organisms use to distinguish self from nonself. In mammalian cells, self/nonself recognition mechanisms mediate pathogen defense, while in basal eukaryotic invertebrates, such as the colonial ascidian *Botryllus schlosseri* and the cnidarian *Hydractinia symbiolongicarpus*, self/nonself recognition functions when individuals fuse to form vascular and hematopoietic chimeras (5). In bacteria, such as *Proteus mirabilis*, swarming colonies can recognize each other as nonself and establish a visible boundary, whereas genetically identical swarms merge (6, 7). In protists such as *Dictyostelium discoideum*, self/nonself recognition limits "self" genotypes to sporulating fruiting bodies (8, 9). In plants, self/nonself recognition is important for both pathogen defense and the prevention of self-fertilization for out-crossing species (10, 11). In filamentous fungi, the syncytial lifestyle combined with cell fusion to form the interconnected hyphal networks that are the growth habit of these organisms makes them superb models for studies of self/nonself recognition mechanisms. In this chapter, we summarize the current knowledge about somatic cell fusion events in filamentous fungi that govern both self and nonself recognition processes and that act prior to and after cell fusion events.

SOMATIC FUSION IN FILAMENTOUS FUNGI AND ITS CONSEQUENCES: BENEFITS AND DETRIMENTS

In filamentous fungi, somatic cell fusion (anastomosis) is essential to develop the hallmark of filamentous fungal growth: an interconnected, multinucleated, syncytial network (Fig. 1). Fusion has been reported in more than 73 species of filamentous fungi covering over 20 genera (12). Unlike other organisms, such as plants or animals, fungi lack biological transport networks (vascular systems). Instead, these organisms build a mycelial network to distribute cytoplasm, organelles (including nuclei), nutrients, and other resources within the syncytium, facilitating growth and rapid spatial expansion of the fungal colony (13–16). In fact, filamentous fungi form the most extensive biological networks characterized so far (17). Anastomosis in hyphae is also critical for host colonization and virulence of pathogenic and symbiotic fungi (18, 19) and for mycoparasitism (20).

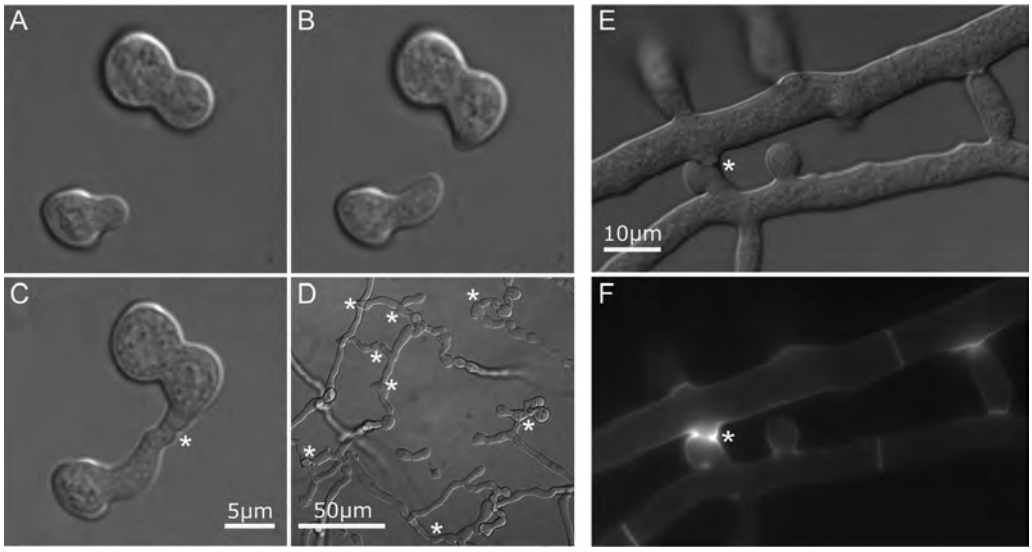

Figure 1 Germling and hyphal fusion in *Neurospora crassa*. (**A–C**) Germinating spores undergo mutual attraction and fusion (A: 0 min; B: 40 min; C: 80 min). (**D**) Consecutive fusion events result in network formation. (**E, F**) Hyphal branches fuse and form cross connections. (E: DIC; F: cell walls stained with calcofluor white). Asterisks in all images indicate fusion points. Adapted from reference 38.

In addition to fusion within a colony, cell fusion can occur between genetically different colonies. Such fusion events of nonclone individuals can be viable and lead to the coexistence of genetically different nuclei in a common cytoplasm (heterokaryon). Heterokaryon formation in filamentous fungi has potential benefits; e.g., it results in functional diploidy and mitotic recombination during the parasexual cycle, which can be especially important for highly clonal species (21, 22). However, heterokaryon formation has risks, because infectious agents can be transmitted via fusion events (23–26). Within a heterokaryon, allorecognition processes determine the fate of the fused cells: compatible genotypes lead to viable heterokaryons indistinguishable from a homokaryotic colony, while heterokaryotic cells resulting from the fusion of incompatible genotypes are rapidly compartmentalized and undergo a programmed cell death (PCD) reaction, termed heterokaryon (or vegetative) incompatibility (HI or VI) (27, 28). It has been proposed that HI limits genome exploitation and represents a defense mechanism that has important adaptive value in the highly competitive biotopes inhabited by most filamentous fungi (29). HI has been shown to limit the propagation of deleterious agents such as mycoviruses, DNA transposons, and senescence plasmids (24, 30–32). However, a recent study by Bastiaans et al. showed that fusion among fungal colonies is mutually beneficial, relative to the absence of fusion upon nonself recognition, suggesting an interplay between beneficial aspects of cell fusion versus the risk factors associated with indiscriminate fusion with other partners (33).

Unlike somatic fusion, where genetic similarity between the fusion partners is favorable, in out-crossing species of filamentous fungi, fusion between genetically dissimilar partners is necessary for sexual reproduction. In heterothallic fungi, genetic dissimilarity is determined by the existence of at least two different mating types. Interestingly, in some fungal species, mating type also serves as an HI factor during somatic fusion, preventing the existence of different mating types within a heterokaryotic colony (34, 35). In species capable of outcrossing, individuals that are somatically incompatible undergo sexual reproduction and production of meiotic progeny, indicating that nonself recognition involved in HI processes must be inactive during the sexual cycle.

RECOGNITION, CELL FUSION, AND COLONY ESTABLISHMENT

In addition to hyphal fusion within a mature colony, somatic fusion events also contribute to the onset of colony formation. For example, cell fusion between germinated asexual spores (germlings) merges numerous individuals into one functional unit, providing the basis for the developing mycelial colony in a number of fungal species (Fig. 1) (36). The ability of germlings

to form a network contributes to fitness, as indicated by more rapid colony establishment and subsequent asexual spore formation (36–39). However, fusion can be particularly risky for germlings. For example, a post-fusion incompatibility reaction (see below) would likely result in the death of both germlings. Therefore, most HI reactions described so far are suppressed at the germling stage (40).

Germlings are especially tractable for analyzing the cellular mechanisms and components involved in the cell fusion process (2). In recent years, more than 60 proteins involved in germling fusion have been identified (41, 42). Most of the cellular components mediating germling fusion processes are also required for hyphal fusion in a mature colony, indicating that both processes share common molecular machinery. Mutual recognition and attraction of the fusion partners employs an intricate signaling network, which comprises conserved eukaryotic factors, such as mitogen-activated protein kinase (MAPK) modules, NADPH oxidases, the striatin-interacting phosphatase and kinase (STRIPAK) complex, and calcium-regulated factors, but also fungal-specific proteins (Fig. 2). A central hub within this network is a MAPK cascade homologous to the pheromone response pathway of *Saccharomyces cerevisiae* (43, 44). Analysis of the subcellular dynamics of the MAPK mitogen-acivated kinase-2 (MAK-2) during germling fusion in *Neurospora crassa* revealed an unusual mode of communication associated with localization of MAK-2 to cell tips during chemotropic

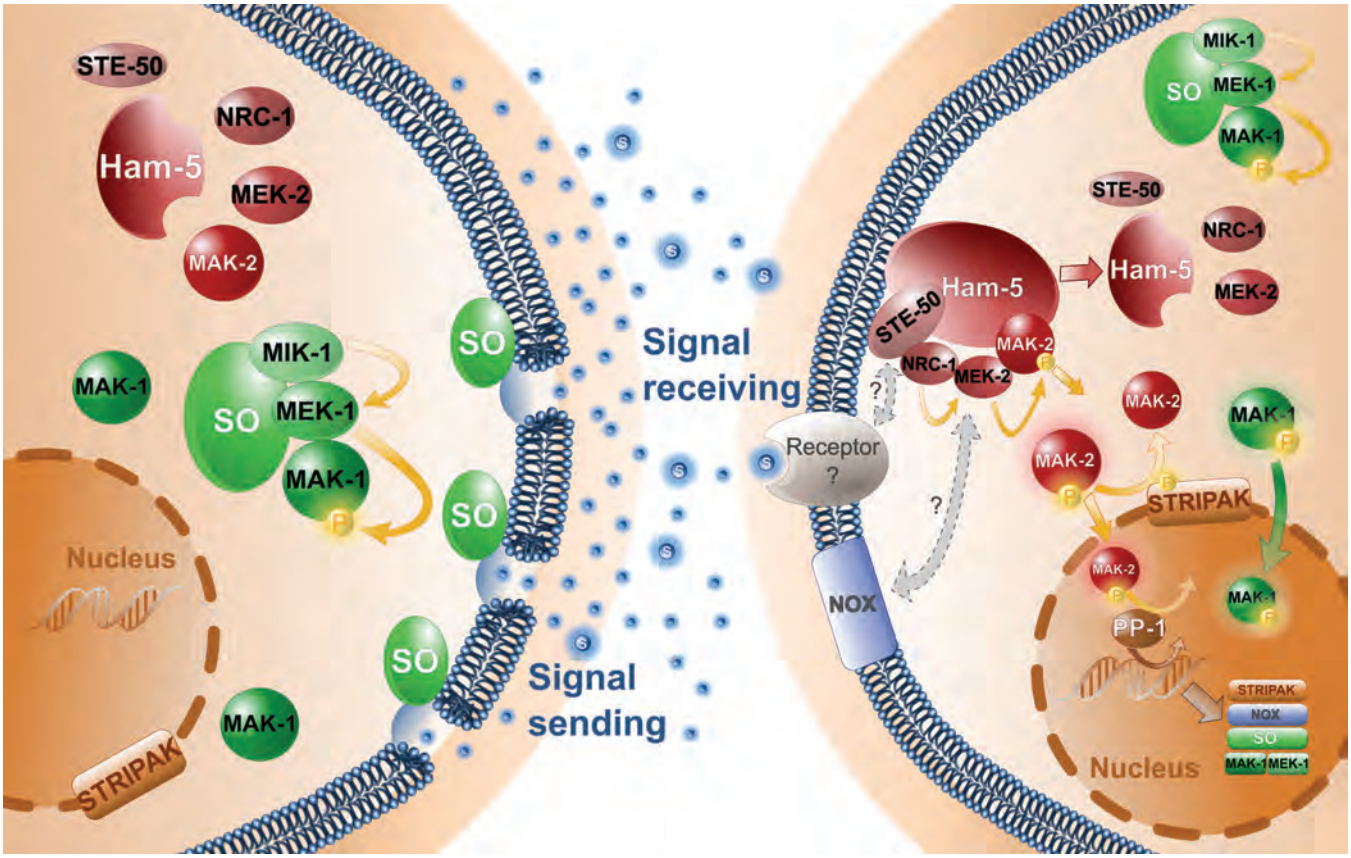

Figure 2 Working model of the molecular events governing germling and hyphal fusion. The signal-emitting cell releases the ligand in a pulse-like manner, probably by exocytosis. Binding of the signal molecules to their cognate receptors results in assembly and activation of the MAK-2 module at the plasma membrane. MAK-2 phosphorylates MOB-3 of the STRIPAK complex, thereby promoting nuclear entry of MAK-1. In the nucleus MAK-2 activates the transcription factor PP-1, which controls cell fusion factor-encoding genes. Activation of MAK-2 involves reactive oxygen species production by the NADPH oxidase (NOX) complex either upstream or downstream of the MAP kinase cascade. Adapted from reference 38.

interactions (45, 46). During the tropic interactions between germlings or hyphae, MAK-2 assembles with its two upstream kinases MEK-2 and NRC-1, the scaffold HAM-5, and the adaptor protein STE50 in an oscillating manner at the plasma membrane of cell tips (45, 47, 48). Within one cell, formation of the MAK-2 complexes at the cell tips alternates with the membrane recruitment of another protein, called SOFT (SO), a factor that is only conserved in filamentous ascomycete fungi and is essential for germling/hyphal fusion (45, 49). The membrane recruitment of the MAK-2 complex or SO alternates between the two fusion partners in a coordinated manner, with one phase lasting between 8 and 12 minutes. These observations indicate that the two fusion cells switch between two physiological states in a highly coordinated manner.

The current working model suggests that the cells take turns in signal sending and signal receiving. Mathematical modeling revealed that this unique mode of communication would allow signaling via a single receptor/ligand pair employed by both partner cells (50). The spatiotemporal coordination of signal sending versus signal receiving would enable genetically and developmentally identical cells to achieve mutual attraction and fusion, while avoiding self-stimulation. While the nature of the predicted signal and receptor activating the MAPK module remains unknown, the linkage of the MAK-2 module and the SO protein within the fusion signaling network is beginning to unfold. In *Sordaria macrospora*, a homolog to SO called PRO40 functions as a scaffold for a second MAPK module, the cell wall integrity pathway (51). Similar to the MAK-2 pathway, this MAPK module is also essential for somatic fusion in several filamentous fungi (43, 51–53). In *N. crassa*, nuclear entry of the MAPK of the cell wall integrity pathway, MAK-1, is controlled by the STRIPAK complex in a MAK-2-dependent manner (54). STRIPAK complexes are multiprotein assemblies that mediate a plethora of biological functions in eukaryotic organisms. Their presence in filamentous fungi was first shown in *S. macrospora*, and their essential role for somatic fusion has been established for several species (54–59). Besides the STRIPAK complex, an additional target of MAK-2 is the transcription factor PP-1, which in turn controls the expression of several fusion-mediating factors, including genes encoding the STRIPAK complex, *so*, *mak-1*, *mek-1*, and NADPH oxidase encoding genes (39). NADPH oxidase complexes are essential for somatic fusion in several filamentous fungi, and their potential interaction with the MAPK signaling modules as targets or activators is currently a major research topic in the cell fusion field (2, 60–62). In general, placing the numerous identified fusion factors into the described signaling network will be one of the main future challenges in this research field. Given, however, the experimental tractability of fungal model systems, hyphal and germling fusion may well advance as paradigms for studying eukaryotic signaling networks and their subcellular dynamics.

NONSELF RECOGNITION EVENTS ACTING PREFUSION

While the molecular basis of chemotropic interactions between genetically identical germlings has been studied extensively, there are only a few studies focusing on processes involved in chemotropic interactions between genetically nonidentical germlings. For example, prerecognition of incompatible strains has been reported in *Tuber borchii* and *Glomus mosseae*, in which incompatible hyphae avoid fusion with each other (63, 64). Although the genes and mechanisms behind these findings remain to be revealed, these observations suggest a link between fusion signaling and nonself recognition. This hypothesis was supported recently in a study by Heller et al. showing that the polymorphic "greenbeard" genes *doc-1*, *doc-2*, and *doc-3* mediate kind discrimination in *N. crassa* populations and act at a distance during chemotropic interactions. Kind discrimination divides *N. crassa* populations into separate communication groups; only individuals with identical sets of *doc* genes (kind individuals) show chemotropic growth and cell fusion. Germlings from different communication groups grow past each other, even when in close proximity, to find a partner of their own communication group. If nonkind germlings are in close proximity, MAK-2 oscillation reinforcement is repressed, resulting in an inability of cells to establish chemotropic interactions (65). These findings show that cellular communication in fungi is even more complex than initially anticipated: due to nonself recognition mechanisms acting at a distance, cells must avoid not only self-stimulation during chemotropic interactions, but also stimulation by nonkind individuals.

NONSELF RECOGNITION MECHANISMS ACTING POSTFUSION

In spite of nonself recognition mechanisms that act prefusion, fusion between genetically different strains occurs frequently. Anastomosis between compatible genotypes results in formation of a viable heterokaryon, while anastomosis between incompatible genotypes triggers HI, resulting in a PCD reaction leading to death of

the fusion cells (Fig. 3). This outcome is widespread in fungi and represents the most probable event after heterokaryon formation. Heterokaryon (or vegetative) incompatibility can be observed by the appearance of a demarcation line, which separates the genetically incompatible strains, termed "barrage." One of the first accounts of this type of rejection of nonself in filamentous fungi was made in the early 20th century by the pioneering mycologist Dorothy M. Cayley on the plant pathogenic ascomycete *Diaporthe perniciosa* (66). After confronting mycelia of monosporic cultures that exhibited the barrage phenotype, Cayley noted that "like must meet like and unlike shows aversion to unlike." HI reactions in nature, mostly on dead tree trunks, or on an agar plate under laboratory conditions, can be detected by assessing whether barrage lines form at interaction zones between genetically distinct individuals (Fig. 4) (67). Microscopically, incompatible heterokaryotic fusion cells are rapidly isolated from the rest of the mycelia by septal plugging (68, 69). Septal plugging in response to stress can be mediated by specialized peroxisome-derived organelles called Woronin bodies (70–73), although the role of the Woronin body in HI is unclear. However, a family of septal pore-associated proteins and the fusion protein SO have been associated with septal plugging during HI in *N. crassa* (74, 75). The HI reaction leads to vacuolization of the fusion cells accompanied by cell wall thickening, lipid droplet accumulation, reactive oxygen species production, and intracellular *de novo* formation of septa (Fig. 5) (70, 76). Furthermore, nuclear DNA degradation during cellular dismantling occurs, drawing parallels between fungal PCD and *apoptosis* in metazoans (77). The complete cellular lysis of an incompatible hyphal compartment can vary in duration, ranging from 20 minutes to more than 6 hours, depending on the genetic determinants triggering the reaction. Autophagy also plays a role in HI, although the autophagosomal process is not required for the execution of cell death (78, 79). It has been proposed that

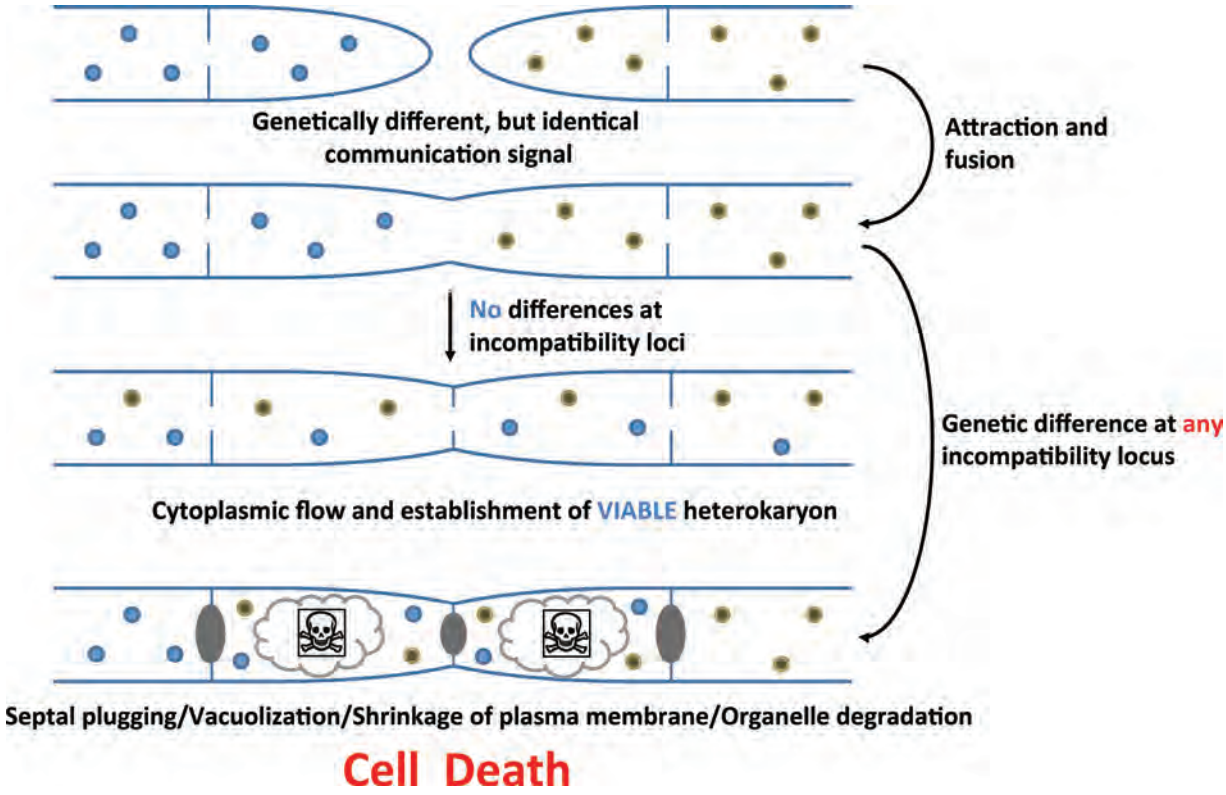

Figure 3 Heterokaryosis and its possible outcomes. Genetically distinct individuals can undergo hyphal anastomosis. If there are no allelic specificity differences at *het* loci, a viable heterokaryon is established and nuclei (blue and brown dots) are exchanged. If allelic specificity is different between the two strains for any of the *het* loci, septal plugging isolates the heterokaryotic compartments and cell death occurs.

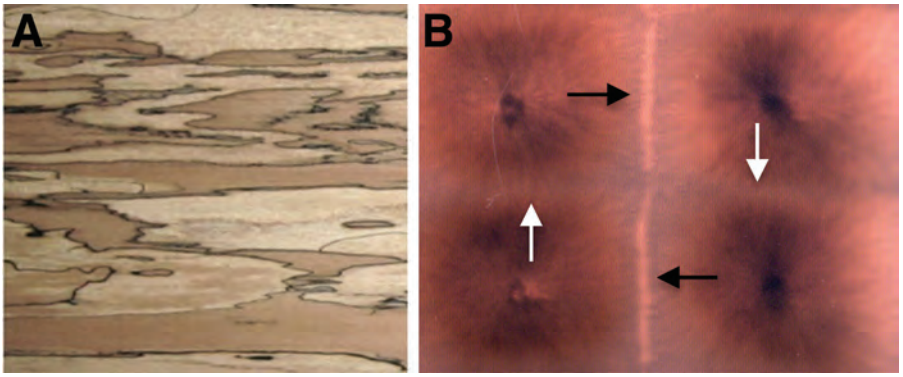

Figure 4 Macroscopic visualization of vegetative incompatibility. The heterokaryon (vegetative) incompatibility reaction is visualized by the occurrence of a demarcation line called "barrage" that separates the incompatible strains. (**A**) Evidence of barrage on wood (spalted wood) occurring in the wild. (**B**) Barrage reaction (black arrows) between genetically incompatible *Podospora anserina* strains. Identical individuals fuse without inducing allorecognition PCD and do not form the barrage (white arrows).

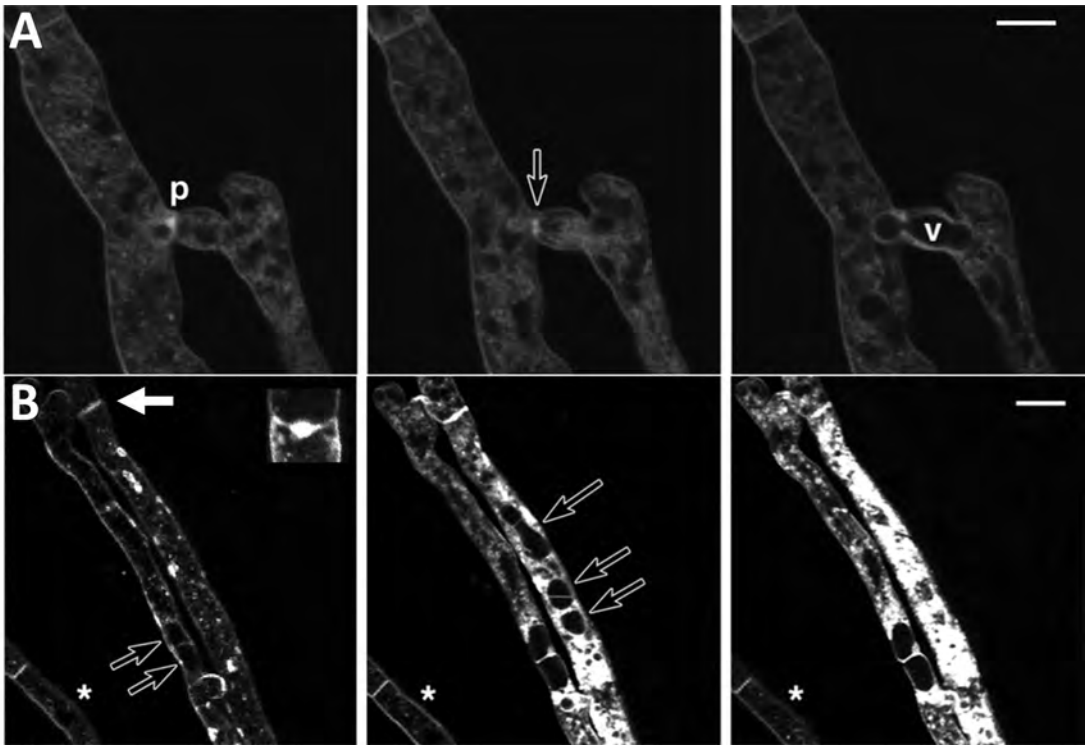

Figure 5 Microscopic visualization of programmed cell death during vegetative incompatibility. A time course of compatible and incompatible hyphal fusion in *Neurospora crassa*. The programmed cell death reaction is followed by the fluorescent vital dye (membrane staining) FM4-64. (**A**) Fusion between two *N. crassa* strains that have identical specificities at all *het* loci. Arrow shows the fusion pore (p). Nuclei or large vacuoles (v) are transported through the pore with the cytoplasmic flow. (**B**) Fusion between two *N. crassa* strains that differ in *het* specificity. Heterokaryotic cells are compartmentalized by septal plugs (solid arrow and insert). Permeabilization of the plasma membrane leads to increased cytoplasmic staining and vacuolization. Open arrows show large vacuoles within incompatible fusion cells, while the asterisk shows a nearby healthy cell. Bar = 10 μM. Adapted from reference 146.

autophagy has a protective role during HI by limiting the spread of the PCD signals, similar to what has been reported in plant immune responses (80).

Genetic Control and Molecular Characterization of Heterokaryon Incompatibility

Early efforts to understand the HI reaction led to genetic mapping of loci involved in its control for a small number of ascomycete species, so-called *het* (heterokaryon) or *vic* (vegetative incompatibility) loci (81, 82). Genetic analyses revealed that the number of *het/vic* loci ranges from 7 to 12 for different species in sampled populations. Nonself recognition in HI systems may be mediated by alternate alleles at a single *het* locus (allelic HI systems) or by alternate alleles at more than one *het* locus (nonallelic HI systems). Within the three species (*N. crassa*, *Podospora anserina*, and *Cryphonectria parasitica*) which have served as model organisms for studying HI, nonallelic HI systems predominate (Fig. 6). Independent of the type of HI system, particular hallmarks of molecular evolution are shared between *het* loci. Foremost, alleles at a particular *het* locus are highly polymorphic in populations and are often found in hypervariable genomic regions (83). Second, alleles conferring alternate specificity are maintained in wild populations in nearly equal allelic frequencies, which is an indication of nonneutral balancing selection operating on these loci (83, 84). The observed signatures of balancing selection can be explained by the associated benefits of preserving incompatible alleles and are in accordance with the proposed adaptive value of HI. The underlying evolutionary process is an example of negative frequency-dependent selection in which the rare genotype is advantageous: strains carrying a less frequent *het* allele would potentially form a higher number of incompatible heterokaryons and therefore possess a fitness advantage by diminishing conspecific parasitism (85, 86). In some cases, the evolutionary pressure on HI determinants surpasses speciation events resulting in trans-species polymorphism in which closely related species share ancestral *het* alleles. Balancing selection and trans-species polymorphisms are described for other self/nonself defining loci such as the major histocompatibility complex in vertebrates and the S locus in flowering plants (87, 88).

In the next section we summarize the molecular details for the currently characterized *het* genes and HI systems of each of the three above-mentioned fungal models.

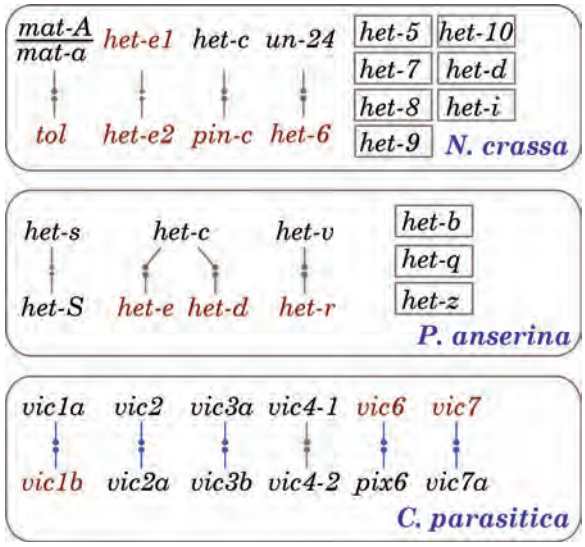

Figure 6 Incompatibility systems and genetically identified *het* (*vic*) loci in model filamentous ascomycete species. Round-headed arrows connecting the *het/vic* genes indicate nonallelic HI systems, and square-headed arrows indicate allelic HI systems. Blue arrows indicate that the incompatibility reaction influences the distribution of mycoviruses that result in hypovirulence in *Cryphonectria parasitica*. Genes in red encode for proteins with a HET domain, and boxed genes (loci) are still not identified molecularly.

N. crassa

N. crassa is a heterothallic ascomycete with a haploid cell cycle and initially was used as a model organism to establish the bases of molecular biology and decipher metabolic pathways (89, 90). Classical genetics assays (complementation or dominance/recessiveness) with haploid monokaryotic strains carrying auxotrophic mutations revealed that heterokaryosis between strains of opposite mating types results in growth inhibition (91). Incompatibility based on differences at the mating type locus is not exclusive to *N. crassa* and is found in several other unrelated species (92, 93). The mating type locus in *N. crassa* is composed of genes that confer mating identity (*mat A* or *mat a*) and are evolutionarily unrelated (termed idiomorphs) (94). The *mat-A1* and *mat-a1* genes of the *mat A* or *mat a* idiomorphs, respectively, encode for transcriptional regulators which trigger HI when coexpressed in heterokaryotic cells (34, 95). The role of mating of the *N. crassa mat* locus is uncoupled with its HI function as demonstrated by strains carrying mutations in *mat-A1* or *mat-a1* that abolish HI but that do not impact mating competency (96, 97). Additional genetic analysis for suppressors of mating type incompatibility led to the identification of a recessive mutation called *tol* (tolerant) (98).

Strains carrying the *tol* mutation mate normally but do not induce the HI phenotype. TOL actively regulates mating type-dependent HI, as shown by introgression experiments between *N. crassa* and the closely related pseudohomothallic species *Neurospora tetrasperma* (99, 100). The *tol* gene encodes for a putative 1,011-amino-acid polypeptide with a HET domain and coiled-coil and leucine-rich repeat regions. Transcriptional repression of *tol* during the sexual reproductive phase has been postulated to allow opposite mating type nuclei to coexist in the dikaryotic ascogenous hyphae (93).

Further investigations of heterokaryosis with nearly isogenic *N. crassa* strains or with the elegant use of strains containing partial chromosomal duplications revealed 10 other *het* loci in *N. crassa* (81, 101, 102). Three of these *het* genes have been cloned and their products examined at the molecular level. Two of the *het* genes, *het-c* and *het-6*, control HI in association with closely linked (adjacent) genes termed *pin-c* (partner in incompatibility of *het-c*) and *un-24*, respectively (81, 103, 104, 105). Nonallelic interactions between *het-6* and *un-24*, the latter encoding the large subunit of ribonucleotide reductase, are considered crucial for the HI phenotype in the *het-6*/*un-24* system (106). Haplotypes of *het-c*/*pin-c* and *het-6*/*un-24* are under balancing selection, show severe linkage disequilibrium—haplotypes are inherited as blocks—and exhibit trans-species polymorphism (84, 107). The product of *het-c* is a glycine-rich cell wall protein, and the HI specificity of the allelic variants is determined by indels in a variable region (108, 109). The *pin-c* gene encodes a protein that shares a region of similarity with the products of *het-6* and *tol*, termed the HET domain (~150 amino acids). Genes encoding predicted HET domain proteins are ubiquitous in ascomycete genomes (83). A HET domain protein is also encoded by the recently characterized *het-e* locus (83), and coexpression of different *het-e* alleles triggers the HI reaction. Proteins encoding a HET domain are a common thread in all molecularly characterized HI systems in *Neurospora*, suggesting downstream similarities in PCD pathways. A combined population genomics and evolutionary approach was used to identify 15 additional candidate *het* loci, all encoding proteins with a HET domain and which displayed at least two long-diverged haplogroups (83). Additionally, deletion of a transcription factor, *vib-1*, suppresses the HI reaction mediated by genetic differences at all molecularly characterized *het* loci in *N. crassa* and was shown to be required for expression of some *het* genes encoding HET domain proteins (110–112).

P. anserina

P. anserina is an ascomycete in the same order (Sordariales) as *Neurospora* (68). Eight HI systems have been genetically defined in *P. anserina* and four have been molecularly investigated (70, 82). To date, none of the characterized *het* loci in *P. anserina* are orthologous to those described in *N. crassa*. As in *N. crassa*, three nonallelic HI systems (*het-d*/*het-c*, *het-e*/*het-c*, and *het-r*/*het-v*) depend on a gene encoding a HET domain protein (*het-d*, *het-e*, and *het-r*) (113, 114). The HET domain itself has been shown to play an essential role in the induction of PCD in *P. anserina* (115). The HET domain is situated at the N-terminus of these proteins next to a central nucleotide-binding NACHT domain and a C-terminal domain composed of WD40 repeats (116). The NACHT domain is associated with regulation of apoptosis and innate immunity in metazoans and mediates the oligomerization of proteins forming multimeric cell death platforms like the apoptosome (117, 118). The WD40 repeats form a doughnut-shaped beta-propeller structure where individual repeats of 40 to 42 amino acids, in beta-sheet conformation, revolve around a central axis and can function in molecular sensing as protein scaffolds (119). APAF-1, the human apoptotic factor assembling the apoptosome, also has a WD40 domain which binds to cytochrome *c*, thus regulating its apoptosis-inducing activity (120). The NACHT and WD40 domains have been shown to be functionally important in HET-E to trigger HI (121).

The coexpression of allelic variants of HET-D or HET-E with antagonistic variants of HET-C—a protein with a GLTP (glycolipid transfer protein) fold—induces a PCD reaction (122, 123). In this nonallelic incompatibility system, the *het-c* gene is not linked to *het-e* or to *het-d* (124). Eleven highly polymorphic *het-c* alleles are present in a population of 110 *P. anserina* strains, falling in seven distinct functional classes with polymorphic positions under positive diversifying selection (high ratio of nonsynonymous to synonymous substitutions per codon) overlapping with positions defining allelic specificity (125). The allelic specificity of HET-D, HET-E, and HET-R is defined by the variability of the WD40 domain (113). Exchange between the WD40 repeats between alleles from the same *het* locus and/or between different paralogous WD40 genes is hypothesized to aid in concerted evolution of alleles (126, 127). The current data support a molecular model for *het-d*/*het-c* and *het-e*/*het-c* HI systems in which direct binding of antagonistic HET-C allelic variants by the WD40 domain of HET-D/HET-E triggers the PCD reaction (128).

One HI system in *P. anserina* that has been extensively studied involves the *het-s* locus, which encodes two functional alleles, *het-s* and *het-S* (129). Importantly, the *het-s* allele encodes a prion protein (the HET-s protein) that can exist as a soluble monomer, in a state termed [Het-s*] or as infectious aggregates (a prion state) termed [Het-s] (130, 131). The appearance of the [Het-s] prion state occurs sporadically at a low rate and converts the [Het-s*] state to the [Het-s] prion, so that strains of the *het-s* genotype are exclusively prion-infected or prion-free. Only prion-infected [Het-s] strains trigger HI with [Het-S] strains (132). The HET-S protein is a pore-forming toxin that is activated upon interaction with the HET-s prion protein, resulting in death of the cell (133, 134). The two alleles *het-s* and *het-S* are under balancing selection and in a wild population of *P. anserina*, with 92% of the strains of *het-s* genotype being prion-infected, thus having the HI competent [Het-s] state (24). These observations underline the adaptive value of the allorecognition system in the wild—a conclusion supported in the same study by the correlated distribution of a deleterious plasmid with the frequency of the *het-s* and *het-S* genotypes in populations (24).

C. parasitica

Six *vic* loci control the incompatibility reaction in *C. parasitica*, an ascomycete that causes the chestnut blight disease (135, 136). As in *Podospora*, HI in *Cryphonectria* is observed by the appearance of a barrage between incompatible strains. Moreover, a systematic exploration of the transmission of virulence-attenuating mycoviruses during heterokaryosis showed that genetic differences at five of the six *vic* loci reduced virus transmission between strains, suggesting fitness benefits associated with HI (31, 137). This approach makes *Cryphonectria* an exciting model to study the relationship between HI and its function as a barrier against mycovirus transmission. The six incompatibility systems in *Cryphonectria* are composed of closely linked polymorphic genes or idiomorphs, and their functional characterization indicates mostly non-allelic interactions (31). Three of the HI systems rely on proteins with HET domains, and one other involves a protein with NACHT-WD40 architecture. As above, the molecularly characterized *vic* genes are not orthologous to *Podospora* or *Neurospora* molecularly characterized *het* loci. Recently, as a consequence of the molecular characterization of the *vic* genes, a super mycovirus donor strain has been engineered that carries multiple deactivated *vic* genes, which could potentially serve as a more potent biocontrol agent against larger sets of wild isolates that are capable of causing the chestnut blight disease (138).

HI Determinants: at the Molecular Crossroad of Allo- and Xenorecognition

Experimental evidence supports the hypothesis that HI, an allorecognition process, has a beneficial role in nature, preventing conspecific parasitism and limiting harmful replicon propagation. However, similarities of some fungal HI-inducing determinants with plant and metazoan innate immunity factors, the latter mediating xenorecognition (nonself discrimination between different species), have prompted the idea that fungal allorecognition (HI) may originate from molecular networks with a primary role in heterospecific nonself recognition (139, 140). For example, HET-E (HET-D and HET-R), controlling HI in *P. anserina*, has a similar domain organization to APAF-1 and NLRC4 (a NOD-like receptor [NLR] protein), which are intracellular molecular sensors operating in mammalian apoptosis and innate immunity, respectively (Fig. 7) (141, 142). An extensive analysis of fungal NLR-like proteins—a protein superfamily that includes HET-E, HET-D, and HET-R from *Podospora* and VIC4-2 from *Cryphonectria*—suggests a similar role in xenorecognition for this class of proteins (143). Furthermore, fungal NLRs not directly involved in HI have been shown to regulate pore-forming toxins that function as *bona fide* HI-factors, like HET-S in *Podospora* (128, 144, 145). These data support the hypothesis regarding the relationship between allo- and xenorecognition systems in fungi and put the HI phenomenon in a broader context of fungal biotic interactions.

CONCLUSIONS AND FUTURE OUTLOOK

Cell fusion is of capital importance for the fungal life style. It is not only related to mating, but it is also important during vegetative growth, facilitating colony establishment, network formation, and heterokaryon formation. Nonself recognition mechanisms that function pre- and postfusion restrict the development of heterokaryons to cells that are more genetically similar. Genetic analyses have identified a large number of genes required for cell fusion, but many of these have not been placed in a cellular pathway, nor is it understood how the different cellular pathways are integrated to accomplish cell fusion events. Another major outstanding question is the relationship between the molecular mechanisms regulating cell fusion events versus those that regulate nonself recognition, both pre- and postfusion. Unlike alleles at loci required for cell

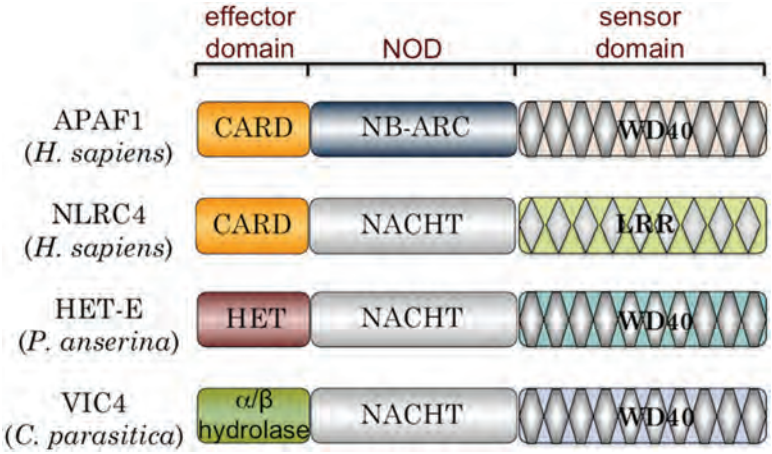

Figure 7 Domain organization of fungal and metazoan NLRs (NOD-like receptors) and NLR-like proteins. The heterokaryon determinants HET-E (also HET-D and HET-R as paralogues of HET-E) and VIC4 present a typical NLR-like domain organization. NLRs have a tripartite domain organization with a central nucleotide-binding and oligomerization (NOD) domain, an N-terminal effector domain, and a C-terminal sensor domain. The sensor domain can be composed of various repeated motifs (LRR or WD40, in the examples presented here) that trigger the activation of the receptors upon recognition of defined molecular cues. The recognition of the signal activates the formation by the receptors of multimeric protein platforms. The oligomerization of the receptors is mediated by the NOD domain (NACHT or NB-ARC type) in characterized cases, such as APAF-1 (the human apoptosis-controlling factor) and NLRC4 (an innate immunity receptor). Abbreviations: CARD, caspase recruitment domain; LRR, leucine rich repeats.

fusion, alleles at loci that function in nonself recognition often display features of balancing selection. The availability of complete fungal genome sequences on the population level will facilitate the identification and characterization of loci that display balancing selection and thus are presumptively involved in either xeno- or allorecognition.

As discussed above, the induction of PCD as a result of nonself recognition and HI seems to be conserved among species of filamentous fungi, even though the proteins used for nonself recognition can vary. However, with the exception of the *het-s/het-S* system of *P. anserina*, the link between the nonself recognition and the death reaction is still unclear for other HI systems. This raises the question of how death is induced on a molecular level. Identifying the signaling networks and exact mechanisms that control the PCD pathway will be at the center of interest for further research on fungal HI.

Cell Biology of Hyphal Growth

11

Gero Steinberg,[1,2] Miguel A. Peñalva,[3] Meritxell Riquelme,[4] Han A. Wösten,[2] and Steven D. Harris[5]

INTRODUCTION

Filamentous fungi are a large and ancient clade of microorganisms that occupy a broad range of ecological niches (1, 2). Fungi are recyclers, being major decomposers of plant debris (3); they form mycorrhizal symbiosis with 93% of all flowering plant families (4), and they serve in the industrial production of proteins (5). However, fungi pose a threat to public health, the ecosystem, and our food security (6, 7). The success of filamentous fungi is largely due to their elongate hypha, a chain of cells separated from each other by septa (8). Hyphae grow rapidly by polarized exocytosis at the apex (9–11), which allows the fungus to extend over long distances and invade many substrates, including soils and host tissues. Hyphal tip growth is initiated by establishment of a growth site and the subsequent maintenance of the growth axis, with transport of growth supplies, including membranes and proteins, delivered by motors along the cytoskeleton to the hyphal apex (12). Among the enzymes delivered are cell wall synthases that are exocytosed for local synthesis of the extracellular cell wall (13). Exocytosis is opposed by endocytic uptake of soluble and membrane-bound material into the cell (14). The first intracellular compartment in the endocytic pathway is the early endosomes (EEs), which emerge to perform essential additional functions as spatial organizers of the hyphal cell (15). Individual compartments within septated hyphae can communicate with each other via septal pores, which allow passage of cytoplasm or organelles (16) to help differentiation within the mycelium (17). This article introduces the reader to more detailed aspects of hyphal growth in fungi.

REGULATION OF HYPHAL MORPHOGENESIS

Hyphal morphogenesis refers to the complex biological processes that directly contribute to the formation of highly polarized hyphae by filamentous fungi. The two fundamental processes that underlie hyphal morphogenesis are polarity establishment and polarity maintenance. The regulation of these processes over time and space presumably accounts for much of the variation in hyphal morphology and growth patterns observed in the filamentous fungi (18). Additional processes that contribute to the complexity of hyphal morphology in those filamentous fungi that belong to the Dikarya include septation and the formation of septal pores (19). The regulation of these processes must also play an important role in specifying the overall organization of hyphae in these fungi. Nevertheless, we are still at an early stage in understanding the temporal and spatial regulation of hyphal morphogenesis. Progress has been achieved in determining how hyphae maintain a polarity axis (20, 21), but we still know little about how polarization sites are initially established in germinating spores and during branch formation. In addition, much remains to be learned about when and where septa are made. The following sections will address these points, but before doing so, it is perhaps useful to focus on the broader regulatory issue of how morphogenesis is coordinated with hyphal growth.

Experimentally, we typically grow filamentous fungi and assess morphogenesis under conditions that are largely homogeneous and in which all needed nutrients are available. This is unlikely to be representative of conditions that hyphae would normally experience in

[1]Department of Biosciences, College of Live and Environmental Sciences, University of Exeter, EX1 1TE Exeter, United Kingdom; [2]Department of Biology, University of Utrecht, 3584 CH, Utrecht, The Netherlands; [3]Department of Cellular and Molecular Biology, Centro de Investigaciones Biológicas CSIC, Madrid, 28040, Spain; [4]Department of Microbiology, Center for Scientific Research and Higher Education of Ensenada, CICESE, Ensenada, Baja California C.P. 22860, Mexico; [5]Center for Plant Science Innovation and Department of Plant Pathology, University of Nebraska, Lincoln, NE 68588-0660.

their natural environment (though there are likely to be important exceptions). In reality, most hyphae propagate in a spatially heterogeneous environment that is characterized by a patchy distribution of nutrients. Accordingly, two possible strategies could conceivably be invoked to account for hyphal extension under variable conditions. First, hyphal growth could be a "brute-force" mechanism by which a hypha harnesses the morphogenetic machinery (i.e., the cytoskeleton and vesicle trafficking machinery) and turgor pressure to plough ahead with colonization of the substrate. Extension rates and the frequency of branching may only be minimally adjusted to account for a changing environment. Alternatively, hyphae may fine-tune extension rates and morphogenesis to reflect the local environment at the tip and at incipient sites of branch formation. It seems reasonable to speculate that some combination of both strategies is deployed within a given mycelium. However, the latter strategy would seemingly rely more on the ability of hyphae to adjust the timing and location of polarization events, as well as to modulate the degree of polarity maintenance, in response to local environmental conditions. Insight into how this might occur comes from the model yeasts *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*. Both normally utilize an internal program to specify the position of localized cell surface expansion and cell wall deposition but are able to override the program in response to external signals such as mating pheromones (22). Accordingly, it is tempting to speculate that the signaling pathways that mediate growth and stress responses in filamentous fungi (e.g., TOR, PKA, HOG) likely interface with the mechanisms that temporally and spatially regulate hyphal morphogenesis. To date, little is known about how these pathways might impact hyphal morphogenesis, though there is growing evidence that they do mediate tropic responses that influence the directionality of hyphal extension (23). Characterization of the links between these pathways and the morphogenetic machinery would appear to be fertile territory for future investigation.

Spatial Regulation of Hyphal Morphogenesis

The key events underlying the spatial regulation of hyphal morphogenesis are the initial specification of a polarity axis (polarity establishment) and the subsequent stabilization of the axis (polarity maintenance). Two types of polarity establishment events are commonly observed in a typical hypha: spore polarization and branch formation (Fig. 1). In both cases, specification of a polarity axis occurs in a cell that is otherwise displaying isotropic or apolar growth (i.e., germinating spores or an existing hyphal compartment). Stabilization of the resulting axis requires the recruitment of the morphogenetic machinery to the specified site. As a result, cell surface expansion and cell wall deposition are subsequently confined to a discrete cortical site, which ultimately leads to the formation of a new hypha.

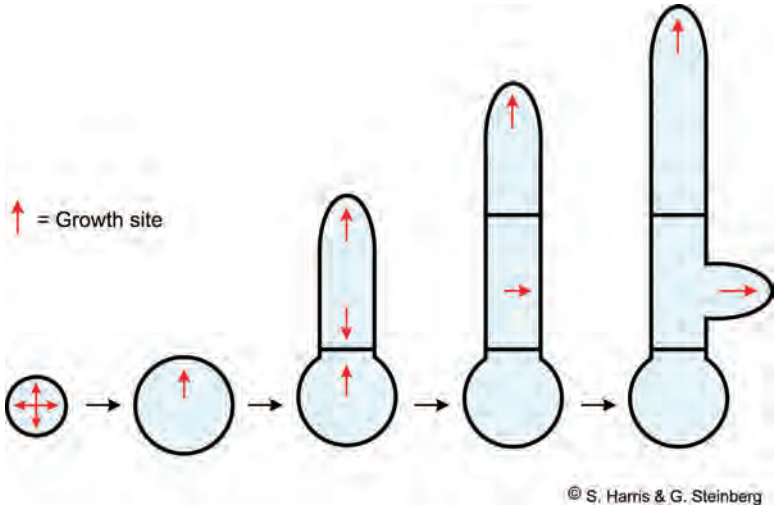

Figure 1 Growth patterns in fungal hyphae. Growth occurs in an isotropic fashion during spore germination. Specification of a polarity axis ultimately results in the formation of a hypha that continues to grow at the tip. While tip growth is maintained, the specification of additional polarity axes enables the formation of septa and lateral branches. Whereas septum formation is transient, branching results in the formation of a secondary hypha that also continues to grow at the tip. Red arrows designate polarity axes.

Detailed studies of *S. cerevisiae* and *S. pombe* have provided significant insight into the nature of the spatial landmarks that direct polarity establishment (22). *S. cerevisiae* utilizes a set of cortical landmark proteins (the Bud proteins) to specify new polarity axes (24), whereas *S. pombe* relies on microtubule-based delivery of a set of marker proteins (the Tea proteins) to position new growth sites (25). By contrast, comparatively little is known about mechanisms that specify new polarity axes in filamentous fungi. The Tea proteins are reasonably well conserved (26) and play a fundamental role in regulating the directionality of hyphal extension (see below). A subset of the Bud proteins is also present in filamentous fungi (27, 28), but instead they regulate septum formation (see below). Accordingly, at this time, the identities of any landmark/marker proteins that mediate polarity establishment in filamentous fungi remain a mystery. There is even some question as to whether a marking system is indeed necessary. Few examples of spatially biased spore polarization have been observed (e.g., reference 23), and when reported, it is in response to signals emanating from a potential plant host. Indeed, for those fungi whose spores are capable of producing multiple hyphae, it appears to be more important to ensure that the second polarity axis is opposite to the first. This type of bipolar spore polarization pattern is often observed and can be perturbed by disruption of the vesicle trafficking machinery, microtubules, and Tea marking system (29, 30).

A unique feature of filamentous fungi that enables the formation of mycelia is the ability to simultaneously sustain multiple axes of hyphal polarity. These axes result in the formation of branches, either lateral branches that emerge from subapical compartments or apical branches that form by "splitting" of the hyphal tip (31). As with spore polarization, branch formation requires the initial specification of a polarity axis followed by its stabilization. To date, the extent to which branching occurs in a defined pattern has not been fully explored. Furthermore, relatively little is known about mechanisms potentially involved in spatial regulation of branch formation in filamentous fungi. Nevertheless, key clues have emerged from a limited number of studies. For example, in *Aspergillus nidulans*, the absence of the Cdc42 GTPase or the FadA heterotrimeric G protein complex largely abolishes the formation of lateral branches and suggests signaling pathways that might be required for the specification of branch sites (32) (S. Harris, unpublished results). More intriguingly, the well-characterized septins appear to play a critical role in the specification and/or stabilization of new polarity axes at lateral branch sites (33). Elegant work using *Ashbya gossypii* suggests that the pivotal function of septins at incipient branch sites is to recognize membrane curvature (34). Lastly, evidence suggests that some fungi (e.g., *A. nidulans*, *Epichloe festucae*) actively suppress lateral branch formation from regions adjacent to hyphal tips through the localized accumulation of reactive oxygen species mediated by NADPH oxidase complexes (35, 36). This presumably ensures that growth is directed toward the tip and facilitates migration away from depleted substrate when nutrients are scarce.

A key feature that distinguishes hyphae from yeast cells is their ability to sustain polarized growth over a considerable distance. This implies that the regulatory systems that stabilize polarity axes must be much more stringent in filamentous fungi to support the long-range vectorial delivery of secretory vesicles to the hyphal tip. Although several components of the morphogenetic machinery have been implicated in the maintenance of hyphal polarity (20, 21), the nature and identity of any regulatory system that organizes the machinery and marks the hyphal tip remain elusive. It has been firmly established that spatially coupled exocytosis and endocytosis are essential for the stabilization of polarity axes (37, 38), and it has been suggested that this could reflect the need to recycle one or more cell surface markers that identify the hyphal tip (39, 40). It should also be added that a secondary role for the coupling of endocytosis with exocytosis might be to enable the spontaneous generation of local asymmetries that are then amplified to define a polarity axis if no functional marker is present. To date, the most compelling candidate for a hyphal tip marker is the *A. nidulans* TeaR protein (a homologue of the *S. pombe* mod5 cell end marker). TeaR is associated with exocytic vesicles that are transported on microtubules and delivered to the cell surface at the hyphal tip, where it mediates the local recruitment of the morphogenetic machinery (41). Recent evidence suggests that membrane-associated TeaR is rapidly dispersed at hyphal tips, only to be replenished again via microtubules (42). This result supports the existence of a dynamic feedback loop that continually establishes transient polarity axes at the hyphal tip that serve to maintain the overall direction of hyphal extension. The presence of lipid microdomains at hyphal tips and their importance in the formation of stable polarity axes raise the possibility that additional regulatory systems may operate in parallel with TeaR to mark the hyphal tip (43, 44).

Filamentous fungi exhibit tropic responses to chemical, mechanical, electrical, and other environmental stimuli (see references 45 and 46). The dynamic nature of polarity maintenance provides a satisfying explana-

tion for how the direction of hyphal extension can be rapidly reoriented in response to external signals. Moreover, it seems likely that the perception and transduction of external signals can override internally programmed polarity systems such as that mediated by TeaR. The demonstration that a chemotropic response is mediated by a cell surface pheromone receptor and a mitogen-activated protein kinase signaling pathway in the root colonizing fungus *Fusarium oxysporum* (23) provides some insight into how an existing polarity axis can be subverted by external signals.

Temporal Regulation of Hyphal Morphogenesis

In uninucleate fungal cells, the maintenance of nuclear content requires precise coordination of cellular morphogenesis with nuclear division. Mechanisms that couple these two processes have been described in some detail in *S. cerevisiae* and relatives. For example, in *S. cerevisiae*, regulatory mechanisms focused on the cyclin-dependent kinase (CDK) Cdc28 coordinate polarity transitions with nuclear division at multiple points in the cell cycle (47). *Candida albicans* is a polymorphic fungus that forms uninucleate hyphal cells, and here also, CDK plays a critical role in controlling the timing of polarity establishment, septum formation, and the transition from budding to hyphal growth (48). Key CDK targets include the septins and polarisome protein Spa2 (49, 50). The importance of CDK for the temporal coordination of morphogenesis with the cell cycle has also been documented in the plant pathogen *Ustilago maydis* (51).

In multinucleate fungal hyphae, the need to coordinate the timing of polarity establishment with nuclear division is not so apparent. Indeed, *A. nidulans* mutants incapable of nuclear division are able to form elongated hyphae (52), and mutants that fail to undergo spore polarization are able to complete multiple rounds of nuclear division (29). Despite this apparent lack of dependency, there is some evidence in *Aspergillus* species that polarity establishment and septum formation are under normal circumstances coordinated with nuclear division (29, 53, 54). This presumably reflects the need to maintain a preferred ratio of cytoplasmic volume per nucleus in growing hyphae. The underlying process, which has been termed the duplication cycle (53), remains poorly characterized, and it is not even clear whether the phenomenon is broadly conserved. For example, hyphal compartments in *Neurospora crassa* and *A. gossypii* can possess >100 asynchronously dividing nuclei, and there is no apparent evidence that hyphal morphogenesis is temporally coupled to the division of these nuclei (e.g., reference 55). One final observation potentially refutes the notion that hyphal morphogenesis is not dependent on nuclear division in filamentous fungi. In particular, the temperature-sensitive *A. nidulans nimL*, *nimM*, and *nimN* (never-in-mitosis) fail to undergo nuclear division and fail to establish polarity (unlike other *nim* mutants; references 29, 52, 56). These mutants are very sensitive to the DNA synthesis inhibitor hydroxyurea and share their polarization phenotype with wild-type conidia exposed to hydroxyurea (29). These observations suggest that completion of an as yet to be defined step in the S phase of the cell cycle might be necessary for spore polarization to proceed.

FUNGAL EXOCYTOSIS

Hyphal growth occurs by apical extension. Cell wall-modifying enzymes, substrates, and the membrane required for cell expansion are delivered to the apex by exocytosis, which suggests that the filamentous habit of growth is strongly dependent on the secretory pathway. Such an apparently simple fact has major implications both in the fungal pathogenicity field (host invasion is dependent on apical extension) and in the field of biotechnology (filamentous fungi are major producers of industrial enzymes). The hyphal mode of growth and its dependence on exocytosis represent an experimental advantage, because mutations impairing exocytosis even to a minor extent often result in reduced colony growth, making them easily scorable (57). Moreover, mutations impairing exocytic regulators delay or preclude polarity establishment (58, 59) or, when inactivated by conditional mutations in rapidly growing hyphae, often result in a tip swelling (60), which can be used as a cell-autonomous indicator of exocytic deficit.

The Golgi and Its Regulation

Although an increasing body of evidence supports the contention that unconventional protein secretion pathways do exist in fungi (61), these are relatively poorly understood. Therefore, this article will focus on the Golgi as the central hub in the conventional secretory pathway that sorts protein cargoes to their final destination, be it the extracellular milieu, the plasma membrane, or the endovacuolar system. Several recent reports testify to the interest that the mechanistic understanding of biosynthetic traffic is spawning. For brevity we will consider here reports using the genetic models *A. nidulans* and *N. crassa*. Pioneering work on motors that move carriers toward their destinations, carried out with *U. maydis*, will be considered below.

As in *S. cerevisiae*, in the filamentous ascomycetes *A. nidulans* and *N. crassa* the Golgi consists of isolated membrane-bound structures that do not pile up to form the characteristic stacks of mammalian cells (62, 63). Even though these isolated membranous structures were initially denoted Golgi "equivalents," they are *bona fide* Golgi "cisternae," equivalent to those in other eukaryotes. Their nonstacked organization represents a major experimental advantage for live microscopy studies because cisternae can be resolved by diffraction-limited optical microscopy (64–66). When imaged with fluorescent proteins, the extensively studied Golgi of *A. nidulans* is seen as a dynamic network of ring-shaped and fenestrated cisternae, often interconnected by tubular structures (64, 67, 68). This morphology is consistent with electron microscopy studies (summarized in reference 63).

The Golgi is an intrinsically transient and compositionally heterogeneous membranous entity that is constantly fed by anterograde coat protein complex II (COPII) carriers budding from transitional endoplasmic reticulum (ER) domains/ER exit sites (Fig. 2). An unanswered question in cell biology is how the protein cargo that exits the ER traffics across the Golgi apparatus and is sorted into plasma membrane- and endosome-bound carriers (69). It is widely accepted that this traffic occurs, at least in part, by cisternal maturation rather than by vesicle-mediated connections between stable cisternae. According to this view, early cisternae, which are formed by ER-derived traffic, progressively change their lipid and protein content, becoming not only gradually enriched in cargo but also, in the end, compositionally competent (see below) to break up into carrier vesicles destined for the plasma membrane and endosomes (Fig. 2). Cisternae at this final stage of maturation are denoted "late" or "TGN" cisternae (see below). The progressive attainment of late composition is thought to be mediated by retrograde COPI vesicle traffic retrieving to cisternae in earlier stages of maturation those components that do not belong to mature (i.e., later) stages (Fig. 2).

Strong support for the cisternal maturation model comes from ground-breaking studies of *S. cerevisiae* (70, 71) and from our own work in *A. nidulans* (Pantazopoulou and Peñalva, unpublished observations; see also below). However, readers should note that the maturation model very likely requires some modification to accommodate the involvement of tubular connections that are often observed between metazoan cisternae (and between fungal ones [68]). These connections could represent highways for certain types of cargo. The model also needs to accommodate the experimentally supported possibility that rapid partitioning mediated by domains of different lipid composition enables the budding of carriers at all levels (72; for overview see references 69, 71). In a useful attempt to relate the compositional and morphological variety of the Golgi with specific roles, Glick and coworkers (73) have proposed that the Golgi consists of cisternae in three different functional stages (Fig. 2). We will use this scheme for further discussion.

In stage I, denoted "cisternal assembly," ER-derived COPII carriers coalesce to form cisternae (Fig. 2). During this stage, ER protein residents that escape to the Golgi incorporated into COPII carriers recycle to their normal destination using COPI-coated retrograde vesicles (74). This is the case, for example, for TM receptors such as *A. nidulans* RerA^{Rer1}, which sorts soluble cargo at the ER into anterograde COPII carriers, and for the syntaxin SedV^{Sed5}, a key component of the SNARE machinery mediating membrane fusion at the Golgi (60, 64, 75). Membranes in stage I contain a network of peripheral proteins recruited to them by Golgi-specific GTPases that tether membranes, thereby facilitating fusion. Among them are *A. nidulans* GrhA^{Grh1} (68) and *N. crassa* USO-1 (65). As cisternae increase in size at the expense of heterotypic and homotypic fusion, they move on to functional stage II (Fig. 2).

Stage II is the glycosylation stage (73). Golgi cisternae at this stage, during which the definitive carbohydrate decoration of protein cargo is laid, are equipped with glycosidases and glycosyltransferases. Golgi glycosyltransferases extend the *O*-mannose core that is attached in the ER to a subset of cargoes, giving rise to the diverse species-specific *O*-glycans decorating fungal secreted proteins. *N*-glycosylated proteins are remodeled, after modification of core *N*-glycan structures also added at the ER, by attachment of further polysaccharide chains of variable size and composition (76). These stage II cisternae are also armed with the transporters needed to import nucleotide diphosphate-activated monosaccharide precursors from the cytosol into the cisternal lumen. GDP-mannose transporters GmtA of *A. nidulans* (77) and VRG-4 of *N. crassa* (65), homologues of budding yeast Vrg4p used in seminal studies on Golgi maturation (70), are useful to define this compartment. Cisternae at this stage no longer receive anterograde COPII carriers. However, stage II cisternae are also furnished with tethers and with the SedV^{Sed5} syntaxin to accept retrograde traffic (presumably COPI-mediated) that retrieves to them carbohydrate-modifying enzymes that escape to cisternae in a posterior stage (stage III) of maturation. The COG (conserved oligo-

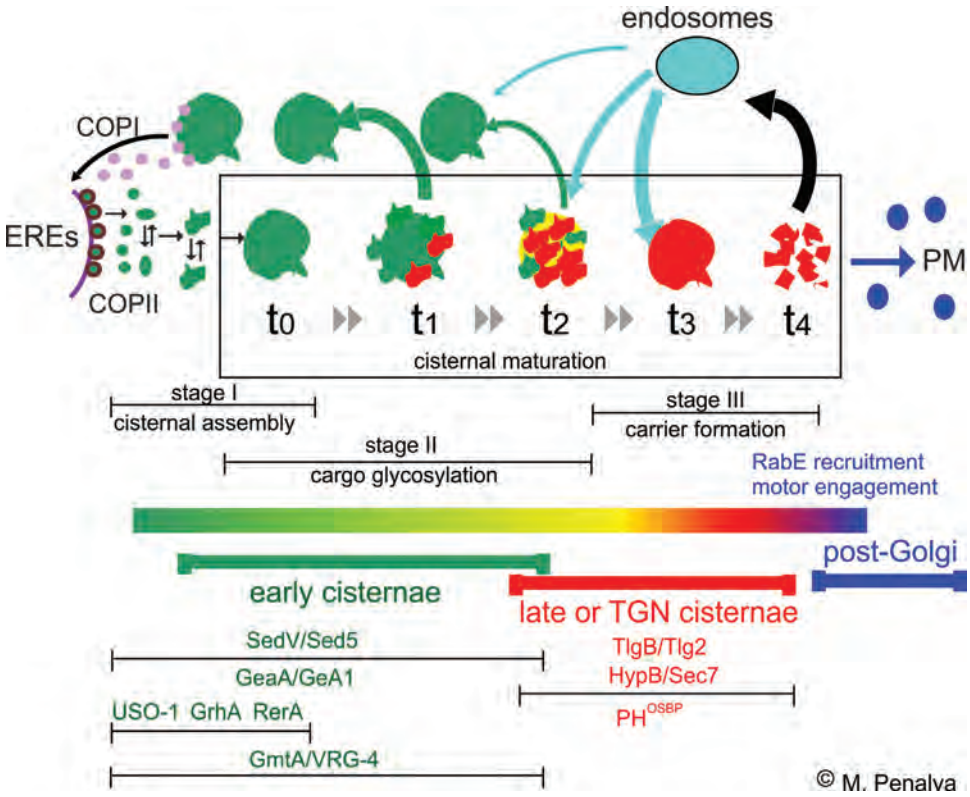

Figure 2 Highly schematic representation of the cisternal maturation process in the nonstacked fungal Golgi, with indication of the different functional stages. COPII-coated vesicles (green) bud off specialized domains of the ER denoted ER exit sites (ERES) or transitional ER (left). COPII vesicles coalesce to form an early Golgi cisterna, represented here as a green fenestrated structure that depicts actual Golgi structures often visible in EM micrographs. Retrograde COPI traffic (violet vesicles) retrieves back to the ER proteins such as cargo receptors that need to be recycled. Early cisternae are equipped with cargo glycosylation enzymes (t0). As time passes (double arrowheads) an early Golgi cisterna becomes progressively enriched in cargo and late Golgi components (represented in red) by delivering early Golgi ones (e.g., glycosylating enzymes) to cisternae in earlier stages of maturation, in a process which is likely mediated by COPI retrograde traffic (t1 and t2). Eventually, late Golgi components become predominate (TGN, t3) and the cargo-enriched cisterna becomes competent to tear off into carriers destined for the plasma membrane (PM) and the endosomes (t4). TGN cisternae also receive traffic from the endosomal system (blue arrows). In the route (dark blue) connecting the cisternae with the PM, the transition between late Golgi and post-Golgi identity is dictated by the recruitment of $RabE^{RAB11}$ to the membranes, which is critically regulated by TRAPPII (see text). Proteins that have been shown by microscopy to localize to specific stages are indicated, with green lettering indicating early Golgi and red lettering indicating TGN. The image summarizes work performed with *A. nidulans*.

meric Golgi) complex (78) also mediates the tethering of these intra-Golgi carriers to stage II cisternae, such that deficient COG function results in glycosylation defects (79). The physiological importance of two *A. nidulans* Golgi COG components, $PodB^{Cog2}$ and $SwoP^{Cog4}$, has been demonstrated by showing that two classical *ts* alleles, *podB1* (polarity defective) and *swoP1* (swollen cell), cause polarization, cell wall, and protein glycosylation defects (80). The role of GmtA was established with the hyperbranching and hypomannosylating *ts* mutation *calI11* (i.e., *gmtA11*), which results in calcofluor white sensitivity (77).

Cisternae that progress to stage III, denoted "carrier forming" (73), acquire a composition that enables them to generate anterograde carriers destined for the plasma membrane and the endosomes (Fig. 2) but that incapacitates them to generate retrograde COPI traffic destined for cisternae at earlier stages of maturation.

Cisternae in this carrier-forming stage have been denoted the *trans*-Golgi network (TGN), by analogy to the most plasma membrane-proximal (*trans*) cisternae of the mammalian Golgi stacks. For all fungal purposes TGN is synonymous with "late Golgi." Traffic exiting the TGN toward endosomes is mediated by clathrin-coated carriers that use AP-1, GGA (Golgi-localized, gamma adaptin ear-containing, ARF-binding), and epsin adaptors to sort appropriate cargo into the clathrin cage. In contrast, as discussed below, carriers connecting the TGN with the plasma membrane are atypical in that they do not appear to involve any protein coat. TGN membranes contain PtdIns4*P* and the late-Golgi Arf1 GEF (guanine nucleotide exchange factor) Sec7, which has been intensively studied in *A. nidulans* (60, 81–84) and used as a prototypic TGN marker in both *A. nidulans* (68) and *N. crassa* (65). However, the most robust marker of the TGN is a fusion protein between mRFP and the PH domain of the human oxysterol binding protein (PH^{OSBP}). This chimera is recruited very efficiently and specifically to TGN cisternae by coincidence detection of active (i.e., GTP-loaded and membrane bound) Arf1 and PtdIns4*P* (85).

The cisternal maturation model implies that TGN cisternae must dissipate as they break up into transport vesicles. A study of *A. nidulans* documented the process by which TGN cisternae give rise to post-Golgi carriers destined for the apical plasma membrane (82). During this process, cisternal membranes progressively lose Golgi identity (i.e., they lose PH^{OSBP} [i.e., Arf1/PtdIns4*P*] and $HypB^{Sec7}$ [the late Golgi Arf1 GEF]) as they become increasingly rich in $RabE^{RAB11}$ (Ypt31/32p in budding yeast), the determinant of post-Golgi identity (82). By the time $RabE^{RAB11}$ peaks at a maternal cisterna, the signal of Sec7/PH^{OSBP} has virtually disappeared. At this point, $RabE^{RAB11}$-rich membranes undergo rapid movement to the Spitzenkörper (SPK), using kinesin and myosin-5 motors that power their long-distance transport to the SPK (82), consistent with a model in which $RabE^{RAB11}$ participates directly or indirectly in the recruitment of the motors (Fig. 2). The fact that cisternae that have acquired $RabE^{RAB11}$ and undergone movement toward the apex leave little signal of TGN markers behind strongly suggests that TGN cisternae largely dissipate into $RabE^{RAB11}$ exocytic carriers, which represents strong evidence for a maturation-based mechanism determining the biogenesis of these carriers (82). The biogenesis of carriers destined for endosomes, which had been filmed in *S. cerevisiae* (86), has been recently documented in *A. nidulans* (87).

Unlike early Golgi cisternae (stages I and II), TGN cisternae contain the t-SNARE $TlgB^{Tlg2}$, which colocalizes with PH^{OSBP} (60). $TlgB^{Tlg2}$ is a Qa syntaxin that forms SNARE bundles with Vti1 as Qb-, $TlgA^{Tlg1}$ as Qc-, and SynA as R-SNARE (75). In all likelihood, this SNARE bundle mediates the fusion of retrograde traffic connecting the earliest endosomal compartment, to which SynA arrives by endocytosis, with the TGN. This is the pathway that is followed by proteins that, like SynA itself, are efficiently taken up by the subapical endocytic ring and pass through the TGN before returning by way of apex-directed exocytosis to the plasma membrane (37, 64, 88). This earliest endosome, which for convenience is designated here as a "sorting endosome," should not be confused with the EEs, which are readily identifiable by their high motility on microtubule and the presence of the GTPase Rab5 (see below).

The SynA pathway is the one that must be responsible for the strong labeling of the SPK with the endocytic tracer FM4-64 (89). Another passenger of this pathway is the *A. nidulans* phospholipid flippase $DnfA^{Dnf1}$ (39). *cis*-acting mutations abolishing endocytosis of SynA (64) or $DnfA^{Dnf1}$ (39) result in a uniform rather than polarized distribution of the cargo, showing that rapid endocytic uptake/recycling combined with slow diffusion across the plane of the membrane generates polarity (90). In *A. nidulans*, traffic of cargoes between the sorting endosome and the TGN requires RAB6 ($RabC^{RAB6}$) (64) and its effector Vps52 (39). Another flippase, $DnfB^{Drs2}$, is a TGN resident that partially localizes, like $DnfA^{Dnf1}$, to the SPK. Remarkably, $DnfA^{Dnf1}$ and $DnfB^{Drs2}$ reside in different regions of the SPK (39). The role of flippases in exocytosis is not understood, but it may have major practical implications: ablation of the *Magnaporthe grisea APT2* gene (homologue of $DnfB^{Drs2}$) does not result in hyphal growth or sporulation defects but precludes the secretion of several extracellular enzymes and, importantly, prevents pathogenicity (91).

$TlgB^{Tlg2}$ is notable in that its genetic ablation is inconsequential for growth and results in a minor effect on SynA localization (75). However, *tlgB* is synthetically lethal when combined with a hypomorphic mutation in *sedV*, the gene encoding the early Golgi syntaxin (75). This indicates that the Golgi can be organized with only one syntaxin ($SedV^{Sed5}$), provided that this syntaxin is fully functional. A plausible explanation is that when $TlgB^{Tlg2}$ is absent, proteins can recycle from sorting endosomes to early Golgi cisternae in a $SedV^{Sed5}$-dependent manner and then move forward to the TGN by cisternal maturation. This interpretation is supported by the observation that $SedV^{Sed5}$, like $TlgB^{Tlg2}$, can form SNARE bundles with SynA, Vti1, and $TlgA^{Tlg1}$ (75). If this interpretation were correct, the only role of $TlgB^{Tlg2}$ would be in the fusion of

retrograde carriers derived from the endosomes with the TGN.

The Master Regulators of the Golgi: RABs, Arf1, and Their Regulators

The budding from the ER of COPII carriers that feed the Golgi, the different stages of Golgi maturation, and the exit of carriers from the TGN are governed by small GTPases of the ARF and RAB families. SarA^{Sar1} is an ER-located ARF that plays a fundamental role in the budding of COPII carriers (92, 93). Temperature shift experiments with *A. nidulans sarA^{ts}* mutations have been used to impair ER exit. As predicted by the cisternal maturation model, in cells shifted to the restrictive temperature, early Golgi residents such as SedV^{Sed5}, which have access to COPI-mediated retrograde traffic, rapidly relocalize to the ER, consistent with their Golgi localization being determined by an equilibrium between anterograde and retrograde traffic. In contrast, the TGN (late Golgi) resident TlgB^{Tlg2} does not rapidly relocalize to the ER, relocalizing instead to a diffuse cytosolic haze (92). This different behavior of early and late Golgi membranes (SedV^{Sed5} and TlgB^{Tlg2} are integral membrane proteins) is consistent with the cisternal maturation model. Notably, prolonged impairment of ER exit by *sarA^{ts}* mutations results in the formation of apical balloons surrounded by a thick wall of chitin. One possible explanation is that chitin biosynthetic enzymes are less dependent on SarA^{Sar1} function than other cell wall biosynthetic activities (92).

ARF1 (ArfA in *A. nidulans*) is an essential regulator of the Golgi (94) that plays different roles at the levels of the early and late cisternae. Two essential ArfA GEFs, GeaA and HypB^{Sec7}, localizing to the early and late Golgi membranes, respectively, ultimately mediate these roles (81). A major (and as yet unexplained) finding that illustrates the power of random classical genetic screens was that *geaA1* resulting in a single Y1022C substitution within a conserved domain of GeaA makes vegetative growth independent of HypB^{Sec7} and thus of the TGN (81). Remarkably, besides the early Golgi, GeaA^{Y1022C} localizes to the apical plasma membrane, suggesting that under these conditions early Golgi membranes can undergo exocytosis.

Three RAB GTPases are needed to organize the Golgi: RAB1 (RabE^{RAB11}, YPT-31), RAB6 (RabC^{RAB6}), and RAB11 (RabE^{RAB11}, YPT-31). RabO^{RAB1}/YPT-1 (60, 65) and RabC^{Rab6} (64) are present in both the early and the late Golgi. Notably, the three Golgi RABs are present also in the SPK (see below).

In *A. nidulans*, RabO^{RAB1} and RabE^{RAB11} are essential (60, 82). The acute inactivation of RabO^{RAB1} rapidly disorganizes both the early and the late Golgi cisternae (60). In addition to exocytosis, *A. nidulans* RabO^{RAB1} plays a crucial role in autophagy (84). The absence of RabC^{RAB6}, albeit not lethal, is severely debilitating and leads to fragmented cisternae (64). It results in delocalization of the VpsT^{VPS10} vacuolar hydrolase receptor, which recycles between the endosomes and the Golgi (64), an observation consistent with the role generally attributed to RAB6 homologues as key regulators of retrograde traffic in the secretory pathway.

RAB11 has been studied in detail in *A. nidulans* (82, 83). As noted above, RabE^{RAB11} is not a Golgi resident, but it is instead recruited to TGN membranes to determine their acquisition of post-Golgi identity. This recruitment must be governed by its GEF, which is therefore crucial for exocytosis. A long-standing question in the literature concerned the identity of the RabE^{RAB11}/Ypt31 GEF and the roles of the TRAPP (oligomeric complex transport protein particle) as a Golgi organizer. TRAPP has been isolated in three versions. TRAPPI (composed of Trs33, Ber3, Bet5, Trs23, Trs31, and Trs20 subunits) is a demonstrated GEF for Ypt1 (yeast RAB1), acting in the ER/early Golgi interphase. TRAPPIII is TRAPPI plus Trs85 and acts as GEF for Ypt1 in the preautophagosome. TRAPPII is TRAPPI plus three additional subunits: Trs120, Trs130, and Trs65. TRAPPII had been proposed to be the Ypt31 GEF acting in the TGN (95), but this role was disputed by others, who concluded that TRAPPII was the late Golgi version of the GEF that activates Ypt1 in early Golgi (96). *hypA1* is a *ts* mutation in the gene encoding *A. nidulans* Trs120 (97). The characterization of extragenic suppressors of *hypA1* combined with biochemical assays established that the physiological substrate of TRAPPII is RabE^{RAB11} (the Ypt31 orthologue). TRAPPII, as visualized with Trs120-GFP, peaks at TGN cisternae preceding their dissipation into carriers, thereby determining the Golgi to post-Golgi transition by governing RabE^{RAB11} recruitment (83). It remains to be established whether TRAPPII is assembled *de novo* in the TGN. Alternatively, TRAPPII might be assembled using as a scaffold the TRAPPI complex already present in the early cisternae that would arrive at the TGN by maturation. If this were the case, anterograde traffic across the Golgi might be mediated by a RAB1 to RAB11 cascade governed by maturation of TRAPPI into TRAPPII (95).

The Fungal SPK and Delivery of Cell Wall-Building Enzymes

The SPK is a conspicuous apical body observed at the growing apices of hyphae in fungal species belonging to the subkingdom Dikarya (Ascomycota and Basidio-

mycota). The SPK was first discovered in fixed cells of the basidiomycetes *Coprinus sterquilinus* and *Coprinus narcoticus* stained with iron-hematoxylin (10). It was later observed in live cells of *Polystictus versicolor*, where it was shown to be important for maintaining hyphal tip elongation, morphology, and growth direction (98, 99). The subsequent characterization of the SPK in diverse fungal species by phase-contrast and transmission electron microscopy identified up to nine SPK patterns (100). Mating projections of *S. cerevisiae*, mating projections and invasive pseudohyphae of *C. albicans*, dikaryotic hyphae of *U. maydis*, and germ tubes of *Uromyces phaseoli* and *Puccinia graminis* display an apical cluster referred to as an SPK-like structure thought to operate as the SPK in hyphae (101–103).

Among the non-Dikarya fungi, only *Allomyces* and *Basidiobolus* have been found to display an SPK (104, 105). Early studies reported the absence of an SPK in the Zygomycetes (106). More recently, several zygomycetous fungi were analyzed (*Gilbertella persicaria*, *Phycomyces blakesleanus*, *Rhizopus oryzae*, *Coemansia reversa*, *Mucor indicus*, *Gigaspora* spp., and *Mortierella verticillata*), and it was shown that they present instead an apical vesicle crescent (13, 107, 108). The apical vesicle crescent corresponds mainly to an accumulation of apical vesicles of different sizes, as for the SPK. However, practically nothing is known about the composition or regulation of the apical vesicle crescent vesicles. In contrast, extensive studies conducted on ascomycetous species have made it possible to identify the main components of the SPK (see below).

Hyphal growth occurs at the apices (10). Autoradiographic analysis of *M. indicus* (formerly *rouxii*) showed accumulation of tritiated *N*-acetyl-D-glucosamine (GlycNAc), a monomeric unit of chitin, preferentially at hyphal tips, indicating that apical growth was correlated to a polarized mechanism of cell wall assembly (9). Several authors proposed that this assembly of cell wall at the apex must include the participation of synthetic as well as lytic (plasticizing, softening) activities (109–111). By contrast, an alternative model not involving lytic activity proposed a plastic cell wall at the apex that would become rigid at the subapex, where remodeling glycosyltransferases would cross-link the cell wall material and rigidify it (11). Recent work with *N. crassa* has revealed two glycosyltransferases belonging to the CAZy family GH17 localized at the plasma membrane of the hyphal dome, excluding the foremost apical region immediately across from the SPK (112) (Fig. 3), in support of cell wall remodeling occurring at the subapex.

At the ultrastructural level the SPK corresponds to an aggregation of vesicles, actin microfilaments, and ribosomes and an amorphous unidentified material (113, 114) (Fig. 3). A computer simulation exercise led to the formulation of the vesicle supply center model for fungal morphogenesis (115). This model proposed that the SPK behaves as a vesicle supply center, from which vesicles travel to and fuse with the apical plasma membrane, providing the enzymatic machinery needed for cell wall expansion. Once inserted in the plasma membrane, (i) chitin synthases take *N*-acetyl glucosamine subunits (GlcNac) from the cytoplasmic side and incorporate them into a growing chain of chitin microfibrils (β-1,4-GlcNAc), and (ii) the glucan synthase takes glucose subunits (Glc) from the cytoplasmic side and incorporates them into an extending chain of β-1,3-glucan (116, 117). The sequencing of fungal genomes allowed the construction of translational fusions of specific genes with fluorescent proteins enlightening many components of the SPK.

The ultimate evidence for the suggested link between the SPK and cell wall assembly at tips was confirmed when cell wall biosynthetic enzymes such as chitin and glucan synthases were identified at the SPK in *N. crassa* (118, 119). Significantly, coexpression of differentially fluorescently tagged enzymes identified chitin synthases and components of the glucan synthase complex at the core and at the outer layer of the SPK, respectively, coinciding with the distribution of microvesicles (chitosomes) and macrovesicles reported at the transmission electron microscopy level (119, 120) (Fig. 3). Small GTPases YPT-1/RabO (Rab1) and YPT-31/RabC (Rab6) have been found occupying the inner and the peripheral layers of the SPK in *N. crassa* and *A. nidulans*, respectively (64, 65). All the above suggests different populations of vesicles containing different cell wall synthesizing activities and being regulated by different molecular switches. We are only starting to discern the lipid composition of membranes and its role in establishing membrane asymmetry and in vesicle traffic. In *A. nidulans* flippases DnfA (Dnf1) and DnfB (Drs2) also occupy distinct strata of the SPK, in support of existing different populations of vesicles (39, 121).

The SPK has been suggested to be a transfer station from cytoplasmic microtubules to actin microfilaments (122, 123). Cytoplasmic microtubules which extend through the cytoplasm and reach the SPK region are thought to participate in the long-distance traffic of vesicles to the SPK, whereas the actin cytoskeleton, found at the SPK core would mediate the flow of vesicles to and from the SPK (124, 125) (Fig. 3). In *A. nidulans* the microtubular and actin cytoskeletons are

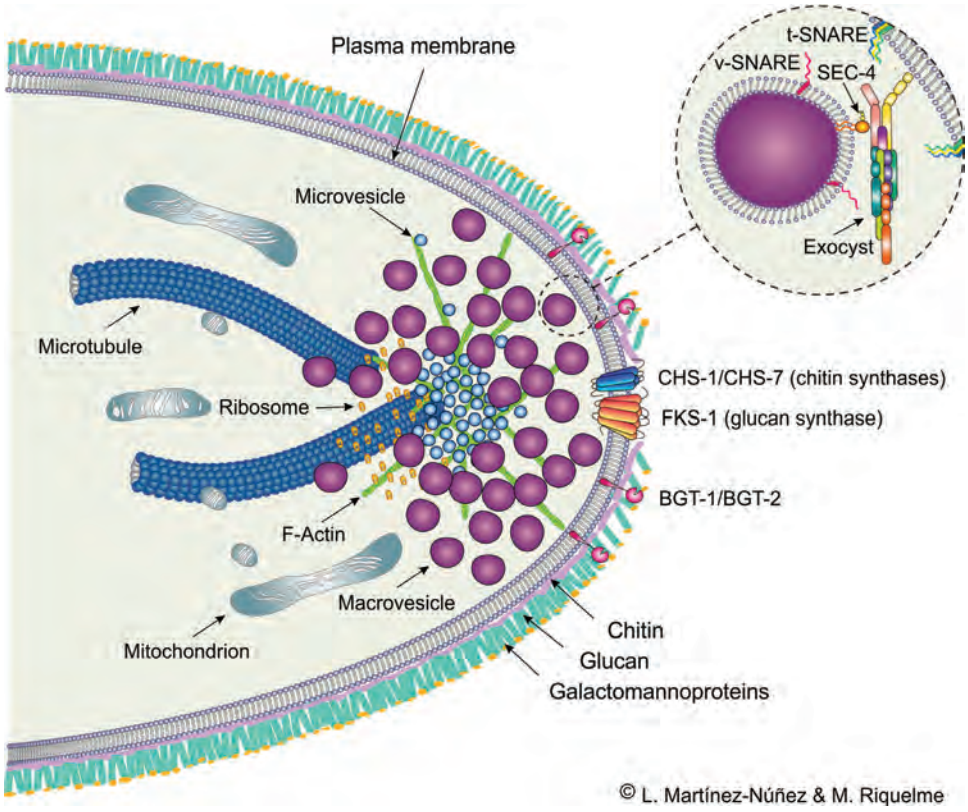

Figure 3 Illustration of a hyphal tip with the main organelles and subcellular components involved in apical cell wall growth. The diagram is based on work with *N. crassa*. (Art: Leonora Martínez-Núñez).

connected at the hyphal tips by cell-end markers (26). TeaA is delivered by microtubules to the tip plasma membrane, where it interacts with TeaR and other components, subsequently leading to the recruitment of the formin SepA, which polymerizes actin cables (126). Interestingly, while cytoplasmic microtubules are important to maintain SPK stability, hyphal morphology, and fast growth rates, they seem dispensable for vesicles to reach the SPK (127, 128).

We lack information on the biogenesis of the vesicles that constitute the SPK. While several fungal organelles have been characterized, we lack information about the post-ER and/or post-Golgi processes relative to the formation and traffic of vesicles that concentrate at the SPK (see above). It has been shown that the exocyst complex has a role in determining the site at the plasma membrane for delivery of cell wall-synthesizing enzymes (129). In *N. crassa* the exocyst components were found at two locations within the hyphal tip: at the apical plasma membrane and at the frontal region of the SPK outer layer. It is well established that an intact SPK is needed to maintain hyphal morphology and growth directionality in ascomycete fungi (130). Recently, it was found that only the aggregation of macrovesicles (not of the microvesicles) at the SPK is dependent on an intact exocyst (120). Finally, it is worth noting that the lipophilic dye FM4-64 stains the SPK in living hyphae (89). FM4-64 is taken up by the cell via endocytosis at the plasma membrane (131) (for more details see below), suggesting a connection between the exo- and endocytosis.

Myosin-Chitin Synthases in Apical Exocytosis

Our knowledge concerning the delivery of vesicles and enzymes to the hyphal tip is largely based on intensive studies of *N. crassa* and *A. nidulans*. Both organisms belong to the phylum Ascomycota, which accounts for ~64% of all fungi (2). The second major group is the basidiomycetes, which provide 34% of all described species (2). Despite the economic and ecological importance of this group, our understanding of secretion pathways in basidiomycetes is restricted to the plant pathogen *U. maydis*. In hyphae of *U. maydis*, microtubules are required to deliver chitin synthase-containing

vesicles to the apical growth region (132). *U. maydis* does not contain a typical SPK, comprised of macro- and microvesicles, but similar to *N. crassa* and *A. nidulans*, vesicles accumulate near the hyphal tip in this fungus (103). How this vesicle cluster is formed is not fully understood, but class V chitin synthases may participate in this process. Class V chitin synthases are fungal-specific cell wall-forming enzymes that carry an N-terminal myosin motor domain. This domain is even found in ancient Cryptomycota (133), suggesting that it is a hallmark of the Fungi. It was shown that the myosin motor domain of the *U. maydis* class V chitin synthase (Mcs1) (134) is not involved in apical delivery of the enzyme. Instead, this is achieved by coordinated activity of the motor proteins kinesin-1 along microtubules and myosin-5 along filamentous actin (135); the myosin-motor domain of the class V chitin synthase tethers delivered vesicles to apical actin. The transient interaction of the motor and actin increases the pausing time of the vesicles at the hyphal apex, thereby supporting polar exocytosis (135).

Interestingly, Mcs1-tethered vesicles also carry a class VII chitin synthase and a β-glucan synthase (a homologue of glucan synthase Fks1 in *N. crassa*) (136). After exocytosis, these cell wall enzymes are immobilized by newly formed polysaccharide chains, suggesting that codelivery and coexocytosis help the coordination of enzymatic activity in building the complex fungal cell wall. Myosin-chitin synthases have also been described in numerous ascomycetes, including *A. nidulans*, (137), *Aspergillus fumigatus* (138, 139), *F. oxysporum* (140), *Colletotrichum graminicola* (141), *Magnaporthe oryzae* (142), and *N. crassa* (143). Ascomycete myosin-chitin synthases have been shown to be required for morphogenesis, development, and pathogenicity (140, 141, 143, 144). As in *U. maydis*, kinesin-1 delivers *A. nidulans* myosin-chitin synthase along microtubules to the hyphal apex (145), where its myosin motor domain interacts with F-actin (146). However, whether ascomycete myosin-chitin synthases act as vesicle tethers at sites of apical exocytosis remains to be determined.

FUNGAL ENDOCYTOSIS AND EE MOTILITY

Fungal Endocytosis

Hyphal tip growth has been described as being due to the tip-ward delivery and the apical release of Golgi-derived vesicles (11, 122). In animal cells, this release (i.e., exocytosis) is balanced by the uptake of material into vesicles that form at the plasma membrane (i.e., endocytosis). These vesicles then fuse with early endosomes, and the contents can be recycled back to the surface or dispatched to the lysosome (i.e., the fungal vacuole) for degradation. For many years, endocytosis was thought to be absent in fungi (147). However, over the past 2 decades, fungal endocytosis has been recognized to be pivotal for cell function. The initial breakthrough came with the use of the lipophilic marker dye FM4-64 in the 1990s in the yeast *S. cerevisiae* (131) and then in the filamentous fungi *Uromyces fabae* (148) and *U. maydis* (149). This fluorescent dye inserts into the plasma membrane from where it is internalized by the formation of endocytic transport vesicles (131). Subsequently, studies of *M. grisea* (150), *A. nidulans* (151), *N. crassa*, and six additional fungi (89) confirmed the endocytic uptake of FM4-64 into fungal cells. These results were complemented by live-cell imaging and mutants studies in numerous fungi, including *U. maydis*, *A. oryzae*, *A. nidulans*, *C. albicans*, *A. gossypii*, and *N. crassa* (37–39, 152–160). Collectively, these studies revealed a critical role for endocytosis and endocytic recycling in hyphal growth of filamentous fungi (for overview see references 15, 57).

The Molecular Machinery for EE Motility

Fungal EEs were first described in the dimorphic fungus *U. maydis* (160). In this fungus, shortly after internalization, the dye FM4-64 concentrates in small, rapidly moving vesicular organelles (160). A putative t-SNARE, Yup1, binds these organelles via a PHOX-domain (i.e., phosphoinositide binding domain) (160, 161) that interacts with the lipid PIP3, characteristic of EEs (reference 162). Consistent with this, the FM4-64-stained organelles carry the small GTPases Rab4 and Rab5 (155, 161), both shown to reside on EEs in mammalian cells (163, 164). Thus, there is little doubt that the rapidly moving FM4-64-positive vesicles are EEs. Rab5-positive EEs were also described in *A. nidulans* (88), *N. crassa* (165), and *Zymoseptoria tritici* (166) but are not found in the yeast *S. cerevisiae*. Thus, motile EEs are a hallmark of filamentous fungi.

Microtubules are biopolymers of tubulin-dimers that support long-distance transport of organelles and vesicles in fungal cells (12, 167). They elongate at their plus end, while the minus end is usually embedded in a nucleation site, such as the fungal spindle pole body. Motility along microtubules is mediated by molecular motors, which use the polarity of microtubules to transport their cargo. In general, kinesins are known to move toward the plus end of a microtubule, while cytoplasmic dynein motors are minus end-directed. Both types of motors are "mechano-enzymes" that hydrolyze ATP to power a conformational change in the motor

domain. Repeating cycles of ATP hydrolysis result in a sequence of ~8-nm steps along the microtubule (168, 169). In filamentous fungi, the first membrane trafficking motors identified were the cytoplasmic dyneins in *N. crassa* (170) and *A. nidulans* (171), which were recognized to play a role in nuclear migration. Shortly after, kinesin motors were identified in *N. crassa* (172), *U. maydis* (149), *Nectria haematococca* (173), and the zygomycete *Syncephalastrum racemosum* (174). Interestingly, all kinesins belong to the same subgroup of kinesin motors (kinesin-1), which is thought to support tip-ward transport of fungal secretory vesicles (135) and to deliver dynein to microtubule plus ends (175, 176) (for more details on general motor function see references 12, 167 and 177). The first insight into the machinery of EE motility was provided by studies of *U. maydis*, where kinesin-3 was identified to be the motor for plus end-directed motility of EEs (178). A similar role of kinesin-3 in EE motility was discovered in *A. nidulans* (179, 180) and *N. crassa* (165). Kinesin-3 motor proteins comprise 8 of the 45 kinesins in the human genome (181) but are absent from *S. cerevisiae*. This emphasizes the similarity of membrane trafficking in filamentous fungi and elongated mammalian cells such as neurons (167, 182).

Fungal EEs have been shown to move in a bidirectional fashion along microtubules (88, 175, 183), suggesting that plus end-directed kinesin-3 gets opposed by minus end-directed cytoplasmic dynein. Indeed, deletion of the gene for kinesin-3 resulted in the accumulation of EEs at microtubule minus ends (178), whereas inactivation of cytoplasmic dynein results in a cluster of EEs at microtubule plus ends in the hyphal apex (175, 179). Interestingly, the deletion of kinesin-1 also led to EE clustering at the hyphal tip. This is due to a role of this motor in delivery of dynein to microtubule plus ends (175, 176) (Fig. 4). Dynein motors accumulate at the plus end to form a "dynein comet" (175, 184). Studies of *U. maydis* have shown that the apical dynein comets consist of ~55 dynein motors. Two mechanisms cooperate in the formation of the comet, namely binding of the dynein-associated complex dynactin to EB1-like proteins at microtubule plus ends and by a stochastic crowding effect (185). Dynein is released from the dynein comet and, while moving toward the subapical minus ends, can randomly pick up kinesin-3-delivered EEs (186) (Fig. 4). The large numbers of dyneins at plus ends increase the probability of such interaction. This ensures that EEs do not fall off the microtubule when they arrive at plus ends, but rather are transported back toward minus ends (185) (Fig. 4).

After dynein takes over, moving EEs still bind kinesin-3 (179, 186). Surprisingly, the amount of kinesin-3 on these organelles is ~4 times higher than that of dynein (186). This suggests that kinesin-3 activity is repressed upon dynein binding. While the exact mechanism underpinning this regulation is not known, the recent iden-

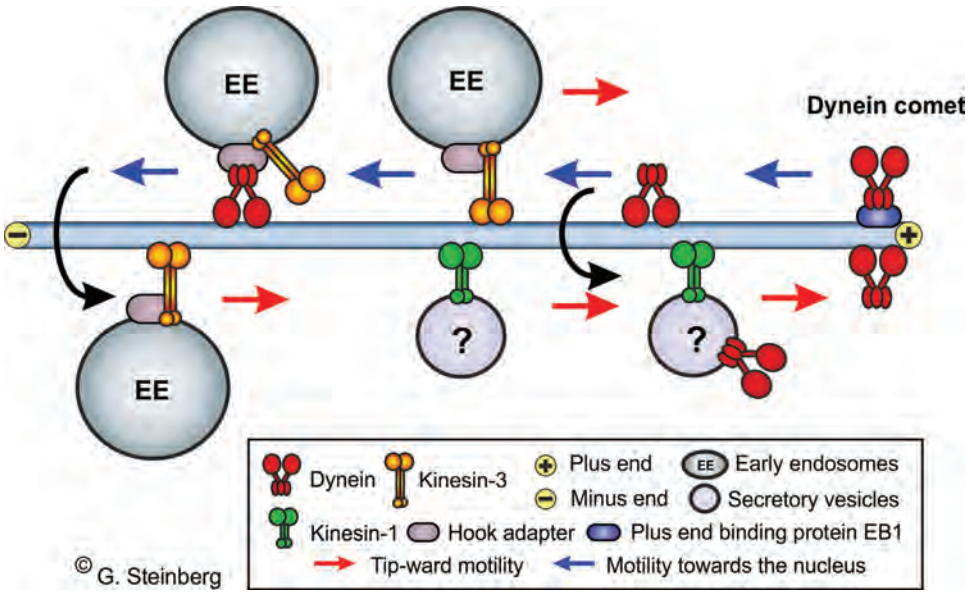

Figure 4 Diagram showing the cooperation of molecular motors in bidirectional EE motility. The illustration is based on results obtained from studies of *U. maydis*. See text for detailed description.

tification of an EE-located motor adapter complex provides the first insight into the complex interplay between kinesin-3 and dynein during bidirectional EE motility. The key protein in this EE adapter complex is a hook protein, which was identified in a genetic screen for mutants defective in EE motility in *A. nidulans* (187) and *U. maydis* (188). Hook forms a complex with two associated proteins, named FTS and FHIP (188), that help anchor the adapter complex to the EE membrane (189). Hook itself interacts with dynein (187, 188) and kinesin-3 (188) and is therefore a good candidate for controlling the activity or the attachment of both motors during bidirectional EE motility (15). This notion is supported by the finding that some kinesin-3 is released from EEs shortly before dynein binds (188). It is likely, however, that more proteins participate in this regulation, because for example, the dynactin subunit p25 is needed for dynein-dependent EE motility (190). However, EE motility may also be regulated by proteins that are not part of the transport machinery or the EE adapter complex. This is illustrated by the vezatin-like protein VezA in *A. nidulans* (191). Mutants in *vezA* show defects in dynein-hook interaction and, consequently, are impaired in retrograde EE motility. Surprisingly, VezA is not located on EEs, and the mechanism by which it controls interaction of dynein and EEs is not fully understood. Furthermore, the microtubule tracks themselves could participate in regulation of EE motility. It was shown in *N. crassa* and *A. nidulans* that kinesin-3 moves cargo preferentially along a subset of modified and less dynamic microtubules (165, 180). However, such selective transport of kinesin-3 was not found in the basidiomycete *U. maydis* (192).

Multiple Functions for Fungal EEs

The discovery of kinesin-3 as the motor for plus end-directed motility of fungal EEs (178) allowed the generation of mutants where EE motility was inhibited. This opened new avenues to investigate the role of these organelles in filamentous fungi. Over the past 10 years, intensive studies of *U. maydis* and *A. nidulans* have revealed multiple roles of EEs in fungal growth and virulence (Fig. 5).

The role of EEs in the endocytic pathway

EEs are the first compartment that sorts incoming material for recycling back to the plasma membrane or for degradation to the vacuole. It was shown that endocytic recycling supports tip growth of hyphae in *A. nidulans*, *A. oryzae*, *N. crassa*, and *A. gossypii* (37, 38, 152, 153, 156, 157). In addition, endocytic receptor recycling is essential during the early steps of pathogenicity in *U. maydis* (155). A role of EEs in recycling

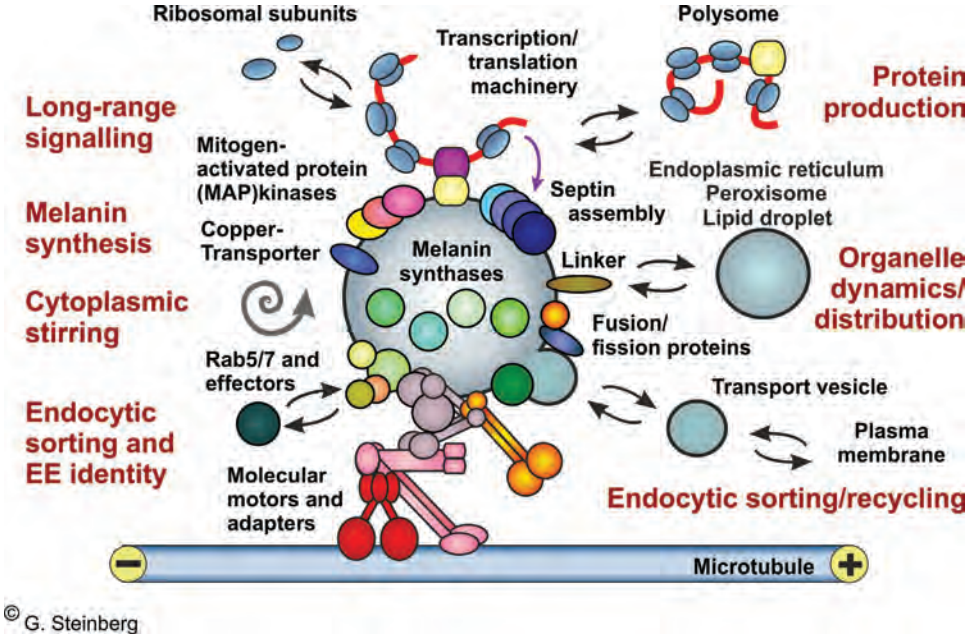

Figure 5 EEs as multifunctional platforms. Proteins that associate with the organelles are shown as colored symbols and described in black; functions are indicated in dark red. The diagram is based on work with *U. maydis*, *A. nidulans*, and *A. fumigatus*. See text for detailed description.

is also indicated by the fact that fungi contain the small GTPase Rab4 (155), which is involved in endocytic recycling at mammalian EEs (164). However, experimental evidence for such a role of Rab4 in filamentous fungi is missing. The second pathway from the EEs involves a maturation process, where Rab5 is replaced by Rab7, as shown in mammals (193), *A. nidulans* (194), and *U. maydis* (161). This maturation process from an EE to a late endosome and finally delivery to the vacuole involves EE motility (161, 194) and a complicated machinery of additional protein factors (75, 195). *A. nidulans* mutants defective in such factors (e.g., Vps33 or $PepA^{Pep12}$) (75) do not form normal colonies, which demonstrates that sorting to the vacuole is crucial for normal hyphal growth.

Hitchhiking of the protein translation machinery and organelles on EEs

Fungal EEs are constantly moving, and their motility is fueled by hydrolysis of ATP (15). The costs for the cell to maintain EE motility are best illustrated by a simple calculation, using parameters from *U. maydis*. Here, ~100 EEs are constantly moving (M. Schuster and G. Steinberg, unpublished results) at a rate of ~2 μm/s (186). Considering a step size of 8 nm (168, 169) and consumption of one ATP per step (196), these 100 EEs consume 90 million ATPs per hour. While EE motility is required to sort endocytosed material to the lysosome (see above), this high energy cost suggests additional functions of EE motility. Indeed, recent studies in *U. maydis* and *A. nidulans* have shown that other cellular cargos can "hitchhike" on moving EEs. The first report of such a mechanism demonstrated that the *U. maydis* mRNA-binding protein Rrm4 travels on EEs (197). Rrm4 links various mRNAs to a FYVE-domain-containing protein, Upa1, which itself is expected to bind to PIP3 lipid (198, 199). While it was initially suggested that this hitchhiking mechanism delivers mRNAs to the ends of the hyphal tip cell (200), a more recent report shows that entire polysomes (ribosomes and mRNA) bind and unbind to EEs, which distributes the protein translation machinery in the cell (161). Thus, transient hitchhiking supports the spatial organization of the translational machinery in the fungal cell.

Interestingly, it was reported that this mechanism is also used to relay organelles. In *U. maydis* (201) and *A. nidulans* (202), peroxisomes also transiently hitchhike on moving EEs. Moreover, lipid droplets and, to lesser extent, ER are distributed by moving EEs (201). Interestingly, when EE motility was blocked, organelles clustered at the hyphal tip (187, 201, 202). It was shown in *U. maydis* that this is due to a pole-ward drift of these organelles, probably powered by myosin 5-dependent delivery of secretory vesicles to the hyphal apex (203). Thus, hitchhiking on moving EEs maintains an even distribution of organelles and polysomes, which is vital for protein production and organelle function. It is worth noting that the process of hitchhiking is not restricted to filamentous fungi but may be a more general mechanism of cargo distribution in eukaryotic cells (204).

Local protein translation on moving EEs

Recent studies of *U. maydis* revealed a novel aspect of mRNA hitchhiking on EEs. It was shown that polysomes, while bound to moving EEs, are translationally active (161, 205). Initially, it was thought that this mechanism may ensure binding of ribosomes to EE-anchored mRNA for cellular distribution (161). However, recent results in *U. maydis* show that all core septin proteins (Cdc3, Cdc10, Cdc11, Cdc12) travel on EEs in an Rrm4-dependent way (206). This suggests that septin mRNA is traveling on EEs and subsequently being translated on the organelles to septin proteins, which assemble into a heteromeric septin building block. Thus, local translation on EEs may help to assemble and transport protein complexes in the hyphal cell.

Mixing the cytoplasm to enhance organelle interactions

EEs are constantly moving along microtubules (186). This raises the possibility that the EE trafficking stirs the fungal cytoplasm. Evidence for such a function was recently provided in *U. maydis*. Here, bidirectional EE motility increases the diffusion of peroxisomes and lipid droplets (203). This is most likely due to perturbation of the cytoplasm or direct collision between EEs and organelles. These unspecific interactions are further fostered by dynein-driven bending of microtubules (207, 208), which allow moving EEs to explore all regions of the cytoplasm within the hyphal cell tube. Mathematical modeling shows that these perturbations increase the local mobility of peroxisomes and lipid droplets, thus raising the chance of organelle-organelle interactions, which are essential for the cellular roles of both organelles (209). Interestingly, EEs in *A. nidulans* were shown to support the aggregation of proteins, which are formed in response to a heat shock (210). How EEs support protein aggregation is not known, but transient interactions between both were reported (210), suggesting that either hitchhiking (see above) or passive collisions support protein aggregate formation.

Participation of EEs in melanin biosynthesis

Melanin is a negatively charged hydrophobic polymer pigment. This polymer mechanically strengthens the fungal cell wall and protects microorganisms against microbicidal peptides, reactive oxygen species, and antifungal drugs. Consequently, melanin is associated with fungal virulence, in both human and plant pathogens (211–213). A genetic screen, designed to identify conidial pigmentation mutants in *A. fumigatus* (214), revealed a novel role for EEs in melanin biosynthesis. In one of the mutants, all melanin synthesis genes were unaffected, but a conserved sorting nexin, Mvp1, was mutated (215). This protein contains a PHOX domain, known to bind to lipids enriched in EEs (162). Subsequent studies led to the discovery that early enzymes of the melanin biosynthesis pathway (Alb1, Arp1, Arp2, Ayg1) are recruited to EEs. This, and the role of the sortin nexin Mvp1 in conidia pigmentation, strongly suggest that fungal melanin biosynthesis is initiated in the endosomal system, from where melanin intermediates are secreted and further processed by late biosynthetic enzymes (Abr1, Abr2) in the cell wall. Thus, EEs may govern aspects of secondary metabolism in filamentous fungi.

Endosomes in Long-Range Signaling

Mammalian neurons and elongate fungal hyphae share a common challenge in long-range signaling from the cell pole to the nucleus. In *U. maydis*, the nucleus is located ~50 μm behind the growing tip (216), and perception of external cues by tip-located receptors requires signaling over this distance. In neurons, such retrograde signaling is supported by moving EEs (217), and it was speculated that fungal EEs also take part in long-range transmission of signals (218). Evidence for this hypothesis comes from work with *U. maydis*. When the fungus enters into its plant host, it secretes effector proteins to suppress plant defense system activation (219–222). But how does the fungal nucleus know that effector genes need to be transcribed? It was shown that retrograde EE motility bridges between the invading hyphal tip and the subapical nucleus and that this motility is required to increase effector gene transcription and subsequent effector protein secretion (219). This supports the notion that EE motility transmits the signal for effector production from the hyphal tip to the subapical nucleus. Neither the plant cues that trigger effector transcription nor the detailed mechanism underpinning signal relay is known. However, the mitogen-activated protein kinase Crk1, described in the control of morphogenesis in *U. maydis* (223), is located on EEs and participates in regulating effector transcription (219). While our understanding of long-range signaling in fungi is still very fragmentary, these findings demonstrate a role for moving EEs in signal transduction.

Since the discovery of EEs in 2000 in *U. maydis* (160), our knowledge of the molecular machinery and cellular role of EE motility has increased significantly. It has emerged that EEs are motile multipurpose platforms that are involved in various essential aspects of fungal biology (Fig. 5). Initially recognized as sorting organelles, involved in recycling and degradation of endocytosed cargo, EEs have now been shown to spatially organize the hyphal cell. They enable long-range signaling and serve as platforms for local protein translation. Thus, motile EEs are pivotal to the fungal cell.

SEPTATION IN FUNGAL HYPHAE

Septum Formation

Fungal cells divide via the process of septation, whereby the localized synthesis of a cross-wall divides an existing cell into two distinct cells. In yeasts, dissolution of the septum physically separates the two cells. However, they remain attached in multicellular hyphae and often retain some degree of cytoplasmic continuity through septal pores. It is well established that the process of septum formation in fungal hyphae requires the presence of intact actin filaments, which assemble into a ring (i.e., the contractile actin ring [CAR]) (Fig. 6) that constricts in a process resembling cytokinesis in animal cells (224, 225). In yeasts, and presumably hyphae as well, the CAR guides deposition of the septal wall material (224, 226). Much of our understanding of the mechanisms that underlie assembly and constriction of the CAR is based on the functional characterization of gene products identified on the basis of their homology to yeast proteins with well-defined roles in septation (e.g., references 226–228). In general, the roles of these gene products appear to be largely conserved in filamentous fungi (224). Additional studies have provided insight into the regulation of septum formation in fungal hyphae, and in some cases they have yielded unexpected surprises (229). These surprises to a large extent reflect novel features of septum formation in multicellular hyphae compared to yeasts. This includes, for example, the precise spacing of septa so that the appropriate compartment size is maintained (230). Achieving a greater understanding of the mechanics and regulation of septum formation in fungal hyphae will go a long way toward revealing key functional features that underlie the unique organization of fungal hyphae.

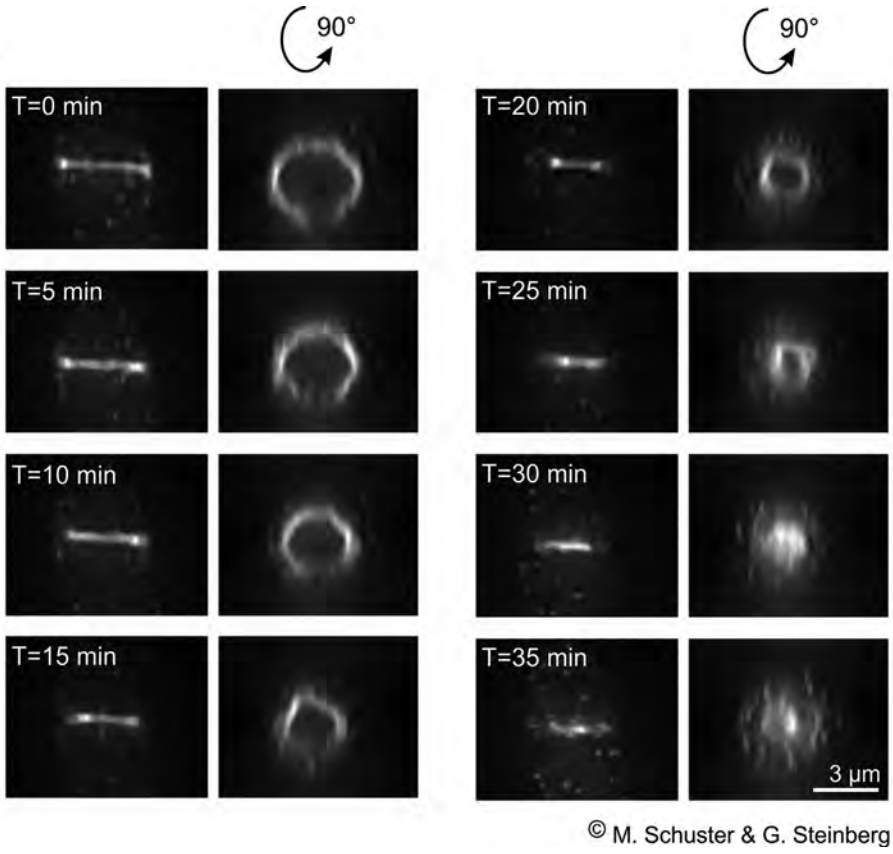

Figure 6 Time course of the contraction of the CAR during septum formation in the wheat pathogen *Z. tritici*. The side view of the three-dimensional image stack shows that the CAR is closing with time. Time in minutes is shown in the upper-left corners. The CAR was labeled using an F-actin-specific GFP-LifeAct probe.

The CAR and deposition of the septum

Like in animal cells, assembly and constriction of the CAR underlies septum formation in fungal hyphae (224, 225). The CAR initially appears at the incipient septation site as a tangle of actin filaments that is associated with myosin and tropomyosin. This structure subsequently consolidates into a thin "proto-CAR" that circumscribes the hypha. Constriction of the CAR coincides with ingrowth of the plasma membrane and the deposition of the new cell wall material that will become the septum. The CAR remains positioned at the advancing edge of the invaginating plasma membrane, which is also the active site of cell wall deposition that is mediated by the delivery of exocytic vesicles. During constriction, the appearance of actin patches that flank the CAR is consistent with localized endocytosis. Unlike cytokinesis in yeast cells, the CAR does not fully close, thereby retaining cytoplasmic continuity between adjacent hyphal cells through the resulting septal pore.

Other than tropomyosin and myosin, other components of the CAR include the anillin-like protein Bud4 (27, 224, 231), formin (224, 232), the actin-nucleating protein Bud6 (233), alpha-actinin (234, 235), paxillin (A. Virag and S. D. Harris, unpublished), and chitin synthase (224, 236). Notably, Bud4 and chitin synthase appear just prior to the initiation of constriction (224) (Fig. 7). Depending on the specific fungus, the absence of any of these components completely abolishes septum formation or results in the formation of abnormal septa. In general, formins, Bud6, and alpha-actinin are directly needed to assemble microfilaments into a CAR (232, 233, 235). The role of Bud4 is particularly intriguing, because Bud4 homologues in *S. cerevisiae* and *S. pombe* associate with septins (237, 238). In filamentous fungi such as *A. nidulans*, *A. fumigatus*, and *N. crassa*, septins also appear as rings at septation sites (e.g., references 239–241). In addition, fungal septins are subject to posttranslational modification such as phosphorylation (242), which likely plays a key role in

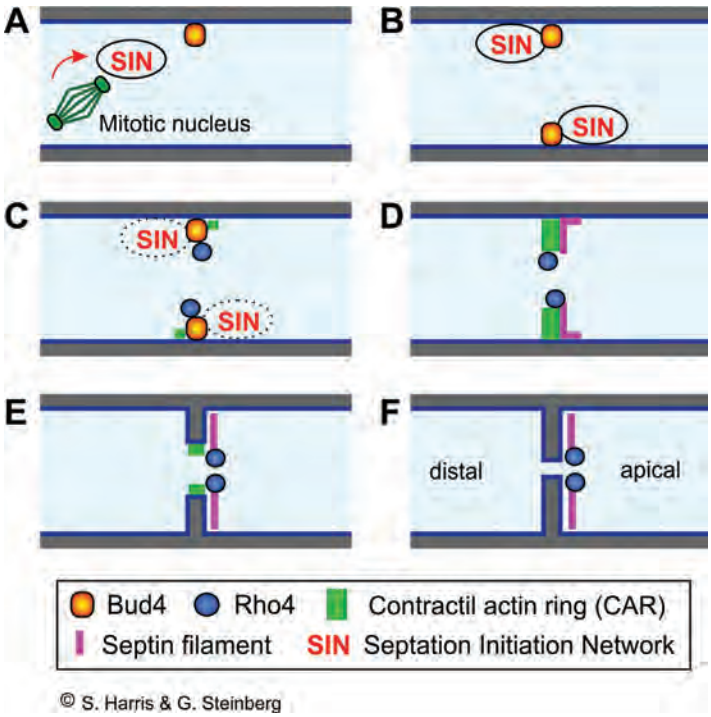

Figure 7 Model for septum formation. (**A**) A signal emanating from mitotic nuclei is relayed to the septation site via the septation initiation network (SIN). (**B**) Components needed for assembly of the contractile actin ring (CAR) (actin filaments, Bud4) are already associated with the septation site and operate in conjunction with the SIN to define the division plane. (**C**) Activation of the GTPase Rho4 at the septation site initiates organization of actin filaments into a CAR. (**D**) Constriction of the CAR is coincident with appearance of a septin ring. (**E**) Deposition of the septum is guided by the CAR. The septin ring disassembles once the final size of the septal pore is reached. (**F**) Several proteins, including calcineurin and Rho4, remain associated with the mature septal pore. The diagram was modified from Beck et al. (345).

determining their association with diverse partner proteins. Nevertheless, the relationship of septin localization and modifications to CARs and the timing of their appearance remain to be determined.

Studies using *A. nidulans* and *N. crassa* show that the monomeric GTPase Rho4 coordinates assembly of the CAR at septation sites (28, 243). Strikingly, Rho4 orthologues are conserved in filamentous fungi and *S. pombe*, but not in *S. cerevisiae* (which possesses a different GTPase known as Rho4). Activated Rho4 appears to recruit formins to the septation site (28), which is presumably an early step in the formation of the proto-CAR. It is interesting to note that weak homologues of *S. cerevisiae* Bud3 serve as guanine nucleotide exchange factors that activate Rho4 (27, 28). Accordingly, *rho4* and *bud3* mutants fail to recruit formins and thus do not assemble CARs or form septa. These results suggest that the Bud3-Bud4 module that provides a septin-associated spatial landmark for polarity establishment in budding yeast could conceivably have been co-opted from an ancestral function in directing CAR assembly at septation sites in filamentous fungi.

Regulation of septum formation in fungal hyphae

The formation of CARs at septation sites is subject to both spatial and temporal regulation (53). The existence of spatial regulation is supported by the uniform distribution of septa in fungal hyphae and their general exclusion from apical regions. Temporal regulation is likely based on the coordination of septum formation with mitosis at least in those filamentous fungi that exhibit parasynchronous nuclear division. Collectively, both forms of regulation presumably ensure that the compartment sizes in a hypha are appropriate for the extant growth conditions.

In *A. nidulans*, results from the use of mitotic inhibitors support the view that signals emanating from

dividing nuclei (e.g., the mitosis spindle or spindle poles) trigger the local formation of CARs (225). A promising source for such a signal is the septation initiation network (SIN), which coordinates CAR assembly and constriction with mitosis in *S. pombe* (244) (Fig. 7). Elements of the SIN pathway are conserved in filamentous fungi and are needed for CAR formation and septation (e.g., references 245, 246). However, they appear to function in a manner that is different from *S. pombe*, because for example, prior association with spindle poles is not required for SIN recruitment to septation sites (247). Although these observations implicate the SIN in the temporal regulation of CAR assembly or maturation, the specific nature of the signal remains to be determined. The timing of septum formation is also subject to regulation by DNA damage and other forms of genotoxic stress (229, 248). For example, low levels of DNA damage permit nuclear division but block septation in *A. nidulans* and *Fusarium graminearum*. In *A. nidulans*, this effect is mediated by inhibition of the same CDK that regulates mitosis (229).

Even though signals emanating from mitotic nuclei are presumably capable of triggering CAR assembly or maturation, it is also evident that not all mitoses are capable of activating formation of a septum. Otherwise, hyphal cells would in principle contain only a single nucleus, which is not the case for many filamentous fungi. Indeed, the regular spacing of septa and the relatively uniform number of septa per hyphal compartment in these fungi imply that septum formation is spatially regulated. That is, the activation of CAR assembly by a given mitosis event seemingly precludes adjacent dividing nuclei from also triggering septation. This could be simply due to titration of one or more key components needed for CAR assembly, but it might also reflect the active repression of septum formation at sites flanking a new CAR even if mitotic nuclei are nearby. How this might occur remains a puzzle, though it is tempting to speculate that cortical landmarks might specify "preseptation" sites that must be activated by an adjacent mitosis event to enable CAR formation or they are otherwise disassembled.

Communication and Differentiation of Hyphal Compartments

In basidiomycetes and ascomycetes, septa divide the hypha into compartments. These septa contain pores of 50 to 500 nm (249–252) that allow intra- and interhyphal translocation of metabolites, proteins, RNA, and even organelles. The rate of mass flow of cytoplasm in the mycelium of the basidiomycetes *Armillaria mellea* and *Serpula lacrimans* is in the range of 3 to 70 μm s^{-1} (253), while a rate of ~5 μm s^{-1} was observed in *N. crassa* (254). These rates underpin the potential for fast mixing of cytoplasm through the mycelium, implying that the mycelium of ascomycete and basidiomycete fungi is continuous like that of lower fungi. This paradigm is, however, changing. Studies have shown that fungal septa with growing hyphae can be closed, thus preventing cytoplasmic exchange between compartments (see "The Mechanism of Septal Pore Closure," below), which allows heterogeneity of hyphal cells within the fungal mycelium.

Hyphal heterogeneity

Zones within fungal mycelia show heterogeneous gene expression patterns and heterogeneity in growth and secretion (255–260; overview in reference 17). For instance, growth is mainly limited to the periphery of colonies of *Aspergillus niger* (255), while protein secretion occurs throughout the colony, with the exception of an intermediate zone, that is primed to sporulate under particular environmental conditions (260). There is differential gene expression across these zones (256, 259), and different proteins are secreted at the periphery and central zones of these colonies (259). Even hyphae within a given mycelial zone are heterogeneous with respect to cytosolic composition (17, 255, 257, 258, 261–265). For instance, part of the hyphae at the outer zone of *A. niger* colonies have high transcriptional and translational activity, which is accompanied by secretion of proteins that are involved in substrate degradation (255, 263–265).

Hyphae show highly polarized apical tip growth. They have at least four regions. The most apical region of hyphae (i.e., the first 1 to 5 μm) contains the Spitzenkörper, some mitochondria, and some smooth endoplasmic reticulum (266, 267). The tip region is also rich in actin filaments but sparse in ribosomes (262, 268). The second region is 2 to 4 times as large and contains mitochondria and some ER cisternae (104). The third region, which ends at the first septum, contains the complete collection of organelles. The fourth and following regions make up the second and following compartments. They contain all organelles, but their structure and abundance are often different from those in the third region. For instance, vacuoles are more abundant in subapical compartments, while 18S rRNA is less abundant, at least in the basidiomycete *Schizophyllum commune* (262).

Mechanisms of cytoplasmic flow

Cytoplasmic streaming depends on the architecture of the mycelium and is the result of turgor pressure

gradients, diffusion, and/or turbulence due to movement of organelles along the cytoskeleton. Hyphal fusion plays an important role in long-distance translocation of nutrients in *N. crassa* (269). This is evident from the finding that transport of nutrients is highly affected in a soft mutant (Δ*so*), which is a mutant strain that lacks the ability to undergo hyphal fusion. Even a 50% reduction in hyphal fusion frequency, as occurs in the Δ*prm-1* mutant, results in decreased nutrient translocation rates from the center toward the periphery of the colony (269).

Turgor pressure-mediated translocation has been proposed as a mechanism of cytoplasmic streaming in several fungi (253, 269–271). For instance, long-distance translocation of the nonmetabolizable glucose analogue 3-*O*-[^{14}C]methyl glucose through the mycelium of *Morchella esculenta* would depend on this mechanism. Translocation of 3-*O*-methyl glucose depends on the formation of sclerotia. A mutant unable to form these survival structures does not transport this glucose analogue through the mycelium (270). To explain these results, it was postulated that nutrients and solutes lower the water potential of the cytosol in the vegetative hyphae, resulting in water uptake from the medium. This uptake generates a higher turgor pressure in the hyphae. However, it is insufficiently high to create a flow through the mycelium. For this to occur, solutes are converted into high-molecular-weight polymers upon their arrival at the sclerotia or are released as exudate into the medium. These processes decrease the turgor within the sclerotia and thus act as a sink by attracting water (i.e., cytosol) from the vegetative hyphae. Addition of the metabolic inhibitor azide strongly reduces translocation of 3-O-methyl glucose, showing that metabolic activity is a prerequisite for turgor pressure gradient-mediated translocation to occur.

Mass transport driven by pressure gradients also dominates intrahyphal transport toward the hyphal tips of *N. crassa* (272). The pressure gradient required for this flow is very low (10^2 to 10^4 Pa cm^{-1}) compared with the 4 to 5 10^5 Pa turgor pressure within these hyphae (273). This low required value of the gradient is caused by the micrometer-range width of the hyphae. Pressure differences in micro-channels in the range of 10^2 to 10^3 Pa result in translocation rates of 50 to 500 μm s^{-1}, with mixing of the fluid dominated by diffusion (274). This velocity agrees with the maximal rate of bulk flow in *N. crassa* hyphae of 60 μm s^{-1}, although average flow rates are only ~5 μm s^{-1} (254). The intrahyphal osmotic gradients required for mass flow in *N. crassa* are likely to result from ion transport, as indicated by experiments using extracellular osmotic gradients. The high concentration of organelles in the cytosol of *N. crassa* hyphae impedes bulk flow of the cytoplasm, causing a so-called partial plug flow (272).

Cytoplasmic streaming in *N. crassa* occurs at ~5 μm s^{-1} (254). In contrast, the *N. crassa* kinesin motor Nkin transports its cargo at 2.1 to 3.8 μm s^{-1} (275). Thus, it is very unlikely that fast cytoplasmic streaming is a direct consequence of motor activity. Indeed, movement of nuclei toward the outer part of the colony was still observed in strains with mutations in microtubule-related motors (dynein and kinesin) and after treatment of wild-type strains with molecules disrupting the cytoskeleton (276). However, motor proteins move organelles in hyphal cells (overview in references 12, 167, 277, 278). Such motor-driven motility of organelles was recently shown to mix the cytoplasm and increase diffusion within the cytoplasm (203), which could support the exchange between adjacent hyphal cells. This notion is supported by findings in *A. niger*, in which depolymerization of actin and tubulin with cytochalasin A and nocodazole, respectively, reduced the rate of cytoplasmic streaming by about 25% (279). While cytoplasmic streaming was shown to support apical translocation of organelles (272, 280), it may also result in an uneven distribution of organelles, as was shown in *N. crassa* (281). Cytoplasm streams toward the apex in this fungus. The stream narrows in the septal pores, resulting in microfluidic eddies on the upstream side of the septum, where nuclei can be trapped. The presence of septa in hyphae thus creates subcellular domains within *N. crassa* hyphae.

It is currently not known if the mechanism underlying cytoplasmic streaming in *N. crassa* applies to all its hyphae or to other fungi. Most of the work on streaming in *N. crassa* has been done with so-called trunk hyphae. These hyphae are wider than the majority of hyphae in the mycelium. Such trunk hyphae have also been observed in other fungi such as *A. niger* (282), where they also represent the minority; cytoplasmic streaming in *A. niger* hyphae has a rate 2,000 times lower than that observed in *N. crassa*, while its growth rate is about 10-fold lower (279). The cytoplasm of fungal cells is able to contract, which was shown in *A. niger*, *N. crassa*, and *Trichoderma atroviride* (283, 284). Thus, motor-driven contractions of the cytoskeleton may contribute to cytoplasmic streaming in filamentous fungi.

Selective transport across closed septa

Fungi have the ability to close their septa, which limits exchange between hyphal compartments (see "Communication and Differentiation of Hyphal Compart-

ments," above). In *A. niger* it was shown that the newly formed compartments are in exchange with neighboring compartments, while older parts of the mycelium are closed off by plugging of the septal pore, with ~90% of the 4th to 8th subapical septa closed, followed by complete sealing of the 9th and 10th septa (279). Closure of these septa is mainly caused by a peroxisome-like organelle, the Woronin body (see "Closing Pores by Woronin Bodies," below). Due to the closure of old septa in the center of the colony, transport of nutrients through the cytoplasm cannot occur. Indeed, measurement of a fluorescent glucose analogue provided no evidence for glucose transport from the periphery to the colony center (282). Surprisingly, however, glucose was found to be transported from the center to the periphery of the mycelium. Because the fluorescent glucose analogue accumulated in the cross-walls of the septa, it was concluded that glucose is efficiently transported across the plasma membrane lining the septal cross-walls (282). This could be mediated by transporters that allow the passive passage of sugars down a concentration gradient. Indeed, a hexose transporter, *mstE*, localizes to septa in *A. nidulans* (285). Such a septal pore-independent and selective transport mechanism would operate independently of septal pore plugging (Fig. 8). Indeed, transport of glucose between different zones of the colony of *A. niger* was not increased in mutants that were devoid of Woronin bodies (282).

The Mechanism of Septal Pore Closure

Filamentous fungi grow by apical tip growth of their hyphae. In ascomycete and basidiomycete fungi and a few subgroups of the zygomycetes, septa partition the hypha into subcompartments. Communication between these compartments is mediated by septal pores, which range in size from 25 nm in *C. albicans* (286) to 360 nm in *N. crassa* (287). The width of the septal pore allows exchange of cytoplasm, including small molecules, ribosomes, and proteins, but also entire organelles such as mitochondria and nuclei (252, 254, 288). However, it is essential for the hyphal cell to keep this exchange under tight control and thus be able to close the septal pore upon stress or cell injury or during particular developmental stages and differentiation. To this end, fungi have developed various ways to plug the septal pore (289). In most cases, insight into the process of pore closure is based on ultrastructural studies, which show closure by organelles, small crystalline bodies, or electron-dense proteinaceous material (289). However, recent research has begun to shed light on the molecular mechanisms underpinning pore closure in filamentous fungi.

Closing pores by proteinaceous material

Plugging of the septal pore by a deposit occurs independently of hyphal injury and is based on *de novo* deposition of proteinaceous material (289). Basidiomycete fungi contain a complex septal pore, the dolipore (252), which was shown in *S. commune* to be plugged by electron-dense proteinaceous material in response to environmental stress (e.g., osmotic shock) or hyphal wounding (290, 291). Such deposition appears to be the only mechanism for pore plugging in basidiomycetes (subphyllum Agaricomycotina). Not much is known about the nature of this electron-dense material. However, it has been suggested that the septal pore cap

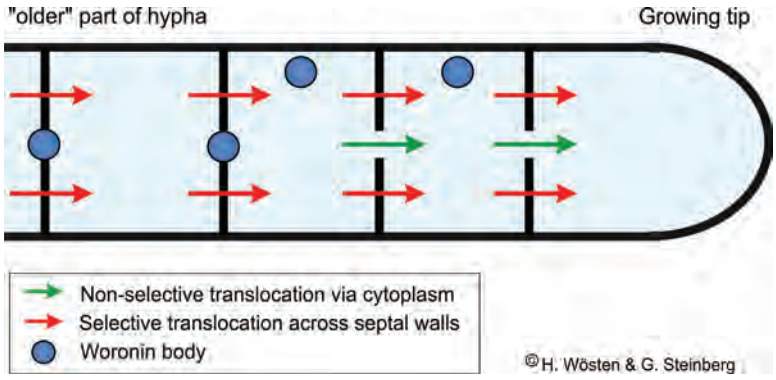

Figure 8 Model for tip-ward translocation in *A. niger*. Newly formed hyphal compartments are in cytoplasmic contact with neighboring cells. The Woronin body is not plugging the septal pore, and cytoplasmic streaming, as well as diffusion through the septal pore, is possible (green arrow). Older septa are plugged by Woronin bodies, which prevents exchange of cytoplasm. However, selective transport of molecules such as glucose toward the growth region is still possible (red arrows). This may involve septum-associated transporters.

(i.e., parenthesomes; Fig. 9) (252) of the basidiomycete dolipore provides a reservoir from which plugging proteins are released (289). The septal pore cap is derived from the endoplasmic reticulum and flanks both sides of the pore channel. Septal pore caps are usually perforated and were suggested to act as sieves that limit passage of organelles through the dolipore (292); passage of nuclei through dolipores requires its degradation and conversion to a simple pore (293). Support for an additional role of the septal pore cap in pore plugging comes from the recent identification of protein SPC18 in *Rhizoctonia solani* (294). SPC18 localizes to septal pore caps but was also found in the pore channels, suggesting that the septal pore cap provides the material for plugging the dolipore. This notion is further supported by a mutant in a septal pore cap protein SPC33 in *S. commune* (295). This mutant lacks septal pore caps and is unable to close the dolipore channel upon wounding. Interestingly, this results in defects in growth and fruiting body formation, indicating that the ability to close the septal pore is a prerequisite for differentiation and development in basidiomycetes.

In older parts of hyphae in the ascomycete fungus *N. crassa*, septal pores contain accumulations of electron-dense material (287), suggesting that protein deposition limits flow between hyphal compartments. Work in *N. crassa*, *Sordaria macrospora*, and *Aspergillus oryzae* revealed a role for the SOFT/PRO40/SO1 protein (hereafter named SO) in plugging septal pores (296–298). SO is a cytoplasmic protein that, upon cell injury or environmental stress, relocates to the septal pore. Mutants lacking SO show slower plugging after cell injury (297) or are significantly impaired in septal closure (298). This suggests that deposition of SO proteins participates in sealing septa. Interestingly, only the C-terminal half of SO is involved in plugging septal pores in *A. orzyae*, whereas the N-terminal half appears to serve a septum-independent role in cell-cell fusion (299). This functional diversity may explain the broad phenotypic variation in SO mutants, which show defects in cell-cell fusion, aerial hyphae formation, and conidiation (298, 300).

Whether SO protein represents the electron-dense material in septal pores of ascomycetes (e.g., references

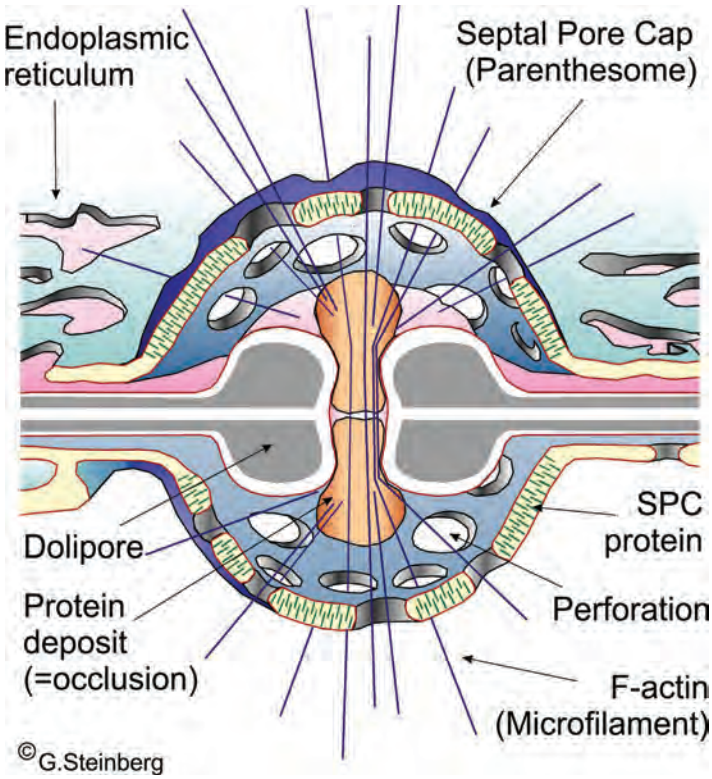

Figure 9 Schematic drawing of a dolipore in the basidiomycete *Polyporus biennis*. The image was redrawn from a reconstruction of electron micrographs, first published in reference 346.

287, 301) is not known. In *A. nidulans*, the NIMA kinase locates at the septum and the septal pore is open (302). Upon entry into mitosis, NIMA leaves the septum to control early steps in mitosis (303). Upon this relocation of NIMA, the septal pore closes, and this isolates the mitotic cell from neighboring interphase cells (302). Thus, NIMA appears to orchestrate septal pore opening during interphase. Surprisingly, this NIMA-controlled plugging occurs independently of SO and of Woronin bodies (see below), suggesting that additional mechanisms exist which close a septal pore. Indeed, the recent identification of 17 additional septal pore-associated (SPA) proteins (304) suggests that various proteins cooperate in pore closure. A subset of these SPA proteins localize to the lumen of the septal pore channel (SPA type II: SPA3, SPA5, SPA6). Thus, these proteins may participate in controlling communication and exchange between hyphal compartments. Such a role in pore plugging is further supported by biochemical data that show that recombinant SPA5 self-assembles into gel-like aggregates (304). However, the precise cellular role of most SPA proteins needs to be elucidated.

Closing pores by Woronin bodies (WBs)

Filamentous ascomycetes (subphylum Pezizomycotina) and imperfect fungi (Deuteromycota) have developed an additional mechanism for septal pore plugging. This is based on a fungus-specific organelle, the WB. WBs were named by A. H. Reginald Buller (305) after the Russian botanist Mikhail Strepanovich Woronin, who first described *kleine Körnchen* (small granules) adjacent to septa in *Ascobolus pulcherrimus* (306). Woronin's observations were confirmed in various fungi, where these highly refractive particles were found to move within the cytoplasm (see reference 305 for references). Subsequent electron microscopy studies revealed that WBs are spherical membrane-bound organelles of 100 to 750 nm in diameter (289). Fungal cells contain usually 3 to 6 WBs adjacent to their septa (305, 307), but a large number of additional WBs are found in the cytoplasm of *A. nidulans* and *A. fumigatus* (302, 308, 309). Septum-associated WBs are nonmobile and anchored at the septal pore (301, 308, 310). In *Neurospora* and *Sordaria*, WBs are larger and are anchored at the cell periphery, which is thought to be an adaptation to the prominent and rapid cytoplasmic streaming seen in these fungi (311).

The main purpose of WB-based septal pore closure is to prevent catastrophic loss of cytoplasm after hyphal injury (289). The first insight into such a function in septal pore plugging was provided by ultrastructural studies that showed WBs sealing septa in wounded hyphae (312–314). A breakthrough came with the identification of the protein Hex1 in WBs of *N. crassa* (315, 316), which was subsequently reported in *M. grisea* (317), *Trichoderma reesei* (318), *A. oryzae* (301), and *A. fumigatus* (308). Hex1 is the main component of the crystalline matrix of WBs (319, 320), and deletion of *hex* genes results in the absence of WBs (301, 308, 315, 316). Strikingly, these null mutants are impaired in sealing their septa after injury, which strongly indicates a role of WBs in septal pore plugging. However, WBs also seal 5 to 13% of septal pores in unwounded hyphae (321). This suggests that WBs have additional roles in restricting flow through septal pores in healthy hyphae, and this may generate heterogeneity within the mycelium (261).

Ultrastructural studies of *F. oxysporum* suggested that WBs originate from microbodies (i.e., peroxisomes and glyoxysomes; reference 322). This conclusion gained support by the finding that antibodies against the peroxisomal targeting signal recognize WBs (323). Hex1 from *N. crassa* contains a peroxisomal targeting signal, and live-cell imaging confirmed that Hex1 crystals are formed at peroxisomes (324), where a Woronin sorting complex (WSC) supports assembly of Hex1 and formation of WBs, as well as cortical anchorage of the organelle (325). A role for the WSC in WB formation was confirmed in *A. fumigatus*, although WSC was not involved in anchorage of WBs near the septum (326). Finally, it was shown that mutants deleted in peroxisomal *pex*-genes (*pex6*, *pex14*, *pex11*), required for proliferation or biogenesis of peroxisomes in *M. grisea*, *N. crassa*, and *A. oryzae*, lack WBs (327–329). Taken together, these studies provide compelling evidence for the conclusion that WBs derive from peroxisomes.

It was recognized early that WBs, once in position, are stationary and even resist fast cytoplasmic streaming (301, 305, 308, 324, 325). Interestingly, when WBs were misplaced by an optical laser trap in *N. haematococca*, they snapped back to their original position at the septum (330). This simple experiment strongly suggests the existence of a physical tether that holds WBs in position. Indeed, ultrastructural studies suggested a fibrous connection between WBs and the septal pore (309). Again, it was work with *N. crassa* that moved the field forward and revealed the molecular nature of this tether. A genetic screen for mutants defective in WB segregation identified the *leashin* (*lah*) locus, which is involved in WB tethering (331). This locus encodes two proteins, LAH-1 and LAH-2. While LAH-1 tethers WBs to the cell cortex, LAH-2 is located at the hyphal apex and the septal pore, where it performs unknown

functions. In most other ascomycetes, only LAH-2 homologues, consisting of 6,000 to 7,500 amino acids, are found that have been shown to tether WBs to the septum. In *A. oryzae* and *A. fumigatus* mutants that lack Lah proteins, WBs are no longer tethered to the septum and hyphae fail to plug their septal pores after wounding (326, 332). Most strikingly, a shorter version of Lah reduces the distance of WBs to the septal pore (from 99 to 50 nm) (332), which adds further evidence for a role of Lah in tethering WBs to septal pores. The molecular details of how Lah proteins tether the WB proteins may differ between fungi, because Lah was shown to interact with WSC in *N. crassa* (331), whereas Lah was reported to bind directly to HexA in *A. fumigatus* (326). How the cytoplasmic tether interacts with the WB core protein HexA is not understood.

The mechanism by which WBs move into the septal pore during plugging remains elusive. A tempting hypothesis is that hyphal injury results in high pressure in the adjacent cells, and bulk flow of cytoplasm moves WBs into the pore channel (310, 313). Indeed, sealing of septal pores takes several seconds, and hyphal cells often show some cytoplasmic bleeding before the pore is plugged (261, 297). However, such a passive mechanism does not explain why only one WB seals the septal pore while the others remain unaffected (307). Alternatively, it was suggested that an active, maybe cytoskeleton-dependent or contractile mechanism could draw WBs toward the septum (307, 310). The nature of such a mechanism is not known, but it may involve the tether protein Lah. Indeed, Lah shares short sequence motifs with the muscle protein titin (331, 332), which were shown to respond to changes in intracellular calcium, thereby changing the elasticity of the protein (333). Hyphal wounding increases calcium levels at the septal pore (304), which supports the idea that Lah could act as an elastic molecular spring that drags WBs into the septal pore.

In *A. nidulans* and *A. oryzae* the vast majority of the WBs are not associated with the septum (302, 308), but rather move rapidly along the cytoskeleton at a speed of ~1.4 μm/s (302). Similar behavior was described by early light microscopists (305 and references therein), suggesting that WB motility is a common feature. Currently, neither the molecular machinery for this motility nor the biological role of these moving WBs is understood. One possibility is that immature WBs are motile until they settle at the septum. Alternatively, WBs may have additional and septum-independent functions in the fungal cell. Assessing this question is further complicated by the fact that contradictory conclusions were drawn from *hex1* mutants in various fungi. While Hex1, and therefore WBs, in *A. oryzae* was found to be essential for conidiaton (301), *N. crassa* mutants deleted in *HEX-1* either showed no defect in conidiation (315) or exhibited poor conidiation (316). Moreover, in the plant pathogen *M. grisea*, the Hex1 homologue MVP1 was reported to be dispensable for virulence (317), whereas another study concluded that Hex1 in this fungus is highly important for its full virulence (334). The reason for such phenotypic variation is currently not known.

Consolidation

The final step after plugging the pore by protein deposit and/or WBs is the development of a permanent seal of the pore. This process, called consolidation, is found in asco- and basidiomycetes (289, 335). It involves synthesis and deposition of electron-lucent cell wall material at the septum and occurs within 30 min to 3 h after hyphal wounding (290, 307, 314). Cell wall formation requires delivery of secretory vesicles, which carry cell wall synthases along the cytoskeleton (135, 136, 336, 337). Indeed, large numbers of vesicles (314), as well as actin filaments and associated myosin-5 motors, concentrate at the septal pore of injured hyphae (304). Thus, consolidation results in permanent sealing, which follows the rapid emergency plugging of septal pores in response to hyphal cell injury.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

In this article, we have summarized our current knowledge of important processes underlying hyphal growth in filamentous fungi. We have shown that hyphal morphogenesis and septum formation are distinct morphogenetic processes that rely on the cytoskeleton and vesicle trafficking machinery to direct localized cell wall deposition to a precise location. Vesicle trafficking also characterizes the conventional secretory pathway in fungi. We have summarized our understanding of the processing of secretory cargo across the Golgi, coat-independent secretory vesicle budding from the trans-Golgi network, and the composition of the Spitzenkörper. Recent identification of nonclassical pathways and the role of fungal-specific myosin-chitin synthases in exocytosis add to the complexity of the secretory pathway in filamentous fungi. In addition, it has emerged that EEs are not only involved in the endocytic pathway; they are also crucial for the spatial organization of the hyphal cell and perform specialized roles in long-range signaling, melanin biosynthesis, septin filament assembly and organizing protein translation in the cell. Finally, we

have summarized our current knowledge of the mechanism of septum plugging and its role in controlling communication between hyphal cells.

While our understanding of various proteins and structures involved in these critical processes is growing rapidly, little is known about the regulatory mechanisms that orchestrate them. Current research is focused on a few model fungi; this limits comparative studies. However, comparative genomics among fungal species belonging to different taxa will allow identification of conserved key core determinants of hyphal tip growth. Furthermore, establishing molecular tools for cytological studies in nonmodel fungi, such as the wheat pathogen *Z. tritici* (166, 338–343) or the grass pathogen species *Ustilago bromivora* and *Brachypodium* spp. (344), will enable more detailed comparison of the cytology of hyphal growth and fungal pathogenicity.

The Fungal Cell Wall: Structure, Biosynthesis, and Function

12

Neil A. R. Gow,[1] Jean-Paul Latge,[2] and Carol A. Munro[1]

INTRODUCTION

Fungal cell walls are dynamic structures that are essential for cell viability, morphogenesis, and pathogenesis. The wall is much more than the outer layer of the fungus; it is also a dynamic organelle whose composition greatly influences the ecology of the fungus and whose composition is highly regulated in response to environmental conditions and imposed stresses. A measure of the importance of the cell wall can be appreciated by the fact that approximately one-fifth of the yeast genome is devoted to the biosynthesis of the cell wall (1, 2). Of these approximately 1,200 *Saccharomyces cerevisiae* genes (2), some are concerned with the assembly of the basic components, others provide substrates for wall materials, and many regulate the assembly process and couple this to environmental challenges. They include genes that encode carbohydrate active enzymes (which can be found in the CAZy database [http://www.cazy.org]) (3) and include multigene families of chitin and glucan synthases as well as remodeling enzymes such as the glycohydrolases (glucanases, chitinases) and transglycosidases. Many of the building blocks of the cell wall are conserved in different fungal species (4), while other components of the wall are species-specific, and there is perhaps no part of the cell that exhibits more phenotypic diversity and plasticity than the cell wall.

Walls are built to be both malleable and mechanically robust. The high total solute concentration inside fungal cells results in the osmotic uptake of water and the pressing of the cell membrane onto the wall. The resulting turgor pressure has been estimated to be between 0.2 and 10 MPa—equivalent to 2 to 20 times atmospheric pressure (5). The melanized cell walls of the appressoria of some plant pathogens such as *Magnaporthe oryzae* can withhold an internal turgor of up to 20 MPa. These cell walls are the most robust of all walls found in nature. Turgor pressure generates the force that enables hyphae to exert mechanical force on the substrates they are penetrating (5, 6). Hyphal forces of between 0.01 and 0.1 μN/μm (5) can be exerted at the hyphal tips which are sufficient to enable most vegetative hyphae to penetrate a stiff 8% (wt/vol) agar. Wall-less cells are invariably spherical, so the cell wall of fungi also determines their complex shapes and changes in cell shape underpinning, morphogenesis, and cellular differentiation. Because the cell wall is also the natural interface between the fungus and its environment, it goes a long way to defining the ecology of fungi by influencing their interactions with substrates and other organisms.

For fungal pathogens of humans, the wall induces innate and adaptive immune responses, and the design of the cell wall sometimes incorporates immune decoys and shields (7). Similarly, for plant pathogenic fungi the cell wall is detected by receptors in the plant cell that induce local and systemic defense responses (8). The cell wall provides a valuable source of most diagnostic antigens that are used to detect human fungal infections, and it represents a rich source of unique targets for chemotherapeutic treatment of pathogens. Therefore, fungi are in no small measure defined by, and live through, the interface of their cell walls. Recent progress has been considerable, yet some of the most important and elusive questions in fungal cell biology relate to basic aspects of fungal cell wall biosynthesis and function. This review focuses on the biosynthesis and functions of fungal cell walls with an emphasis on model pathogenic species where the most detailed information is often available.

COMPOSITION AND STRUCTURE

Structural Organization and Cell Wall Layers

Fundamentally, fungal walls are all engineered in a similar way. The wall structure directly affects wall function and interactions with the environment including immune recognition by plants and animals. Fibrous and gel-like carbohydrate polymers form a tensile and robust core scaffold to which a variety of proteins and other superficial components are added that together make strong, but flexible, and chemically diverse cell walls. Most cell walls are layered, with the innermost layer comprising a relatively conserved structural skeletal layer and the outer layers more heterogeneous and tailored to the physiology of particular fungi. In most fungal species the inner cell wall consists of a core of covalently attached branched β-(1,3) glucan with 3 to 4% interchain and chitin (9, 10). β-(1,3) Glucan and chitin form intrachain hydrogen bonds and can assemble into fibrous microfibrils that form a basket-like scaffold around the cell. This exoskeleton represents the load-bearing, structural component of the wall that resists the substantial internal hydrostatic pressure exerted on the wall by the cytoplasm and membrane. This branched β-(1,3):β-(1,6) glucan is bound to proteins and/or other polysaccharides, whose composition may vary with the fungal species (Fig. 1). However, yeast cells have bud scars that tend to have fewer outer cell wall layers covering them and therefore have exposed inner wall chitin and β-(1,3) glucan (11). The inner walls of many fungal spores and so-called black yeasts contain complex amorphous polymerized phenolic compounds called melanins, which also add protection—particularly from oxidants and some exoenzymes.

The outer layers of fungi vary much more than the inner skeletal layer (Fig. 1). Yeasts such as *Candida* and *Saccharomyces* species and the human pathogen *Pneumocystis jiroveci* have an outer cell wall comprising highly mannosylated glycoproteins that covers the inner wall. In the yeast cells of some polymorphic fungi such as the human pathogen *Histoplasma capsulatum*, the outer wall has a layer of α-(1,3) glucan that prevents dectin-1-mediated immune recognition of the underlying β-(1,3) glucan by immune cells (12).

α-(1,3) Glucan plays a prominent role in the organization of the cell wall of many human pathogens but is absent from the *Candida* and *Saccharomyces* cell walls. In *Aspergillus*, an α-(1,3) glucan along with some other amorphous polysaccharides is represented in the alkali-soluble cell wall fraction (13). The basidiomycetous yeast *Cryptococcus* has a cell wall that is enveloped by a gelatinous capsule composed of glucuronoxylomannan (GXM) and galactoxylomannan (Fig. 1) and that is anchored to the main wall via α-(1,3) glucan (14). The GXM (~90% of the mass of the capsule) is composed of α-(1,3)-linked mannan with glucuronic acid, xylose, and *O*-acetyl branches. The galactoxylomannan is composed of an α-(1,6) galactomannan (GM) backbone with GM side chains substituted with variable numbers of xylose residues (Fig. 1). The synthesis of the *Cryptococcus neoformans* capsule polysaccharides remains incompletely understood, and few transglycosidases involved in this process have been characterized (15, 16). Interestingly, it has been shown that capsule polysaccharides are synthesized intracellularly and secreted via exocytosis through the cell wall (17).

The conidial spores and aerial hyphae of mold are often covered by highly hydrophobic proteins called hydrophobins that form rodlets that protect the spores from enzymes, oxidants, and foraging phagocytes (18). For example, the conidial rodlet protein RodA of *Aspergillus fumigatus* prevents alveolar macrophages from inducing an immune response, which is delayed until this layer cracks upon spore swelling and germination (Fig. 1) (19, 20). However, once the integrity of the rodlet layer of these spores is breached, then the underlying galactosaminoglycan (GAG) and GM and β-(1,3) glucan layers can be recognized by alveolar macrophages, enabling the innate immune response to be initiated (21).

The individual components of the cell wall are covalently cross-linked to one another. In *A. fumigatus*, the branched β-(1,3)(1,6) glucan is covalently bound to chitin, a linear β-(1,3)(1,4) glucan with a [3Glcβ1-4Glcβ1] repeating unit and a branched galactomannan composed of a linear α-mannan with a repeating mannose oligosaccharide unit [6Manα1-2Manα1-2Manα1-2Manα] and short chains of β-(1,5) galactofuranose residues (22). In *Candida albicans*, β-(1,3) glucan is bound to chitin and β-(1,6) glucan, a polymer that is absent from *A. fumigatus*. In *C. albicans*, β-(1,6) glucan plays an essential role in the structural organization of the cell wall (23) interconnecting β-(1,3) glucan and chitin (Fig. 1). In *C. neoformans* and most other fungi, the covalent linkages between glucans and the other polymers have not been investigated.

In *C. albicans* and *S. cerevisiae*, β-(1,6) glucan acts as a linker molecule binding cell wall proteins (CWPs) to the β-(1,3) glucan-chitin skeleton via a glycosylphosphatidyl inositol (GPI) remnant (24). In yeast cells of these species, the CWPs represent 30 to 50% of the dry mass of the wall, of which only 10 to 20% is polypeptide. A few proteins with internal repeats (Pir)

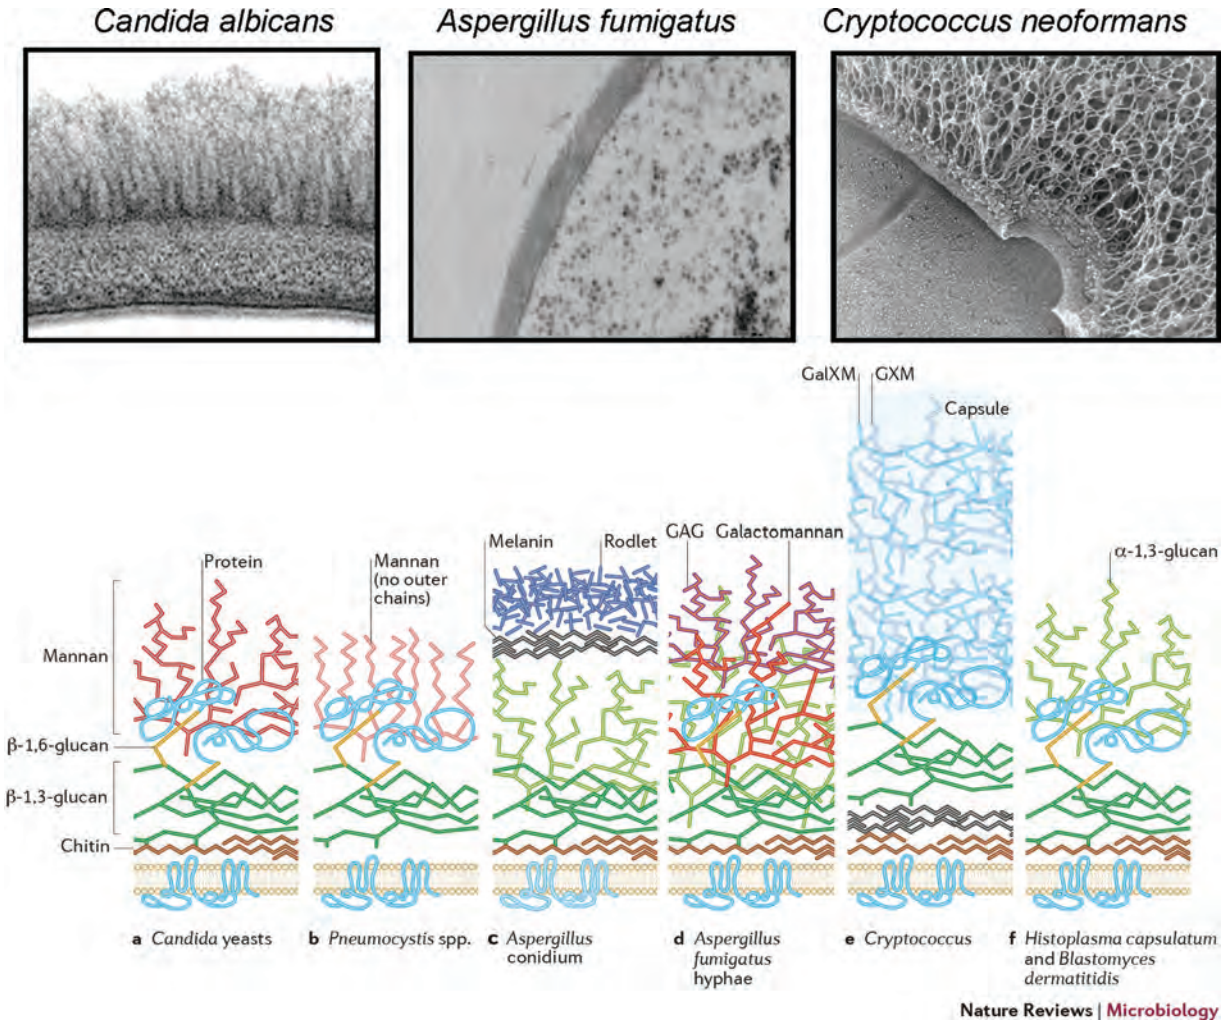

Figure 1 Structural organization of the cell walls of fungal pathogens. The upper panels show transmission electron micrograph sections of the cell walls, revealing mannoprotein fibrils in the outer walls of *C. albicans*, the fibril-free cell wall of an *A. fumigatus* hypha, and the elaborate capsule of *C. neoformans*. The cartoons (below) show the major components of the wall and current hypotheses about their interconnections. Most fungi have a common alkali-insoluble core of branched β-(1,3) glucan, β-(1,6) glucan, and chitin but differ substantially in the components that are attached to this. In *C. albicans*, the outer wall is heavily enriched with highly mannosylated proteins that are mostly attached via glycosylphosphatidylinositol remnants to β-(1,6) glucan and to the β-(1,3) glucan-chitin core. In *A. fumigatus*, typical of many filamentous fungi, mannan chains are of lower molecular weight and are modified with β-(1,5) galactofuran. These mannans are not components of glycoproteins but are attached directly to the cell wall core. The cell wall core polysaccharides of *A. fumigatus* are β-(1,3)-β-(1,4) glucans and are attached to an outer layer of alkali-soluble linear α-(1,3)(1,4) glucan. Conidial walls of *Aspergillus* have an outer hydrophobin rodlet layer of highly hydrophobic portions (hydrophobins) and a melanin layer; hyphae of *Aspergillus* have α-(1,3) glucan GM, and galactosaminoglycan (GAG) in the outer cell wall and limited glycosylated proteins. In *C. neoformans*, an outer capsule is composed of glucuronoxylomannan (GXM) and lesser amounts of galactoxylomannan (GalXM). The capsule is attached to α-(1,3) glucan in the underlying wall, although peptides or other glycans may also be required for anchoring the capsule to the cell wall. The inner wall has a β-(1,3) glucan-β-(1,6) glucan-chitin core, but most of the chitin is deacetylated to chitosan, and some of the chitosan/chitin may be located further from the membrane. *C. neoformans* also has a layer of melanin whose precise location is not known, but it may be incorporated into several cell wall polysaccharides and may assemble close to the chitin/chitosan layer. *Pneumocystis* cell walls may lack chitin and the outer chain *N*-mannans but retain core *N*-mannan and *O*-mannan modified proteins (56). Hyphae of *H. capsulatum* and *Blastomyces dermatitidis* have an outer cell wall layer of α-(1,3) glucan that prevents efficient immune recognition of β-(1,3) glucan in the inner cell wall. (From reference 7, with permission.)

can be attached directly to β-(1,3) glucan via an alkali-sensitive *O*-linkage via a mannose side chain (24). In *A. fumigatus*, the cell wall has a much reduced glycol protein content, and galactosylated mannoproteins are not cell wall-associated and are secreted proteins in transit in the cell wall.

This general arrangement places the structural elements of the cell wall close to the membrane to provide mechanical support, and places the gel-like or hydrophobic polymers to the outside where they can protect the load-bearing elements from degradative enzymes in the environment or act as adhesins to anchor the cell to substrata. A major unresolved issue is how the cell wall polysaccharides and membrane proteins are bound together to guide the cell wall morphogenesis.

Biofilms

Some of the external gel-like polymers of the outer surface of fungi are extremely well organized, such as in the capsule of *C. neoformans*, while other fungi, such as some *Candida* species, form biofilms growing on solid surfaces, where the extracellular matrix has a more loose structure composed of glucans, chitin, nucleic acids, and other polymers (25, 26). On top of the *C. neoformans* capsule there may also be a superficial biofilm that contains GXM as well as polysaccharides that differ from those found in the capsule, with significant amounts of glucose and fucose (27). Biofilms of *Pneumocystis carinii* and *C. albicans* are rich in β-(1,3) glucans and DNA (28–30), while *Candida tropicalis* has a biofilm matrix rich in GlcNAc (31). In *C. albicans*, growth of the fungus in a biofilm community results in cell wall architectural changes. In *A. fumigatus*, the extracellular matrix plays an essential role in the organization of the colony by gluing together mycelial threads and is composed of 25% polysaccharides and 70% monosaccharides with some hydrophobic proteins and melanin. The extracellular matrix of *A. fumigatus* contains α-(1,3) glucan, GM, and GAG, like the outer cell wall layer (32), and in contrast to other species, lacks β-(1,3) glucan and chitin. In human pathogens this biofilm material has been implicated in blocking recognition and immune capture by phagocytic cells.

GENETICS, ENZYMOLOGY, AND BIOSYNTHESIS

Biosynthesis of the Polysaccharides

Polysaccharides such as chitin and glucan are synthesized at the plasma membrane (PM) by transmembrane enzymatic complexes that are targeted to the PM in an inactive form via secretory vesicles and then activated after insertion into the PM (see below). This is in contrast to mannans and other glycoconjugates that are synthesized in the endoplasmic reticulum and Golgi, where they may be conjugated to cell wall proteins, and then brought to the cell wall by the classical secretory route via secretory vesicles. All synthases use nucleotide diphosphate-sugars as substrates, so enzymes of the metabolic pathways responsible for the synthesis of nucleotide sugars are essential for the construction of the cell wall and are rate-limiting.

Core Polysaccharides: Chitin and β-(1,3) Glucan

The major synthases that make chitin and glucans reside in the PM and use UDP-sugars as the substrate for the formation of the nascent polysaccharide that is extruded into the cell wall (Fig. 2A). In the cell wall, polysaccharides can then hydrogen-bond together or be cross-linked or branched by enzymes that reside in the cell wall (Fig. 2B,C). The pathway of cell wall synthesis therefore comprises biosynthetic reactions that take place inside the cell in the Golgi, at the PM, and in the cell wall itself.

UDP-*N*-acetylglucosamine is the substrate for chitin synthesis. Chitin is composed of linear chains of β-(1,4) *N*-acetylglucosamine and represents the most ancestral structural polysaccharide in the fungal cell wall. Families of chitin synthases responsible for the synthesis of chitin have been identified bioinformatically, with molecular weights of 100 to 130 kDa. The exact biochemical functions of many chitin synthase isoforms remain to be established (33–36), and although some isoforms may have redundant functions, in several species there is evidence that individual chitin synthase enzymes perform distinct and specific functions under normal growth conditions. Although the enzymological product of all chitin synthase enzymes is a homopolymer with only one linkage, individual chitin synthase enzymes can synthesize chitin fibrils of differing architecture, perhaps due to differences in the folding and intrachitin hydrogen bonding of the primary chain (37). Two families of fungal chitin synthases with three classes in the first family (I, II, III) and four classes in the second family (IV, V, VI, VII) have been identified based on amino acid sequence (38). Four classes (III, V, VI, VII) are specific to filamentous fungi (36, 39). The significance of each of these seven classes is not well understood, since mutations in members of a common family do not always result in a similar phenotype. However, two groups of mutants can be identified: the

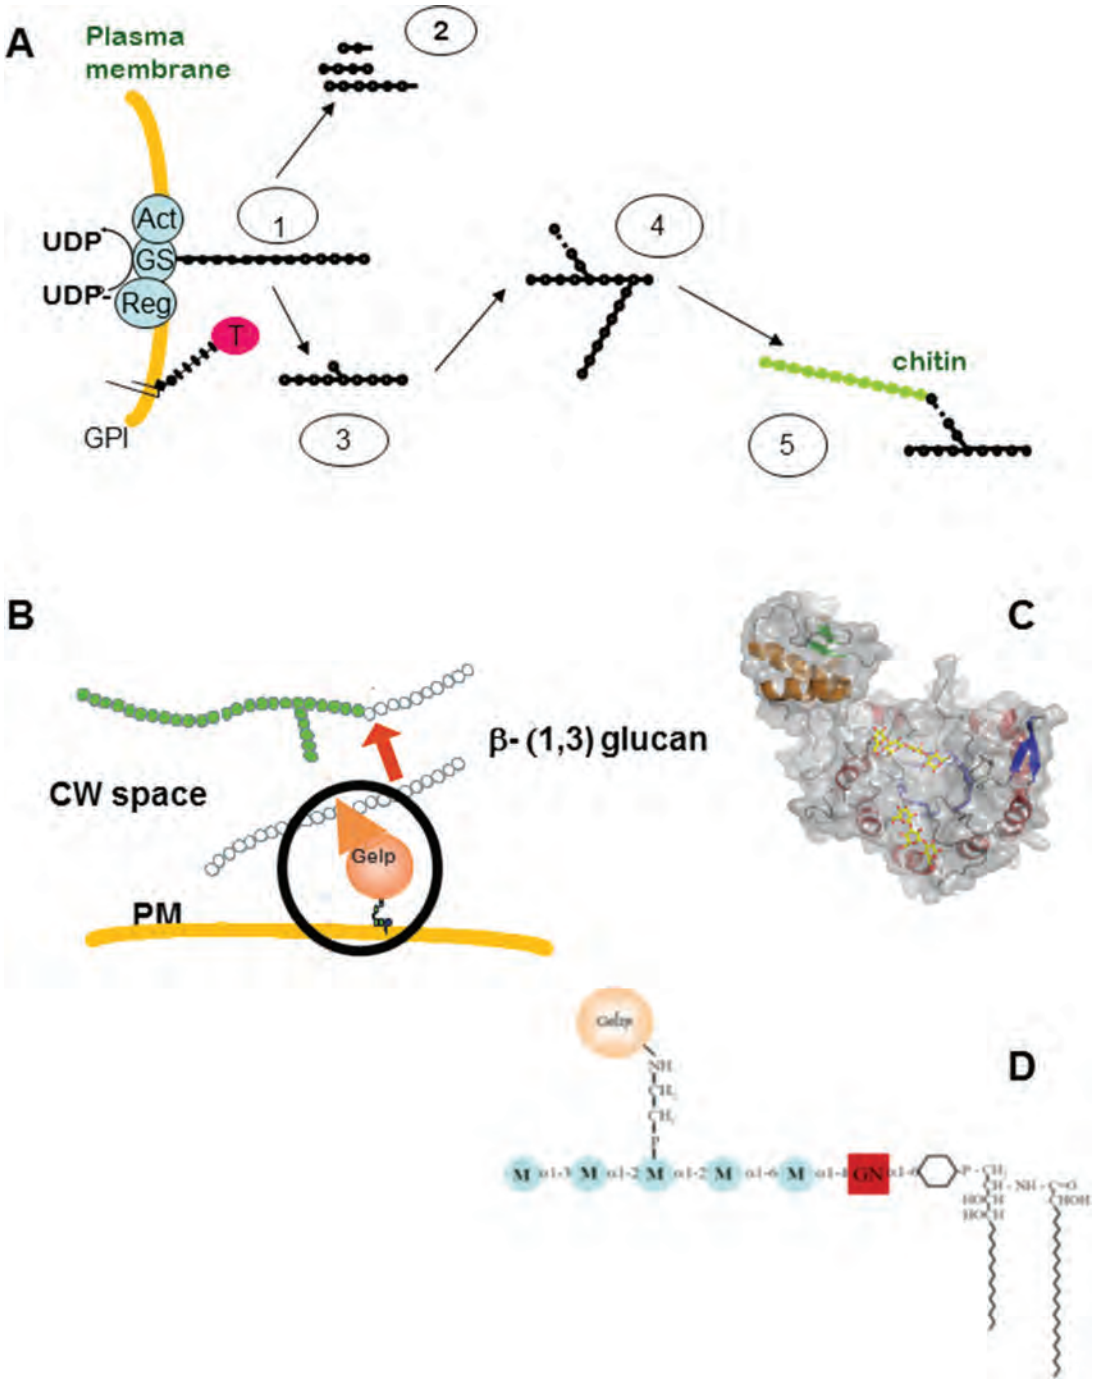

Figure 2 Synthesis and remodeling of β-(1,3) glucan. (**A**) Putative sequential or concomitant events in the synthesis and remodeling of β-(1,3) glucan. 1. Synthesis of linear glucan chains (glucan synthase complex composed of a catalytic [GS], activating [Act], and regulating [Reg] subunits). 2. Hydrolysis of glucans. 3. Branching of β-(1,3) glucan. 4. Elongation of β-(1,3) glucan side chains. 5. Cross-linking with branched [β-(1,3)] glucan. GPI-anchored transglycosidase or hydrolases (T) bound to the membrane can act on the polysaccharides in the cell wall space. Panel A provides example. (**B**) An example of GPI-anchored Gel1 protein involved in the elongation of β-(1,3) glucan inside the cell wall space. (**C**) Crystal structure of the *S. cerevisiae* Gel1 orthologue, Gas2 complex with acceptor and donor oligosaccharides. The enzyme is shown as a ribbon, the glucan binding domain with green strands and orange helices, and the catalytic domain with blue strands and red helices. A gray transparent molecular surface is shown, revealing an elongated groove on the catalytic domain, in which the laminarioligosaccharides (shown as sticks, with yellow carbon atoms) bind. (**D**) Biochemical organization of a GPI-anchored protein in *A. fumigatus*. The three domains of the GPI anchor are (i) a phosphoethanolamine linker covalently bound to the protein, (ii) a mannan-glucosamine-myo-inositol oligosaccharide, and (iii) a ceramide tail attaching the GPI anchor to the cell membrane. (Data from reference 86).

first has reduced chitin content but normal chitin synthase activity *in vitro*, whereas the second is affected in enzyme activity but has regular cell wall chitin content. In addition, other genes, named *CHS*, are not associated with chitin synthase activity but are involved in the regulation of chitin synthase activity or localization. Some chitin synthases appear to be zymogens that are activated by proteolysis, and there is also evidence that some chitin synthase enzymes are regulated by phosphorylation (40, 41). Some fungi have more than 20 *CHS* genes, and some have only 1 (42). *A. fumigatus* and *C. neoformans* are both predicted to have eight *CHS* genes, and *Wangiella dermatitidis* has five; all of these *CHS* genes are nonessential, although the *chs3* mutant of *C. neoformans* cannot grow at 37°C. In contrast, *C. albicans* has a *CHS* family of four genes, and the class II *CHS1* is essential for cell viability (43). In *Aspergillus* species, some double chitin synthase mutants are lethal, but most single mutants are viable (39).

The class V and class VII chitin synthase enzymes of filamentous fungi have unconventional myosin-motor-like domains (MMD) (44). These enzymes are often essential for growth, morphogenesis, and virulence, as well as stress tolerance. It is likely that the MMD functions in actin-mediated cytoplasmic transport, and there is evidence for this domain's ability to bind actin and to influence apical localization (45). However, this domain is not required for cellular motility in *Aspergillus nidulans* and *Ustilago maydis*, and (46) instead the MMD may function in tethering vesicles in the apical dome, increasing the residence time at that location, and thereby favoring vesicle fusion with the PM (47).

β-(1,3) Glucan, the other major cell wall polysaccharide, is synthesized by a PM-bound glucan synthase complex which uses UDP-glucose as a substrate and extrudes linear β-(1,3) glucan chains through the membrane into the cell wall, where it can act as a substrate for various transglycosidase enzymes (see below) (48). The protein complex contains at least two proteins: (i) the putative catalytic subunit encoded by the gene(s) *FKS*/*GSC* and (ii) a regulatory subunit encoded by *RHO1* with an M_r of ~20 kDa. The Fks/Gsc subunits are the target of the echinocandin family of antifungal drugs and the recently described plant metabolite poacic acid (49, 50). Fks subunits have an M_r of >200 kDa with up to 16 transmembrane helices and a central hydrophilic domain of about 580 amino acids, which displays a remarkable degree of identity (>80%) with all known Fks proteins (48). Two external loops of Fks contain so-called hot-spot regions: sites in which common mutations confer reduced sensitivity to echinocandins (51). Rho1-GTPase is regulated by switching between a GDP-bound inactive state to a GTP-bound active state with accompanying conformational changes (1). There are fewer glucan synthase genes than chitin synthase genes in pathogenic fungi. In *A. fumigatus* and *C. neoformans*, *FKS1* is unique and essential (52). In *C. albicans*, three *FKS* orthologues have been identified, but only one of them, *orf19.2929*, is associated with echinocandin resistance (53).

Recently, it was shown in *U. maydis* that the class VII chitin synthase Mcs1 and the class V chitin synthase 6 (Chs6) can be cotransported on the same secretory vesicle along with the β-(1,3) glucan synthase Gsc1 (Fig. 3) (45). Moreover, the cocomplex of glucan and chitin synthases seems to be retained at a localized spot of exocytosis and wall synthesis by the tethering effect of the synthases to their nascent polysaccharides that reside within the fabric of the external cell wall (45).

Biosynthesis of Mannan and Other Decorating Polysaccharides

The yeasts *S. cerevisiae* and *C. albicans* have an outer layer of proteins that are highly glycosylated with α and β-linked oligomannosyl residues by mannosyltransferases that use GDP-mannose as a substrate. *N*-glycans are the major form of mannoprotein modification and consist of a core structure, which is similar in all eukaryotes and is further elaborated in the Golgi to form an outer chain comprising a linear α-(1,6) mannan backbone that is highly branched with α-(1,2)- and α-(1,3)-containing side chains (54, 55). In some species these may be further modified with mannosyl phosphate that may contain β-(1,2) mannan. *O*-Linked mannans of fungi tend to be short, linear chains composed of α-linked mannose sugars. In *A. fumigatus* and other molds, long mannan chains are also bound to core polysaccharides (9), and mannosyl groups also form part of GPI anchors. Although the mannan structural organization of fungi can differ substantially, a comparative genomic study has indicated that orthologues of most yeast mannosyltransferase genes can be found in the genome of *A. fumigatus* and other filamentous molds, although other branched chain mannans do not seem to be represented in the genome of *Pneumocystis* and possibly other fungi (56). In *A. fumigatus*, deletion of 11 genes coding for putative mannosyltransferases had little effect on the growth or physiology of *A. fumigatus* (57).

The synthesis of other decorating polymers remains less well understood. For example, in the case of α-(1,3) glucan synthesis, only the genes encoding putative α-(1,3) glucan synthases have been identified (13, 58). They are the largest known genes (~8 kb) involved in

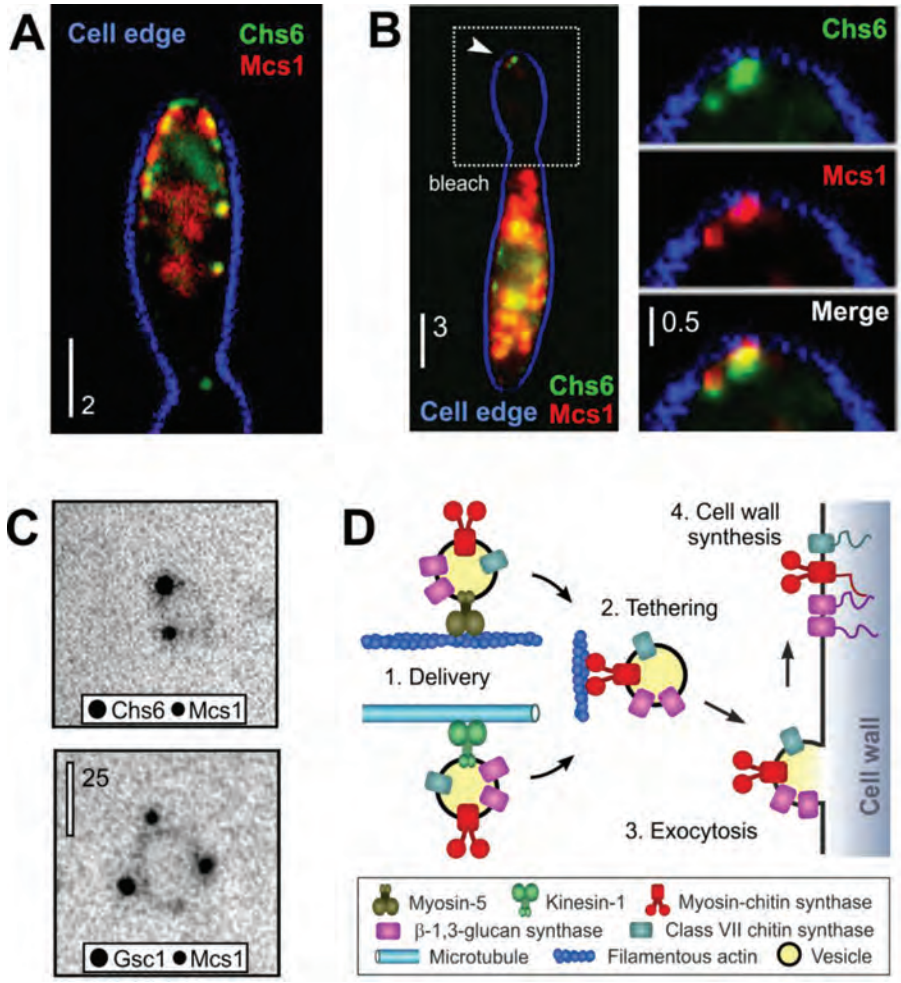

Figure 3 Glucan synthase (Gsc1), chitin synthase (Chs6), and myosin chitin synthase (Mcs1) of *U. maydis* are codelivered on the same secretory vesicles and colocalize at bud and hypha tips. (**A**) mCherry3-Mcs1 (red) and Chs6-GFP3 (green and yellow) colocalized Mcs1 and Chs6 at the bud tip. Scale bar, 2 μm. In (**B**) the bud is photobleached with a laser, and the codelivery of mCherry3-Mcs1 (red) and Chs6-GFP3 (green) into the photobleached bud is revealed after 5 minutes. Scale bars, 3 μm (left) and 0.5 μm (right). (**C**) Electron microscopy of secretory vesicles that have been colloidal-gold-labeled with antibodies showing Chs6 and Mcs1 colocalization in a single vesicle. Scale bars: 100 nm. (**D**) A model for the delivery and secretion of vesicles containing both Chs6 and Msc1 via actin- and microtubule-based cytoplasmic transport systems to the apical cell membrane. After fusion with the apical membrane, the nascent polysaccharide chains of chitin and β-(1,3) glucan are inserted into the cell wall—a process that anchors the synthases *in situ*, ensuring coordinated synthesis and tethering at the biosynthetically active apical region of the cell. (From Schuster et al. [45], with kind permission and modification by Gero Steinberg.)

cell wall polysaccharide synthesis and are characterized by two putative hydrolase and synthase domains separated by a single transmembrane domain. Deletion of a single α-(1,3) glucan synthase gene (NcAGS-1) or multiple genes (AGS1, AGS2, and AGS3) generates defects in the conidial cell wall in *Neurospora crassa* and *A. fumigatus*, respectively (59, 60), without impacting the growth of the vegetative mycelium. Deletion of the three *AGS* genes in *A. fumigatus* also resulted in attenuation in virulence in a mouse aspergillosis model. Similarly, genes involved in β-(1,6) glucan synthesis have been identified based on the resistance of mutants to the K1 killer toxin, which kills yeast by binding to β-(1,6) glucan (61). Many of these *KRE* genes such as

KRE2, *KRE5*, *KRE6*, and *KRE9* impact glucan synthesis without being directly associated with an enzymatic activity (9, 62). Permeabilized *S. cerevisiae* cells are capable of synthesizing β-(1,6) glucan when supplied with UDP-glucose, and the amount of product was reduced in the absence of Kre5 or Kre9 (61, 63–65). Deletion of *KRE5*, *KRE6*, or *SKN1* in *C. neoformans* provided evidence that these genes are also involved in β-(1,6) glucan synthesis in this pathogen and that the mutations also affected capsule formation, chitosan levels, and retention of cell wall mannoproteins (66).

In *A. fumigatus*, the UDP-glucose 4-epimerases Uge3 and Uge5 are required for synthesis of UDP-galactopyranose. Galactofuran side chains of GM are synthesized by the sequential action of the UDP galactose mutase Ugm1 and the galactofuranosyltransferase Gfsa. More recently, a cluster of genes has been implicated in the biosynthesis of the galactosaminogalactan GAG in *A. fumigatus* (67). This cluster contains the *ADG3* gene encoding a protein with a deacetylase domain, which deacetylates GAG, giving it polycationic properties, which are required for it to adhere to the hyphal surface and for biofilm formation. GAG has been shown to be an important virulence factor of *A. fumigatus* responsible for conidial adherence to epithelial cells as well as man-made surfaces (68, 69), with anti-inflammatory effects in mice (70).

Melanin

Melanins are negatively charged hydrophobic pigments of high molecular weight that are composed of polymerized phenolic or/and indolic compounds (71, 72). Little is known about the detailed structure of melanin mainly because of the lack of suitable technologies to analyze amorphous, insoluble materials that are resistant to harsh chemical treatments. Indeed, most of the structural information about melanin comes from molecular studies deciphering the melanin metabolic pathways. Two main types of melanin are found in the fungal cell wall: the DHN-melanin of *Aspergillus* species and black fungal pathogens such as *W. dermatitidis* or *Sporothrix schenckii* and the 3,4-dihydroxyphenylalamine (DOPA)-melanin found in *C. neoformans*. Enriching growth medium with L-DOPA has even been shown to induce melanin production in *C. albicans* (73). A third form of water-soluble pyomelanin whose functional significance is less clear also exists in some fungi and bacteria.

Melanin in *C. neoformans* is synthesized by a laccase located in the outer layer of the cell wall in the presence of DOPA. A model structure has been established in which the concentric melanin layers in the wall come from irregularly shaped melanin granules. The spaces between granules would determine the size of the pores controlling the passage of different secreted molecules (74). In addition, solid-state nuclear magnetic resonance data have identified a putative covalent linkage between melanin and mannose-containing polysaccharide motifs, suggesting that melanin may be anchored to the cell wall via linkages with galactoxylomannan or mannosylated proteins. Other work also suggests associations of melanin with chitin or chitosan (73, 75).

DHN-melanin (named from one pathway intermediate 1,8-dihydroxynaphthalene) is formed from malonyl-CoA by the action of several enzymes including a polyketide synthase and several reductases and dehydratases. Deletion of the genes encoding the polyketide synthase (alb1 = pksP) of *A. fumigatus*, the initial step in the pathway, results in the production of conidia with a variety of different colors (76). In contrast to DOPA-melanin, no microstructure of cell wall-associated DHN-melanin has been obtained. Nor is it understood how the putatively intracellularly synthesized melanin crosses the cell wall barrier to become immobilized on the conidial surface. In addition, DOPA-melanins can be formed by *Aspergillus* and other black fungi (77, 78). Based on studies of plant pathogenic fungi, it can be predicted that the structural role of melanin in human fungal pathogens is to increase cell wall rigidity, enabling hyphae of black fungi such as *W. dermatitidis* to penetrate host tissues and pigmented conidia of *Aspergillus* or yeast cells of *Cryptococcus* to remain turgid when desiccated.

Cell Wall Proteins

There are multiple classes of proteins in the cell wall of fungi, whose functions are diverse and sometimes species-specific. They can serve in modifying the properties of the wall, in adherence to surfaces, and in protecting the fungus from harmful environmental elements or disguising it from phagocytes.

GPI proteins

The complement of cell wall-associated proteins and, in particular, those predicted to be GPI-anchored appear to be rapidly evolving, with a number of species-specific proteins evident (4, 79). Genome-wide analyses have been performed to predict all proteins that can be modified by the addition of a GPI anchor (80, 81). While *S. cerevisiae* is predicted to have around 66 GPI proteins, many fungal pathogens have many more, with some *Candida* species having well over 100 predicted GPI proteins (79, 80). Within this cohort in *Candida*

are a number of families, such as the Als, Iff, Epa, Sap/yapsins, and Sod proteins. These families show marked variation both in the number of members and in the case of the Als and Iff families in the number of intragenic tandem repeats within family members between and within different species (80–82). Furthermore, many predicted GPI proteins are species-specific, with no known orthologues (80). Whether the diversity among the surface proteins has consequences in terms of relative pathogenicity of the different species remains to be firmly elucidated, because many species-specific GPI proteins have unknown functions.

In *C. albicans*, many of these *CWP* genes are highly regulated at the transcriptional level. Some are regulated during yeast-to-hypha morphogenesis, during the response of *C. albicans* to various environmental changes and stresses and, presumably, *in vivo* during the establishment of *C. albicans* infections (83). Non-gel proteomics using tandem liquid chromatography-mass spectrometry/mass spectrometry is now providing a global view of the cell wall proteome. It is possible not only to detect which proteins are cell-wall-localized (82, 84) but also to quantify them (85). This approach has identified 15 to 21 cell wall proteins on the surface of *C. albicans* when grown under rich laboratory culture conditions. Altering the environmental conditions such as carbon source, iron limitation, or hypoxia has a direct effect on the cell wall proteome composition and the abundance of certain wall proteins (86–88). We still have little knowledge of cell wall protein expression, both quantitative and qualitative, during infection. Although many cell wall proteins are known to be immunogenic and hence likely to be expressed *in vivo* and to play roles in adaptive immunity, their significance in growth and pathogenesis is not known (89).

In most natural situations, the outer cell wall is impregnated with, or loosely attached to, a greasy outer layer of cell wall-associated proteins, sometimes called "moonlighting proteins." Much has been made of the apparent conundrum that these proteins are predominantly of cytoplasmic origin such as enolase, collagen, translation elongation factors, and certain heat shock proteins, which do not have a signal sequence for export across the cell membrane (86, 90, 91). Such proteins are readily removed by extraction protocols using SDS and reducing agents such as β-mercaptoethanol and dithiothreitol, which had been thought mild enough to preserve the integrity of the cell (91). However, it has been demonstrated that such treatment may partially solubilize the membrane, leading to the leakage of cytosolic contents (91). Biotinylation of cell wall proteins can also potentially permeabilize the cell membrane at moderate temperatures (91). Therefore, the likelihood is that most of these cell wall-associated proteins leak out of cells and become incorporated at the cell surface when cells are treated with reagents that semipermeabilize the cell membrane.

It is clear that the cell walls of fungi such as *C. albicans* have a significant capacity to absorb soluble proteins from the environment and that fungal surfaces are normally contaminated with cytoplasmic proteins that are picked up from the environment. Alternatively, it is possible that exosomes (secreted vesicles that transit intact through the cell wall) deliver cytoplasmic proteins to the surface, bypassing the normal secretory pathway (92). Once deposited on the cellsurface, some of these proteins can impart important properties such as the binding of plasminogen and other host proteins (93), or opsonization, and could therefore have a direct effect on the function of the cell wall. In *C. albicans*, the hydroperoxide peroxidase-like protein Tsa1p is bound specifically to hyphal cells despite being expressed at approximately equal concentrations in yeast and hyphal cells (90, 94). This suggests that different cell surfaces are differentially receptive to protein binding and that the composition of cell wall-associated proteins could vary substantially between and within species and different cell types.

Transglycosidases

While most of the cell wall biosynthetic processes occur in the Golgi and at the cell membrane, part of the biosynthesis of the fungal cell wall takes place within the wall itself. Neosynthesized polysaccharides are linear or amorphous and become cross-linked to other polysaccharides by transglycosidases that are putatively anchored to the PM or located in the cell wall space to form the rigid three-dimensional network typical of the cell wall (Fig. 2B,C). The first transglycosidase identified as contributing to cell wall organization is a GPI-anchored enzyme encoded by the genes *GEL* and *PHR* in *Aspergillus* and *Candida* and *GAS* in *Saccharomyces* that splits internally a β-(1,3) glucan molecule and transfers the newly generated reducing end to the nonreducing end of another β-(1,3) glucan molecule (95, 96) (Fig. 2B). The generation of a new β-(1,3) linkage between the acceptor and donor molecules results in the elongation of β-(1,3) glucan chains. Transglycosidases that play such an essential role in branching and cross-linking polysaccharides should be common to all fungal species. Comparative genomic and proteomic analyses of ascomycete fungal species have identified

six families of conserved, GPI proteins: Sps2, Gas/Gel, Dfg, Plb, Crh, and Yps (79, 96). The Sps2 and Dfg5 families are involved in cell wall construction, and the Crh family is involved in cross-linking β-(1,6) glucan and chitin (97–99).

Cell wall hydrolases and deacetylase plasticizing the rigid cell wall

There is clear evidence that endo β-(1,3) glucanases and chitinases participate in cytokinesis since mutations in these genes and inhibitors of these enzymes affect the separation of mother and daughter cells (100, 101). In filamentous fungi, which do not undergo cytokinesis, some models of cell wall synthesis invoke a delicate balance between cell wall synthesis and hydrolysis at the hyphal apex (102). However, there is no unequivocal evidence that cell wall hydrolases are required for tip growth, and mutants in *C. albicans* and *A. fumigatus* with single and multiple mutations in chitinase and endo β-(1,3) glucanase genes do not appear to differ in growth rate or hyphal morphogenesis (103, 104).

Similarly, in zygomycetes, ascomycetes, and basidiomycetes substantial deacetylation of chitin to chitosan occurs, creating a more flexible molecule that becomes resistant to chitinases. Chitin deacetylase genes have been identified, but in general, their role in fungal morphogenesis is not clear yet. In *C. neoformans*, disruption of all three chitin deacetylase genes (105) attenuates virulence and results in a defect in cell wall integrity. In plant pathogens, chitin deacetylation can prevent plant receptors from recognizing chitin of plant pathogens (see below).

Yapsins

The yapsins play important roles in cell wall remodeling and in maintaining a robust cell wall. They comprise a subset of the aspartyl proteinase family, and in contrast to other members that are secreted, they are tethered to the membrane and the wall via the addition of a GPI anchor. The cell wall-localized proteolytic activity of ScYps1 was shown to be pH-regulated, and it was shown that Yps1 acted as a "sheddase," releasing a number of GPI proteins from the wall—notably itself and Gas1 (106). In *C. albicans*, deletion of both the yapsin genes *SAP9* and *SAP10* resulted in reduced adherence to epithelial cells and in a reduction in epithelial damage in a reconstituted human epithelial model of oral infection (107). Similarly, *Candida glabrata* has a family of eight yapsins that have been implicated in virulence as well as in maintenance of cell wall integrity (108).

Adhesins

One vital property of the fungal cell wall that promotes virulence is adhesion to host cells and tissues. Several cell wall proteins have adhesin-like properties (86, 109). The best characterized are the *C. albicans* Als family of eight proteins (110) and the *C. glabrata* Epa family (111), both comprising GPI proteins. A more extensive family of GPI-anchored adhesin-like proteins has been identified in *C. glabrata* (112). Both the Als and Epa families have a characteristic domain organization with N-terminal adhesin domains that impart specificity of host protein/glycan binding to different family members (113–116). The *C. albicans* hyphal-specific cell wall protein Hwp1 aids adherence to oral epithelial cells by acting as a substrate for host transglutaminases (117). Both Hwp1 and the Als family play significant roles in biofilm formation, and complementary binding between these adhesin types enhances the attachment of *C. albicans* cells to each other during biofilm generation (118). Interestingly, in pathogenic molds, proteins do not seem to act as adhesins, and this role seems to be a function of cell wall α-(1,3) glucans and GAG (67, 69).

In *C. albicans*, a number of other cell wall proteins have also been shown to contribute to biofilm formation, including Eap1 (119), Sun41 (120–122), and members of a family that contains a CFEM-like domain (Rbt5, Pga10/Rbt51 and Csa1/Wap1) (123).

Hydrophobins

Hydrophobins form a class of amphipathic proteins that can self-assemble to form rodlets, generating a hydrophobic interface between filamentous fungi and their environments (124). The rodlets resemble amyloid fibrils and form a monolayer around aerial structures such as hyphae and fruiting bodies, coating hydrophilic surfaces to make them hydrophobic (18, 19). Hydrophobins play roles in morphogenesis, may be developmentally regulated (125), and are also involved in adhesion of fungal cells to surfaces and hence have been associated with virulence of fungal plant and insect pathogens (126–128). In human pathogens only RodA and RodB, the hydrophobins present on the *A. fumigatus* conidial surface, have been characterized in detail (19). RodA contributes to pathogenesis by protecting conidia from alveolar macrophage killing (20). This rodlet layer has also been shown to be an immune-shield masking the detection of conidia or a range of molds by macrophages and dendritic cells (21). Detection only occurs once the spores swell and germinate—a process that leads to cracking of the hydrophobin layer and hence revealing of the underlying immunologically active glucans.

REGULATION AND SIGNALING

The Cell Wall Salvage Response

The cell wall can be built in different ways depending on environmental conditions and exposure of agents that induce cell wall damage. The integrity of the β-(1,3) glucan-chitin cell wall scaffold must be monitored and regulated constantly to enable growing walls to remain plastic enough to allow turgor-driven cell expansion yet robust enough to prevent bursting of the cell. It is not fully understood how this delicate balance between the rigidity and the compliance of the cell wall is maintained, but it is known that the nascent cell wall at the hyphal apex is thinner, has less hydrogen bonding between the antiparallel α-chitin chains, and has fewer cross-links between chitin and β-(1,3) glucan than the mature wall of the parallel sides of the hypha (102).

Regulation of cell wall biosynthesis occurs at many levels ranging from availability of substrate for biosynthetic enzymes to protein phosphorylation. A number of signaling pathways have been implicated in the regulation of cell wall biosynthesis and in the maintenance of a robust wall (Fig. 4). The pathways often impinge on different elements of the same promoter, allowing fine-tuning of gene expression.

The key pathway that controls cellular integrity via maintenance of the cell wall is the protein kinase C pathway (129) (Fig. 4). Best characterized in *S. cerevisiae*, this pathway is conserved in most fungal species, including human pathogens (130). Highly glycosylated integral membrane sensors, Mid2, Wsc family, and Mtl1, sense perturbations in the cell wall, and ScWsc1 has been shown to act as a nano-spring detecting wall stretching to trigger a response by activating Rho1. This GTPase relays signals to protein kinase C (Pkc1) and also regulates actin polymerization, polarized secretion, and glucan synthesis (129). Pkc1 lies at the top of a mitogen-activated protein kinase (MAPK) cascade and phosphorylates the Bck1 MAPKKK in addition to a number of other substrates, including chitin synthase (41). The signal passes down the MAPK cascade via a phosphorylation relay and ultimately activates transcription factors that regulate target gene expression.

Other pathways that play significant roles in the regulation of cell wall biosynthesis are the Ca^{2+}/calcineurin pathway; a second MAPK cascade, the HOG pathway; and the pH-sensing RIM101 pathway (131). Activation of cell wall compensatory or salvage mechanisms often results in elevated chitin levels in the cell wall and an increase in the number of GPI proteins that are covalently attached to chitin rather than β-(1,3) glucan, reflecting significant alterations to cell wall architecture (132). Transcript profiling experiments in *S. cerevisiae* in various cell wall mutant backgrounds and in cells treated with cell wall perturbing agents have identified a core set of regulatory genes including Rlm1, Crz1, SBF (Swi4/Swi6), Msn2/Msn4, Ste12, and Tec1 that are activated upon cell wall assault (133). Some orthologous genes have also been identified as upregulated in *C. albicans* in response to caspofungin (134, 135), Ca^{2+} (136), and cell wall mutations.

Activation of cell wall salvage pathways, specifically the protein kinase C pathway, is one of the responses to sublethal doses of the echinocandin antifungal drugs (137, 138). Synergism has also been shown between immunosuppressive drugs that block the Ca^{2+}/calcineurin pathway (FK506, cyclosporine A) and the echinocandins in *C. albicans*, *C. neoformans* (139), and *A. fumigatus* (140). Mutants blocked in the protein kinase C pathway, Ca^{2+}/calcineurin, and certain steps of the HOG pathway (but not Hog1) are hypersensitive to echinocandins (138, 140, 141). Echinocandin hypersensitivity has been used as a screen to identify signaling components that are involved in the response of *C. albicans* to this class of antifungal (134, 135). These screens identified a novel *C. albicans*-specific transcription factor, Cas5 (134), and Sko1, the transcription factor thought to be downstream of the Hog1 MAP kinase. Interestingly, Hog1p itself was not required for the echinocandin response via Sko1, but the Sko1-dependent activation of genes induced by caspofungin was dependent on another protein kinase, Psk1 (135).

Regulation of Septation

Redundancy exists in the strategies employed to assemble the fungal cell wall under both normal and cell wall stress conditions (Fig. 5A). This is also evident in the observation in *S. cerevisiae* that a septum can be fabricated in mutants that lack enzymes that are required to make the normal septum. A greatly thickened salvage septum can be made by the Chs3 enzyme in the absence of the ScChs2 chitin synthase that normally synthesizes the chitinous primary septum (33). In *C. albicans*, a septum can still be formed that permits cell division in a mutant that lacks both CaChs3 and CaChs1 (the orthologue of ScChs2), the normal chitin synthase machinery required for septation (138, 142) (Fig. 5B).

Three distinct types of salvage septa were identified in *C. albicans* that could be synthesized in the absence of Chs1 by different combinations of Chs2, Chs3, and Chs8 (142). An implication of this work is that all four chitin synthases in *C. albicans* can be employed for septum formation—a prediction supported by observations

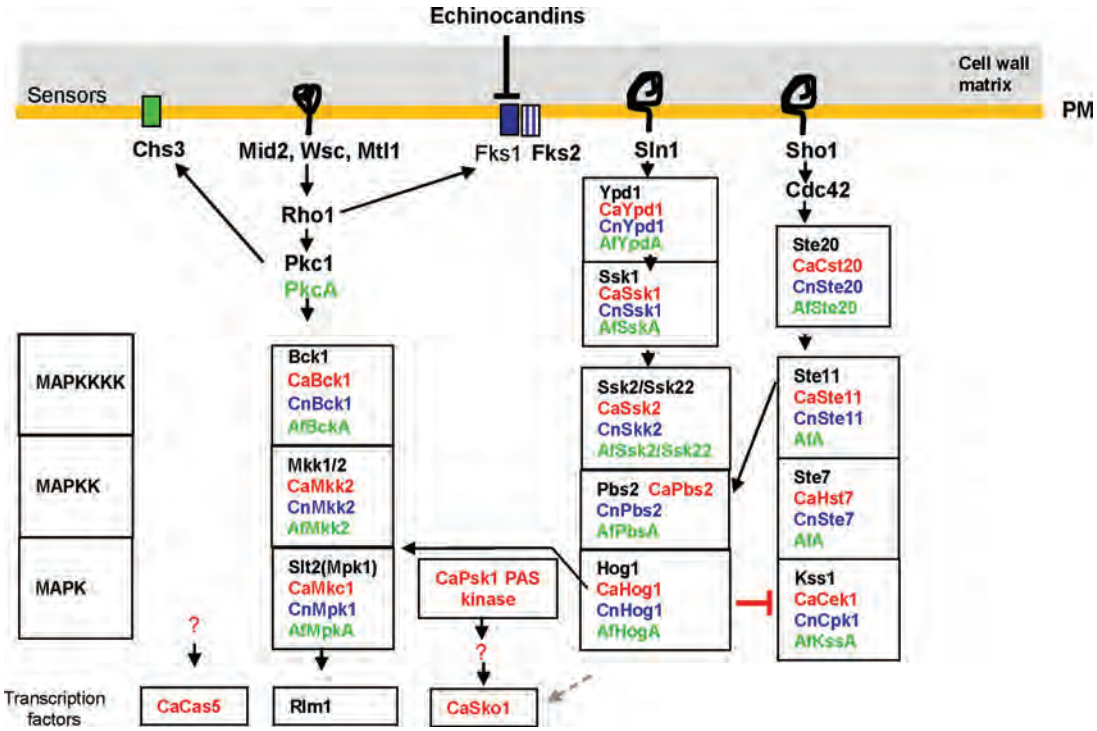

Figure 4 Signaling pathways that regulate cell wall remodeling and cell integrity. Integral, glycosylated, membrane sensors (Wsc family, Mid2, Mtl1, Sho1, and Sln1) detect specific perturbations in the wall and transduce the signal to the downstream pathway elements that feed into MAP kinase cascades. Transcription factors at the bottom of the pathway activate gene expression to promote remodeling of the cell wall architecture to maintain cell integrity. In *S. cerevisiae*, Pkc1 is involved in targeting Chs3 to the plasma membrane in response to heat shock, and Rho1 activates the Fks1 subunit of β-(1,3) glucan synthase. Black text denotes *S. cerevisiae* proteins; red, *C. albicans*; blue, *C. neoformans*; and green, *A. fumigatus*. The fungal pathogen orthologues may not have been fully characterized, and their position in the pathways reflects the *S. cerevisiae* paradigm. However, significant rewiring of signaling pathways is evident in *C. albicans*; for example, the role of the CaSko1 transcription factor in response to caspofungin is independent of the Hog1 MAP kinase (135) but involves the Psk1 PAK kinase. Furthermore, in *C. albicans*, there is no evidence of Ste11 activating Hog1 like there is in *S. cerevisiae* (213). In *C. albicans*, the Cas5 transcription factor also contributes to the transcriptional response to caspofungin, and there are no Cas5-orthologues in *S. cerevisiae* (134). The CaCek1 MAP kinase is also implicated in cell wall remodeling and is constitutively activated in a *hog1* null mutant background (213). Fungal pathogen orthologues of the elements upstream of the MAP kinase cascades are not shown but exist, although the membrane sensors appear to have significantly diverged. Exogenous calcium enters cells primarily through the Cch1/Mid1 channel complexes. A third Ca^{2+} channel, Fig1, plays a role in Ca^{2+} transport during mating, but no orthologues of Fig1 have been identified in *C. neoformans* or *A. fumigatus*. Ca^{2+} binds to and activates calmodulin (Cmd1), which in turn activates the phosphatase calcineurin, composed of a catalytic (Cna1) and a regulatory (Cnb1) subunit. *S. cerevisiae* has two Cna1 isoforms (Cna1/Cmp1 and Cna2/Cmp2). Calcineurin activates the transcription factor Crz1 by dephosphorylation to induce expression of genes that contain calcium-dependent response elements within their promoter sequences. No Crz1 orthologue has been identified in *C. neoformans*. Some data also suggest that calcineurin has regulatory functions that are independent of Crz1 (136). Several of the *A. fumigatus* proteins that may be related to this pathway remain unannotated, so putative orthologs have been ascribed but have not been experimentally validated. The pathway can be blocked via FK506 binding to Fpr1 or cylosporin A binding to cyclophilin Cpr1, and both interactions result in calcineurin inhibition. (Adapted from references 129, 130, 214–216).

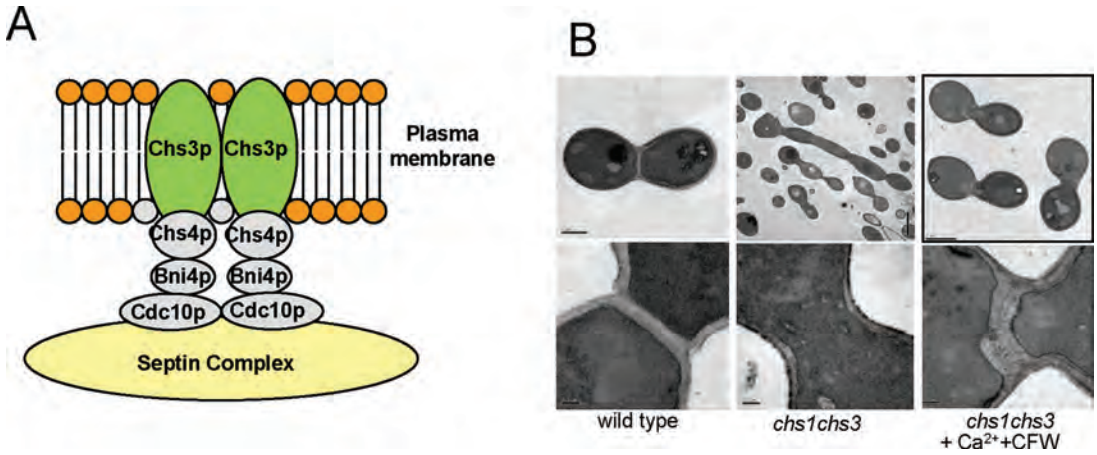

Figure 5 Chitin synthesis and septum formation in yeasts. (**A**) Septation involves a protein scaffold that tethers the Chs3p chitin synthase that assembles the chitin ring to Cdc10p of the septin ring complex via Chs4p and Bni4p. (**B**) The structure of the wild-type septum of *C. albicans* (transmission electron microscopy image on right) is shown alongside septumless yeast cells in a *chs1 chs3* conditional mutant (middle transmission electron microscopy image) and salvage septa (transmission electron microscopy image on left) made in the same mutant strain after stimulation of the cell wall salvage pathways by growth in the presence of calcium ions and calcofluor white. (Reused from reference 138 under CC BY 4.0).

that CaChs1, CaChs2, CaChs3, and CaChs8 are all located at the site of cytokinesis under normal conditions (37, 143). Similarly, all eight chitin synthases localize to the septa of *Ustilago* (143). In *S. cerevisiae*, the septum is assembled on a complex scaffold of proteins that are linked in turn to the septin rings (144) (Fig. 5A). This scaffold involves Bni4p, which tethers the Chs3 chitin synthase enzyme to the mother-bud neck by forming a bridge between a regulatory protein Chs4 and the septin Cdc10. In *C. albicans*, *BNI4* was shown not to be essential for chitin ring formation, but null mutants were affected in bud formation, suggesting that some, but not all, features of this scaffold are conserved between these two species (145). It remains to be established how the various salvage septa of fungi are constructed and how and whether they are assembled on a normal septin ring structure. Septins also play key roles in filamentous fungi. For example, they have been shown to play multiple roles in septation, conidiation, the function of clamp connections, and nuclear dynamics (146, 147).

Septation is a complex process tightly coupled to the cell cycle. The transcription factor Ace2 regulates the expression of many genes that orchestrate the process of cytokinesis. Among these are chitinases and glucanases that in some fungi have been shown to aid the septation of daughter cells by digesting the interstitium of the wall between the completed septal structures (100, 148). Fks1 localization and activation require the Rho1 GTPase as a regulatory subunit (1). Chitin synthase phosphorylation may also be involved in regulating its localization throughout the cell cycle (40, 41), but the details of how chitin synthase and other cell wall biosynthetic genes are targeted in the cell cycle remain to be established.

Regulation of Polarized Growth

Polarized cell wall growth requires the concerted activity of the cytoskeleton and cortical patches of membrane proteins that regulate secretory vesicle traffic to the sites of cell wall growth (149–152). In filamentous fungi, cytoplasmic transport must move vesicles and organelles to the apex over long distances. In hyphae this transport occurs in two stages. Vesicles are delivered to the apical surface first via cytoplasmic transport, probably mediated by microtubules, to a vesicle supply center near the apex called the Spitzenkörper (apical body). Subsequently, docking and fusion with the PM are mediated by the "Arp2/3 complex," which organizes apical actin (151), and an "exocyst complex" which is responsible for vesicle docking and fusion (152). An additional group of apical proteins called the "polarisome," which contains the essential Cdc42 Rho GTPase, is responsible for recruitment of actin and other components required for polarized cell growth. This dynamic process therefore involves the secretory pathway, cytoskeleton function, and the activities of multimeric protein complexes that establish

and maintain polarity. In filamentous fungi with chitin synthases that have an MMD, the MMD contributes to the docking process by retaining the enzymes in the apical dome (47). A detailed description of this integrated process is beyond the scope of this review but has been published elsewhere (138, 141–143). However, ultimately, the cell shape and growth of fungi relate to how the vectorial secretion of secretory vesicles is regulated and to the overall composition of the cell wall (152–155).

Most pathogenic fungi are dimorphic (sometimes polymorphic), and the prevailing morphotype existing in the environment is normally different from the invading form. Cell wall composition varies with morphotype, but data in this area are rather scarce. Universal relationships between morphology (for example, spherical or tubular) and cell wall structure and composition do not exist. In the yeast of *C. albicans* or the conidium of *A. fumigatus*, the amount of chitin is reduced in comparison to the mycelium. However, in *Blastomyces dermatitidis* or *Paracoccidioides brasiliensis*, the amount of chitin is lower in the mycelial form (156, 157) than in the yeast form. β-(1,3) Glucan is higher in yeast of *P. brasiliensis* but lower in conidia of *A. fumigatus* than in their respective mycelial stages. β-(1,3) Glucans are present in higher amounts in the conidia of *A. fumigatus* and almost absent in the yeast phase of *B. dermatitidis* and *P. brasiliensis* compared to their respective mycelial stages. β-(1,3) and β-(1,6) glucans are also absent in the biotrophic hyphae of the plant pathogen *Colletotrichum* (158). In *Sporothrix schenkii*, no difference in composition of the structural polysaccharides is seen between yeast and mycelial cell walls. For some fungi such as *C. albicans*, all morphotypes are hyaline; for others such as *A. fumigatus*, conidia are pigmented, whereas the mycelium is hyaline, and for black fungi such as *W. dermatitidis*, all morphotypes contain melanin. Links between morphology and cell wall composition are even more difficult to establish because cell wall composition is not only stage- and strain-specific but is also dependent on culture conditions (159).

CELL WALL AS A TARGET

Antifungal Target

The cell wall is composed almost exclusively of molecules that are not represented in the human body yet are important or essential for fungal growth viability or virulence. As such, the wall is a near ideal target for the design of antifungal drugs for clinical use. Nikkomycins and polyoxins are specific chitin synthase inhibitors of chitin synthases, and although they often potently inhibit enzyme activity in *in vitro* assays, they are not efficiently taken up *in vivo* and consequently are often not effective antifungals (160).

The newest class of clinically used antifungals are the echinocandins, which are fungal secondary metabolites that inhibit β-(1,3) glucan synthesis in the cell wall. Echinocandins have a cyclic hexapeptide core with a lipid side chain that is responsible for their antifungal activity and determines species specificity. Three compounds are in clinical use—caspofungin, anidulafungin, and micafungin—and new agents such as CD101 (Biafungin) are under development. These drugs have proven to be safe and effective, but they are insoluble drugs requiring intravenous administration. Clinical resistance has been shown to be due to the acquisition of point mutations in one of two hotspots in the outer face of the Fks1 β-(1,3) glucan synthase target protein, and the efficacy of the drugs can be offset by the induction of chitin synthesis in the cell wall (see above) (161, 162).

Target for Mammalian Immune System

In recent years it has been increasingly evident that there are conserved aspects in the ways both animals and plants detect and respond to fungal invaders. Indeed, defense mechanisms against fungal pathogens have been discovered in all higher organisms that have been investigated.

In humans and other mammals, the innate immune system has evolved to recognize conserved microbial structures called pathogen-associated molecular patterns (PAMPs) via a range of pattern-recognition receptors (PRRs) on their cell surfaces (Fig. 6). Detailed analyses of this recognition system for fungi have been extensively reviewed and are beyond the scope of this article (7, 163). However, recognition of the fungal cell wall ultimately results in the uptake and killing of fungal invaders by phagocytes and the induction of innate and adaptive immunity. Almost all of the main components of the fungal cell wall can be detected by immune cells, and there are more PRRs that detect fungus-specific PAMPs than for any other class of organism. Mannans and mannoproteins are recognized by mannose receptor and Toll-like receptor 4 (TLR4), phospholipomannan by TLR2, and β-mannosides by galectin-3 (163). β-(1,3) Glucan is recognized by the C-type lectin dectin-1 (163–165), and chitin can be detected by the mannose receptor and by Nod2 and TLR9 (Fig. 6). Chitin and chitosan have emerged as important immmunoreactive polysaccharides, with chitin having anti-inflammatory

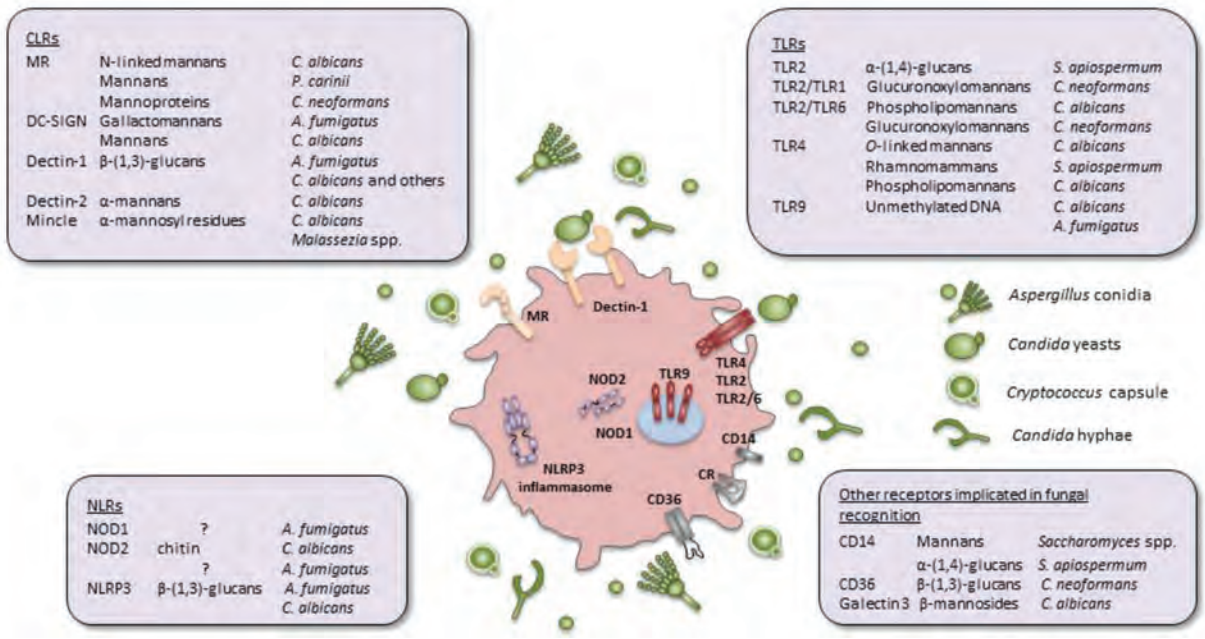

Figure 6 Recognition of human fungal pathogens. PAMP-PRR interactions for fungal cell recognition are shown as described in the text. Interactions with CLRs (C-type lectins), TLRs (Toll-like receptors), NLRs (Nod-like receptors), and a range of other receptors are shown in the purple boxes along with the relevant fungal PAMPs and examples of organisms for which given PRR-PAMP recognition phenomena have been described.

properties, while chitosan is more proinflammatory in nature (166–168). Chitin isolated from *Aspergillus* was shown to have both pro- and anti-inflammatory properties depending on the presence of costimulatory PAMPs, and IgG-opsonized chitin was shown in this study to be recognized by a novel Fcγ receptor-dependent mechanism (169). Chitin recognition is also complicated by the fact that particle size plays an important role in its ability to engage with receptors and induce the secretion of cytokines (170).

Dectin-1 detection of β-(1,3) glucan represents a major recognition mechanism by the immune system. This polysaccharide is often masked by the outer layers of the cell, resulting in shielding of β-(1,3) glucan and escape of immune recognition (7). Various unmasking treatments, such as heat-killing, echinocandin treatment, or genetic deletion of superficial mannans or glucans of several fungal pathogens, have been shown to enhance signaling of leukocytes via dectin-1 (11, 171–173). In the architecture of fungal cell walls, superficial mannoproteins, α-glucans, conidial spore hydrophobins, and melanin can all mask the exposure of β-(1,3) glucan and thereby prevent dectin-1-mediated recognition (Fig. 1) (174). Fungal cell wall PAMPs can be detected singly or in combination by PRP complex leukocytes (175), and the relative importance of individual PAMPs is likely to vary substantially in different immune cell types. It is most likely that recognition of the fungal cell wall involves detection of multiple components of the cell wall that may vary according to fungal species and during different stages and different sites of clinical infections.

Resisting immunity: *Cryptococcus* capsule

More than 40 years ago, it was shown that encapsulated cryptococci are resistant to phagocytosis (176). Capsular polysaccharides are able to scavenge oxygen-related oxidants as well as antimicrobial peptides that are essential for killing phagocyte effectors (177). However, the protective effect of the capsule varies with the phagocyte cell since a recent study shows that *C. neoformans* enters the endolysosomal compartment of dendritic cells and is killed by lysosomal components despite the presence of a capsule (178). However, it is clear that capsular polysaccharides play an essential role in escaping phagocytosis. Moreover, the enlargement of the capsule size associated with *in vivo* growth is essential for fungal survival and replication inside phagocytic cells. Recent observations have shown that *C. neoformans*, and other species of yeasts, can induce

its own expulsion from the phagosome (179, 180). After the expulsive event, both the macrophage and the expelled *C. neoformans* continue to grow normally. This mechanism, which allows the pathogen to escape the phagocyte without triggering host cell death and subsequent inflammation, is entirely dependent on the presence of the capsule since acapsular cells do not promote phagosomal extrusion.

Resisting immunity and stress: melanin

Melanins are an adaptation of fungi to resist environmental stress. Melanized fungal cells resist extreme temperature and UV and ionizing radiation; indeed, melanized fungi in soils have been shown to be able to harvest energy from ionizing radiation for growth (181, 182). Melanin also binds to heavy metals or antifungal drugs, resulting in their detoxification. Internalization by phagocytes of *C. neoformans*, *S. schenkii*, or *F. pedrosoi*, but not *Aspergillus*, can be directly affected by the presence of melanin in the cells. Melanin also protects microbes from host defense reactions since albino strains are more susceptible to killing after phagocytosis. Resistance is due to quenching of nitrogen- or oxygen-derived radicals (67) or microbiocidal peptides (67, 183). After phagocytosis, the only material left is the melanin ghost, confirming the extreme resistance of this compound not only to chemical treatments but also to immunological aggression. These data explain why melanin confers a survival advantage for the melanized morphotypes in the environment and especially to enzymatic degradation by the surrounding hostile microflora.

Target for the Plant Immune System

Plant immunology is now a well-established discipline, and it is clear that plants also recognize fungal PAMPs to trigger immunity (8, 184, 185). Plant PRRs can be located on the plant cell surface or receptor-like proteins that bind fungal and other PAMPs of damage-associated molecules.

Recognition of chitin plays a major role in plant immunity to fungi. Two major chitin PRRs have been characterized. The chitin binding protein LysM-receptor-like protein CEBiP was first identified in rice, while in *Arabidopsis*, chitin-triggered plasmodesmatal closure is induced by LysM-receptor kinase LYK4 (8, 184, 185) (Fig. 7). Plants and fungi have been engaged in an immunological arms race that mediates recognition and disguise of fungal chitin. Plant chitinase secretion can liberate chitin fragments that promote recognition. Reciprocally, some fungal pathogens synthesize α-(1,3) glucan or secrete effector molecules to block chitin recognition or chitinase-mediated attack (186, 187) (Fig. 7). Some fungi produce high-affinity chitin-binding effector scavengers that bind chitin and prevent its interaction with plant chitin receptors or block chitin-induced chitin receptor dimerization that is required for signaling. Some fungi convert chitin to chitosan to escape chitinase degradation and prevent recognition by chitin receptors of the plant immune response (Fig. 7) (188).

An excellent example comes from a study of the hemibiotrophic plant pathogen *Colletotrichum graminicola*, which infects maize. The invading biotropic hyphae of this fungus coordinately downregulates *GLS1*, *KRE5*, and *KRE6*, resulting in the formation of hyphae with little or no exposed β-(1,6) and β-(1,3) glucan (158, 188). They also induce chitin deacetylation in the hyphal walls. As a result, the fungus can colonize the plant tissue without inducing PAMP-triggered immunity.

Diagnostics and Immunotherapeutic Targets

Promising vaccines and immunotherapies are under development that are mainly based on cell wall or cell wall-associated components (189–192). Examples that have been shown to be efficacious in mouse models of systemic mycoses include *C. albicans* vaccines based on the N-terminal regions of Als1 (193) and Als3 (194), synthetic glycopeptides that are based on epitopes of cell wall-associated proteins conjugated to mannose trisaccharides (195), and anti-Mp65 antibodies (196). Vaccination of mice with recombinant versions of the allergen Aspf3 protected mice from invasive aspergillosis (197). An antibody against GXM of the *C. neoformans* capsule conveys protection in animal models and has undergone phase I clinical trials (198). An antilaminarin [anti-β-(1,3) glucan] monoclonal antibody can inhibit growth of *A. fumigatus*, *C. albicans*, and *C. neoformans*, suggesting that a single therapy of this type may be efficacious against a wide range of fungi (199–201).

Cationic antimicrobial peptides also play important roles in host defense against microbial pathogens including fungi (202) and have been shown to be important in the oral cavity, lungs, and GI tract. The action of salivary Histatin 7 is mediated through heat shock proteins Ssa1 and Ssa2 (203), which have been shown to be cell wall and membrane associated. Novel therapies based on antimicrobial peptides have much potential in the clinic and can be used, for example, to coat inanimate medical devices such as indwelling catheters to prevent microbial biofilm formation, one of the risk factors associated with invasive fungal infections (204).

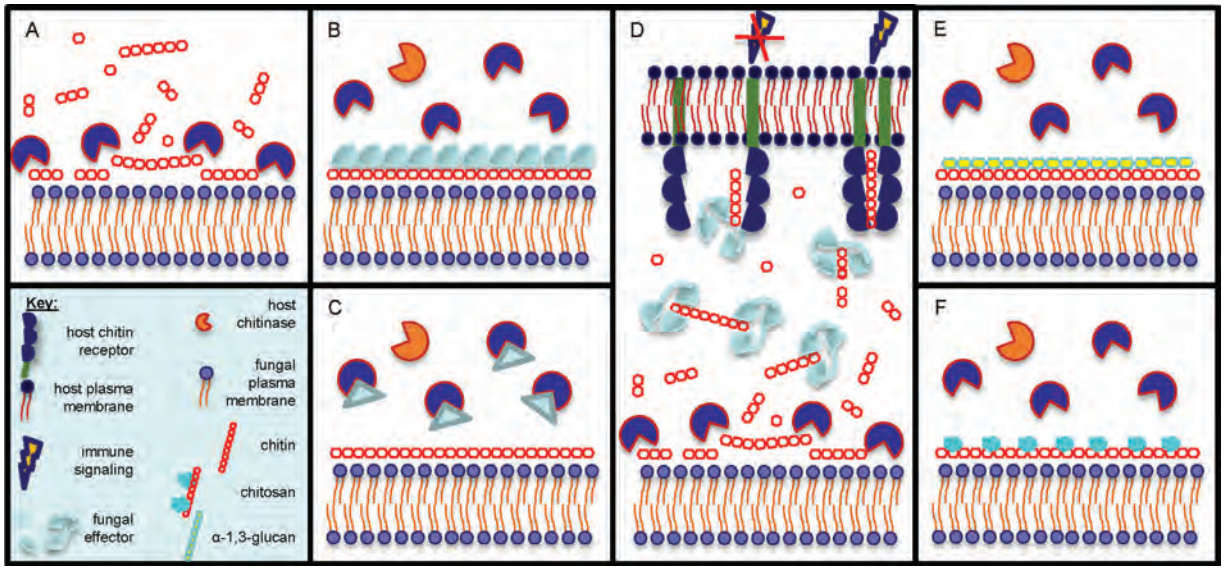

Figure 7 Recognition and avoidance of the recognition of chitin by plant pathogens. The detection of fungal chitin is used to trigger PAMP-mediated immunity in plants. To counter this, plant pathogenic fungi have evolved a range of mechanisms to avoid detection, including the following. (**A**) The liberation of chitin fragments by host chitinase attack can activate host immunity. (**B**) Countering this, some phytopathogens secrete effectors that block access to chitinase or (**C**) inhibit chitinase activity. (**D**) Fungal LysM-type effectors block recognition either by tight binding to prevent engagement with the host PRR or by interfering with host receptor dimerization. (**E**) The synthesis of an outer cell wall layer of α-(1,3) glucan (as in certain human pathogenic species) prevents chitinase action and access to inner cell wall PAMPs. (**F**) Some fungal pathogens convert, to a greater or lesser extent, chitin into chitosan by inducing chitin deacetylases. This modified form of chitin is a poor substrate for chitinase and only weakly induces plant immune recognition. (From Bart Thomma with permission [adapted from reference 186]).

Diagnostic Antigens

Cell wall polysaccharides have formed the basis of the development of serological tests for the diagnosis of systemic fungal infection since their presence in the biological fluids of infected immunocompromised patients is directly correlated to fungal growth. An increase in the circulating antigen results from expanded fungal growth synonymous with a worsening of the disease, whereas successful antifungal therapy or immune reconstitution is associated with a reduction in antigen concentration. Galactomannan, mannan, and glucuronoxylomannan are the specific cell wall polysaccharides of interest for the diagnosis of aspergillosis, candidiasis, and cryptococcosis, respectively.

A monoclonal antibody directed against galactofuranose residues is used for the diagnosis of aspergillosis (205). The sensitivity of the commercially available sandwich enzyme-linked immunosorbent assay test is very high (on the order of nanograms per milliliter). This is due to the presence of epitopes not only on the cell wall polysaccharides but also on glycoproteins and glycolipids of *Aspergillus* species. This MAb recognizes β-(1,5) linked galactofuranose residues but also terminal Gal*f* β-(1,2) linked to mannan of *N*-glycans (206).

Identifying the presence of both α- and β-mannan increases the specificity and sensitivity of candidemia diagnosis. In the case of candidiasis, parallel monitoring of circulating mannan and antimannan antibodies can be performed. A decrease in antibody titer often correlates with an increase in antigen detection (207, 208).

Polyclonal antibodies have been raised against a mixture of complex capsular polysaccharides (GXM) of *C. neoformans* to develop EIA or latex agglutination tests able to recognize all serotypes of this fungal species (209).

A test for the detection of β-(1,3) glucan has also been developed using a modification of the *Limulus* proteolytic cascade identifying a β-(1,3) glucan as an ancestral innate defense reaction undertaken by arthropods. The sensitivity of this test is very low since it can

detect 10 to 50 pg of β-(1,3) glucans/ml (210, 211). All these tests, however, have associated problems with false positives and negatives, insufficient early detection in comparison with clinical signs, and interaction with serum proteins including antibodies that require a proteolytic or EDTA treatment of the serum. In addition, the exact composition of the antigens produced *in vivo* as well as an understanding of the antigen secretion process is often unknown (62, 212).

CONCLUSIONS

The cell wall represents a major organelle of the fungus, determining viability, shape, and interactions with the environment. The assembly of the cell wall involves more than a thousand genes that encode a complex network of metabolic, signaling, and biosynthetic functions. Recent research has shown that redundant pathways exist to activate cell wall salvage mechanisms under conditions of cell wall damage and that the assembly of the wall can be modified and adapted to cope with stress. Although the walls of most fungi have a common skeleton, they also comprise a huge diversity of specialized molecules that are attached to the skeleton that define their specific ecologies. A range of mechanisms exist that ensure that the surface characteristics of the wall are hugely variable, and indeed, it is likely that no two cell walls that are identical have ever been assembled in any fungus. For fungal pathogens, the cell wall remains an ideal yet somewhat unrealized target for chemotherapy since its enzymology is fungus-specific. Similarly, the unique set of fungus-specific polysaccharides and glycoproteins that compose the outer and inner cell wall layers represent fungus-specific pattern recognition molecules and antigens that stimulate immune function of animals and plants. However, the inherent variability of the cell wall means that it is a moving target for both antifungal chemotherapy and for immune surveillance, and a raft of immune recognition avoidance mechanisms has evolved for both plant and animal pathogens that drives a "detect-or-escape" arms race between the host and pathogen.

Fungal Ecology: Principles and Mechanisms of Colonization and Competition by Saprotrophic Fungi

13

Lynne Boddy and Jennifer Hiscox

INTRODUCTION

Decomposer fungi, by their very nature, continually deplete the organic resources in which they grow and feed. They therefore rely on continual successful spread to new resources. In terrestrial ecosystems resources are distributed heterogeneously in space and time (1, 2). They are often discrete, ranging in size from small fragments, e.g., bud scales, to large tree trunks, though discrete leaves *en masse* can form a continuous layer on the forest floor. The processes of arrival and spread are thus crucial to the success of saprotrophic fungi. Following arrival at a resource, their competitive ability determines whether they are successful in colonization and how long they retain that territory. Colonization and competition are the main focus of this paper and are discussed separately below, largely drawing on wood decay fungi for illustrative examples.

In view of the large number of decomposer fungi, and the variety of organic material that is available for them potentially to feed on, it is not surprising that they have evolved a range of different life history strategies to cope with the environment they inhabit, the three major drivers being stress (S-selected), disturbance (R-selected or ruderal), incidence of competitors (C-selected), or a combination of these (3–5). Characteristics defining these life history strategies are listed in Table 1. These strategies are relative depending on the communities being considered, and they vary in different stages of the life cycle and between regions of the same mycelium exhibiting different physiological states. The wood-decaying basidiomycete *Phlebia radiata*, for example, has a rapidly extending aseptate mycelial margin, which can utilize only simple carbon sources and does not recognize antagonists (R-selected characteristics), whereas the more mature septate mycelium is able to use the lignocellulose complex and is antagonistic to other mycelia (C-selected characteristics) (6). Thus, taxa should not usually be classified *per se* as having a specific life history strategy, but their behavior in a particular context can be defined by these terms. Further, fungi often have combinations of characteristics from different strategies (R-C, R-S, C-S, or R-C-S; Fig. 1).

COLONIZATION

Arrival

Most fungi can only spread between resources by producing asexual spores, sexual spores, or sclerotia. These fungi are termed resource-unit-restricted, as opposed to non-resource-unit-restricted fungi that grow out of resources and spread as mycelium. Spores can enable rapid spread, sometimes over many kilometers (7–11), though most basidiospores, for example, land within a few meters of the basidiocarp that produced them (9, 11). Spores, however, usually contain only small food reserves, and the chance of landing on a suitable new resource with an appropriate environment for germination and growth is small if spread by wind or rain, though greater if transported by animal vectors (5, 12). Sclerotia often contain larger food reserves and allow survival in time, though spread is more limited than for most other spore types (13). Thick-walled chlamydospores also enable survival in time, e.g., the wood-decaying basidiomycetes *Botryobasidium* spp.,

School of Biosciences, Cardiff University, Cardiff CF10 3AX, United Kingdom.

Table 1 Characteristics defining the life history strategies of ruderal, combative, and stress-tolerant species

Characteristics	Ruderal (R)	Combative (C)	Stress-tolerant (S)
Characteristic features	Rapid growth; primary resource capture	Tolerance of specific stresses (e.g., temperature extremes, low water availability, extremely low or high pH, allelopathic chemicals)	Antagonistic ability against competitors
Growth rate	Rapid spore germination and growth	Sometimes slow	Not particularly slow
Enzymatic ability	Relatively narrow ability	Wide ability	Wide ability
Substrates utilized	Easily assimilable	More recalcitrant	More recalcitrant
Timing of reproduction	Early in life cycle	Later in life cycle, sometimes sporadic	Later in life cycle, sometimes sporadic
Commitment of biomass to reproduction	Rapid and substantial	Relatively low	Relatively low
Persistence within the resource	Low; easily replaced	Persistent while specific stress remains	Persistence depends on ability to capture and defend territory

Hyphodontia paradoxa, *Piptoporus quercinus*, and *Trechispora* spp., allowing them to survive severe abiotic stress, e.g., desiccation (see 5 and references therein).

Though the inoculum potential of an individual spore is small, it can be considerably increased if genetically identical spores, e.g., conidia, germinate close to one another. Germ tubes home in on each other and fuse to form a network (14). In contrast, when spores are genetically different, and hence somatically incompatible, competition is likely to result (15). When basidiospores germinate, the mycelia that develop are usually homokaryotic. It is generally thought that this homokaryotic stage is short-lived and that mycelia soon (within hours or days of germination) encounter a suitable conspecific and, following a successful mating, become heterokaryotic. However, even common fungi such as *Trametes versicolor* and *Heterobasidion annosum* can sometimes remain homokaryotic for several years (11, 15–17), and rare species, e.g., *Hericium* spp., might be expected to remain homokaryotic for much longer (18). Homokaryotic and heterokaryotic mycelia do not necessarily behave the same in terms of growth rate, decay ability, competitive ability, etc., though there does not seem to be a general trend where one is better (has higher "fitness") than the other (19 and references therein).

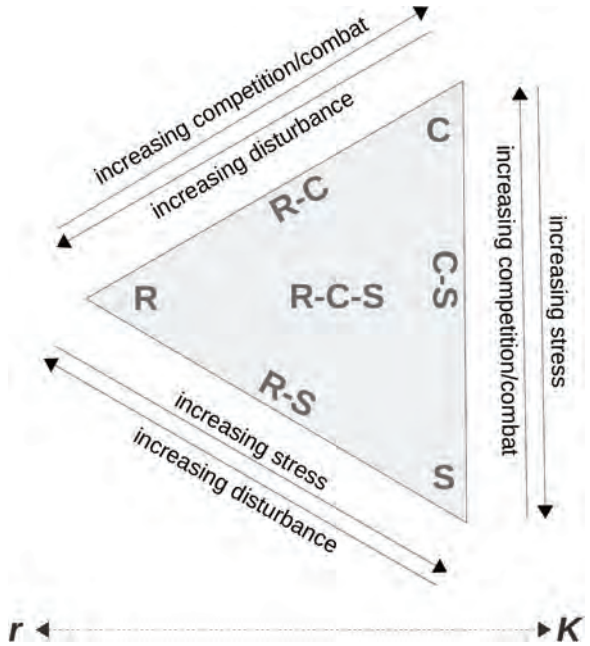

Figure 1 How R-C-S characteristics relate to r-K strategies.

In contrast to arrival as spores, arriving as mycelium allows the fungus to draw upon a much larger supply of nutrients (20). Mycelial spread can be as individual hyphae, albeit sometimes forming dense mycelia or fronts, or as hyphae aggregated to form linear organs—mycelial cords and rhizomorphs (2, 21, 22). Some leaf litter decay fungi can form large patches, e.g., *Collybia* spp. and *Marasmius* spp., or "fairy rings," e.g., *Clitocybe nebularis* (20, 23). These patch formers colonize individual fallen leaves but spread by mycelial growth from one leaf to another as if the litter layer was one large continuous resource. In contrast to mycelial patches, which exhibit no particular pattern, fairy rings comprise a 30- to 40-cm-wide annulus of mycelium which is highly polar, growing outward from an initial site of establishment, with death of older mycelium forming a central zone devoid of the fairy ring former (20, 23).

The mycelial systems of fungi that produce linear organs of aggregated hyphae are unique. The structure of the linear organs covers a spectrum of complexity, from simple loose aggregations through to hyphae that

are highly aggregated to form cords; e.g., *Hypholoma fasciculare*, *Megacollybia platyphylla*, *Phallus impudicus*, and *Phanerochaete velutina* form cords with a thick outer rind that are differentiated internally, in contrast to the thick-walled melanized rhizomorphs of *Armillaria* spp. (21, 22, 24, 25). Rhizomorphs grow from the tip, whereas cords tend to form behind an actively growing front of individual hyphae. When mycelia grow out from a resource, they exhibit different branching patterns which vary between species and depend on many biotic and abiotic factors including size, quality and states of decay of the resource, soil type, microclimatic environment, antagonistic fungi and other microbes, and grazing invertebrates (12, 20, 26, 27). Some can be considered short-range foragers, with highly dense hyphae and mycelia, yielding a mass fractal dimension close to 2 in two dimensions, e.g., *H. fasciculare* (27) (Fig. 2A). They are likely to be successful in encountering small organic food resources. Others are longer-range foragers with more open systems and a lower mycelial mass fractal dimension, e.g., *P. velutina* and *Resinicium bicolor* (Fig. 2B,C). Even longer-range foragers have a mass fractal dimension of close to 1, e.g., rhizomorphs of *Armillaria* spp. (27).

When mycelia of cord-forming species encounter new resources, they are able to exert considerable "inoculum potential" for colonization, being able to draw on nutrient reserves from the mycelial network, which gives them considerable advantage over spores. If colonization of the newly encountered resource is successful, there is often reallocation of mycelial biomass, with thickening of cords interconnecting the original and new resource, and regression of nonconnecting mycelium (2). Thus, a network of cords interconnecting woody resources develops on the forest floor and can operate a sit-and-wait strategy, colonizing wood when it falls onto the network, as well as an active-search strategy (12). These networks can be extensive, though dynamic, covering many square meters or even hectares; networks of rhizomorphs of *Armillaria* spp. constitute one of the largest organisms on the planet (20, 28–32). While in temperate and boreal forests such mycelial networks are confined to the forest floor, in tropical forests similar networks are found both on the floor and in the canopy (33), in the latter case catching small leaf litter and wood components before they reach the forest floor.

Entry and Establishment

Plant tissues that have recently died are usually colonized initially by endophytic fungi already present and/or by prolifically sporing R-selected species which happened to arrive first (34, 35); thus, at early stages the absence of species commonly considered to be later colonizers reflects arrival time rather than an inability to colonize newly available plant tissues. On the forest floor, arrival by mycelium can, however, sometimes happen early on if the resource is located on or close to an active mycelia patch or network of mycelial cords.

Entry and establishment in an uncolonized dead organic resource, be it following arrival as spores or mycelium, depend largely on the enzymatic ability of the fungus. If the fungus has the enzymatic capacity to use compounds available within the resource, it will colonize, establish, and remain present until it (i) is ousted by another species, (ii) is inhibited or killed by adverse abiotic conditions, (iii) uses up the food supply, or (iv) is triggered to fruit or grow out of the resource

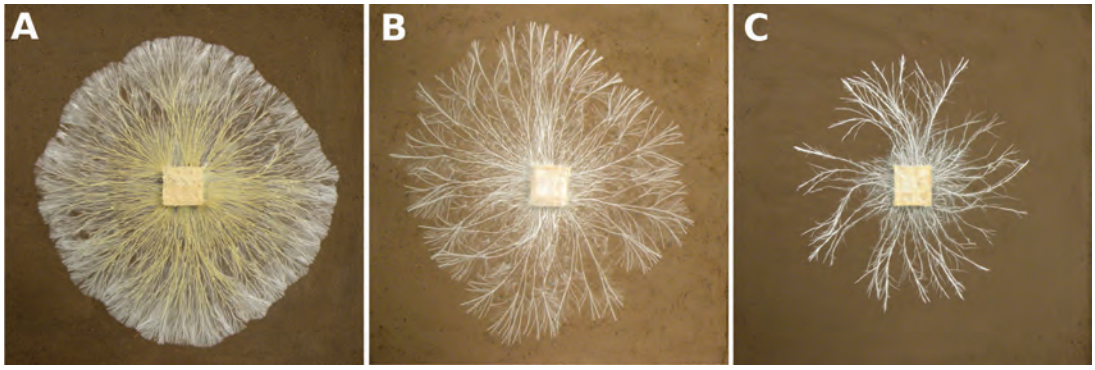

Figure 2 Foraging strategies of cord-forming basidiomycetes growing out of precolonized beech wood blocks across compacted soil. (**A**) *Hypholoma fasciculare*, a short-range forager, produces highly dense hyphae and mycelia. (**B**) *Phanerochaete velutina* is a longer-range forager with a more open cord system. (**C**) *Resinicium bicolor* has an even more open system than *P. velutina*, with thicker cords.

in search of others. If the fungus exits the resource by fruiting, it may or may not commit all of its mycelial biomass to reproduction, depending on its life strategy (see above). Timing of production of reproductive structures also depends on life strategy, ruderal (R-selected) species committing themselves rapidly and prolifically to reproduction and others (C- or S-selected) tending to reproduce later in life and not usually committing all of their mycelial biomass to reproduction (Table 1). Fungi that are able to exit by mycelial spread (those with C- and S-selected characteristics) do so at different times following colonization, with the exact timing varying depending on the species, other biotic and abiotic factors, and on the relative size/nutrient status of the resource compared with other resources in the network (2).

During colonization simple compounds are typically used first followed by more recalcitrant cellulose, hemicellulose, and lignin. Colonization of the nonlignified tissues is relatively easy for mycelia, but woody tissues are more challenging. In wood, most rapid spread is usually along vascular tissues; tangential and radial spread necessitates boring through lignocellulose in the cell walls (35). Plant anatomy often results in the characteristic longitudinally extensive decay columns seen in wood (Fig. 3).

Community Development

Communities that develop initially depend on the environmental conditions when the resource becomes available for colonization, ranging between low environmental stress, where fungi with R-selected characteristics dominate initially, to high stress, e.g., due to extreme abiotic variables, where species that dominate have appropriate S-selected characteristics often combined with some R-selected characteristics (3, 5) (Fig. 4). High-stress conditions include heartwood of trees containing allelopathic compounds; extreme temperature of hot deserts and Arctic, Antarctic, and alpine tundra; and the desiccating conditions of tree canopies. Though some of the initial fungal colonizers have the enzymatic ability to completely break down the resource that they are colonizing, most are usually replaced sooner or later by other species when abiotic conditions worsen (stress aggravation) or improve (stress alleviation), when the habitat is disturbed, or when competition/combat (see next section) with other fungi ensues (Fig. 1). Changes to the abiotic conditions occur due to changes in microclimate but are also brought about by fungi altering the physical and chemical environment as they metabolize the resource they are colonizing (see next section). Disturbance occurs when resources are suddenly made available (enrichment

Figure 3 Sectioned beech trunk showing decay columns running longitudinally through the wood. Arrows indicate dark zone lines (pseudosclerotial plates) surrounding different decay columns.

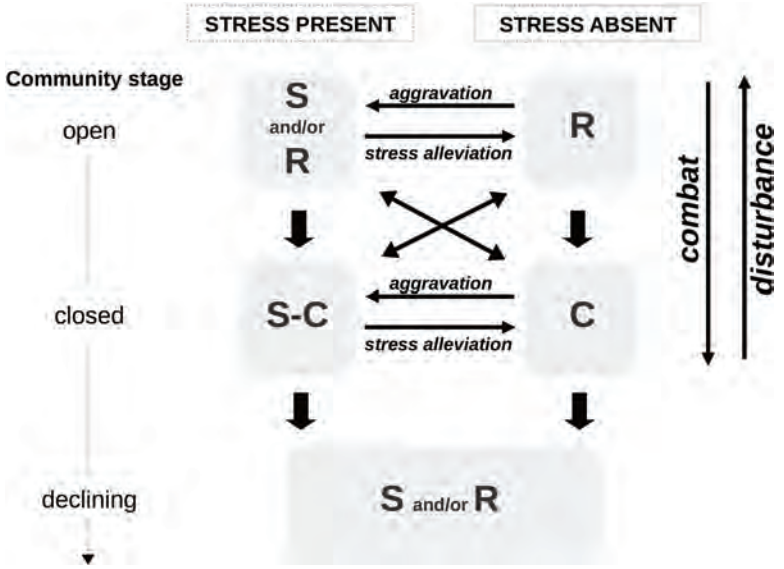

Figure 4 Fungal community development pathways in woody resources. Newly available wood (top) becomes progressively colonized, initially through primary resource capture in an open community stage where there is still unoccupied territory, until all territory becomes occupied, resulting in a closed community where further colonization occurs as secondary resource capture. As the community moves from open to closed, combat becomes the driving force for change. Finally, communities in well-decayed wood are characterized by substrate modification and invasion by soil invertebrates. The ecological characteristics of the dominant organisms are indicated in boxes: R, ruderal; C, combative; S, stress-tolerant. Driving forces are indicated in italic, and direction of community change is indicated by arrows. The community may be driven toward the left by stress aggravation or to the right by stress alleviation, although destructive disturbance will drive the community toward species with R-selected characteristics. (Adapted from references 5 and 58.)

disturbance) or when part or all of the resident mycobiota is destroyed, e.g., following fire. Competition/combat occurs when the expanding territory of fungi in freshly available resources overlaps and when new colonizers arrive at a resource via spores or mycelial spread.

Thus, communities of primary, secondary, and late secondary (or tertiary) colonizers develop. Community development is not a simple ordered sequence, but a complex ever-changing mosaic. The general order of colonizing species—succession—has been determined in many types of organic substrata, but three-dimensional structure has been mostly studied in decaying wood, because the mosaic of different individual fungi is clear to see at all but the earliest and latest stages of community development (Fig. 5A). Since organic substrata are opaque, they have to be destructively sectioned to reveal the individual decay columns. The patterns revealed can be mapped, isolations can be made onto agar media and subsequently identified, or DNA can be directly extracted from wood and the three-dimensional community can be determined (Fig. 3, Fig. 5A). Isolation onto agar has the benefit that isolates of the same species can be paired to determine, in the case of basidiomycetes, whether the isolates are the same genotype/individual based on somatic incompatibility (11, 36). The same can be done with ascomycetes, but different individuals/genotypes can sometimes belong to the same vegetative compatibility group (36, 37), so the situation is not so clear-cut. Experimental pairings can also be made between different species to give indications of relative combative ability, which can aid in understanding of community development pathways.

Sectioning is destructive, so patterns of community development cannot be followed in an individual organic substratum, but rather must be inferred by analyzing many units at different stages of decay. Extracting DNA samples from substrata, e.g., by collecting sawdust from holes drilled into wood, can reveal species composition (e.g., reference 38). Such samples could be extracted at different times to reveal a temporal sequence of colonization, but sampling may alter abiotic conditions in the resource and/or allow different fungi to colonize. The presence of fruit bodies provides a vague idea of the fungi present and has been used to

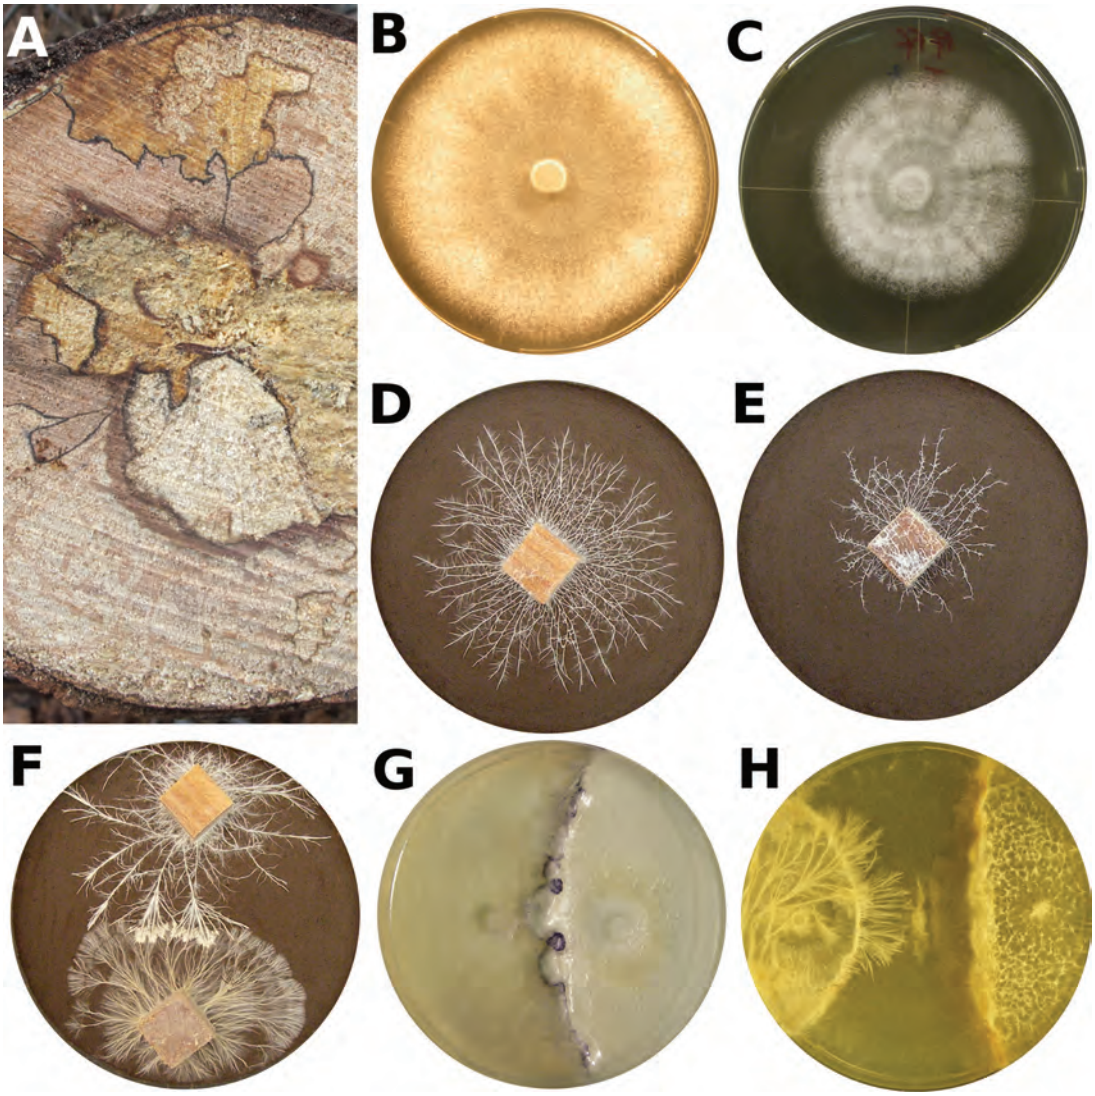

Figure 5 Interspecific interactions of fungi growing in natural and artificial media. (**A**) Cross section of a decaying beech branch with dark zone lines (pseudosclerotial plates) surrounding competing mycelia. (**B, C**) Growth of *Trametes versicolor* when exposed to the diffusible organic compounds (DOCs) from uncolonized malt broth (control) (**B**) or DOCs from *Fomes fomentarius* (**C**). (**D, E**) *Phallus impudicus* cord systems growing across compacted soil when exposed to volatile organic compounds (VOCs) from uncolonized soil (control) (**D**) or VOCs from *Hypholoma fasciculare* growing across soil (**E**). (**F**) Interaction between *H. fasciculare* and *Resinicium bicolor* cord systems across compacted soil. (**G**) Accumulation of reactive oxygen species (ROS) at the interaction zone between *Bjerkandera adusta* (left) and *T. versicolor* (left) on 2% malt agar (MA). ROS are stained purple using nitro blue tetrazolium (methods in reference 92). (**H**) Three-way interaction between mycelia of *H. fasciculare* (left), *P. velutina* (center), and *Stereum hirsutum* (right) growing on 2% malt agar (MA). *H. fasciculare* cords are beginning to encroach over the *P. velutina* mycelium, while *H. fasciculare* itself is overgrown by *P. velutina* cords. A thick barrage separates the mycelia of *S. hirsutum* and *P. velutina*, with a distinct orange/yellow band of pigment deposited in the agar at the regions of contact between the two mycelia.

infer colonization sequence. Sequences of fruit bodies occurring on dung provide an early cautionary tale (see reference 39). The order in which fruit bodies appear and disappear is largely related to their simplicity: mucorales, e.g., *Mucor*, *Pilaria*, and *Pilobolus* spp., are usually visible within a few days, declining after a week; after 5 to 6 days fruit bodies of discomycetes, e.g., *Ascobolus* and *Coproboia* spp., are evident; these are joined fruiting after 9 to 10 days by pyrenomycetes and loculoascomycetes, e.g. *Sordaria* and *Podospora* spp.; finally, basidiomycetes, e.g., *Coprinus*, *Stropharia*, and *Paneolus* spp., fruit. The fungi are, however, often already present in the dung when it is deposited or have colonized very early. Some species have evolved adaptations to passage through the gut and may even be able to germinate and grow while still within the near-anaerobic conditions of herbivore rumens. *Sporormiella minima*, for example, begins to grow before sheep dung is deposited, allowing it to colonize and fruit much more quickly than other species with similarly complex fruit bodies (40).

In wood, the order of fruit body appearance depends, to some extent, on the order within succession, but also on the ecological strategy, with fungi with S- and C-selected characteristics tending to fruit sporadically and much later in their life cycles. However, fruit bodies of some species repeatedly and sometimes almost exclusively follow those of other specific species (41–44). For example, *Antrodiella hoehnelii* almost always fruits following *Inonotus nodulosus* and *Inonotus radiatus*, while *Hericium coralloides* fruits following *Inonotus obliquus, Inonotus cuticularis*, or *Fomes fomentarius* on angiosperm wood in central Europe and Scandinavia (41, 43). This has led to the idea of predecessor-successor relationships and priority effects.

The order in which species arrive at a resource, i.e., the assembly history, affects the composition and development of the community which follows. When earlier colonizing species affect the colonization success of species that arrive later, whether as spores or mycelium, they are described as exerting priority effects (45, 46). Such effects can be stimulatory or inhibitory. Wood decay fungi again provide good examples: they change the resource they occupy both chemically and physically by utilizing different components of the wood cell wall, making nutrients available and altering wood chemistry, pH, and water content. This can prevent some species from capturing territory, acting as a sort of constitutive defense (35), or can select for certain species that prefer the altered environment (44, 47–50). The presence of a certain species can make a resource easier to colonize by specific fungi; for example, wood colonized by *Trametes* spp. may be more attractive to *Lenzites betulina* than is other wood, since the latter is temporarily mycoparasitic (see next section) on the former and can gain easy access via the mycelium of its host (51). Once *L. betulina* has taken over the territory occupied by *Trametes* spp., it switches strategy and exhibits interference competition to defend and gain territory from other fungi (see next section for mechanisms involved in interference competition). Similarly, *Trametes gibbosa* is temporarily mycoparasitic on *Bjerkandera adusta* (51). Priority effects are common in the development of wood decay communities (e.g., references 45, 46, 49, 52–55), although they may be less evident in the later stages of decay (56).

COMPETITION

Competition is the negative effect that one organism has on another by using up, or inhibiting access to, a resource of limited availability (57). When one organism inhibits the other and limits access to resources, it is termed interference competition, whereas when one organism depletes a resource, consequently reducing its availability, it is termed exploitation competition (57). The sequestration of nutrients by mycelia growing through soil, hence preventing other fungi from using them, is an example of exploitation competition. However, when saprotrophic basidiomycetes and xylariacious ascomycetes are growing in and feeding on solid organic resources, e.g., wood and leaf litter, the distinction between exploitation competition and interference competition is not clear, and they cannot sensibly be divorced from each other (58). This is because these fungi compete to obtain and defend three-dimensional territory within the organic resource; within the territory the resources can be used at the fungus' leisure. Thus, competition for nutrients is effectively brought about by competition for territory/space.

Fungal competition in organic resources is often divided into (i) primary resource capture, when a fungus colonizes and gains influence over a previously unoccupied territory/resource, and (ii) secondary resource capture, when a fungus captures territory from fungi that have already colonized a resource (3, 58). Another aspect to secondary resource capture is defense of territory from potential invaders. R-selected characteristics favor primary resource capture, whereas success in secondary resource capture depends on combative/antagonistic mechanisms (predominantly C-selected characteristics). Combative/antagonistic interactions can occur at a distance and following contact, comprising mycoparasitism and larger-scale mycelial interactions.

Antagonism at a Distance

Antagonism between fungi can occur in the absence of mycelial contact, through the production of volatile and diffusible organic compounds (VOCs and DOCs, respectively) (59). Fungi produce a wide range of these so-called secondary metabolites, spanning a variety of chemical classes, from short-chain alcohols and ketones to aromatic compounds and terpenes (60–62). Different species tend to produce a characteristic metabolite profile (63, 64), although this profile can be perturbed by growth substrate, pH, culture age, and temperature (65–67).

While DOCs have antagonistic potential in circumstances in which they can accumulate or diffuse through substrata (i.e., locally), VOCs function in much more heterogeneous environments and can act over greater distances (68, 69). Mycelia exposed to the DOCs or VOCs of a competitor exhibit altered spore germination, mycelial morphology, foraging behavior, and enzyme production (47, 67, 68, 70–72). For example, the extension rate of *T. versicolor* was reduced when grown on media containing DOCs from *F. fomentarius* cultures (Fig. 5B and C), and the extension of *P. impudicus* cords across soil was reduced as a result of exposure to VOCs from *H. fasciculare* (Fig. 5D and E) (67). The antagonistic potential of VOC and DOC profiles depends on the chemical composition of that profile and the susceptibility of the combatants; effects of VOCs and DOCs may be stimulatory and function as attractants to competitors, mycoparasites, or invertebrates (47, 72).

Mycoparasitism

Mycoparasitic relationships occur when one mycelium gains nutrition directly from another (35). The mycoparasite may cause the death of the host mycelium and utilize nutrients from the dead or dying hyphae (necrotrophy), or it may derive nutrition from living mycelia (biotrophy). There is a spectrum of relationships between these extremes, and some fungi may grow biotrophically on certain hosts but necrotrophically on others (73). Not only do fungi parasitize other mycelia, but they can also parasitize fruiting bodies, spores, and sclerotia (73).

Biotrophic mycoparasitism

Biotrophic mycoparasitic relationships are complex, controlled, and specialized associations between mycoparasite and host. Biotrophic mycoparasites have a narrow host range, and the mycoparasite is frequently dependent on the host for survival; for example, *Coniothyrium minitans* is an obligate mycoparasite of certain *Sclerotinia* and *Botrytis* spp. and lacks a free-living saprotrophic stage (74). The establishment of biotrophic associations requires high specificity in recognition between the host and the mycoparasite (73). The associations are relatively nondestructive, with the cytoplasm of the host remaining relatively healthy, but abstraction of nutrients from the host results in reduction in host biomass, often causes distortion of host hyphae, and has adverse effects on host sporulation (73, 75, 76). Three subdivisions of biotrophic mycoparasitism have been described based on physiological characteristics. First, the intracellular biotrophs function by the entire thallus entering and developing within the host cells and absorbing nutrients directly from the host cytoplasm. Second, haustorial biotrophs penetrate host cell walls by the production of appressoria and the development of specialized absorptive branches (haustoria) which invaginate the host plasma membrane. Host nutrients are absorbed across the plasma membrane into the haustorium. Third, fusion or contact biotrophs produce specialized hyphae which closely adpress to the host hyphae and form channels or micropores in the host cell wall, allowing the biotroph plasmalemma to fuse with that of the host and absorb nutrients directly from the host cytoplasm (37, 76).

Necrotrophic mycoparasitism

Necrotrophic mycoparasites tend to have a broad host range and utilize relatively unspecialized, destructive parasitic mechanisms. For many necrotrophs parasitism is more opportunistic than biotrophy and, as mentioned above, can even be temporary, providing the parasite with a means of access to a different food source. As with biotrophic mycoparasites, the necrotrophs can be subdivided based on their physiological relationship with the host. Noninvasive necrotrophs make contact with, or grow very close to (within a few micrometers), host hyphae, which they attack by a process known as "hyphal interference." The mycoparasite secretes nonenzymic diffusible toxins, which cause impaired membrane function and result in lysis of organelles, invagination of the plasma membrane, and eventual death of the hyphal compartment (73). Death of the whole mycelium may occur if multiple contacts are made. In contrast, invasive necrotrophs coil around and penetrate host hyphae (73). Contact and recognition of a host often stimulates production of specialized structures on the mycoparasite cell wall, with which it binds to host hyphae (77). The mycoparasite produces antifungal metabolites and lytic enzymes to disrupt host cytoplasm, resulting in vacuolation and lysis of hyphal walls and organelles. For example, vigorous

necrotrophs in the genus *Trichoderma* secrete antibiotic peptides called peptaibols, which disrupt cytoplasmic membranes and cause hyphal leakage and eventual cell death, and they also secrete cell wall-degrading chitinases and proteases (78).

Larger-Scale Mycelia Interactions: Antagonistic Mechanisms

For saprotrophic fungi, the territory occupied by a mycelium is also its nutrient source, and as such, mycelia attempt to maximize their territory by replacing other mycelia and defending themselves from replacement. This is clearly seen in communities of wood decay fungi; the territories occupied by different mycelia in decaying wood are often delineated by pigmented barriers, or "pseudosclerotial plates," which are the interfaces between competitors (Fig. 5A) (58). The establishment of physical contact between two competing mycelia, often termed "gross mycelial contact," results in large-scale changes in the growth, gene expression, and metabolite production in both competitors and in the induction of antagonistic mechanisms. The outcomes of antagonistic interactions range from replacement of one competitor by another to deadlock, where neither species can capture any territory from the other (58). Between these extremes are partial replacement, where one species is able to capture some but not all of the opponent's territory, and mutual replacement, where one species obtains some of the territory formerly occupied by the other and, simultaneously, *vice versa*. Outcomes are determined by the relative abilities of the opponents to capture and defend territory, and different species may exhibit different strategies during combat, displaying traits that may benefit them in attack and/or defense (79). Some fungi are good at both attack and defense, whereas others are good at one of these but not the other. For example, the secondary colonizer *Stereum hirsutum* is relatively poor at gaining new territory in decaying beech wood but can defend the territory it occupies against more combative later secondary colonizers such as *H. fasciculare* and *P. velutina* (49). Further, the progress and outcomes of interactions can be altered and even reversed by changing environmental conditions such as invertebrate grazing, gaseous regime, water availability, and temperature (79–82).

Morphological changes

Antagonistic mechanisms utilized by mycelia to attack or defend against competitors include morphological changes, production of enzymes and toxins, detoxification of competitor toxins, and alteration of metabolic rate. Changes in mycelial morphology are most dramatic in areas in direct contact with the competitor—the interaction zone. Hyphae may aggregate to form defensive barrages to physically block invaders or to form invasive replacement fronts or cords to penetrate competitor defenses (Fig. 5F and H) (58). Different types of hyphal assemblage can be found in different regions of the same interaction front, indicating that antagonistic mechanisms are deployed dynamically and in response to local stimuli (68). Changes in morphology during interactions are reflected in changes in expression of genes involved with cell division, cellular transport, and cytoskeleton rearrangement compared to noninteracting mycelia (83–85).

Secondary metabolite production

Profiles of VOCs and DOCs alter quantitatively and qualitatively during interactions, often involving production of interaction-specific compounds not produced by either competitor during growth alone (66–68, 72, 86–88) (Table 2). Interaction-specific VOCs are often identified as terpenoids, frequently sesquiterpenes (66, 67, 87). Many sesquiterpenes are known to be bioactive, displaying antifungal activity or functioning as attractants or repellants to fungi and invertebrates (61, 89, 90). Some compounds that were produced constitutively may be upregulated following contact with a competitor (Table 2); for example, the production of a potentially antifungal quinolinium-type compound by *H. fasciculare* doubled during interactions with *T. versicolor* compared to during growth alone (72).

Accumulation of reactive oxygen species (ROS)

ROS accumulate at interaction zones, although their exact role is unclear (Fig. 5G) (84, 91, 92). ROS may be produced by one or both competitors to generate a toxic oxidative environment, and increases in potential sources of ROS, such as increased expression of genes encoding NADPH oxidase and increases in peroxidase and phenoloxidase activity, have been detected at interaction zones (84, 92, 93). Increases in expression of genes encoding catalase and putative DNA repair proteins have also been detected at interaction zones, which suggests attempts by the mycelium to mitigate ROS toxicity and repair oxidative damage (83, 84). However, a direct role for ROS toxicity during interactions between wood decayers seems unlikely since these fungi are adapted to tolerate the oxidative stress caused by activity of their own ligninolytic enzymes. Instead, ROS accumulation may be incidental and occur as a result of disruption of cellular metabolism caused by

Table 2 Secondary metabolite production during antagonistic interactions[a]

Chemical class	Compound name	VOC/DOC	Change in production	Interaction (species) reported in and substrate	Reference
Benzenoid	1,2-Dihydroxyanthaquinone	DOC	Increase	*Stereum hirsutum* vs. *Coprinus disseminatus* on MA	86
	5-Methyl,1,3-cyclohexadiene	VOC	Interaction-specific	*Trametes versicolor* vs. *Stereum gausapatum* in malt broth	72
Carboxylic acid	Fusaric acid	DOC	Increase	*Ustilago maydis* vs. *Fusarium verticillioides* on PDA	103
	Malic acid	DOC	Increase	*S. hirsutum* vs. *C. disseminatus* on MA; *Trichoderma viride* vs. *Schizophyllum commune* on PDA	86, 100
Sesquiterpene	α-Bulnesene	VOC	Increase and decrease (depending on species involved)	*Hypholoma fasciculare* vs. *Phanerochaete velutina*; *Resinicium bicolor* vs. *Phallus impudicus*; *Phanerochaete veutina* vs. *P. impudicus*; *R. bicolor* vs. *P. velutina*; *H. fasciculare* vs. *P. impudicus*; all in beech wood	67
	Selinene (α and β)	DOC	Interaction-specific	*Nodulisporium* sp. vs. *Pythium aphanidermatum*; *Nodulisporium* sp. intraspecific interaction; both on PDA	88
Monoterpene	Pinene	VOC	Interaction-specific	*T. viride* vs. *Aspergillus niger* in straw powder	87
	γ-Terpinene	DOC	Interaction-specific	*Nodulisporium* sp. vs. *P. aphanidermatum* on PDA	88
Sugar alcohol	Erythritol, meso-erythritol	DOC	Increase	*T. viride* vs. *S. commune* on PDA; *S. hirsutum* vs. *Coprinus micaceus* on MA; *S. hirsutum* vs. *Coprinus disseminatus* on MA	86, 100
Sugar alcohol	Glycerol	DOC	Decrease	*T. viride* vs. *S. commune* on PDA	100
Ketone	3-Octanone	VOC	Increase and decrease (depending on species involved)	*H. fasciculare* vs. *P. velutina*; *R. bicolor* vs. *P. impudicus*; *P. veutina* vs. *P. impudicus*; *R. bicolor* vs. *H. fasciculare*; *H. fasciculare* vs. *P. impudicus*; all in beech wood	67
	Bicyclo-oct-6-en-3-one	DOC	Interaction-specific	*Nodulisporium* sp. intraspecific interaction on PDA	88
Alkane	Alkanes (C7-C54)	VOC/DOC	Interaction-specific	*T. viride* vs. *A. niger* in straw powder; *Nodulisporium* interspecific interaction on PDA	87, 88
Alcohol	2-Methyl-1-butanol	DOC	Interaction-specific	*Nodulisporium* sp. vs. *P. aphanidermatum* on PDA	88
Aldehyde	2,3,4-Trihydroxybutanal	DOC	Increase	*T. viride* vs. *S. commune* on PDA	100

[a]Select examples of the volatile and diffusible organic compounds (VOCs and DOCs, respectively) that have been detected as changing in production during interspecific fungal interactions. Metabolites belong to a wide variety of chemical classes and may increase or decrease in production during interactions relative to solo growth or may be specific to the interaction. Interaction experiments were performed in a variety of substrates, including malt agar (MA) or broth, potato dextrose agar (PDA), beech wood, and straw powder.

other antagonistic mechanisms. Alternatively, increases in ROS levels may function as a defense signaling response similar to that in plants, for example, triggering biosynthesis of pigment (92, 94). Increases in another potential signaling compound, nitric oxide, have also been detected during interactions between *Phellinus morii* and *I. obliquus*, triggering the production of antifungal phenylpropanoid metabolites (95).

Oxidative enzyme activity

Activities of peroxidases and phenoloxidases (laccases) are also upregulated at interaction zones (19, 83, 93)

(Table 3). This may function to increase decomposition and could be associated with increased utilization of the resource during combat. However, laccases and peroxidases are also secreted in response to stress and could function during interactions to detoxify competitor VOCs and DOCs (19, 85). Other enzymes involved in detoxification are also upregulated during interactions; for example, increases in the expression of genes encoding oxidoreductases, aldo/ketoreductases, and glutathione *S*-transferases were detected in *T. versicolor* and *Pycnoporus coccineus* during interactions with various competitors (84, 85). Laccases may also function to wall off and protect hyphae during interactions through production of melanin, which insulates hyphae from ROS, toxins, temperature extremes, and hydrolytic enzymes and may also have direct antibiotic properties (96, 97). Pigmentation is frequently observed at interaction zones (Fig. 5H), and while there is some indication that this is the result of deposition of DOCs, this may also be the result of melanization (72).

Table 3 Extracellular enzyme production during antagonistic interactions[a]

Enzyme	Function	Proposed role in interactions	Change in activity	Interaction (species) reported in and substrate	Reference
Laccase (phenoloxidase)	Degradation of lignin	Detoxification of competitor metabolites; pigment production; ROS generation	Increase	e.g., *Trametes versicolor* vs. *Stereum gausapatum* on MA; *Humicola grisea* vs. *Trichoderma harzianum* in CLN broth; *Pleurotus* sp. vs. *Dichomitus squalens* on wheat straw	19, 93, 104
			Decrease	e.g., *T. versicolor* vs. *Fomes fomentarius* on MA	19
Peroxidase					
Manganese peroxidase	Degradation of lignin	Detoxification of competitor metabolites; pigment production; ROS generation; enhanced nutrient uptake	Increase	e.g., *Trametes maxima* vs. *Paecilomyces carneus* on PDA; *Pleurotus ostreatus* vs. *Phanerochaete chrysosporium* in NWS; *T. versicolor* vs. *S. gausapatum* on MA	19, 105, 106
Lignin peroxidase				e.g., *Pleurotus ostreatus* vs. *Phanerochaete chrysosporium* in NWS	105
General peroxidase				e.g., *Phlebia radiata* vs. *Phlebia rufa* on MA; *Serpula lacrymans* vs. *Coniophora puteana* on MA	107, 108
Cellulase	Cellulose degradation	Enhanced nutrient uptake	Increase		
β-Glucosidase				e.g., *T. versicolor* vs. *Bjerkandera adusta* on MA	19
α-Glucosidase				e.g., *H. fasciculare* vs. *Phanerochaete velutina* on soil	98
Cellobiohydralase				e.g., *H. fasciculare* vs. *P. velutina* on soil	98
Cellobiase				e.g., *T. versicolor* vs. *T. harzianum* in LN broth	99
N-acetyl glucosaminidase (chitinase)	Chitin degradation	Attack of competitor cell walls, degradation after secondary colonization	Increase	e.g., *T. versicolor* vs. *Hypholoma fasciculare* on MA; *Fomitopsis pinicola* vs. *Resinicium bicolor* on spruce veneer	19
Acid phosphatase	Phosphate release	Enhanced nutrient uptake	Increase	e.g., *T. versicolor* vs. *Daldinia concentrica* on MA; *H. fasciculare* vs. *P. velutina* on soil	19, 98

[a]Select examples of enzymes with changes in activity detected during interspecific fungal interactions relative to growth in solo cultures. Interactions were performed in a variety of substrates, including cellulose low nutrient (CLN) broth, malt agar (MA), potato dextrose agar (PDA), wheat straw, wheat bran-neem hull-sugarcane bagasse (WNS), low nitrogen (LN) broth, spruce veneer, or across soil. The interactions reported represent a few examples, and only a fraction of the studies that have been performed are included in the table.

Energy expenditure during interactions

Antagonism is energetically expensive. Production of invasive mycelial cords by one or both competitors is associated with increases in respiration, indicating that this requires upregulation of metabolic processes (49). Enhancement of nutrient acquisition through increased production of cellulases and phosphatases occurs at interaction zones and throughout the competing mycelia (85, 98, 99). The concurrent reduction in biomass accumulation during interactions between *P. coccineus* and *Coniophora puteana* suggests that this increased nutrient acquisition functions to fund antagonistic mechanisms rather than mycelial growth (85). Metabolism was also found to increase in newly captured territories (i.e., regions where a mycelium had replaced a competitor), and it is likely that the observed increases in activity and gene expression of proteases and chitinases in these regions function to recycle the mycelium of the displaced competitor (85, 100–102). Similarly, genes whose products are involved in carbohydrate and nitrogen metabolism were upregulated in *T. versicolor* mycelium during interactions in which it replaced competitors, but not during interactions in which it was out-competed (84).

CONCLUSIONS

Fungal community development within decaying resources is ultimately driven by the abiotic conditions the resource is subjected to and by the local pool of potential colonizing species. Fungi have evolved different life history strategies to exploit different niches during community development within decaying resources, although certain species may often have combinations of characteristics from different strategies or vary in their strategy during different stages of the life cycle or in different contexts. The communities that develop in newly available resources depend on the levels of abiotic stress present; this determines which of the latently present colonizers, and which of those that arrive as spores or via mycelial spread from local species pools, are most likely to establish within the resource. Changing abiotic conditions, modification of the resource by colonizers, and arrival of more combative species drive shifts in community composition, and in some cases the assembly history determines subsequent community development. Acquisition of previously colonized resources by more combative species is achieved through the deployment of antagonistic mechanisms, which can begin before mycelia establish physical contact through production of volatile and diffusible organic compounds. Interacting mycelia undergo a slew of morphological and biochemical changes, which may be aggressive or defensive in function, and the changes that occur differ depending on the combination of species involved. Interaction outcomes, and thus community change, are determined by the relative combative abilities of the fungi involved, but these outcomes can be altered or even reversed under different environmental conditions.

Many questions remain to be answered for us to fully understand the processes underlying community development of saprotrophic fungi. First, how far do spores spread, and how do they manage to establish within resources that are already colonized; what exactly is the success rate of a spore? Perhaps communities within decaying resources are determined through all initial stages of decay by propagules that are latently present; emerging sequencing technologies will allow a much more comprehensive profile of latent colonizers to assess the extent of their contribution to community development. Further, how strong are priority effects and how resilient are these pathways of community development to global environmental change? Finally, utilization of emerging molecular and biochemical approaches will allow better understanding of the mechanisms involved in antagonism or facilitation within decay communities, which drive changes in community composition throughout the decomposition process.

Acknowledgments. *The authors would like to thank Sarah Johnston, Nawal El Ariebi, Don A'Bear, and Emma Gilmartin for providing images for figures.*

Long-Distance Dispersal of Fungi

14

Jacob J. Golan and Anne Pringle

INTRODUCTION

The relative degree to which organisms move is a process operating at multiple temporal and physical scales (1). In recent years dispersal has received a great deal of attention in fields ranging from mathematics and physics to ecology and molecular biology, but only a patchy framework exists to explain dispersal over very large distances. Modeling patterns of long-distance dispersal (LDD) among macroorganisms, ranging from vertebrates and flying insects to seed plants, appears tractable, but documenting the geographic distributions and dispersal dynamics of microscopic propagules and microbes presents multiple theoretical and methodological challenges (2–4). The majority of empirical research directly measuring the dispersal of microbes or microscopic propagules is restricted to relatively short distances, and tracking dispersal at greater spatial scales involves mathematical or genetic models, e.g., in studies of moss (5–9), ferns (10–13), bacteria (14–19), and fungi (19–23). However, fitting dispersal data (e.g., from the tracking of spore movement) to mathematical functions often over- or underestimates LDD and imprecisely describes the trajectory of spore movement across large distances (24–28). Inferences based on population genetics data capture rare instances of successful LDD but incompletely describe underlying demographic processes and typically cannot speak to mechanisms of LDD (1). Besides the limitations of mathematical and genetic methods, important details about the natural history of species are often ignored or remain unknown, leaving many questions unanswered, including, e.g., how ephemeral propagules remain viable while exposed to harsh environments over extended periods of time.

Here we consider LDD as it relates to fungi. Although most research focuses on only a small number of fungi, the kingdom is extremely diverse, housing an estimated 1.5 to 10 million species (29). The ability of fungal dispersal structures (e.g., conidia, basidiospores, ascospores, sclerotia, etc.) to disperse over large distances may be highly context dependent (Fig. 1). Moreover, while LDD for a rust fungus, e.g., *Puccinia graminis*, may be over several kilometers, LDD for a bird's nest fungus, e.g, *Crucibulum laeve*, may be only several dozen meters (30, 31). The delimitation of cryptic species by phylogenetic techniques has also in many cases revealed that a fungus once considered widespread in fact consists of several separate species, each with nearly indistinguishable morphological characteristics, and raises questions about the prevalence of LDD (32–34). Further complicating matters, direct evidence for LDD beyond several kilometers is lacking (35). Thus, any discussion of the dispersal dynamics of fungi as a whole is problematic, especially if comparisons are made or inferred between one fungal group and another (e.g., aquatic fungi compared to ectomycorrhizae) (19, 22, 23, 30, 36).

One common feature among sporulating fungi is the tremendous abundance of both sexual and asexual spores (e.g., a single gall of *Ustilago maydis* [corn smut] contains up to 25 billion spores, and a single sporangium of *Rhizopus stolonifer* [common bread mold], up to 50,000) (35). Fungal spores are orders of magnitude smaller than the smallest seeds—smaller than most moss and fern spores and comparable in size to some plant pollen (e.g., *Triticum aestivum*, or wheat, pollen) (37–40) (see Fig. 2 and 5). However, unlike pollen, many fungal spores are short-lived and highly susceptible to desiccation and UV radiation, and it is often unclear whether spores survive, e.g., transcontinental and oceanic transport (41–45).

Given these taxonomic, empirical, and methodological challenges, a sound conceptual framework to guide and synthesize research is urgently needed. Mycologists have yet to integrate the abundant physiological, morphological, and biogeographic data available for hundreds of species into a unifying paradigm of fungal

Department of Botany, Department of Bacteriology, University of Wisconsin–Madison, Madison, WI 35706.

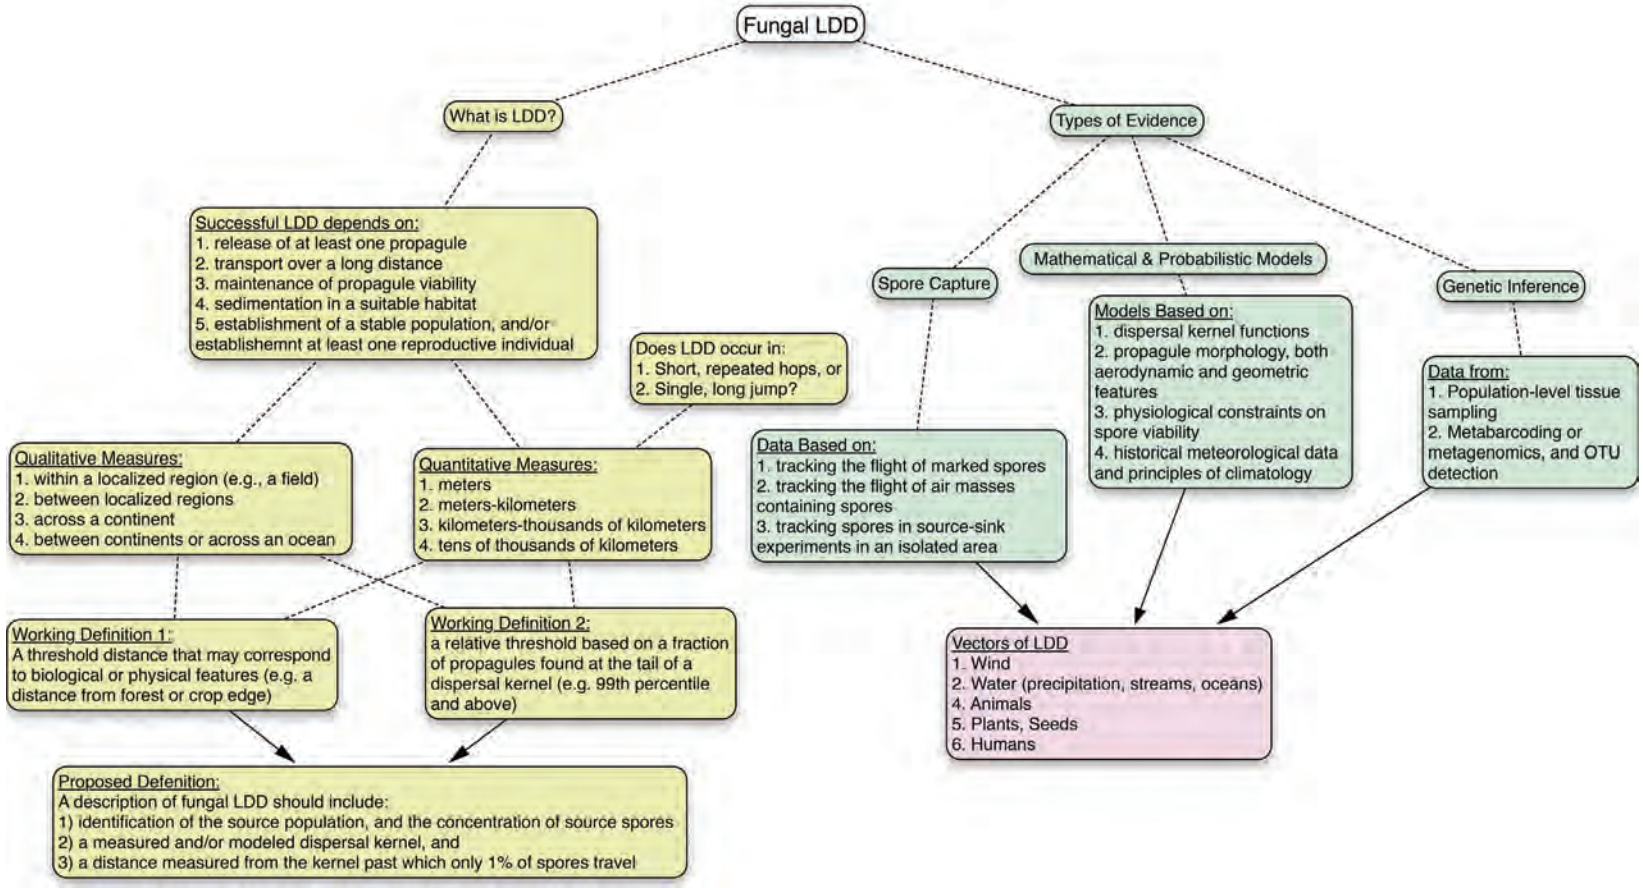

Figure 1 A framework for understanding fungal LDD.

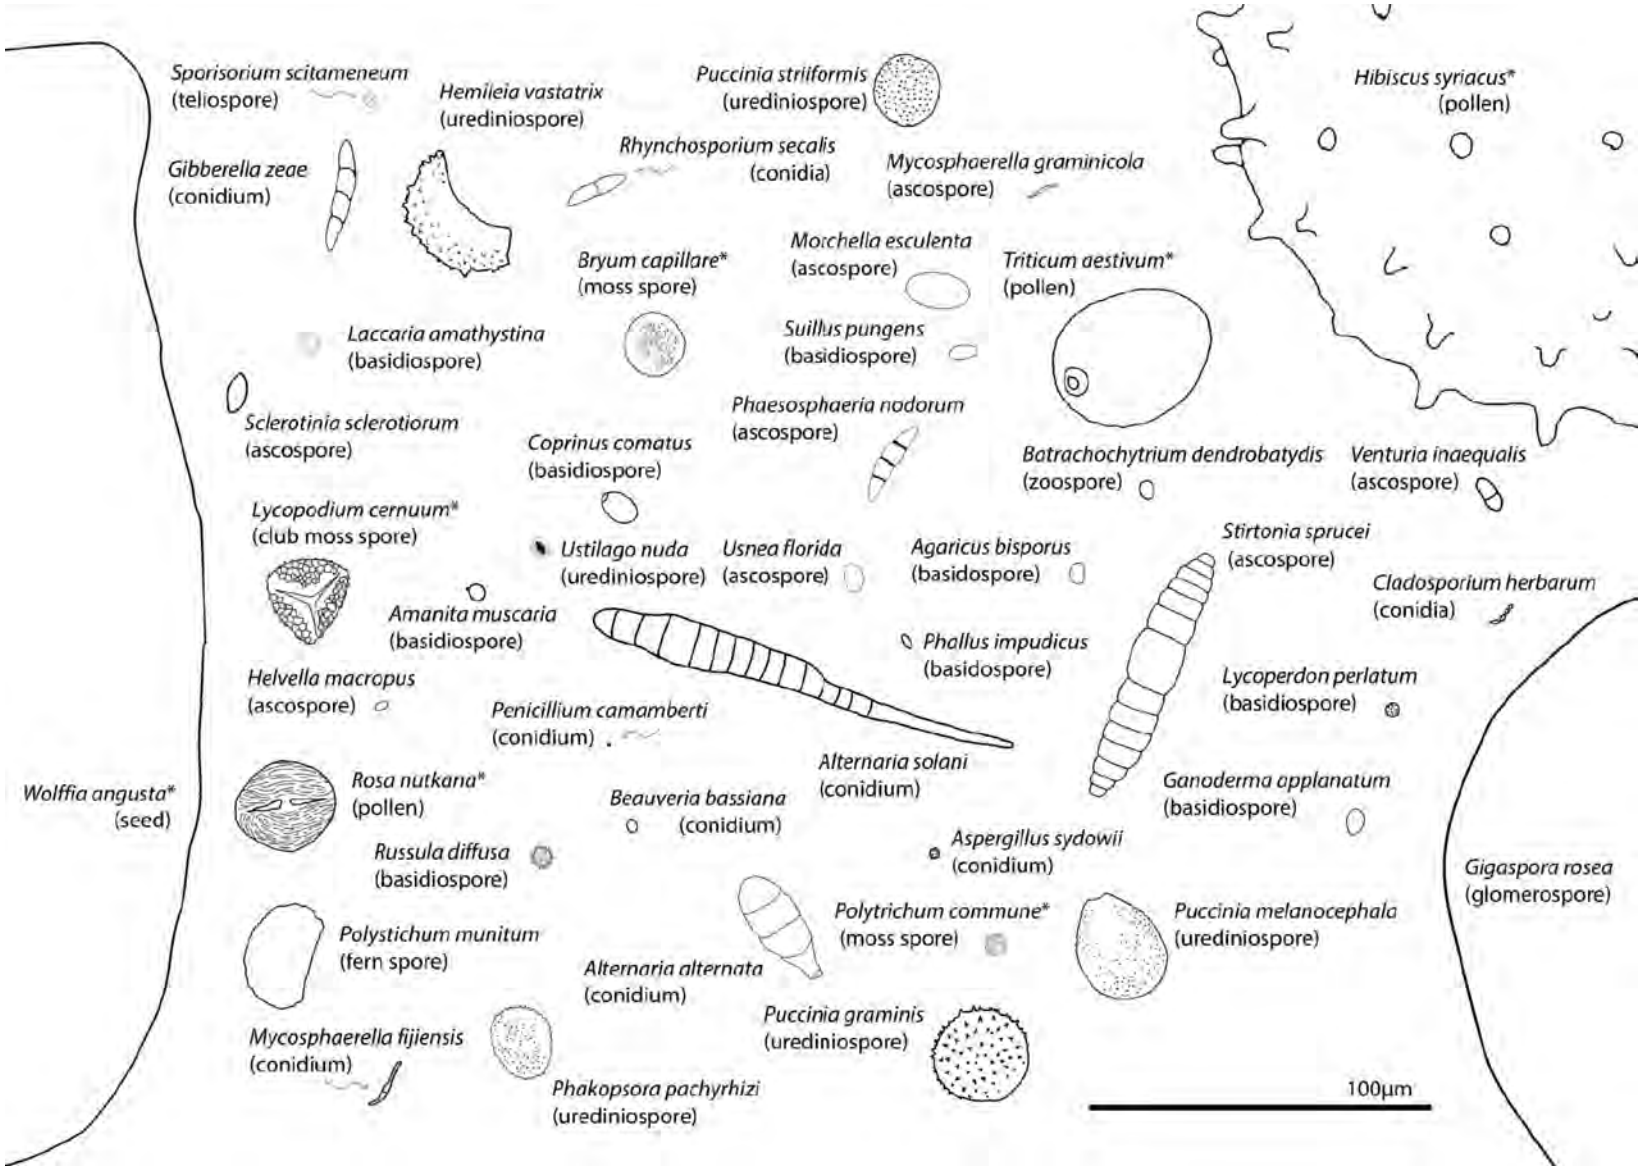

Figure 2 Sizes of fungal spores and other airborne particles. Some species are wind dispersed (e.g., *P. graminis*), while others have other means of dispersal (e.g., *Gigaspora rosea*). The smallest plant seed, *Wolffia angusta*, the pollen grains of *Hibiscus syriacus* and *T. aestivum*, and a glomerospore of the arbuscular mycorrhizal *Gigaspora rosea* are provided for comparison. Species labeled with an asterisk are not fungi.

LDD. If comparisons are to be effective or relevant, the highly relative nature of the spatial scales involved must be explicitly acknowledged in any discussion of LDD (46).

DEFINING FUNGAL LDD

In a general framework focused on dispersal, Nathan (28) highlights two general definitions of LDD that are often used in studies of animals and plants: movement exceeding (i) an absolute threshold equivalent to a chosen distance (e.g., 100 km) and (ii) a relative threshold based on a fraction of propagules found at the tail of a dispersal kernel (e.g., 99th percentile and above). However, a translation of these definitions to research on fungi is hindered by the incommensurate priority given to plants and animals in dispersal ecology (cf. 47–49) and by a lack of appropriate empirical data (e.g., spore sources are often inferred through reverse trajectory models that reveal little about source inoculum density, making inferences about fungal dispersal kernels [required by definition ii] difficult) (1, 28, 50). Moreover, definitions involving absolute threshold distances involve discretionary demarcations of LDD, resulting in a lack of consistency among studies. For example, definitions of LDD range from beyond 100 m (*Fusarium graminearum*), to beyond 1,000 m (*Mycosphaerella fijiensis*), to transoceanic transport (*Aspergillus sydowii*) (43, 51, 52). Using definitions based on a relative threshold facilitates comparisons of dispersal kernels of different species, but only if a common percentile is routinely used.

While it may be appropriate to have alternative definitions of fungal LDD for different species, at the moment there is no comprehensive approach to organizing the myriad methods used to think about fungal LDD. An accurate description of successful LDD must include, at a minimum, the magnitude of the source inoculum, the physical and biological probability of LDD (including, e.g., the vector[s] involved and the longevity of spores or tissues), the availability of suitable landing sites, and the probability of establishing a stable population and reproducing (Fig. 1). Any of these variables can prevent successful dispersal, perhaps explaining why fungal LDD appears extremely rare. Additionally, differences between stepwise vs. single-leap LDD must be distinguished. LDD involving sequential, shorter-distance dispersal is likely the more common phenomenon, while LDD involving a single successful spore moving a long distance is a very low-probability event that would coincide with optimal conditions for both fungus and vector.

To unify the disparate approaches used to describe and measure fungal LDD, we propose a synthetic three-part definition built on the framework presented by Nathan (1, 28). Any description of fungal LDD should include (i) identification of the source population and a measure of the concentration of source spores and (ii) a measured and/or modeled dispersal kernel. With this information LDD is defined as (iii) the distance found within the dispersal kernel beyond which only 1% of spores travel (Fig. 3). The 1% threshold provides a useful, common reference point; other choices are possible, but in any discussion the chosen threshold should be clearly identified. Using this standard definition, or discussing how any particular experiment relates to this definition, would facilitate an integrated approach to understanding fungal dispersal.

MEASURING LDD

Empirical measures of spore dispersal are difficult to make, but direct measures of movement remain critical to understanding the scale of a species' dispersal as a whole (51–53). It cannot be assumed that spores traveling beyond the limits of an experimental setup are statistically and/or ecologically insignificant. Moreover, while spore viability is often ignored, successful LDD requires that, e.g., a spore that has crossed an ocean is also viable. Novel approaches to measuring both spore trajectories and the probabilities of survival are critically needed, and experiments involving creative thinking, and perhaps taking advantage of new technologies, will likely help to better address the many unanswered questions about fungal LDD.

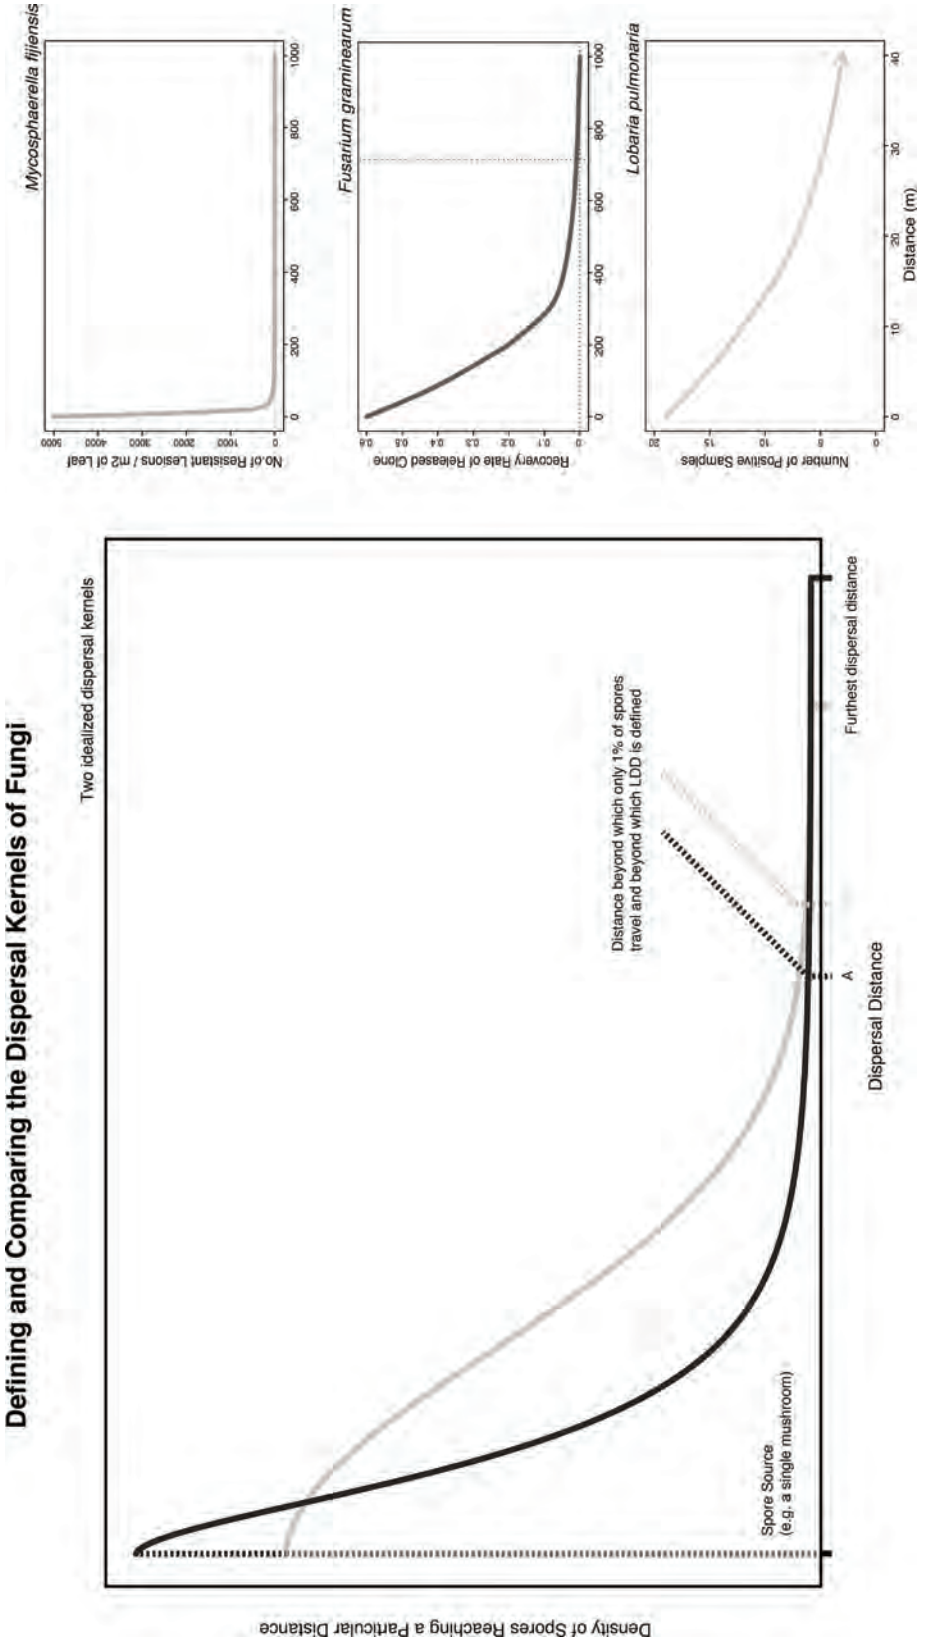
Once a greater array of empirical dispersal data is available, new dispersal kernels can be developed to better quantify fungal LDD (for a review of kernel functions see reference 54). However, many kernel models are best suited to describe either the source or tail end of dispersal, but not both simultaneously, and when applied to entire trajectories, such models tend to either over- or underestimate LDD (24–27). Describing the mathematics behind these models is outside the scope of this review, but examples of their use can be found in many studies of fungi (31, 45, 55–58).

The majority of studies of fungal LDD employ molecular approaches to compare the genetics of populations across a geographic range. However, genetic inferences reveal little about the underlying biological, physiological, and ecological forces at play and may be less relevant to our proposed definition. Studies often compare allele frequencies among discrete populations to infer dispersal, e.g., among Southern Hemisphere

populations of *Ganoderma applanatum-australe*, globally distributed populations of *Tuber* species, and pan-Arctic populations of many ectomycorrhizal fungi (20, 21, 59, 60). If two populations that are very far away from each other appear closely related in a phylogeny (e.g., Israeli populations appear more closely related to populations from Indiana than they are to Syrian populations), then LDD is inferred (Fig. 4) (61–64). Phylogenetic methods allow inferences of rare LDD to be made with less intensive sampling than the direct capture of spores but cannot provide critical information on spore longevity, nor information about the role of meteorological patterns, spore physiology, putative vectors, and human mediation. Genetic approaches cannot be used to model dispersal kernels and reveal little about dispersal mechanisms, regardless of geographic scale.

However, the best examples of LDD are based on a variety of approaches. Considering the different limitations to direct sampling, statistical modeling, and genetic inference, it is not surprising that the best-known cases of fungal LDD are typically generated using these methods in combination. For example, several reports of fungal trans-Atlantic dispersal in Saharan dust manage to capture viable fungal material, describe a dispersal kernel, and use meteorological backtracking to identify air masses as having originated from Africa (42, 43, 65–67). For other taxa, researchers sample directly from within the planetary boundary layer using towers or aircraft, in addition to tracking the trajectories of air masses (68–71). Genetic methods are also combined with spore capture techniques, usually by first determining the genotype of a specific fungal strain and subsequently allowing it to release spores (58). The relative proportions of that genotype collected by spore traps are then used to construct a dispersal kernel.

DISPERSAL VECTORS



Wind

Wind is the most commonly considered vector of fungal dispersal. Aerosolized course particles (greater than 2.5 μm in diameter) have been photographed moving hundreds of kilometers from northern Africa across the Atlantic, depositing an estimated 500 million to over 1 billion tons of material per year in the Caribbean and Amazon basin (43, 66). Sand, soil, and, in smaller proportions, biological matter including bacteria and fungal spores have also been found in air samples retrieved from towers or aircraft (36, 68, 71). Further evidence that spores can move in the atmosphere is provided by tracking wind patterns. The biogeography of mosses and ferns, as well as lichens, in the Southern Hemisphere may be better described by wind patterns than by geographic distances between land masses (72), providing indirect evidence for LDD via "wind highways" (45). Wind patterns are also used to infer atmospheric LDD of fungal pathogens, e.g., the introduction of *Hemileia vastatrix* (coffee leaf rust) from Africa to Brazil, and of *Puccinia melanocephala* (sugarcane rust) from West Africa to the Caribbean and the United States (73, 74).

Samples of dust from surfaces are also used to infer fungal LDD. Metabarcoding data taken from North American dust reveal a low percentage of common species across regions, but some degree of overlap suggests that LDD is a real, albeit rare, phenomenon (19, 23). Alternative hypotheses posit that the ubiquity of some species is caused by short-distance dispersal over long time scales or that species appearing broadly distributed are complexes of cryptic species, each with restricted geographic ranges (75, 76).

Other studies track dispersal in wind by capturing spores. Peay et al. (30, 77) documented the dispersal of ectomycorrhizal assemblages at least 10 kilometers away from their source by placing uninfected "trap" seedlings at different distances from a source population. Data reveal that species richness and trap seedling colonization drop significantly beyond 1 kilometer. Additionally, viable ascospores of the wheat pathogen *F. graminearum* have been captured 50 meters to 1 kilometer above the Earth's surface in all seasons in Virginia—even during winter, when its plant host is absent. The capture of spores during winter suggests that the source of spores is kilometers away, because there was no wheat in the vicinity of the experimental setup when the *F. graminearum* spores were collected (68, 70, 71).

The most complete picture of wind LDD emerges from research on *A. sydowii*, the causal agent of aspergillosis of the Caribbean sea fan, *Gorgonia ventalina*. An outbreak of the disease occurred during the 1980s and coincided with the highest recorded deposition of African dust in the Caribbean Sea (42). Air samples taken from African dust plumes revealed the presence of *A. sydowii* conidia, and by inoculating *G. ventalina* in laboratory assays, these same dust-borne conidia were shown to cause the same symptoms of aspergillosis as occurring in the Caribbean (42, 67). Furthermore, only samples derived from African air masses moving over the Caribbean contained viable *A. sydowii* material, while samples from air masses of different origins did not (78).

Distance (m)

Atmospheric LDD may involve more than wind and may be facilitated by a combination of meteorological phenomena, including cloud, storms, and precipitation. In fact, spores may serve as rain- and cloud-forming nuclei, although the limited evidence for this phenomenon is debated, and it is still unclear how water can condense on the potentially hydrophobic outer surface of spores (see section below on morphological, biophysical, and physiological properties influencing LDD).

Fire may also play a role in initiating LDD because it can rapidly heat air and cause high-velocity updrafts (79). For example, back trajectory modeling of air masses suggests that viable spores captured from smoke over the Gulf Coast of Texas originated 1,500 km away in forest fires in the Yucatán Peninsula, Mexico (80). Sugarcane agriculture provides an excellent model for exploring how fire promotes LDD, because fields are frequently burned prior to harvest and are often plagued by one of the most widely referenced putative long-distance dispersers, *P. melanocephala*—among the first fungal species described as having undergone trans-Atlantic dispersal (79, 81). Fire-borne updrafts, perhaps often caused by humans, may facilitate the spread of *P. melanocephala*, challenging hypotheses of the unassisted dispersal of spores across oceans (cf. 73, 74).

Plants

Plants are another agent of fungal dispersal, and their ability to vector fungi is unsurprising given the close ecological association between the two kingdoms. Fungi inhabit both living and dead plant tissues, and there are many opportunities for fungi to codisperse, e.g., with seeds, senesced leaves, or branches.

Driftwood is an often overlooked substrate in which fungi disperse. Saprotrophic fungi are often found in decaying logs floating in bodies of water, and if hyphae or spores are able to withstand saline conditions, driftwood may be able to transport species across oceans. For example, Rämä et al. (82) sampled logs from across the North Sea and successfully cultured 147 fungal operational taxonomic units of Ascomycota, Basidiomycota, Mucormycotina, and Chytridiomycota, 50% of which were identified as terrestrial (nonmarine). Driftwood kept afloat by ice flows during the late Weichselian or early Holocene is suggested as a mediator of LDD for several trans-Arctic plant species and likely also their fungal symbionts (83). Data already support the long-distance movement of driftwood; e.g., Hellman et al. (84) show that logs collected in Greenland and Svalbard originated from western and central Siberia and North America. However, the

Figure 3 To integrate the disparate approaches used to describe and measure fungal LDD, we propose a synthetic three-part definition building on the general framework presented by Nathan (1, 28). A description of fungal LDD should include (i) identification of a source population and measure of source inoculum concentration (e.g., the number of spores in a single rust pustule), (ii) a measured and/or modeled dispersal kernel, and (iii) a measure of the distance, based on the dispersal kernel, past which only 1% of spores travel. Adopting a standard approach would mitigate the confusion caused by differing definitions and measurements of LDD and facilitate comparisons among the dispersal kernels of different species. In the illustration, the blue and red dispersal kernels demonstrate idealized kernels for two hypothetical species. LDD is defined per species at distances A and B, respectively—the distance beyond which only 1% of spores travel. We next used our approach with real dispersal data of *M. fijiensis* (measured as the number of resistant lesions per square meter of banana leaf measured from a source to 1,000 m) (52), *Fusarium graminearum* (measured as the recovery rate of ascospores of a unique clone released from a source to 1,000 m) (58), and *Lobaria pulmonaria* (measured as the proportion of DNA from snow samples identical to an isolated source of soredia up to a distance of 40 m [193]) to estimate dispersal kernels and identify LDD for each species. We smoothed the published data to estimate an approximate dispersal kernel, and the distance beyond which 1% of spores traveled was found by integrating the area under each kernel from 0 m to the distance at which 99% of spores had been captured. Although both *M. fijiensis* and *F. graminearum* are capable of dispersing to approximately 1,000 m, the proportion of spores that fit our definition of LDD varies considerably, because LDD is defined past 714 m for *F. graminearum* and past 250 m for *M. fijiensis*. A holistic comparison of the two dispersal kernels suggests that different dynamics will shape the effective reach of each species. The dispersal kernel of *L. pulmonaria* illustrates how truncated experimental setups can impact measures of LDD. At the furthest collection point (40 m), a large proportion of samples tested positive, and the best dispersal kernel that can be modeled from the data (193) provides what is likely an underestimate of LDD, at approximately 39 m (15% of the positive samples collected at 0 m were detected). Ideally, the tail end of a modeled dispersal kernel should very closely approach a horizontal line at $y = 0$.

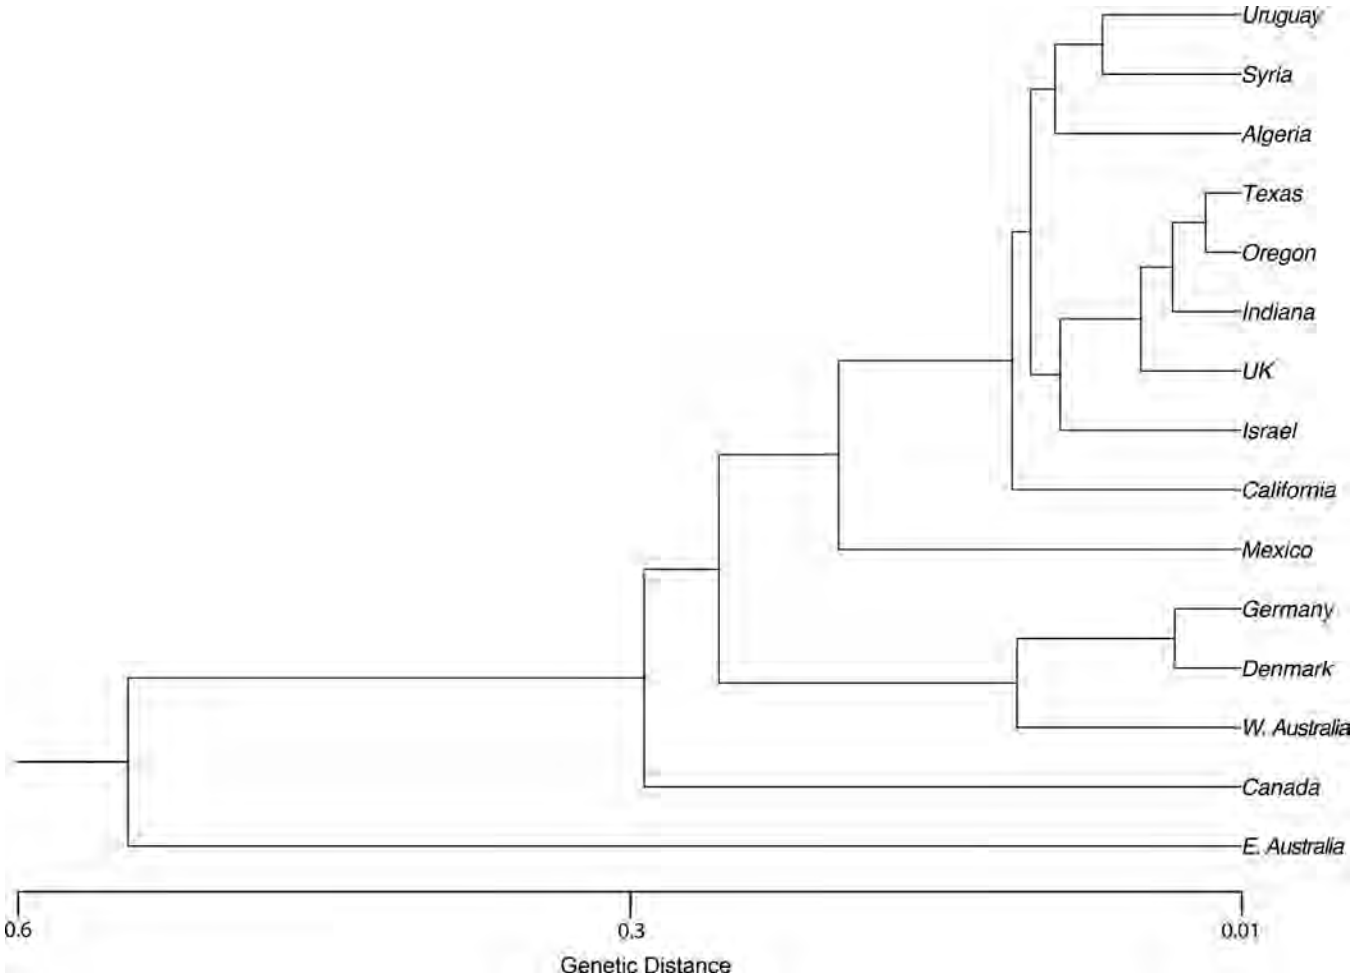

Figure 4 A phylogram of genetic distances among 15 geographic populations of *Mycosphaerella graminicola*. The fact that geographically distant populations of *M. graminicola* are grouped together, e.g., Uruguayan populations are grouped with Algerian and Syrian populations, likely suggests movement mediated by humans. *M. graminicola* infects one of the most traded agricultural products (wheat), and its ascospores cannot survive prolonged exposure to, e.g., dry air (183). Data adapted from Zhan et al. (64); similar clustering of geographically distant populations is found from data on *Phaeosphaeria nodorum* (129), *Rhynchosporium secalis* (131), and *M. fijiensis* (60).

majority of wood was logged, again suggesting that humans play a key role in many different kinds of LDD. The problem of driftwood-associated fungi remains a promising area for future research, and open questions concern patterns of driftwood movement and their possible relationship to fungal introductions and whether some logging practices increase the likelihood of LDD.

Living plant material transported by ocean currents is another putative mediator of fungal LDD. Symbiotic fungi are associated with plant roots as mycorrhizae and with leaves, stems, and seeds as endophytes. Thus, ocean-dispersed plant material, including floating seeds, asexual propagules, or entire root balls, may explain the geographic range of some fungi that are found on two sides of, e.g., an ocean. Little to no direct evidence for this phenomenon has been collected to date, and phylogenetic analyses testing whether plants and fungi disperse together are, surprisingly, lacking (85). Anecdotal evidence of arbuscular mycorrhizae occurring most frequently and with greater biomass on Hawaiian endemic beach grass species has been used to suggest fungus-plant long distance codispersal (86, 87). However, Koske and Gemma (87) provide alternative hypotheses such as concurrent, independent dispersal and sea bird-mediated dispersal of arbuscular mycorrhizae. A codispersal hypothesis is also suggested as an explanation

for evidence of recent gene flow between island and mainland ectomycorrhizae, though vectors such as wind cannot be ruled out (85, 88).

Oceans, Rivers, and Lakes

Large bodies of water can act as vectors of fungal dispersal. Oceans and lakes provide large areas across which some fungi can freely travel by, e.g., moving with microcurrents and upwelling, while rivers and streams provide continuous movement in the direction of their flow. The number of fungi specifically adapted to an aquatic or amphibious lifestyle is estimated at more than 10,000 species, although only approximately 500 have been formally described (89). Aquatic species are informally divided into two major groups: Ingoldian fungi, found on decaying leaves in streams and lakes, and aquatic ascomycetes (traditionally referred to as hyphomycetes), found on submerged wood (90). The uncommon shapes of many aquatic fungal spores may facilitate dispersal, as well as adherence to various substrates, in aquatic environments. Conidia are typically sigmoid or tetraradiate, while ascospores are generally fusiform with bipolar mucilaginous pads (see Fig. 5N) (91).

Whether spores are passively or actively released remains unclear. Most marine ascomycetes appear to release their spores passively, while many tropical freshwater ascomycetes actively eject their spores away from the fungal thallus (92). A possible explanation for this pattern may involve wind dispersal of spores during seasonal drying of streams and rivers. Alternatively, storms can cause flooding and the accumulation of substrate on, e.g., riverbanks and subsequently expose ascocarps to airflows once waters subside (92). In both cases spores are hypothesized to be sometimes dispersed by air, although the interplay between aquatic and terrestrial habits of these kinds of fungi requires further study.

At least a few Ingoldian fungi appear to have cosmopolitan ranges, suggesting they may be capable of LDD (90). For example, recent phylogenetic methods have elucidated that there is no geographic structure to populations of the widely distributed marine fungus *Lignicola laevis*, hinting that the species may be a long-distance disperser. However, only two loci were used in the study, and including several more genetic regions may reveal more restricted population assemblages (75, 76, 89). Pang et al. (89) list several other species which seem to have similar cosmopolitan distributions—*Aniptodera cheasapeakensis*, *Ceriosporopsis halima*, *Corollospora maritima*, *Savoryella lignicola*, *Torpedospora radiata*, and *Zalerion maritima*—suggesting that aquatic fungal LDD may be an as yet undescribed phenomenon.

Aquatic environments may be an ideal place for LDD to occur considering that fungal dispersal is often limited by spore desiccation, UV damage, and harsh temperatures. Water temperature fluctuates more slowly than that of air, and water attenuates light penetration at relatively shallow depths (especially in highly trophic waters). Moreover, water provides a greater degree of buoyancy than air, increasing the time before spore sedimentation. Aquatic dispersal is perhaps the least commonly considered mechanism of LDD, and future studies might address the coupling of, e.g., spore hydrodynamics with river flow velocity, as well as the population structure of putatively cosmopolitan aquatic fungi.

Animals

Animals are also vectors of fungal dispersal. Many animals migrate across continents on an annual basis and may transport fungi either internally or externally as spores, hyphae, sclerotia, or symbionts (93–98). Fungal propagules sheltered deep within fur or feathers are potentially protected from some harsh environments as they move over large distances.

Flying animals clearly serve as fungal vectors, and there is a great deal of evidence for birds and insects as mediators of fungal dispersal, especially of pathogens. Examples in arthropods include the spread of *Entomophaga maimaiga*, an introduced pathogen of gypsy moths used for biocontrol in North America (99); *Aspergillus flavus*, which infects desert locusts in India (100); *Sphaeropsis sapinea*, a pathogen of conifers worldwide that is spread by the pine engraver beetle (101); *Ophiostoma* spp. and *Knoxdaviesia proteae*, commensal species of mites secondarily vectored by beetles in South Africa (102, 103); and many others. However, dispersal by insect vectors tends to be restricted within a localized range, e.g., a few hundred kilometers, while dispersal across, e.g., continents or oceans, is more commonly caused by the human-mediated movement of insects and fungi together (103, 104).

Migrating birds are another common agent of animal-mediated dispersal. Examples include *Gibberella fujikuroi* (*Fusarium moniliforme*), a pathogen of rice vectored by hummingbirds (105); *Encephalitozoon* and *Enterocytozoon* spp., microsporidian human pathogens collected from several bird species (106, 107); and 2,337 filamentous fungi isolated from 216 migrating Mediterranean birds, of which *Cladosporium cladosporioides*, *Alternaria alternata*, and *Aspergillus niger* were the most abundant (108).

(*Geomyces destructans*), is another example of flying animal-mediated fungal dispersal. The mycosis appears to be spread among congregating bats and by their subsequent movement to other caves (109). The recent emergence of the disease in North America has resulted in the death of millions of bats, but it is unclear if the epidemic has resulted from the introduction of a European species or from the recent emergence of a newly virulent North American strain (110). In either case, the disease is spreading on a continental scale, and in addition to bats, humans may play a role in its spread (109).

Finally, the spread of chytridiomycosis of amphibians, caused by *Batrachochytrium dendrobatidis*, is perhaps the most commonly cited example of putative animal-mediated LDD. In recent years chytridiomycosis has spread rapidly, perhaps facilitated by a changing climate, as shown in Central America (111). The disease is heterogeneously distributed across all continents except Antarctica, but the reasons for its disjointed distribution are unknown (112, 113). It is not entirely clear how the fungus moves over large spatial scales, but its spread may be caused by a combination of localized amphibian movement coupled with, again, human mediation via the international trade of *Xenopus laevis* (the African clawed frog) and other amphibians (114–116).

Humans

Ancient fungal dispersal mediated by human migrations is suggested by data on population structures (117–119). The range expansion of the fungal pathogen *Coccidioides immitis* into South America parallels human migration routes during the Pleistocene (120–122). Similarly, the diversification of *Saccharomyces cerevisiae* strains mirrors their use and movement with human populations (123).

Contemporary dispersal mediated by human vectors merits special consideration as the inadvertent transportation of biological materials continues at unprecedented spatial and temporal scales. Plant disease epidemics caused by introduced fungal pathogens are among the clearest examples of the impact of human-mediated LDD, e.g., *Cryphonectria parasitica* (chestnut blight), *Ophiostoma ulmi* and *Ophiostoma novo-ulmi* (Dutch elm disease), and *Cronartium ribicola* (white pine blister rust) (124–127). But human-mediated LDD is not restricted to pathogens. For example, Vellinga et al. (128) show that many genera of ectomycorrhizae have also been introduced to novel ranges and spread globally by the human movement of plants and soil.

The global transport of agricultural products, as well as exotic plants, animals, and soil, all serve either indirectly or directly as platforms by which fungi can disperse over large distances at an accelerating rate. Modern transportation enables fungi—including fungal tissue that cannot independently disperse—to traverse continents in less than 24 hours. For instance, fruits and vegetables grown in North America typically spend a maximum of 5 days in intracontinental transit following harvest, and the transport time of produce grown in the Southern Hemisphere for U.S. consumption can take as little as a few days, depending on the mode of transportation (46).

Although many examples of human-mediated fungal dispersal are well documented, circumstantial evidence points to an even greater array of human-mediated dispersal events that are less well understood. Examples include *M. fijiensis* (black sigatoka) and *Mycosphaerella graminicola* (septoria leaf blotch), *Puccinia striiformis* f. sp. *tritici* (wheat yellow rust), *P. melanocephala* (sugarcane rust), *H. vastatrix* (coffee rust), and *Rhynchosporium secalis* (barley scald) (59, 63, 64, 73, 74, 129–131). Many of these species are intimately associated with agriculture, are planted over vast areas, and are regularly moved (either superficially on or within plant tissue) on a global scale. These same species are also frequently cited as prime examples of fungi capable of LDD (25). However, few to no data on fungal characteristics enabling or inhibiting LDD are available;

to travel, e.g., across oceans, spores must presumably surmount considerable biophysical constraints. Many of these pathogens are also globally distributed—as are their crop hosts—and an alternative hypothesis explaining what appears as LDD would involve a global network of commerce that provides multiple opportunities for infectious material to be transported between locations.

Consider the global populations of *M. graminicola* studied by Zhan et al. (64), of which, e.g., populations in Syria and Uruguay are genetically less distant from each other than geographically close populations sampled from both eastern and western Australia (Fig. 4). The fact that geographically distant populations of *M. graminicola* are grouped together, e.g., Uruguayan populations are grouped with Algerian and Syrian populations, suggests movement by humans. *M. graminicola* infects a highly traded agricultural product, wheat, and its ascospores cannot survive prolonged exposure to, e.g., dry air (132). However, with enough time, if gene flow were to completely halt, geographic populations could diverge and no longer appear as nested populations, although relationships between genetic and geographic distances would remain difficult to interpret. Highlighting the connection between human-mediated LDD and its effects on population structure may prove itself as a key variable to consider when trying to determine vectors and mechanisms of fungal LDD.

MORPHOLOGICAL, BIOPHYSICAL, AND PHYSIOLOGICAL PROPERTIES INFLUENCING LDD

Spore Size and Shape

The most obvious and perhaps most important agent of dispersal is the spore, whose size and shape may critically affect movement over large distances (Fig. 5) (133). A spore's ability to reach airflows, remain aloft, and then land in a suitable location is influenced by aerodynamic forces operating at a microscopic scale, and such forces may be harnessed by manipulating spore morphology (133, 134). Although Jenkins et al. (135) report no correlation between propagule size and dispersal distance in general cases, aspects of spore morphology are clearly optimized for movement. For example, Fritz et al. (136) have shown that among some Ascomycetes, spore dimensions precisely fit apical ring size to maximize launch distance with minimal energy. Others show that spore size can also be correlated to environmental parameters in ways that might maximize the probability of LDD. For example, Kauserud et al. (137, 138) show a relationship between spore size and the calendar date of sporulation and reason that spore morphology enables some fungi to take full advantage of seasonal wind velocities. However, when we compiled data on spore sizes and dispersal distances claimed as fungal LDD (Table 1) we found no relationship between spore morphology and dispersal distance (Fig. 6), but we hypothesize that the lack of any apparent correlation reflects the different measures and definitions of LDD used in the literature and not necessarily the lack of a biological relationship.

There is likely a compromise between small spore size, which can enable dispersal over longer distances, and large spore size, which can facilitate settling onto a favorable substrate (Fig. 5C, D). In principle, smaller spores should remain aloft for greater time intervals, but their reduced mass makes landing more difficult and increases their susceptibility to adverse environmental pressures, including UV exposure and desiccation (139). Greater and improved data on a range of spore parameters—emphasizing spore size, shape, longevity, and density—are required to further explore the tradeoffs involved in successful LDD. Often, the aerodynamic diameter (defined as the diameter of a spherical particle with equal density and terminal velocity to the particle of interest) of a spore is the sole parameter considered in estimates of spore dispersal (140). The focus on aerodynamic diameter may be problematic because many spores are not spheres, and also because density measurements specific to species of interest are not available but are necessary for accurate extrapolations of dispersal in heterogeneous airflows (140–142).

Successful fungal dispersal appears also to rely on a critical interplay between drag reduction (to maximize launch height) and drag maintenance (to maximize flight time). Roper et al. (143) have shown that explosively launched spores of many Ascomycetes have drag-minimizing shapes. Drag minimization enables spores to breach the boundary layer of still air surrounding sporocarps to reach more turbulent air layers. However, once aerosolized, successful LDD may require spores to remain aloft for extended periods (133). Wong et al. (144) have shown that remaining aloft is more a function of spore volume than of shape and have observed that the drag constants of spores are surprisingly proportional to their surface area (discounting shape and type of particle). Therefore, spore size appears to have, overall, a greater effect on settling velocity than do shape and density, suggesting that the latter characteristics may be less important in determining sedimentation rates (140, 142). An exciting direction for future

Table 1 Spore parameters for putative long-distance dispersers

Putative LDD fungal species	Spore type	Spore dimensions[a]	Shape	Habit	Pigment	Clump	Reference
B. graminis f. sp. *tritici*	Ascospore	20–30 μm (l) × 10–13 μm (w)	Ellipsoid	Plant pathogen	Hyaline	Yes	201
Gibberella zeae/Fusarium graminearum	Ascospore	13–28 μm (l) × ~4 μm (w)	Long ellipsoid	Plant pathogen	Light brown to hyaline		202
M. fijiensis	Ascospore	11.5–16.5 μm (l) × 2.5–5 μm (w)	Fusiform	Plant pathogen	Hyaline		41
M. graminicola/Septoria tritici	Ascospore	8–10 μm (l) × 2–2.5 μm (w)	Fusiform	Plant pathogen	Hyaline to light brown		65
Mycosphaerella musicola	Ascospore	14.9 μm (l) × 4.6 μm (w)	Fusiform	Plant pathogen	Dark brown		203
Phaeosphaeria nodorum	Ascospore	20–31 μm (l) × 4–5 μm (w)	Fusiform	Plant pathogen	Yellow-brown		129
Sclerotinia sclerotiorum	Ascospore	12 μm (l) × 6 μm (w)	Ellipsoid	Plant pathogen	Hyaline	Yes	204
Venturia inaequalis	Ascospore	11–15 μm (l) × 5–7 μm (w)	Ellipsoid	Plant pathogen	Brown		205
G. applanatum-australe	Basidiospore	Applanatum: 6.5–8.5 μm (l) × 4.5–6 μm (w); australe: 8–13 μm (l) × 5.5–9 μm (w)	Ellipsoid	Saprotroph	Brown		88
Laccaria amethystina	Basidiospore	6.16–8.47 μm (diam)	Globose, ornamented	Mycorrhiza	White		206
A. alternata	Conidia	20–63 μm (l) × 9–8 μm (w); often produced in chain of more than 5 conidia	Obclavate to obpyriform	Plant pathogen	Beige to brown	Yes	19
A. sydowii	Conidia	2.5–4.0 μm (diam)	Globose	Animal biotroph	Hyaline		68
C. herbarum	Conidia	1–12 μm (l) × 1–10 μm (w) with 50–100 nm × 50–400-nm bundle-like structures	Ellipsoid	Plant pathogen	Melanized	Yes	19
R. secalis	Conidia	12–20 μm (l) × 2–4 μm (w)	Fusiform	Plant pathogen	Hyaline		131
Peronospora hyoscyami f.sp. *tabacina*†	Oospore	17–28 μm (l) × 13–17 μm (w)	Globose	Plant pathogen	Hyaline		207
Sporisorium scitamineum	Teliospore	5 μm (diam)	Ovoid	Plant pathogen	Brown	Yes	208
Ustilago nuda	Teliospore	6.5 μm (l) × 5.8 μm (w)	Subglobose	Plant pathogen	Golden brown		197
H. vastatrix	Urediniospore	29.7–34.5 μm (l) × 18.9–37.3 μm (w)	Ellipsoid	Plant pathogen	Yellow	Yes	198
Phakospora pachyrhizi	Urediniospore	18–34 μm (l) × 15–24 μm (w)	Globose	Plant pathogen	Pale yellow to hyaline	Yes	209
P. graminis f.sp. *tritici*	Urediniospore	28.3 μm (l) × 17.5 μm (w)	Globose	Plant pathogen	Brown	Yes	210
P. melanocephala	Urediniospore	28–33 μm (l) × 18–23 μm (w)	Obovoid	Plant pathogen	Cinnamon brown		162
P. striiformis f.sp. *tritici*	Urediniospore	14–36 μm (l) × 13–23 μm (w)	Ellipsoid	Plant pathogen	Yellow to brown	Yes	211
B. dendrobatidis	Zoospore	3–5 μm (diam); posterior flagellum (19–20 μm long)	Ovoid	Animal pathogen	Hyaline		212

[a]Dimensions are given for major (l) and minor (w) axes or, when spherical, for diameter (diam). †, oomycete.

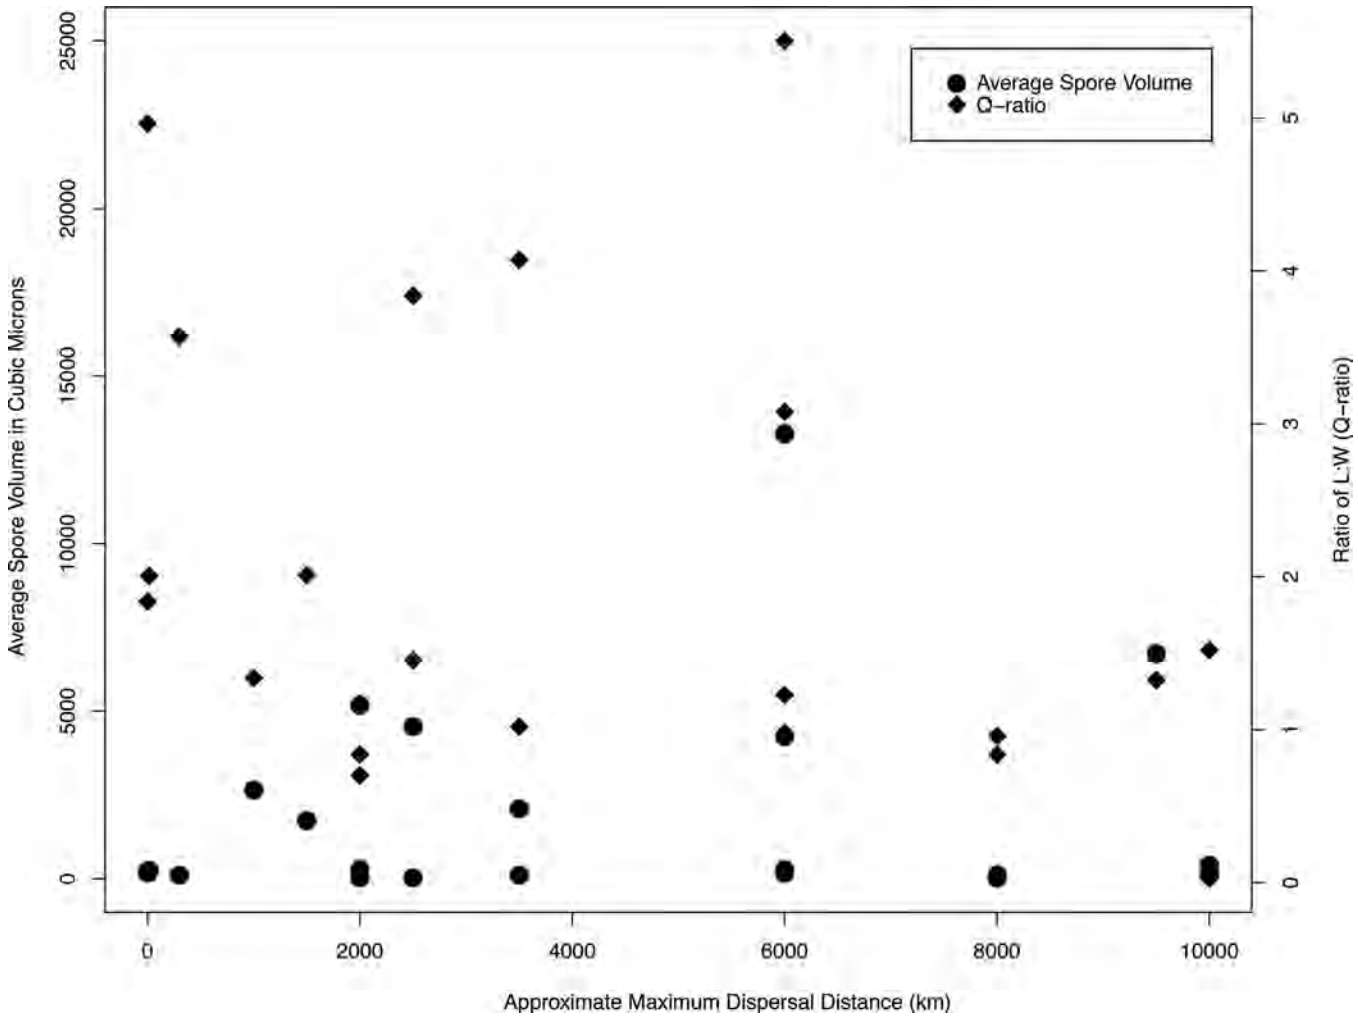

Figure 6 Comparing spore sizes to reported maximum dispersal distances. Spore volume in square micrometers is measured on the left-hand vertical axis, and spore Q-ratio (the ratio of spore length to width) is measured on the right. Data points were calculated from the parameters listed in Table 1. There is a poor correlation between approximate maximum dispersal distance and both average spore volumes ($R^2 = 0.0167$, $P = 0.5568$) and Q-ratios ($R^2 = 0.1113$, $P = 0.1198$). The lack of any correlation likely reflects inconsistent definitions and measurements of LDD, rather than any biological reality.

research involves more thorough testing of whether or how fungi have adapted to take advantage of aerodynamic principles, especially among putative long-distance dispersers.

A Spore's External Surface

Additional aspects of morphology that may influence spore dispersal include ornamentation and hydrophobicity, although these features appear to be more rarely studied than shape and size, despite limited data suggesting their key role in dispersal. For example, Halbwachs et al. (145) report that asymbiotic agaric species tend to be more ornamented than ectomycorrhizal agarics, while the latter tend to have smoother, more pigmented spore walls; differences may reflect distinct dispersal dynamics; e.g., ectomycorrhizae may require more pigmentation for UV protection while dispersing greater distances to find a plant host (but see reference 146 for criticisms related to methodology). The many unanswered questions surrounding ornamentation and its potential impact on dispersal include, How does a spore's outer morphology affect spore-to-spore aggregation, surface impaction, and dry or wet deposition (147) (Fig. 2)?

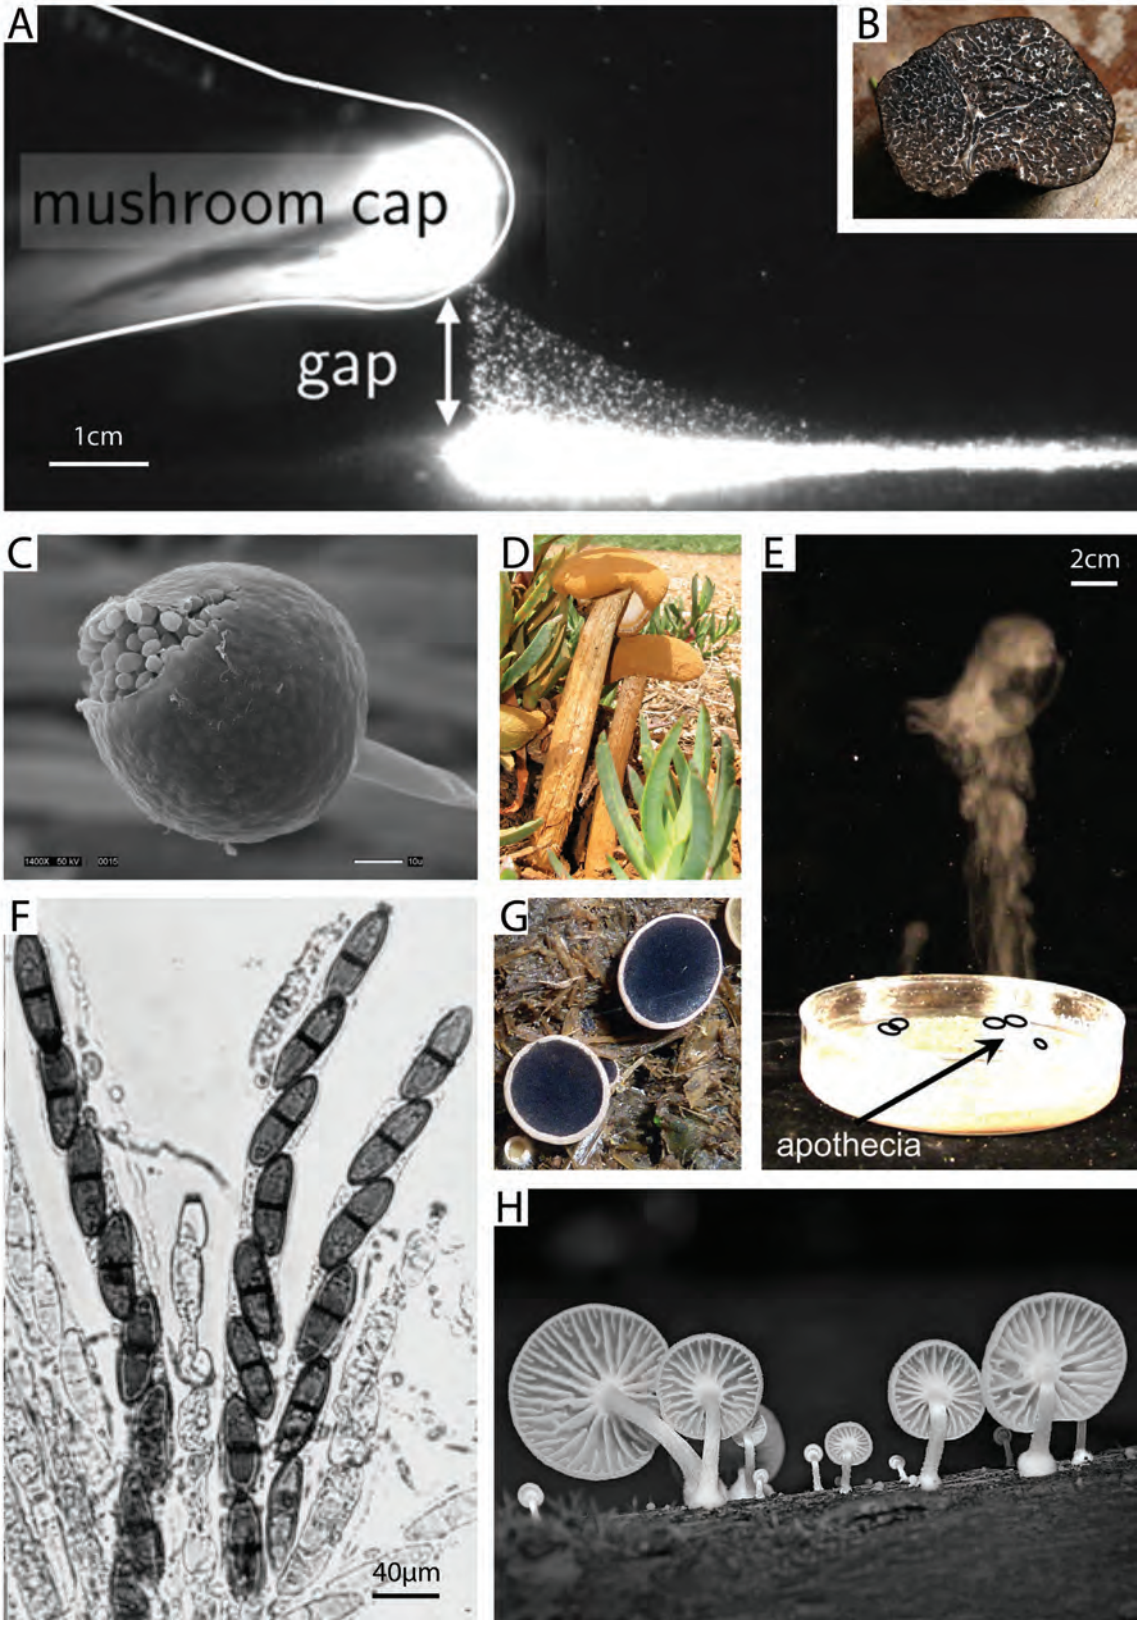
Slightly more is known about spore surface hydrophobicity. Aimanianda et al. (148) have shown that hydrophobic surface proteins on fungal spore walls allow many species to remain dormant inside animal lungs without causing an immune response. While spores rarely escape from lungs, spore hydrophobicity may protect spores in other animal cavities, e.g., the gut, and hydrophobins may enable survival over the relatively large distances covered by many animals. If spores remain undetected and viable in animal digestion tracts until excretion, spore hydrophobicity may well play a role in long-range movement of fungi within animals (149, 150).

Spore surface hydrophobicity also raises questions about whether spores can play a role in meteorological phenomena, either as cloud-condensing nuclei or ice nuclei (143, 151, 152). Spores can theoretically disperse within cloud formations, e.g., at the core of an ice particle, but how water would condense on hydrophobic spore walls remains an open question (153–155). Some kinds of plant pollen do act as cloud-condensing nuclei in high-humidity environments, despite a waxy outer layer. Pope (156) hypothesizes that the small pores found on pollen surfaces (approximately 1 μm in diameter) cause a localized reduction in vapor pressure and, as a result, capillary condensation. Similar morphologies are seen on ornamented fungal spores and, famously, on the adaxial surface of many basidiospores (143, 157–159). These structures may affect nucleation, although to date no study has tested whether spore wall ornamentation drives water condensation.

Do Spores "Clump?"

Dispersal may also be influenced by the ability of spores to aggregate, or form clumps. Clumping is reported for a variety of species, including *P. graminis*, *P. striiformis*, *A. alternata* (Fig. 5D), *Cladosporium herbarum* (Fig. 5F), *Blumeria graminis*, *Phakopsora pachyrhizi* (Fig. 5I), and *H. vastatrix* (Fig. 5H) (160–163). Clumping may improve individual fitness by stimulating germination (164) and may facilitate impaction on substrates by providing greater inertial mass (150, 165). Moreover, the outermost spores in airborne clumps may shield the innermost spores from harmful environmental conditions, e.g., solar radiation (163). However, whether clumping provides a net benefit to spores remains unknown. While the lower mass of a single spore may facilitate launch into turbulent air layers, the greater mass of clumped spores may shape horizontal displacement and deposition. Moreover, data on clumping are limited to a handful of fungal species (164, 165), and more research is needed to understand when, how, and how commonly spore clumps form.

The Physiological Hardiness of Spores



Fungal LDD may be constrained by the physiological tolerances of spores to solar radiation (especially UV), air moisture (relative humidity), and temperature. The resilience of a spore to any of these variables will vary according to species or taxonomic group. For example, urediniospores of *P. striiformis* var. *tritici* die quickly when exposed to high solar radiation, while ascospores of *Gibberrella zeae* are more susceptible to low relative humidities, and urediniospores of *P. pachyrhizi* cannot tolerate cold temperatures (166–168).

Because of the diversity of physiologies involved, the ability of species to withstand stresses must be tested individually. For example, if a species is hypothesized to have traveled from West Africa to Brazil by wind (cf. 73), verifying whether the spores of that particular species can withstand the UV, relative humidities, and temperatures likely encountered over the predicted path of flight is a critical and simple check on the plausibility of LDD. These kinds of data would complement evidence of inferred LDD, e.g., population genetics data, and enable a more comprehensive understanding of the likelihood of dispersal.

Sporocarp Properties Influencing LDD

Whether sporocarps influence LDD depends on the context in which dispersal occurs. Fungal species whose dispersal is animal-mediated, whether externally or internally, have evolved sporocarps with specific mechanisms to attract vectors. For example, *Tuber* spp. synthesize volatiles to encourage fungivory by mammals, while *Phallus* spp. produce foul aromas to attract insects (169–173).

Intriguingly, recent evidence suggests that sporocarps also play an active role in mediating wind dispersal. Within Ascomycetes, despite the diversity of spore and ascus apical ring shapes involved, the launch velocity of 90% of ascospores is within 2% of optimal energy conservation, so the morphology of the ascus facilitates ascospore penetration beyond the boundary layer of still air surrounding an ascocarp (Fig. 7F) (133, 136). Apothecia can also synchronize the release of spores, enabling groups of spores to move through still air to heights that could not be reached by the forcible discharge of a single spore (134). Basidiomycete mushrooms also appear to manipulate dispersal by using water evaporation from the pileus to generate convective airflows and move spores by at least several centimeters vertically (Fig. 7A) (174).

Less clear is whether sporocarps can control the timing of spore release to take advantage of local weather that might enhance the probability of LDD. Using a Lagrangian stochastic model, Savage et al. (175) show that fungal spores released during the hottest times of day are most likely to undergo LDD, presumably because updrafts formed by heated low-altitude air masses can lift spores into turbulent flows at higher altitudes. Extreme weather events, including thunderstorms and tornados, can also generate intense vertical updrafts and lift air into the upper troposphere. Anecdotal evidence suggests that fungi may release a greater concentration of spores just before thunderstorms (when updrafts are prevalent), and there are records of asthma outbreaks caused by fungal spores specifically prior to thunderstorms (40, 176–179). Efforts to track the timing and number of spores released during atmospheric updrafts, and in relation to other meteorological phenomena, remain an interesting direction for future research and may offer additional perspectives on the ability of fungi to manipulate LDD.

UNKNOWN AND CONFOUNDING VARIABLES: FREQUENCY OF LDD, VICARIANCE, AND CHANGING PATTERNS OF HUMAN-MEDIATED DISPERSAL

The frequency of LDD for any particular species often remains unknown. Frequent LDD requires movement to be unhindered by (i) physical barriers, (ii) lack of vectors, or (iii) unsuitable habitat. If LDD is frequent enough and occurs on a global scale, it results in what appears as a global population structure (32). Rare LDD might involve a single stochastic founding event and would be reflected in population structures where shared alleles become rare over time. Different rates of LDD are important because they result in very different dynamics when, e.g., a novel adaptive mutant (e.g., a genotype able to take advantage of a novel host) arises in one population.

When population structure is determined by geological events, rather than the movement of organisms themselves, the concept of vicariance is often invoked. Vicariance is typically defined as the fragmentation of a single population by changes in a landscape, causing limited to no gene flow between the resulting disjunct populations (180–183). Vicariance is relevant to a discussion of LDD because when data do not suggest vicariance, LDD often emerges as the default explanation for population structures. If populations appear related, despite a clear physical barrier (e.g., an ocean separating populations of the same species on two continents), LDD is often hypothesized to be the process causing the observed population structures (60, 184–187) (Fig. 4).

As discussed previously, when LDD is inferred from genetic data, the mechanism of LDD remains unknown. Natural vectors, especially wind, are typically invoked as an explanation, but the literature on vicariance and LDD may provide strong indirect evidence for the role humans play in mediating dispersal across extreme physical barriers, e.g., oceans and mountain ranges. This hypothesis is seldom discussed, but the inability of physical and/or genetic data to explain contemporary population structures for many species is highly suggestive of humans playing an expanding role in fungal LDD (20, 129, 131). As the entire field of invasion biology attests, there are different dynamics at play when humans become involved in mediating dispersal (188). Technology (e.g., commercial aircraft, ocean vessels, etc.) facilitates the movement of goods, and in recent times the spatial and temporal scales of potential fungal dispersal have clearly amplified. Understanding whether apparent gene flow is a function of changing human behaviors, and not part of an autonomous pattern more typical of the past thousands or millions of years, would usefully inform our understanding of, e.g., disease and changing patterns of biodiversity.

CONCLUSIONS: UNANSWERED QUESTIONS AND FUTURE DIRECTIONS

Many unanswered questions remain, including, What shapes the end stages of successful LDD (defined as the

Figure 7 Images of spore dispersal structures among fungi. (**A**) Basidiospores of *Lentinula edodes* carried vertically by evaporative airflows from mushroom cap (Fig. 1e of reference 174). growth and reproduction of an individual following its dispersal) (Fig. 1)? Dispersal can mitigate intraspecific competition and parent-offspring conflict, but dispersal to new habitats also involves demographic risks, e.g., the lack of mates, inbreeding depression, and other problems of small populations. Difficulties may be especially acute for individuals establishing at the tail end of a dispersal kernel. Other unanswered questions include, Which characteristics have evolved in some fungi to optimize the likelihood of LDD, and do some fungi take advantage of stochastic meteorological events, e.g., storms, or other local environments, to facilitate LDD?

Our definition of fungal LDD simplifies comparisons among species because it provides a relative measure of LDD for any species under consideration. LDD may involve tens of meters (e.g., a soil yeast) to kilometers (e.g., a smut fungus), and exact scales depend on the measured dispersal kernel for any given fungus. While our definition does not explicitly account for differences in the number of propagules found in, e.g., a mushroom, an infected plant, a field, etc., theoretically, a well-defined dispersal kernel will scale proportionately with the number of spores released. But whether the concentration of spores at a source affects the shape of a fungal dispersal kernel remains an open question. Greater numbers of spores may change the shape of a kernel if more spores increase the likelihood of, e.g., clumping, spore-to-spore wind entrainment, and wet deposition.

As global change affects the current ecological ranges of species, and biological materials continue to be moved on a global scale, defining LDD and understanding the mechanisms by which it occurs emerge as key research priorities. Fungal LDD has the potential to impact international food security and public health, as witnessed by emerging threats to soybeans in the United States and increasing cases of mucormycosis across the globe (132, 189–192). Human-mediated dispersal may drive current fungal LDD (cf. 28), though mycologists seem reluctant to mention the likely role of humans as dispersal agents. A mushrooming realization of the breadth of fungal biodiversity suggests that much is still to be learned about fungal dispersal.

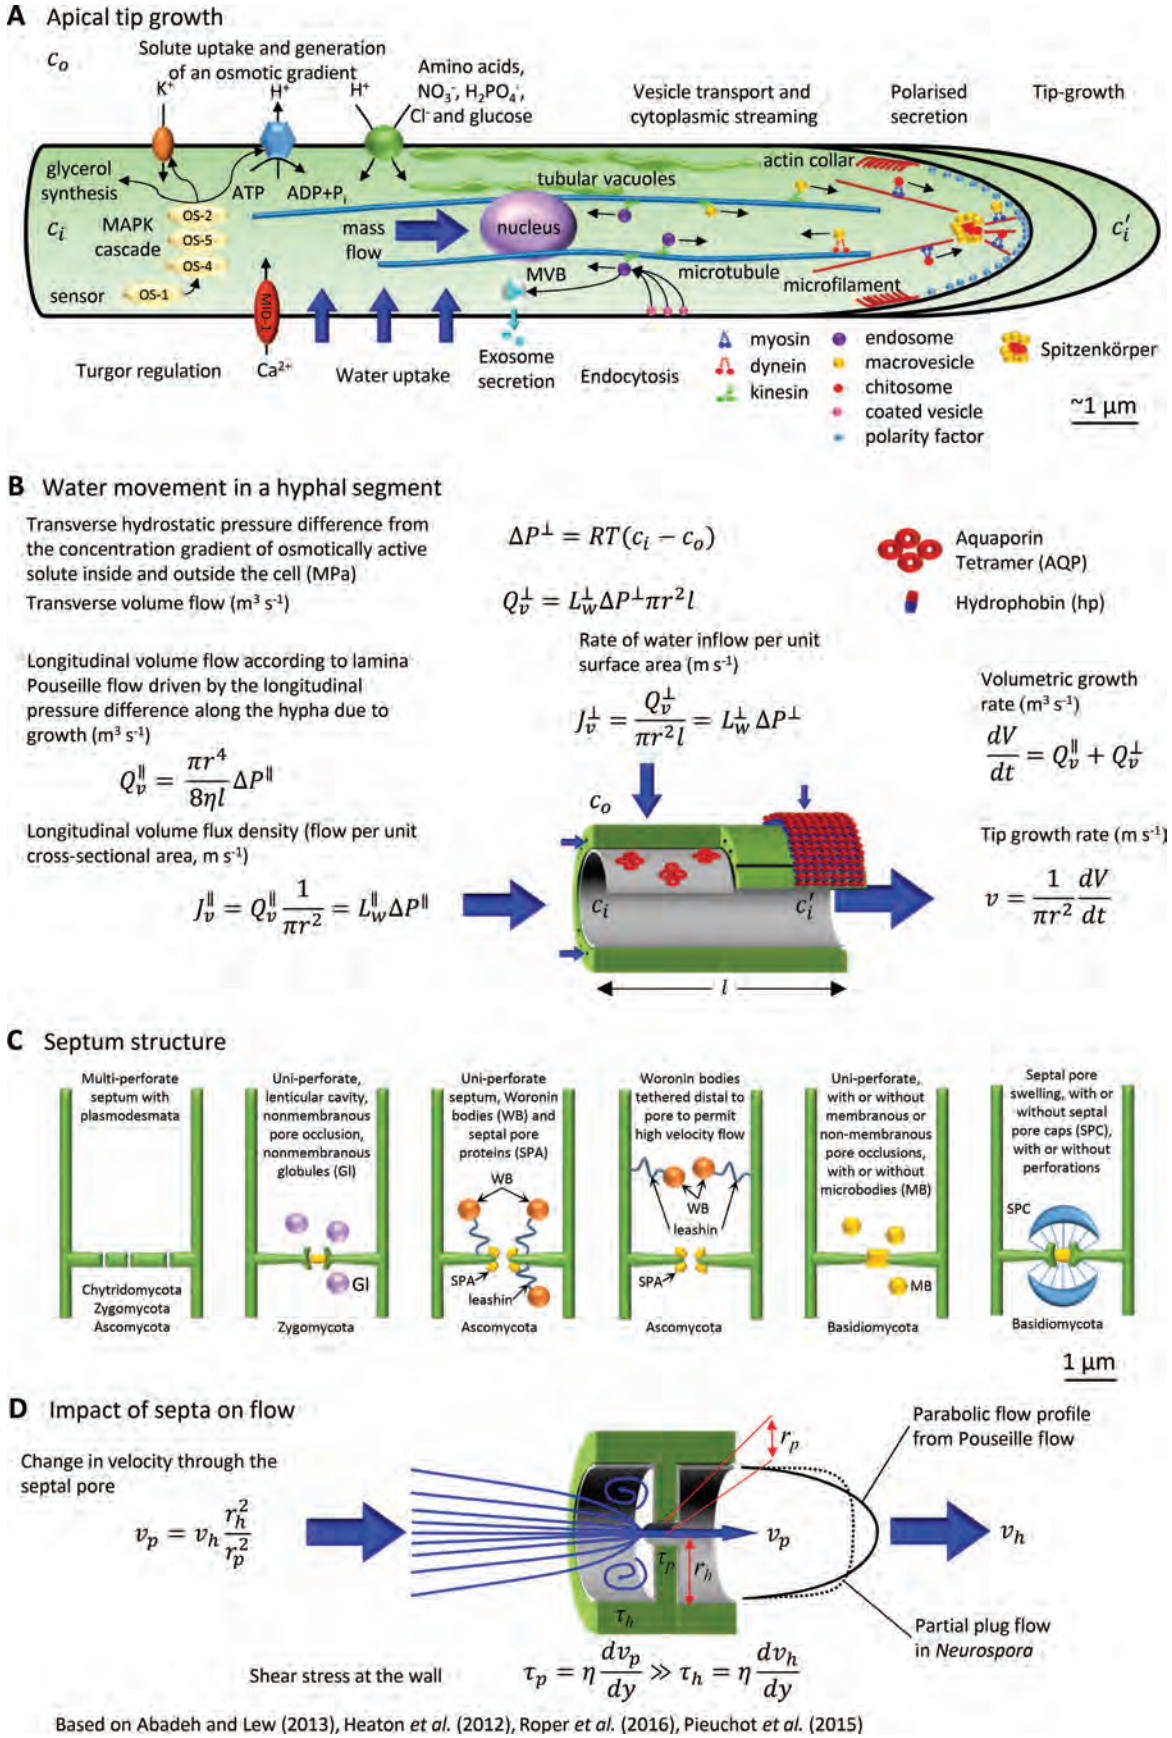
The Mycelium as a Network

15



Mark D. Fricker,[1] Luke L. M. Heaton,[1,2]
Nick S. Jones,[2] and Lynne Boddy[3]

INTRODUCTION

Growth as an interconnected mycelial network is characteristic of filamentous fungi and has been subject to scientific investigation since the seminal works of Buller at the start of the 20th century (1–3). We have increasingly detailed understanding of the fundamental cellular processes needed to form a network, such as hyphal tip growth (4), septation (5, 6), hyphal orientation (7), branching (8), and fusion (9–13) (Fig. 1A and C). In contrast, we know far less about the molecular events at the next physical scale that leads to hyphal aggregation and hyphal differentiation, and how these impact physiological processes such as long-distance resource distribution and biomass recycling. For example, while direct uptake and intrahyphal nutrient diffusion may be sufficient to sustain short-range local growth when resources are abundant (14), long-distance translocation is required to deliver nutrients at a sufficient rate to growing tips, particularly in fungi that form large networks on the forest floor that are too large to distribute nutrients through diffusion alone. We know little about the quantitative contribution of different potential transport pathways, such as cytoplasmic streaming, vesicle transport, growth-induced mass flow, or evaporative mass flow, to net fluxes and overall nutrient dynamics, and how they might vary between species and developmental stage (15–17). Nevertheless, the behavior of the growing mycelial network emerges from the interaction of many such processes and requires an integrated view to understand the overall impact on fungal behavior (18–20). Our understanding is further constrained by inferences drawn from a limited number of genetically tractable model filamentous species grown under laboratory conditions (abundant, evenly dispersed, low-molecular-weight resources, high relative humidity, constant light and temperature) compared with real-world conditions (patchy, recalcitrant, ephemeral resources, fluctuating temperature, light and relative humidity).

At the whole-colony level, there is a wealth of observational data describing fungal behavior (usually of non-model but ecologically relevant species) in qualitative terms, and some progress has been made in quantitative measurements of network architecture and dynamics, in parallel with development of predictive models for network function (21–33). The challenge is to construct a framework that can integrate information across scales into a coherent model to explain fungal behavior. We start this construction process by considering the biophysical properties of the mycelial network at each scale, with particular emphasis on the interplay between the network architecture and transport of resources through the network. Most of our knowledge on network structure and dynamics comes from non-resource-unit-restricted (i.e., fungi that can extend as mycelia from their food source) wood decay basidiomycetes that forage on the forest floor for resources distributed heterogeneously in space and time (34–36). We focus on these for discussion here for this reason, and because mycorrhizal networks have been comprehensively reviewed recently (37, 38). We also examine advances in image analysis techniques to extract the network architecture, empirically based modeling and simulation techniques to predict network behavior, and experimental approaches to map the actual functional flows within the network. We finally explore how network concepts may help to define a new set of fitness traits that can be experimentally determined (39).

THE BUILDING BLOCKS FOR NETWORK CONSTRUCTION

Growth at the Hyphal Tip

The mycelial network comprises individual hyphae ranging from about 2 to 20 μm in diameter that grow by tip expansion following highly localized polar secretion of wall materials (4) (Fig. 1A). Secretory vesicles are transported to the apical cell wall using a combination of microtubule and microfilaments, powered by molecular motors such as kinesin, dynein, and myosin (4, 40–42). Excess membrane is then recycled locally by endocytosis or sorted more extensively by motile early endosomes distal from the tip (40, 41, 43). Early endosomes may also play a role as a general transport system for other cellular components, such as ribosomes and mRNA (40, 44).

Motor-driven transport of vesicles and organelles concomitantly generates cytoplasmic streaming that serves to increase the effective transport rate for solutes and other cytoplasmic components (40). This is important because the synthesis of sufficient new wall material for maximal growth requires a minimum volume of cytoplasm distal to the tip (see "Modeling tip growth and branching" below) which has to be supplied by nutrient uptake and transport, often remote from the tip (42). Synthesis starts with accumulation of external ions, sugars, and amino acids present in the soil or following breakdown of organic substrates, using proton-coupled cotransporters or in response to the membrane potential via ion channels (Fig. 1A). The low intracellular water potential from solute accumulation leads to water uptake, which is required for the increase in hyphal volume during growth, and also leads to an increase in turgor pressure. Turgor is sensed by the conserved high-osmotic glycerol (HOG) mitogen-activated protein (MAP) kinase cascade and regulates plasma-membrane ion transport (Fig. 1A). In addition, osmolytes such as glycerol, arabitol, other polyols, proline, or trehalose may be synthesized internally to maintain turgor (45, 46). Stretch-activated plasma-membrane channels, such as Mid1, may respond directly to membrane stretch and also regulate solute uptake (Fig. 1A). For most fungi, some minimum turgor pressure is required for tip extension, but turgor pressure *per se* does not appear to be rate limiting for normal growth, because hyphae experiencing different turgor pressures can grow at the same rate. Indeed, some fungus-like oomycetes and wall-less fungal mutants can grow in the absence of turgor pressure, when the cytoskeleton alone may be sufficient to drive the tip of the hyphae forward (41, 47–50).

Transport at the Tip

Several parallel systems contribute to solute and organelle movement within the apical and subapical com-

Figure 1 Mycelial network formation: tip growth and fluid flows. (**A**) Hyphae grow by extension at the tip through polarized secretion of wall materials from macrovesicles and chitosomes at the apex, choreographed by the Spitzenkörper. Membrane is recycled distal to the tip into early endosomes by endocytosis. Endosomes may also form multivesicular bodies (MVBs) that may be involved in unconventional secretion of exosomes. Transport of secretory vesicles, endosomes, and other organelles along microtubule and microfilament networks also generates cytoplasmic streaming within the apical compartment. Although wall plasticity controls hyphal extension, the driving force involves maintenance of sufficient turgor pressure by water uptake through osmosis in response to accumulation of solutes. Turgor pressure may be sensed and regulated by a mitogen-activated protein kinase (MAPK) cascade or stretch-activated channels, such as mid1. If the site of water uptake required for the volume increase during growth is distal to the tip, growth-induced mass flows will also help to move organelles and solutes toward the tip. Based on references 4, 43, 49, and 64. (**B**) Water uptake into the hypha occurs to allow tip expansion and is driven by the transverse hydrostatic pressure in response to the difference in concentration of osmotically active solutes between the medium and the hypha. The transverse hydraulic conductivity depends on the permeability of the plasma membrane and aquaporins (AQPs) in parallel, and the wall and other surface layers, such as hydrophobins, in series. Longitudinal flow in the lumen of the hypha is lamina and follows Poiseuille flow. Based on references 32, 33, 49, and 79. (**C**) Variation in septal pore structure in different fungal taxa. Redrawn from reference 96 with permission. (**D**) Impact of the septa and septal pores on fluid flows. The change in cross-sectional area causes an increase in velocity by several orders of magnitude and also increases the wall shear stress within the pore. Flow may deviate from parabolic profile expected from the Hagen-Poiseuille equation because of the density of organelles in the cytoplasm. In addition, there may be eddy currents near the pore opening that trap nuclei, vacuoles, and other organelles. Based on references 32, 65, 68, and 69.

partments. In all systems, solutes will move by diffusion through the cytosol (51, 52) or the dynamic tubular vacuolar system (53–55), and this may be sufficient to allow bidirectional source-sink nutrient movements in slow-growing species (56), particularly as diffusion is constrained effectively to one dimension within the hyphae (52, 53), or "non-translocating" species that do not show protoplasmic streaming (57). For example, the time (t_D) for a species j to diffuse length l scales as l^2/D_j. Thus, ions and small molecules with a diffusion coefficient (D_j) of 1 to 2×10^{-9} m^2 s^{-1} would transit a typical apical compartment in *Phanerochaete velutina* (400 μm) in ~2 min, while proteins, with a diffusion coefficient of 2×10^{-11}, would take ~2 h. Transport over a small colony (10 mm) would take 20 h for small molecules and 7 weeks for proteins, and over a 25-cm microcosm transport would take 1.5 and 100 years, respectively. In practice, macromolecules are unlikely to have to move across the whole colony diameter, because transcription, translation, and localization in the case of proteins, or synthesis, packaging, and vesicle delivery in the case of wall components, are spatially localized on a much shorter length scale. Nevertheless, there is some evidence for long-distance protein translocation during fruiting in *Agaricus* (58).

In comparison with diffusive movement, motor-driven organelle transport can provide constant velocity transport in both directions over medium-length scales (millimeters to centimeters) both for the cargo transported, and also the bulk cytoplasm that becomes entrained (40). Fungi have some of the fastest microtubule motors known (1 to 4 μm s^{-1}) (59), while myosin V in yeast transports secretory vesicles at ~3 μm s^{-1} (44, 60). The maximum speed at which motors can move also places an upper bound on the velocity that can be achieved by motor-driven movement to approximately 4 μm s^{-1} (14.4 mm h^{-1}) (61). Actin-myosin-based cytoplasmic streaming in other systems, such as pollen tubes, can reach higher velocities, typically 40 to 60 μm s^{-1}, and reaching 100 μm s^{-1} with myosin XI in characean algae (62), but such high-speed motors do not seem to operate in fungi. The energetic costs of motor-driven movement would be expected to scale with the length of the transport pathway, particularly the cost of assembling the microfilament and/or microtubule tracks, the size of vesicles or organelles transported, the speed of movement, and the cytoplasmic viscosity (62). There are no quantitative estimates in fungi to our knowledge, but it is likely that the energetic costs are excessive, particularly in comparison with mass flow (see below). Nevertheless, this rate of movement may well be sufficient for species that do not forage far beyond their food resource, termed resource-restricted or non-translocators (57, 63), or for mycorrhizal fungi that have access to an abundant and consistent supply of carbon/energy from the host plant.

In addition to motor-driven transport, passive movement of solutes and organelles, such as vacuoles and nuclei toward the tip, can occur through mass flow of cytoplasm arising from a combination of expansion of the apical cell wall to create new volume, and subapical uptake of water and solutes (32, 33, 64–68), termed growth-induced mass flow (see Fig. 1B, 2B, and 3) (33). Quantitative microscopic measurements have been made on *Neurospora* hyphae, which have a relatively large diameter and grow at a maximum rate of 1 μm s^{-1} equivalent to 3.6 mm h^{-1} (69), thus capturing the fastest local transport events required for tip growth in any species. Injection of oil droplets, which cannot interact directly with motors and the cytoskeletal system, provides direct evidence for growth-induced mass flow, as the rate of movement (about 5 μm s^{-1}) exceeds the rate of tip extension (0.2 to 0.5 μm s^{-1}) in these experiments (66). The actual velocity expected for mass flow depends on the number of downstream tips (Fig. 2B; see "The impact of branching on transport" below). Likewise, nuclei, vacuoles, and mitochondria in apical compartments all migrate toward the growing tips at the same or greater rate than the tips extend (64, 66–68). Such movement would be consistent with mass flow driven by the continuous subapical water influx required to sustain volume increases at the tip during growth.

The time (t_A) taken for solutes or organelles to advect a distance l at velocity v is l/v, while the relative importance of advection compared with diffusion is given by the Péclet number, $t_A/t_D = vl/D_j$ (62). Advection dominates if this ratio is greater than 1, while diffusion dominates if this ratio is less than 1. Thus, the Péclet number for the apical compartment of *Neurospora* growing at 1 μm s^{-1} is approximately 0.3 for solutes and 20 for proteins. An alternative measure considers the length scale for localization of macromolecules, such as proteins and mRNA, depending on diffusion, advection, and their lifetime () before degradation (65). Thus, localization scales as $\sqrt{D_j}$ if diffusion and degradation dominate, v if flow and degradation dominate. The ratio $C = \sqrt{D_j/v^2}$ of these two distances is a dimensionless number. If $C > 1$, then most transport occurs by diffusion, and if $C < 1$, then most transport is by flow (65).

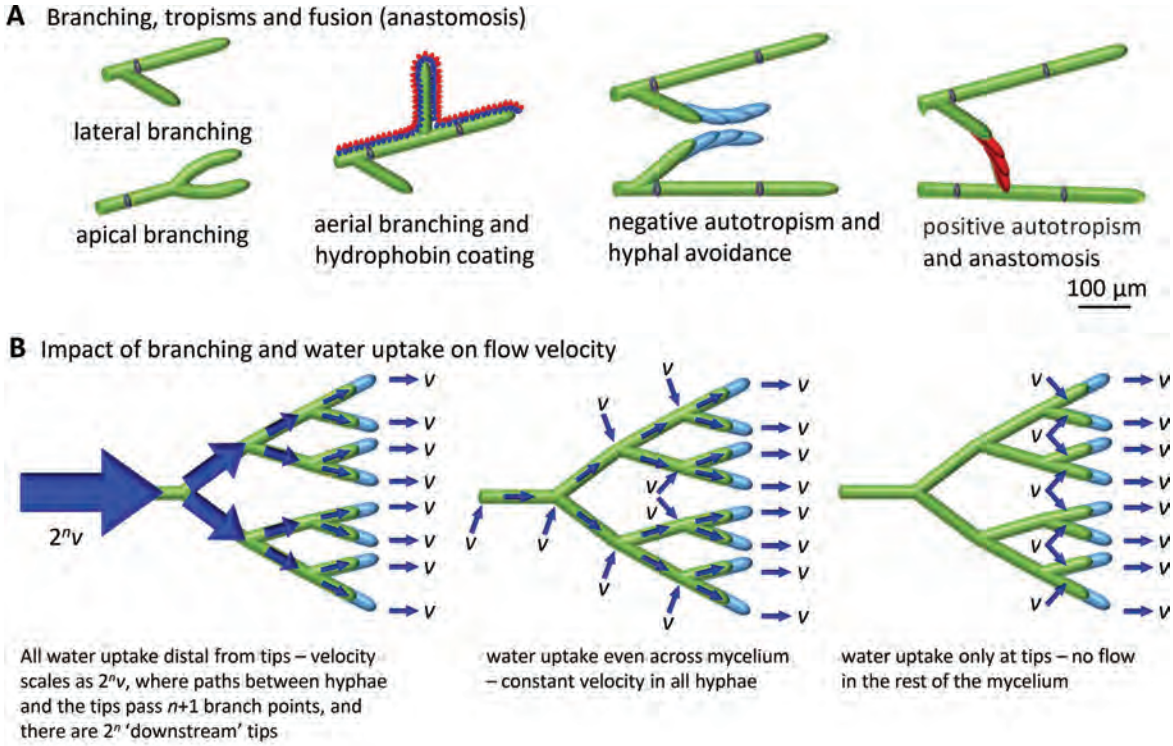
Water Permeability and Water Uptake

The extent to which longitudinal mass flow occurs is critically dependent on precisely where water influx

occurs in the colony. In principle, water could be taken up anywhere along the hyphae, but the actual site of uptake has profound implications for the magnitude and direction of internal mass flows. A second critical observation is that regardless of intrahyphal concentration gradients and turgor pressure resulting from solute accumulation, mass flow only takes place when water is able to exit the translocation pathway. A range of possible routes exists through either localized exudation (70–73), hydraulic redistribution to soil with lower water potential (74), evaporation during fruit body formation (e.g., *Phycomyces* sporangia) (75), coupling to the plant evapotranspiration stream in mycorrhizas (76), or by moving into a region of new growth (33, 66).

Fungi have a particular challenge to maintain a balanced water economy to allow water uptake for growth, while preventing excess evaporation from their extensive surface area. Equally, controlled evaporation may drive solute movement into aerial hyphae (75) and evaporative cooling may be required to aid spore dispersal by establishing convection currents (77), or through formation of "Buller's drop" by condensation (78). The plasma membrane provides some impedance to water movement, with permeability dependent on the lipid composition and temperature (79). Thus the osmotic permeability (P_f) of the plasma membrane in yeast mutants lacking aquaporins (AQPs) increases from 0.34 μm s^{-1} at 7°C to 2 μm s^{-1} at 23°C (80), equivalent to a plasma membrane water hydraulic conductivity coefficient ($L_w^{pm} = P_f V_w / RT$) of ~2.5 to 15 × 10^{-15} m s^{-1} Pa^{-1}. It is worth noting that these values are 1 to 2 orders of magnitude lower than plant and mammalian cell membranes at the same temperature. Indeed, the presence of ergosterol in fungi, rather than cholesterol in other organisms, may be linked to greater resistance to desiccation (81, 82).

The presence of AQPs (Fig. 1B) also significantly increases water permeability in parallel to the lipid bilayer. For example, overexpression of AQPs in yeast increased P_f by 9-fold at 7°C. Likewise, expression of AQPs from the filamentous mycorrhizal fungus *Laccaria bicolor* in *Xenopus* oocytes increased the membrane permeability to up to 147 μm s^{-1} (83). Whereas the precise role of AQPs in water uptake has not been resolved, AQPs do appear to be critical in hydraulic coupling during fruiting and between mycorrhizal fungi and the host plant (84–86).



In both plant and animal systems there is also evidence for movement of water against the free energy gradient by chloride/cation cotransporters (CCC) (87, 88). CCC sequences are present in fungal genomes, but their role in fungal water economy has not been investigated to date. Nevertheless, this presents the interesting possibility that the low intrinsic plasma membrane water permeability in fungi, particularly at temperatures typically encountered in soils, might allow much greater regulated spatial control of the water economy through the localization and activation of aquaporins and CCC water pumps.

Hydrophobins and Control of Water Loss

To restrict water loss, many mycelia produce small (15 kDa) secreted cysteine-rich hydrophobin proteins that self-assemble to form a rodlet layer, particularly on aerial hyphae (Fig. 1B and 2A), and increase the hydrophobicity of the surface, thus restricting water movement (89–91). One benefit of using hydrophobins to reduce evaporation is that their intrinsic organization varies with water availability, with no additional sensing or control other than their synthesis and secretion, allowing them to function autonomously outside the cell. Nevertheless, hydrophobins represent an expensive investment of scarce nitrogen resources, particularly as the cost of forming a functional barrier scales with the surface area of the hyphae covered. Thus, in more mature systems and multihyphal aggregates, hyphal walls tend to be impregnated with other compounds, such as melanin and phenolics, to reduce water evaporation and act as protection against damage and fungivores (92). Species vary in the extent of hyphal hydrophobicity, and this characteristic has been used to group mycorrhizal species as hydrophobic or hydrophilic (73).

In addition to chemical impregnation, there are biophysical constraints on water evaporation through the wall interstices depending on the diameter of pores in the cell walls generating a matric potential. There are few measurements of pore size in fungi, but in the water mould *Achlya* a value of 2 nm was determined experimentally (93). If terrestrial fungi have similar values, this would restrict evaporation, even at low external relative humidity, depending on the radius of the pores and wettability of the walls (79). While the role of matric potentials is well understood for the soil-plant-atmosphere continuum (79), we are only at the beginning of understanding water fluxes through the more complex soil-mycorrhiza-plant-atmosphere or soil-saprotroph-atmosphere systems (76, 94).

Insulating the hyphal wall leads to secondary problems on how the fungus can then sense the external chemical environment, how enzymes needed to decompose organic resources can be delivered, and how the products are then absorbed. Interestingly, there is evidence that enzyme delivery may be mediated by

The Impact of Septation on Transport

In Dikarya, after a period of growth, the apical cell divides to establish a series of septal compartments that retain cytoplasmic continuity through the septal pores (Fig. 1C). Septa exhibit a variety of pore structures from narrow plasmodesmatal connections or simple uniperforate pores, to pores with associated Woronin bodies or other pore-occluding structures in the Ascomycota, and the more complex septal pore caps in the Basidiomycota (Fig. 1C) (96). The pore size ranges from 10 to 70 nm in the case of plasmodesmata and from 50 to 500 nm for most other pore types but is often partially occluded by electron-dense material (6, 96). Septal pores allow the passage of nutrients, macromolecules, and organelles between septal compartments. In some species, nuclei can also migrate through the septal pore (67, 69), while in the basidiomycetes, nuclear movement in heterokaryons is strictly controlled through the formation of clamp connections adjacent to the septum. The pore may be blocked reversibly or irreversibly by Woronin bodies (WBs) and septal pore associated (SPA) proteins in ascomycetes, or the septal pore cap (SPC) and its various elaborations in basidiomycetes (6, 97). Interestingly, the precise positioning and tethering of WBs have recently diverged in the Pezizomycotina, with more distal anchorage in rapidly growing species such as *Neurospora* (Fig. 1C), regarded as an adaptation to prevent accidental pore occlusion as high flow velocities sweep the WBs into the pore (98). While pore occlusion has a role in preventing loss of cytoplasmic contents after damage (6), there is increasing evidence that pore closure (99) or opening (100) can occur as part of a developmental sequence, and closure may be reversible depending on environmental conditions (101).

Even when open, the septal pore places an interesting constriction on fluid flow between septal compartments (Fig. 1D). The velocity of flow through septal pores (v_p) increases in proportion to the relative area of the pore to the cross-sectional area of the hypha (r_h^2/r_p^2), with experimentally measured velocities in excess of 200 μm s^{-1} in *Neurospora* (69), sufficient to restrict backward diffusion against the flow (65). Various organelles also accumulate in local eddies adjacent to the septa and, in the case of nuclei, appear to alter their protein complement as a result (69). Indeed, accumulation of secretory vesicles at septa may also be part of the trigger initiating branch formation (102, 103).

Fluid flows induce wall shear stresses, and in the case of laminar flow, the wall shear stress τ produced can be estimated using the formula $\tau = 4\eta v/r$, where η is the dynamic viscosity of the fluid, v is the mean velocity of fluid flow, and r is the radius of the vessel (104). In the typical case where the fungal cytoplasm has dynamic viscosity of 2 g s^{-1} m^{-1} and the hypha has a radius of 6 μm, the wall sheer stress is $\tau = v \times 10^{-3}$, where τ is measured in Pascals and v is measured in μm s^{-1}. By way of comparison, the wall shear stresses in mammalian arterial systems are in the range of 0.2 to 2 Pa, and it is known that stresses of that scale induce changes in gene expression (105). Hence, it is plausible that a 6-μm-radius hypha could detect and respond to internal velocities of the order of 1 mm s^{-1}, but along the length of most hyphae the wall shear stress will be negligible. However, because the mean velocity of fluid flow is inversely proportional to cross-sectional area, and wall shear stress is proportional to the velocity

Figure 2 Mycelial network formation: branching, fusion, and multihyphal aggregate formation. (**A**) Hyphae may branch subapically or by tip splitting to explore the substrate or to form aerial hyphae that are often insulated by hydrophobins. At the colony margin, tips avoid each other, while secondary branch hyphae in the colony interior can show positive autotropism and fuse by anastomosis. (**B**) The velocity of mass flow within the network depends critically on the site of water uptake for growth. If all water uptake is distal from the tips, the velocity scales in proportion to the number of downstream tips. If uptake is equal everywhere, the flow rate is constant at the speed of hyphal extension, while if uptake is solely at the tips, there is no long-distance movement. Based on references 32 and 33. (**C**) Schematic representation of the formation of strands, cords, and rhizomorphs, showing progressive differentiation of vessel hyphae as potential conduits for long-distance transport. Scale bars are approximate. Based on references 127, 129, 134, 228, and 265. (**D**) Schematic representation of how circulating fluid flows might operate within a hyphal cord. Acropetal mass flows would take place in the vessel hyphae in response to growth, evaporation, or exudation at the tips, while basipetal flows take place simultaneously through cytoplasmic hyphae by cytoplasmic streaming. Redrawn from reference 17 with permission.

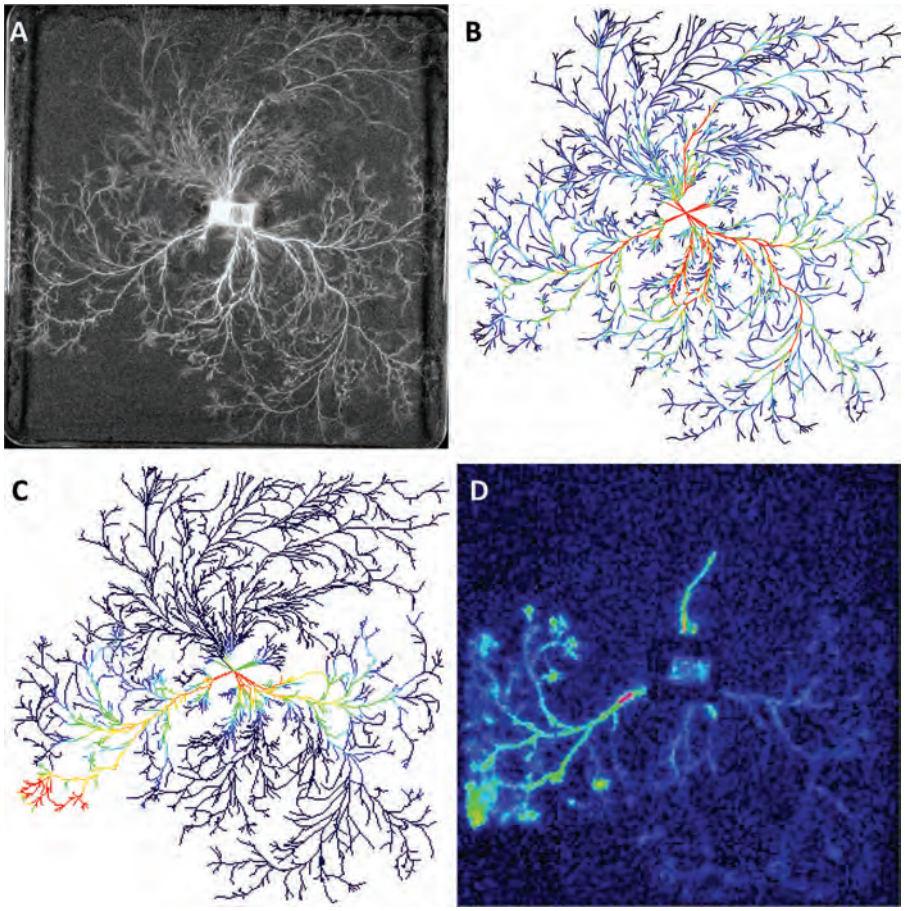

Figure 3 Growth-induced mass flows explain long-distance nutrient movement in *Phanerochaete velutina*. (**A**) Structure of the mycelial network after 21 days growing from a wood resource across compressed black sand. (**B**) The network architecture is extracted using intensity-independent, phase-congruency tensors and watershed segmentation from experimental time series. The output is a set of weighted adjacency matrices of the length, width, and volume of each cord. In this image, the cord width is pseudo-color coded from 50 μm (blue) to 500 μm (red). (**C**) The network structure and growth are input into a biophysical advection/diffusion/delivery (ADD) model, using growth-induced mass flow to predict the pattern of resource translocation. The predicted amount of radiolabel is color coded on a rainbow scale from blue (zero) to red (maximum). (**D**) The actual pattern of nutrient movement is then determined experimentally by using the nonmetabolized amino acid analogue ^{14}C-amino isobutyrate (^{14}C-AIB) and photon-counting scintillation imaging (PCSI). The amount of ^{14}C-AIB is color coded on a rainbow scale from blue (low) to red (high). The ADD model of growth-induced mass flow predicts the distribution of radiotracer in a complex network of fungal cords with a Pearson correlation coefficient 0.56. From Heaton et al. (32) with permission.

gradient at the wall, wall shear stress at the septal pore will be approximately r_h^3/r_p^3 greater than the wall shear stress elsewhere (where r_h and r_p are the radii of the hyphae and pore, respectively). This means that even the modest flows that have been measured in fungi can be expected to produce physiologically significant mechanical forces at the septal pore. Indeed, the scale of those forces can be estimated by measuring the elasticity of the cell wall and the amount of deflection that occurs during transient pore plugging, and in *Neurospora crassa* it has been calculated that the deflection-associated pressure difference is as large as 2 bar (69). Also note that the above equations somewhat underestimate wall shear stress, because the velocity profile deviates from the parabolic profile expected from Poiseuille flow due to the high density of organelles

moving within the fluid (68). This analysis suggests that septal dissolution, branching, and other aspects of hyphal development may be directly influenced by the relative scale of flows within the hyphae (33), because the mechanical forces are large enough to degrade septa (69), and it is also plausible that fluid flows could be detected by proteins located at the septal pore, leading to flow-dependent changes in the pattern of gene expression.

Modeling Tip Growth and Branching

The number of growing tips at the colony margin increases by apical or subapical branching and daughter hyphae typically show avoidance behavior (negative autotropism, Fig. 2A) regulated by the Cdc42 signaling pathway (7, 106) to increase exploration of the substrate (Fig. 2A). The fact that fungi grow by apical extension, although intercalary growth has been observed (107, 108), implies that there is a fundamental relationship between the overall colony growth rate and the branching rate. This relationship can be clarified by letting A denote the mean cross-sectional area of individual hyphae, $N(t)$ denotes the number of hyphal tips at time t, $g(t)$ denotes the specific growth rate of the colony (that is, the rate of change of volume per unit volume of fungus), and $v(t)$ denotes the mean velocity of hyphal tips. If all growth is due to apical extension, it follows that the mean volumetric growth rate of an individual tip is $Av(t)$, and the total volumetric rate of growth $\frac{dV}{dt} = V(t)g(t) = AN(t)v(t)$. It follows that:

$$N(t) = \frac{V(t)g(t)}{Av(t)} \quad (1)$$

When the specific growth rate g and the mean velocity of hyphal tips v are constant, the rate of change of the number of tips is:

$$\frac{dN}{dt} = \frac{\frac{dV}{dt}g}{Av} \quad (2)$$

Equations 1 and 2 imply that when the specific growth rate g and velocity of hyphal tips v are constant, we have:

$$\frac{\frac{dN}{dT}}{N} = \frac{\frac{dV}{dt}}{V} = g \quad (3)$$

Note that the number of tips is increased by each branching event and decreased by each fusion (anastomosis) event, so we cannot conclude that the branching rate is simply equal to the specific growth rate g. Nevertheless, it is reasonable to assume that the branching rate is only slightly larger than the specific growth rate g, which is a claim that has empirical support (102, 109). If the branching rate is equal to the specific growth rate, there must be a constant relationship between the volume of hyphae and the number of hyphal tips. In 1959, Plomley (110) observed that exponential colony growth requires continual branching, and he speculated that when a species is growing exponentially, there is a constant volume of fungus per hyphal tip termed the "hyphal growth unit." This is the key concept behind the mathematical models of hyphal growth developed in the 1970s (102, 109, 111–113), which recapitulate the experimental observation that the velocity of hyphal tips is initially proportional to the volume per hyphal tip (e.g., reference 69). Thus, the rate of germ tube extension is initially exponential as the increasing volume of cytoplasm provides more vesicles per tip. As the colony grows, the rate of vesicle delivery reaches a maximum and the mean tip velocity approaches a constant as a result, obtaining a value for the hyphal growth unit that is characteristic of the species in the given environment and manifest at a colony level as the width of the peripheral growth zone (111).

Linking Growth and Branching to Nutrient Status

Like all organisms, fungi require a source of energy and nutrients to sustain growth, and so the specific growth rate and branching rate of fungi must be smaller for fungi that grow on substrates that are recalcitrant or nutrient poor (114, 115). This kind of energetic constraint on fungal growth has implications for the optimal allocation of resources toward vegetative growth, the production of digestive enzymes, and the production of spores (31). Any successful model of hyphal growth must recapitulate the fact that nutrient availability enables growth, and rapid growth is associated with rapid branching. However, because of the difficulty of observing fungal growth and a lack of understanding of the control of branching, there are few statistics concerning the location of branching events in a growing fungus (116). On a macro scale, models of the branching process generally make the reasonable assumption that branching is more likely to occur in regions with a higher density of tip-growth vesicles (29, 102), which may occur when vesicles are too far downstream of the apex to be able to contribute to growth of the apex itself and are therefore diverted to form a new growing tip (102, 117). On a micro scale, it has been suggested that branching is associated with septa because vesicles may accumulate around septal pores (102, 103, 109, 117). However, it is not known wheth-

er, all else being equal, younger hyphae are more likely to branch, or whether hyphae that carry relatively large mass flows are more likely to branch.

Hyphae can also form in older parts of the colony by secondary or lateral branching, to an extent dependent on the species, the medium of growth, and other environmental factors (8, 118, 119), but there are significant differences in the cellular mechanisms involved in apical and secondary tip formation (120). Watters et al. (121) demonstrated that the distribution of distances between adjacent branch points is independent of tip extension rate in *N. crassa* at a range of temperatures. However, following a sudden increase in temperature (and metabolic rate), there is a transient increase in branching rate, while, following a sudden decrease in temperature, hyphae produce an unusually long branch interval (122). These observations are consistent with the following four assumptions:

1. The rate of tip extension is proportional to the rate of vesicle deposition.
2. The rate of branching is proportional to the number of vesicles in the colony.
3. The rate of vesicle production is proportional to the metabolic rate of the colony, and this rate changes relatively rapidly when the metabolic rate is altered by changing temperature.
4. The rate of vesicle deposition at the tips is proportional to the metabolic rate of the colony, and this rate changes relatively slowly when the metabolic rate is altered by changing temperature.

If these plausible assumptions are correct, a sudden increase in temperature will increase the rate of vesicle production more quickly than it increases the rate of vesicle deposition, creating a transient increase in the density of vesicles within the colony, which produces an increase in the branching rate. Also note that, if the velocity of hyphal tips and the specific growth rate of a fungus remain fairly constant, the diameter of the fungal colonies will grow in a linear manner, while the volume of that same colony will grow exponentially. This implies that the density of the fungal growth will increase, although at some point population effects will start to inhibit growth because, in the dense core of the colony, the concentration of inhibitory waste products will be relatively high and there will be relatively few nutrients or space to enable further growth.

The Impact of Branching on Transport

Branching reduces the radial distance that can be supplied by diffusion alone (53), but has no effect on the velocity of motor-driven transport, although the total flux is halved at each branch point. The extent to which branching affects organelle and resource distribution by mass flow depends on the site of water uptake (16, 32, 33). At one extreme, if water uptake only occurs at the initial inoculum, volumetric mass flow scales with the number of downstream tips that are growing (Fig. 2B). If water uptake takes place equally across the network and the cross-sectional area is constant, the velocity in each hypha matches the rate of growth, while, if all uptake takes place at the tips, there is no mass flow in the rest of the colony. In wild-type or the *so* mutant of *Neurospora*, which is unable to fuse and thus only grows as a branching tree (123), nuclear movement occurs predominantly by mass flow, and the rate scales with the number of downstream tips, reaching values of 5 to 20 $\mu m\ s^{-1}$ (67, 69), consistent with water uptake at the center of the colony or germinating conidium. Thus, in *Neurospora*, even though water is freely available in the substrate, uptake is highly spatially regulated to ensure high rates of longitudinal flow through the colony.

The Impact of Hyphal Fusion on Transport

Fusion may take place early in colony formation *via* conidial anastomosis tubes (CATs) that potentially link multiple conidia into a supracellular network (11–13). Secondary branch hyphae also develop in more mature regions when daughter hyphae typically show positive autotropism and fuse with neighbors to create a microhydraulic network with loops (7, 9, 11–13, 49). Fusion appears to be required for high rates of long-distance nutrient translocation, as the *so* mutant in *Neurospora* shows reduced radiolabeled amino acid movement (124). Nevertheless, loops are probably more critical in providing multiple pathways to improve network resilience and to allow rapid reallocation of resources in response to local demands. For example, lateral movement of radiotracers at the colony margin (125) probably occurs as a result of anastomosis.

Hyphal Differentiation and the Formation of Multihyphal Aggregates

In many species, there is some differentiation into leader or trunk hyphae and aerial hyphae at the colony margin (Fig. 2C). However, formation of linear hyphal aggregates, such as cords and rhizomorphs, only occurs to a lesser extent on agar, so there is comparatively little information on the development and internal structure of these organs from laboratory studies.

Cords form behind the front of apically extending hyphae, with the degree of hyphal aggregation within the growing front varying between species (126, 127).

Close to the growing front, both large- and smaller-diameter hyphae are normally present with many branches and anastomoses interconnecting both hyphal types. In corded systems, large-diameter hyphae are initially cytoplasmic, with progressive cellular disorganization and appearance of empty vessel hyphae with distance from the front (17, 128). In *Serpula lacrymans* narrow tendril hyphae emerge from the clamp connections and then branch and grow both acropetally and basipetally around neighboring hyphae (129). In more developed cords, cross sections at the light or EM level show further differentiation of thick-walled fiber hyphae and vessel hyphae, with diameters of approximately 10 to 15 μm, that are likely to improve flow (Fig. 2C). During early development, movement of radiotracers and fluorescent dyes appears to be restricted to particular routes that probably correspond to developing cords (125, 130–132), although tracking the internal connectivity has been rarely attempted. The size of the vessel hyphae can have an impact on the flow rate, which scales as r^4, but flow will be more critically dependent on the size of the septal pores and the extent of septal dissolution associated with cord formation (126, 127). Nevertheless, ectomycorrhizal cords of *Paxillus* have swollen clamp connections at the nodes that provide continuity with the branches, but only limited septal dissolution in the vessel hyphae (133).

Rhizomorphs are more highly differentiated root-like structures that extend from a meristematic-like region at the tip (Fig. 2C). They consist of a central lacuna surrounded by an inner medulla with large thin-walled vessel hyphae that form high-conductivity channels, an outer medulla containing loosely packed hyphae that are only about 2 μm wide, and a thick melanized, hydrophobic rind that insulates them from the environment. The longitudinal hydraulic conductivity ($L_w^{\parallel}$) through the cords varies from 1.5 to 3×10^2 cm^2 bar^{-1} s^{-1} (134). The hydraulic conductivity perpendicular to the hyphal axis ($L_w^{\perp}$) for such cords has not been measured, but is likely to be low.

Pressure-Driven Mass Flow on a Macroscopic Scale

The velocity of water movement in corded systems or rhizomorphs is vastly in excess of values that could be achieved by motor-driven movement, and initially led to the idea of pressure-driven mass flow as the major transport mechanism in foraging fungi (15, 135). Thus, estimates of water transport in *Suillus bovinus* were 27 cm h^{-1} (136), while measurements in *S. lacrymans* have a mean value of 148 cm h^{-1} (70). Likewise, a range of different solutes is transported in *Armillaria* at velocities in excess of 20 mm h^{-1} (137), in *Serpula* ranging from 10 to 50 mm h^{-1} (138) to 20 to 30 cm h^{-1} (135, 139), or 20 to 100 mm h^{-1} in *P. velutina* depending on the extent of cord formation (32, 33, 131, 132; Fricker et al., unpublished data). Similarly, even movement of larger organelles, such as nuclei, by mass flow can reach velocities of up to 4 mm h^{-1}, although there is wide variation in velocity between different hyphae in the network (67).

The magnitude of growth-induced mass flows has been empirically determined by measurements of network growth at the level of individual cords (Fig. 3A and B) (33), and input into an advection-diffusion-delivery (ADD) model to predict the pattern of resource translocation (Fig. 3C) (32). The actual pattern of nutrient movement was then determined experimentally using non-metabolized radiotracers and photon-counting scintillation imaging (PCSI; Fig. 3D). The ADD model of growth-induced mass flow is surprisingly effective at predicting the distribution of the amino acid analogue ^{14}C-amino isobutyrate (^{14}C-AIB) in a complex network of fungal cords (compare Fig. 3C with Fig. 3D). This is remarkable considering the conceptual simplicity of the biophysical model, and that there is essentially only one free parameter, the fraction of the cord that carries nutrient flow.

The magnitude and direction of mass flows can be altered by experimental manipulation of the external water potential, but it is also clear that, under natural conditions, the external water potential can have an impact on transport through the network. Thus, substantial water flow (18 cm h^{-1}) can be driven by hydraulic redistribution from moist to dry soil (74), or through hydraulic coupling to the host plant (27 cm h^{-1}) in the case of mycorrhizas (136, 140).

Biomass Recycling

As some hyphae expand and mature, other regions of the mycelium regress and their contents are recycled. In particular, there is extensive remodeling of redundant parts of the mycelium in larger mycelia grown from woody resources (see "Colony dynamics and behavior" below), presumably to redeploy resources to the growing margin to forage more efficiently in highly heterogeneous environments (14, 31, 56, 141, 142). Interestingly, in other systems, such as blood vascular networks and slime molds, recycling and network remodeling occur in response to flow rate (143), and there is evidence that a similar relationship between high flow and cord thickening, versus low flow and cord thinning, holds for fungi (33, 144).

At a molecular level, recycling probably involves autophagy and controlled apoptotic-like mechanisms, rather than necrosis (145, 146). Nevertheless, how decisions are made to trigger autophagy in particular hyphae are not clear, nor is it clear how the cytoplasm and wall materials are broken down and transferred to the growing front.

Bidirectional Movement and Oscillations

There is plenty of evidence for nutrient translocation from resources to the growing margin where they are needed for growth. However, in several systems, radiotracer measurements indicate that nutrients can move both acropetally and basipetally in the same colony or following colony fusion (125, 137, 138, 147–152). Bidirectional movement is likely to be critical to achieve mixing of spatially distributed food resources between constantly changing sources and sinks and therefore promote maximum colony growth in a heterogeneous environment, and may also contribute to colony-wide control of behavior (56). Over short length scales, diffusion and motor-driven transport may achieve transport at a sufficient rate, but responsive resource allocation in larger colonies requires mass flow. However, simultaneous bidirectional movement is difficult to explain based solely on pressure-driven mass flows, which would be expected to operate in one direction at a time, so models have invoked distinct pathways that involve acropetal mass flows in vessel hyphae and basipetal streaming in adjacent cytoplasmic hyphae (Fig. 2D) (17). In addition, some species, such as *P. velutina* (131, 132, 153), but not others, such as *S. lacrymans* (138) or *N. crassa* (124), show marked oscillations superimposed on the net transport. The origins of the oscillations are not known, but may represent a reciprocating transfer of material, rather than the continuous circulatory system shown in Fig. 2D. This is reminiscent, albeit at a much longer time scale, of the shuttle streaming in *Physarum polycephalum* that leads to efficient mixing within the plasmodium (154).

COLONY DYNAMICS AND BEHAVIOR

In discrete organic resources saprotrophic mycelial networks typically operate on a millimeter to centimeter scale, depending on the size of the resource and size of the genetic individuals. However, large individuals occupying extensive decay columns in tree trunks and branches operate over a larger scale. Furthermore, those fungi that are non-resource-unit-restricted extend from their main food base into the surrounding environment in search of new resources (Fig. 4 through 7), and often operate on the scale of meters. Thus, saprotrophic systems of mycelia cords and rhizomorphs cover several square meters to many hectares (Fig. 4) (135, 155, 156, 157). Currently, the largest recorded genet is of *Armillaria ostoyae* spanning 965 hectares, with a maximum separation of extending fronts of 3,810 m (157), although the extent of internal connectivity is unknown.

There is little information on mycelia networks within organic resources (see "Extension of network analysis to 3-D" below), except for the boundaries of territory occupied by individual mycelia, indicated by interaction zone lines (36). Likewise, little is known of the structure of networks of non-resource-unit-restricted fungi foraging in relatively homogeneous resources, e.g., fairy ring formers and colonizers of leaf litter patches (36). The latter are particularly interesting because they extend through the leaf litter layer as an ever-increasing annulus of mycelium, about 30 to 40 cm wide in the case of *Clitocybe nebularis*, differentiated into several distinct zones (158).

A wide variety of patterns of mycelial outgrowth from organic resources has evolved, ranging between slowly extending search fronts densely populated by hyphae, which are unlikely to miss new resources, e.g., *Hypholoma fasciculare*, to more rapidly extending but sparser systems, e.g., *P. velutina*, and at the furthest extreme *Armillaria* species. The slow-dense foragers are often considered short-range foragers, and have sometimes been termed "phalanx or phalangeal foragers" (34, 35, 159), by analogy with foraging of clonal plants that grow relatively slowly and have tight aggregated rosettes (160–163). The fast-effuse foraging, on the other hand, is often considered long-range foraging, and has been likened to "guerrilla" foraging of plants (clones of which have fast-growing branches that are loosely aggregated). Similar concepts have been developed for mycorrhizal networks that include short-range "contact exploration types" and "long-distance exploration types," where the mycelium is highly differentiated into strands (164). Other similar, but not identical, ideas have been put forward by plant ecologists, such as "clump" plants characterized by frequent branching at large angles and with short spacers, which exploit resources at a particular site, and "runners" with infrequent branching and long spacers, which explore more widely for resources (165, 166). Parallels have also been drawn between fungal and animal foraging (163, 167).

Perhaps the most dramatic alterations in mycelial network structure occur when new resources are discovered, either by a foraging mycelial front, or when

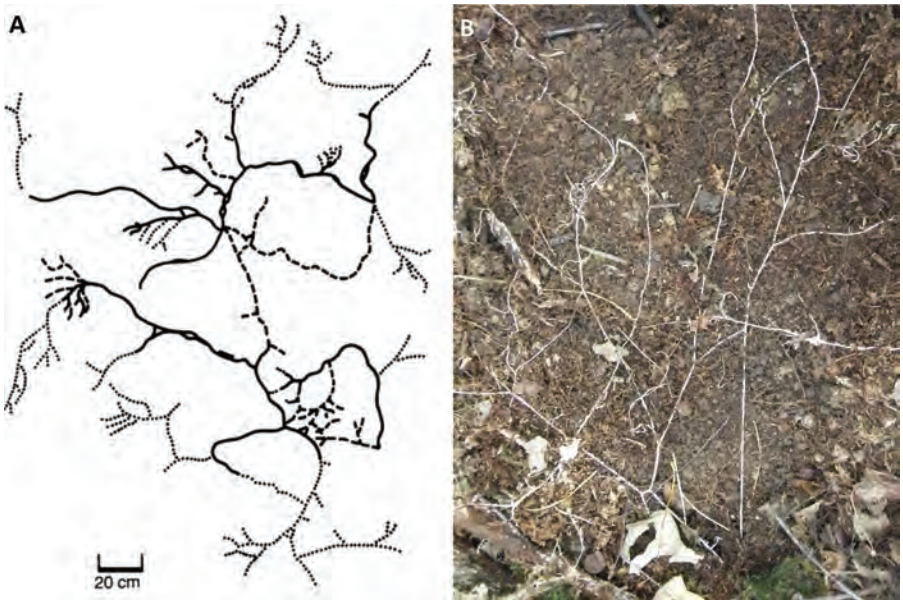

Figure 4 Mycelial networks in woodland. (**A**) Map of a mycelial cord network of *Phanerochaete velutina* revealed by carefully removing surface litter layer, recovering, and then rerevealing 13 months later. From Thompson and Rayner (155) with permission. (**B**) Network of *Megacollybia platyphylla* on the floor of a mixed deciduous woodland, following removal of surface litter.

resources land on an established system (Fig. 5). When mycelium encounters a new resource, parts of the network connecting the original with the new resource aggregate to form mycelial cords, while nonconnecting mycelium dies back (168). The rapidity and extent to which this occurs depends, among others, on the foraging strategy of the fungus, the relative size/quality of the original and new resources, and the presence/absence of invertebrate grazers (34, 35, 169, 170). Short-range foragers reallocate their biomass rapidly and extensively, with often only the connective cord and outward growth from the newly colonized resource remaining after a few months. In contrast, little reallocation of mycelial biomass occurs in long-range foragers unless the newly encountered resource is considerably more substantial than the original resource. The process is speeded up if grazing invertebrates are present; fine mycelium disappears more rapidly than if they are absent, leaving only larger mycelial cords (Fig. 5). These processes occur repeatedly on the forest floor, producing large, open networks of cords interconnecting discrete organic resources ranging from small twigs to large tree trunks (Fig. 4). How the decision is made to strengthen or recycle a particular cord is not clear, nor is the mechanism that serves to retrieve useful breakdown products and redirect them to regions of new growth.

Interestingly, strands of *Pleurotus ostreatus* and rhizomorphs of *Armillaria gallica* (formerly *bulbosa*) both show spontaneous action potentials between 0.5 and 5 Hz, and the frequency increases in response to addition of nutrients (171, 172). Furthermore, the signal propagated across the colony at a speed of 0.5 mm s^{-1} over distances of a few centimeters when nutrients were added remotely. Similar potentials have been reported in a number of other species, and it has been proposed that they may play a role in coordinating growth and differentiation by preventing hyphae from undergoing apoptosis and strengthening cord formation (172).

QUANTITATIVE ANALYSIS OF NETWORK ARCHITECTURE

Constraining the Problem to 2-D

Our understanding of the coordinated growth and behavior of fungal networks has been limited by the immense practical difficulties associated with measuring organisms that exhibit indeterminate, highly plastic growth. Although fungi would normally grow as three-dimensional networks through opaque media such as soil, wood, plant, or animal tissue, most morphological studies have constrained growth to two spatial dimen-

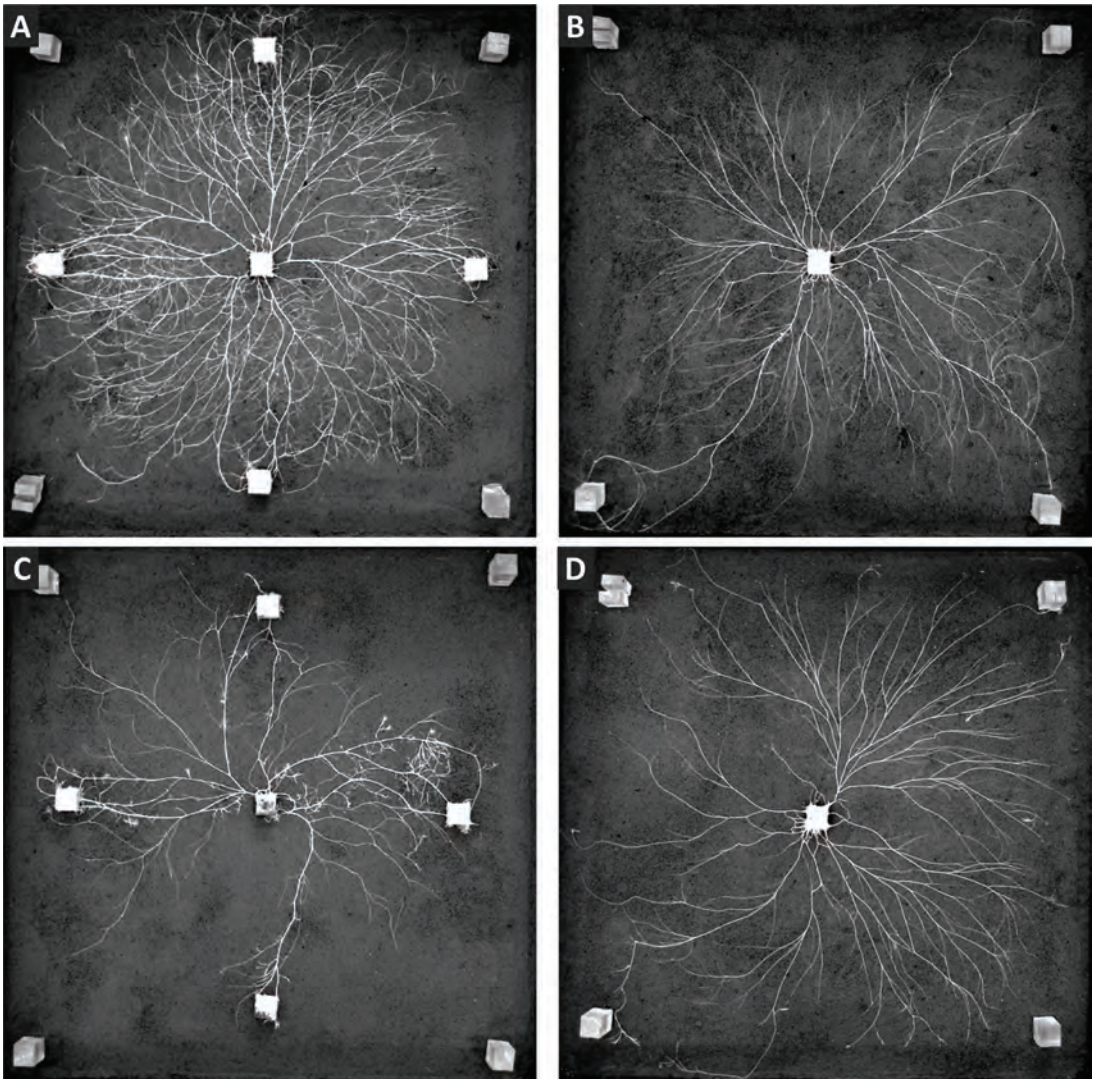

Figure 5 Effects of resource addition and grazing on mycelial networks. Mycelial cord systems (99 days old) of *Phanerochaete velutina* growing from centrally positioned beech wood inocula across the surface of compressed nonsterile soil in 50 × 50 cm trays. (**A**) With four additional beech wood blocks added behind the mycelial margin 36 days after central inoculation. (**B**) With no additional resources added. (**C**) As in A, but with 250 laboratory-reared collembola, *Folsomia candida*, added 49 days after the central inoculums. (**D**) As in C, but with no additional resources. From Wood et al. (170), with permission.

sions to simplify image collection and analysis. Furthermore, the substrate is usually limited to transparent media such as agar plates (e.g., 173), often overlaid with cellophane membranes (174, 175), or as dispersed mycelia in submerged cultures (176–178). There is a challenge to achieve both sufficient magnification to resolve individual hyphae and sufficient scale to map the entire network. Magnifications typically range from 10 to 100× using microscopes (179, 180), but photographic enlargers (174, 175, 181) or flatbed scanners can also be used (173). Colonies can also be grown on cellulose nitrate membranes on agar (182) or soil (183), and visualized following fixation, staining, and rendering the membrane translucent with immersion oil to enhance contrast (182). Alternatively, colonies grown on soil can be repeatedly sampled and growth quantified by using an immunoblotting technique (184).

Network organization is relatively easy to observe at the growing margin of the colony on transparent media. However, submarginal growth is denser and

includes aerial hyphae, which makes it difficult to track individual hyphae and discern the pattern of branching and anastomosis. Thus, most network analysis is limited to a short period (<72 h) of surface growth over short distances (millimeters to centimeters) (e.g., 173), although confocal imaging can be used to analyze 3-D distribution of aerial and penetrative hyphae labeled with Congo Red (185, 186). More recently, confocal fluorescence imaging following wall labeling with calcofluor white has allowed quantitative measurements of early colony formation in 3-D over an extended period (17 days) and represents the first time the dynamics of critical parameters such as branching length and angle have been determined throughout a colony (116). At a more macroscopic scale (centimeters to meters), saprotrophic fungi have been studied the most because they are straightforward to culture from woody resources as a planar 2-D system on nonsterile compressed soil or sand that can be readily imaged (Fig. 4 through 7).

Fractal Measures and Hyphal Coverage

The simplest quantitative measure of colony behavior is surface area coverage from the number of pixels that make up a mycelial image. However, like many natural structures, mycelia are approximately fractal, and fractal geometry may be more appropriate to describe the systems (173, 187, 188). The fractal dimension quantifies the extent to which mycelia fill space relative to the size of the mycelial system. In two dimensions, e.g., the surface of soil, its value ranges between 1 (a line) and 2 (a filled surface). In three dimensions it could take an upper value of 3, although three-dimensional mycelial systems have rarely been investigated. Two types of fractal dimension have been used to provide different measurements of the branching/space filling of mycelia: the mass fractal dimension (D_M) and the surface (or border) fractal dimension (D_S, a subset of D_M), which only describes the edge of the mycelial system. Both are important because they allow a distinction to be made between systems where there are gaps inside (i.e., hyphae do not entirely fill the space), and those systems that have plane-filled interiors and are only fractal at their edges/borders.

Several methods are available for calculating fractal dimension, the most commonly used for mycelia in natural and seminatural (i.e., not agar) situations, e.g., mycelia growing across the surface of soil, is the box-counting technique (188). Effectively, a series of grids of square boxes of different sizes (i.e., different numbers of pixels in an image; 3 to 63 being appropriate for mycelia in small [24 × 24 cm] soil microcosms) is overlaid onto an image of the mycelium. The number of boxes intersecting pixels of the mycelium is recorded. The box-count fractal dimension is given by D in equation 4:

$$N(s) \approx cs^{-D} \quad (4)$$

where $N(s)$ is the total number of boxes having side length s that intersect the mycelium image; c is a constant. There are two types of boxes: interior boxes (i.e., those that contain only pixels of the mycelium) and border boxes (i.e., those that contain at least one mycelial pixel and contain or adjoin at least one nonmycelial, e.g., soil, pixel). So the total number of boxes, $N(s)$, is given by equation 5:

$$N(s) = N_{border}(s) + N_{interior}(s) \quad (5)$$

Regression of the linear part of a plot of log $N_{border}(s)$ against log s provides an estimate of D_S (equation 6):

$$\log N_{border(s)} = \log c - D_s \log s \quad (6)$$

Likewise, regression of the linear part of a plot of $N_{interior}(s)$ against log s provides an estimate of D_M. D can be estimated for entire mycelia, or for distinct areas of local interest by using software such as FracLab for MatLab (https://project.inria.fr/fraclab/) or FracLac for ImageJ (189).

Fractal dimension and hyphal coverage per unit area vary considerably between species, during mycelial development, depending on abiotic conditions, and are altered by interspecific interactions with other organisms (188). D_M of mycelia in small (24 × 24 cm) microcosms of compressed soil (nonsterile, i.e., similar to the natural environment) ranges from 1, for the linear rhizomorphs of fungi such as *Armillaria* spp. and *Megacollybia platyphylla*, to close to 2, for the densely packed mycelia of *H. fasciculare* and *Stropharia caerulea* (Fig. 6). However, even for the latter two species, D_M decreases with time and increasing size of the system, with networks becoming sparser as mycelial cords form and interstitial hyphae die back. These mycelia with, at least, initially high D_M have lower D_S, indicating that they are surface/border fractal systems, i.e., only the edge of the system is fractal. Others have similar D_M and D_S, indicating that the whole system is fractal. Those fungi that are mass fractal tend to extend more rapidly than those that are border fractal, implying that there is a balance between space filling and extension rate. Trade-offs when deploying mycelial biomass in search of new resources, and for other attributes such as resilience, are considered in more detail below.

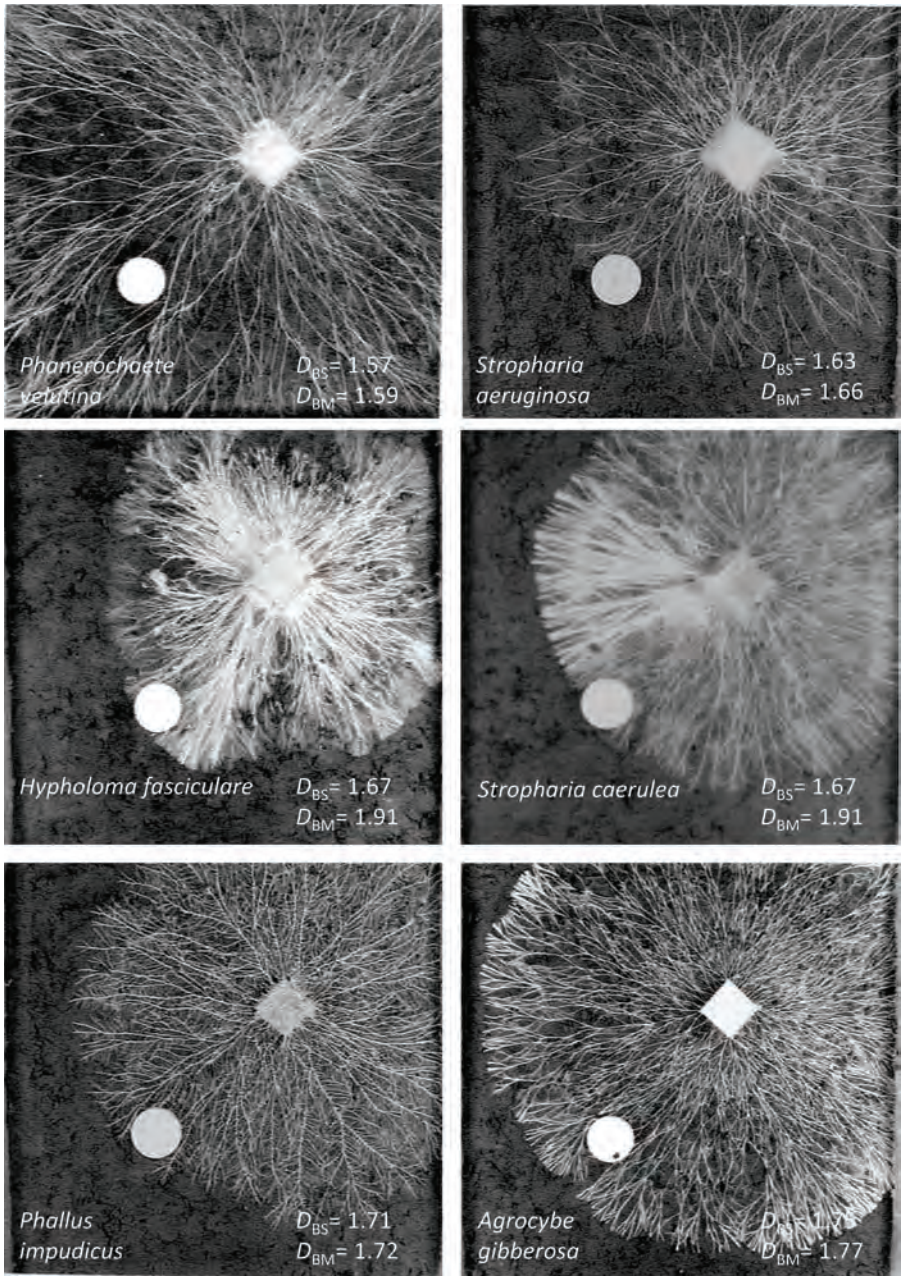

Figure 6 Species variation in fractal dimensions. Mycelia of six wood decay fungi extending, for 28 days, from centrally positioned beech wood inocula across the surface of compressed nonsterile soil in 24 x 24 cm trays. White circles are inert plastic discs. Note the different surface (D_{BS}) and mass (D_{BM}) fractal dimensions of the mycelia of different species. Photographs courtesy of Damian P. Donnelly. From reference 35 with permission.

Fractal geometry is affected by the quantity and quality of the resources available to the mycelium, including size of resource, number of resources, addition or encounter with new resources, and the nutrient status of soil through which the mycelium is growing (35, 187, 188). For example, D_{BM} and D_{BS} of *H. fasciculare*, *P. velutina*, and *Resinicium bicolor*, but not *S. caerulea*, increased with increasing inoculum size (from 0.5 to 4 cm^3). *S. caerulea* systems growing from well-decayed (84 days old) inocula took 10 days longer to achieve the same D_{BM} and D_{BS} values as when mycelia were growing from relatively undecayed (22 days

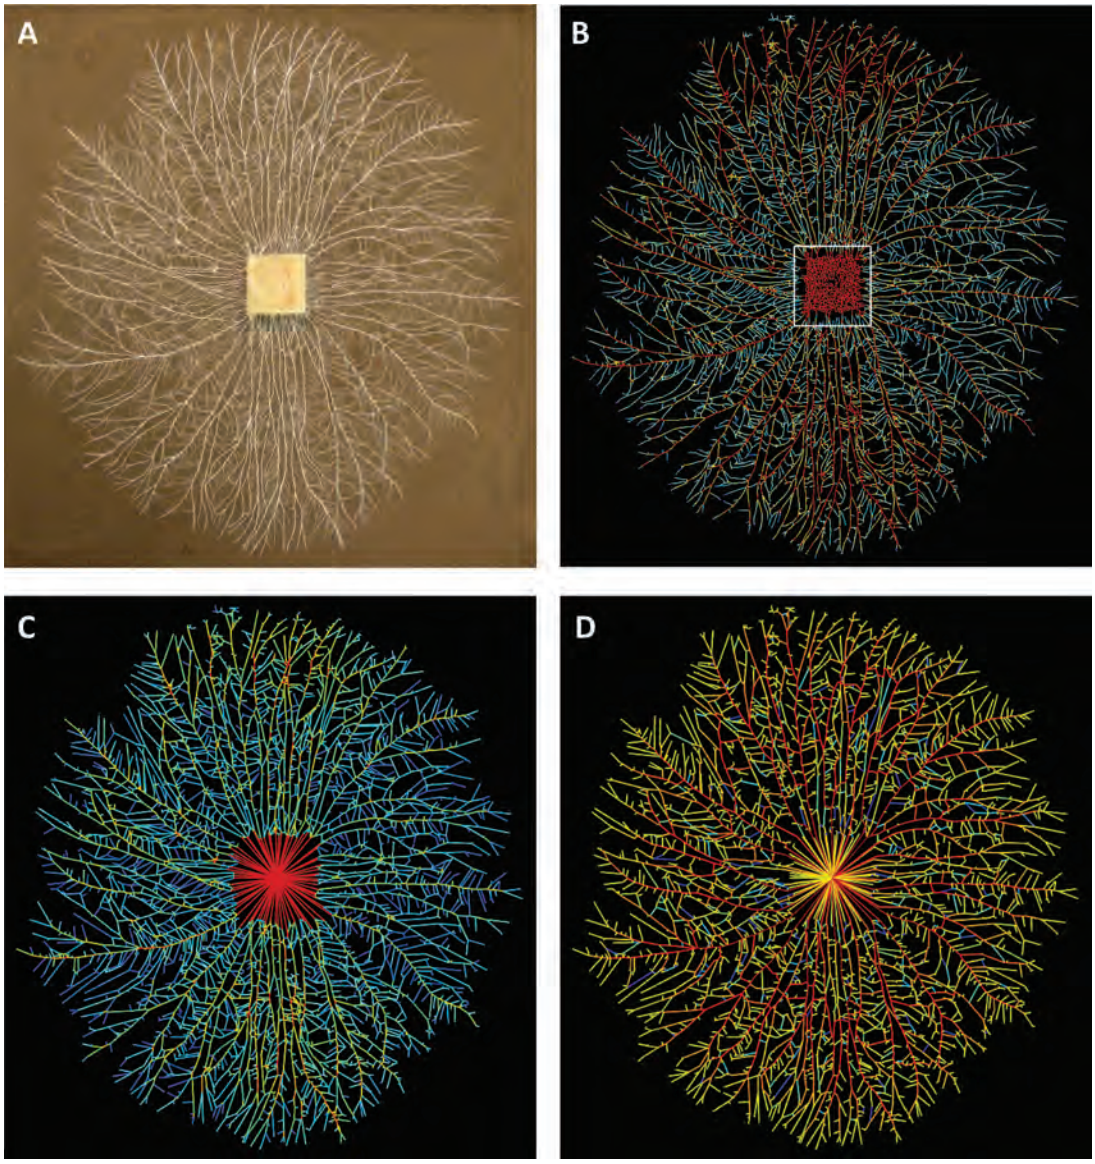

Figure 7 Macroscopic network analysis of *Phallus impudicus* growing on compressed soil. (**A**) Original image of the mycelial network after 21 days. (**B**) Network architecture automatically extracted using phase-congruency edge enhancement, watershed segmentation, and link pruning to give a single-pixel-wide skeleton pseudo-color coded by the cord width. (**C**) Conversion to a graph representation whereby each node (junction or tip) is connected by edges that are pseudo-color coded by the average width of the cord segment from 50 μm (blue) to 500 μm (red). The structure of the network within the wood resource cannot be defined so any cord incident on the boundary is connected to a central node with a link set to the maximum width. (**D**) Characterization of the cord betweenness centrality as a measure of how important each cord is to transport through the network from the resource to every other node, with the color code ranging from blue (low importance) to red (high importance).

old) inocula. D_{BM} and D_{BS} were often lower for mycelia growing across soils with relatively low phosphorous and nitrogen content, short-range foragers often being more responsive to nutrient addition than the longer-range foragers. Non-nutrient environment factors, including water potential, temperature, and pH, also sometimes affect D (188). For example, D_{BS} of *S. caerulea* decreased with increasing water potential

(i.e., getting wetter) from −0.02 MPa to −0.002 MPa, whereas with *P. velutina* there was little effect. D_{BM} and D_{BS} of *P. velutina* were significantly less at 5°C than at 10 to 25°C for several weeks, although the effects on *S. caerulea* were variable. Interactions with other fungi can also dramatically influence mycelium characteristics including hyphal coverage and fractal dimension, which varies between combinations of species and alters locally reflecting attack or defensive responses (190).

Graph-Theoretic Network Representations

Fractal measures capture some aspects of network organization, but advances in image analysis now mean that an explicit representation of the network structure is possible. Early image analysis routines (reviewed by references 176 and 177) used simple gray-scale thresholding (116, 180) or Sobel or Canny edge detectors followed by image opening and hole filling (191) to segment the hyphae. The resultant binary image is typically thinned to a single-pixel-wide skeleton and can be converted to a graph representation, where each junction is classed as a node and the intervening segment as a link. These approaches have the advantage that they can be readily implemented in open-source software packages, such as ImageJ (e.g., 182, 192).

More recent approaches use additional ridge enhancement algorithms, adaptive thresholding, and pruning steps to aid segmentation (173, 193, 194). Most current algorithms for network extraction were originally developed for blood vascular systems or neurons, and typically involve enhancement of the "ridge" nature of the hypha or hyphal aggregate. The most common approaches use second-order derivatives of a Gaussian over a range of angles and scales (e.g., 195), although pattern-matching templates can also be used (196). Anisotropic kernels are more powerful because they emphasize the elongated shape of network segments and have recently been developed specifically to analyze mycelial networks (197). The maximum response of the filter provides information on the edge strength and its orientation, while additional measures, such as the anisotropy of the first three eigenvalues, give a measure of how strongly the edge corresponds to a (blood) vessel ("vesselness," 195). An alternative approach uses local phase congruency to give an intensity-independent approach to edge enhancement. This provides better segmentation for larger microcosms with cords, when the edges vary in intensity as well as scale and orientation (Fig. 7A and B), but at the expense of greater computational cost. The phase-congruency measure can also be combined with tensor-based measurements to give the phase-congruency equivalent of "vesselness" (193, 198). The enhancement step is followed by segmentation using non-maximal suppression and hysteresis thresholding (197), watershed segmentation, and edge pruning (193), or a reverse diffusion-based algorithm (196) to give a single-pixel-wide skeleton.

A complete description of the mycelial network also requires an assumption of the hyphal width (e.g., 173), or experimental estimation from the network image (32, 33, 144, 169, 175, 193). This is still a technically challenging area with a number of methods available that use slightly different assumptions. For example, a granulometry approach can be used whereby the intensity image is subject to a series of image openings (erosion followed by dilation) that successively remove structures as the size of the opening kernel exceeds the underlying object (193, 198). The intensity of each pixel initially decreases slowly as the kernel samples more of the object, but then reduces dramatically once the boundary of the object is reached, and the kernel only samples the background. The transition point for any pixel is determined from the maximum (negative) gradient of the granulometry curve. However, this approach constrains the radius to integer pixel values, and also suffers from digital approximation of small kernels to a true disk-shaped kernel. Thus, rather than extract a specific size threshold, the integrated intensity under the granulometry curve can be calculated to provide a more nuanced interrogation of the local image intensity profile. The integrated intensity cannot be directly related to the physical width without additional assumptions about the relationship between intensity and sampled volume through calibrated microscopic measurements. Nevertheless, this approach does help with estimation of relative hyphal widths, even if they are subresolution objects, provided it is assumed that the intensity scales with the width of the hyphae (Fig. 7B). Including estimates of the hyphal width gives the volume of the mycelium at any point and, if time series are collected, how the volume changes with growth or recycling.

Conversion to a Graph Representation

The graph representation is based on translation of the pixel skeleton to a planar, weighted, undirected graph (Fig. 7C), with nodes located at hyphal tips, branches, and anastomoses, and edges representing hyphae or cords, with weights based on the Euclidean length (L) and radius (r) of each cord, combined either as the cylindrical volume ($V = r^2L$), to represent the material cost of the cord, or the predicted conductance ($G = r^2/L$), assuming cords are bundles of equally sized vessels

rather than a single vessel with increasing radius (144, 173, 175, 182, 199–201). The network cannot be resolved within the resource, so it is represented as a single node connected to all the edges incident on the resource boundary (Fig. 7C). The graph conversion step also makes additional assumptions about the functional connectivity of the network, because every junction or crossing point is automatically defined as a fully connected node in 2-D planar systems irrespective of whether there is an actual anastomosis present, although 3-D imaging can help to separate fusions from overlaps (116). In addition, the inferred conductivity assumes all the septal pores are open and hyphae behave as simple pipes.

Summary statistics, such as the number of tips, junctions, and edges; the total hyphal length, area, and volume; or the distribution of branching angles and internodal lengths can be readily extracted from the pixel skeleton or graph representation of the fungal network (116, 144, 173, 175, 199–202). Measures can also be referenced to 2-D space to give tip densities and fractal dimensions (173, 175). Topological network measures, such as node degree, α-index or shortest path metrics, such as betweenness centrality (Fig. 7D), can also be readily calculated and show species-dependent developmental changes over time (144, 173, 199–203).

In more realistic microcosms with patchy resources, in competition with other species, or in the presence of fungivores, there is considerably more variation in spatial network architecture than is captured in a single summary network statistic. Such heterogeneity may be identified by algorithms that identify regions of the network with a higher local density of connections than other regions of the network than would be expected by chance, and are termed "communities" in network parlance. Communities are initially identified by progressively partitioning the network into smaller and smaller units by breaking links depending on the strength of their interaction, by tuning a resolution parameter. There is considerable flexibility in the choice of the interaction term that forms the basis of the analysis, which can be based on measures such as edge volume, conductance, or resilience (204, 205). The profile of key summary statistics, such as the number of communities, or the energy and entropy of the system, as the resolution parameter is changed, are used to define a set of mesoscopic response functions (MRFs) for each network. Networks are then clustered based on an estimate of the distance between the MRFs to give a dendrogram (Fig. 8). This provides a biologically sensible clustering of networks from different species, and also of developmental stages for a particular species, or exposure to different experimental conditions (204, 205). These approaches allow objective groupings of networks across species, treatments, and laboratories. Nevertheless, these methods are in their infancy and the challenge now is to understand whether the groupings can be interpreted from a biological perspective to yield additional insight that cannot be captured from qualitative description of each network alone.

Integrating Structure and Flows Using Modeling

Constructing models that meaningfully represent processes ranging from the micron scale in individual hyphae to hyphal networks operating at an ecologically relevant scale is extremely challenging. At the microscopic scale, sophisticated biophysical models have been developed to explain the growth of individual hyphal tips, including vesicle delivery and viscoelastic wall deformation (42, 206–211), followed by wall aging through cross-linking of wall polymers (4, 212, 213). While, at a macroscopic scale, the growth of fungi in the environment can be modeled by using differential equations to represent changes in the density of fungal mycelia and spore production, along with changing resource density. Such an approach can be effective for modeling the spread of fungal crop pathogens (214), or modeling carbon cycling in the environment (215), but these kinds of model are essentially blind to the fact that fungal biomass grows as an interconnected network. Here, we consider an intermediate scale, namely the growth of individual mycelial networks.

Continuum Models at the Colony Level

One strategy for modeling the interaction between tips, hyphae, growth-limiting nutrients, and inhibitory waste products is to represent the mycelium as a continuum and use differential equations to model processes such as the uptake of nutrients by hyphae, the extension of tips to form hyphae, the formation of new tips through branching, and the loss of tips because of anastomosis. Such models have their roots in the work of Edelstein and coworkers (216), and they have been reasonably successful in explaining the gross morphology of colonies with dense mycelia, which can be observed growing on agar, plant surfaces, or building materials. For example, when *Aspergillus orzae* grows on agar, the morphology of the colony depends on the concentrations of nutrient and agar (217, 218). At low nutrient concentrations, colonies are uniform with a smooth, circular growth front provided that it is difficult for nutrients and waste products to diffuse through the agar. If the agar concentration is decreased, the effective

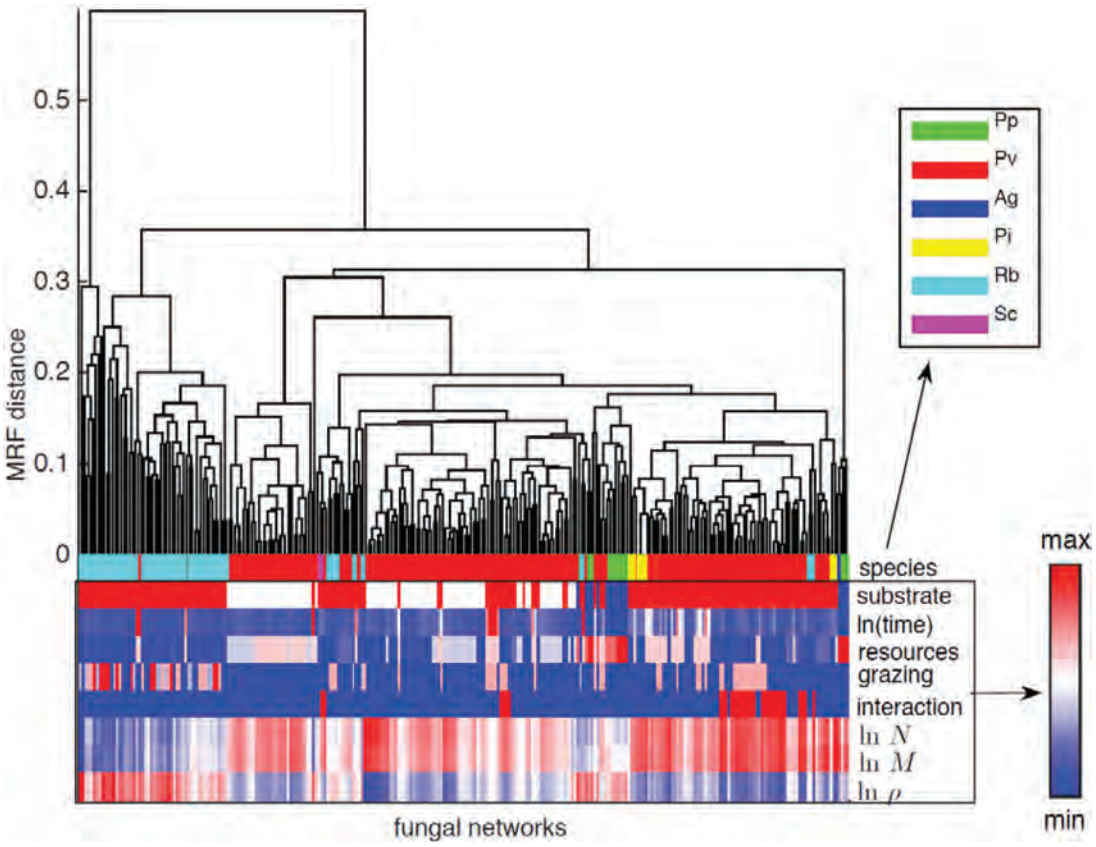

Figure 8 Network taxonomy. Taxonomies of 270 fungal (and slime mold) networks based on community structure using modularity optimization with path score (PS) values as the edge weights (205). The dendrogram was produced from the mesoscopic structure of each network as an indication of how similar different networks are to each other. The species abbreviations are coded as follows: Pp, *Physarum polycephalum*; Pv, *Phanerochaete velutina*; Ag, *Agrocybe gibberosa*; Pi, *Phallus impudicus*; Rb, *Resinicium bicolor*; and Sc, *Strophularia caerulea*. The levels of resources and amount of grazing are color coded from low (blue) to high (red). Substrate is coded as blue for agar, white for sand, and red for compressed, nonsterile soil. Interactions are coded as blue for no interaction, or red grown in competition with *Hypholoma fasciculare*. At the bottom of the figure, the logarithms of number of nodes N, number of edges M, and the edge density $= 2M/N(N-1)$ are also shown. From reference 205 with permission.

diffusion coefficient of waste products and nutrients is increased, and colonies condense into branched forms, with a tortuous, irregular growth front. This morphological instability can be explained by constructing a reaction-diffusion type model that takes into account the build-up of waste inhibitors and the provision of growth-limiting nutrients. Essentially, if the nutrients needed for growth can only be obtained by growing into new territory, a low-density colony will gradually fill the dish, maintaining circular symmetry. If nutrients can diffuse into already colonized regions, this will enable denser growth. However, in that case the build-up of inhibitory molecules can prevent some regions from growing out of the dense core, and any point on the growth front that happens to be further away from the inhibitory core will be more likely to grow, producing positive feedback and an unstable, irregular growth front.

Including Biomass Recycling in Continuum Models

Another feature of fungal physiology that can be incorporated into continuum models is the distinction between mobile and immobile fungal biomass. Metabolically active hyphal tips mature into relatively inert hyphae, or fully vacuolated vessels that are not metabolically active. Uptake of nutrients is generally believed to be greatly reduced behind the hyphal tips, and, in some

species, hyphae develop into cords or metabolically inert transport vessels that are highly insulated from the environment (17, 35, 219). Although some biomass is static, the cytoplasmic contents of the fungal colony is free to move by pressure-driven mass flows, diffusion, or various mechanisms of active transport. Furthermore, some internal resources may be remobilized, as parts of the fungal colony are broken down and recycled to fuel further growth (see "Biomass recycling" above). Energetic arguments suggest that the process of recycling is of much greater benefit to organisms that live on recalcitrant or nutrient-poor substrates (31), and modeling suggests that the rate of recycling may also have a significant impact on colony morphology (142). There are three extreme morphologies: (i) "fairy rings," with an annulus of high-density growth surrounding a region with low or zero density; (ii) colonies of relatively constant density; or (iii) rings that alternate between higher and lower densities (220; see "Colony dynamics and behavior" above). The distribution of densities of fungal growth depends on both the nutrient environment and the species in question, and models indicate the importance of nutrient transport and biomass recycling in determining such morphologies (24, 26, 142). The fact that fungal growth is space filling is critically important, because the capacity to take up nutrients, water, or pollutants from the environment is proportional to the surface area. There is no reason to suppose that the total surface area of a fungal colony is a simple function of its diameter, which suggests that fungal growth and its environmental consequences may not be well represented by assuming some density of growth. One approach is to represent the space-filling capacity of fungi in terms of fractal dimension (188, 221–224) as the dimension of a space will influence the dynamics of any exchange process (225) (see "Fractal measures and hyphal coverage" above).

Spatially Explicit Network Models

A promising but computationally intensive approach is to adopt a spatially explicit representation of all the hyphae in a network (26, 29, 226). Each hyphal tip can be associated with a location and a direction, and the movement of those tips can be modeled so that tip velocity and changes in tip direction recapitulate empirical observations. These agent-based models can either be constrained to a lattice, or, at the expense of additional computational cost, the orientation of hyphal tips can be lattice free (28, 30). In all such "tip-and-trail" models, hyphae are present wherever the moving tips have passed, and those locations can be given traits such as internal and external concentration of growth-limiting resource. This approach enables the modeling of hyphal fusion, which is assumed to occur whenever a tip grows into a location that is already occupied by hyphae or tips.

Branching angle can also be modeled to recapitulate empirical observation, but there are fundamental difficulties in modeling branching frequency. One approach is to simply impose the distribution between branch points that has been observed experimentally (226). This may be appropriate when branching rate is constant and all branching events are apical or subapical because in that case it is relatively easy to measure branching frequency and the location of branching events is relatively well determined. Such a model can be used to determine the relationship between branching rate, branching angle, and the expected distribution of fungal density for colonies of various sizes (226), but in cases where the environment is heterogeneous and branching rate is not constant, it is not clear which branching rate should be imposed. An alternate approach is to suppose that tip growth and branching rate are a function of the internal concentration of some growth-limiting resource (29, 227). Such models effectively reveal the importance of nutrient transport, but the internal concentration of nutrients will depend on the scale and mechanisms of nutrient uptake and translocation about which we still have little quantitative information (16, 56, 147, 228). Thus, it is not clear whether these models represent the mechanisms of nutrient transport with sufficient accuracy, nor is it clear whether they capture the actual relationship between branching rates and local conditions. Crucially, the connected nature of mycelial networks means that local behavior can be affected by conditions in remote parts of the colony, especially by the translocation of nutrients (32, 219, 229, 230).

Furthermore, because the flow of cytoplasmic contents is relatively unimpeded, turgor pressure will tend to equalize rapidly across the colony. Hence, turgor pressure and the rate of water uptake necessarily reflect the osmotic potential of the entire colony and its environment, not just the local conditions (49, 231). This implies that the behavior of the colony is dependent on the interaction between the genotype and a complex spatial convolution of environmental conditions (26, 142, 232, 233). It should also be noted that not all cords are equally important when a dynamic process occurs on a network. In a heterogeneous environment some cords will carry more resources than other, nearby edges (28), and empirical observations confirm that the distribution of velocities of fluid flow within a fungal network are highly heterogeneous, with some cords

carrying much larger mass flows than others (32, 33, 67). This heterogeneity is presumably related to the fact that some hyphae branch and form hyphal aggregates or cords, while other hyphae are degraded and recycled. There is some evidence that cords which carry greater currents are more likely to thicken (33), but there is a substantial body of open questions concerning the developmental logic of fungal networks.

Comparison with Other Types of Transportation Networks

Given the importance of nutrient transport, it is worth considering how fungal networks compare with other transportation networks (32, 144, 219). In particular, modeling may be able to shed some light on the trade-offs involved in forming cross-links, because it is notable that some fungal networks contain numerous loops, while other fungi essentially grow as branching trees (16, 199, 201). There is a considerable literature on the optimal design of distribution networks, and fractal branching trees are known to be optimal for the case where a single source is connected to multiple sinks (234–236). Furthermore, when a metabolism-limiting resource is distributed through a fractal branching tree, we should expect to see scaling effects such that larger organisms have a lower metabolic rate. As theory predicts, there is evidence in the animal kingdom that metabolic rate is proportional to $M^{3/4}$, where M represents the mass of the animal (234, 235). However, while mammals use a cardiovascular system to distribute oxygen, glucose, and other metabolism-limiting substances throughout the body from a single heart, fungal colonies generally cannot be represented as a single-source system. Nutrients may be gathered from across the colony, and such organisms may thrive by foraging phosphate from one location and nitrogen from another, and distributing both resources throughout the mycelium (147, 219). Hence, in the case of fungi, the distance that determines the scale of the transport challenge is not the radius or the mass of the colony, but the typical distance between the site of nutrient uptake and the place where those nutrients are consumed.

Whatever the spatial distribution of sources and sinks, any efficient flow pattern must be such that, at every point, the flow moves materials away from the source and toward the sink. In other words, although there may be loops in the network, optimally efficient flows always transport materials in a directed manner. This feature of efficient material flows is common to many definitions of "efficient," and it is inevitable when the flows are driven by differences in potential. That is because, at every point in any given network, material moves from regions of high potential to low potential. Hence, material can never backtrack, because that would require movement against the potential gradient. However, although it is most efficient for particles to move in a directed manner, there are circumstances in which the most efficient network is one that contains loops. In particular, if a network has to function in the face of random damage, or a network needs to connect a fluctuating distribution of sources and sinks, the most efficient choice of the network may be one that contains loops (237). Further modeling may help to elucidate the trade-offs that arise between the conflicting demands of efficient directed transport and efficient mixing. In many cases, the primary interest is in the functional consequences of fungal growth, such as the production rate of desirable compounds, the rate of nutrient or pollutant uptake, rates of soil acidification, wood degradation, and so on (227). Some of these macroscopic rates of interest have been connected to microscopic fungal parameters, such as branching rate or fungal density, but more effective predictive models may require a deeper understanding of how fungal development shapes and responds to the environment in which growth occurs. The increasingly quantitative nature of experimental data concerning tip growth, branching, nutrient transport, and cytoplasmic flow should provide valuable material for future modeling efforts (116), and advances in imaging technology will surely enable a more detailed analysis of the architecture and functional significance of developing fungal networks.

Network Robustness and Resilience

In natural environments mycelial networks are subject to physical damage and attack by fungivores. The intrinsic robustness of the network at a particular time point is determined by the network architecture, including thickness and toughness of hyphae and mycelial cords, palatability to grazers, and extent of interconnectedness. In particular, networks with loops formed by anastomosis are more robust, because they already maintain alternative routes for nutrient translocation to circumvent damaged regions. Fungi can also respond to damage or attack by network remodeling leading to greater resilience. Experiments can be conducted with real networks in the presence of fungivores, or by using an *in silico* approach based on network analysis in other domains, whereby a property of the network, such as the largest connected component or the predicted transport efficiency, is calculated as cords are removed according to some rule. Thus, long thin cords might be removed first to simulate grazing by collembola with

small mouth parts, or a local region of the network might be deleted as a chunk to simulate grazing by wood lice.

Experiments in Soil Microcosms

The effects of invertebrates grazing on mycelia of cord-forming wood decay basidiomycetes have been studied extensively in microcosms (24 × 24 cm or 50 × 50 cm) of compressed nonsterile woodland soil (238–240). Intense grazing can completely destroy mycelia and prevent them from growing out of organic resources, but less intense grazing can dramatically alter mycelial morphology and physiology, in different ways depending on the grazing species, the fungus, and the grazing intensity. Mycelia are grazed in different regions and to different extents depending on fungal species: collembola grazing on the relatively unpalatable *H. fasciculare* tends to be at hyphal tips; in contrast, *R. bicolor* extending from beech wood is indiscriminately grazed, and, with *P. velutina*, fine hyphae within the colony and hyphal tips are grazed (241). While microfauna and mesofauna often graze on fine hyphae, macrofauna such as woodlice (*Oniscus asellus*) graze in large swathes including severing thick cords (242).

Susceptibility to grazing also depends on the age and stage of development of the mycelium and the resources to which it has access. Mycelia comprising individual hyphae or thin cords, at early stages of development or supported by a dearth of resources, are more prone to grazing than mycelia that have formed highly sclerotized cords interconnecting between woody resources (170, 239). Mycelial systems occupying large (50 × 50 cm) trays of soil had similar hyphal coverage after several months irrespective of whether or not they had been grazed by collembola (170), apparently because collembola grazed on the fine hyphae that would have died anyway as the system became more open. Greater mycelial interconnectedness, i.e., more cross-links forming tangential connections, also limits the effects of grazing and other damage (Fig. 5 and 9) (169, 243). Connectedness is greater in some species than others, e.g., greater in *Phallus impudicus* than *P. velutina* (see above), in mycelia developing from larger resources and in more mature systems (144, 169, 243, 244).

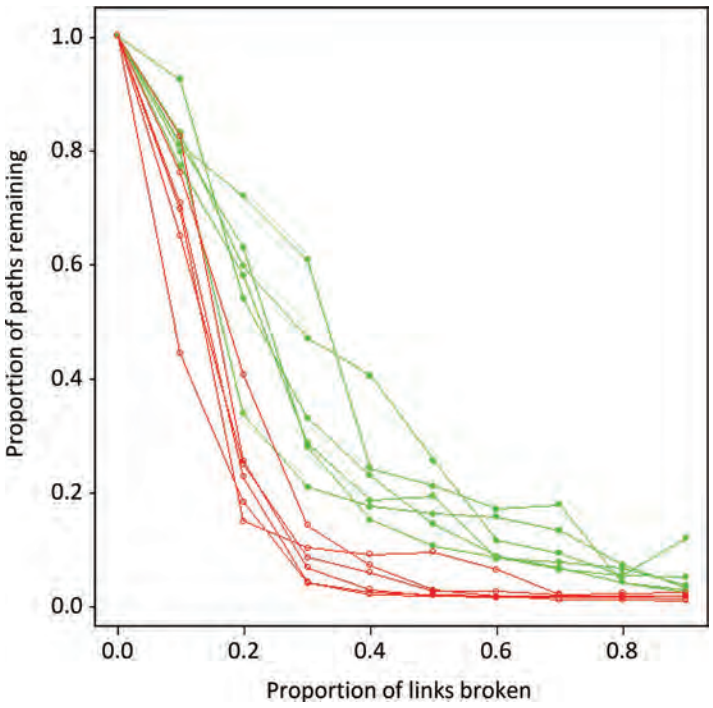

Figure 9 *In silico* evaluation of network robustness. Networks of *Phanerochaete velutina* (red) and *Phallus impudicus* (green) were attacked *in silico* by progressively removing links in the network at random, and calculating the number of paths in the network that still remain. In each case, five examples are shown. Note that the *P. velutina* network breaks down more rapidly than the *P. impudicus*. From D. A'Bear, L. Boddy, and M. D. Fricker, unpublished data.

Effects of grazing depend not only on the intrinsic robustness but also on how mycelia respond to damage or grazing, i.e., resilience. Although extension rate often decreases as a result of invertebrate grazing (239), it sometimes increases, switching from slow, exploitative to fast, explorative growth (242). These changes sometimes occur at or close to the site of grazing, further away, and in all directions around a mycelial margin. The latter is invertebrate density dependent (239) and has been interpreted as compensatory growth, similar to that which occurs in plants during herbivory (238). During interactions between mycelia of *P. velutina* and *H. fasciculare* growing across soil, grazing by collembola curtailed growth of the former except in the region of the opponent, where rate of overgrowth rapidly increased (243). Remarkably, although collembola grazing of *P. velutina* tends to reduce interstitial hyphal biomass overall, some of these fine hyphae survive, and thicken, increasing the local level of cross-connectivity, and hence increasing robustness (169).

Network Risks: Control of Systemic Infection

Network organization may be useful for long-distance transport and coordinated colony behavior, but also poses a risk of rapid systemic infection. Indeed, approximately 30 to 80% of fungi are thought to harbor persistent systemic mycovirus infections that spread horizontally via hyphal anastomosis between compatible fungal hosts, or vertically through spore formation, with no extracellular mode of infection (245, 246).

FUTURE PROSPECTS

Extension of Network Analysis to 3-D

It is already possible to collect sets of tiled 3-D confocal images of fungi growing on agar with sufficient resolution to identify individual hyphae, and sufficient spatial and temporal scales to map colony development over a period of days, which gives a much richer source of information for modeling (116). Recent progress has also been made on 3-D imaging of fungi in wood or soil with sub-micron resolution using X-ray computed tomography (247–250). However, manual or automated segmentation and analysis routines are still challenging, as the invasive hyphae can be very narrow and it is currently difficult to achieve sufficient contrast to segment fungal hyphae from the woody tissue (247, 248, 250). Imaging mycelial networks in soil has used osmium vapor staining and use of X-ray translucent polystyrene substrate to create sufficient contrast (249). Nevertheless, at this point, it is not possible to extract a connected 3-D network from either substrate, but it is anticipated that further methodological improvements will overcome some of the current technological challenges.

Intercellular and intracellular hyphal networks formed during host-mycorrhizal interactions have been successfully imaged at cellular resolution using confocal microscopy after labeling with various fluorophores (133, 251–253), using label-free imaging (254), by *in situ* hybridization (255), or following combined KOH maceration, resin embedding, physical sectioning, and confocal imaging of fluorescently labeled wheat germ agglutinin lectin (256, 257). Quantitative measurements of volumes and surface areas are possible, even from dense arbuscules (251). Techniques to visualize arbuscular mycorrhizal networks by sandwiching between Millipore filters give impressive images of the mycelial network and have allowed quantitation of hyphal lengths and number of anastomoses (258, 259), and could easily be subject to network analysis. Likewise, cord-forming ectomycorrhizal networks can be imaged and analyzed by using the same approaches developed for saprotrophic systems (Fig. 10), although it is more complex to segment the fungal mycelium from the root because they span different scales and the color discrimination from each other and the soil is difficult.

In a similar manner, pathogens invading their host can be labeled by using nonspecific stains or fluorochromes or by following expression of fluorescent proteins (260–262). Lesion development can be followed by automated segmentation and analysis by using the HyphArea program (191), which has the potential to provide a complete, quantitative representation of the invasive hyphal network. The length scale that most pathogen infections operate over is quite limited (millimeters to centimeters), which suggests that growth and internal nutrient movement can be accomplished easily by diffusion and cytoplasmic streaming rather than by mass flow.

Network Analysis and Fitness Traits

The network formed by different species is recognizable at a macroscopic level, and tools to quantify network architecture and dynamics are emerging. At this point, we do not know which metrics may best describe network organization and how these relate to fitness (263), but it is not unreasonable to propose that each species operates a slightly different set of local rules to balance growth, transport efficiency, recycling, resilience, and reproduction that collectively maximize the long-term global success of the organism (31, 264). Thus, network

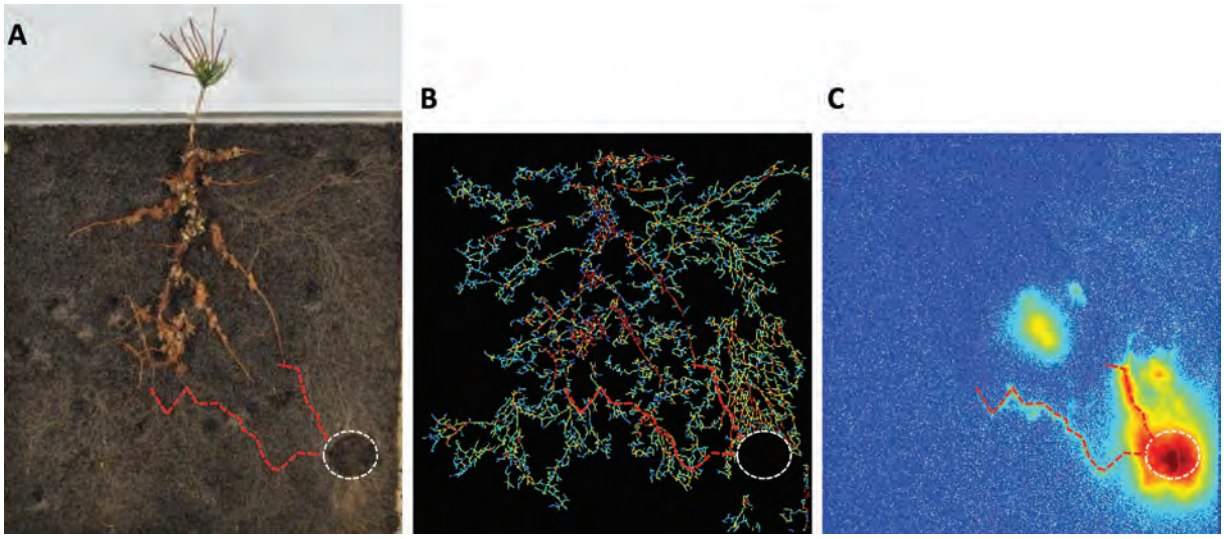

Figure 10 Network analysis of the ectomycorrhizal fungus *Paxillus* on pine. (**A**)*Pinus* seedling infected with *Paxillus*. The dotted white circle marks the loading site for radioactive ^{14}C-AIB. The dotted red lines indicate the routes for preferential transport of isotope to the roots from C. (**B**) Automated extraction of both the plant root and extra-radical mycorrhizal network using phase-congruency enhancement, watershed segmentation, and cord width measurement. (**C**) Scintillation image of nutrient movement along selected pathways from the fungus to the plant root. From R. Tajuddin, D. Johnson, and M.D. Fricker, unpublished data.

analysis may help to provide quantitative measures of traits that fulfill the criteria of ecological versatility, wide scope throughout the fungal kingdom, and measurability set out by Aguilar-Trigeros et al. (39).

The Geomycology of Elemental Cycling and Transformations in the Environment

16

Geoffrey Michael Gadd

INTRODUCTION

The significance of fungi in natural environments is extensive and profound. Their most obvious roles are as decomposers of organic materials and as animal and plant pathogens and symbionts. It is therefore obvious that they are of major importance in the global carbon cycle through such activities and as important determinants of plant growth and productivity. However, their importance in terms of nutrient and element cycling greatly extends beyond these core activities, and they are involved in the biogeochemical cycling of many other elements and substances, as well as many other related processes of environmental significance. The growing discipline of geomicrobiology addresses the roles of microorganisms in geological and geochemical processes (1, 2), and geomycology can be considered to be a part of this topic that focuses on the fungi (3, 4). The often clear demarcation between mycological and bacteriological research has ensured that the geoactive properties and significance of fungi have been unappreciated in wider geomicrobiological contexts. The range of prokaryotic metabolic diversity found in archaea and bacteria, including their abilities to use a variety of different terminal electron acceptors in respiration and effect redox transformations of many metal species (5, 6), has also contributed to a narrow overall view of the significance of eukaryotic organisms in important biosphere processes. A recent collection of geomicrobiology review articles managed to completely exclude fungi (as well as algae), even to the extent of defining "microbes" as being only bacteria and archaea (7). Nevertheless, appreciation of fungi as agents of geochemical change is growing, and their significance is being discovered even in locations not usually regarded as prime fungal habitats, e.g., rocks, acid mine drainage, deep aquatic sediments, hydrothermal vents, and the igneous oceanic crust (8–11). Their significance as bioweathering agents of rocks and minerals is probably better understood than bacterial roles (12), and this ability is of prime importance in the weathering of human structures in the built environment and cultural heritage (13–15). On the positive side, the geoactive properties of fungi can be used for human benefit, and several aspects may contribute to providing solutions to several important global challenges. Geomycology is relevant to reclamation and revegetation of polluted habitats, bioremediation, nuclear decommissioning and radionuclide containment, biorecovery of important elements, and the production of novel biomaterials. This chapter outlines important geoactive properties of fungi in relation to important environmental processes, their positive and negative applications, and their impact on human society.

THE FUNGAL HABITAT

Fungi are ubiquitous components of the microbial communities of any terrestrial environment, including such hostile habitats as the Arctic, hot deserts, and metal-rich and hypersaline soils (16). They are significant inhabitants of the aquatic environment as decomposers of organic matter but are also involved in other elemental cycles, e.g., manganese oxidation (17). Fungi are ubiquitous in habitats polluted by xenobiotics, toxic

Geomicrobiology Group, School of Life Sciences, University of Dundee, Dundee, Scotland, United Kingdom and Laboratory of Environmental Pollution and Bioremediation, Xinjiang Institute of Ecology and Geography, Chinese Academy of Sciences, Urumqi 830011, People's Republic of China.

metals, and radionuclides, both terrestrial and aquatic, as well as leachates and other solid and liquid wastes (18). In such habitats, fungi may exhibit a variety of mechanisms that determine tolerance and survival and which are also components of elemental cycles for pollutant elements (18). These "extreme" locations may also act as a reservoir of novel organisms with unusual properties. For example, acid mine drainage is now known to harbor fungal communities, the preponderance of earlier research on this habitat being devoted to prokaryotes, and some isolates possess unusual element bioaccumulation properties. New species include *Fodinomyces uranophilus* and *Coniochaeta fodinicola* from uranium mine locations that can bind mobile uranium (10, 19) and a *Penidiella* sp. from an acidic abandoned mine location that was capable of accumulating rare earth elements such as dysprosium (Dy) (20). A global fungal role in biogeochemical cycling of the elements (e.g., C, H, N, O, P, S, metals, metalloids) is therefore obvious and is interlinked with the ability to adopt a variety of growth, metabolic and morphological strategies, adaptive capabilities to environmental extremes, and symbiotic associations with animals, plants, algae, and cyanobacteria (16, 21, 22).

The ability of many fungi to grow oligotrophically by scavenging nutrients from the air and rainwater helps them survive on stone and rock surfaces which are considered to be an inhospitable environment (9, 23). In addition, organic and inorganic residues on mineral surfaces or within cracks and fissures can act as nutrient sources in the subaerial rock environment (24). One of the most successful means for fungi to survive in the extreme subaerial environment is underpinned by their symbiotic associations with algae and cyanobacteria as lichens, where the phototrophs provide a source of carbon and protection from light and irradiation (24, 25). Lichens enable colonization of a wide range of environments including those at climatic extremes such as the Arctic and Antarctic, exposed rock surfaces, and dry deserts.

In the deep subsurface, the research emphasis is mostly on prokaryotes, but the presence of fungi is now well known (11, 26–28). Fungi occur in abundance and high diversity in such varied environments as deep-sea sediments (29), hydrothermal vents (30, 31), and methane cold-seeps (29, 32). They are now also known as abundant inhabitants of the igneous oceanic crust, which has consequently been described as the largest fungal habitat on Earth (11). Fungi seem to play an important ecological role in the igneous oceanic crust, because they exist in symbiosis with chemolithotrophic prokaryotes, decompose organic matter, dissolve and form minerals, and therefore are involved in the cycling of elements (11, 33, 34). Fossilized microorganisms have been observed in drilled cores and dredged samples from the ocean floor, with a majority of these findings representing fungi (34, 35). These fungi existed in a close symbiotic-like relationship with two types of prokaryotes, which appeared to use the structural framework of the mycelium for their growth (34). It therefore seems clear that geomycological processes are significant in a wide range of biosphere habitats, including those traditionally thought to be inimical to fungal growth and development (36).

ORGANIC MATTER DECOMPOSITION AND BIOGEOCHEMICAL CYCLING OF COMPONENT ELEMENTS

Organic matter decomposition is the attribute most commonly associated with fungi and is a major contribution to global biogeochemistry as well as the spoilage of foodstuffs and organic materials (21, 36). Fungal processes represent a potential control point in the global carbon cycle (37). To some extent, research on this aspect of chemoorganotrophic metabolism has obscured the wider global implications of decomposition in terms of the cycling of other elements and nutrients, and also contributed to a lack of attention to fungal roles in wider geochemical cycles.

Most biogeochemical attention on fungi has been given to carbon and nitrogen cycles, and the ability of fungi to utilize a wide spectrum of organic compounds is well known. Simple compounds such as sugars, organic acids, and amino acids can easily be transported into the cell, while more complex molecules are first broken down into smaller molecules by extracellular enzymes before cellular entry. Such compounds include natural substances such as cellulose, pectin, lignin, lignocellulose, chitin, and starch and anthropogenic products such as hydrocarbons, pesticides, and other xenobiotics (21, 37). Organometals (compounds with at least one metal-carbon bond) can also be attacked by fungi. Degradation of organometallic compounds can be carried out by fungi either by direct enzymic action or by facilitating abiotic degradation, e.g., by alteration of external pH through metabolite excretion. Tributyltin oxide and tributyltin naphthenate may be degraded to mono- and dibutyltins by fungal action, inorganic Sn^{II} being the final degradation product (38). Organomercury compounds may be detoxified by conversion to Hg^{II} by fungal organomercury lyase, the Hg^{II} being subsequently reduced to Hg^{0} by mercuric reductase, a system analogous to that found in mercury-resistant bacteria.

Some fungi have remarkable degradative properties, and ligninolytic fungi, such as the white rot *Phanerochaete chrysosporium*, can degrade xenobiotics including aromatic hydrocarbons, chlorinated organics, polychlorinated biphenyls, nitrogen-containing aromatics, and many other pesticides, dyes, and xenobiotics (39, 40). Such activities are important in polluted habitats and have been applied in bioremediation where ligninolytic fungi have been used to treat soil contaminated with substances such as pentachlorophenol (PCP) and polynuclear aromatic hydrocarbons (PAHs) (21, 41–43). In many cases, xenobiotic-transforming fungi need additional utilizable carbon sources for cometabolism because although capable of degradation, they cannot adequately utilize these substrates as an energy source. Inexpensive utilizable lignicellulosic wastes such as corn cobs, straw, and sawdust can therefore be used as nutrient additions for enhanced pollutant degradation. Wood-rotting and other fungi have also received considerable attention forthe bleaching of dyes and industrial effluents, and biotreatment of various agricultural wastes such as forestry, pulp, and paper by-products; sugar cane bagasse; coffee pulp; sugar beet pulp; apple and tomato pulp; and cyanide (42).

Fungi are highly important in the degradation of naturally occurring complex molecules in terrestrial and aquatic habitats. Since around 95% of plant tissue is composed of carbon, hydrogen, oxygen, nitrogen, phosphorus, and sulfur, decomposition activities of fungi are clearly important in relation to redistribution of these elements between organisms and environmental compartments. As well as C, H, O, N, P, and S, another 15 elements are typically found in living plant tissues: K, Ca, Mg, B, Cl, Fe, Mn, Zn, Cu, Mo, Ni, Co, Se, Na, and Si. However, all 90 or so naturally occurring elements may be found in plants, mostly at low concentrations, although this may be highly dependent on environmental conditions. These include toxic and inessential metals and metalloids including As, Hg, Pb, and U. Some plants accumulate relatively high concentrations of metals such as Ni and Cd. Plant metal concentrations may reflect environmental conditions and provide a bioindicator of toxic metal pollution or a metalliferous substrate. Metal-accumulating plants are also receiving attention in bioremediation (i.e., phytoremediation).

Similar concepts of element cycling also relate to animal and microbial biomass. Animals also contain multiple elements in varying amounts. The human body (like other organisms) is mostly water, and around 99% of the mass comprises oxygen, carbon, hydrogen, nitrogen, calcium, and phosphorus. However, many other elements are present in lower amounts including substances taken up as contaminants in food and water. It follows that decomposition and degradative and pathogenic activities of fungi are linked to the redistribution and cycling of all these constituent elements on local and global scales. There must be a fungal component, therefore, in the biogeochemical cycles of virtually all biomass-associated elements (3, 21). The release of elements and nutrient moieties through degradation makes them available to other microorganisms and plants, as does chemical interaction with the environmental pool of different chemical species.

FUNGAL INTERACTIONS WITH THE INORGANIC ENVIRONMENT: ROCKS, MINERALS, AND METALS

Bioweathering

Rocks and minerals represent a vast reservoir of elements, many essential for life, and such elements must be released in forms that may be assimilated by the biota. These include essential metals as well as elements such as S and P (3, 44). Many important microbial processes are influenced by minerals including nutrient acquisition, cell adhesion, and biofilm formation (45). Essential nutrients and environmental contaminants sorbed to mineral surfaces can be acquired or removed by organisms including metals and organic compounds (46, 47). Other elements and nutrients may be released from minerals as a result of bioweathering, and fungi have notable activities in this context (3, 16, 24, 48).

Bioweathering can be defined as the erosion, decay, and decomposition of rocks and minerals mediated by living organisms. Fungi are well suited as geoactive weathering agents since they possess a variety of growth, metabolic, and morphological strategies and can be resistant to a range of environmental extremes such as metal toxicity, UV radiation, and desiccation. Their mutualistic associations with plants (mycorrhizas), algae, and cyanobacteria (lichens) are particularly significant geoactive agents (3, 16, 24, 48). The ability of fungi to translocate water, ions, and nutrients within the mycelial network is another important feature for exploiting heterogeneous environments (49–51).

Fungi appear to be ubiquitous components of the microbiota of all rocks, building stone, and concrete, and have been reported from a wide range of rock types, e.g., limestone, marble, granite, sandstone, basalt, gneiss, dolerite, and quartz, even from the most extreme environments (9, 16, 48). Rock surfaces may

be subject to moisture deficit and nutrient limitation, although many species can tolerate extremes of UV irradiation, salinity, pH, and water potential (16, 24, 25, 48, 52). Nutrients can be scavenged from the atmosphere and rainwater, and they also use organic and inorganic residues on surfaces or within cracks and fissures, waste products of other microorganisms, decaying plants and insects, dust particles, aerosols, and animal feces as nutrient sources (24). Fungi may receive protection from environmental extremes by the presence of melanin pigments and mycosporines in their cell walls and by the production of mucilaginous exopolymeric substances that may entrap inorganic particulates, e.g., clay minerals, providing further protection (9, 53). Fungal interactions with rock-mineral substrates can result in dissolution and biodeterioration but also the formation of patinas, films, varnishes, and crusts (3, 9). In soil, fungus-mineral interactions are also an integral component of environmental cycling of elements and nutrients (4, 21).

Biomechanical deterioration of rocks and minerals can occur through hyphal penetration and burrowing into decaying material and along crystal planes in, e.g., calcitic and dolomitic rocks (3, 24, 54). Intracellular turgor pressure may be a significant factor in biomechanical disruption (55, 56). Spatial exploration of the environment to locate and exploit new substrates is facilitated by a range of sensory responses that determine the direction of hyphal growth such as thigmotropism (or contact guidance) (57). Biochemical weathering of rocks and minerals can occur through excretion of geoactive metabolites (58, 59), and this is believed to be a more significant process than mechanical degradation, although a combination of mechanisms is often likely. This can result in pitting and etching of surfaces to complete dissolution of mineral grains (60–62). Bioweathering is a highly significant process and has direct consequences not only for rock and mineral dissolution, but for the mobilization and immobilization of metals, nutrient release, and the formation of secondary minerals (2, 3).

Metal Mobilization

Metal mobilization from rocks, minerals, soil, and other substrates can be a consequence of protonolysis, carbonic acid formation from respiratory CO_2, complexation by Fe^{III}-binding siderophores and other excreted metabolites (e.g., amino acids, phenolic compounds, and organic acids), and methylation (e.g., Hg, Se, and As), which can result in volatilization. Fungus-excreted carboxylic acids can attack mineral surfaces, providing protons as well as a metal-chelating anion, e.g., citrate (58). Oxalic acid can leach metals that form soluble oxalate complexes, e.g., Al and Fe (63). Solubilization mechanisms can result in metal mobilization from toxic metal-containing minerals, e.g., pyromorphite [$Pb_5(PO_4)_3Cl$], contaminated soil, and other solid wastes (64–66). Fungi may also mobilize metals and attack mineral surfaces by redox transformations: Fe^{III} and Mn^{IV} solubility is increased by reduction to Fe^{II} and Mn^{II}, respectively. Fungal reduction of Hg^{II} to volatile elemental Hg^0 has also been recorded (67). As discussed earlier, metals may be mobilized from organic substrates during decomposition (21).

Metal Immobilization

Fungi are effective accumulators of metals and related substances. Important mechanisms include biosorption to cell walls, pigments, and exopolymers, intracellular transport, accumulation and sequestration, and bioprecipitation on and/or around hyphae (3, 53, 68–76). Living and dead fungal biomass are effective biosorbents for a variety of metals including Ni, Zn, Ag, Cu, Cd, and Pb as well as actinides, e.g., U and Th, with a variety of functional groups being involved (24, 53, 76). The presence of chitin, and pigments such as melanin, may enhance the ability of fungal biomass to act as a biosorbent. Fungal biomineralization processes lead to metal immobilization as biominerals or elemental forms, as described below (3).

Biomineralization

Biomineralization is the processes by which organisms form minerals. Biologically induced mineralization is where the organism modifies the local microenvironment, creating conditions amenable for extracellular chemical precipitation of mineral phases. The organism does not appear to control the biomineralization process in biologically induced mineralization, while a great degree of control over biomineralization is exerted in biologically controlled biomineralization, e.g., the complex cellular biomineral structures found in certain other eukaryotes such as diatoms (77). Fungal biomineralization therefore usually refers to biologically induced mineralization. This can result from the bioweathering mechanisms discussed previously such as redox transformations and metabolite excretion (78, 79) and organic matter decomposition where released substances reprecipitate with metals in the microenvironment and *vice versa* (4, 21, 80–82). Fungal surfaces provide many reactive sites for sorption (i.e., biosorption), and this can also lead to the formation of mineral precipitates (2, 71, 83).

Common Mineral and Biomineral Transformations by Fungi

Fungi are involved in many environmental mineral transformations at differing scales (84–86). They are clearly a very important group of geoactive organisms, especially when considering their ubiquity and capacity for production of mineral-transforming metabolites, their symbiotic associations, and the aforementioned consequences of their major significance in organic matter decomposition (4, 5).

Carbonates

Insoluble carbonates may be broken down by fungal attack, usually the result of acid formation (87–89). Such activity is particularly evident on limestones and marble used in building construction but can also occur in natural limestone (88, 90). Fungal attack on carbonates (dolomites and limestones) can result in transformation of these substrates to dolomite [$CaMg(CO_3)_2$], glushinskite ($MgC_2O_4.2H_2O$), weddellite ($CaC_2O_4.2H_2O$), whewellite ($CaC_2O_4.H_2O$), and possibly struvite ($NH_4MgPO_4{\cdot}6H_2O$) (91).

Certain fungi can deposit calcium carbonate extracellularly (92–95). Calcite ($CaCO_3$) and calcium oxalate monohydrate (whewellite; $CaC_2O_4.H_2O$) were precipitated on hyphae of *Serpula himantioides* when grown in simulated limestone microcosms (93). Urease-positive fungi degrade urea-liberating carbonate (96). This process results in the precipitation of metal-containing carbonates, which provides a means of metal immobilization and biorecovery (94). Incubation of *Neurospora crassa* in urea-containing media resulted in the formation of calcite, as well as carbonates containing other metals. When a carbonate-laden *N. crassa* culture supernatant was mixed with $CdCl_2$, the Cd was precipitated in the form of highly pure otavite ($CdCO_3$) (94). After incubation in media containing urea and $CaCl_2$ and/or $SrCl_2$, *Pestalotiopsis* spp. and *Xepiculopsis graminea* (syn. *Myrothecium gramineum*), isolated from calcareous soil, precipitated calcite ($CaCO_3$), strontianite ($SrCO_3$), vaterite in different forms [$CaCO_3$, $(Ca_xSr_{1-x})CO_3$], and olekminskite [$Sr(Sr,Ca)(CO_3)_2$], suggesting that urease-positive fungi could play an important role in the environmental fate, bioremediation, or biorecovery of Sr or other metals and radionuclides that form insoluble carbonates (95). *Paecilomyces javanicus* mediated the formation of an unknown lead mineral phase after incubation in liquid media with lead shot. After 2 weeks of incubation, precipitated mineral phase particles were found to contain plumbonacrite [$Pb_{10}(CO_3)_6O(OH)_6$]. However, after 4 weeks of incubation, the lead particles that accumulated inside the fungal pellets were transformed into a white mineral phase composed of lead oxalate (PbC_2O_4), hydrocerussite [$Pb_3(CO_3)_2(OH)_2$], and a new lead hydroxycarbonate mineral species, thus revealing novel steps in lead carbonation by fungi (97).

Oxalates

Calcium oxalate is the most common form of oxalate in the environment, occurring as the dihydrate ($CaC_2O_4.2H_2O$, weddellite) or the more stable monohydrate ($CaC_2O_4.H_2O$, whewellite) (59, 79). Calcium oxalate can be associated with free-living, pathogenic, and plant symbiotic fungi and lichens and is formed by precipitation of soluble calcium as the oxalate (59, 61, 87, 98, 99). Fungal calcium oxalate can exhibit a variety of crystalline forms (tetragonal, bipyramidal, plate-like, rhombohedral, or needles) (100). Calcium oxalate has an important influence on soil biogeochemistry, acting as a calcium reservoir, and can also influence phosphate availability. Fungi can produce many other metal oxalates on interacting with a variety of metals and metal-bearing minerals, e.g., Ca, Cd, Co, Cu, Mg, Mn, Sr, Zn, Ni, and Pb (3, 59, 64, 79, 101–103). The formation of toxic metal oxalates may contribute to fungal metal tolerance (53, 102). In many arid and semiarid regions, calcareous soils and near-surface limestones (calcretes) are secondarily cemented with calcite ($CaCO_3$) and whewellite (calcium oxalate monohydrate, $CaC_2O_4.H_2O$) and the presence of fungal filaments biomineralized with these substances has been reported (52). Calcium oxalate can also be degraded to calcium carbonate, and this may again cement preexisting limestones (104). Other experimental work has demonstrated fungal precipitation of secondary calcite, whewellite, and glushkinskite ($MgC_2O_4.2H_2O$) (3, 16, 48, 93). Fungal attack on a dolomitic and seawater substrate resulted in the formation of Ca-oxalates (weddellite, $CaC_2O_4.2H_2O$; whewellite, $CaC_2O_4.H_2O$) and glushinskite ($MgC_2O_4.2H_2O$) (105).

Oxides

Several fungi can oxidize Mn^{II} to $Mn^{IV}O_2$, including *Acremonium* spp. (17, 106, 107). Fungal oxidation is probably nonenzymatic in many cases, although involvement of laccase and/or multicopper oxidases has been shown in ascomycetes (17, 106). Non-enzymatic microbial Mn^{2+} oxidation may be effected through production of organic acids such as citrate, lactate, malate, gluconate, or tartrate. Some fungi can oxidize Mn^{II} and Fe^{II} in metal-bearing minerals such as siderite ($FeCO_3$) and rhodochrosite ($MnCO_3$), resulting in their precipitation as oxides (108). Manganese and iron oxides

are major components (20 to 30%) along with clay (~60%) and various trace elements in desert varnish (9, 108). Oxidation of Fe^{II} and Mn^{II} by fungi can lead to the formation of dark patinas on glass surfaces (109). Manganese-reducing microbes may mobilize oxidized manganese, releasing it into the aqueous phase. Most of those fungi that reduce Mn^{IV} oxides reduce them indirectly (non-enzymatically), with the likely mechanism being the production of metabolic products that act as reductants for Mn^{IV} such as oxalate (1, 103).

Phosphates

Phosphorus occurs primarily as organic phosphate esters and inorganic forms, e.g., calcium, aluminum, and iron phosphates. Organic phosphates are broken down by phosphatases which liberate orthophosphate during the microbial decomposition of organic material. Fungi also mobilize orthophosphate from insoluble inorganic phosphates by producing acids or chelators, e.g., gluconate, citrate, oxalate, and lactate, which complex the metal, resulting in dissociation. Phosphate-solubilization is very important in the plant mycorrhizosphere (110). Microbes can also play a role in the formation of phosphate minerals such as vivianite [$Fe_3(PO_4)_2.8H_2O$], strengite ($FePO_4.2H_2O$), and variscite ($AlPO_4.2H_2O$). The orthophosphate may be derived from organic phosphate degradation, while Fe or Al may arise from solubilization of other minerals. Such formation of phosphate minerals is probably most common in soil (1). Fungal biodeterioration of metallic lead can result in pyromorphite [$Pb_5(PO_4)_3X$ (X= F, Cl or OH)] formation (111–113). Many fungi can solubilize uranium oxides and depleted uranium and reprecipitate secondary uranium phosphate minerals, uramphite, and/or chernikovite, which can encrust fungal hyphae to high accumulation values (73, 74, 114). These minerals appear capable of long-term U retention (73, 74, 114, 115). *Aspergillus niger* and *P. javanicus* precipitated U-containing phosphate biominerals when grown with an organic P source with the hyphal matrix acting to localize the uranium minerals. The uranyl phosphates identified included potassium uranyl phosphate hydrate ($KPUO_6.3H_2O$), meta-ankoleite [$(K_{1.7}Ba_{0.2})(UO_2)_2(PO_4)_2.6H_2O$], uranyl phosphate hydrate [$(UO_2)_3(PO_4)_2.4H_2O$], meta-ankoleite [$K(UO_2)(PO_4).3H_2O$], uramphite ($NH_4UO_2PO_4.3H_2O$), and chernikovite [$(H_3O)_2(UO_2)_2(PO_4)_2.6H_2O$] (80). These organisms could also mediate lead bioprecipitation during growth on organic P substrates (81). These minerals were identified as pyromorphite [$Pb_5(PO_4)_3Cl$], which was only produced by *P. javanicus*, and lead oxalate (PbC_2O_4), which was produced by *A. niger* and *P. javanicus* (81). Several yeasts could also mediate lead bioprecipitation when utilizing an organic phosphorus-containing substrate (glycerol 2-phosphate, phytic acid) as the sole phosphorus source. The minerals precipitated here included lead phosphate [$Pb_3(PO_4)_2$], pyromorphite [$Pb_5(PO_4)_3Cl$], anglesite ($PbSO_4$), and the lead oxides massicot and litharge (PbO). All yeasts examined produced pyromorphite, and most produced anglesite (82).

Silicates

Silicates comprise 30% of all minerals and about 90% of the Earth's crust (116) (1, 60, 116). Many species of fungi play a role in the dissolution of silicates and therefore in the formation of clay minerals, and in soil and sediment formation (54, 87, 117–122). The presence of clay minerals can be a typical symptom of rock bioweathering by lichens and ectomycorrhizas (118, 119). Bioweathering is mainly indirect, through the production of metabolites together with biomechanical effects (123, 124). Geoactive metabolites may be excreted into the bulk phase but may also be produced by adhering organisms on silicate surfaces, resulting in etching (125, 126). After colonization of sheets of muscovite, a phyllosilicate mineral, by *A. niger*, dissolution was evident by a network of fungal "footprints" that reflected coverage by the mycelium (126). New biominerals resulted from fungal interactions with both zinc silicate and zinc sulfide, largely resulting from organic acid excretion. Zinc oxalate dihydrate was formed, and mineral surfaces showed varying patterns of bioweathering and biomineral formation (127). Silicate dissolution may release limiting nutrients such as bound P and Fe. In lichen bioweathering of silicates, calcium, potassium, iron, clay minerals, and nanocrystalline aluminous iron oxyhydroxides become mixed with fungal organic polymers (118), while biotite [$K(Mg,Fe(II))_3AlSi_3O_{10}(OH,O,F)_2$] was penetrated by fungal hyphae along cleavages, partially converting it to vermiculite [$(Mg,Fe(II),Al)_3(Al,Si)_4O_{10}(OH)_2.4H_2O$] (117). The fungal partner has also been reported to be involved in formation of secondary silicates such as opal ($SiO_2.nH_2O$) and forsterite (Mg_2SiO_4) in lichen thalli (128). The transformation rate of mica and chlorite to clay minerals was pronounced in ectomycorrhizosphere soil and was probably a result of production of organic acids and direct extraction of K^+ and Mg^{2+} by fungal hyphae (119). Fungal-clay mineral interactions also play an important role in soil development, aggregation, and stabilization (16, 129). Interaction between clay minerals and fungal biomass alters the sorptive properties of both clay minerals and fungal hyphae (130, 131) and also affects the size, shape, and structure of mycelial pellets (132).

Reduction or oxidation of metals and metalloids

Many fungi can precipitate reduced forms of metals and metalloids, e.g., Ag^{I} reduction to elemental silver Ag^{0}; selenate (Se^{VI}) and selenite (Se^{IV}) to elemental selenium (Se^{0}); and tellurite (Te^{IV}) to elemental tellurium (Te^{0}) (133–135). Reduction of Hg^{II} to volatile Hg^{0} can also be mediated by fungi (67, 68). Increased arsenate reduction contributed to tolerance in an *Aspergillus* sp. (136, 137). Mn oxidation/reduction is described above.

Other mycogenic minerals

A range of minerals other than those mentioned above have been found in association with fungi (2, 3, 73, 74, 77, 80–82, 114). Mycogenic secondary minerals associated with fungal hyphae and lichen thalli include desert varnish (MnO and FeO), ferrihydrite ($5Fe_2O_3.9H_2O$), iron gluconate, calcium formate, forsterite, goethite [α-$Fe^{3+}O(OH)$], moolooite [$Cu(C_2O_4).0.4H_2O$], halloysite [$Al_2Si_2O_5(OH)_4$], and hydrocerussite [$Pb_3(CO_3)_2(OH)_2$] (16, 48, 52, 108, 120, 128, 138). Another biogenic mineral (tepius) has been identified in association with a lichen carpet occurring in high mountain ranges in Venezuela (128).

Halide transformations

Several fungi have the ability to produce a variety of atmospheric methyl halides. This ability is widespread in both free-living and symbiotic fungi and is dependent on substrate concentration and community composition (139, 140). The production of chloromethane (CH_3Cl) by wood-rotting fungi, e.g., *Phellinus* spp., may be particularly significant, with one estimate of annual global input to the atmosphere from this source being 160,000 tons, of which 75% is released from tropical and subtropical forests (139). Filamentous fungi may also contribute to the global circulation of stable iodine and the long-lived radioiodine, ^{129}I (half-life: 1.6×10^7 years), released from nuclear facilities (141).

FUNGAL SYMBIOSES IN GEOMYCOLOGY

Many fungi form partnerships with plants (mycorrhizas) and algae or cyanobacteria (lichens) that are significant geoactive agents. In general terms, the mycobiont is provided with carbon by the photobionts, while the mycobiont may protect the symbiosis from harsh environmental conditions (e.g., desiccation, metal toxicity), and provide increased access to inorganic nutrients such as phosphate and essential metals.

Lichens are fungi that exist in facultative or obligate symbioses with one or more photosynthesizing partners occurring in almost all surface terrestrial environments (142). Lichens play important roles in retention and distribution of nutrient (e.g., C, N) and trace elements, in soil formation, and in rock bioweathering (54, 87, 143). Lichens can accumulate metals such as lead (Pb) and copper (Cu) and many other elements, including radionuclides (144). They also form a variety of metal-organic biominerals, e.g., oxalates, especially during growth on metal-rich substrates (98, 143). On copper sulfide-bearing rocks, precipitation of copper oxalate (moolooite) can occur within lichen thalli (145, 146).

The majority of terrestrial plants depend on symbiotic mycorrhizal fungi (147, 148). Mycorrhizal fungi can mediate metal and phosphate solubilization from mineral sources, effect extracellular precipitation of metal oxalates, and immobilize metals within biomass (65, 66, 149–157). Such activities lead to changes in the physico-chemical characteristics of the root environment and enhanced bioweathering of soil minerals (55, 157, 158). Furthermore, ectomycorrhizal mycelia may respond to different soil silicate and phosphate minerals (e.g., apatite, quartz, potassium feldspar) by regulating growth and metabolic activity (159, 160).

Mycorrhizal fungi often excrete bioweathering agents such as low–molecular-weight carboxylic acids and siderophores (65, 161). Ectomycorrhizal fungi can also form narrow pores in weatherable minerals in podzol E horizons, probably by dissolution of Al silicates (162, 163). Such excretions can also release elements from apatite and wood ash (K, Ca, Ti, Mn, Pb) (164). Ericoid mycorrhizal and ectomycorrhizal fungi can dissolve several cadmium, copper, zinc, and lead-bearing minerals including metal phosphates (65, 66, 152, 161, 165). Mobilization of phosphorus from inorganic and organic phosphorus sources is generally regarded as one of the most important functions of mycorrhizal fungi, and this can also result in redistribution of incorporated metals and the formation of other secondary minerals including other metal phosphates. The ericoid mycorrhiza *Oidiodendron maius* can solubilize zinc oxide and phosphate (161). Many ericoid mycorrhizal and ectomycorrhizal fungi are able to solubilize zinc, cadmium, copper phosphates, and lead chlorophosphate (pyromorphite), releasing phosphate and component metals (65, 152). An association of arbuscular mycorrhizal fungi with *Lindenbergia philippensis*, sampled from a Zn-contaminated settling pond at a zinc smelter, enhanced Zn accumulation in Zn-loaded rhizosphere sediment compared to treatments that suppressed arbuscular mycorrhizal fungi colonization. A significant proportion of Zn was present as crystalline and other solid materials that were associated with the root

mucilaginous sheath (166). Such results may indicate a role for arbuscular mycorrhizal fungi in enhancing Zn immobilization in the rhizosphere of plants that successfully colonize Zn mining and smelting disposal sites (153, 166–168).

ENVIRONMENTAL AND APPLIED SIGNIFICANCE OF GEOMYCOLOGY

The kinds of processes detailed previously can impact human society not only through their environmental significance and biotechnological applications, but also in deleterious contexts such as biodeterioration and biocorrosion. The biodeterioration of stone and mineral artifacts represents a loss of cultural heritage (13, 14). Materials used to stabilize building blocks (mortar) and to coat surfaces prior to painting (plaster or stucco) are also susceptible to biodeterioration (13). Highly deteriorated stone surfaces provide a "protosoil" for colonization by mosses, ferns, and higher plants (14). Mechanisms of stone deterioration are complex and include most of the direct and indirect mechanisms previously discussed for mineral dissolution (13, 169). Extracellular polymeric substances are also capable of metal complexation and weakening of mineral lattices through wetting and drying cycles, as well as the production of efflorescences, i.e., secondary minerals produced through the reaction of anions from excreted acids with cations from the stone (170). Physical damage may be caused by hyphal penetration of weakened areas (88, 138). Lichens cause damage due to penetration by their rhizines, composed of fungal filaments, and expansion/contraction of the thallus on wetting/drying (171). "Lichen acids," mainly oxalic acid, cause damage at the stone-lichen interface, and lichen thalli may accumulate up to 50% calcium oxalate, depending on the substrate (172, 173). In addition, carbonic acid formed in the lichen thallus can solubilize calcium and magnesium carbonates in calcareous stone (174). Fungal biodeterioration of ancient ivory (natural apatite; walrus tusk) was accompanied by widespread etching and tunneling by hyphae and extensive formation of calcium oxalate monohydrate, whewellite (175). Concrete and cement can be biodeteriorated, and in some environments, fungi dominate the concrete-deteriorating microbiota (13, 14, 176–178). Microbial attack on concrete is mediated by protons, inorganic and organic acids, and the production of hydrophilic slimes leading to biochemical and biomechanical deterioration (13, 75, 169). Several species of microfungi were able to colonize samples of the concrete used as a radioactive waste barrier in the Chernobyl reactor and leached iron, aluminum, silicon, and calcium and reprecipitated silicon and calcium oxalate (75).

Mineral and metal solubilization mechanisms enable metal removal from industrial wastes, low-grade ores, and metal-bearing minerals. This may have applications in bioremediation, metal biorecovery, and recycling (58, 68, 179, 180). Metals can be solubilized from fly ash (originating from municipal solid waste incineration), contaminated soil, electronic scrap, and other waste materials by fungal activity (179, 181). Although fungal systems cannot compare with the efficiency of bacterial bioleaching, they may be more suited to specific bioreactor applications (58). A variety of fungal mechanisms result in metal immobilization such as biosorption, bioaccumulation, and bioprecipitation. Biosorption is a physico-chemical process and is a property of both living and dead organisms (and their components), and fungi are effective agents for removal of metals, radionuclides, and other substances from solution (69–71, 76, 130, 182–193). Urease-positive fungi can be used to precipitate metal-containing carbonates, some in nanoscale dimensions, thus providing a means of metal biorecovery as well as potentially useful nanoscale biomineral products (94, 95). Similarly, the formation of other insoluble metal compounds by fungi or their metabolites could also be considered as a means to biorecover metals, metalloids, and radionuclides, e.g., oxalates, oxides, and phosphates, as well as the production of elemental metal or metalloid forms (2, 78). Some biomineral and elemental products, including those of nanoscale dimensions, are relevant to the production of novel advanced biomaterials, with applications in metal and radionuclide bioremediation, antimicrobial treatments (e.g., nano-silver), solar energy and electrical battery applications, and microelectronics (194). In a novel approach, urease-positive *N. crassa* was used to precipitate manganese carbonate. After thermal treatment at 300°C, the carbonized biomass-manganese oxide composite material was used in lithium-ion batteries and supercapacitors, where it was found to exhibit excellent electrochemical properties. In lithium-ion batteries, around 90% charge capacity was retained after 200 charge-discharge cycles (195).

The ability of fungi and bacteria to transform metalloids has been successfully used for bioremediation of contaminated land and water. Selenium methylation results in volatilization, and this has been used to remove selenium from the San Joaquin Valley and Kesterson Reservoir, California (196). Mycorrhizal associations may have applications in phytoremediation (197, 198), the use of plants to remove or detoxify

environmental pollutants (199), by metal phytoextraction or by acting as a biological barrier (200–202). Glomalin, an insoluble glycoprotein, is produced in copious amounts on hyphae of arbuscular mycorrhizal fungi and can sequester metals such as Cu, Cd, and Pb (203). Arbuscular mycorrhizal fungi can also decrease U translocation from plant roots to shoots (204–206). For ericaceous mycorrhizas, the fungus prevents translocation of Cu and Zn to host plant shoots (147, 207, 208). The development of stress-tolerant plant-mycorrhizal associations may be a promising strategy for phytoremediation and soil amelioration (161, 209, 210).

Some of the geomycological processes detailed previously may have consequences for abiotic soil treatment processes, notably the immobilization of toxic metals by phosphate formation. Apatite [$Ca_5(PO_4)_3$(F, Cl,OH)], pyromorphite [$Pb_5(PO_4)_3Cl$], mimetite [$Pb_5(AsO_4)_3Cl$], and vanadinite [$Pb_5(VO_4)_3Cl$] are the most common prototypes of the apatite mineral family. Such minerals hold promise for stabilization and recycling of industrial and nuclear waste and have been explored for treatment of lead-contaminated soils and waters (211–216). The stability of these minerals is therefore of interest in any soil remediation strategy seeking to reduce the effects of potentially toxic elements such as Pb, V, and As. For example, pyromorphite is a highly insoluble lead phosphate mineral under a wide range of geochemical conditions and has often been suggested as a means to reduce Pb bioavailability. However, solubilization of pyromorphite and formation of lead oxalate by several free-living and symbiotic fungi demonstrate that pyromorphite may not be as effective at immobilizing lead as some previous studies have suggested (64, 65). Similarly, despite the insolubility of vanadinite, fungi exerted both biochemical and biophysical effects on the mineral including etching, penetration, and the formation of new biominerals (217). Lead oxalate was precipitated by *A. niger* during the bioleaching of vanadinite and mimetite, which suggests a general fungal mechanism for the transformation of lead-containing apatite-group minerals (e.g., vanadinite, pyromorphite, mimetite) (217, 218).

This pattern of fungal bioweathering of lead apatites could be extended to other metal apatites, such as calcium apatite [$Ca_5(PO_4)_3(OH,F,Cl)$]. Here, the formation of monohydrated (whewellite) and dihydrated (weddellite) calcium oxalate can be accomplished by many different fungal species (79, 93, 99, 175, 219, 220). The ability of free-living and mycorrhizal fungi to transform toxic metal-containing minerals should therefore be taken into account in risk assessments of the long-term environmental consequences of *in situ* chemical remediation techniques, revegetation strategies, or natural attenuation of contaminated sites. The bioweathering potential of fungi has been suggested as a possible means for the bioremediation of asbestos-rich soils. Several fungi could extract iron from asbestos mineral fibers (e.g., 7.3% from crocidolite and 33.6% from chrysotile by a *Verticillium* sp.), thereby removing the reactive iron ions responsible for DNA damage (221).

CONCLUSIONS

The geoactive roles of fungi have often received scant attention in geomicrobiological contexts, but they are of clear importance in several key areas. These include a variety of organic and inorganic transformations important in nutrient and element cycling, rock and mineral bioweathering, mycogenic biomineral formation, and metal-fungal interactions. Lichens and mycorrhizas are of special significance as geoactive agents. Organic matter decomposition is important for the cycling of major biomass-associated elements, e.g., C, H, N, O, P, and S as well as all other elements that may be found in lower concentrations. Transformations of metals and minerals are central to many geomicrobial processes, and fungi can effect changes in metal speciation, toxicity, and mobility, as well as mediate mineral formation or dissolution. Such mechanisms are important components of natural biogeochemical cycles for metals as well as associated elements in biomass, soil, rocks, and minerals, e.g., S and P, and metalloids, actinides, and metal radionuclides. It is within the terrestrial environment where fungi have the greatest abundance and geochemical influence. However, they are also important in aquatic habitats and are now recognized as significant components of aquatic sediments and the deep subsurface. Geomycological processes can have beneficial or detrimental consequences in a human context. Beneficial applications in environmental biotechnology include metal and radionuclide bioleaching, biorecovery, detoxification, and bioremediation, and in the production of biominerals or metal(loid) elements with catalytic or other properties in nanoparticle, crystalline or colloidal forms. The latter may be relevant to the development of novel biomaterials. Adverse effects include biodeterioration and destruction of natural and synthetic materials; rock and mineral-based building materials (e.g., concrete); cultural heritage; biocorrosion of metals, alloys, and related substances; and adverse effects on radionuclide speciation, mobility, and containment. The ubiquity and importance of fungi in biosphere processes underlines the importance of

geomycology as a conceptual framework encompassing the environmental activities of fungi, their impact, and their applied significance.

Ecology of Fungal Plant Pathogens

17

Aad J. Termorshuizen

INTRODUCTION

Plant pathogens are parasites that live at the expense of their host. While fungal pathogens are the largest group of plant pathogens, other important plant pathogens include bacteria, protists, chromists, nematodes, and even plants. Although this wide variety of pathogens share many aspects in epidemiology and management, here we deal only with fungal plant pathogens. The economic importance of fungal plant pathogens in the production of food, feed, materials, and ornamentals is undisputed (1). Direct costs include yield loss and use of resistant cultivars or pesticides. Indirect costs include the inability to grow certain crops or cultivars at a given location. Inspection and quarantine protocols to prevent the dispersal of pathogens (2) are indirect costs that are rarely taken into account. In contrast, as will be shown in this review, plant pathogens in nature are regarded as crucial contributors to the maintenance of biodiversity, similar to the role major animal predators play in wildlife.

Plant pathogens comprise a heterogeneous group of organisms that share the ability to infect their hosts. Pathogens able to infect apparently healthy plants are referred to as primary pathogens. Secondary pathogens typically appear after infection by a primary pathogen. Weak or minor pathogens usually cause negligible yield decline, although stronger yield loss can result if the host is stressed by other biotic or abiotic factors. The remarkable heterogeneity of plant pathogens can be expressed in multiple ways (3):

- **Nutrition:** Biotrophic (e.g., powdery mildews and rust fungi) or necrotrophic (e.g., most leaf spot diseases).
- **Host range:** From polyphagous (e.g., *Botrytis cinerea*) to plant species- or cultivar-specific (e.g., *Puccinia graminis* causing black rust on wheat).
- **Survival:** Inside living host tissue or on crop debris and in soil.
- **Infection:** Through stomata (e.g., rust fungi), direct penetration (e.g., many leaf spot diseases and smut diseases) or through wounds (many wood-rotting fungi).
- **Dispersal:** By wind (long range, e.g., many airborne pathogens, water-splash (short range, e.g., *Cercospora* leaf spot), growth in soil (short range soil-borne pathogens), or vectors, mainly insects (mid- to long-range, e.g., *Ophiostoma novo-ulmi*); for agronomic plant pathogens, anthropogenic dispersal is probably most important (infested soil and infected plants including seeds).
- **Symptoms:** E.g., ongoing necrosis of stem (stem blight) or leaves (leaf blight), limited necrosis development (leaf spot or anthracnose), wilting, seed or flower infection, root rot, seedling damping-off.
- **Taxonomic position:** Chytridiomycota (mostly pathogens of algae), Ascomycota (containing most of the fungal plant pathogens) and Basidiomycota (mostly wood rot-causing fungi but also includes the important pathogen *Rhizoctonia solani* [syn. *Thanatephorus cucumeris*]). Except for some post-harvest diseases, the Zygomycota are of lesser importance.
- **Persistence:** Variable longevity (from days to years); typically, soil-borne pathogens are persistent, with a minimal survival time of 1 year.
- **Plant-pathogen interaction:** Monogenic gene-for-gene relation or polygenic.
- **Activity inside the host:** Remaining local (many leaf spot fungi) to having the ability to move within the plant through systemic growth (e.g., powdery mildews) or through xylem tissue (wilt fungi).
- **Life cycle:** Monocyclic or polycyclic (i.e., referring to the number of generations within one growing season); with or without a sexual phase, with or without host alternation.

Soil Cares Research, 6709 PA Wageningen, The Netherlands.

Knowledge of these attributes of plant pathogens provides keys to their management. Examples include the following:

- Obligate pathogens often tend to respond strongly to host nutritional status, which can be influenced by fertilization management.
- Pathogen host range provides information on crops that can be cultivated.
- Site of pathogen survival determines what plant parts (e.g., cuttings) can be safely transported.
- Pathogen dispersal strategy impacts the need for forecasting systems.
- Disease symptomatology is needed for proper pathogen recognition.
- Pathogen persistence provides information on the time a farmer has to refrain from cropping a host on the infested soil.
- Host relationship indicates the perspectives of resistance breeding.
- Pathogen activity within the host predicts disease development within a host.
- Pathogen life cycle attributes predict epidemic disease development.

Because plant pathogens threaten the world's food security, most research has been done on pathosystems in arable and greenhouse farming. In addition, they infect a range of ornamental crops of great economic value. Only recently has the significance of pathogens in natural ecosystems been appreciated (4).

PLANT DISEASE

Plant disease is an abnormal behavior of plant development. What abnormal plant development actually is can be a semantic discussion (5), but in its extreme, i.e., heavily attacked plants which die prematurely, it is obvious. On the other hand, a minor infection of, say, a few pustules per plant of a rust pathogen, is practically harmless but can be the initial stage of a major epidemic. Plant diseases may remain undetected because the symptoms they produce are invisible or indistinguishable from other factors. For example, in potato *Verticillium dahliae* incites the crop to die a few weeks earlier than would be the case in its absence, which often goes unnoticed by the farmer (6). In agriculture, a pragmatic approach is that a disease is only deemed significant if the pathogen affects the marketable yield.

The classic conceptual framework for evaluating disease is the so-called disease triangle (7). Although many variants of the original disease triangle have been published (e.g., reference 8), they all essentially state that plant disease depends on the characteristics of host, pathogen, and environment. Thus, the minimum requirement for plant disease to develop is the presence of a virulent pathogen, a susceptible host, and suitable biotic and abiotic environmental conditions. The outcome of this interaction (plant disease and potentially a subsequent epidemic) depends on quantitative characteristics such as the amount of pathogen and host present, the rate of pathogen and host development as a function of environmental conditions, and the sensitivity of the host. An interesting example of how the disease triangle could be used in predicting the coexistence of plant biodiversity is provided by Mordecai (9).

Disease Triangle Elements: Plant Pathogen

Pathogens are classified primarily on the basis of their genus and species name. Pathogens often appear more variable than initially assumed. For example, the great majority of *Fusarium oxysporum* organisms occurring in soil are not plant pathogenic, and only a minority are able to infect root tissue. Morphological differences between pathogenic and nonpathogenic strains are absent, and pathogenicity toward a single host can be polyphyletic (10, 11). The same is true for *R. solani*, which is differentiated into anastomosis groups on the basis of vegetative incompatibility of agar-cultivated mycelia. These anastomosis groups have been differentiated into subgroups and sub-subgroups which, respectively, show some and limited vegetative incompatibility (12). These subdivisions appear functional because they exhibit different ecological traits in, e.g., host range and temperature characteristics. In some cases, the inability to anastomose in pure culture has led to improved insight into speciation (e.g., intersterility groups in the *Armillaria mellea* species complex [13]), whereas in other cases this is much less the case (e.g., vegetative compatibility groups in *V. dahliae* [14]). For *Synchytrium endobioticum*, the causal agent of potato wart, a range of pathotypes exist that can only be differentiated on the basis of bioassays (15). All these infraspecific rankings are confusing, and therefore a call has been made to include sequence data in all research and publications and to infer from this information the genetic basis and characteristics of the particular strain being studied (16, 17). While this approach is needed for improving our knowledge of pathogens, their accurate scientific names are essential for efficient communication among a variety of stakeholders such as farmers, their advisors, and policy-makers.

Pathogens may interact with each other. For example, synergistic effects between wilt fungi (*V. dahliae* and *F. oxysporum*) and plant parasitic nematodes

(*Pratylenchus* and *Meloidogyne*) are known (18). The mechanism of this fungus-nematode interaction is not well understood. The nematode may provide infection courts for the wilt fungus, but spatial separation of the fungus and nematode also aggravates disease (19). Leguminous crops are well known for the consortia of fungi (including oomycota) that cause root rot (20, 21).

Pathogen density, along with host density (see below), plays a crucial role in the development of an epidemic. When host density in a given crop does not vary, pathogen density is of great importance to predict disease caused by soil-borne pathogens. Therefore, preplant soil inoculum densities can be used to decide the crop or cultivar choice (e.g., reference 22).

Disease Triangle Elements: Host

Host density plays a prominent role in the epidemic development of a disease. For several diseases, a lower-threshold host density for dispersal has been defined (23, 24). For example, attempts to establish plantations of *Hevea brasiliensis*, the source of natural rubber, within its native range have largely failed due to epidemic occurrence of rubber leaf blight caused by *Pseudocercospora ulei* (syn. *Microcyclus ulei*). This pathogen is only of minor importance at natural sites of the rubber tree, and the difference within plantations has been attributed to the unnaturally high density of the host in plantations (25). By and large, this is true for many of the pathogens that are important in agroecosystems, where they cause greater damage due to high host density than in plant species-rich natural vegetation (26). The level and type of resistance of the host plant is another decisive factor in disease development. For instance, the threshold inoculum level of *V. dahliae* for cotton was estimated at 4 and 7 CFU per gram of soil for susceptible and resistance cultivars, respectively (22).

Disease Triangle Elements: Environment

The environment comprises the whole array of biotic and abiotic conditions that define host susceptibility and pathogen status. Soil type and nutrition play important roles in the response of the host to a pathogen. A shortage of essential macro- or micronutrients may lead to increased susceptibility (27); in particular, ammonium and nitrate nutrition can interact with certain obligate pathogens (28). Tropical pathogens can be frost-sensitive (e.g., *Macrophomina phaseolina* and *Sclerotium rolfsii*), while others are inactive at high temperatures that prevail in the (sub)tropics (e.g., *V. dahliae*). Certain biota are able to suppress pathogens, e.g., yeast fungi in the phyllosphere (29) and certain bacteria and fungi in the soil (30). Abiotic stress leading to increased susceptibility or resistance of the host to later infection is referred to as predisposition (reviewed in reference 31). An example is the off-site planting of *Cupressus macrocarpa*, where cypress canker, caused by *Seiridium cardinale*, causes much damage (32). The host grows well in these off-site, relatively dry conditions in the absence of the pathogen, but in the pathogen's presence it suffers much damage, whereas at its native site, more humid and cool, the pathogen is virtually absent. This differential effect may reflect the allocation of resources to growth at the expense of defense actions (33). Abiotic factors enhancing pathogens under certain conditions enhance predisposition. It has been suggested that tree seedlings that typically grow in dry habitats cannot do so in wet conditions, due to their sensitivity to soil-borne pathogens that thrive well in those conditions (34).

Three major groups of plant pathogens are usually recognized; soil-, air-, and seed-borne plant pathogens. Soil-borne pathogens are able to survive in soil for at least 1 year but usually for multiple years in the absence of a host (35). Only a few soil-borne pathogens sporulate aboveground, so the majority of them have limited dispersal capability (but see reference 36 for some exceptions). Airborne pathogens are not able to survive a cropless period within soil. They either survive on organic debris situated on the soil (e.g., grain stubble) or, in the case of perennial hosts, inside the living host. If they survive consistently within seeds, they are generally referred to as seed-borne fungi. These traits have major consequences for their management in agroecosystems (Table 1): inocula of airborne pathogens on crop debris incorporated into the soil will be inactivated quickly. Predicting the occurrence of epidemics of airborne pathogens is difficult because of their long-range dispersal. Fungicides may have strong effects on airborne pathogens, but in soil they are decomposed quickly by the soil microbial community, rendering many of them ineffective. Resistance genes are available for airborne pathogens but much less so, or not at all, for soil-borne pathogens. Predicting disease caused by soil-borne pathogens is based on the estimation of soil inoculum density. Such tests are usually costly, especially if spatial distribution (which very often is patchy) is to be taken into account. Soil-borne pathogens can be managed using proper rotations, while this is not the case for airborne pathogens. The primary focus of managing seed-borne pathogens is to produce uninfected seeds and to carry out effective seed treatment to clean infected seeds.

These three major groups of soil-, air- and seed-borne pathogens do share specific characteristics. Host range

Table 1 Characteristics of the three major ecological groups of fungal plant pathogens[a]

Characteristic	Soil-borne pathogens	Airborne pathogens	Seed-borne pathogens
Survival	In soil; often multiple years in the absence of a host	On infected crop debris for a relatively short duration, in seeds, or in perennial hosts	Within seeds
Dispersal	Natural dispersal short-range, slow, usually by root-to-root contact but also by airborne soil dust (dust storms); anthropogenic dispersal by moving infested soil and infected planting material	Natural dispersal long-range, fast, by massive spore production that is transported by air or by splash; anthropogenic dispersal by infected planting material	By infected seeds; subsequent sporulation on infected plants
Disease cycle	Usually monocyclic	Usually polycyclic	Mono- or polycyclic[b]
Key epidemiological parameters	Soil inoculum density, persistence	Climate models, mode of dispersal (wind- or splash-transmitted)	Quantity of seed infection, presence of sporulation on infected plants[b]
Management	Crop rotation, soil quality improvement	Pesticides, resistant cultivars, disease forecasting	Seed disinfestation, pesticides, use of uninfected seeds

[a]Not all pathogens fit into this classification. For example, *Sclerotinia sclerotiorum* and several smut fungi are highly persistent in soil and have a phase of airborne dispersal of spores as well.
[b]Many seed-borne pathogens have an airborne phase in which they are polycyclic.

in these groups varies from very small to very wide. For example, a small host range occurs in the soil-borne potato wart disease caused by *S. endobioticum*, which infects only potatoes, and in many airborne powdery mildew fungi and seed-borne smut fungi that have only a single host plant. Very wide host ranges are exemplified by the soil-borne *Verticillium* wilt caused by *V. dahliae*, which is able to infect hundreds of hosts, and the airborne *B. cinerea*, which is able to cause all kinds of shoot, flower, and fruit rot in many plant species.

LATENT INFECTIONS AND ENDOPHYTES

One of the basic elements of plant pathogen disease cycles is their latency period, which is defined as the time between infection and the appearance of the first disease symptoms (3). Infections before symptom development are usually only detected by isolating the pathogen. In international trade, such latency periods can be the reason for keeping suspected material in quarantine for some time. However, also after the appearance of the first disease symptoms pathogens can move into an asymptomatic, latent stage. Examples include the survival of pathogens in seeds or in overwintering buds of trees. Latent infections impede the inspection of plant health since they are easily overlooked.

Some pathogens are also able to infect hosts without causing any disease symptoms, whereas in others they readily cause disease. For example, Malcolm et al. (37) reported symptomless infection of *V. dahliae* (a primary wilt pathogen of, i.e., olive, strawberry, and cotton) in 9 agronomic crops and 25 weed species. Plant-infecting fungi not causing disease symptoms are referred to as endophytes (38, 39). Thus, whether *V. dahliae* should be classified as pathogen or endophyte is host-dependent. This endophytic behavior of a primary pathogen in other hosts makes inspection procedures difficult. To complicate matters further, *V. dahliae* is known to have two types of latent stage: first, the infection of root systems and, second, the interruption of wilt development at temperatures above 30°C (40). Despite this variable behavior, *V. dahliae* is still regarded as a single species (16). Some important widespread pathogens appear to be clonal in nature (e.g., Panama disease of banana caused by *F. oxysporum* f. sp. *cubense* race 4 [41]), but in general, the adage is "Show me a plant pathogen, and I will show you a species complex" (42). For example, *Colletotrichum acutatum* appeared to consist of 31 taxa (43). Failure to scout diseased strawberry plants infected by *C. acutatum* (44), the causal agent of anthracnose, due to its latent presence caused large economic losses in many places (45). Other examples of latent pathogens are provided by Crous et al. (17).

EFFECTS OF FUNGAL PLANT PATHOGENS

The dilution effect hypothesis predicts a lower abundance of pathogens if their hosts occur in biodiverse

plant communities (46). There is a vast body of data supporting this conclusion (46). For example, the leaf area infected by fungal pathogens was on average 3 times higher in single-species grasslands than in a mixed grassland containing 24 planted species (47), and the number of host-specific leaf pathogens of trees is fewer in mixed forests (48). The magnitude of the dilution effect depends on the phylogenetic composition of the vegetation and the host range of the plant pathogens (49). The main hypothesis explaining the dilution effect hypothesis is host camouflage: pathogens have a lower probability of arriving at a host's surface if more nonhosts are present, because nonhosts intercept airborne propagules or because host-specific signals are diluted. An additional mechanism could be differential behavior of auto-infections (i.e., infections arising from inoculum produced on the same plant) compared to allo-infections: auto-infections of wheat by *Puccinia triticina* lead to shorter latent periods (i.e., the period from infection to producing new inoculum) than allo-infections (50). Irrespective of the outcome of a host-pathogen interaction, that is, disappearance of host or pathogen or coexistence, Salama et al. (51) argued that in a natural ecosystem the magnitude of the seed bank of the host would dampen these effects.

The Janzen-Connell hypothesis predicts that host-specialized pathogens maintain high diversity by elevating mortality when plant species occur at high density; i.e., if more host plants exist, the pathogen causes greater disease and the number of host plants is reduced (52, 53). More specifically, this hypothesis has been used to explain the high tree species biodiversity in tropical forest ecosystems. It is now widely accepted that natural enemies, including fungal pathogens, play a major role in this. For example, in the tropical rainforests of Belize, the negative density dependence of seedling mortality was attenuated after application of broad-spectrum fungicides (54). In a more detailed study, the low germination of seedlings of *Ormosia glaberrima* in forests with a high density of mature specimens of this species was reversed by fungicide treatment (55). The authors suggested that *F. oxysporum* could have been the cause of this. Where pathogens limit the development of certain plant species, they leave space for other species, thus promoting vegetation diversity in space (56) or in time (57).

In forests, canopy gaps are crucial elements for forest dynamics and diversity (58). In unmanaged *Pinus mugo* forests, canopy gaps appeared to be heavily infested with *Heterobasidion annosum* and *Armillaria ostoyae*, suggesting that they were the causal factors of these gaps (59). A range of root pathogens can occur in and on the fine roots of older trees, as was observed by Chavarriaga et al. (60) for seminatural and planted *Pinus sylvestris* in Scotland. Pathogen enrichment in soils underneath older trees reducing the growth of conspecific seedlings has been observed in a seminatural forest for seven out of eight tree species studied (61). Similarly, Packer and Clay (62) reported that fungus-like *Pythium* spp. isolated from mature *Prunus serotina* incited mortality of conspecific seedlings, and they suggested that this explained the usually large distance between trees in their native range in the United States. Burdon et al. (63) mentioned other examples of this intriguing phenomenon. It would be interesting to see if this hypothesis could be falsified for vegetation that has reached its final successional stages, such as beech forest. The Janzen-Connell hypothesis was formulated for narrow host range pathogens (52, 53). However similar mechanisms for wide host range pathogens can also be applicable, because their quantitative effects on plant growth and development are usually strongly host-species-dependent (64) and may also be shaped by differential effects of the environment on the host-pathogen relationship (9).

Clearly, the dilution effect and the Janzen-Connell hypothesis are closely linked, with the focus of the first more on host density, and the second on pathogen (and pest) enrichment. Both hypotheses originate from work on natural ecosystems, but agroecosystems fit well in the picture. The Janzen-Connell hypothesis is well illustrated by the fruit tree replant disease (65, 66): a variety of pathogens present on the relatively large root systems of older trees successfully attack the small root systems of younger, recently planted trees, because they are likely stressed shortly after planting. Gilligan and coworkers showed that threshold densities of hosts were needed to achieve focus expansion by the soil-borne pathogen *R. solani* (24). The same idea applies for the time dimension. The majority of soil-borne pathogens increase their population size if more hosts in the rotation are included (67). For example, problematic enrichment of a multitude of pathogens has been demonstrated for the perennial grass *Ammophila arenaria* planted to stabilize coastal sand dunes. Under natural conditions, these pathogens have been shown to accelerate vegetation succession (68). Similarly, pathogen enrichment of *F. oxysporum* f. sp. *asparagi* was shown to be a common phenomenon in the cultivation of asparagus, shortening its cultivation by several years. Because of the extreme persistence of the pathogen, once infested, a field was rendered unproductive for this crop for decades (69). In its most simple form, arable farming systems exemplify the dilution effect

hypothesis, where diseases generally are more prominent if more hosts per unit of area are cultivated (70). Lowering host density by introducing intercropping, mixed cropping, or widening rotations could reduce these problems, but these methods usually face significant practical difficulties with mechanized crop treatments such as sowing and harvesting.

Host-specific pathogens may play a role in the development of host root density. Evidence of this is suggested by the repeatedly reported overyielding of root biomass in species mixtures compared to their respective monocultures (71, 72). This can be seen as a special case of the dilution effect hypothesis. After soil sterilization or fungicide treatment, root biomass in monocultures increases to levels similar to that of the plant mixtures (73, 74). Also, pathogen-suppressive microorganisms enriched in specific rhizospheres may play a role. This has been observed repeatedly; specifically, plant growth is less constrained if the soil is enriched with rhizosphere microorganisms from other plant species rather than from its own rhizosphere (reviewed in reference 72).

Although high host density creates good conditions for pathogen build-up, pathogen distribution is often highly erratic. The dispersal of airborne pathogens depends strongly on climatic conditions, and dispersal of soil-borne pathogens is often facilitated by using infected planting material or machines with infested soil adhering to them. The degree to which pathogens shape vegetation composition may vary, because other conditions can be decisive as well. For example, McCarthy-Neumann and Kobe (75) determined that shading is an important factor for explaining vegetation biodiversity. Kos et al. (76) discovered that distribution of *Jacobaea vulgaris* was explained by local nutrient availability and seed bank density.

BIOINVASIONS OF FUNGAL PLANT PATHOGENS

Invasion of pathogens in new areas (bioinvasions) are often mediated by humans and are the cause of major disease outbreaks. In newly invaded regions, hosts and pathogens may not have coevolved, resulting in high host susceptibility and dramatic epidemics. For example, the Dutch elm (*Ulmus* spp.) disease, caused by *Ophiostoma ulmi* and later by *O. novo-ulmi*, was transported by unknown means from Central Asia to Europe, where elms were destroyed, and later elsewhere by human transportation (77). Karnal bunt on wheat, a smut disease caused by *Tilletia indica*, has been dispersed through anthropogenic means from India to Mexico and the United States. Though the disease does not cause much damage, its further dispersal is unwanted because of its extremely high persistence, and therefore it inflicts high costs because of export constrictions (78). Another recent example is the outbreak of ash (*Fraxinus*) dieback, which is caused by two related, initially spatially separate strains of *Hymenoscyphus*. After sexual crossing, a highly virulent new species, *Hymenoscyphus fraxineus*, evolved, which now is causing a major epidemic in European ash trees (79). New arrivals may cause considerable damage for some time, but eventually natural enemies may appear, such as viruses infecting these fungal pathogens (80, 81), as has been shown for chestnut blight of *Castanea sativa* caused by *Cryphonectria parasitica* (82) in Europe. Bioinvasions are also mediated by changes in the environment, such as climate change (reviewed by Bebber [83]). The majority of agronomic diseases are examples of bioinvasions, because many crops, and therefore their pathogens, are grown outside their natural distribution area. More generally, novel diseases may arise from several sources: coevolution during domestication, pathogen hybridization, host shift and host jump, and horizontal gene transfer (84, 85).

Coevolution during Domestication

Stukenbrock et al. (84) have provided examples of coevolution during domestication, such as rice blast caused by *Pyricularia oryzae*. Coevolution leads to more specialization: nonrice strains appeared less pathogenic on rice (86). If this is a common phenomenon, then it would predict reduced effects of these pathogens on natural vegetation. Remarkably, the topic of how agronomic pathogens shape natural ecosystems has barely been addressed. Their effects may be limited: in the many examples of pathogens inflicting damage in natural vegetation, Gilbert (87) did not mention major agronomic pathogens.

Pathogen Hybridization

Infection by powdery mildew (*Blumeria graminis* f. sp. *triticale*) on triticale, an artificial hybrid of wheat and rye, has been known only since 2001. It recently became clear that this pathogen originated after hybridization of *B. graminis* f. sp. *tritici* on wheat and *B. graminis* f. sp. *secalis* on rye (88). Hybrids between *O. ulmi* and *O. novo-ulmi* have been recorded (89), and although they appear less aggressive than their parents, they may eventually lead to increased pathogenicity (84). The diploid *Verticillium longisporum* appears to be the result of multiple hybridization events

of an unknown *Verticillium* species with isolates of *V. dahliae* (90). *V. longisporum* attacks brassicaceous hosts, in contrast to the large majority of *V. dahliae* isolates. The above-described recent outbreak of ash dieback is probably also the result of hybridization. With the increased worldwide movement of pathogens due to trade, occurrence of hybridization is likely to become more important (91).

Host Shift

Host shifts occur when a pathogen invades phylogenetically close host relatives. An example is *C. parasitica*, the causal agent of chestnut blight, which coexists with the host in Eurasia but which causes extensive tree death in North America. This is thought to be due to the lack of coevolution and hence high virulence of the pathogen (92). Another host shift was assumed for *R. solani* anastomosis group 1 IA, from rice to signal grass (*Urochlora* sp.) in Colombia and Brazil (93). Host shifts of tree-pathogenic members of the Ophiostomatales were assessed to be significant for phylogenetically closely related hosts when wood-boring beetle vectors are present (94).

Host Jump

Host jumps occur when a pathogen infects a phylogenetically distant host. Host jumps are likely to occur for many soil-borne pathogens, for which vertical, monogenic resistance is the exception rather than the rule. The soil-borne wilt-causing and now cosmopolitan *V. dahliae* appears to exhibit little spatial differentiation in genetic structure, and global invasion through anthropogenic distribution of infested soil or planting material seems the best explanation (95), yet its host range is massive (96), and many host jumps must have occurred.

Horizontal Gene Transfer

Transfer of the *ToxA* gene from *Parastagonospora nodorum* (syn. *Phaeosphaeria nodorum*) (which causes wheat blotch) into *Pyrenophora tritici-repentis* (which causes tan spot in wheat) has been described (97). The limited number of interspecific polymorphisms in both coding and noncoding DNA suggest that this transfer occurred recently and is consistent with the fact that tan spot was observed for the first time in 1941 (97). Also, toxins of pathotypes of *Alternaria alternata* have likely been acquired by horizontal gene transfer (98). Although horizontal gene transfer seems to occur only sporadically, it is clear that once it has occurred, the damage may be quite large, as exemplified by *P. tritici-repentis*, which is now distributed worldwide.

Many records of novel bioinvasive diseases are due to the introduction of pathogens outside their native range. The immediate danger of this is host jumps and host shifts, but rare events such as pathogen hybridization and horizontal gene transfer are important as well. Stukenbrock and McDonald (92) argued that agriculture may increase the frequency of these events compared to natural ecosystems, because pathogens on crops occur in high densities and, consequently, in vast amounts.

Fungal pathogens play an important role in suppressing the dynamics of their hosts. Being bioinvasive weeds elsewhere, in their native range *Centaurea maculosa* (spotted knapweed) (99), *P. serotina* (57, 100), and *A. arenaria* (101) are maintained at low densities because of the presence of root pathogens. Both wide and narrow host range pathogens seem to be implicated in this, as well as other pest organisms (57, 102–109). However, once introduced into a new locality where these weeds did not previously occur and their fungal pathogens are absent, these plants may become invasive. Thus, bioinvasiveness can be regarded as a special case of the above-discussed Janzen-Connell hypothesis, i.e., the absence of natural enemies, including fungi.

SEED-BORNE PLANT PATHOGENS

Seed pathogens are important drivers of the soil-borne seed bank (110). Their importance is usually shown by measuring seed germination in fungicide-treated soils compared to untreated soils (111). An array of fungi have been found to be associated with decaying seeds, including typical seed-borne fungi that have infected the seed aboveground, such as *Alternaria* spp., and typical root pathogens such as *Neonectria* (syn. *Cylindrocarpon*) (112), as well as opportunists or secondary pathogens such as *Penicillium* spp. The effects of these organisms are strongly mediated by soil moisture content (113). Three ecological groups of organisms that reduce populations of soil-incubated seeds have been recognized: (i) primary pathogens able to kill the healthy seed under appropriate environmental conditions, (ii) opportunistic pathogens that contribute to seed decline after its vitality has been negatively affected by other environmental conditions, and (iii) pathogens that kill the seed directly after germination. Beckstead et al. (114) identified a negative correlation between the germination rate of seeds of *Bromus tectorum* and infection by the weak pathogen *Pyrenophora semeniperda*: thus, rapid germination leads to escape from the pathogen.

CONCLUSIONS

Fungal plant pathogens are ubiquitous and highly diverse. Together with other biotic stress factors they shape plant biodiversity in natural vegetation and in managed, species-rich grasslands, but in less biodiverse cropping systems they cause great losses. In these agroecosystems, resistance breeding has been only partially successful, and additional methods to manage pathogens are needed. The most important of these are measures to avoid soil-borne pathogens, the application of fungicides to control airborne pathogens, and production of clean seeds together with the application of seed disinfestation techniques. The basic prerequisites for an epidemic to develop are the same for natural and cropped ecosystems, i.e., a threshold density of host plants and pathogens, as well as proper environmental conditions. Host and pathogen density are the basic elements of the Janzen-Connell hypothesis and the dilution effect hypotheses, and thus, both hypotheses have much in common. Also, the phenomenon of overyielding of root biomass in plant mixtures relative to monocultures refers to these same basic elements of the disease triangle. The essential difference between natural and agricultural systems is that the replacement of diseased plants by other plant species occurs spontaneously in natural but not in agricultural systems. The introduction of fungal pathogens outside their natural distribution area is primarily due to international transportation of agricultural and horticultural products. This may have direct effects on existing or novel hosts and results in increased opportunities for hybridization or horizontal gene transfer, which can result in novel plant diseases. Although all plant pathogens occurring in agriculture originate from nature, it is questionable whether these pathogens have significant effects on natural ecosystems. Coevolution during domestication of crops may explain why the effects of these pathogens in natural environments seem limited.

INTRODUCTION

Phylogeny of Zoosporic True Fungi and Fungus-Like Microorganisms

The "Aquatic Phycomycetes" (*sensu* Sparrow) (1) constitutes an ecologically and economically important assemblage of eukaryotic microorganisms that share many morphological traits and ecological functions and interact with each other in the same aquatic ecosystems. There is molecular and structural evidence that the aquatic phycomycetes is a diverse, polyphyletic assemblage of species. For many years little research has been conducted with the aquatic phycomycetes, possibly because they were thought to be ecologically and commercially insignificant, but this perception has recently changed. Many of these species have been found to play key roles in biomass conversion in food webs (Fig. 1) and in the carbon cycle (2).

Baldauf (3, 4) divided eukaryotic organisms into eight supergroups based on a consensus phylogeny. The fungus-like species described in the "Aquatic Phycomycetes" *sensu* Sparrow (1) have been reassigned by Baldauf (3, 4) into four of these eight supergroups: the Opisthokonta, Straminipilia, Alveolata, and Rhizaria. The true fungi, the fungus-like organisms with uniflagellate zoospores (including chytrids, rumen chytrids, rosellids, and aphelids that are closely related to the true fungi), the mesomycetozoa (distantly related to the true fungi), the choanozoa, the slime molds, several groups of uniflagellate amoebae, and the phyla of multicellular animals were all placed in the Opisthokonta. One whiplash flagellum is usually present on zoospores of those species in the Opisthokonta, which produce motile stages for dispersal in their life cycles. Baldauf (3, 4) placed the fungus-like species with biflagellate zoospores into the supergroups Alveolata, Rhizaria, and Straminipilia. Many of the fungus-like species have heterokont zoospores with one anterior tinsel flagellum with mastigonemes and one posterior smooth whiplash flagellum without mastigonemes, but other species have zoospores with two whiplash flagella or one tinsel flagellum (5).

Ruggiero et al. (6) recently proposed a new higher-level classification of all living organisms. In this new proposal the eight supergroups of eukaryotes used by Baldauf (3, 4) have been replaced by five kingdoms: Animalia, Chromista, Fungi, Plantae, and Protozoa. The microorganisms within the "Aquatic Phycomycetes" *sensu* Sparrow (1) have been split by Ruggerio et al. (6) among three kingdoms: the kingdoms Chromista, Fungi, and Protozoa. The organisms within the supergroup Opisthokonta have been split among three kingdoms: the kingdoms Animalia, Fungi, and Protozoa. The microorganisms in the supergroups Amoebozoa, Discicristates, and Excavates have been placed into the kingdom Protozoa, and the organisms in the supergroups Alveolata, Rhizaria, and Straminipilia into the kingdom Chromista by Ruggerio et al. (6). Furthermore, some of the names for phyla have been changed by Ruggiero et al. (6). For example, the phylum Oomycota has been replaced by the phylum Pseudofungi.

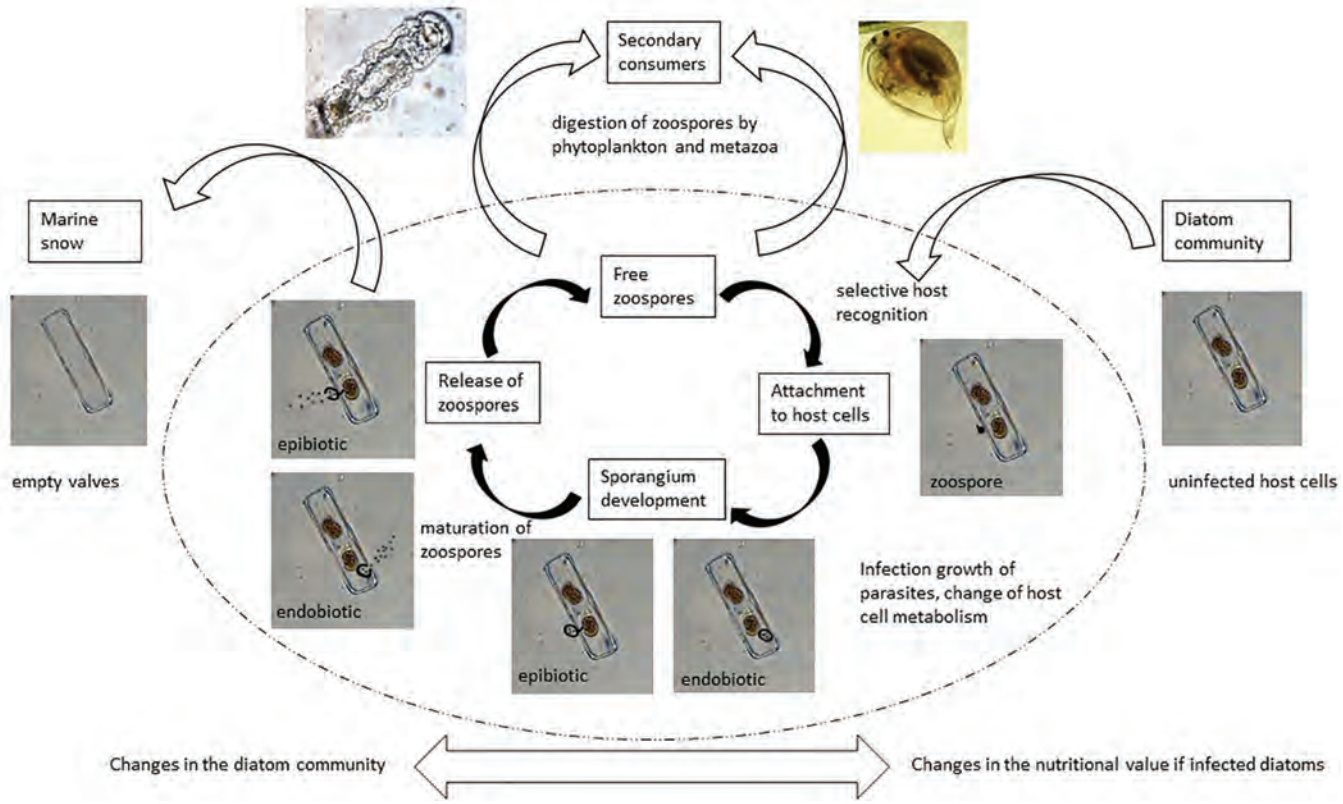

Figure 1 Schematic life cycle of endo- and epibiotic zoosporic parasites infecting marine diatoms. Besides the main cycle (solid black arrows), ecological effects on the marine planktonic and benthic community compositions, as well as interactions, are also depicted (unfilled outlined arrows).

Most fungus-like opisthokonts (Table 1) have a single, basal, whiplash, smooth flagellum on reproductive cells (zoospores and gametes), cell walls composed of chitin and plate-like mitochondrial cristae (1, 7–9). Most of the zoosporic true fungi, which Sparrow (1) and Barr (7) originally placed into the phylum Chytridiomycota (*sensu* Barr), have recently been reassigned into four newly described phyla (Blastocladiomycota, Chytridiomycota, Monoblepharidimycota, and Neocallimastigomycota) and the Olpidium clade (9–11). Sparrow (1) included *Rozella* in the phylum Chytridiomycota, but recently its species have been transferred to their own phylum, the Cryptomycota or Rozellida (12). Also, two new phyla of fungus-like microorganisms, which were unknown to Sparrow, have been recently added to the Opisthokonta supergroup: Aphelidea (9) and Mesomycetozoea (13). Busk et al. (14) reported about low sequence similarity between, and high overall diversity of, the genes encoding for secreted biomass-degrading enzymes produced by species of Blastocladiomycota, Chytridiomycota, Monoblepharidimycota, and Neocallimastigomycota.

Data from the sequences of rDNA and other genes have been used to describe a new phylum, the Rosallida (Cryptomycota), found in freshwater bog samples as a basal fungal clade (15) and the estimation of the molecular diversity of this clade as equivalent to that of the entire fungal kingdom (12). Species of Rosallida (Cryptomycota) are parasites of host species in the Chytridiomycota and Oomycota. Sparrow (1) described many species of *Rozella* based on their preferred hosts. The aphelids (phylum Aphelidea) are a small group of intracellular parasitoids of common species of eukaryotic phytoplankton with three known genera (*Aphelidium, Amoeboaphelidium*, and *Pseudaphelidium*) and 10 valid species that form, along with related environmental sequences, a very diversified group as well (16). The phylum Aphelidea is also new. The species in these two related phyla could easily be mistaken as chytrids because of similar morphology.

The use of software programs to compare DNA sequences of ribosomal and other conservative genes in living organisms has provided new insights into phylogeny and evolution. However, many questions have risen

Table 1 Currently described phyla in the supergroup Opisthokonta[a]

Phyla	Superphyla	Group	Cluster	Propagules
Basidiomycota	Holomycota	Eumycota	Dikarya	Thick-walled spores
Ascomycota				
Zygomycota			Sporangiospores	
			Zygospores	
Glomeromycota				
Olpidium clade[b]			Zoosporic	Zoospores
Monoblepharidomycota[b]			True fungi	(amoebae rarely)
Blastocladiomycota[b]				
Neocallimastigomycota[b]				
Chytridiomycota[b]				
Microsporidia		Opisthosporidia	True fungi	Walled spores
Rozellomycota[b]			Fungus-like	Zoospores
Aphelidea		Zoospores and amoebae		
Nucleariida				Amoebae
Fonticulida (MAFO)[c]				
Mesomycetozoea	Holozoa	Mesomycetozoea	Fungus-like	Thick-walled endospores
Cl. Dermocystida[b]				Zoospores
Cl. Ichthyophonida		Amoebae		
Acanthoecida		Choanozoa		Zoospores
Craspedia				
Fistasterea				
Animal phyla	Metazoa		Multicellular	

[a]Unifying characteristics are (i) uniflagellate zoospores usually, (ii) plate-like mitochondrial cristae; and (iii) if present, cell walls composed of chitin.
[b]Only the groups marked [b] were part of the "aquatic phycomycetes" as defined by Sparrow (1). The groups in bold fonts are zoosporic true fungi and will be considered in this article.
[c]MAFO, marine Fonticulida.

about phylogenetic relationships and evolutionary history from molecular studies, especially at the higher taxonomic levels, and remain unanswered. It is hoped that when complete genomic sequences of many more organisms become available, we will have a clearer understanding of phylogenetic relationships among all species of living organisms. The phylogenetic patterns proposed by Baldauf (3, 4), Adl et al. (17), and Ruggiero et al. (6) are based primarily on vertical gene transfer. Horizontal gene transfer has occurred between many species of both prokaryotes and eukaryotes, including fungi, and recent studies comparing complete genomes suggest that horizontal gene transfer has been more common than previously thought (18–20). Horizontal gene transfer must be considered in evolutionary history as well as vertical gene transfer. The precise phylogenetic relationships between many of the phyla of eukaryotic microorganisms are not clearly understood at present, and these higher-level classifications will probably be changed periodically in the near future as more sequence data become available.

In the past, lack of knowledge about aquatic zoosporic fungi and their ecological functioning has been compounded by misidentification of fungal zooflagellates, for example, as phagotrophic nanoflagellates (21). The identification of isolates of zoosporic true fungi and fungus-like microorganisms is complex, because of the lack of morphological characters visible in the light microscope, and often requires ultrastructural characterization of zoospores and other structures (22–24). Also chytrid sporangia and rhizoids exhibit phenotypic plasticity with morphological changes due to nutrient or other environmental conditions (25, 26). Furthermore, the parasitic species can be either epibiotic, with the zoosporangium on the surface and the rhizoids inside the host cell, or endobiotic, with both the zoosporangium and the rhizoids inside the host cell (27). Endobiotic parasites are very difficult to see under the light microscope. Recently, SSU rDNA sequences have been useful for understanding the phylogeny of zoosporic fungi (28).

Objectives of This Review

In this article, only the phyla that are closely related to the true fungi, which have adapted to aquatic environments and which produce motile zoospores usually with one whiplash flagellum, are considered (Table 1). All these species are within the supergroup Opistho-

konta (3, 4). Species of true fungi that produce thick-walled, nonmotile spores, but have adapted to aquatic environments, such as the aquatic hyphomycetes, are not considered in this review. Finally, the fungus-like organisms in the supergroups Alveolata, Rhizaria, and Straminipilia (or the kingdom Chromista) are not considered here either, because they are not considered to be true fungi, even though they share many morphological and physiological characteristics with true fungi and often inhabit similar environments. Some of these characteristics could have come across from species of true fungi to fungus-like species by lateral gene transfer during evolutionary history. For example, Richards et al. (19) and Richards and Talbot (20) discussed exchange of genes between groups of protists, in general, and specifically the lateral transfer of genes for pathogenicity from Ascomycota to Oomycota since these groups originally evolved. Although the Mesomycetozoea have some fungus-like characteristics, they are more closely related to the Choanozoa than the true fungi and will not be considered here.

This review focuses on some of the recent research on the ecology of zoosporic true fungal and fungus-like species in four phyla, Aphelidea, Chytridiomycota, Neocallimastigomycota, and Rosallida (Cryptomycota), and the interactions between these species and their substrates. Most of these species tend to be monocentric (unicellular), but there are polycentric (filamentous) species. Their lifestyles are considered based on the nature of symbiosis in aquatic habitats: saprotrophic, parasitic, and mutualistic lifestyles. It is essential for a thorough understanding of ecological processes that we correctly identify all species in all food webs in each ecosystem. Consideration of only species in the kingdom Fungi in ecosystems causes a dilemma, but our investigations have to begin somewhere, and thus, for this article, the scope of the topics covered must be limited.

DESTRUCTIVE MECHANISMS IN THE LIFE CYCLE OF ZOOSPORIC TRUE FUNGI

Zoospores

Zoosporic parasites produce motile zoospores. Some aspects of the physiology and ecology of zoospores have been reviewed by Fuller and Jaworski (29) and Gleason and Lilje (30). Motile zoospores are released from zoosporangia in large numbers into water and can swim for several hours. They are capable of navigating quickly through chemical gradients to their substrates (chemotaxis). After attachment, they encyst, germinate, and produce rhizoids, which penetrate their hosts and release digestive enzymes. The process of chemotaxis has only been studied in detail in the frog parasite *Batrachochytrium dendrobatidis* (31), in *Rhizophydium littoreum* (32), and in chytrid parasites of diatoms (33). In contrast, walled spores and cysts of other groups of parasites are carried by air or water currents to their hosts by chance or by vectors, such as animals.

Recent research into the chemotaxis of chytrid zoospores (33), using four marine chytrid-diatom tandem cultures in combination with different potential triggers, has shown that whole-cell extracts of the light-stressed hosts attracted the highest numbers of zoospores (86%), followed by the combined carbohydrate standard solution (76%), while all other compounds acted as weak triggers only. The triggers include aqueous host extracts grown under different stress conditions and standards of eight carbohydrates, six amino acids, five fatty acids, and three compounds known as compatible solutes (in individual and mixed solutions). In light of the results, it is tempting to hypothesize that pathogen zoospores were preferentially attracted to the fast-growing cells by photosynthesis-derived carbohydrate exudates. The chytrid-diatom tandem cultures comprised *Chytridium* sp./*Navicula* sp., *Rhizophydium* type I/*Nitzschia* sp., *Rhizophydium* type IIa/*Rhizosolenia* sp., and *Rhizophydium* type IIb/*Chaetoceros* sp., and could not be further isolated by the use of conventional methods (e.g., pollen) (33).

Rhizoids

The functions of rhizoids include penetration of the substrate, delivery of extracellular digestive enzymes, and absorption of food sources. Rhizoids exhibit phenotypic plasticity with morphological changes due to nutrient or other environmental conditions (19, 20).

Extracellular Enzymes

Proteases

Many species of zoosporic true fungi and fungus-like organisms can grow on substrates containing protein (1). Krarup et al. (34) demonstrated that some saprotrophic species of zoosporic true fungi also produce proteases. These extracellular enzymes are presumably released by rhizoids, which penetrate into utilizable nonliving substrates. Piotrowski et al. (35) found that the parasite *B. dendrobatidis* also produced proteases. Joneson et al. (36) describe significant lineage-specific expansions in three protease families (metallo, serine, and aspartyl proteases) in *B. dendrobatidis*. They show that expansion of these protease gene families occurred after the divergence of *B. dendrobatidis* from its an-

cestors. Finally, they demonstrated that the timing of these expansions predates the emergence of *B. dendrobatidis* as a globally important amphibian pathogen. Most likely, other groups of zoosporic parasites also use a variety of proteases in different families to digest the tissues in their animal hosts.

Cellulases

Rhizophlyctis rosea is a common chytrid, which grows quickly on plant debris containing cellulose in soil and aquatic ecosystems. In culture, this species is capable of the digestion of crystalline cellulose in the form of lens paper, filter paper, and powdered filter paper, and grows well with noncrystalline carboxymethyl cellulose or cellobiose, but cannot use starch or maltose as sole carbon sources in liquid and on solid media (37). Lange et al. (38) discovered that *R. rosea* zoospores excrete endocellulase GH45, which is thermostable.

The nature of cellulases excreted by other fungi is currently under study.

Cellulose, hemicellulose, and pectin are the polysaccharides in plant cell walls (39); cellulose has a linear structure of β-1,4-linked D-glucose that can be degraded to oligomers by the combined action of cellobiohydrolases, endocellulases, and lytic polysaccharide monooxygenases (LPMO) and further degraded to glucose by β-glucosidases (14). In higher plant species, cellulose is protected from degradation by the complex structures of plant cell walls including both covalent links between cellulose and hemicellulose and entanglement of the cellulose with other macromolecules. These structures make enzymatic digestion of cellulose difficult (14). Busk et al. (14) used PPR to classify GH families 1 to 131 and the AA families 9 to 11 (i.e., the LPMOs) into subfamilies. They found that enzymes with different properties are necessary for degradation of cellulose in different complex substrates. Also, that clustering of the fungi based on their predicted enzymes indicated that Ascomycota and Basidiomycota use the same enzymatic activities to degrade plant cell walls. They also found that the subfamilies could be used not only to predict the function of known GH-encoding genes but also to find all GH- and LPMO-encoding genes in a fungal genome and predict their functions (14).

GLOBAL DISTRIBUTION OF FRESHWATER AND MARINE TRUE FUNGI AND FUNGUS-LIKE MICROORGANISMS

Zoosporic true fungi (within the Eumycota and Opisthosporidia groups) (Table 1) are found in most aquatic and wet terrestrial ecosystems throughout the world. The phylum Chytridiomycota is one of the largest taxa of fungi (within the superphylum Holomycota) found in aquatic ecosystems (40). Since the 1960s, many species of freshwater zoosporic true fungi have been described (1, 7, 41, 42). However, ecological studies on these species have been limited. Phytoplankton and heterotrophic flagellates have traditionally been considered of primary importance in aquatic environments, while fungal diversity has been largely neglected (43). In recent years, discoveries in molecular methods of rDNA sequencing of small-subunit (SSU) rRNA genes (9, 44, 45), combined with broad meta-analysis of fungal populations in lacustrine, high-altitude soils under glaciers, and Arctic freshwater habitats (43, 46, 47), have revealed that zoosporic true fungi are predominant in these ecosystems and are likely to perform crucial ecological roles, like the degradation of pollen by saprotrophic freshwater zoosporic fungi (47).

Freshwater zoosporic fungi in freshwater ecosystems may be important parasites of phytoplankton and zooplankton. Planktonic chytrids are both parasitic and saprobic on the freshwater phytoplankton of Lake Inba, Japan (48). Chytridiomycota-like sequences with many novel lineages dominate the fungal diversity of temperate Lake Tahoe, United States, and freshwater Arctic habitats. Zoosporic fungi were positively correlated with either total chlorophyll a concentrations or with proportions of diatom sequences, indicating the likely parasitism of algae (43). *Olpidium gregarium* in the *Olpidium* clade was associated with declines in populations of rotifers (freshwater zooplankton) in the Rio Grande Reservoir, United States (49). In mesotrophic Lake Bourget in eastern France, zoosporic fungi in the *Rhizophydium* and *Nowakowskiella* clades were strongly represented among the fungi during May when the Chlorophyta and Bacillariophyta were also abundant (45). Zoosporic fungi may also be the primary decomposers of fine organic particulates and pollen grains in some freshwater environments (1). In the lakes of northeastern Germany, four fungal phyla were identified attached to pollen grains; 49% of the sequences were from the Chytridiomycota, predominantly the order Rhizophydiales. The zoosporic fungi in this study often appeared to be particle attached rather than free living (47). Pollen grains, leaves, insect and crustacean exoskeletons, pieces of snake skin, and live host species are excellent substrates for many chytrid species and have been used in the past to isolate chytrids into pure culture (1).

Historically, only a few species of zoosporic true fungi have been found in marine ecosystems, which led to the belief that these microorganisms were mainly lo-

cated in freshwater (50). Recent research has challenged this conclusion because of the discovery of many new marine species (discussed later).

SAPROTROPHS

The Effect of Environmental Factors on Growth and Development

Freshwater zoosporic true fungi encounter variations in physical conditions such as pH, soluble metals, temperature, and salinity. Although the temperature range of growth in aquatic zoosporic fungi has been little studied, many saprotrophic zoosporic fungi found in the soil have a maximum temperature for growth at 30°C, some species at 35°C and 37°C, and a few species at 40°C, but none survived incubation in liquid media above 45°C (51–53).

Fluctuations in pH are common in freshwater aquatic systems because of acid rainfall and runoff, sediments and fertilizers, algal blooms, and aquatic plant respiration. Zoosporic true fungi appear to tolerate extremely low pH, but not extremely high pH (1, 54). DNA sequences attributed to zoosporic fungi have been reported from the Rio Tinto River in Spain, which, as well as historically highly polluted with heavy metals, has been recorded as low as pH 2 (55). However, DNA sequences from the Rio Tinto River give no clues whether the inoculum was alive or dead; in addition, it cannot be excluded that the inoculum came from a tributary with higher pH. In comparison, zoospores from seven species of the plant parasitic *Phytophthora* (Oomycota), isolated from one reservoir, had optimal growth rates at acidic, neutral, or alkaline pH. However, some zoospores from all seven species survived at pH 3 and 11 (56).

Toxic metals affect many freshwater zoosporic fungi and fungal-like organisms with effects dependent on the type of metal and stage of the organism within its life cycle. Zoospores, which have a cell membrane rather than a cell wall, are more sensitive than any other stage. For example, gold is toxic to zoospores of the oomycete genus *Phytophthora* at 50 ppb (57). Some effects of metals on zoospores include increased encystment (58) and increased germination (59–61). A stimulatory effect on zoospore release at low levels of copper (10 ppm), lead (60 ppm), and zinc (10 ppm) was demonstrated for four isolates of zoosporic true fungi (62).

The level of osmolarity tolerated by zoosporic fungi varies based on their environment of origin. For example, the tolerance of an estuarine ecotype of *R. littoreum* to sodium, potassium, magnesium, and calcium ions was higher than freshwater ecotypes but lower than those in seawater (63), while maximum growth rate of the same ecotype in the presence of sodium ions was at 237 mM, approximately one-half the concentration of seawater (64). Zoosporic true fungi soil and freshwater isolates from several different genera were tested for growth at different salinities (65). All 20 isolates of zoosporic fungi in the orders Blastocladiales, Chytridiales, Cladochytriales, Rhizophydiales, Rhizophlyctidales, and Spizellomycetales grew on complex solid media supplemented with 170 mM NaCl, but not with 340 mM NaCl, indicating they would not survive in seawater.

Until recently, there have been relatively few studies on identifying marine zoosporic true fungi and fungus-like microorganisms, as opposed to freshwater zoosporic true fungi, which have been extensively studied (50). Those few studies mostly focused on chytrid parasites of dinoflagellates (50, 66) and diatoms (33). The identification of marine of zoosporic fungi has been problematic, because identification of species relied largely on morphology, which, in the case of some zoosporic fungi, with inconspicuous structural components, is extremely difficult (1, 67). However, the use of rDNA sequencing over the past few years has improved the species identification process, enabling researchers to quantitatively measure and compare the diversity and abundance of zoosporic fungi in marine environments, including the water column (9, 28, 44). Taylor and Cunliffe (68) recently used fungi-specific high-throughput sequencing and quantitative PCR analysis of plankton DNA samples collected over 6 years from the coastal site off Plymouth, United Kingdom, and assessed changes in the temporal variability of mycoplankton diversity (mainly Ascomycota, Basidiomycota, and Chytridiomycota) and abundance in relation to co-occurring environmental variables. Repeating mycoplankton blooms were linked to nitrogen availability and temperature, and specific relationships were found between mycoplankton and other plankton groups, for example, seasonal chytrid blooms matching diatom blooms in consecutive years. The study identified possible environmental drivers for mycoplankton diversity and abundance, with both diversity and abundance increasing with reduced salinity, and also when substrate availability was increased (68). With efficient and accurate methods of species identification now readily accessible to more researchers, we would expect that many more studies on the influence of environmental factors on diversity and distribution of marine zoosporic true fungi and fungus-like microorganisms will be undertaken in the near future.

Colonization Strategy

Saprotrophic zoosporic fungi colonize solid substrates in freshwater and soil ecosystems by using rhizoids, which release extracellular enzymes in order to penetrate the substrate to consume plant debris and fibers (1, 30, 69). (The colonization of fibrous plant material by fungi in the rumen is discussed in detail later in this review.) These enzymes are essential for the decomposition of organic matter in aquatic systems, because of their ability to degrade cellulose, the major component of vegetable debris (70, 71). Of interest is the recent discovery of an aquatic saprobe, *Synchytrium microbalum*, occurring within a genus of over 200 otherwise parasitic terrestrial species of zoosporic fungi (72).

PARASITES

Parasites of Marine Phytoplankton

Recent research revealed the presence of parasitic chytrids in marine coastal habitats. Several microalgae species, besides some dinoflagellates (66) and cyanobacteria (e.g., *Nodularia*), first and foremost bacillariophytes (diatoms), such as *Pseudo-nitzschia pungens* (73), *Chaetoceros*, *Amphora ovalis, Rhizosolenia, Biddulphia* (27, 74–76) (Fig. 2), *Thalassiosira, Skeletonema* (77), *Bellerochea*, and *Cylindrotheca* (78), were identified as host species for such zoosporic pathogens. Overall, only one chytrid, *Dinomyces arenysensis* infecting various dinoflagellates including toxic species of *Alexandrium*, has been identified and properly characterized by Lepelletier et al. (66, 79).

Traditionally, species description has been based on morphology of host and parasite (1, 67), which has been extended by discoveries in rDNA sequencing over the past years (9, 44). In addition, chytrids can show considerable morphological differences caused by nutrient availability or environmental conditions (25, 26). Also, many species might have been described previously, but their taxonomy has never been resolved or updated to fit our current phylogenetic concepts.

In general, molecular methods based on the amplification, cloning, and sequencing of SSU rRNA genes are a powerful tool to study the diversity of prokaryotic and eukaryotic microorganisms for which morphological features are not conspicuous (80). While DNA

Pathogens were visualized by using calcofluor white stain in combination with transmission light and fluorescence excitation (UV light, 330 to 380 nm). Image by B. Scholz. Bar, 100 μm.

barcodes for terrestrial oomycetes are available and widely used (81), and genome regions for potential fungal barcodes have been identified (82), DNA barcodes for most other zoosporic parasites are, despite considerable effort (83), missing or not conclusive and the existing ones rarely allow identification, even at genus level (44). In all cases, further difficulties of DNA-based methods are primer bias within mixed samples going hand in hand with the troublesome establishment and maintenance of "pure" dual cultures of host and chytrid (44). However, current high-throughput sequencing approaches have revealed an unappreciated diversity and abundance of eukaryote parasites in the marine environment (de Vargas et al. [84]). Although reported as low in abundance and diversity (28, 84), marine true fungal sequences retrieved in metagenomic surveys are in most cases new to science (85). The phylum Chytridiomycota alone accounted for more than 60% of the reads in six near-shore sites around Europe (28, 86). Taking into account another fungal taxon likely to include parasites, such as the CRA (Cryptomycota/Rozell[ida]/Aphelid) group (28), this percentage increases by another 5%. Furthermore, the phylogenetic analysis of the same data set, together with other eukaryotic environmental sequences, suggested the existence of a whole clade of unknown marine chytrids and reported two clades branching close to known parasite species of phytoplankters (*Chytridium polisiphoniae* and *Amoeboaphelidium protococcarum*) (28).

In general, chytrid parasites may impact marine planktonic and microphytobenthic populations; therefore, large-scale, targeted approaches to monitor different habitats will result in increased knowledge about these parasites. In order to quantify chytrid infections in marine samples, the use of calcofluor white stain in combination with epifluorescence according to the protocol given by Rasconi et al. (87) for phytoplankton samples, as well as the much more cumbersome protocol for microphytobenthic samples (74), has shown the first acceptable results (27, 76). Another detection protocol involves the use of wheat germ agglutinin staining of chitin in environmental samples (28), with the side effect of staining Gram-positive bacteria due to its affinity for *N*-acetylglucosamine. The clear disadvantage of these methods is that they are time-consuming and do not lead to a secured identification of the parasite.

Although our knowledge of marine infectious disease dynamics is limited and often biased toward an economic point of view, there is much evidence to suggest that the occurrence of marine infectious diseases will increase with currently observed climatic trends (88), such as the alteration of epidemiology through effects on pathogen growth rates, transmission, virulence, and susceptibility, with potentially devastating results (79). Thus, it is necessary to draw attention to the importance of the host-parasite system in the marine environment, and emphasize the increasingly crucial role this system will play as, for example, aquaculture becomes more important in order to sustain the growing human population (79). Since infection by zoosporic parasites may not always significantly affect population size of hosts or microbial succession, in general, it is important to apply and develop new qualitative and quantitative techniques to study host-parasite interactions.

Parasites of Freshwater Phytoplankton

The infection of freshwater phytoplankton by chytrid parasites has been documented for a variety of dinoflagellates, diatoms (Fig. 3), and cyanobacteria and in a variety of environments. There is accumulating evidence that the pelagic zone of lakes is housing a significant unexplored diversity in chytrid species (89). These discoveries are particularly interesting when the system concerned is exhibiting significant ecological and environmental change. For example, Leshem et al. (90) recently characterized a new species of chytrid parasit-

Figure 3 Chytrid parasites infecting a freshwater diatom (*Pinnularia* sp.) collected from a freshwater pond in Centennial Park, Sydney, Australia. Image by D.J. Macarthur. Bar, 50 μm.

izing the dinoflagellate, *Peridinium gatunense*, in Lake Kinneret, Israel, a system that has been the subject of studies detailing its pronounced shifts in phytoplankton community structure (91). Similarly, chytrid infection of the cyanobacteria *Planktothrix* has been extensively analyzed in Lake Kolbotnvannet, Norway, a system that has experienced increased urbanization over the past 35 years (92). In this study, it was found that improved water quality conditions, due to better water quality management practices, favored a single *Planktothrix* chemotype. It was hypothesized that the loss of diversity would allow the chytrid species known to parasitize *Planktothrix* to dominate and therefore reduce the dominance of the single chemotype and return the system to a diverse equilibrium. Contrary to the hypothesis, it was found that the chemotype-chytrid relationship remained in equilibrium. It was therefore further hypothesized that this was due to the *Planktothrix* moving deeper in the water column, taking advantage of increased light penetration as a result of the improved water quality. As a result of this movement, environmental stresses, such as decreased temperature, have increased for the chytrids and limited their ability to dominate. These contextual studies are beginning to add a further dimension into our perspective on the anthropogenic effects of ecological interactions. Elucidated host-parasite relationships are emerging as excellent models for garnering insight into the traditionally opaque ecological dynamics of aquatic food webs (93). This insight has been experimentally confirmed and is known informally as the "Mycoloop" (94).

The Mycoloop is a trophic transfer loop, where the release of zoospores by chytrid parasites of phytoplankton provides an additional and potentially very important source of food for grazer zooplankton (94). This dynamic is particularly crucial where phytoplankton species are not a suitable food source for zooplankton, such as the large diatom *Asterionella* (95). The significance of the presence of chytrid zoospores in food webs has been explored mathematically by Grami et al. (96), who did extensive sampling of Lake Pavin in France and quantified bacteria, heterotrophic nanoflagellates, nanoplankton and microphytoplankton, ciliates, metazooplankton, and chytrids. These data combined with physiochemical measurements of water were used to construct a pelagic food web model. The inclusion of chytrids in this model resulted in significant increases in lake carbon flows, suggesting a mathematical replication of the conceptual Mycoloop. In addition, the presence of chytrids in the system increased the number of trophic links and the length of trophic pathways, which contribute to the overall stability of the system (2).

Much research has been committed to attempting to explain and manage the potentially devastating toxins produced by cyanobacteria, particularly in light of global elevated temperatures and stratification in water bodies favoring the physiological strategies employed by these prokaryotes (97, 98). Studying the relationship between the filamentous toxin-producing cyanobacteria *Planktothrix* and its chytrid parasite *Rhizophydium megarrhizum* revealed that the synthesis of microcystins in *Planktothrix* provided a significant defensive aid against infection, whereas mutants of *Planktothrix* with toxin-synthesis genes knocked out exhibited an enhanced vulnerability to parasitic infection (99). This study is arguably the most concrete in discerning the ecological function of toxins synthesized by phytoplankton, an area that is still characterized by ambiguity.

Evidence is emerging that the interactions between the chytrid parasite and its host may involve strong phenotypic selection pressures. An unpublished study by D. J. Macarthur (NSW Environmental Trust 2006/RDS/0007) involved the inoculation of cultures of the bloom-forming cyanobacteria *Anabaena circinalis* and *Microcystis aeruginosa* with diatoms infected with chytrids and with pure cultures of chytrids in the Rhizophydiales. One of these chytrids, which was isolated in pure culture from a phytoplankton sample containing infected diatoms (by E. Lefèvre, Department of Civil and Environmental Engineering, Duke University, Durham, NC) and was tentatively identified as *Rhizophydium* sp., adapted to the new host environments by parasitizing both species of cyanobacteria. These results support the theory of Kagami et al. (100) that the host range of chytrid parasites, often thought to be host-specific, could be altered by environmental stress. More interesting, however, was an apparent enhancement of growth and survival of *A. circinalis* cultures (101). Apparently, there were benefits to both the chytrid parasite and the cyanobacteria host. However, more data are required to unravel the complicated interactions between the chytrid parasite and its host. The growth and survival of chytrids are quite sensitive to physical factors, such as moisture, temperature, salinity and dissolved oxygen (102), and possibly toxic chemicals. With global warming and increased environmental deterioration, more research is required on the ecology of the chytrids in aquatic ecosystems. There is growing evidence that the survival of many aquatic ecosystems may depend on the activities of chytrids along with other groups of microorganisms.

More recently, Frenken et al. (103) demonstrated that warming can significantly interact with chytrid-

bloom dynamics. Mesocosms with a blooming population of the diatom *Asterionella*, which was also being parasitized by chytrids resembling *Zygorhizidium planktonicum*, exhibited earlier bloom termination times in response to a warming treatment of 4°C. This result was accompanied by cascade effects in the zooplankton population; *Keratella* numbers peaked earlier and at a higher density, but exhibited a more rapid and dramatic decline in the postbloom stages of the mesocosms. These results hint at the potentially huge significance chytrid parasites may have in aquatic ecosystems.

A key but contentious theory in evolutionary ecology, the Red Queen Hypothesis (104) has also been explored in the context of chytrid parasites of freshwater phytoplankton. The theory states that host-parasite relationships are evolutionary balancing acts, where hosts and parasites are coevolving to resist infection, or infect at a higher incidence, respectively. The theory is conceptually pleasing as a driver of rapid microbial evolution, but Gokhale et al. (105) found that a mathematical representation of the theory, based on classic Lotka-Volterra dynamics, resulted in frequent system collapse rather than a stable persisting relationship. However, a field study examining the long-term relationship between a genetically monotonous population of *Planktothrix* and their chytrid parasite in sediment cores from Lake Kolbotnvannet, Norway, showed a very stable relationship over many years (92). As discussed previously, there are several plausible reasons for this, most notably the seasonal patterns of the lake providing intermittent "thermal refugia," where the temperature drops below the tolerable threshold for the chytrid, but not for *Planktothrix*, allowing the host population to stabilize. The presence of hyperparasites, such as the zoosporic *Rozella* sp., in the system could also theoretically act as an additional pressure on the parasite population (106), but the influence of these enigmatic organisms is still very poorly characterized.

Similar to the paradigm of negativity surrounding blooms of phytoplankton, which may be perfectly natural and even essential biological "resetting" events, there is a negativity associated with diseases and parasitism, mostly derived from their potentially devastating economic effects. This dynamic has been associated with chytrid infection of commercial algae crops (107), which, because of rigorous strain selection, suffer substantially from infection. However, being a component of the so-called biological "dark matter" (108), these fungi should be considered as evidence of further uncharted levels of biodiversity, which deserves a certain respect and appreciation.

SYMBIONTS

Distribution

Fungi that thrived in the absence of oxygen were first detected in the form of motile zoospores in the rumen fluid of ruminant animals by Liebetanz and Braune as early as 1910 (109, 110). At the time, these remarkable organisms were mistakenly described as ciliated protozoa. More than 6 decades later, Orpin consistently observed vegetative fungal growth while attempting to isolate ciliated protozoa from the sheep rumen (111, 112). The morphology of these microorganisms and the presence of chitin in their cell walls provided further proof that they were in fact spores of a new lineage of true fungi (111, 113, 114). Since their original discovery in sheep, anaerobic gut fungi have been isolated from and detected based on microscopy in the rumen, hindgut, and feces of at least 24 different host genera representing eight different animal families (115, 116). Among these are all foregut fermenters, including the ruminants (families Bovidae and Cervidae), pseudoruminants (e.g., hippopotamus, camel, llama, alpaca, and vicugna) and foregut nonruminants (e.g., marsupials), as well as some hindgut fermenters (e.g., elephant, horse, and rhinoceros). Anaerobic fungi have further been identified in the intestine of laboratory mice (117), in guinea pigs (118), and in some larger herbivorous rodents, e.g., the mara (*Dolichotis patagonum*) (119), but not in some other small hindgut-fermenting animals (presumably because of the shorter duration time of ingested plant material in their smaller cecum) (116). The panda, which lacks foregut and hindgut fermentation chambers, has also not been found to harbor anaerobic fungi (120), and this has been attributed to the simplicity of its alimentary tract (116). Anaerobic fungi were, however, detected in the gut of the marine iguana (*Amblyrhynchus cristatus*) (121, 122). These herbivorous reptiles feed on marine algae and have fermentative digestion processes similar to those in herbivorous mammals. However, some other herbivorous reptiles (i.e., tortoises) do not seem to be colonized by anaerobic fungi (122). In the sea urchin, *Echinocardium cordatum*, zoosporic true fungi have been observed to make up part of the microflora in the anterior cecum, intestinal cecum, and coelomic fluid (123). Some parts of the digestive system are thought to be relatively anoxic and the microflora to be obligately anaerobic. This species of sea urchin digs and feeds in anaerobic muddy substrates in marine environments. Sea urchins are herbivores and feed primarily on marine macroalgae. Whether the zoosporic true fungi observed in *E. cordatum* are phylogenetically related to rumen fungi

found in herbivorous mammals and reptiles is not yet known because of the lack of molecular data.

Life Cycle and Ecology

The strictly anaerobic fungi (phylum Neocallimastigomycota, order Neocallimastigales) (124) play a pivotal role in the functioning of the alimentary tract of herbivorous mammals and reptiles (125), and so it is not surprising that anaerobic fungi comprise some 20% of the microbial biomass of sheep feeding on high-forage diets (126). Forages mainly consist of crystalline cellulose and noncrystalline hemicellulose from plant cell walls and represent the most important carbon and energy sources for terrestrial herbivorous mammals and reptiles. In a mutualistic relationship with their host, anaerobic fungi, together with bacteria, archaea, and protozoa, realize the degradation of the ingested plant material, which the host could otherwise not use (114, 125). While sexual reproduction has not been reported for anaerobic fungi of the phylum Neocallimastigomycota, asexual reproduction occurs through the production of flagellated zoospores from sporangia (127). The formation of sporangia, zoospore differentiation, and their subsequent maturation are thought to be induced by heme and other related porphyrins, which are released from ingested plant material (111, 112, 118, 128, 129). Two types of zoospores have been observed: monoflagellate and polyflagellate zoospores. During this motile stage, anaerobic fungi rapidly locate surfaces for colonization *via* chemotaxis toward soluble sugars that leak from damaged plant material (111, 112, 130). Upon attachment to the fiber, the zoospores shed their flagella and form a cyst (111, 114). Development of the cyst varies depending on whether the fungus is monocentric (one sporangium develops from single zoospore) or polycentric (many sporangia develop from a single zoospore) (131). In monocentric taxa, the nucleus remains within the cyst (endogenous), which enlarges to form a zoosporangium. Thus, the rhizoids remain anucleate. In polycentric taxa, the nuclei migrate into the rhizoidal system (exogenous), thereby enabling the formation of multiple sporangia on each thallus (125, 129). The genera *Caecomyces* and *Cyllamyces* form bulbous holdfasts and appear to represent intermediate forms (132). In both genera, nuclei are observed in the holdfast, consistent with exogenous development, and, in the case of *Cyllamyces*, also in the branched sporangiophores. However, the development of these thalli, while not as strictly determinate as the monocentric/rhizoidal *Neocallimastix* and *Piromyces*, is clearly more limited than in the polycentric/rhizoidal *Anaeromyces* and *Orpinomyces* (116). The rhizomycelium of the anaerobic fungi is characterized as being either filamentous or bulbous, the latter possessing spherical holdfasts (132, 133). Distinct intercalary rhizoidal swellings are occasionally observed in the genus *Oontomyces* (134). The developing rhizoids physically penetrate rigid, undamaged plant cell walls using an appressorium-like structure (113, 135–138). The so revealed internal plant tissues become accessible to enzymatic breakdown and provide nutrients that enable the development and maturation of the sporangia, which may then produce and release zoospores before the cycle repeats (139, 140). The initial attack of plant fiber by anaerobic fungi appears to facilitate a more rapid breakdown of forage feed by fibrolytic bacteria, which have difficulty penetrating large food particles (141, 142). In addition to using physical force, anaerobic fungi also produce cellulolytic and hemi-cellulolytic enzymes, in contrast to their mammalian and reptilian hosts that mediate the breakdown of plant cell wall carbohydrates, especially lignocellulose (143–147), thereby supplying reducing equivalents in the form of hydrogen to the bacterial and archaeal communities (148–150). The presence of hydrogen- and ATP-generating hydrogenosomes in anaerobic fungi was first demonstrated in the rumen anaerobic fungus *Neocallimastix patriciarum* (151). Axenic cultures of fungal species within this genus produced hydrogen during a (bacterial-type) mixed-acid fermentation of carbohydrates (152, 153), but the mechanism of hydrogen production had not been established and the presence of specialized redox organelles not reported. Yarlett et al. (151) showed hydrogenase activity in both the motile zoospore stage and the nonmotile vegetative reproductive stage of the fungus. Since then, the mitochondrial origin of anaerobic fungal hydrogenosomes has been demonstrated (154, 155), and their presence confirmed in several other genera of anaerobic fungi (143, 156). The end products of microbial fermentation, including short-chain fatty acids such as acetate, propionate, and butyrate, are taken up by the host via the epithelium (148–150). Anaerobic fungi successfully disperse between hosts, and it is believed that transition occurs via the formation of aerotolerant life stages, such as the two- to four-chambered spores formed by some *Anaeromyces* spp. (132, 157), although the processes whereby these develop and later germinate remain to be elucidated (116).

Taxonomy

Currently, the anaerobic fungi are classified in a single order (Neocallimastigales) within the recently erected phylum Neocallimastigomycota (124) and are most closely related to the Chytridiomycota. Within this

order, eight genera of anaerobic fungi are recognized: *Anaeromyces* (158), *Buwchfawromyces* (159), *Caecomyces* (160), *Cyllamyces* (132), *Neocallimastix* (161), *Oontomyces* (134), *Orpinomyces* (162), and *Piromyces* (160). Since 18S rRNA genes of anaerobic fungi are too conserved to distinguish between different genera and species, the internal transcribed spacer 1 (ITS1) has been recommended as molecular barcode marker (82, 157, 163). Several studies used this gene region to evaluate anaerobic fungal diversity in the alimentary tracts of a wide range of wild and domesticated, ruminant and nonruminant herbivores (122, 164–172). Some of these studies reported the existence of several as yet uncultivated novel groups of anaerobic fungi (122, 168, 169). Based on anaerobic fungal ITS1 sequence and secondary structure information, Koetschan et al. (173) established a comprehensive and stable phylogeny and pragmatic taxonomy of the Neocallimastigomycota, which may be used for highly resolved taxonomic assignment of high-throughput sequence data. Studies using next-generation sequencing technologies have recently allowed comprehensive new insights into the diversity and community structure of anaerobic fungi in the guts of a wide range of herbivorous animals (122) or in the rumens of cattle (171, 174), deer (175), or sheep feeding on different diets (176) or exhibiting different methane emission phenotypes (177). It appears that even hosts from highly distant families that feed on rather unique diets can harbor large numbers of shared sequence types (122), and that there are no (apparent) geographical restrictions in the occurrence of anaerobic fungal sequence types (168). It is likely, however, that some anaerobic fungal species are indeed host specific, as has been suggested for some of the novel as-yet uncultivated clades (122) and the recently described species *Oontomyces anksri*, which was isolated from the Indian camel (134). The recently conducted sequence-based surveys have broadened our understanding of the ecology of anaerobic fungi and provided a glimpse into their global genus-level diversity. Interestingly, the relative lack of overlap between the novel lineages identified in the different studies suggests that additional, yet-unknown novel candidate genera may exist in nature (116).

CONCLUSIONS

The diversity and abundance of zoosporic true fungi have been recently analyzed by using fungal sequence libraries and advances in molecular methods, such as high-throughput sequencing. This review focuses on four phyla, the Aphelidea, Chytridiomycota, Neocallimastigomycota, and Rosellida (Cryptomycota). Zoosporic fungi appear to be both abundant and diverse in many aquatic habitats around the world, with abundance exceeding other fungal phyla and numerous novel genetic sequences identified. Zoosporic fungi are able to survive extreme conditions, such as high and extremely low pH, but more work remains to be done. They appear to have an important role as saprobes in the decomposition of particulate organic substrates such as pollen, plant litter, and dead animals; as parasites of zooplankton and algae; as parasites of vertebrate animals (such as frogs); and as symbionts in the digestive tracts of mammals. Some chytrids cause economically important disease of plants and animals. They also regulate sizes of phytoplankton populations. Further metagenomics surveys of aquatic ecosystems are expected to enlarge our knowledge of the diversity of the zoosporic true fungi. Coupled with studies on their functional ecology, we are moving closer to unraveling the role of zoosporic fungi in carbon cycling and the impact of climate change on zoosporic fungal populations.

Nutrient Sensing at the Plasma Membrane of Fungal Cells

19

Patrick van Dijck,[1,2] Neil Andrew Brown,[3] Gustavo H. Goldman,[4] Julian Rutherford,[5] Chaoyang Xue,[6] and Griet van Zeebroeck[1,2]

INTRODUCTION

To respond to the changing environment, cells must be able to sense external conditions. This is important for many processes including growth, mating, the expression of virulence factors, and several other regulatory effects. Nutrient sensing at the plasma membrane is mediated by different classes of membrane proteins that activate downstream signaling pathways: nontransporting receptors, transceptors, classical and nonclassical G-protein-coupled receptors, and the newly defined extracellular mucin receptors. Nontransporting receptors have the same structure as transport proteins, but have lost the capacity to transport while gaining a receptor function. Transceptors are transporters that also function as a receptor, because they can rapidly activate downstream signaling pathways. In this review, we focus on these four types of fungal membrane proteins. We mainly discuss the sensing mechanisms relating to sugars, ammonium, and amino acids. Mechanisms for other nutrients, such as phosphate and sulfate, are discussed briefly. Because the model yeast *Saccharomyces cerevisiae* has been the most studied, especially regarding these nutrient-sensing systems, each subsection will commence with what is known in this species.

NONTRANSPORTING RECEPTORS SENSING GLUCOSE

Glucose Sensing by Snf3 and Rgt2 in *S. cerevisiae*

The uptake of glucose, the preferred carbon source of *S. cerevisiae*, is mediated by 17 closely related hexose transporters (1). Their expression is coordinated according to the availability of extracellular glucose, which is sensed by the two glucose receptors, Snf3 and Rgt2 (2) (see "GPCR-mediated carbon sensing in *S. cerevisiae*" and Fig. 1). Snf3 and Rgt2 sense the internal/external ratio of glucose to adjust glucose uptake (3), which is also influenced by intracellular glucose metabolism (glycolysis) (4). Although these receptors are structurally similar to hexose transporters, they cannot transport glucose and contain unusual long C-terminal tails that are important for glucose sensing (5).

In the absence of glucose, the Rgt1 transcriptional repressor is found in the nucleus, interacting with the corepressors Mth1-Std1 (6), thereby recruiting the general corepressor complex Ssn6-Tup1 to the promoters of the different *HXT* genes, blocking their transcription (7). Snf1-dependent phosphorylation of Rgt1 triggers its repressor activity as well as its propensity to bind DNA (8). In addition, Snf1 also affects *HXT* expression via repression of the carbon catabolite repressors, Mig1/2, which in turn repress the expression of *STD1*, *MTH1*, and *SNF3* genes (9). Glucose detection by Snf3-Rgt2 recruits the corepressors Mth1-Std1 to the plasma membrane where they are subsequently phosphorylated by type I casein kinases Yck1/2 (10). Upon phosphorylation, Mth1-Std1 are targeted for SCF E3 ligase Grr1-mediated ubiquitination and proteasomal degradation (11). Collectively, these events lead to a protein kinase A (PKA) dependent hyperphosphorylation of Rgt1, which induces the dissociation of Ssn6-Tup1 from the DNA, resulting in the derepression of the *HXT* genes (12, 13).

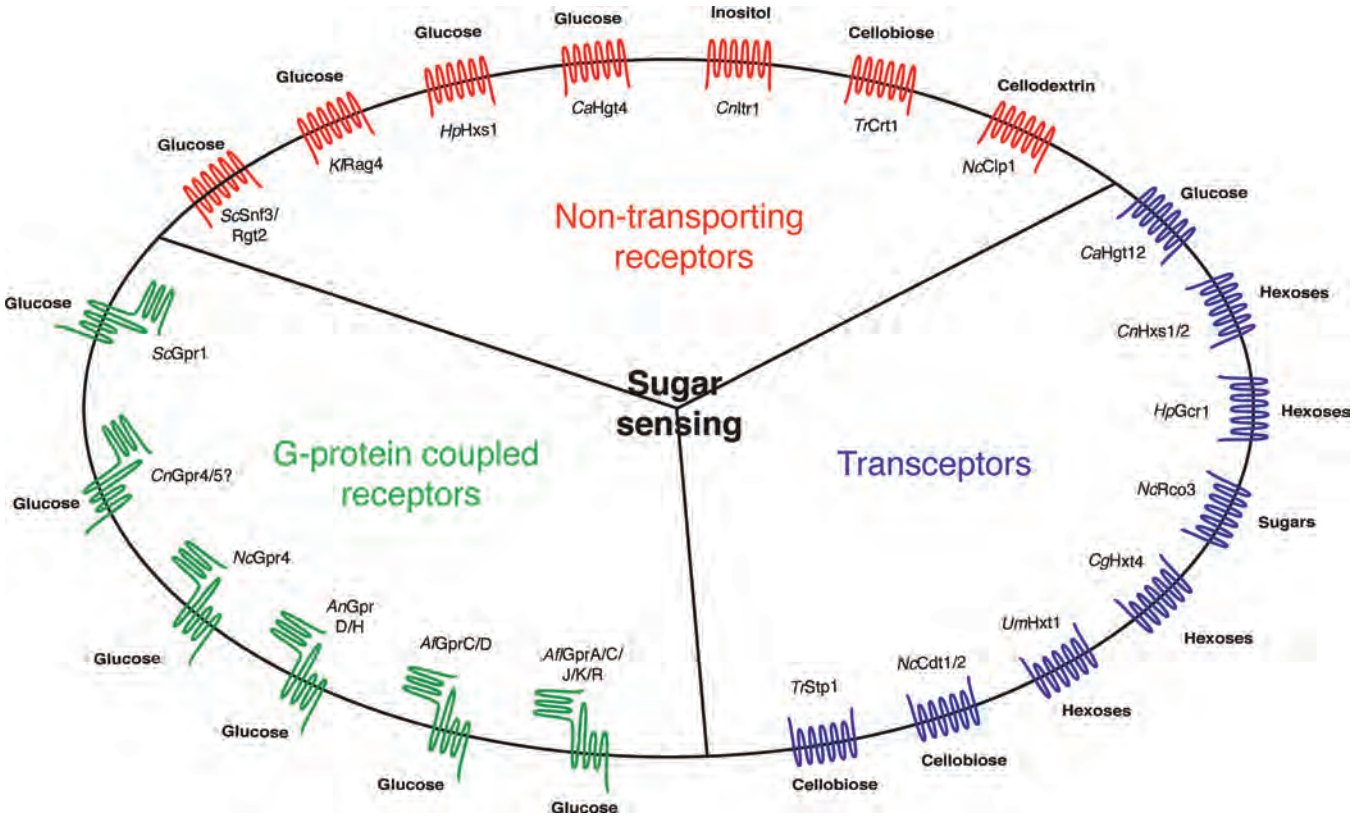

Figure 1 Sugar-sensing proteins in the plasma membrane of fungal cells. Nutrient-sensing proteins in general can be divided into nontransporting receptors, transceptors, and G-protein-coupled receptors (GPCRs). Nontransporting sugar receptors include the *Saccharomyces cerevisiae* (*Sc*) glucose sensors Snf3/Rgt2, the *Kluyveromyces lactis* (*Kl*) glucose sensor Rag4, the *Hansenula polymorpha* (*Hp*) glucose sensor Hxs1, the *Candida albicans* (*Ca*) glucose sensor Hgt4, the *Cryptococcus neoformans* (*Cn*) inositol sensor Itr1, the *Trichoderma reesei* (*Tr*) cellobiose sensor Crt1, and the *Cn* cellodextrin sensor Clp1. Sugar transceptors include the *Ca* glucose sensor Hgt12, the *Cn* hexose sensors Hxs1/2, the *Hp* hexose sensor Gcr1, the *Neurospora crassa* (*Nc*) sugar sensor Rco3, the *Colletotrichum graminicola* (*Cg*) hexose sensor Hxt4, the *Ustilago maydis* (*Um*) hexose sensor Hxt1, the *Nc* cellobiose sensors Cdt1/2, and the *Trichoderma reesei* (*Tc*) cellobiose sensor Stp1. Sugar GPCRs include the *Sc* glucose sensor Gpr1, the *Cn* glucose sensors Gpr4/5, the *Nc* glucose sensor Gpr4, the *Aspergillus nidulans* (*An*) glucose sensors GprD/H, the *Aspergillus fumigatus* (*Af*) glucose sensors GprC/D, and the *Aspergillus flavus* (*Af*) glucose sensors GprA/C/J/K/R.

Homologs of the *Sc*Snf3-*Sc*Rgt2 pathway have been identified in other yeasts (Fig. 1). In *Kluyveromyces lactis*, this is the Rag4 sensor (14), which regulates the expression of the glucose transporter gene *RAG1* (15). In addition, the downstream regulatory pathway is similar to that described for *S. cerevisiae* (16–18). In the methylotrophic yeast *Hansenula polymorpha*, the *Hp*Hxs1 is nonfunctional as a glucose transporter, but is responsible for the glucose-dependent induction of the functional transporter *Hp*Hxt1 (19). The C terminus of this receptor is essential for its function, and the mutation of one conserved residue (R204K) converts it into a constitutively signaling form.

Carbon Sensing in *Candida albicans* and *Cryptococcus neoformans*

C. albicans has over 20 hexose transporter homologs (20). Among them, Hgt4, an ortholog of the *S. cerevisiae* glucose receptors Snf3 and Rgt2, has been identified as a high-affinity glucose sensor (21) (Fig. 1). Hgt4 shares sequence and structure similarity with other hexose transporters, with the exception of a long C-terminal tail containing 254 amino acids, similar to Snf3 and Rgt2. Hgt4 is required for glucose induction of the hexose transporter genes *HGT12*, *HXT10*, and *HGT7*. Mutagenesis demonstrated that the *hgt4* mutant is defective in growth on fermentable sugars, such as fruc-

tose, mannose, and glucose. The *hgt4* mutants are hypofilamentous, indicating that Hgt4 affects the yeast-to-hyphal morphological switch. Interestingly, Hgt4 is also required for fungal virulence because the mutant showed attenuated virulence in a murine model for systemic infection. These findings demonstrate that *C. albicans* cells need to sense and regulate sugar levels for fungal filamentation during infection. The downstream regulatory mechanism of glucose repression in *C. albicans* is conserved with its counterpart in *S. cerevisiae* (12, 22). However, it remains unclear whether Hgt4 has glucose uptake activity or not.

Also in *C. neoformans*, glucose sensing and utilization are critical for its development and virulence. Besides being utilized as a preferred energy source for cell growth, glucose is required for capsule production both as a substrate and a signaling molecule. Glucose induces capsule enlargement through the Gpa1-cAMP-PKA signal transduction pathway, which plays a central role in fungal virulence (see "GPCR-mediated carbon sensing in *C. albicans* and *C. neoformans*" below) (23). Despite its biological significance, glucose sensing is less well understood in *C. neoformans*, in comparison with *S. cerevisiae* and *C. albicans*. There are ~50 transporters that share high sequence similarity with hexose transporters (24). Although some of them may transport sugars other than glucose, how this large family of hexose transporters is regulated remains unknown. Among these hexose transporter homologs, Hxs1 and Hxs2 share the highest sequence identity with *Sc*Rgt2/*Sc*Snf3 glucose receptors, but neither of them has a long C-terminal tail (24). Hence, it is possible that the *C. neoformans* glucose-sensing system is different from those of *S. cerevisiae* and *C. albicans*. These two proteins will be discussed in the section "Transceptor-Mediated Carbon Sensing in *C. albicans* and *C. neoformans*" because evidence suggests that they may have both transport and regulatory functions (Fig. 1).

Inositol is a small carbohydrate molecule that functions as an essential structural and signaling molecule in eukaryotes, including fungi (25). In *C. neoformans*, inositol can be used as a sole carbon source (26). Inositol can also stimulate *Cryptococcus* mating (27). As one of the most abundant metabolites in the mammalian brain (28), inositol utilization is required for *C. neoformans* virulence in murine infection models by promoting brain infection (29–32). Therefore, *C. neoformans* is likely to utilize the abundant inositol available inside the brain for its pathogenesis. Inositol can also stimulate *C. neoformans* capsule growth, which may contribute to its role in fungal virulence. The cryptococcal genome reflects the evolutionary adaptations associated with the expanded role of inositol in this organism. In particular, *C. neoformans* contains an unusually large number of inositol transporters (*ITR*s) that consist of more than 10 members (27, 29). Functional analysis of the *ITR* gene family demonstrated that two members (Itr1a and Itr3c) have high inositol uptake activity, while the function of the other members remains undefined. Among them, Itr1 was suggested as an inositol transceptor because it does not show uptake activity in the yeast heterologous system, it regulates the expression of *ITR* genes, and the *itr1* single mutant exhibits a defect in mating, hyphal production, and sporulation (29, 32). Therefore, transceptors for inositol may exist in *C. neoformans*.

Carbon Sensing in Filamentous Fungi

The mechanisms by which filamentous fungi sense saccharides in the environment are beginning to emerge. It is becoming increasingly clear that, because of the metabolic plasticity of filamentous fungi and their ability to utilize numerous nutrient sources, sensory mechanisms and pathways are far more complex than those in yeasts. This knowledge has been fundamental to the industrial application of filamentous fungi in the production of second-generation biofuels and green chemistries. Lignocellulolytic filamentous fungi, such as *Trichoderma reesei, Aspergillus nidulans*, and *Neurospora crassa*, secrete an array of carbohydrate-active enzymes (CAZymes) that deconstruct and utilize lignocellulose. Primarily, the activity of a few scavenging fungal enzymes releases potent saccharide inducers, such as cellobiose, from the plant biomass, which induces the secretion of hundreds of CAZymes by the fungus, promoting lignocellulose deconstruction (33). However, the detection of simple saccharides, such as glucose, xylose, or an abundance of cellobiose, results in CreA/Cre1-mediated carbon catabolite repression (33). Therefore, distinct mechanisms for sensing plant-derived saccharides exist to enable the efficient regulation of fungal metabolism and alternative carbon usage.

In contrast to the aforementioned yeasts, homologs of the Snf3 and Rgt2 glucose receptors have not been functionally defined in filamentous fungi. In *T. reesei* a putative major facilitator superfamily (MFS) sugar transporter Crt1 was required for full cellulase activity and growth on cellulose or lactose (34). The absence of Crt1 did not compromise cellobiose or sophorose uptake, implying that the function of Crt1 in cellulase induction did not rely on its transporting activity. However, in *N. crassa* cellobiose promotes cellulase

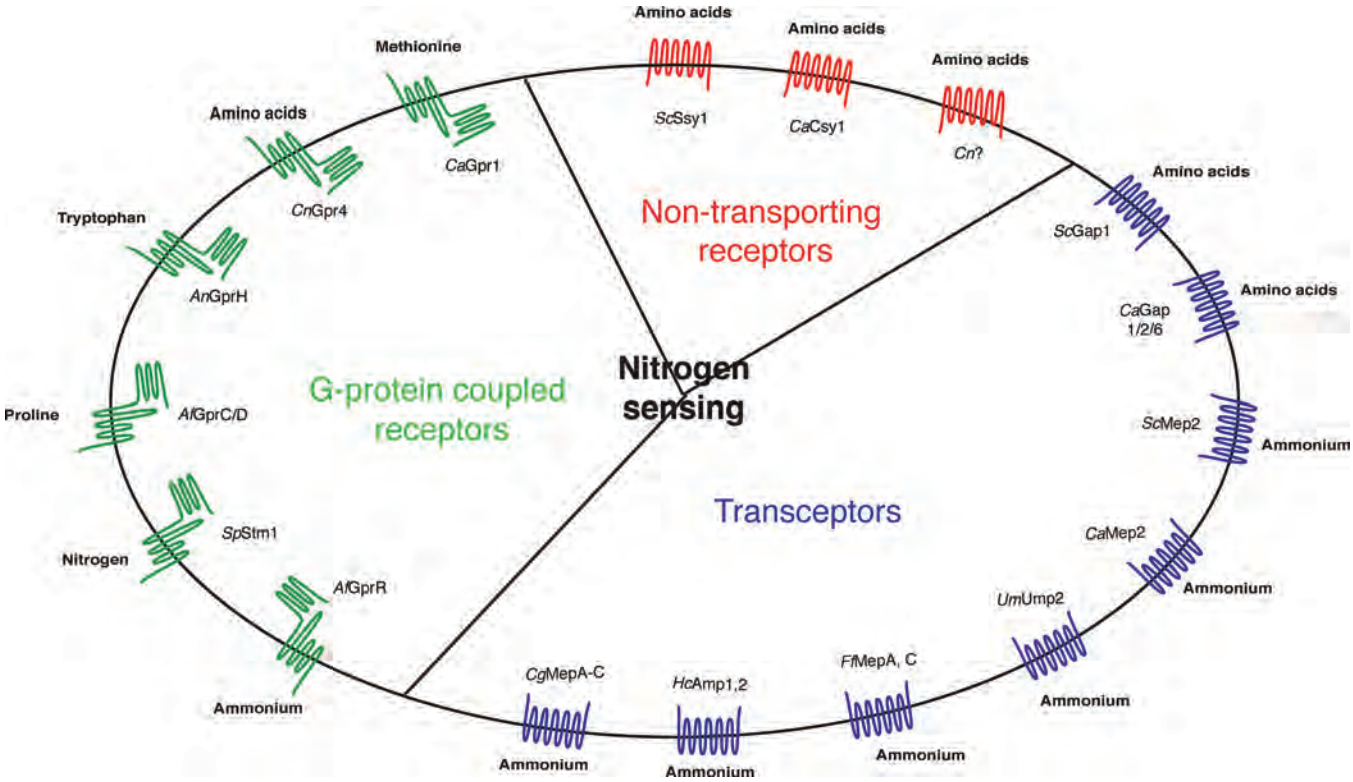

Figure 2 Nitrogen-sensing proteins in the plasma membrane of fungal cells. Nutrient-sensing proteins, in general, can be divided into nontransporting receptors, transceptors, and G-protein-coupled receptors (GPCRs). Nontransporting nitrogen receptors include the *Saccharomyces cerevisiae* (*Sc*) amino acid sensor Ssy1, the *Candida albicans* (*Ca*) amino acid sensor Csy1, and an unknown *Cryptococcus neoformans* (*Cn*) amino acid sensor. Nitrogen transceptors include the *Sc* amino acid sensor Gap1, the *Ca* amino acid sensors Gap1/2/6, the *Sc* ammonium sensor Mep2, the *Ca* ammonium sensor Mep2, the *Ustilago maydis* (*Um*) ammonium sensor Ump2, the *Fusarium fujikuroi* (*Ff*) ammonium sensors MepA-C, the *Hebeloma cylindrosporum* (*Hc*) ammonium sensors Amt1-3, the *Tuber borchii* (*Tb*) ammonium sensor Amt1, and the *Colletotrichum gloeosporioides* (*Cg*) ammonium sensors MepA-C. Nitrogen GPCRs include the *Ca* methionine sensor Gpr1, the *Cn* amino acid sensor Gpr4, the *Aspergillus nidulans* (*An*) tryptophan sensor GprH, the *Aspergillus flavus* (*Af*) proline sensor GprC/D, the *Schyzosaccharomyces pombe* (*Sp*) nitrogen sensor Stm1, and the *Af* ammonium sensor GprR.

production independent of glucosidase activity, indicating that cellobiose itself is the inducer for the cellulolytic regulon (35), suggesting that cellobiose detection may occur prior to internalization. However, only a few cases of nontransporting (putative) receptors have been reported in filamentous fungi. In addition, a novel cellodextrin transporter-like protein, Clp1, also forms a critical component in the regulation of cellulase production (36). However, Clp1 did not import cellodextrins, and actually suppressed the transcription of cellulases and other cellodextrin transporters in response to cellobiose or cellulose (36). Therefore, despite the knowledge of nontransporting receptors in filamentous fungi being elusive, they appear to exist and can function either as inducers or repressors of the lignocellulolytic machinery.

NONTRANSPORTING RECEPTORS SENSING NITROGEN (AMINO ACIDS, AMMONIUM, OTHER SOURCES)

Nitrogen is essential for the synthesis of many cellular components (amino acids, nucleotides, …). Therefore, cells developed a whole series of systems to sense and take up these nutrients. Apart from plasma membrane localized systems, discussed in this review, also the target of rapamycin complex 1 (TORC1) is a major growth regulator in response to nitrogen quality and

quantity. This is described in detail in a review on target of rapamycin (TOR) signaling (183).

Amino Acid Sensing by Ssy1 in *S. cerevisiae*

In *S. cerevisiae*, amino acids are detected at the plasma membrane by a multiprotein complex composed of Ssy1, Ptr3, and Ssy5 (SPS) (37) (Fig. 2). This results in induced expression of amino acid transporter genes as well as other nitrogen-metabolizing enzymes (38). Ssy1 is a unique member of the amino acid permease (AAP) family and is the receptor of the SPS (Ssy1-Ptr3-Ssy5) complex (39). Although Ssy1 does not transport amino acids, it does undergo a conformational change upon binding of its ligand (40). Direct binding of the amino acid to Ssy1 was proven by the identification of hyper- and hyporesponsive mutants (41, 42). The extremely long Ssy1 N-terminal tail is highly conserved in other yeast species, and it is required for its function as a sensor-signal transducer (43).

Ptr3, the least understood component of the complex, is induced by Yck1/2-dependent phosphorylation (44). Recent results indicate a key role for Ptr3 as an adaptor protein, linking the amino-acid-induced conformational change of Ssy1 to Yck1/2-Ssy5 access (45). Ptr3 multimerization, a well-established concept for G-protein-coupled receptors (GPCRs) as well as receptor tyrosine kinases (46, 47), occurs via the WD40-like domains, and is essential for downstream activation.

The chymotrypsin-like protease Ssy5 is synthesized as two domains, a catalytic domain and an inhibitory prodomain. Autocatalytic cleavage occurs during synthesis; however, the parts remain associated forming an inactive complex (48). In the presence of amino acids, the prodomain is released, leading to activation. The release of Ssy5 requires phosphorylation by type I casein kinases Yck1/2 followed by ubiquitination by SCFGrr1 (49, 50). Ubiquitination leads to proteasomal degradation of the prodomain, yet the direct involvement of the 26S proteasome has been questioned (50). The Ssy5 prodomain contains a phosphodegron, which may represent the site of Yck1/2 recognition (51). This sequence was also found in Mth1 and Std1, effector components of the Snf3/Rgt2 glucose-sensing pathway that also requires Yck1/2 and SCFGrr1 (52).

The amino-acid-induced receptor-activated proteolysis (RAP) of Ssy5 results in endoproteolytic removal of the N-terminal tail of the transcription factors Stp1/2, which are synthesized as latent cytoplasmic precursors (53). The processed forms of Stp1/2 are translocated into the nucleus where they bind to, and induce the expression of, their target genes. Although homologous, Stp1/2 are functionally divergent, possessing a different N-terminal tail, and also showing differential degradation and distinct cellular localization, providing a mechanistic explanation for Stp2 being the primary activator (54, 55).

Several control levels to maintain the derepressed state of signaling in the absence of inducing amino acids exist. First, Ssy5 activity is controlled by its Rts1/PP2A-dependent dephosphorylation, which antagonizes the Yck1/2-dependent phosphorylation of the prodomain, and thereby mutes Ssy5 activity in the absence of amino acids (44, 45, 56). Second, the Asi1-3 inner nuclear membrane proteins restrict entrance of full-length Stp1/2 in the nucleus because of its N-terminal region (57, 58). A third level of regulation is the targeting of unprocessed Stp1 for degradation, thereby diminishing its nuclear abundance (59). An additional level of Stp1 regulation occurs by TOR; inactivation of TOR by rapamycin results in the degradation of Stp1 in the nucleus, which is dependent on the phosphatase 2A (PP2A)-like phosphatase, Sit4 (60). All these control systems show that the cells have invested a lot in order to have activation of the pathway only in conditions where this is relevant. More information on TOR signaling is presented in reference 183.

Amino Acid Sensing in *C. albicans* and *C. neoformans*

The transcriptional regulation of AAP genes by the presence of their substrates in *C. albicans* occurs in a manner similar to that of *S. cerevisiae* (61). The *Candida* genome encodes homologs of all characterized components of the SPS complex (62). *Ca*Csy1, the *Sc*Ssy1 homolog, similarly acts as the primary receptor (Fig. 2). Despite the high degree of homology, the N terminus of both proteins is very divergent, potentially contributing to their differences in specificity (61). *C. albicans* cells lacking *Ca*Csy1 show altered morphology and hyphal formation, indicating a role in amino acid (serum)-induced hyphal morphogenesis.

Similar to *S. cerevisiae*, the sensor complex induces proteolytic processing of two latent transcription factors, *Ca*Stp1/2, upon amino acid detection (63). Both proteins are activated upon amino acid addition, to differentially activate two modes of nitrogen acquisition: *Ca*Stp2 activates genes required for amino acid uptake, while *Ca*Stp1 induces genes involved in extracellular protein degradation and peptide uptake. In addition, the levels of *Ca*Stp1 itself are also amino acid regulated, indicating that *Candida* cells preferentially use amino acids (63). Recent results indicate that the control of *STP1* expression is mediated by the two GATA

transcription factors, *Ca*Gln3 and *Ca*Gat1 (64). With the use of the insect host, *Drosophila*, it was shown that a functional SPS sensor and proper Stp1 gene control are required for host protein catabolism and utilization, while being essential for full virulence. *Ca*Stp2, on the other hand, is dispensable for virulence (65).

Recently, eight global affinity amino acid permeases and two methionine permease homologs have been identified in *C. neoformans* (66). From this low number of permeases, it is apparent that this pathogen is more dependent on amino acid biosynthesis than on uptake. Transcriptional profiling revealed that these genes are subjected to regulatory mechanisms known to respond to the nutritional status in other fungi, such as nitrogen and carbon catabolite repression and SPS sensing as well as general amino acid control. Inhibitors of these pathways caused *in vitro* growth arrest. Despite the presence of *ScSSY1* and *ScSTP2* homologs, an SPS sensing pathway as in *S. cerevisiae* or *C. albicans* has never been described in *C. neoformans*.

To date, nontransporting amino acid receptors have not yet been described in filamentous fungi, while nontransporting ammonium sensors have not been described in any fungal species.

TRANSCEPTORS (TRANSPORTING RECEPTORS) SENSING CARBON SOURCES

Transceptor-Mediated Carbon Sensing in *S. cerevisiae* and Other Yeasts

In *S. cerevisiae*, none of the hexose carriers has been directly implicated in activating/repressing downstream signaling pathways. Glucose repression appears to be independent of plasma membrane transceptors (67). This is different from the situation in mammalian cells where transporters such as GLUT1, GLUT2, and GLUT4 have been shown to activate downstream signaling pathways (68–71).

Transceptor-Mediated Carbon Sensing in *C. albicans* and *C. neoformans*

The presence of carbon-sensing transceptors in *C. albicans* or *C. neoformans* has not been clearly demonstrated. In *C. albicans*, Hgt4 and Hgt12 have been reported to be transceptors that regulate glucose sensing and uptake (Fig. 1). Whether Hgt4 has glucose uptake activity remains untested, but Hgt12 seems to have glucose transport activity, potentially indicating that this may be a *bona fide* transceptor (21, 72, 73). Hgt12 is specifically expressed during macrophage infection, probably as a response to the absence of glucose in the phagolysosome (72). In *C. neoformans*, Hxs1 has high sequence identity with *Sc*Snf3/*Sc*Rgt2, yet it still shows glucose uptake activity (24). Mutagenesis showed that Hxs1 is required for efficient glucose uptake and fungal growth under low-glucose conditions. Hxs1 is not required for regulating the expression of hexose transporter candidates, and heterologous expression of *HXS1* does not complement the *S. cerevisiae snf3*Δ *rgt2*Δ phenotype. Therefore, whether Hxs1 also functions as a glucose sensor remains to be defined. Importantly, however, Hxs1 is required for fungal virulence in a murine infection model of cryptococcosis. Whether Hxs2 could function as a glucose sensor remains unclear. Interestingly, Hxs1 and Hxs2 do not have the long C-terminal tail that has been shown to be essential for sensory function of their orthologs in *S. cerevisiae* and *C. albicans*. Similarly, in the methylotrophic yeast *H. polymorpha*, the hexose transporter homolog Gcr1 also lacks the typical C terminus, but its regulatory role, along with its involvement in hexose transport, has been demonstrated (74). Therefore, a long C-terminal tail may not be essential for glucose sensing in some fungal glucose transceptors.

Transceptor-Mediated Carbon Sensing in Filamentous Fungi

In filamentous fungi, transceptors are proposed to perform roles in the detection and uptake of polysaccharides, which in turn influences how these fungi interact with their environment. A dual role in signaling and in sugar transport has been shown for *N. crassa* Rco3, lacking the unique C terminus, although it is not fully clear whether this protein has an active transport capacity (14, 75) (Fig. 1). Similarly, Hxt4 from the hemibiotrophic maize pathogen *Colletotrichum graminicola*, which has very low similarity to the *Sc*Hxt, *Sc*Snf3, or *Sc*Rgt2 receptors in *S. cerevisiae*, was shown to be a sensor of nutritional status (76). Recently, Hxt1 from *Ustilago maydis*, a ubiquitous pest of corn, was characterized as a high-affinity hexose transporter that also functions as a receptor, which is required for full virulence (77). First, overexpression of a mutant (R164K), resulting in constitutive signaling in Snf3/Rgt2, leads to downregulation of hexose transport under glucose deprivation and complete loss of virulence. Second, heterologous expression of high-affinity transporters *C. graminicola HXT3* and *Arabidopsis thaliana STP1* only complement the growth defect of an *hxt1* strain and not its decreased virulence. How exactly the signal is transduced downstream is not yet elucidated. However, *U. maydis* possesses a homolog of the membrane-bound casein kinase I (Yck1/2), but no

homologs of all the other downstream components of the *Sc*Snf3/*Sc*Rgt2 pathway have been identified.

Transporters of cellodextrins, the breakdown product of cellulose, have been identified and shown to be fundamental to the regulation of cellulase production. Two cellodextrin transporters, Cdt1 and Cdt2, from *N. crassa*, were shown to contribute to cellulose sensing, and mutants lacking both transporters were unable to induce cellulases in response to cellulose (78). Insertion of these cellodextrin transporters into *S. cerevisiae* along with a *N. crassa* β-glucosidase enabled cellobiose fermentation (79, 80), demonstrating their transporter activity. However, the impairment of cellobiose transport, by introducing point mutations into CDT-1 or CDT-2, did not greatly impact cellulase induction in response to cellobiose, suggesting that the cellodextrin transporters act as transceptors with dual functions in the transport and the detection of cellobiose (78). In *T. reesei*, Stp1, an MFS sugar transporter capable of transporting cellobiose, was identified. However, its absence enhanced cellulase production, demonstrating how Stp1 repressed cellulase production (34). Hence, these studies have provided novel insights into the detection of cellulose by filamentous fungi and how cellobiose transceptors can regulate the lignocellulolytic enzyme production.

TRANSCEPTORS SENSING NITROGEN (AMINO ACIDS, AMMONIUM, OTHER SOURCES)

Transceptor-Mediated Amino Acid Sensing in *S. cerevisiae*

In *S. cerevisiae*, the uptake of amino acids involves several general as well as specific transporters, all belonging to the AAP family (81). One of the general permeases is Gap1, a proton symporter catalyzing transport of all L-amino acids including L-citrulline, 4-aminobutyric acid, some D-amino acids, and toxic analogs as well as polyamines (82, 83) (Fig. 2). The expression as well as the activity of Gap1 are tightly regulated by both the quality and quantity of the nitrogen sources available. Transcriptional regulation occurs via the nitrogen catabolite repression pathway, by the transcriptional activators, Gln3 and Gat1, and inhibitors, Dal80 and Deh1 (84, 85). Fine-tuning of the amount of plasma membrane-localized molecules according to nitrogen availability is regulated by the coordinated action of the Npr1 kinase, the α-arrestins Aly1/2, as well as the ubiquitin ligase adaptors Bul1/2 leading to ubiquitination of Gap1 by the ubiquitin-ligase Rsp5, followed by endocytosis and degradation in the vacuole (86–89). Some amino acid analogs, however, trigger oligo-ubiquitination without endocytosis, indicating that an additional modification is required to initiate the internalization process (90). An additional level of regulation at the plasma membrane is reversible inactivation, due to a conformation change, upon binding of amino acids (91).

Upon studying the amino-acid-induced activation of the PKA pathway it was found that the well-known transporter Gap1 has an additional role as an amino acid receptor (92). The involvement of metabolism and intracellular sensing has been excluded in order to prove the direct receptor function. High L-citrulline concentrations do not trigger signaling in a *gap1*Δ strain, despite its transport by other carriers. The involvement of metabolism was excluded because nonmetabolizable D-amino acids trigger the same activation as their metabolizable L-counterparts. Moreover, deletion of the first enzyme required for L-citrulline catabolism does not abolish L-citrulline-induced activation. Direct binding of the agonists as well as identification of two residues, Ser^{388} and Val^{389}, exposed with their site chain in the binding site, was obtained by the substituted cysteine accessibility method (SCAM) analysis of the eight transmembrane domain (93). An additional strong argument that transport through the transceptor is not required to trigger signaling was the identification of nontransported signaling agonists. A recent study showed that, for both signaling and endocytosis, different substrates elicit specific conformational changes upon movement through the passageway, indicating that all these events (transport, signaling, or endocytosis) can occur independently of one another (90). Despite indications for the involvement of certain proteins in the downstream signaling, such as the PKA complex, the Sch9 protein kinase, and the *S. cerevisiae* PDK1 orthologs (Pkh1-3), the exact mechanism by which the Gap1 transceptor relays the signal downstream remains unclear (94, 95). For example, a basal level of cAMP is required, but there is no transient increase in cAMP upon amino acid activation (96).

Transceptor-Mediated Amino Acid Sensing in *C. albicans* and *C. neoformans*

C. albicans expresses six orthologs of the *S. cerevisiae GAP1* (97). Complementation experiments in the *Scgap1*Δ strain showed that *Ca*Gap1, 2, and 6 can also function as transceptors because they are able to rapidly activate the PKA pathway upon addition of their substrates to nitrogen-starved cells (97) (Fig. 2). Although the different *Ca*Gap permeases share high

sequence similarity, substrate specificity differs substantially. It remains to be determined whether these proteins also function as transceptors in *C. albicans*.

In *C. neoformans*, there are at least seven *Sc*Gap1 homologs in the H99 genome database. However, the function of this gene group has not been analyzed in detail. It remains unknown whether there is any transceptor-mediated amino acid sensing in *C. neoformans*.

Transceptor-Mediated Amino Acid Sensing in Filamentous Fungi

So far, no studies have shown the presence of transceptor-mediated amino acid sensing in filamentous fungi.

Transceptor-Mediated Ammonium Sensing in Yeasts

Ammonium is an important nitrogen source acquired from the breakdown of nitrogenous compounds or its specific uptake from the environment. A conserved family of transporters mediates ammonium import, and some additionally act as transceptors (98–104). When levels of easily metabolizable nitrogen sources are low, or when cells are grown on a poor nitrogen source, fungi experience nitrogen limitation, resulting in reduced growth. During this nitrogen limitation, the ammonium transceptors regulate mating in *C. neoformans* and filamentous growth in *S. cerevisiae*, *Schyzosaccharomyces pombe*, *C. albicans*, and *U. maydis* (98–104). The *S. cerevisiae* genome encodes three ammonium transporters (Mep1-3); however, only Mep2 is a transceptor, acting as a regulator of pseudohyphal growth and PKA pathway activation when ammonium is reintroduced to nitrogen-starved cells (98, 100, 105). Expression of the *MEP* genes is regulated by nitrogen catabolite repression, while the Mep2 protein is controlled by the TORC1-regulated Npr1 kinase (106, 107). Mep2 phosphorylation is not required for plasma membrane targeting and stability, but exerts a positive control on protein activity by initiating a conformational change in the cytoplasmic C-terminal domain of the protein (107, 108).

Ammonium transporters are homotrimers with each monomer forming a right-handed helical bundle that surrounds the pore through which ammonium translocation takes place. Substrate binding occurs at a discriminating extracellular site and two overlapping phenylalanine residues block the pore opening (108–112). Unlike bacterial homologs, the pores of Mep2 from both *S. cerevisiae* and *C. albicans* are closed on the cytoplasmic side of the protein (108). Molecular dynamics simulations support the deprotonation of the ammonium ion in bacterial transporters and the movement of ammonia gas and protons separately through the protein (113–116). A similar mechanism of transport may occur in the fungal transceptors because they contain two histidine residues (His_1-His_2) in the pore that may act as a proton relay system (108, 116). Nonsensing fungal ammonium transporters contain a glutamate and a histidine residue (Glu_1-His_2) at the equivalent positions, although the significance of this difference with regard to sensing has not been established (117). Sensing is dependent on ammonium import through the transceptor, and mutations have been identified that uncouple transport and signaling and that distinguish between PKA activation in starved cells and pseudohyphal induction (105, 118). The Mep2 His_2 residue is particularly interesting because it is dispensable for transport, but essential for signaling, and is involved in blocking the cytoplasmic side of the pore (108, 118). The potential importance of the His_2 residue in signaling is supported by mutation of an adjacent residue that generates a hyperactive sensor (107).

Transceptor ammonium sensing does not reflect changes in internal nitrogen metabolism, because the nonmetabolizable ammonium analog methylamine induces the rapid activation of the PKA pathway, and signaling mutants that import ammonium exist (105, 117). These findings suggest that it is the action of the protein as a transporter that is important for the sensing event. In one model the conformational changes that occur during the transport process could be channeled to a signaling partner. In support of this model, conformational changes occur in Mep2 in response to phosphorylation, and the closed nature of the pore suggests additional conformational changes might occur during ammonium transport (107, 108). Furthermore, a physical interaction has been identified between the Ump2 receptor and the signaling protein Rho1 in *U. maydis* (119). In *S. cerevisiae* and *C. albicans* genetic interactions between Mep2 and the PKA signaling pathway have been identified (100, 101, 118). It has also been proposed that signaling and nonsignaling transporters may influence internal pH differently if one mediates electrogenic rather than electroneutral transport (117). In this model, sensing would be dependent on a downstream pH sensor.

Transceptor-Mediated Ammonium Sensing in Filamentous Fungi

The number of ammonium transceptors that have been studied suggests that this mode of signaling may be widespread in fungi. To support this, homologs from diverse fungi restore signaling in a *S. cerevisiae* strain

lacking the Mep2 transceptor, including transporters from the filamentous rice pathogen *Fusarium fujikuroi* (MepA and MepC) and the ectomycorrhizal fungus *Hebeloma cylindrosporum* (Amt1 and Amt2) (120, 121). Although these proteins are able to restore pseudohyphal growth in *S. cerevisiae*, the processes they regulate within their native organism remain unclear. In the broad-range plant pathogen *Colletotrichum gloeosporioides*, transceptor-mediated ammonium sensing has been shown to be important for invasive growth and virulence (122).

G-PROTEIN-COUPLED RECEPTORS

GPCRs communicate changes in the extracellular environment to intracellular G proteins, which initiate signaling events that coordinate the appropriate response. GPCR-ligand binding causes the dissociation of the heterotrimeric G proteins into the Gα-subunit and a Gβγ-dimer, which activate downstream pathways (123). G-protein functions are transient and regulated by repressors of G-protein signaling (RGS), which promote G-protein reassociation and RGS ubiquitination/degradation feedback mechanisms. Despite the general GPCR-signaling mechanism being highly conserved in eukaryotes, significant differences exist between yeasts and filamentous fungi. Five main categories of classical GPCRs exist, including pheromone, carbon, nitrogen, cAMP, and microbial opsin receptors. Additional nonclassical GPCRs include the orthologs of Pth11 (*Magnoporthe oryzae*), mPR (humans), a hormone receptor (rat), and *At*Rgs1 (*A. thaliana*). However, relatively few GPCR-G-protein interactions in fungi are characterized, and even fewer pathway-activating ligands have been identified.

GPCR-Mediated Carbon Sensing in *S. cerevisiae*

The addition of various carbon sources, such as glucose, sucrose, mannose, or fructose, to glucose-deprived cells triggers rapid activation of the cAMP-PKA pathway (124–126). PKA becomes activated because of an increase in cAMP, as a result of adenylate cyclase activation via a dual-glucose-sensing system, extracellular detection through a GPCR, as well as intracellular sensing dependent on sugar uptake and phosphorylation (127) (Fig. 1). The activation of PKA results in the phosphorylation of a wide spectrum of target proteins associated with rapid cell growth (128).

Extracellular sugar sensing is mediated via the GPCR, Gpr1, the Gα-protein Gpa2 (129), and its RGS protein, Rgs2 (130). Detailed analysis of the *Sc*Gpr1 receptor, using cysteine-scanning mutagenesis and SCAM, identified specific amino acids in transmembrane domain 6 that bind glucose and sucrose as ligands, thereby mediating the activation of the PKA pathway (125).

In addition to a role in activation of the PKA pathway, Gpr1 is required for pseudohyphal filamentous growth and also accounts for the glucose sensitivity of the mating pathway (131). The Sks1 kinase was recently identified as a novel component linking glucose sensing by Gpr1 and induction of genes involved in pseudohyphal differentiation (132). Gpa2 is an atypical Gα-protein, in that it is not part of a heterotrimeric complex; however, some proteins have been identified as candidate Gβγ-subunits: the Kelch repeat proteins, Krh1/Gpb2 and Krh2/Gpb1 (133, 134), as well as Asc1, a protein binding to Gpa2 in a guanine nucleotide-dependent manner (135). The Krh proteins, activated by Gpa2, downregulate PKA by increasing the cAMP dependency (136). In this way, they are part of an adenylate cyclase bypass, allowing the direct activation of PKA by activated Gpa2. In addition, the Krh proteins provide a negative feedback loop by phosphorylating the PKA regulatory subunit, Bcy1, and hence promoting its association with the catalytic subunits (137, 138). Recently, Gpr1 was also shown to be required for the induction of the mating pathway (139).

GPCR-Mediated Carbon Sensing in *C. albicans* and *C. neoformans*

In *C. albicans*, the situation regarding the number of GPCRs is similar to that of *S. cerevisiae*. There are two mating-factor GPCRs and one ortholog of the *ScGPR1*, *Ca*Gpr1 (140–142). Deletion of *CaGPR1* results in a strong morphogenetic defect on hyphae-inducing media, less damage in a reconstituted tissue infection model but only a slight effect on virulence in a systemic infection model system (141) (Fig. 1). Contrary to the situation in *S. cerevisiae*, *Ca*Gpr1 is not required for the glucose-induced cAMP increase. Although the exact ligand still remains to be identified, it is possible that *Ca*Gpr1 is a glucose sensor that does not activate adenylate cyclase. Another possibility is that methionine is the ligand, because it was shown that *Ca*Gpr1 is internalized in the presence of methionine (resembling the ligand-induced internalization known in other receptors) and there is no methionine-induced morphogenesis in the *Cagpr1* mutant (141, 143). This latter phenotype is only observed in the presence of low physiological concentrations of glucose, however, so it cannot be excluded that *Ca*Gpr1 is a low-glucose sensor.

In *C. neoformans*, glucose is a preferred carbon source and a known signal to activate the homologous

Gpa1-cAMP-PKA signal transduction pathway, which controls the production of major virulence factors (capsule and melanin) and is essential for fungal virulence (144). But it remains unknown how glucose activates Gpa1 and what is the GPCR for glucose sensing in *C. neoformans*. Multiple GPCR candidates have been identified based on the basic seven-transmembrane domain structure, but none of them share extensive sequence identity with *Sc*Gpr1, except maybe Gpr4 (145). Both Gpr4 and *Sc*Gpr1 have a large third cytoplasmic loop and a long C-terminal tail. Despite the structural similarity, Gpr4 is not important for glucose sensing, but, as mentioned below, is classified as a methionine receptor. Gpr5 also contains a large third intracellular loop and shares high sequence identity with Gpr4, and Gpr5 was found to play a role in regulating fungal cell size ("Titan" cell formation) during infection, likely by sensing certain unidentified host signals in the lung (146). Phylogenetic analysis based on protein sequences shows that Gpr4 and Gpr5 are more closely related to GprH in *A. nidulans* and cAR1 in *Dictyostelium discoideum* than to Gpr1 in *S. cerevisiae* (145). This is also consistent with the data indicating that Gpr4 and Gpr5 are not glucose receptors. How glucose is sensed remains to be understood. It is possible that there is functional redundancy among GPCRs in glucose sensing that complicates the identification of glucose receptors.

GPCR-Mediated Carbon Sensing in Filamentous Fungi

In contrast to yeasts, filamentous fungi can utilize a diverse array of nutrient sources including hexose, pentose, and complex saccharides. This nutritional plasticity may therefore be reflected in the presence of additional Gα-proteins and the dramatic expansion of putative GPCRs (123).

In *N. crassa*, the putative carbon sensor, Gpr4, interacts with the G protein, Gna1, influencing cAMP production and asexual development in a carbon source-dependent manner (147) (Fig. 1). The absence of Gpr4 resulted in reduced growth on glycerol, mannitol, and arabinose, a phenotype that was partially recovered via the addition of exogenous cAMP. In *A. nidulans*, a putative carbon receptor, GprD, influences hyphal growth, germination, and primary metabolism (148). Interestingly, GprD and the pheromone receptor, GprB, possess opposing functions in the regulation of sexual development (149). Similarly, the *A. nidulans* cAMP receptor-like GPCR, GprH, was induced during carbon starvation and was shown to be involved in glucose and amino acid sensing, while influencing primary metabolism via the cAMP-PKA pathway and acting as a repressor of sexual development (150). In *Aspergillus fumigatus*, two putative carbon receptors, GprC and GprD, were fundamental to germination, hyphal extension, and branching (151). Furthermore, the absence of GprC or GprD increased sensitivity toward environmental stress caused by reactive oxygen intermediates and displayed attenuated virulence in a murine infection model. Transcriptome analyses indicated that both GprC and GprD promoted primary metabolism, while inhibiting secondary metabolism (151). A wider evaluation of the function of all 15 classical GPCRs in *Aspergillus flavus* revealed multiple GPCRs potentially involved in carbon sensing, as the individual absence of GprA, GprC, GprJ, GprK, or GprR impaired growth on several carbon sources (152). Therefore, in contrast to yeasts, filamentous fungi appear to possess multiple GPCRs involved in sensing a broad range of carbon sources, reflecting the complexity of the environments that they inhabit, their metabolic plasticity, and their capacity to utilize a diverse array of carbon sources.

GPCR-Mediated Amino Acid Sensing by GPCRs in *C. albicans* and *C. neoformans*

Apart from the above-mentioned amino acid receptors, some GPCRs have also been reported to sense amino acids in fungi. In *C. albicans*, Gpr1, the homolog of the glucose sensor *Sc*Gpr1 has been suggested as a possible receptor for methionine. Methionine is important for the yeast-to-hyphal transition on solid agar medium; the *gpr1*Δ/*gpr1*Δ mutant blocks fungal filamentation under such inducible conditions. Gpr1 senses methionine to activate the cAMP-PKA pathway, which in turn controls the filamentation in the presence of glucose as a carbon source (141, 143). It is not yet excluded, however, that *Ca*Gpr1 may actually sense low (or physiological) glucose levels.

In *C. neoformans*, the GPCR protein Gpr4 also plays a role in sensing amino acids to activate cAMP-PKA signaling (145) (Fig. 2). Mutagenesis demonstrated that Gpr4 is required for capsule production and fungal mating, two cellular functions controlled by the Gpa1-cAMP-PKA pathway. The direct interaction between Gpr4 and Gpa1 G protein has also been confirmed in a membrane-based yeast two-hybrid system. Methionine can trigger Gpr4 internalization and induces a transient cAMP production in a Gpr4-dependent manner. In addition, a low level of methionine can induce mating hyphal elongation in *C. neoformans*, which is blocked by the deletion of *GPR4*. These data indicate that Gpr4 may function as a receptor for amino acids, such as

methionine (145). However, the direct binding of amino acids to *Ca*Gpr1 or *Cn*Gpr4 has not been observed. Whether these GPCRs sense extracellular amino acid, intracellular amino acid, or both, also remains to be determined.

GPCR-Mediated Amino Acid Sensing in Filamentous Fungi

GPCRs in filamentous fungi have been reported to sense amino acids. The cAMP receptor-like GPCR in *A. nidulans*, GprH, shows distant homology to the cAMP receptors of *D. discoideum* and *A. thaliana*, as well as to *Gpr4* in *C. neoformans* (123). Nonetheless, GprH was revealed to be a putative receptor for both glucose and the amino acid tryptophan, forming part of the cAMP-PKA pathway and influencing primary metabolism, while repressing sexual development, during carbon starvation (150, 153). GprH also shows homology to the putative *N. crassa* carbon receptor, Gpr4. The absence of this receptor caused defects in perithecial development and ascospore discharge. However, the binding of this putative ligand was not defined (154). Therefore, the function of cAMP receptor-like GPCRs in regulating sexual development appears to be conserved in fungi, while receptors of this class may dually detect both sugars and amino acids. Additionally, in *A. flavus*, the absence of the putative carbon receptors, GprC and GprD, which showed homology to the *S. pombe* glucose GPCR Git3, inhibited growth on the amino acid, proline (152). Hence, filamentous fungal GPCRs of several classes may potentially influence various amino acid and carbon nutrient-sensing pathways.

GPCR-Mediated Ammonium Sensing in Filamentous Fungi

In contrast to yeasts, very little is known of ammonium sensing in filamentous fungi. The *A. flavus* genome encodes four receptors that show homology to the *S. pombe* Stm1 sensor, which regulates cell cycle progression in response to nitrogen starvation (155). The absence of one of these receptors, GprR, impaired growth on ammonium chloride and the amino acid, proline (152). This again suggests that in filamentous fungi a single GPCR may play a role in multiple nutrient-sensing pathways.

GPCR-Mediated Host Sensing in Filamentous Fungal Pathogens

In filamentous fungi, GPCR-regulated signaling pathways include the cAMP-dependent PKA and the mitogen-activated protein kinase (MAPK) cascades, which regulate growth, metabolism, mating, morphogenesis, cell division, cell-to-cell fusion, chemotaxis, toxicogenesis, and virulence (156). It is becoming increasingly apparent that GPCRs can bind multiple ligands and, in turn, possess additional functions. The vascular root phytopathogen, *Fusarium oxysporum*, demonstrates chemotaxis toward specific nutrients (glucose, glutamate, and aspartate, but not glutamine, methionine, ammonium, or galactose) and host tomato plant root exudates, in particular, a class II peroxidase that is associated with root hairs that represent a potential site for invasion (157). Chemotropic sensitivity to the α-pheromone is far greater than nutrients, suggesting that the two responses are mediated by distinct mechanisms. Accordingly, mutants in the Fmk1 filamentous growth pathway are impaired in their response to glutamate or glucose, but not the α-pheromone, while mutants in the Mpk1 cell wall integrity pathway are impaired in their chemotaxis toward the α-pheromone, but not glutamate or glucose. The absence of Ste2/Pre2 pheromone receptor in *F. oxysporum* abolishes chemotropism toward the α-pheromone and tomato root exudates, while having a minor impact on virulence, demonstrating how Ste2 GPCR-mediated signaling, which was previously thought to be exclusively involved in pheromone sensing, is also involved in detecting host cues and promoting virulence (157).

In the foliar rice pathogen, *M. oryzae*, the Gαβγ-subunits, and the nonclassical GPCR, Pth11, sense surface hydrophobicity and plant cutin monomers, regulating appressorium formation and virulence in a cAMP-dependent manner (158). Evaluation of the spatiotemporal dynamics of G-protein signaling during pathogenic development showed key components, including Pth11, MagA, Rgs1, and the adenylate cyclase, to be sequestered to the tubulovesicular network, where late endosomes controlled the geometry and activation/deactivation of the cAMP signal during pathogenesis (159). Subsequently, numerous Pth11-related receptors have been identified in *M. oryzae* and other filamentous fungi from the ascomycete subphyla, *Pezizomycotina*, including *A. nidulans*, *N. crassa*, and *Fusarium graminearum*, while none were found in other ascomycete subphyla, such as the yeasts or the basidiomycetes (123, 160). Hence, this nonclassical receptor class represents the most highly expanded receptor class in filamentous ascomycete fungi. In turn, a recent analysis of the classical and nonclassical GPCRs in *N. crassa* identified numerous Pth11 homologs and revealed their involvement in nutrient sensing. The absence of three Pth11 homologs in *N. crassa*, Gpr32, Gpr36, and Gpr39, enhanced growth on cellulose as

an alternative to sucrose (161). Therefore, in filamentous fungi Pth11-like receptors appear to participate in sensing plant-related compounds, applicable to a saprophytic and a pathogenic interaction with plants.

EXTRACELLULAR MUCIN RECEPTORS IN FUNGI

Extracellular Mucin Receptors in *S. cerevisiae*

Exposure of *S. cerevisiae* to nitrogen deprivation activates pseudohyphal and invasive growth, in addition to biofilm formation, via activating MAPK signaling to enable nutrient foraging and survival (162–165). Extracellular signaling mucins act as sensors of nutrient availability and physical contact, regulating the connection between cells or to a surface (Fig. 3). Fungal and human signaling mucins utilize a highly conserved induction mechanism that results in GTPase activation (166). Nutrient deprivation promotes the proteolytic cleavage of an extracellular inhibitory mucin domain, activating intracellular Msb2-mediated MAPK signaling (162, 167). The highly glycosylated extracellular mucin domain of Msb2 is cleaved off by the Yps1 yapsin protease, releasing the inhibitory domain into the surrounding environment to create mucous glycoprotein layers around cells, analogs of MUC1/2 mucins in humans (166, 167). Upon starvation, the Mig1 carbon catabolite repressor that inhibits alternative carbon usage is phosphorylated by Snf1, promoting its dissoci-

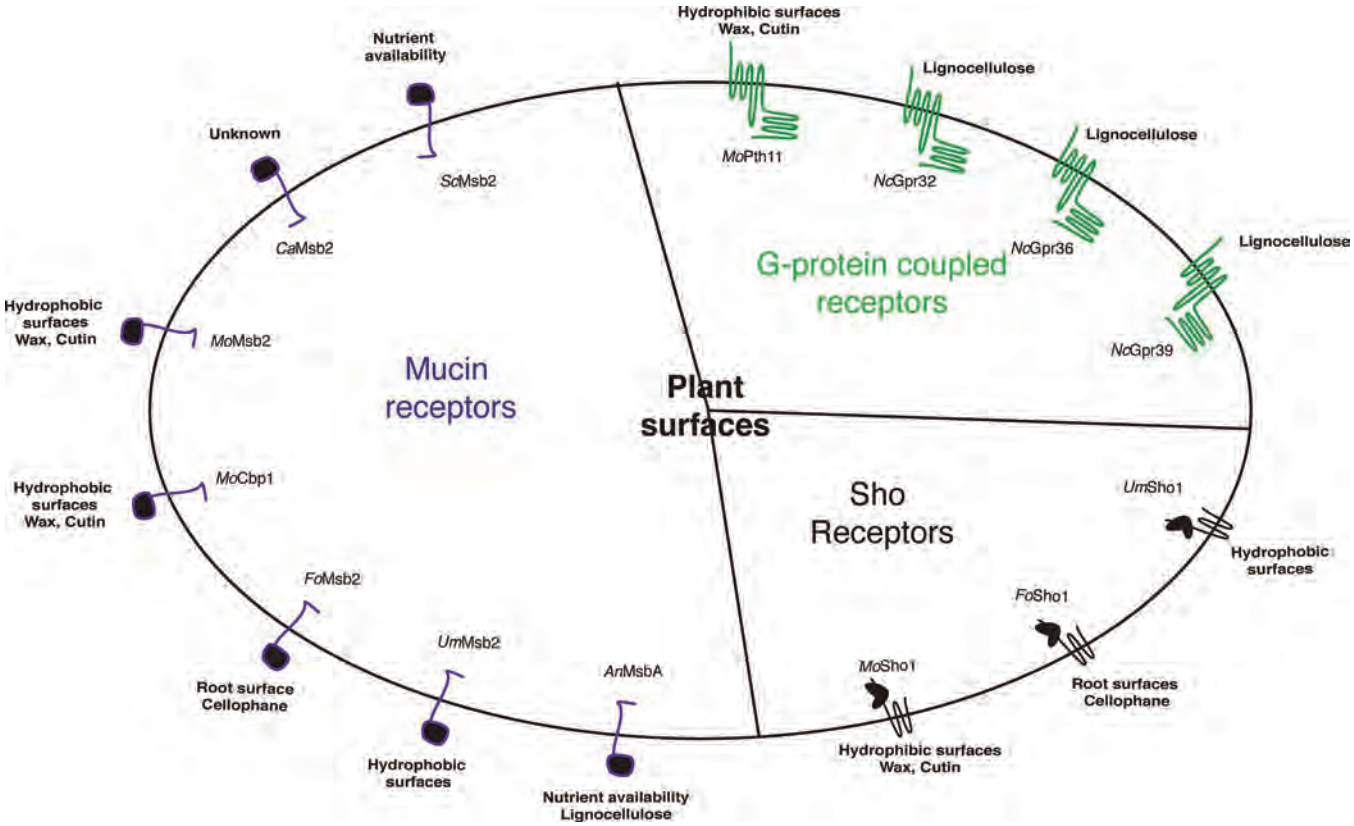

Figure 3 Surface-sensing proteins in the plasma membrane of fungal cells. Characterized surface-sensing proteins can be divided into G-protein-coupled receptors (GPCRs) and the interacting Sho receptors and the extracellular mucin receptors. The nonclassical, Pth11-type, GPCRs include the *Magnaporthe oryzae* (*Mo*) Pth11 receptor of hydrophobic surfaces and the *Neurospora crassa* (*Nc*) Gpr32, Gpr36, and Gpr39 putative lignocellulose receptors. The Sho receptors include the orthologous *Ustilago maydis* (*Um*), *Fusarium oxysporum* (*Fo*) and *Mo*, hydrophobic surface Sho1 receptors. The extracellular mucins include the orthologous *Aspergillus nidulans* (*An*), *Um*, *Fo*, *Mo*, Msb2 hydrophobic surface receptors, in addition to the Msb2 receptors of *Candida albicans* (*Ca*) and *Saccharomyces cerevisiae* (*Sc*) that have not been characterized as detecting surfaces, plus the additional Cbp1 mucin receptor of hydrophobic surfaces from *Mo*.

ation from the DNA, its migration from the nucleus, and its interaction with multiple members of the pseudohyphal MAPK cascade, including Msb2, which influences filamentation (164). The Snf1-Mig1 mechanism for preferential carbon usage is therefore interlinked to the pseudohyphal MAPK pathway, coordinating cellular metabolism and proliferation in response to nutrient availability (164). Cell adhesion is also controlled by the Ras, cAMP-PKA, and MAPK pathways in response to nutrient deprivation and other exogenous stresses (168), while adhesion impacts pseudohyphal growth and biofilm formation (169, 170). The Msb2-pseudohyphal MAPK pathway regulates the secretion of the Flo11 flocculin, which is essential for adhesion and pseudohyphal growth (169). Therefore, in response to nutrient availability, Msb2-MAPK signaling induces filamentous growth, cell adhesion, and biofilm formation to promote nutrient foraging and survival.

Extracellular Mucin Receptors in *C. albicans*

The regulation of MAPK cascades by Msb2, controlling filamentous growth, is conserved in *C. albicans*, where shedding of Msb2 and the induction of MAPK signaling promote filamentous growth and influence biofilm formation (171, 172) (Fig. 3). In *C. albicans*, Msb2, in cooperation with Sho1, controls the activation of the Cek1 MAPK under cell wall or osmotic stress. The absence of Msb2 had a stronger impact on invasive growth on certain solid media, such as mannitol or sucrose, and under hypoxia than the loss of Sho1 (171). Similar to *S. cerevisiae*, in *C. albicans* the Sap8 aspartic protease cleaves the extracellular Msb2 mucin domain, activating Cek1 signaling and biofilm formation (172). The absence of Msb2 or Sap8 resulted in the increased exposure of β-glucans and the loss of Msb2-attenuated virulence in a murine model of oral candidiasis. Additionally, Msb2 shedding also protects against antimicrobial peptides (173, 174). Therefore, in addition to regulating invasive growth and biofilm formation, the Msb2 pathway in *C. albicans* performs an essential function in reducing the exposure of pathogen-associated molecular patterns that trigger host defenses and in increasing the tolerance of exogenous stresses such as antimicrobial peptides by creating a mucous layer. However, the nutritional and/or environmental signals that promote Msb2 signaling remain to be determined in *C. albicans*.

Extracellular Mucin Receptors in Filamentous Fungi

Surface recognition is one of the most critical processes for both saprophytic and pathogenic filamentous fungi. In the heterogeneous semisolid environment, naturally occupied by fungi, the majority of nutrients are locked away as insoluble biomass. Hence, fungi have to actively search for and attach to a desirable source of nutrients. Subsequently, during this foraging period, starvation and contact sensing are hypothesized to participate in the localization and deconstruction of complex nutrient sources. In the lignocellulolytic fungus, *A. nidulans*, the extracellular mucin, MsbA, influences growth under nutrient-poor conditions including those on lignocellulose. Through the modulation of both the cell wall integrity and filamentous growth MAPK cascades, MsbA regulates adhesion to solid surfaces, biofilm formation, and lignocellulolytic enzyme secretion (175), in particular, the CbhA cellobiohydrolase required to release cellobiose from lignocellulose and the induction of the lignocellulolytic machinery. Therefore, starvation and/or surface sensing represent a new dimension to the already multifaceted regulation of nutrient sensing, CAZyme production, and lignocellulose deconstruction (Fig. 3).

In the case of filamentous phytopathogens, the recognition of host surfaces, and their subsequent penetration, is paramount for the establishment of infection. The filamentous growth MAPK pathway is central to the establishment of invasive growth and virulence (156). In the vascular root pathogen, *F. oxysporum*, Msb2 induces the phosphorylation of Fmk1, which promotes cellophane and tomato root penetration, contributing to fungal virulence (176). Similarly, the *F. oxysporum* Sho1 receptor was also required for Fmk1 phosphorylation, extracellular pectinolytic activity, cellophane penetration, plant tissue colonization, and virulence (177). The dimorphic pathogen of maize, *U. maydis*, switches from budding to hyphal growth and the development of appressoria in response to the detection of the hydrophobic, waxy, plant surfaces. In *U. maydis* the interacting Msb2 and Sho1 receptors function upstream of the Kpp2-Kpp6 MAPK cascade, and are key to the development of appressoria in response to hydrophobic surfaces, in addition to priming the fungus for biotrophic development (178, 179). These examples of the overlapping functionality of Msb2 and Sho1 suggest a genetic interaction between the two receptors, which was noted in yeasts, is conserved in filamentous fungi.

In the foliar rice pathogen, *M. oryzae*, multiple surface sensors detect rice leaf surfaces, appressorium formation, and host invasion, including the aforementioned nonclassical GPCR, Pth11, plus the Msb2, Sho1, and Cbp1 receptors (158, 180, 181). Similar to Pth11, the absence of Msb2 significantly reduced appressorium

formation and virulence, while the absence of Sho1 only resulted in a slight reduction in virulence. The dual absence of Msb2 Sho1 resulted in an inability to respond to cutin monomers and an inability to form appressoria on artificial hydrophobic surfaces. Appressorium formation on hydrophobic surfaces, leaf waxes, or primary alcohols was more severely inhibited in the dual absence of Msb2 and Sho1 than in the absence of just Msb2. This suggests that the two interacting receptors possess overlapping functions, yet Msb2 is critical for sensing surface hydrophobicity and cutin monomers, while Sho1 appears to be important in recognizing rice leaf waxes. Therefore, in addition to surface hydrophobicity and cutin monomers, primary alcohols in leaf epicuticular waxes are utilized as signals for fungal infection (180). *M. oryzae* possesses another putative mucin, CBP1 (named for chitin-binding protein 1), and the absence of Cbp1 also resulted in an inability to produce appressoria on hydrophobic surfaces, while retaining the ability to form appressoria on leaves (182), potentially because of the action of Msb2. In accordance, the absence of both the extracellular mucins, Msb2 and Cbp1, blocked Pmk1 MAPK phosphorylation, impeded appressorium formation, and abolished virulence, suggesting that the Msb2 and Cbp1 mucins have overlapping functions in the recognition of environmental cues required for the penetration of host tissues (181). Therefore, in filamentous fungi the extracellular mucin and Sho1 receptors appear to have evolved the ability to detect the hydrophobic, waxy, alcohol composition of plant surfaces and, in doing so, perform a fundamental role in plant pathogenesis.

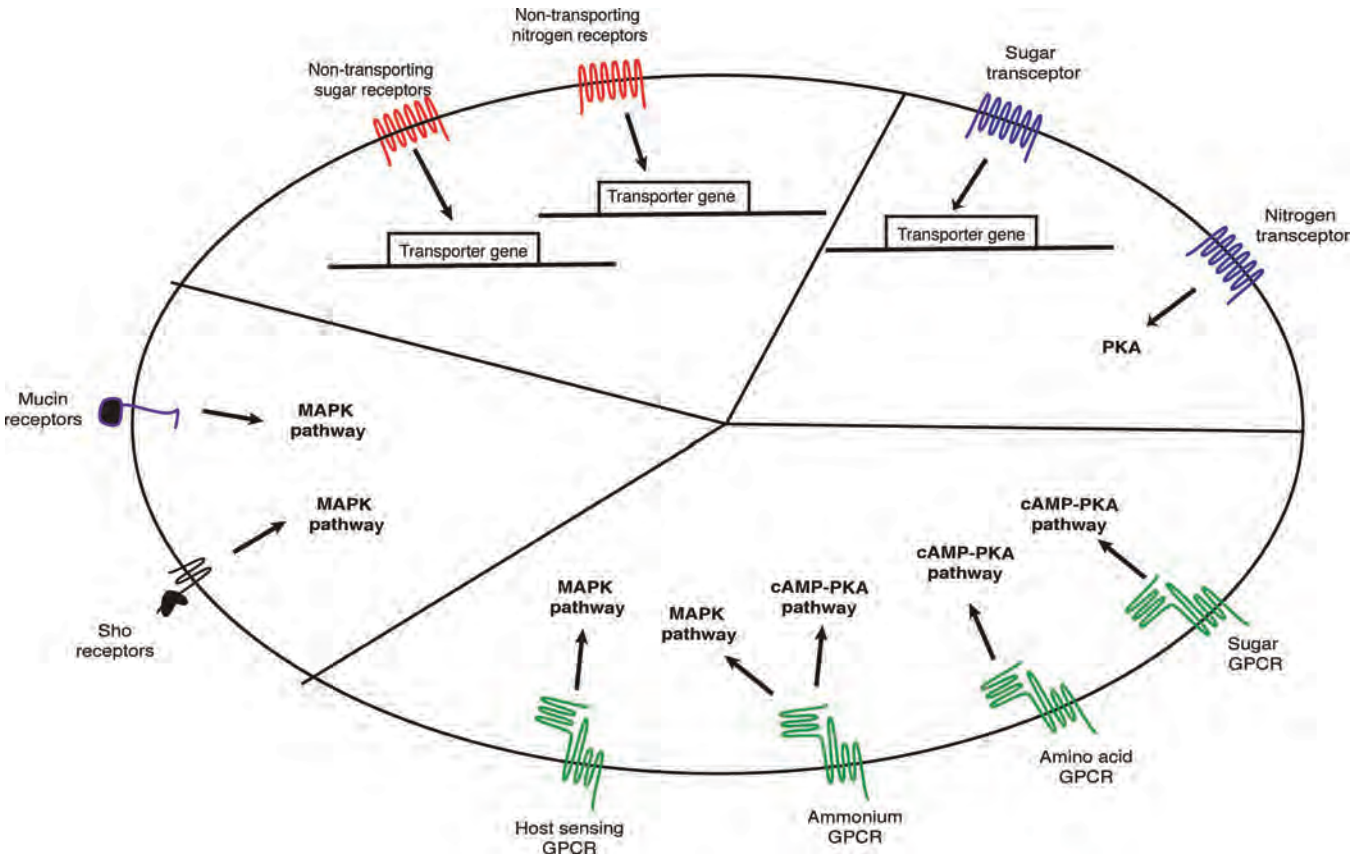

Figure 4 Nutrient- and surface-sensing proteins in the plasma membrane of fungal cells and the downstream signal transduction pathways they trigger. Examples for the different classes of nutrient (nontransporting receptors, transceptors, and GPCRs) and surface (mucin and Sho) sensing proteins are shown. Sensing of nutrients by nontransporting receptors and sugar transceptors results in the induction of nutrient transporter genes. Nitrogen transceptors (e.g., *Sc*Gap1) result in the activation of the PKA pathway upon sensing appropriate nitrogen sources. Depending on the type of GPCR, they can activate the cAMP-PKA pathway, the MAPK pathway, or both. The surface receptors activate the MAPK pathway.

MEMBRANE-LOCALIZED TRANSCEPTORS OR RECEPTORS LINK THE AVAILABILITY OF NUTRIENTS TO DOWNSTREAM SIGNAL TRANSDUCTION PATHWAYS

In this review, we described the nature of the receptors by which different nutrients are sensed by fungi. We distinguished between nontransporting sugar or nitrogen receptors, sugar or nitrogen transceptors, sugar, nitrogen, and host sensing GPCRs, as well as mucin receptors. In our review, we briefly mentioned the signal transduction pathways that are activated upon the sensing of nutrients by these receptors. Figure 4 gives an overview of what is currently known about the downstream signaling pathways, which we also briefly touched upon. The two most important downstream pathways are the MAPK and cAMP-PKA pathways, which are not only involved in nutrient sensing but are also involved in mating (183). Nontransporting receptors and some transceptors regulate the expression of nutrient transporters upon sensing that specific nutrient. A detailed description of these pathways is discussed elsewhere.
