

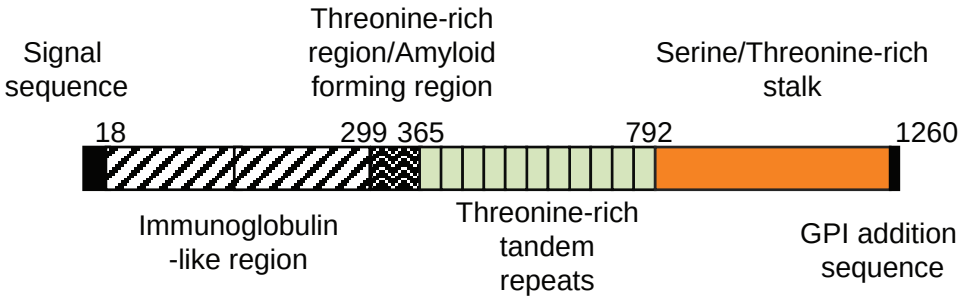

Figure 2 Als1 structure. Domains of Als proteins that are discussed in the text are depicted with amino acid coordinates of Als1 indicated.

sequence composition can have two distinct roles in Als5 activity. It would be interesting to know whether the two TR functions are separated genetically and if they are both critical for biofilm formation.

There is a serine- and threonine-rich region adjacent to the TR region. Mutations that reduce the length of this region prevent surface exposure of *S. cerevisiae*-expressed Als1 (21). These results are consistent with detailed work on the *Candida glabrata* adhesin Epa1 (22), which revealed that lack of the corresponding region caused the adhesin to be embedded within the cell wall rather than surface-exposed (22). The serine- and threonine-rich regions of several other *C. albicans* adhesins, Eap1 and members of the Hyr/Iff family, are also required for surface exposure (23, 24). Thus, the function of this region, to enable surface exposure of an N-terminal ligand-binding domain, seems to be similar among many adhesin-like proteins. This region is sometimes called the stalk, a name that seems to reflect its function quite well.

At the very C terminus of Als proteins (and many other cell wall proteins) is a short hydrophobic peptide that serves as a GPI-anchor addition signal. The GPI anchor, which is added in the endoplasmic reticulum, possesses a lipid tail that serves as a membrane tether. Upon trafficking to the cell surface, some GPI-anchored proteins remain tethered to the outer face of the plasma membrane, whereas others are transferred to become covalently linked to cell wall β-1,6 glucan (25). In *C. albicans* (26), as in *S. cerevisiae* (27), amino acid residues neighboring the GPI-anchor addition site determine whether the protein becomes localized primarily to the plasma membrane or cell wall. Beyond this generic function for the GPI-anchor addition signal, Ahmad et al. have provided evidence that this region influences the affinity of Als5 for its ligands (28). However, the study used recombinant proteins, and it will be exciting if this function can be demonstrated in live fungal cells. In general, the most broadly documented function for the GPI-anchor addition signal is to mediate cell wall attachment of adhesins and other mannoproteins (25).

How can you determine if a protein functions as an adhesin? Various approaches have been used to answer this question. One way to show adhesive function is to express the protein in a nonadherent organism. Fanning and colleagues utilized a *bcr1/* mutant strain of *C. albicans* that is defective in expression of most known adhesins, including Als1 and Hwp1 (29). Therefore, this strain does not adhere to surfaces under a variety of conditions. By overexpressing various genes of interest, Fanning et al. showed that several known adhesins (Als1, Als4, Als2) restored adherence in a *bcr1/* mutant.

The model yeast *S. cerevisiae*, like the *C. albicans bcr1/* mutant, does not adhere well to many surfaces. Therefore, it has been widely used as a heterologous expression system for assessing adhesive protein function. Als1, Als3, Eap1, Hwp1, and Rbt1 have each been heterologously expressed in *S. cerevisiae* and shown to be functional adhesins (30–32). The *S. cerevisiae* cells expressing these proteins attached and formed biofilms on abiotic and cellular substrates, albeit to varying degrees (30–32). Using *S. cerevisiae* to express *C. albicans* proteins is an effective way to reduce the redundancy of adhesins and other adherence mechanisms that are utilized by *C. albicans* cells. However, it is important to note that *C. albicans* translates the CUG codon as serine, while most other organisms including *S. cerevisiae* translate CUG as leucine (33). This coding difference may cause unintended structural consequences if the protein is not codon-optimized.

Biofilm integrity probably depends on a balance of cell-substrate adherence and cell-cell adherence (sometimes called cohesion [34]). The importance of this balance was emphasized in the studies by Cabral et al. of a panel of *C. albicans* strains that overexpressed 531 different individual genes, including many cell wall protein genes (35). They made the perplexing observation that overexpression of certain cell wall proteins affected a strain's ability to form biofilms differentially, based on whether the biofilm was a mono-culture or multistrain biofilm (35). For example, when cell wall genes were overexpressed in a pooled biofilm assay of 531 strains, the *PGA22*-overexpressing strain had increased abundance compared to other strains. However, when the strain was grown in a single-strain biofilm assay, the *PGA22*-overexpressing strain showed decreased biomass. The study found that overexpression of *PGA22* in *C. albicans* or a *PGA22*-derived hybrid gene in *S. cerevisiae* augmented cell-cell adhesion, and the resulting clumps of cells had increased sensitivity to shear force (35). Therefore, the flow conditions under which these biofilm assays were conducted could remove exposed cell aggregates in single-strain biofilms but could not dislodge the *PGA22*-overexpressing cells that were shielded by their 531 cousins in mixed-strain biofilms. This imaginative study illustrates the importance of a balance of adhesion to cells and substrates, as well as that cell-cell interactions within a biofilm can allow increased cell diversity.

The mold pathogen *A. fumigatus* also forms adhesive biofilms, though many of its properties are quite different from *C. albicans*. Biofilm formation in *A. fumigatus* occurs *in vitro* when grown under static aerial conditions or when grown attached to human

bronchial epithelial cells. The biofilm is characterized by a mat of hyphae encased in ECM and shows increased resistance to antifungal cells compared to planktonic cells (36, 37). For biofilms to form, these infections begin with inhaled conidia that adhere to bronchial epithelial cells or macrophages. *A. fumigatus* RodA was discovered as a hydrophobin—a surface protein that confers hydrophobicity—that is expressed on conidia (38). A *rodA* mutant was shown to have decreased adhesion but was dispensable for virulence in a mouse model of systemic infection (38). Similarly, CalA, a predicted adhesin, was shown to bind mouse lung cells and laminin (39). However, its role in virulence or biofilm formation remains to be determined. Current understanding of *A. fumigatus* biofilms suggests that an ECM component, discussed in the next section, may have a more significant role in biofilm formation than any cell wall proteins.

ECM MATERIAL

One of the hallmarks of all biofilms is the presence of ECM (3, 40). The ECM can have diverse functions, including surface adherence, cell-cell aggregation, and nutrient storage (41). Of special relevance to biofilm infections, ECM can present a barrier that buffers biofilm cells from antimicrobial agents as well as host defenses (42, 43).

ECM has been characterized from biofilms of several *Candida* species (summarized in reference 44). We focus here on two species, *C. albicans* and *A. fumigatus*, whose ECM has been studied in detail. We note that ECM abundance and composition can vary considerably with growth conditions (45), as does the biofilm structure itself (Fig. 1B), so some conclusions may differ between studies because of the use of distinct media.

Initial characterization of the *C. albicans* ECM through chemical analysis revealed the presence of glucose, hexosamine, protein, extracellular DNA (eDNA), and a few other components (46). This analysis was complemented through functional assays for biofilm integrity and adherence after enzymatic hydrolysis of ECM components (47). Overall biofilm integrity was found to depend on multiple ECM components, including β-1,3 glucan, chitin, protein, and eDNA.

Are there unique proteins in the ECM? A combination of electrophoretic separation and mass spectrometry identified abundant *C. albicans* biofilm matrix proteins and compared them to planktonic culture supernatant proteins (48). There was good correspondence between the samples, which included both conventionally secreted proteins, which have an N-terminal signal sequence, and unconventionally secreted proteins, which lack a signal sequence (49). No biofilm-specific ECM proteins were identified. Therefore, if any ECM proteins have unique functions in biofilm properties, these functions must arise in the context of ECM, perhaps as a result of high concentration or association with other ECM components.

The composition of *C. albicans* ECM has recently been defined comprehensively through a chemical and biochemical tour de force (50). The major components were proteins, carbohydrates, lipids, and eDNA. Most importantly, an abundant mannan-glucan complex called MGCx (sometimes pronounced "magic X") was identified. It comprised branched β-1,6 mannan complexed with linear β-1,6 glucan. Because this complex is present at low levels if at all in cell wall preparations, it cannot arise from inadvertent contamination of ECM with cell wall fragments. In fact, MGCx may be the first *C. albicans* biofilm-specific marker.

How might an ECM-specific marker like MGCx be assembled? A fascinating answer comes from a study in which candidate genes were used to make mutants defective in individual ECM carbohydrate components (51). One surprising result was that accumulation of three ECM carbohydrates—mannan, β-1,3 glucan, and β-1,6 glucan—is coordinated: mutations that reduce accumulation of one component generally reduce accumulation of all three. The most intriguing finding was that mixed biofilms comprising mutants blocked in production of different carbohydrate components displayed extracellular complementation, accumulating all components at levels as great or greater than the wild type. These findings indicate that ECM is assembled extracellularly (51). Perhaps the high local concentrations of substrates and enzymes for ECM assembly in the biofilm enable the reactions to proceed more rapidly than in the relatively dilute supernatant of a planktonic culture.

A second important finding from the comprehensive ECM analysis came from proteomic studies of biofilms formed *in vivo* in animal infection models (50). Specifically, although ECM from *in vitro* biofilms had 565 *C. albicans* proteins, ECM from *in vivo* biofilm models (venous catheter, urinary catheter, and denture) had only 16 *C. albicans* proteins. The vast majority of ECM proteins found *in vivo* were from the host. Therefore, host proteins may make unique functional contributions to the ECM from infecting biofilms. Interestingly, Nett et al. found a group of 14 host proteins in common among ECM samples from the three *in vivo* biofilm models (52), a very manageable number for functional assessments. The significance of the host protein contri-

bution is illustrated by the fact that an inhibitor of *C. albicans*-fibronectin interaction blocks biofilm formation *in vivo* in a catheter infection model (53). These exciting findings reinforce the importance of testing conclusions from *in vitro* studies in an *in vivo* biofilm model to validate their potential clinical significance.

A. fumigatus engages in biofilm growth during infection of the lung, where it clearly forms a cohesive multicellular aggregate enmeshed in ECM (54, 55). (*A. fumigatus* is also linked to some medical device-associated infections [56]). The *A. fumigatus* ECM comprises galactomannan, β-1,3 glucan, monosaccharides, polyols, melanin, and a small amount of protein (54). Importantly, *A. fumigatus* aggregates, called aspergillomas, resected from the lungs of patients contain both galactomannan and β-1,3 glucan, thus emphasizing the relevance to infection of these ECM components (55).

One of the major *A. fumigatus* ECM components is a polymer made of galactose and *N*-acetyl-galactosamine (galactosaminogalactan [GAG]). Comparison to *Aspergillus nidulans*, which makes a GAG that is low in *N*-acetyl-galactosamine, argues that *A. fumigatus* GAG has a major role in promoting biofilm formation (57). GAG is localized to *A. fumigatus* germ tubes and mycelia (58), and it mediates a multitude of virulence phenotypes. For example, it promotes adherence to abiotic surfaces through hydrophobic interactions and has been shown to interact with and bind to host cells such as pneuomocytes (58). GAG also interacts with the immune system and is necessary for resistance to killing by neutrophil extracellular traps (57). There is growing evidence that *C. albicans* ECM also functions in immune evasion and manipulation of the host response (59).

A. fumigatus ECM formed *in vitro* has some eDNA content (60, 61). Rajendran et al. found that chitinase activity accumulates in mature biofilms (60), and the association of chitinase with autolysis (62) suggests that autolysis leads to DNA release into the ECM. In support of this hypothesis, addition of a chitinase inhibitor reduced ECM eDNA content (60). DNAse treatment disrupts *A. fumigatus* biofilm integrity, thus indicating that eDNA plays a structural role in this species' biofilm (60).

DISPERSED CELLS

Dispersion is an important step in the developmental cycle of biofilm formation. The propagation of new biofilms necessitates the release and dispersal of new cells, because fungi are nonmotile. Uppuluri et al. measured the kinetics of dispersion of *C. albicans* cells using a flow biofilm model to mimic *in vivo* conditions where blood or other fluids create flow over implanted medical devices (63). They showed that even at early time points in biofilm formation, cells were being dispersed from the biofilm. Logically, the released cells were not composed of true hyphae, but the vast majority of cells were polarized yeast-form cells. Although dispersed cells were predominantly yeast, the cells showed unique phenotypic properties such as increased adhesion compared to planktonic yeast cells. The dispersed cells also displayed increased virulence in a mouse model of disseminated candidiasis. This suggests that the dispersed cells represent a distinct class of cell type in *C. albicans*.

Environmental signals can impact dispersion. Uppuluri showed that the amount of cell dispersion positively correlated with the amount of glucose in the media (63). Understanding the circumstances under which cells are most likely to be released from a biofilm and enter a patient's bloodstream could be important for clinical applications. Similarly, preventing dispersal of these highly virulent cells could be a way to combat systemic fungal infections caused by biofilms on implanted medical devices. In that context, promoter shut-off experiments have identified four regulators—Ume6, Pes1, Nrg1, and Hsp90—that govern cell dispersion from preformed biofilms (56, 63, 64). In addition, defects in a histone deacetylase complex encoded by *HOS2*, *SIF2*, *SNT1*, and *SET2* reduce the abundance of dispersed cells (65). These regulators and the genes they control may be useful pharmacological targets for limiting biofilm accumulation.

DRUG RESISTANCE AND PERSISTENCE

All biofilms are notorious for their resistance to antimicrobial drugs and antiseptics, and *C. albicans* biofilms are no exception. One of the most careful comparisons of resistance of *C. albicans* biofilm and planktonic cells, in the same assay format, comes from the pioneering studies of Hawser and Douglas (66). They observed that biofilm growth conferred 5- to 7-fold greater tolerance to amphotericin B, flucytosine, or several azoles. Time-course studies by Chandra et al. revealed that *C. albicans* biofilms develop resistance to amphotericin B, fluconazole, and other treatments rapidly—between 2 and 12 h after initiation of biofilm formation (67). How does biofilm resistance arise? Our current understanding is that several mechanisms contribute to this phenotype, which makes it robust and quite consistent among different *C. albicans* isolates and *Candida* species (66).

One factor that contributes to resistance is the upregulation of drug efflux pump genes *CDR1*, *CDR2*, and *MDR1* early in biofilm development (68, 69). Mutant analysis indicates that these genes have measurable impact on fluconazole resistance early in biofilm formation. As biofilms mature, though, other mechanisms make more prominent contributions to resistance.

A second factor is the presence of extracellular matrix material. One of the functional matrix constituents is DNA: it contributes to resistance to amphotericin B and caspofungin, as shown by the increased susceptibility of biofilm cells after DNAse treatment (70). Interestingly, the treatment did not affect fluconazole susceptibility, thus indicating that overall biofilm properties were not disrupted by the treatment. The mechanism by which matrix extracellular DNA confers resistance is not known. Soluble β-1,3 glucan is a second functional matrix constituent; it has a major role in biofilm azole resistance, as shown by Nett and colleagues through engineering altered expression of the β-1,3 glucan synthase gene *FKS1* (71). They observed that changes in *FKS1* expression were accompanied by corresponding changes in soluble β-1,3 glucan in the matrix. The phenotypic impact was dramatic: reductions in *FKS1* expression yielded biofilms that were extremely fluconazole-sensitive. The effect was biofilm-specific, in that the same strains were unaffected in fluconazole sensitivity during planktonic growth (71). Direct binding assays revealed that soluble β-1,3 glucan binds directly to fluconazole, thus indicating that drug sequestration is the mechanistic basis for biofilm fluconazole resistance (71). A follow-up study of candidate genes showed that three genes—*BGL2*, *PHR1*, and *XOG1*—also govern fluconazole susceptibility and matrix β-1,3 glucan production (72). These three genes specify extracellular glucan modification enzymes, making them inviting targets for antibiofilm therapeutics that might be combined with fluconazole.

Another biofilm feature that contributes to the resilience of biofilms against antifungals is the presence of persister cells. Persister cells are a distinct portion of dormant cells in a genetically identical population that can survive concurrent lethal rounds of antimicrobial treatments (73). *C. albicans* persister cells are unique in that they form only when grown in a biofilm (74); bacterial persister cells have been shown to form during both stationary phase and biofilm growth. This implies a distinct mechanism underlying persistence formation for fungal cells. When treated with amphotericin B or chlorhexidine, *C. albicans* cells grown to stationary or exponential phase are killed efficiently, but when the cells are grown as a biofilm they show a distinct biphasic curve of killing. Interestingly, *efg1/*, *cph1/*, and *mkc1/* mutants, which are defective in biofilm formation, still formed persister cells at consistent levels. This suggests that the mechanism of persistence formation is independent of formation of a normal biofilm; evidence points to the idea that attachment to a surface may be sufficient to induce persister formation (74). Additionally, the phenomenon of persister cells in *Candida* infections was shown to be clinically relevant through the screening of 22 patients that presented with long-term *Candida* infections. Perplexingly, the *C. glabrata* strains that were recovered showed low levels of persister formation. On the other hand, the *C. albicans* isolates formed high levels of persister cells (75).

One clue to the genetic basis of persister cells in *C. albicans* comes from Bink et al. (76), who showed that SOD (superoxide dismutase) mutants generate lower percentages of persister cells when treated with miconazole. SODs function by converting ROS (reactive oxygen species) to O_2–, thereby detoxifying the ROS. The reduction in persister cell formation was only true when using the antifungal miconazole, which had been shown to raise ROS levels in cells. However, these mutants did not completely eradicate the persister cells, so undoubtedly there is still research to be done to understand the genetic regulation of this phenomenon.

GENE EXPRESSION

There has been long-standing interest in the identification of genes that are induced during biofilm formation. Such genes were thought to be—and have proven to be—enriched for genes that contribute to biofilm formation, and they can be informative in terms of broader biological processes that are biofilm-relevant. As such, biofilm-associated genes can reveal the identities of major regulatory systems and environmental signals that act during biofilm formation. Below we call these genes "biofilm-associated genes" because they have been defined through many kinds of comparisons. Any one particular comparison may yield a distinctive set of genes that are upregulated in biofilm cells.

Is there a fundamental biofilm-associated gene expression pattern? There have been a few different approaches to this problem. García-Sánchez et al. profiled biofilm cells grown under diverse conditions in comparison to planktonic cells also grown under diverse conditions (77). They arrived at a set of 325 genes (out of only 2,002 represented on their microarrays) whose

differential expression was characteristic of biofilm cells from multiple comparisons; 214 genes were upregulated in biofilms. These 214 genes were enriched in transcription and translation genes as well as biosynthetic genes for amino acids, polyamines, nucleotides, and lipids. Upregulation of numerous translation-associated genes in biofilm cells was also observed in a comparison that looked for shared gene expression features among two wild-type strains, SC5314 and WO-1 (78). These findings argue that biofilm growth enables cellular biogenesis to occur over a prolonged period compared to planktonic growth in the same medium. A simple explanation is that a biofilm may capture excreted metabolites, thus facilitating their utilization when preferred metabolites are exhausted.

Many studies have reported that hyphal genes are upregulated in biofilms compared to planktonic cells (79–81). García-Sánchez et al. filtered those genes out by design through inclusion of a nonfilamentous mutant grown under biofilm and planktonic conditions (77); it was discovered that the mutant had the novel ability to form a biofilm on a glass surface. However, in the RNA-Seq biofilm-planktonic comparison of both SC5314 and WO-1, downregulation of hyphal genes was consistently observed in biofilm cells (78). The biofilm time-course analysis of Fox et al. (82) may explain these disparate results: at early times, hyphal genes were upregulated in biofilm cells, but at later times, they were downregulated, relative to planktonic hyphae. Perhaps sufficiently high concentrations of quorum sensing molecules such as farnesol accumulate in mature biofilms (83, 84), inhibiting hyphal growth and hyphal gene expression at late times.

How do gene expression features compare between biofilms grown *in vitro* and *in vivo*? Profiling of *C. albicans* catheter biofilms by Nett et al. (85) revealed some consistent responses. Specifically, amino acid biosynthetic genes and transcription/translation genes were upregulated in biofilm cells *in vivo*. In addition, numerous transporters were upregulated, suggesting that biofilm cells may be limited for nutrients. The study compared biofilm cells to planktonic hyphae, a likely basis for the failure to detect upregulation of hypha-associated genes in biofilm cells. Overall, then, the correlations among broad trends in gene expression indicate that *in vitro*-grown biofilms serve as a useful model for catheter biofilms that form *in vivo*.

Have biofilm-associated genes been validated functionally? In other words, is gene regulation a predictor of gene function? One approach is to use biofilm-associated gene properties to deduce biofilm-relevant regulatory pathways. The d'Enfert lab implemented this approach in their initial study of biofilm gene expression (77). Because many amino acid biosynthetic genes were upregulated in biofilm cells, they inferred that the general amino acid control regulator, Gcn4, may be critical for biofilm formation. Indeed, they observed that a *gcn4/* mutant produced a defective biofilm, one with reduced biomass compared to the wild-type strain (77). Another illustration of this kind of thinking comes from the observation that biofilm-associated gene expression resembles the response to hypoxia (86), an observation first reported for *Candida parapsilosis*. That observation suggests that a mutant defective in hypoxic regulation may be defective in biofilm formation. Indeed, Bonhomme et al. found that Tye7, a transcription factor required for the hypoxic response (86), is required for many features of *C. albicans* biofilms (87). A third example comes from the point raised above that hypha-associated genes have often been observed to be upregulated in biofilms (depending on the specific biofilm-planktonic comparison). That observation makes sense because hyphae are a prominent feature of *C. albicans* biofilms grown under almost any condition, and it suggests that mutants defective in expression of hypha-associated genes will be defective in biofilm formation. That prediction has turned out to be correct time and again (80, 88–90). Therefore, inferences from biofilm profiling data about biofilm-relevant regulatory pathways have proven successful in terms of functional validation.

The second approach to functional validation is to determine whether each specific biofilm-associated gene has a measurable function in biofilm formation. Here the results have been mixed, though there may be some useful lessons for the future. The initial study of this kind, from the d'Enfert group, examined deletion mutants of 38 biofilm-associated genes for defects in biofilm biomass or hyphal morphogenesis (87). The genes had been chosen based on the magnitude of their upregulation in biofilms after elimination of likely essential genes and members of gene families. Eight of the 38 mutants produced biofilms with moderately reduced biomass but had no planktonic growth defect; one mutant had severely reduced biofilm biomass and a severe planktonic growth defect. On its face, the results were slightly disappointing because the yield of biofilm-defective mutants was low and because the biofilm-defective mutants identified had mild defects. In a related approach, Desai et al. focused on genes that were upregulated in biofilms of two clinical *C. albicans* isolates (78). Of the 62 most highly upregulated genes, viable insertion mutants could be isolated for 25 genes. The mutants were screened for a panel of biofilm-

related phenotypes, including biofilm formation, drug tolerance, quorum-sensing signaling, and others. Most of these mutants, 20 of 25, had significant defects in at least one biofilm-related phenotype. The high yield of biofilm-relevant phenotypes in this study may have reflected both the gene selection criteria and the range and sensitivity of the phenotypic assays.

The validation approaches and results presented above apply to *in vitro*-grown biofilms. However, the specific *in vitro* conditions used can have dramatic effects on biofilm properties (34, 91), and some mutations cause a biofilm defect only under a subset of *in vitro* conditions (92). In fact, one theme that has emerged repeatedly in all aspects of infection biology is that *in vitro* conditions can be poor mimics of *in vivo* conditions. Hence, the key validation approach in our view is to determine whether a biofilm-associated gene can be shown to function in an animal model of biofilm infection. The most frequently used model is a rat venous catheter biofilm model (93). Several mutant strains have similar biofilm defects *in vitro* and *in vivo* (7, 56, 72, 78, 80, 94–96). However, there are examples in which the severity of a mutant defect is much greater *in vitro* than in a catheter model *in vivo*, and vice versa (78, 80, 97, 98). It would accelerate biofilm research considerably if there existed an *in vitro* model that could accurately predict *in vivo* outcomes.

BIOFILM GENE REGULATION

For three main reasons, it has proven useful to identify biofilm regulators. First, because a single transcription factor often controls many functionally related target genes, a single biofilm-defective transcription factor mutant can lead to discovery of many biofilm-relevant genes among the target genes that it regulates. One of the initial illustrations of this principle came from studies of the *S. cerevisiae* mating type locus, which specifies master regulators whose target genes confer individual cell type-specific properties (99). Second, there are many examples in which a transcription factor mutant has a more prominent phenotype than mutants defective in individual target genes of the transcription factor. A simple illustration comes again from studies of *S. cerevisiae*, this time studies of meiosis and spore formation: many mutations that caused a prominent sporulation defect affected meiotic regulators rather than the machinery that mediated specific meiotic events (100). This outcome could reasonably be considered a result of the first principle. Third, some biofilm regulators identified in *C. albicans* have orthologs in other *Candida* species that also govern biofilm formation (discussed below). Hence, a biofilm regulator can provide an entry point for definition of biofilm-relevant genes and biological processes in many organisms.

The transcription factors that control biofilm formation have been identified through several approaches. One approach is deductive logic based on expression profiling or other biofilm features, as discussed above (87–90). A second approach is to screen a set of transcription factor mutants for defects in biofilm formation or related phenotypes. For example, panels of both insertion and deletion mutants have been screened for failure to form biofilms (80, 82, 101). An elegant variation on this approach was to assay mutants at several time points in biofilm formation (82). Another related screen was for mutants that were defective in adherence to a silicone substrate (97). Overall, 51 transcription factor genes have been shown to affect biofilm-related properties in these large-scale screens as well as more focused studies (88, 102).

These studies have revealed that there is a major biofilm regulatory network, sometimes called the "core network" (102), comprising transcriptional regulators of hyphal morphogenesis and hyphal genes. These transcription factors include Flo8, Rfx2, Gal4 (82), Brg1, Bcr1, Rob1, Efg1, Ndt80, and Tec1 (80, 90, 101). They are functionally interconnected, in that each binds to at least one other network regulator's upstream region and regulates its expression (80, 82). Rfx2 and Gal4 are negative regulators of biofilm formation; the respective null mutations cause increased biofilm formation (82), and for Rfx2, an increase in expression of many hyphal genes (103). The other transcription factors in this network are positive regulators of biofilm formation; null mutations cause reduced biofilm formation and reduced expression of hyphal genes (80, 82, 90, 101). For many of the positive regulators in this network, current evidence indicates that adhesin genes *ALS1*, *ALS3*, and *HWP1* are critical downstream target genes, because overexpression of one of these genes can restore considerable biofilm formation (7, 9, 80). However, there are likely to be additional network target genes that contribute to biofilm formation, because phenotypic rescue by adhesin overexpression is only partial in some cases (80). There are 21 transcription factor genes whose *5′* regions are bound by one or more network regulators and that govern biofilm-relevant phenotypes (*AHR1*, *BPR1*, *CAS5*, *CRZ2*, *CZF1*, *FCR3*, *GCN4*, *GRF10*, *GZF3*, *MSS11*, *NRG1*, *RFG1*, *RIM101*, *TRY4*, *TRY5*, *TRY6*, *TYE7*, *UME6*, *ZAP1*, *ZCF31*, and *ZCF8*) (88, 102). Hence, this regulatory network controls adhesins and, potentially, many additional diverse biofilm properties.

Are all biofilm properties under the control of this core network? It is not clear as of yet. There are 21 transcriptional regulatory genes that control biofilm formation or biofilm-relevant properties, including *ACE2*, *ADA2*, *ARG81*, *DAL81*, *FGR27*, *LEU3*, *MET4*, *NOT3*, *RLM1*, *SNF5*, *SUC1*, *TAF14*, *TRY2*, *TRY3*, *UGA33*, *WAR1*, *ZCF28*, *ZCF34*, *ZCF39*, *ZFU2*, and *ZNC1* (102). These regulators govern such properties as the level of ECM (104) or the adherence of yeast-form cells (97). These features could conceivably be regulated independently of hyphal adhesins. Whether they are regulated through the core network is an interesting question for future studies.

Have we found all of the biofilm regulators? One could reasonably argue that 51 regulators are enough. We suspect that there are others, though, and that they are worth studying because of the *in vitro-in vivo* differences mentioned earlier in this article. Specifically, our lab has identified transcription factors that are required for biofilm formation *in vivo* but not *in vitro* (97). Thus, we hypothesize that the systematic screens used so far may have overlooked other transcription factors with these properties. Perhaps they could be identified through application of the elegant mutant pool screens used by Noble (105) to assay *in vivo* biofilm formation assays.

CONSERVED FEATURES

Are there conserved features among biofilms of different *Candida* species? There are certainly some conserved features, even though the biofilm architecture of each species has been shown to vary. Several researchers have investigated this question of conservation by comparing *C. albicans* and *C. parapsilosis* biofilms. Evidence suggests that the major regulators of biofilm formation are conserved by both species. This may come as a surprise, because *C. parapsilosis* does not form true hyphae. Ding et al. (106) showed that the transcription factor Bcr1 is a major regulator of biofilm formation in *C. parapsilosis*, comparable to *C. albicans*. Also, some downstream targets of Bcr1 are conserved between the two species. Specifically, Bcr1 was shown to regulate genes encoding a family of proteins called CFEM (Common in Fungal Extracellular Membrane) in both species. The CFEM proteins have been implicated in biofilm integrity (107, 108) in *C. albicans*, but Ding found no evidence that CFEM mutants in *C. parapsilosis* are defective in biofilm formation *in vitro* (106). Several CFEM proteins also function in heme iron acquisition (109), and their regulation by Bcr1 is consistent with the iron utilization defect of the *C. albicans bcr1/* mutant (106). However, the specific Bcr1-regulated genes that are required for *C. parapsilosis* biofilm formation remain to be identified.

Holland et al. were the first to make an extensive deletion collection in *C. parapsilosis*, which included homozygous deletions of 100 different genes, including many transcription factor genes (110). From this study, many of the phenotypes were shown to be conserved between *C. albicans* and *C. parapsilosis*. In the roles of biofilm formation, Efg1, Bcr1, and Ace2 have all been confirmed as major regulators in both *Candida* species. However, Holland found several other transcription factors (Cph2, Czf1, Gzf3, and Ume6) that played a role only in *C. parapsilosis*. Upon sequencing of the biofilm transcriptome from each species, Holland found that similarities between the two species clustered around genes involved with metabolism (110). Similarly, when biofilms of both species were grown under hypoxic conditions, there was good correlation between the two transcriptional profiles (86). For example, Upc2 is required in both species for regulation of ergosterol biosynthesis genes during hypoxia (111). It seems that the transcriptional landscape of biofilm formation in *C. albicans* and *C. parapsilosis* may be broadly conserved, but with some distinct divergences among regulators.

CONCLUSION

Inspection of the inside-out biofilm leads to a simple question: Will a biofilm turn out to be simply the sum of the parts? It is almost certainly not the sum of the parts that we know at this time. We still have limited understanding of the drivers and determinants of cell heterogeneity, as well as the flip side of heterogeneity, which is cell-cell cooperation. Biofilms, like tissues, present a considerable systems-level challenge. We often conceive of the collection of genes that govern biofilm formation as a network that acts within a single cell, much like the systems-level view of *S. cerevisiae*. However, consideration of cell heterogeneity makes a compelling case to us that many different networks are active among the diverse cells of a biofilm.

An additional challenge that underlies the sum-of-the-parts question is that our biofilm parts list is incomplete. One reason it is incomplete is because our *in vitro* biofilm models fail to recapitulate many features of *in vivo*-grown biofilms; hence, mutant phenotypes differ *in vitro* and *in vivo*. Each kind of biofilm—venous catheter, mucosal, etc.—is likely to reflect a distinct balance of biofilm phenotypes and regulatory inputs. Going forward, it seems imperative to validate experi-

mental results with *in vivo* models to see which biofilm determinants are most relevant to infection biology.

Despite those challenges, a brief reflection on the history of fungal biofilm research underscores our optimism and excitement for the future. It was only about 20 years ago that Julia Douglas' lab first viewed *C. albicans* biology through the lens of the biofilm paradigm. Investigators have since elucidated the genetic and biochemical determinants of the many biofilm features discussed in this chapter. We now have a solid foundation from which to build our understanding of a fungal biofilm from the inside out.

Acknowledgments. *We thank Carol Woolford, Fred Lanni, Jeniel Nett, David Andes, Jigar Desai, Jack Edwards, and Scott G. Filler for many helpful discussions about biofilms and related topics. Our biofilm work has been supported by NIH grant R01 AI067703.*

Fungal Recognition and Host Defense Mechanisms

43

I. M. Dambuza,[1] S. M. Levitz,[2] M. G. Netea,[3] and G. D. Brown[1]

CONCEPTUAL FRAMEWORK FOR IMMUNOLOGY

The immune system has over millennia evolved strategies to discriminate between what is "self" and what is foreign (nonself) as well as "normal self" and "injured or altered self," with the ultimate purpose being to defend and repair self. First, to fully appreciate the framework that governs most of our current understanding of how the immune system operates, it is imperative to be cognizant of some of the immunological models that have laid the foundation on which we stand.

Self-Nonself Discrimination Models

The 1960 Nobel Prize in Physiology or Medicine was awarded to F. MacFarlane Burnet and Peter Medawar for the discovery of immunological tolerance. Burnet suggested that each B lymphocyte, an immune cell responsible for the production of antibodies (or immunoglobulins), expresses numerous clones of cell surface immunoglobulin receptors specific for a foreign body (antiforeign body) and that when antibody receptor recognizes its cognate antigen, an immune response is initiated (1). This idea was solidified by Billingham, Brent, and Medawar's findings, which demonstrated that adult mice "tolerate" skin grafts if they are transplanted at birth; that is, the immune system can learn to tolerate the foreign antigens until defensive intolerance is acquired (2).

The self-nonself discrimination model became the *modus operandi* of the immune system until it was modified in 1969 by Bretscher and Cohn, who postulated that a quiescent B lymphocyte requires interaction with a "helper" cell (now known as helper T lymphocyte) specific for the same antigen to induce an activation signal, whereas inactivation ensues when antigen is recognized in the absence of the helper cell (3). In 1975, Lafferty and Cunningham introduced a requirement for a costimulation signal and proposed that recognition of antigen by the helper T cell (which provides *signal 1*) together with a "stimulator cell" (*signal 2*) (known now as antigen-presenting cell [APC]) induced activation of the immune system (4, 5). Over a decade later, Jenkins and Schwartz provided experimental evidence for the requirement of costimulation for activation of resting lymphocytes (6). However, the prerequisite of costimulation introduced a conundrum because this meant that immune activation hinges on APCs that capture and present both self and nonself antigens; therefore, immunity could not be solely targeted against the invading foreigners.

Noninfectious Self and Infectious Nonself Model and the Inception of Pattern Recognition Receptors

Charles Janeway provided an elegant solution to the costimulation conundrum mediated by APCs. In his 1989 article Janeway suggested that the immune system has evolved specifically to recognize and respond to infectious organisms and that this involves recognition not only of antigenic determinants but also of certain characteristics or patterns common in infectious organisms but absent from the host, and he coined the term "pattern recognition receptor" (PRR) (7). He also pointed out that these germline-encoded receptors would act early during an immune response and imagined that they also play a role in shaping the adaptive T and B cell responses. Another piece of the puzzle was added by Polly Matzinger, who in 1994 proposed

[1]MRC Centre for Medical Mycology, Aberdeen Fungal Group, Institute of Medical Sciences, University of Aberdeen, Aberdeen AB252ZD, United Kingdom; [2]Department of Medicine, University of Massachusetts Medical School, Worcester, MA 01605; [3]Department of Internal Medicine and Radboud Center for Infectious Diseases (RCI), Radboud University Medical Center, Nijmegen, The Netherlands.

that resting APCs are activated by stimuli associated with host-cell damage, which she termed "danger signals" (8). She posited that by definition, pathogens damage the host and that recognition of damage could be instrumental in validating initiation of an immune response. A summary of the history of the immune models discussed above is depicted in Fig. 1.

PRRs INVOLVED IN SENSING FUNGI

Several classes of PRRs have been discovered since their initial identification, providing experimental support for Janeway's theory. It is noteworthy that pioneering work emanating from the use of fungi and their antigenic determinants has contributed significantly to our understanding of the initiation of an immune response (for a detailed timeline, see reference 9). Here, we will discuss PRRs that have been demonstrated to sense the presence of fungi and activate antifungal host immune responses as well as the implications of defective receptor/signaling networks on susceptibility to fungal infections.

Due to the ubiquitous presence of fungi in the environment, humans are constantly exposed to them; in fact, it has been proposed that we have coevolved with commensals such as *Candida* spp. and *Malassezia* (10). Despite this, fungi are associated with various diseases ranging from asthma to mucocutaneous infections to severe life-threatening systemic infections in patients with a compromised immune system (e.g., organ tissue transplant patients and HIV-infected individuals).

Fungi are eukaryotes and thus are similar to mammalian cells; however, they possess a cell wall, which is absent in mammalian cells. The cell wall is thought to provide several advantages to fungi including protection against environmental stresses and structural rigidity for invading ecological niches (11). For many fungal species, the molecular details of the structural composition and organization of cell wall components have not been fully elucidated. However, for most of the medically relevant fungi, polysaccharides account for more than 90% of the wall content, with the central core comprising branched β-1,3 and β-1,6 glucan that

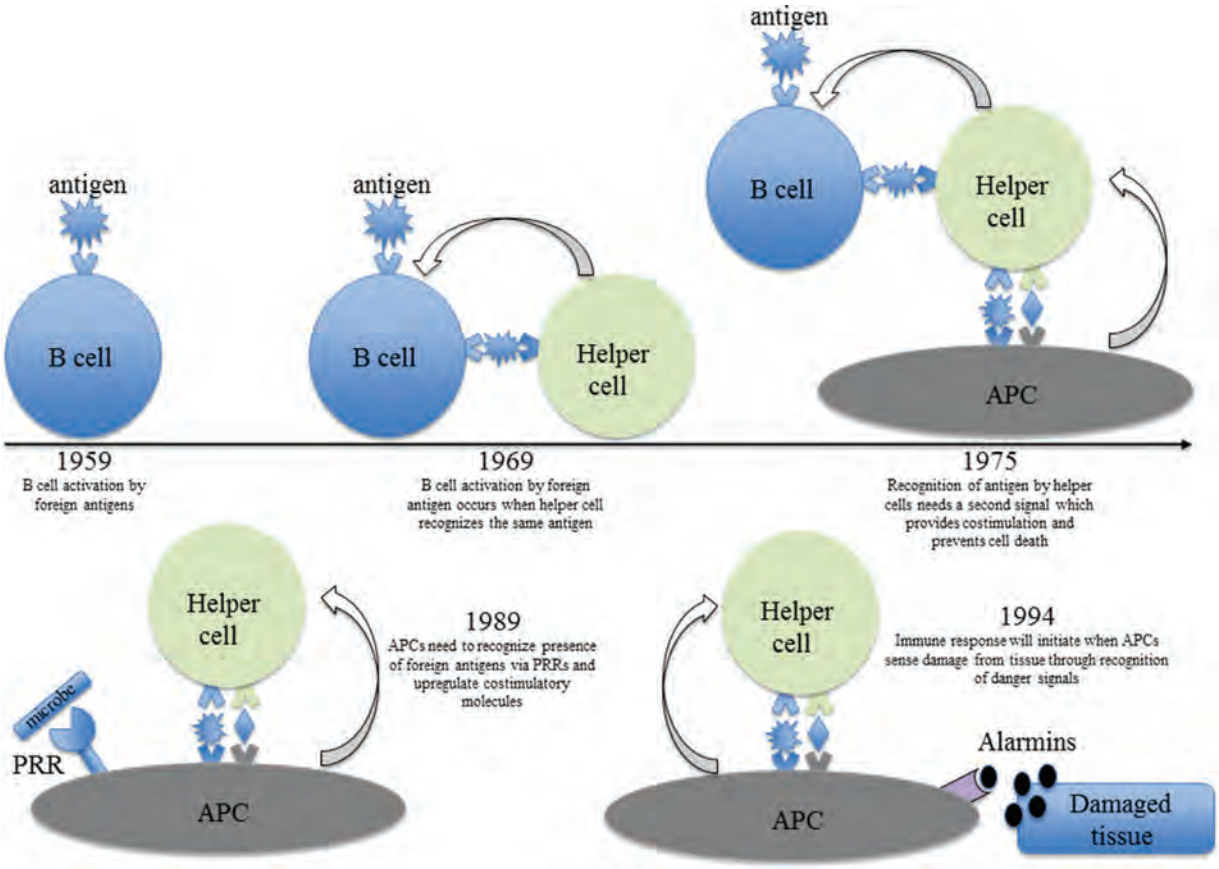

Figure 1 More than half a century of immunogical theories.

associate with chitin via a β-1,4 linkage (11). The core structure is decorated by unique extensions depending on the pathogen; for instance, *O*- or *N*-linked mannans and mannoproteins are found in *Candida* yeasts, while glucuronoxylomannan and galactoxylomannan coat *Cryptococcus* (12). Because of their exclusivity, the components of the fungal cell wall contribute a large reservoir of Janeway's "patterns," which are now commonly termed "pathogen-associated molecular patterns" (PAMPs). Chitin, mannans, and β-glucan are the three major PAMPs present in all fungi that cause human disease, with the possible exception of *Pneumocystis jirovecii* which lacks chitin (13, 14). Thus, the framework for induction of an immune response to most fungi follows similar sets of rules and involves recognition of PAMPs by several classes of germ-line-encoded PRRs expressed by innate immune cells, including C-type lectin receptors (CLRs), Toll-like receptors (TLRs), nucleotide-oligomerization domain (NOD)-like receptors (NLRs), and retinoic acid-inducible gene 1 (RIG-I)-like receptors (RLRs), discussed below.

TLRs and Fungal Sensing

By the mid-1980s, the nuclear factor-κB (NF-κB) was known to mediate upregulation of many genes involved in immunity and stress in mammalian cells (15). In *Drosophila melanogaster*, the NF-κB homologue, Dorsal, was shown by Nüsslein-Volhard and colleagues to drive expression of genes involved in development (16). Furthermore, activation of Toll by its ligand Spätzle was found to be the critical receptor involved in triggering the signaling cascade resulting in activation and nuclear translocation of Dorsal (17). Notably, work emanating from the Hoffman laboratory also demonstrated the expression and nuclear translocation of Dorsal upon microbial challenge (18). Importantly, this group demonstrated that the Spätzle-Toll-Dorsal signaling axis mediated expression of the antifungal peptide drosomycin, with Toll mutant flies succumbing to infection with *Aspergillus fumigatus* (19). Of interest to note is that *Drosophila* possesses only an innate immune system, while mammals also have an adaptive immune system. Medzhitov and Janeway subsequently demonstrated that a human cDNA clone of Toll homologue (now known as TLR4) also activated NF-κB and induced expression of costimulatory molecule B7.1 required for activating the adaptive immune responses (20). Seminal findings from Buetler's laboratory using mice with genetic mutations that abolished recognition of lipopolysaccharide, a major PAMP conserved in Gram-negative bacteria, established that TLR4 is the innate immune sensor of infection critical for host immunity (21).

Since the discovery of TLR4, over 12 mammalian TLRs have been described and their ligands and functions in immunity extensively studied (22). Similar to *Drosophila* Toll, the extracellular domain of TLRs contains leucine-rich repeat motifs and the intracellular domain structure that is homologous to the interleukin-1 (IL-1) receptor and pathogen resistance proteins found in plants—hence the name TIR (Toll/IL-1 receptor/resistance domain) (23, 24). TLRs transmit signals by interacting with several TIR-containing proteins such as myeloid differentiation primary response (MyD88), TIR domain-containing adaptor protein inducing interferon-β (IFN-β) (TRIF), and TRIF-related adaptor molecule (Fig. 2). With the exception of TLR3 and to some degree TLR4, all TLRs couple the MyD88 adaptor, which interacts with the IL-1 and IL-4 receptor-associated kinase (IRAK1/4) via its N-terminus death domain, resulting in downstream activation of several transcription factors including NF-κB, activation protein 1, interferon regulatory factor (IRF) 3, IRF5, IRF7, and mitogen-activated protein kinases that induce expression of inflammatory mediators (25).

Mice lacking MyD88 have been shown to be sensitive to infections with various pathogens, presumably, in addition to TLR unresponsiveness, defective immune activation due to a lack of IL-1R, IL-18R, and IL-33R signaling, which also utilize the TIR-MyD88 module (26–28). In experimental settings, MyD88-deficient mice displayed broad susceptibility to bacterial, viral, parasitic, and fungal pathogens, although only selected bacterial infections were observed in humans with deficiencies in MyD88 or IRAK4 (see reference 29 for a detailed review). Nonetheless, polymorphisms in TLR4 were found to be associated with pulmonary infections with *Aspergillus* and systemic candidiasis (30–32). Additionally, mutations in TLR3 resulting in reduced activation of NF-κB and decreased production of IFN-γ were associated with cutaneous candidiasis (33). Furthermore, defective TLR9 expression was implicated in allergic bronchopulmonary aspergillosis in humans, suggesting a possible accessory role of TLRs in antifungal mammalian immunity (32). Thus far, fungal PAMPs including α-1,4-glucan, glucuronoxylo/phospholipido-mannans, cytosolic nucleic acids, and *O*-linked/rhamnomannans have been reported to be recognized by TLRs (12) (Fig. 3).

Contribution of NLRs and RLRs

NLRs comprise a large family of cytoplasmic receptors made up of three characteristic domains (NH_2-terminal protein-protein interaction domain, a central NOD, and a C-terminal leucine-rich repeat) and can be grouped

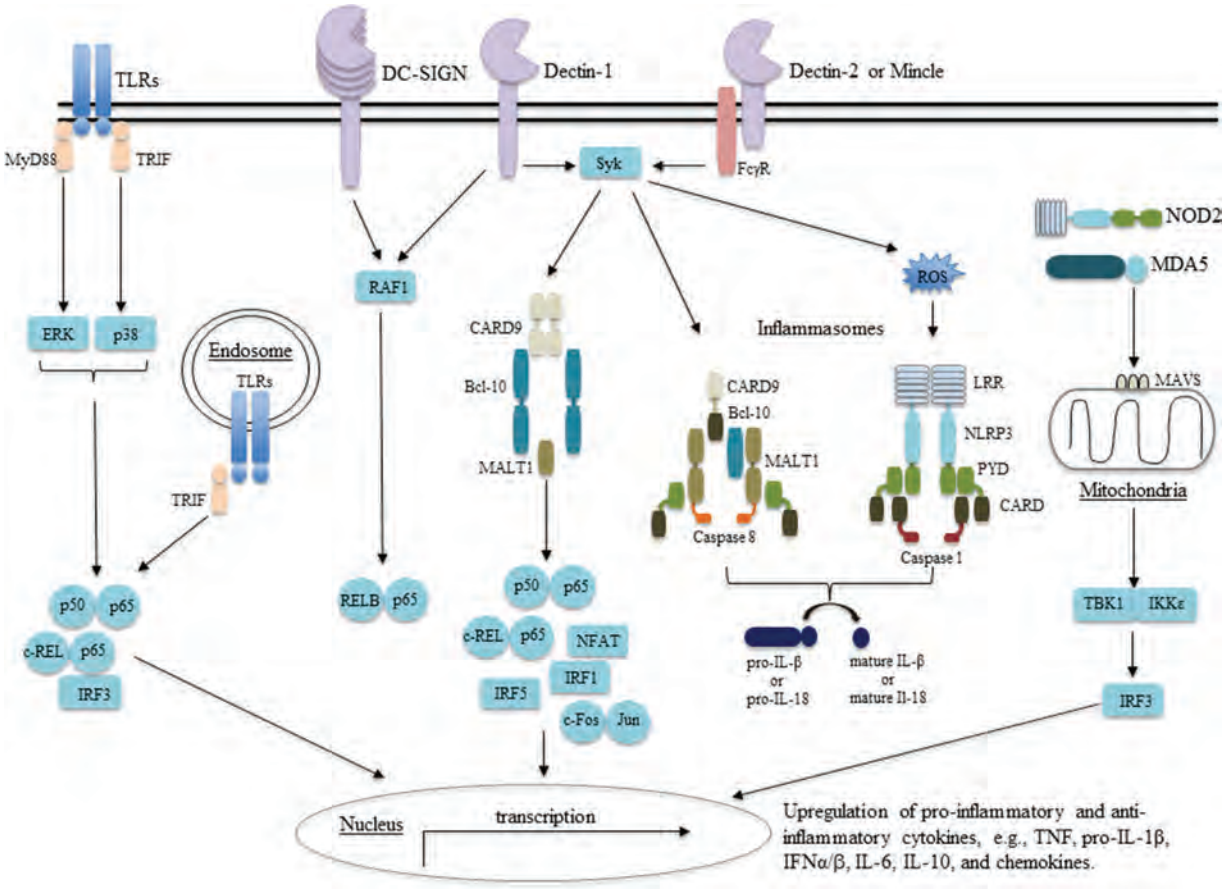

Figure 2 Signaling pathways involved in antifungal immunity.

into subfamilies based on the nature of the NH_2-terminal domain structure (34). Of particular interest to antifungal immunity is NALP3—or NACHT (NAIP [neuronal apoptosis inhibitor], CIITA [MHC class II transcription activator], HET-E [heterokaryon incompatibility protein], and TP1 [telomerase-associated protein])–LRR (leucine-rich repeats)–PYD (pyrin domains)-containing protein 3—which activates a multiprotein complex known as the inflammasome by recruiting the adaptor molecule apoptosis-associated speck-like protein containing a caspase-associated recruitment domain (CARD) to the protein-protein interaction pyrin domain that subsequently activates caspase-1-mediated cleavage of the inflammatory cytokines, pro-IL-1β and pro-IL-18, to their mature forms (35–38) (Fig. 2). To this end, several studies have linked defective NALP3-mediated IL-1β release with susceptibility to several fungi including *Candida albicans* and *A. fumigatus* (39–42). Interestingly, the main component of *Cryptococcus neoformans* capsule, glucoronoxylomannan, was suggested to facilitate intracellular survival of this pathogen via inhibition of Syk-mediated NALP3 inflammasome activation (43).

RLRs are another important family of cytosolic sensors responsible for detecting double-stranded RNA and are distinct from TLR detection of endosome-associated RNA (22). Members of this family include RIG-I, melanoma differentiation-associated gene 5 (MDA5), and laboratory of genetics and physiology 2 (LGP2). All these proteins have a central ATPase-containing DExD/H box helicase domain as a common feature (22). RIG-I and MDA5 also contain N-terminal CARD domains that facilitate downstream signaling via an adaptor molecule mitochondrial antiviral signal, resulting in activation of mitogen-activated protein kinase, NF-κB, type I IFNs (IFNα/β), and IFN-stimulated genes (44–46) (Fig. 2).

To date, MDA5 is the only member of the RLR family suggested to play a role in antifungal defense. In both mice and humans, altered expression or function of MDA5 correlated with chronic mucocutaneous candidiasis and was associated with susceptibility to systemic

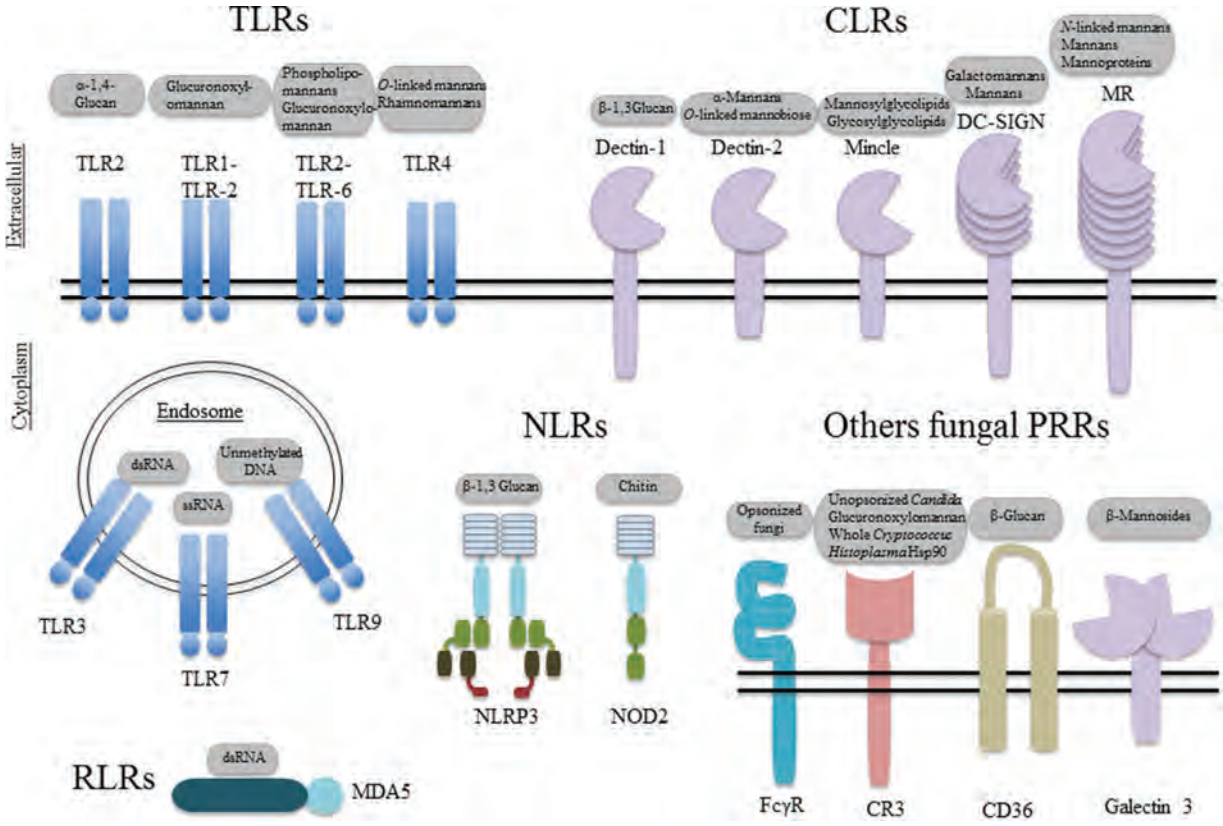

Figure 3 PRRs and the fungal components they recognize. (Adapted with modifications from reference 12).

Candida infections, presumably due to reduced expression of type I IFNs (47). Although the *C. albicans* ligand(s) that mediates activation of MDA5 is currently unknown, there is a possibility that fungal components gain access to the cytosol and induce immune responses, but this warrants further investigation. The role of type I IFNs, IRFs, and IFN-stimulated genes in antifungal immunity also needs more clarity. For instance, a protective role of IFNs was reported in mice and humans infected with *C. albicans* (48, 49), whereas in a different study using *Candida glabrata*, these cytokines were associated with susceptibility to infection (50).

CLRs Are Central for Recognition of Fungi and Antifungal Host Defense

CLRs constitute a superfamily of more than 1,000 soluble and membrane-bound proteins classically characterized by the presence of at least one C-type lectin domain (CTLD) and can be clustered into at least 17 subgroups based on architecture of the CTLD (51). The EPN (Glu-Pro-Asn) motif within the CTLD specifies binding to mannose, *N*-acetylglucosamine, L-fucose, and glucose, whereas QPD (Gln-Pro-Asp) confers specificity to galactose and *N*-acetylgalactosamine (52). While calcium-dependent binding of carbohydrates is commonly associated with the function of the CTLD, many CTLDs are known to bind a vast array of non-carbohydrate ligands including proteins, lipids, and lipoproteins (51). Of note are membrane CLRs expressed on myeloid cells that function as PRRs and prime the immune system such as the dendritic cell-associated C-type lectin 1 (Dectin-1, also known as CLEC7A), discovered in 2001 by Brown and Gordon as the receptor for β-1,3-glucan (a PAMP expressed in many, if not all, medically important fungi) (53).

Dectin-1 binding of β-glucan results in phosphorylation of the integral immunoreceptor tyrosine-based-like motif embedded in the cytoplasmic tail providing docking sites for the Src homology 2 domain of spleen tyrosine kinase (Syk) (54). Syk subsequently activates the signaling scaffold CARD9-Bcl-10-Malt-1 through PKCδ and a recently described complex of CARD9-H-Ras-Ras-GRF-1, which promotes nuclear translocation of several transcription factors including NF-κB,

nuclear factor and activator of transcription, IRF1, IRF5, and the activation of extracellular-regulated kinases pathway (55). In addition, unlike the Syk pathway, which activates both classical NF-κB (p65 and c-Rel) and noncanonical NF-κB (RelB), Dectin-1 also activates the Raf-1 kinase pathway that sequesters RelB by forming inactive p65/RelB dimers, thereby promoting Syk-mediated activation of p65 (56) (Fig. 2). Signaling via Dectin-1 regulates several processes including phagocytosis, autophagy, NETosis, respiratory burst, and gene expression of proinflammatory mediators including cytokines such as tumor necrosis factor (TNF), IL-23, IL-6, and chemokines (C-C motif) CCL2, CCL3, and (C-X-C motif) CXCL1 (57). Activation of the Dectin-1-Syk-CARD9 signaling pathway by fungi upregulates IL-1β and IL-18 transcripts and is implicated in "priming" of the NALP3/caspase 1 inflammasome, while reactive oxygen species, potassium efflux, and cathepsin B activate inflammasome activity (58, 59). More recently, the Dectin-1-Syk pathway was reported to activate a noncanonical inflammasome comprising MALT1-caspase 8 and apoptosis-associated speck-like protein containing a CARD domain that cleaved pro-IL-1β (60).

Several studies in mice have demonstrated a critical role of Dectin-1 in host defense against fungal infections. In mice lacking Dectin-1, a failure to sense the presence of fungi results in tissue overgrowth of *C. albicans* or *A. fumigatus* and is associated with an overall failure to induce appropriate inflammatory responses (such as IL-6 and granulocyte colony-stimulating factor [G-CSF]) that would normally result in the recruitment of monocytes and neutrophils to the site of infection (61–64). Importantly, individuals with polymorphisms in Dectin-1 that affect the ability of leukocytes to bind β-glucan display increased susceptibility to chronic mucocutaneous candidiasis, recurrent episodes of vulvovaginal candidiasis, onychomycosis, and intra-abdominal *Candida* infections and a reduced Th17 cell response (discussed below) (65).

CLRs such as Dectin-2, macrophage-inducible C-type lectin (Mincle), dendritic cell-specific intercellular adhesion molecule-3-grabbing nonintegrin (DC-SIGN), and the mannose receptor have also been shown to elicit an immune response against fungi (66–68). Dectin-2 recognizes α-mannans from several fungi including *C. albicans*, *Histoplasma capsulatum*, and *C. neoformans*, as well as glycoproteins containing O-linked mannobiose-rich residues from *Malassezia* (69, 70). Signals transmitted via Dectin-2 activate the Syk-CARD9 pathway through association with an integral immunoreceptor tyrosine-based-bearing Fc receptor γ chain (FcRγ) adaptor molecule, which results in improved reactive oxygen species production by neutrophils, expression of IL-23p19, and IL-1β release by APCs (71, 72). Dectin-2-deficient mice display increased susceptibility to infection with *C. albicans* (Fig. 2) (73, 74). Similar to Dectin-2, Mincle recognition of glucosyl- and mannosylglycolipids from *Malassezia* and ill-defined ligands from *C. albicans* and *Fonsecaea pedrosoi* also activates the Syk-CARD9 pathway via the FcRγ adaptor (75). However, the role of Mincle in antifungal immunity may be context dependent. In a recent report, interaction of Mincle with the causative agent of chromoblastomycosis, *Fonsecaea monophora*, was shown to suppress IL-12p35 (an important cytokine required for T helper cell polarization) via Syk-CARD9 activation of E3 ubiquitin ligase Mdm2-dependent degradation of the transcription factor IRF-1 (76).

DC-SIGN and the mannose receptor recognize branched *N*-linked mannans and have been implicated in trafficking of mannosylated fungal antigens into the APC endocytic pathway, facilitating antigen processing and presentation to T helper cells (77, 78). In mice, a lack of mannose receptor was shown to result in susceptibility to infection with *C. neoformans* but not *C. albicans* (79, 80).

Although mouse models and *in vitro* studies with human leukocytes provide experimental support for a role in immunity of CLRs, mentioned above, to date, only polymorphisms in Dectin-1 and mutations in the signaling adaptor molecule CARD9 (which acts downstream of Syk-coupled CLRs) have been associated with susceptibility to fungal infections in humans. While polymorphisms in Dectin-1 were predominantly linked with superficial infections, CARD9 deficiency in both mice and humans was found to be critical for protection against systemic *Candida* and *Exophiala* infection, particularly of the central nervous system (49, 65, 81–83). CARD9-mediated protection against *Candida* spinal osteomyelitis and meningoencephalitis was shown to require neutrophil chemotaxis into the central nervous system (49, 65, 81, 84, 85).

EFFECTOR MECHANISMS DRIVING HOST PROTECTION FROM FUNGI

Epithelium

Apart from the obvious physical barrier function, the epithelium, through secretion of factors such as mucins and antimicrobial peptides, plays an important role in protection against microbial tissue invasion (86). Salivary mucins in host defense and disease prevention

were shown to repress formation of *C. albicans* hyphae (a morphological form thought to be associated with host invasion) and displayed direct candidacidal activities in the oral cavity, respectively (87).

Although research into "self versus nonself" interactions has for the most part focused on pathogens, commensal microorganisms, including the mycobiota (fungal communities), colonize mucosal surfaces such as the gut, and their role in health and disease is slowly gaining attention (88). For instance, increased *Candida* gut colonization and differential fungal profiles were observed in patients with inflammatory bowel disease and in ulcerative colitis patients, respectively (89–91). Notably, in these studies, an absence of Dectin-1 signaling correlated with severe forms of ulcerative colitis in both mice and humans. Intriguingly, Dectin-1 and CARD9 have also been implicated in regulation of intestinal homeostasis by modulating gut microbiota. Dectin-1-mediated induction of antimicrobial peptides S100A8 and S100A9 paralleled decreases in *Lactobacilli* numbers; these are commensal gut bacteria best known for metabolizing tryptophan into aryl hydrocarbon receptor ligands and generation of regulatory helper CD4 T cells (discussed below) (92, 93). By contrast, gut microbiota from CARD9-deficient mice failed to metabolize tryptophan and consequently displayed decreased aryl hydrocarbon receptor ligands and IL-22 and increased sensitivity to colitis (94).

Phagocytes

Derived from the Greek term *phagein*, meaning "to eat," phagocytes are critical for clearing foreign bodies and debris from dead or dying cells. Tissue-resident macrophages and neutrophils are key phagocytic cells that mediate host protection against fungi (95). Here, a few examples of the mechanisms deployed by phagocytic cells in antifungal immunity are described. Upon sensing fungi, macrophages recruit other immune cells to sites of infection through secretion of proinflammatory cytokines and chemokines, discussed above (95). *In vivo* depletion of macrophages or deficiency of CX_3C-chemokine receptor 1 (CX_3CR1), which is associated with poor survival of macrophages, was observed to result in unrestricted fungal growth in tissues and heightened mortality rates in mice systemically challenged with *C. albicans* (96). Importantly, patients with decreased expression of CX_3CR1 are highly susceptible to disseminated candidiasis (96). In the lung, alveolar macrophages kill inhaled *A. fumigatus* conidia and *Pneumocystis carinii* cysts through mechanisms involving reactive oxidant intermediates (97, 98). As immunologists increasingly define functional "subsets" of cells, specific populations of monocytes and macrophages that protect against fungi are being described. For instance, several studies have reported a protective role of $CCR2^{+}Ly6^{hi}$ inflammatory monocytes in systemic candidiasis (99, 100). In mice, depletion of this subset resulted in lethal invasive aspergillosis (101).

The importance of neutrophils is underscored by the fact that neutropenia is one of the major risk factors driving disseminated fungal infections in mouse models and in humans (95, 102, 103). Neutrophils accomplish their potent fungicidal activities through generation of reactive oxygen radicals and nonoxidative effector mechanisms including secretion of lysozyme, lactoferrin, elastase, β-defensin, gelatinases, and cathepsin G (104). Neutrophil extracellular traps, released during the last stages of neutrophil active cell death, known as NETosis, have been implicated as another strategy of antifungal defense (105–107). Neutrophil extracellular trap formation coincides with neutrophil degranulation and release of microbicidal factors such as cathelicidin (108). Proteinase 3-mediated cleavage of cathelicidin into LL-37 was shown to interfere with fungal cell membranes, suppress formation of biofilms and fungal attachment, induce reactive oxygen species production, enhance chemotaxis, and suppress neutrophil apoptosis (109–114).

Reinforcing Effectors: Cytokines

The basics of the immune process as we currently understand it were discussed in the preceding sections; that is, PAMPs are recognized by PRRs expressed by innate immunocytes, resulting in activation of the innate immune system. As described above, the bridge between innate and adaptive host immunity is mediated by professional APCs, dendritic cells, discovered in 1973 by Steinman and Cohn (115). Dendritic cells provide *signal 1* (antigen-presentation) and *signal 2* (costimulation) to naive T helper CD4 cells (bearing αβ T cell receptors) initiating "effector" antigen-specific helper CD4 T cell responses (116, 117). Other aspects including generation of cytotoxic CD8 T cells and B cell development into immunoglobulin-producing plasma cells are also activated but will be not be discussed here. In the last section, we discuss the nature of helper cells induced upon fungal recognition and the type of help they provide (Fig. 4).

Cytokines produced by APCs in response to PAMPs provide *signal 3i*, which instructs polarity of T cells (Th) into functionally distinct helper subsets. Members of the IL-12 family of cytokines are known critical mediators of Th polarization, and these include IL-12 (IL-12p35:IL-12p40), IL-23 (IL-12p19:IL-12p40), IL-27

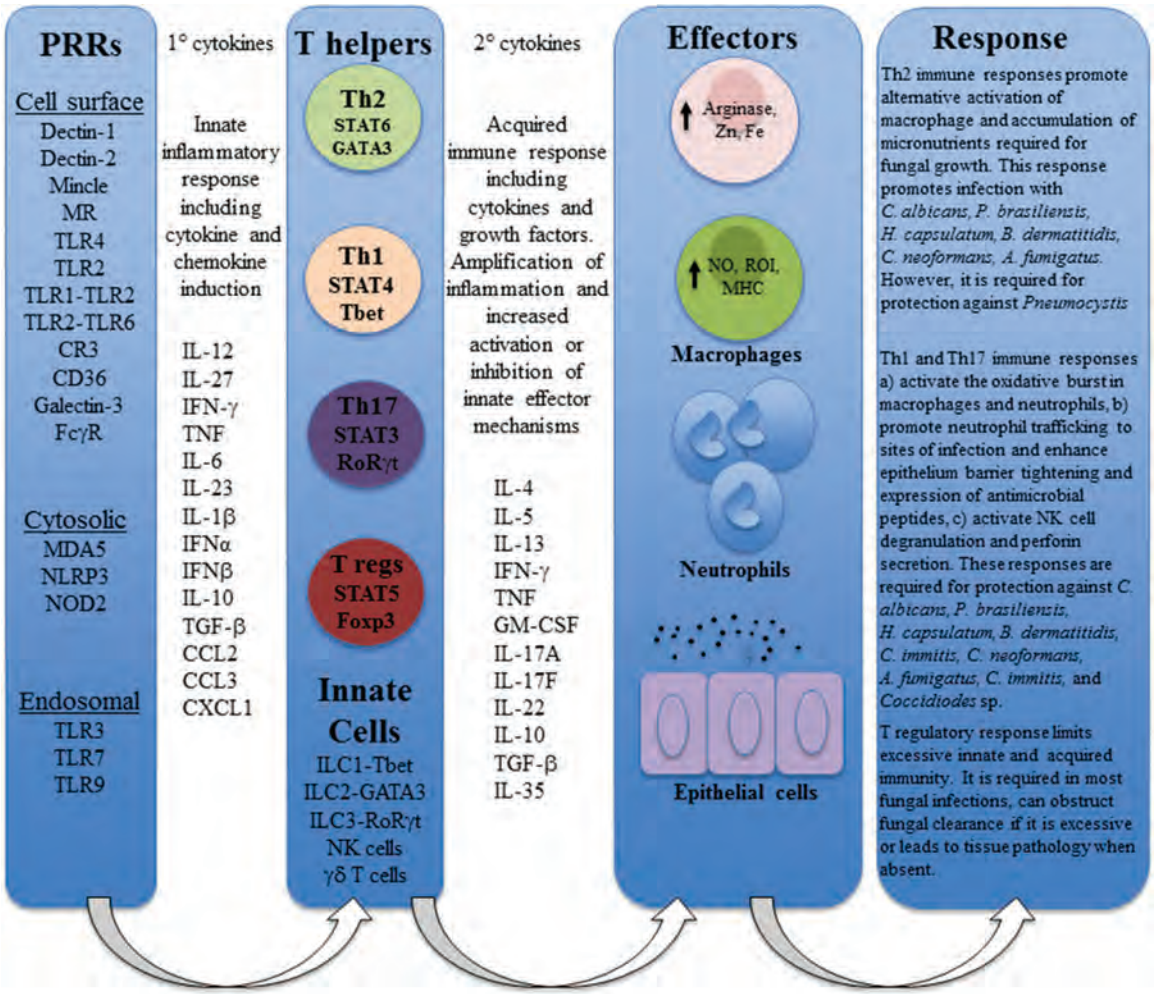

Figure 4 Schematic representation of the sequential inflammatory immune reaction involved in antifungal immune responses.

(IL-12p28:EBi3), and IL-35 (IL-12p35:EBi3) (118). Binding of these cytokines to their cell surface receptors activates the Janus kinase and signal transducer and activator of transcription (STAT) signaling pathways, trans-activating gene expression, and in the case of naive T cells, differentiation (119).

IL-12 and IL-27 secretion by innate immune cells as well as innate lymphocyte-derived IFN-γ skew naive cells toward a Th1 differentiation program driven by STAT1, STAT4, and T box transcription factor T-bet (120, 121). Classically, Th1 cells are defined by production of mainly IFN-γ but also produce other important proinflammatory cytokines such as TNF and GM-CSF. The role of Th1 cells in protective immunity against most fungal pathogens in both experimental mouse models and humans is well established. Several laboratories have shown that IFN-γ and TNF stimulate macrophages to release nitric oxide and reactive oxygen species, causing intracellular growth arrest of several fungal species such as *H. capsulatum* (122–124). An absence of Th1 immunity or expression of the effector cytokines as demonstrated in IL-12, IFN-γ, or TNF deficiency in both mice and humans results in increased susceptibility to a myriad of fungal infections, including *C. neoformans*. Patients on IFN-γ immunotherapy show augmented protection against aspergillosis, cryptococcosis, and coccidioidomycosis (125). GM-CSF, on the other hand, was shown to mediate antifungal responses in macrophages by a mechanism involving sequestering intracellular zinc (a micronutrient required by yeast cells), stimulating reactive oxygen species, as well as neutrophil recruitment (126, 127). In contrast, several laboratories reported that STAT1 (signal transducer of IL-27, type I IFNs, and IFN-γ) gain of function

mutations in humans resulted in autosomal dominant chronic mucocutaneous candidiasis, potentially due to excess induction of type 1 IFNs which promote IL-27 and IL-10, resulting in inhibition IL-17-producing T cells (128, 129) (Table 1).

It is now well established that IL-17-producing T cells play a significant role in the clearance of fungi, particularly at the mucosae. This lineage differs from Th1 in that it requires STAT3 activation by IL-6 and IL-21 as well as transforming growth factor β induction of retinoid-related orphan receptor γt, while IL-23 is required for stabilization of the phenotype (130). Effector cytokines, particularly IL-17 and IL-22, were shown to promote the release of various antimicrobial peptides by keratinocytes and epithelial cells as well as strengthening of the mucosal barrier preventing disease dissemination (131–134). The importance of this lineage is made obvious by the heightened susceptibility to a wide range of fungal infections in individuals with loss of function mutations in STAT3 or defects in the IL-17 signaling axis (135–138). In addition, mutations in the autoimmune regulator gene that result in antibodies targeted at Th17 cytokines predispose to chronic and recurrent mucocutaneous candidiasis as noted in individuals with autoimmune polyendocrinopathy with candidiasis and ectodermal dystrophy (APECED) (125). Decreased antimicrobial peptide secretion as well as reduced neutrophil-attracting CXC chemokines due to a lack of Th17-mediated immune responses are thought to be key drivers of susceptibility to mucosal fungal infections (135, 138).

Polarization toward the Th2 subset requires IL-4-mediated STAT6 activation and GATA3 expression, which drive induction of the signature cytokines: IL-4, IL-5, and IL-13. Th2-cytokines are considered important for promoting alternatively activated macrophages reported to permit intracellular growth of fungi due to decreased nitric oxide expression (139). In mouse models, a pathogenic role of an elevated Th2 immune response is best exemplified by the observation of progressive lung infections with *C. neoformans* and *H. capsulatum* (69).

Regulatory T cells (T regs) are unique helper cells that play the essential role of restraining immune responses limiting collateral damage to the host. Mechanisms of action mediated by T regs include secretion of inhibitory cytokines such as IL-10, transforming growth factor β, IL-27, IL-35, contact-dependent mechanisms, and sequestration of IL-2 (125). Decreased T reg numbers as observed in TLR2- or CCR5-deficient mice are thought to drive efficient clearance of several fungal infections including *C. albicans* (140, 141). Interestingly, defective natural T reg development is associated with pathogenesis of chronic mucocutaneous candidiasis in APECED patients, highlighting the importance of the delicate balance between host-driven immune pathology and resolution of infection (142).

Table 1 Selected human genetic associations with fungal susceptibility discussed in this article

Gene	Immunological phenotype	Associated disease
Dectin-1	Dimunition of cytokine responses	Chronic mucocutaneous candidiasis, vulvovaginal candidiasis, onychomycosis, and intra-abdominal *Candida*
CARD9	Dimunition of cytokine responses Defective neutrophil chemotaxis	Disseminated candidiasis
TLR1	Decreased IL-1β, IL-6, and IL-18	Candidemia
TLR2	Decreased IFN-γ and IL-8	Candidemia
TLR3	Reduced activation of NF-κB and decreased IFN-γ	Cutaneous candidiasis
NALP3	Decreased IL-1β?	Candidiasis-mediated vestibulitis
MDA5	Decreased type I IFNs	Systemic candidiasis
STAT1	Decreased IL-17 production, elevated cell response to IFNs, IFN-γ,s and IL-27 Defective IL-12R and IL-23R signaling	Chronic mucocutaneous candidiasis, coccidioidomycosis, histoplasmosis
STAT3	Defective Th17 polarization, decreased IL-17/IL-22-expressing T cells, decreased IL-17-induced antimicrobial peptides	Chronic mucocutaneous candidiasis, coccidioidomycosis, histoplasmosis, cryptococcosis, aspergillosis, nail dermatophytosis
Autoimmune regulator	Neutralizing antibodies to IL-17 and IL-22	Chronic mucocutaneous candidiasis
IL-17/IL-17R	Lack of IL-17 cellular responses	Chronic mucocutaneous candidiasis
IL-12RA	Impaired IL-12 and IL-23-mediated expression of IFN-γ	Coccidioidomycosis, paracoccidioidomycosis, histoplasmosis, cryptococcosis

AIDS and susceptibility to fungal infections such as *Cryptococcus*, *Candida*, *Pneumocystis*, and *Histoplasma* have focused attention on the critical contribution of T cells to the host defense arsenal against fungal pathogens (143). Yet cells of the innate immune system such as natural killer cells, γδ T cells, and the recently described innate lymphoid cells also contribute to the effector cytokine pool, and the contribution of these cells in antifungal defense is under intense investigation (133). A case in point is work from LeinbundGut-Landmann's laboratory demonstrating that antibody depletion of innate lymphoid cells in Rag-deficient mice (which lack mature classical T helper cells) resulted in attenuation of IL-17 and increased susceptibility to oropharyngeal candidiasis infection (144). Moreover, this group also reported that IL-17-mediated immune responses are critical for natural killer cell activation and secretion of GM-SCF, which is essential for antifungal immunity (145). Another study reported natural killer cell direct killing of *C. neoformans* and *Cryptococcus gattii* through mechanisms that involved perforin (146). The contribution of these cells to invasive fungal disease and their relevance in human disease are still under investigation.

IMMUNE-BASED THERAPIES AGAINST FUNGAL INFECTIONS

Vaccines

A major hurdle in this area has been largely impacted by the lack of understanding of the requirements for induction of protective immunity and defining surrogate markers for these responses. This is made apparent by the lack of any fungal human vaccine approved for clinical use to date. However, there are exciting developments including studies showing that mice immunized with β1-3-D-glucan-laminarin-diphtheria toxoid conjugate vaccine or antigens encapsulated with glucan particles induce a strong antibody response and a long-term antifungal T cell response that protects mice against several fungal species including *Cryptococcus* and *Candida* (147, 148). The use of a live vaccine strategy has also shown promising results in several settings. Examples such as immunization with a *C. neoformans*-expressing IFN-γ strain offer advantages for developing therapeutic vaccines that offer protection in conditions where CD4 helper T cells are deficient (149).

Adaptive Cell Therapies

Fungal-specific T cell transfer studies have been shown to improve disease outcomes in high-risk individuals such as hematopoietic transplant patients by providing enhanced control of *Aspergillus* antigenemia and reducing the mortality rate (150). More recently, T cells bearing modified chimeric antigen receptors have been investigated for potential use in fungal diseases (for details about chimeric antigen receptor technology see reference 151). In a proof-of-concept study, T cells bearing Dectin-1 (directing T cell specificity to fungal cell wall glucans) were shown to mediate protection against *A. fumigatus* (152).

As discussed above, neutropenia is associated with susceptibility to fungal infections, and approaches that reduce the duration of neutropenia in chemotherapy patients have obvious attractive therapeutic implications. Thus, using G-CSF and GM-CSF to increase the yield of granulocytes from donors is gaining a lot of interest in clinical settings where granulocyte transfusions are frequently used as supportive therapy (153). Another exciting approach is immune modulation via exogenous provision of costimulation to effectively activate the immune responses. This was demonstrated by a recent study showing that chronicity of chromoblastomycosis caused by *F. pedrosoi* was due to lack of costimulation with TLRs; thus, topical application of TLR ligands such as imiquimod (which signals via TLR7) resulted in an adequate inflammatory response that resolved the infection (154).

FUTURE PERSPECTIVES

In the 27 years since the inception of the PRR theory, much progress has been accomplished. We now know that there are other pathogen-sensing mechanisms exemplified by ideas such as the guard theory, which posits that the mammalian immune system detects cellular processes that are targeted by the pathogen's virulence factors. Furthermore, identification of the cell biology components such as compartmentalization of sensing receptors into membrane-bound, cytosolic, or endosomal modules has emerged as an important framework for the activity of the innate immune system. Understanding how all of these pathways are integrated and controlled from different compartments in the context of fungal infections will be essential for advancing our understanding of antifungal immune responses and developing future immunotherapies. Moreover, additional efforts using a systems biology approach to better define immunological, cellular, and molecular pathways involved in antifungal responses at different anatomical sites will also expand our knowledge. Studies characterizing the complex interplay between host genetics, microbiota, and the virome

in health and disease will help decipher an age-old question: what is the basis for mammalian protective immunity?

Antifungal Drugs: The Current Armamentarium and Development of New Agents

44

Nicole Robbins,[1] Gerard D. Wright,[1] and Leah E. Cowen[2]

INTRODUCTION

Importance of Fungal Pathogens

Disease and death caused by fungal infections have transitioned from a rare curiosity to a major global health problem. Because the vast majority of fungi capable of causing life-threatening infections target individuals with impaired immunity, recent decades have witnessed a stark rise in fungal infections due to medical interventions such as chemotherapy for cancer and immunosuppression for organ transplantation and due to the prevalence of HIV infection (1). Pathogenic fungi are the causative agents of billions of infections annually, with ~1.5 million attributable mortalities (2). The public health burden is comparable to that observed with more notable infectious diseases such as tuberculosis and malaria, yet the impact of fungal infections on human health has been largely overlooked (3).

The predominant fungal pathogens of humans include *Candida albicans*, *Cryptococcus neoformans*, and *Aspergillus fumigatus*. *C. albicans* is a common component of the human mucosal microbiota and is responsible for millions of superficial infections in immunocompetent individuals, such as thrush and oropharyngeal candidiasis. It is also the most prevalent fungal etiological agent of life-threatening invasive infections, with mortality rates approaching 40% despite treatment (1). The CDC has classified *Candida* species as a serious threat to human health due to the dramatic rise in resistance to antifungal drugs (4). Cryptococcosis caused by *C. neoformans* and the closely related species *Cryptococcus gattii* affects over a million individuals annually, with mortality rates as high as 70% in Latin America and sub-Saharan Africa (2). Recently, *C. gattii* was associated with outbreaks of cryptococcosis in healthy individuals on Vancouver Island (5) and other regions of the Pacific Northwest (6), making *Cryptococcus* a public health threat to immunocompromised and immunocompetent individuals. Finally, *A. fumigatus* is a significant cause of invasive infections in individuals with impaired immune function, including those with neutropenia, solid organ transplant recipients, and patients on immunosuppressive therapies such as high-dose corticosteroids (2). It is estimated that more than 200,000 cases of invasive aspergillosis occur each year, with staggering mortality rates of up to 50% with treatment and 100% if left undiagnosed (2). Thus, these chief opportunistic invaders are a leading cause of human mortality and impose a dire need for effective antifungal therapeutics to combat these infections.

In this article we aim to describe the current armamentarium of antifungal agents and the most promising emerging therapies in the antifungal development pipeline. We also highlight the innovative strategies being leveraged to identify novel antifungal targets and uncover new therapeutic strategies to combat fungal infectious disease.

Challenges for Treatment of Fungal Infections

Fungi are eukaryotic, like their human hosts, limiting the number of molecular targets that can be selectively exploited for drug development without the risk of cross-target toxicity. The current arsenal of antifungal compounds approved for the treatment of invasive infections consists of only three classes of antifungal agents

[1]Michael G. DeGroote Institute for Infectious Disease Research and Department of Biochemistry and Biomedical Sciences, McMaster University, Hamilton, ON L8N 3Z5, Canada; [2]Department of Molecular Genetics, University of Toronto, Toronto, ON M5S 1A8, Canada.

directed against a limited number of cellular processes. Perhaps of greater concern is that there are few discovery programs devoted to the development of new antifungal therapeutics because of the expectation of limited financial return for pharmaceutical companies (2). Most antifungals target ergosterol, the functional fungal analogue of cholesterol; the biosynthesis of ergosterol; or the biosynthesis of (1,3)-β-D-glucan, a major component of the fungal cell wall (Fig. 1). This paucity of fungus-specific targets is problematic because of the prevalence of cross-resistance to all drugs with a common target. Resistance to all widely deployed antifungals has been documented in both the laboratory and the clinic (7) and continues to be a growing problem in the medical community. There is a pressing need to bolster the antifungal pipeline, as highlighted by the Generating Antibiotic Incentives Now (GAIN) Act (H.R. 2182), which promises a major effort to reduce the incidence of drug-resistant fungi and bacteria in the United States through antimicrobial discovery.

CLASSES OF ANTIFUNGAL DRUGS IN CLINICAL USE

Polyenes

Since the 1950s, the fungicidal polyenes have served as a powerful but highly toxic last line of defense for combating invasive fungal infections. Polyenes are amphipathic, consisting of a hydrophobic polyene hydrocarbon chain and a hydrophilic polyhydroxyl chain. For decades the prevailing theory was that these molecules elicited their toxic effects by intercalating into ergosterol-containing membranes to form membrane-spanning channels that cause leakage of cellular components and, ultimately, cell death (8, 9). However, recent detailed structural and biophysical studies highlighted that polyenes act more like an "ergosterol-sponge," forming large extramembranous aggregates that extract the essential membrane-lipid ergosterol from the plasma membrane (Fig. 1) (10). Given that polyfunctional lipids such as ergosterol serve as central molecular nodes in cellular physiology and function, resistance to the polyenes is strongly evaded and comes at a significant fitness cost to the fungus (11). The differential binding affinity of amphotericin B for ergosterol over cholesterol, the mammalian membrane sterol, accounts for its selectivity; however, amphotericin B does affect mammalian cells, and nephrotoxicity is a common side effect of clinical usage that can be mitigated somewhat by liposomal formulations (8). Despite these drawbacks, amphotericin B is still used for the treatment of the most serious fungal infections, in large part due to its broad spectrum of activity.

Pyrimidines

Pyrimidines such as flucytosine (5-fluorocytosine) were first used to treat fungal infections in the 1960s. However, the rapid onset of resistance precludes the use of flucytosine as a monotherapy, and consequently it is only used in combination with other antifungals such as amphotericin B. This drug combination remains the "gold standard" for treating *Cryptococcus* infections and other less common invasive mycoses (12). Flucytosine is a synthetic fluorinated analogue of cytosine. Upon entry into the cytosol, flucytosine becomes rapidly deaminated to generate 5-fluorouracil by fungal specific cytosine deaminases (13). 5-Fluorouracil acts as a potent antimetabolite that causes RNA miscoding and inhibits DNA synthesis (Fig. 1).

Azoles

The azole antifungals encompass compounds with both imidazole and triazole moieties. They are the most widely deployed class of antifungal in clinical use because of their impressive safety profile and availability in both oral and intravenous formulations. For example, oral azoles are more broadly accessible in resource-limited settings such that oral fluconazole is widely used to treat cryptococcal meningitis in these regions despite treatment outcomes being much better with the i.v.-administered combination of amphotericin B and flucytosine (14). Furthermore, voriconazole is the drug of choice for aspergillosis based on its superiority to amphotericin B in a head-to-head clinical trial (15, 16). The azoles consist of a five-membered nitrogen-containing heterocyclic moiety, which binds to an iron atom in the heme group located in the active site of the drug target lanosterol 14-α demethylase (also referred to as cytochrome $P450_{14DM}$ and Erg11) (Fig. 1). Azole binding blocks the demethylation of lanosterol, resulting in ergosterol depletion and the accumulation of toxic sterol intermediates, which ultimately impedes cellular growth and division and induces severe membrane stress (7, 8). Most of the antifungal imidazoles are formulated for topical use, as a consequence of toxicity or bioavailability problems that limit their potential as systemic agents. The only agents licensed for treatment of invasive fungal disease are triazoles and include fluconazole, itraconazole, posaconazole, voriconazole, and isavuconazole (8, 17). The azoles are typically fungistatic, with the notable exception of voriconazole, which has fungicidal activity against *A. fumigatus*. The fungistatic nature of azoles imposes strong directional

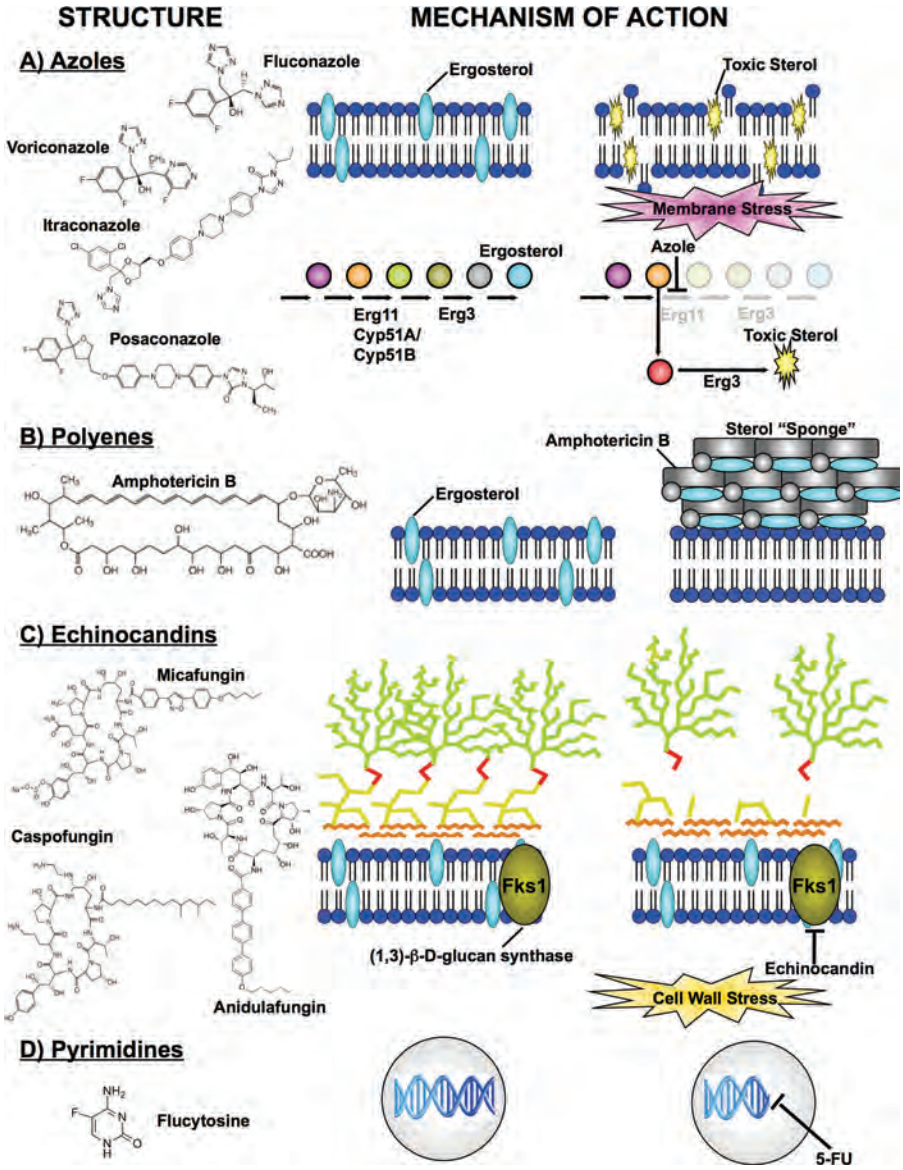

Figure 1 Structures and mechanisms of action of clinically relevant antifungal drugs. (**A**) The azoles function by targeting the ergosterol biosynthetic enzyme lanosterol demethylase, encoded by *ERG11* (*C. albicans* and *C. neoformans*) or *cyp51A* and *cyp51B* (*A. fumigatus*), causing a block in the production of ergosterol and the accumulation of a toxic sterol produced by Erg3. This toxic sterol exerts a severe membrane stress on the cell. (**B**) Polyenes such as amphotericin B primarily exist in the form of large extramembranous aggregates that extract ergosterol from lipid bilayers. (**C**) Fungal cell walls are composed of (1,3)-β-D-glucans covalently linked to (1,6)-β-D-glucans as well as chitin, mannans, and cell wall proteins. The echinocandins act as noncompetitive inhibitors of (1,3)-β-D-glucan synthase (encoded by *FKS1* in *C. albicans*, *C. neoformans*, and *A. fumigatus*) and thereby cause a loss of cell wall integrity and severe cell wall stress. (**D**) Pyrimidines such as flucytosine become rapidly deaminated in the cytosol to generate 5-fluorouracil (5-FU) by fungal-specific cytosine deaminases. 5-FU acts as a potent antimetabolite that causes RNA miscoding and inhibits DNA synthesis. Adapted from reference 185 with permission.

selection for the evolution of resistance. Moreover, several *Candida* species such as *Candida glabrata* and *Candida krusei* are intrinsically less susceptible to this class of drugs.

Echinocandins

The echinocandins are the only new class of antifungal to reach the clinic in decades, with three echinocandins currently available for clinical use: caspofungin, micafungin, and anidulafungin. These compounds are cyclic hexapeptides that act as noncompetitive inhibitors of (1,3)-β-D-glucan synthase, an enzyme involved in cell wall synthesis (Fig. 1). (1,3)-β-D-Glucan is an essential cell wall polysaccharide that provides structural integrity. Inhibition of (1,3)-β-D-glucan synthesis culminates in a loss of cell wall integrity and severe cell wall stress (18). The safety profile of these compounds is impressive and likely attributable to a fungal-specific target that is not conserved in mammals. Despite their potent activity against *Candida* and *Aspergillus*, these compounds are completely ineffective at combating *Cryptococcus* infections (18). Echinocandins have emerged as an important treatment option for candidiasis, especially in the context of the increasing prevalence of azole resistance.

DEVELOPMENT OF IMPROVED AGENTS WITHIN EXISTING CLASSES

Polyenes

In an attempt to improve the therapeutic index of amphotericin B, alternative lipid-associated formulations have been developed and incorporated into clinical use since the 1990s (19). Amphotericin B lipid complex (ABLC) consists of amphotericin B in a complex with two lipids: L-α-dimyristoyl phosphatidylcholine and L-α-dimyristoyl phosphatidylglycerol (19). The large molecular size of the compound results in rapid uptake of the drug by macrophages, which distribute the compound throughout the mononuclear phagocyte system including target organs such as the liver and spleen (19). Consequently, compared with the conventional formulation, there are lower circulating amphotericin B serum concentrations and reduced accumulation in the kidneys. Also of benefit, ABLC fails to stimulate myriad proinflammatory signaling molecules *in vitro* (20). Liposomal amphotericin B (L-AmB), marketed as AmBisome, is composed of a small unilamellar vesicle formulation consisting of hydrogenated soy phosphatidylcholine, cholesterol, and distearoyl phosphatidylglycerol. Amphotericin B is tightly bound to the liposome through charge pairing between the amino group of the amphotericin B and the phosphate group of distearoyl phosphatidylglycerol. Tissue concentrations in patients receiving L-AmB tend to be highest in the liver and spleen and much lower in the kidneys and lung. In a rabbit model of hematogenous *C. albicans* meningoencephalitis, L-AmB accumulates in the brain at higher levels than standard amphotericin B, significantly decreasing fungal burden in this tissue (21). This supports the preference for L-AmB in treatment of invasive central nervous system infections. Amphotericin B colloidal dispersion, marketed as Amphocil and Amphotec, encompasses two molecules of amphotericin B bound to two molecules of cholesteryl sulfate. Similar to the other liposomal formulations, there is reduced drug accumulation in the kidneys. However, unlike the other liposomal formulations, amphotericin B colloidal dispersion induces a high degree of inflammatory gene upregulation (20), which was likely a contributing factor related to the adverse side effects observed in several clinical studies (22, 23).

In addition to these lipid polyene formulations, alternative preparations continue to be developed. A cochleate formulation of amphotericin B displayed efficacy in experimental models of candidiasis and aspergillosis (24–26). Cochleates are a novel lipid-based delivery vehicle consisting of crystalline phospholipid-cation structures that form spiral lipid sheets. They represent a new technology platform for oral delivery of clinically important drugs that possess poor oral bioavailability. Initial biodistribution studies of cochleate amphotericin B administered orally in mice found that cochleates deliver significant levels of amphotericin B to target organs (24, 26). Despite these successes in animal models, clinical trials conducted by BioDelivery Sciences International appear to have been discontinued.

For the treatment of most invasive fungal infections, an amphotericin B lipid formulation provides a safer alternative than conventional amphotericin B, especially in the context of nephrotoxicity. Unfortunately, despite their use in the clinic for close to 20 years, it is difficult to conclude which (if any) of these lipid formulations possesses superior *in vivo* antifungal activity compared to amphotericin B or compared to each other due to a paucity of well-designed, randomized trials and also due to the multitude of invasive infections caused by evolutionarily diverse fungal pathogens.

Due to the pharmacological importance of amphotericin B in treating systemic mycoses, medicinal chemists have made extensive efforts to generate amphotericin B derivatives with more favorable pharmacological

properties and reduced toxicity. Modification of the mycosamine appendage through a double reductive alkylation generated a semisynthetic molecule with improved efficacy against amphotericin B-resistant *C. albicans in vitro* and reduced hemotoxicity (27). Improvements to the therapeutic index of amphotericin have also been made in a C2′deoxyamphotericin B derivative (28). Often the major limitation of these derivatives is the limited synthetic access, which precludes future development. Recently, synthetic chemists reported urea derivatives of amphotericin B that are easily accessible from the natural product by using a three-step synthesis reaction (29). These derivatives bind ergosterol with far greater selectivity than amphotericin B *in vitro* and maintain potent antifungal activity with reduced toxicity in mouse models of disseminated candidiasis (29). Moreover, urea-containing amphotericin B derivatives strongly evade resistance (29). The promising biological activities coupled with favorable synthetic properties suggest bright prospects for these amphotericin B derivatives in combating invasive fungal disease.

Azoles

Given that azoles are the most widely deployed class of antifungal, there is a long history of developing novel analogues with improved efficacy and safety. Isavuconazole was developed as an orally active, water-soluble prodrug that is also amenable to intravenous formulations (Fig. 2). The prodrug, termed BAL-8557, becomes cleaved in a reaction catalyzed by plasma esterases in mammalian cells (30). It exhibits a long elimination half-life, has broad-spectrum activity against *Candida* and *Aspergillus* species, and has demonstrated good efficacy in several clinical trials (31). One such study supported the safety and tolerability of isavuconazole as a prophylactic treatment in immunosuppressed patients at high risk of fungal infections (32). This compound has undergone phase III clinical trials to evaluate efficacy in the treatment of *Aspergillus* infections in renally impaired patients and those infected with other rare fungi (clinicaltrials.gov NCT00634049), as well as to compare efficacy to a caspofungin-voriconazole cotherapy against *Candida* infections (NCT00444366 and NCT00413218). In 2015, isavuconazole was approved by the U.S. Food and Drug Administration (FDA) for the treatment of invasive *Aspergillosis* and invasive mucormycosis.

Albaconazole is another triazole currently under development with potent broad-spectrum antifungal activity, good pharmacokinetics, and excellent oral bioavailability (Fig. 2). A phase II clinical study evaluated the therapeutic effects of a single dose of albaconazole in women with acute *Candida* vulvovaginitis and found that doses of ≥40 mg had greater therapeutic effects than fluconazole at 150 mg (30). Despite the efficacy in treatment of vulvovaginitis, it remains unclear whether albaconazole will have utility in treatment of invasive fungal infections.

Echinocandins

The echinocandins were first introduced into the clinic in 2001. Since this time there has been incentive to develop novel analogues in this class, primarily to overcome the current limitation of echinocandins to daily intravenous dosing regimens. Aminocandin (Fig. 2), also referred to as IP960 or HMR3270, is a semisynthetic fermentation product from *Aspergillus sydowii*. Its long half-life makes infrequent dosing a feasible option, and it has shown promising *in vitro* and *in vivo* activity against *Candida* and *Aspergillus* species (33, 34). Similarly, Cidara Therapeutics has developed an echinocandin derivative, CD 101 IV, which shows a dramatically extended half-life in animal models of *C. albicans* infection (35, 36). Preclinical evaluations in rats uncovered no hepatotoxicity at doses up to 20 mg/kg for 2 weeks (37). Currently, this compound is in phase I clinical trials (NCT02551549) and has been designated a qualified infectious disease product with fast track status from the FDA.

Enfumafungin is a structurally distinct natural product class that is similar to the echinocandins in targeting glucan synthase (38). The current development candidate MK-3118 is an orally active, semisynthetic derivative of enfumafungin with potent *in vitro* activity against glucan synthase and potent *in vivo* activity against *Candida* and *Aspergillus* species (Fig. 2) (39, 40). Thus, novel echinocandin derivatives and distinct antifungals targeting glucan synthase activity represent promising new treatment options to combat *Candida* and *Aspergillus* infections.

WHAT CHEMICAL MATTER SHOULD WE BE THINKING ABOUT FOR NEW DRUGS?

The optimal chemical space for antifungal compounds is poorly defined. Unlike antibacterial drugs that are dominated by microbial natural products, antifungals include both synthetic and natural product compounds in equal proportion (Fig. 1). In fact, synthetic compounds dominate the fungicides used in agriculture. This should be good news for antifungal drug discovery because, in contrast to antibacterial campaigns, existing libraries of synthetic compounds in pharmaceutical

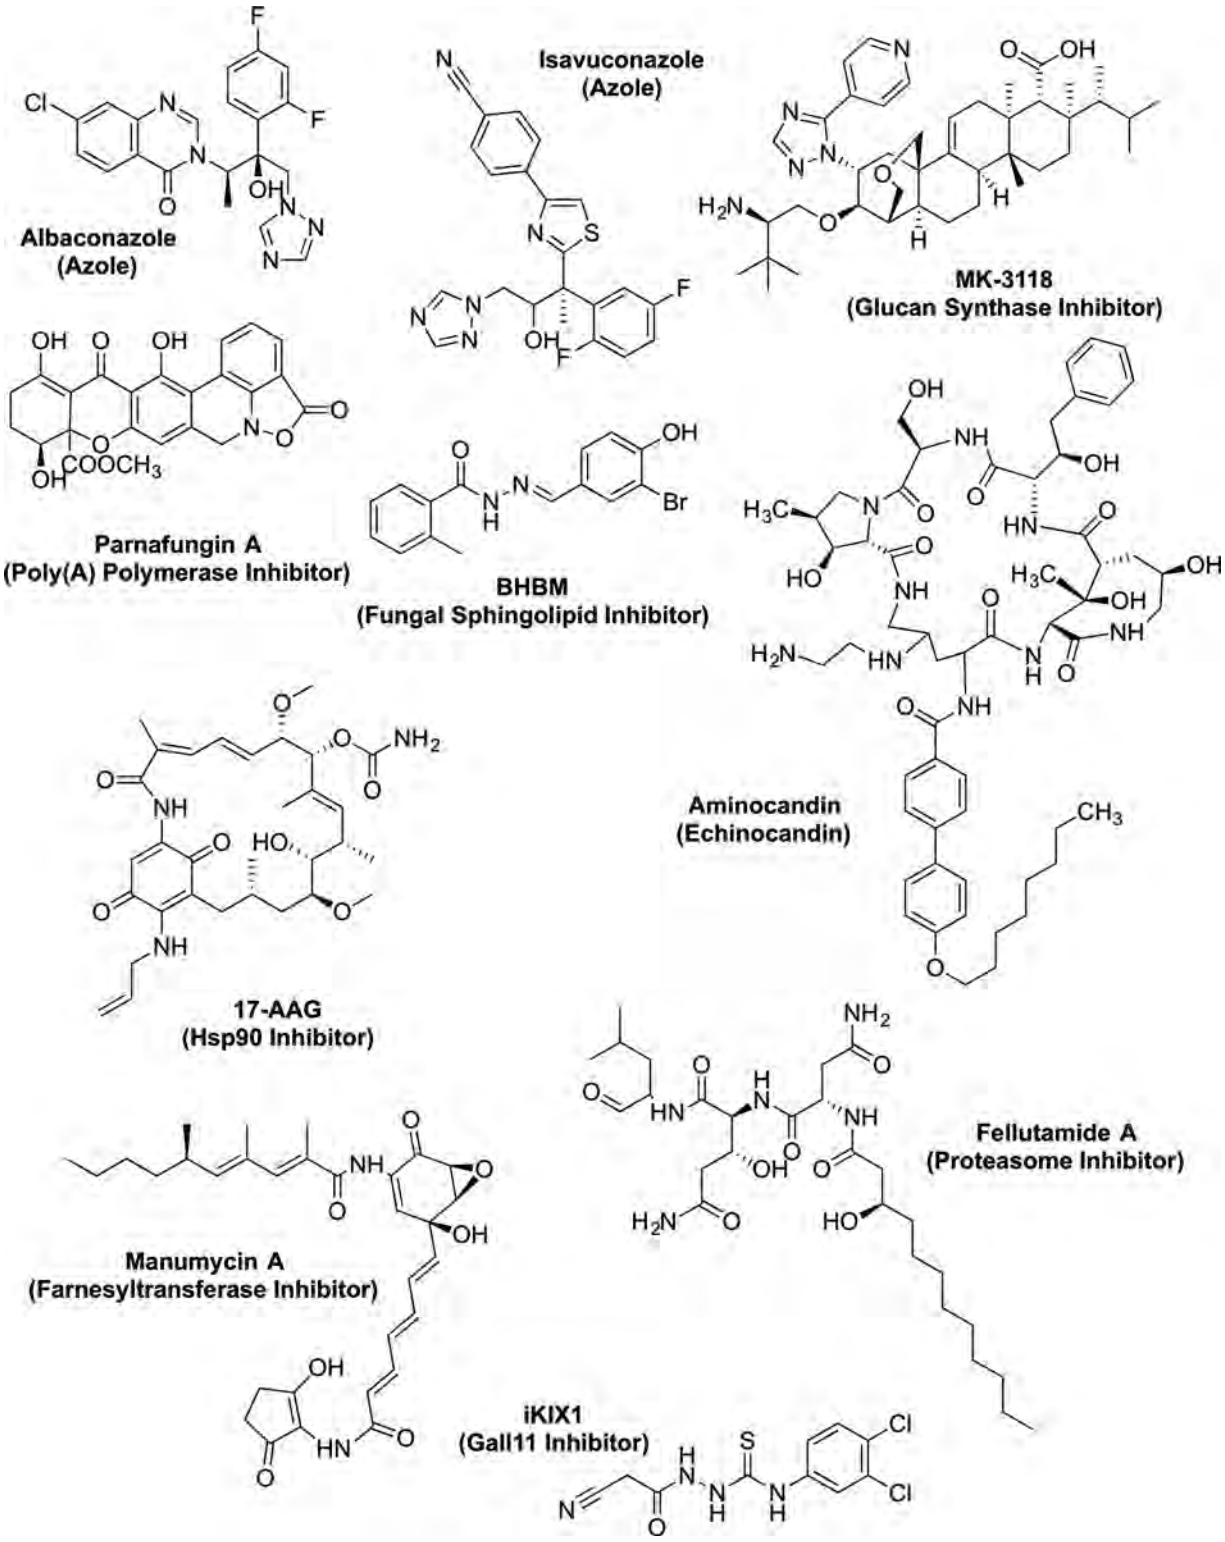

Figure 2 Structures of compounds with antifungal activity. Chemical structures of antifungal molecules highlighted throughout the review. The description in brackets describes the molecular target of the chemical compound.

companies are likely to be good starting points for antifungal screens. There are challenges in using these compounds, however. For example, there are fungal-specific PAIN (pan assay interference) compounds such as the rhodanines that are promiscuous in antifungal campaigns but have a poor likelihood of generating good leads in drug development (41). Additionally, the synthetic compounds that dominate pharmaceutical company libraries are enriched in molecules with physicochemico characteristics such as the Lipinski rule of five (42), which emphasize human targeted drugs. As a result, compounds identified in antifungal screens from such libraries often overlap with compounds that have bioactivity against human cellular targets. This reflects the relatively narrow unique target space between fungi and host biology (human, animal, or plant). Threading the needle between uniquely antifungal targets and the host is significantly challenging, especially if screened compounds are biased toward human biology. Indeed, as noted below, many highly useful drugs for human diseases, such as rapamycin, were first identified in antifungal screens. Not surprisingly then, most antifungal drugs have significant off-target effects that are reflected in host toxicity.

Expanding screens of synthetic molecules to libraries that typically have not yielded bioactivity in human targets (so-called chemical dark matter) can also offer an entry point into a selective antifungal target space. A group at Novartis specifically mined such chemical dark matter in a screen for antifungal compounds that identified a new compound and a new target, heme biosynthesis (43).

Another option is a return to screens of natural products to identify new leads in antifungal drug discovery and development. Screens of microbial natural product extracts often return polyenes such as amphotericin, but these can often be quickly dereplicated based on their characteristic absorption spectra. The Merck group has been especially active in this area over the past decade, developing new screening technologies (44) and reporting a series of novel natural products with antifungal activity that modulate new targets such as poly(A) polymerase (45) and the fungal proteasome (46).

The narrow target space for antifungal drugs, the diversity of fungal physiology, and the absence of systematic physicochemico rules for nontoxic antifungal agents complicate antifungal drug discovery. Nevertheless, clever screens for new targets and judicious mining of natural products and synthetic molecule libraries continue to yield new antifungal leads and offer encouragement for future success.

NEW ANTIFUNGAL DRUG TARGETS IN DEVELOPMENT

Our current arsenal of antifungal drugs target either ergosterol synthesis (azoles), ergosterol itself (polyenes), or cell wall synthesis (echinocandins). These targets account for a minor fraction of the potential drug targets encoded by genomes of fungal pathogens (47). Here we highlight some of the most promising new antifungal drug targets currently being explored for development of novel therapeutics.

Fungal Sphingolipids

Sphingolipids are ubiquitous eukaryotic membrane components that play a central role in signal transduction, cell regulation, and virulence in pathogenic fungi (48). There are a variety of fungal-specific sphingolipids present in the cell membrane and cell wall including glucosylceramides (GlcCer), which are glycosphingolipids composed of a glucose unit bound via a glycosyl linkage to a ceramide moiety. As proof-of-principle, genetic studies have established that targeting sphingolipid biosynthesis holds promise for blocking fungal virulence. In *C. neoformans*, strains lacking GlcCer synthase 1 are avirulent in a mouse inhalation infection model (49). Similarly, deletion of genes required for sphingolipid biosynthesis in *C. albicans* renders the pathogen avirulent (50). These genetic studies predict that small molecules targeting sphingolipid biosynthesis and/or function may serve as novel antifungal agents.

High-throughput screening efforts have been fruitful in identifying small molecules that target sphingolipid biosynthesis. A screen of 49,120 small molecules to identify inhibitors of fungal sphingolipid GlcCer synthesis identified two compounds: [*N′*-(3-bromo-4-hydroxybenzylidene)-2-methylbenzohydrazide (BHBM) (Fig. 2) and 3-bromo-*N′*-(3-bromo- 4-hydroxybenzylidene) benzohydrazide (D0)] (51). BHBM and D0 were efficacious against *C. neoformans in vitro*, in an intranasal infection model, and in an invasive infection model of the central nervous system (51). Paradoxically, although BHBM and D0 did not show potent antifungal activity against *C. albicans in vitro*, they were efficacious in a model of invasive candidiasis (51). Genome sequencing of drug-resistant mutants identified four candidate targets of BHBM: Apl5, Cos111, Mkk1, and Ste2, which are involved in vesicular transport and cell cycle progression (51). Thus, this study has identified promising compounds that inhibit fungal GlcCer.

Beyond small molecules, additional strategies to target sphingolipid biosynthesis show considerable promise. Monoclonal antibodies specific to *C. neoformans* GlcCer provide protection against *C. neoformans* infec-

tion, likely due to downregulation of the inflammatory response (52). Moreover, treatment with Cerezyme, a recombinant enzyme that metabolizes GlcCer, hydrolyzes fungal GlcCer in growing *C. neoformans* cultures, disrupts membrane integrity, and exhibits *in vivo* efficacy in an inhalation murine model of cryptococcosis (53). Notably, sphingolipid biosynthesis is also important for the host. Compromised sphingolipid biosynthesis in mice confers hypersensitivity to *C. albicans* infection due to the inability of immune cells to phagocytose yeast and clear the infection (54). These studies reinforce the potential of sphingolipids as an antifungal drug target and highlight the importance of specifically targeting fungal, and not mammalian, sphingolipids.

GPI Anchor Biosynthesis

Many cell surface proteins are modified at their C-terminus by the addition of a glycosylphosphatidylinositol (GPI) anchor, which consists of a lipid group, myoinositol, glucosamine, several mannose residues, and a phosphoethanolamine group that connects the GPI anchor to the protein through an amide bond (55). This posttranslational modification results in proteins being transported from the endoplasmic reticulum (ER; the site of modification) to the plasma membrane and cell wall, where they are directly or indirectly involved in cell wall organization. GPI anchoring is a conserved posttranslational modification in eukaryotes, although the number of mannose groups and the position of side chains on the GPI anchors vary widely between species. In *C. albicans*, deletion of *GPI7*, a gene with important roles in GPI anchor synthesis, results in abnormal morphogenesis and reduced virulence (56). In *A. fumigatus*, transcriptional repression of genes involved in GPI-anchor biosynthesis results in cell wall defects, abnormal morphology, attenuated virulence, and increased cell death through autophagy and necrosis (57, 58). Further, the GPI-anchored protein Ecm33 has important roles in *A. fumigatus* morphogenesis, cell wall stress response, and virulence (59).

Multiple small molecules that inhibit GPI-anchor biosynthesis have been discovered. The first was identified by a screen for molecules that interfere with the cell wall localization of a GPI-anchored reporter protein (60). The initial hit was 1-[4-butylbenzyl] isoquinolone, a molecule shown to target the acyl transferase Gwt1 (60). Medicinal chemical-based optimization led to development of the pyridine-2-amine-based molecule E1210, a compound with potent antifungal activity against numerous pathogenic fungi (61). Subsequently, a small molecule originally identified as an inducer of ER stress, gepinacin, was determined to be a specific inhibitor of Gwt1, a critical acyltransferase required for the biosynthesis of fungal GPI anchors (62). Sublethal concentrations of gepinacin or genetic disruption of GPI-anchored proteins exposes elevated levels of (1,3)-β-D-glucan on the cell surface, enhancing the host immune response against *C. albicans* (62, 63).

Farnesyltransferase

Farnesyltranferase is a ubiquitous eukaryotic enzyme that catalyzes posttranslational lipidation on the C-terminus of more than 120 important signaling proteins in mammalian cells (64). This acts as a signal, which culminates in the translocation of proteins from the ER to the plasma membrane. Protein substrates of farnesyltransferase bear a C-terminal CAAX sequence motif: cysteine (C), two aliphatic residues (AA), and a variable (X) residue. Ras proteins are key modulators of diverse signaling cascades in eukaryotes and are an example of proteins modified by farnesyltransferases. In pathogenic fungi, Ras signaling pathways regulate virulence, morphogenesis, and cell cycle control (65, 66). In the model yeast *Saccharomyces cerevisiae*, deletion of the gene *RAM1* encoding farnesyltransferase results in reduced fitness, but it is not essential for viability (67). However, farnesyltransferases are essential for growth and virulence in *C. neoformans*, *C. albicans*, and *A. fumigatus* (68–70). Farnesyltransferase inhibitors such as manumycin A (Fig. 2), originally developed as an anticancer therapeutic, have antifungal activity against *C. neoformans* and block localization of *C. neoformans* Ras1 to the cell membrane (71). Manumycin A also displays some activity against *A. fumigatus* and *C. albicans* (72). Additional farnesyltransferase inhibitors, such as ethylenediamine inhibitor #2 and tipifarnib, also show some antifungal activity against *C. neoformans*, particularly in a mutant deficient in capsule production (71). Finally, farnesyltransferase inhibitor III blocks the *C. albicans* morphological transition from yeast to hyphae, a virulence trait regulated by Ras signaling (73).

Key physical interactions between farnesyltransferases and their inhibitors have been illuminated through structural studies comparing fungal farnesyltransferases with their human homologs. Using X-ray crystallography, conformational differences between these enzymes from humans and *C. neoformans* have been identified, supporting feasibility of the development of fungal-selective farnesyltransferase inhibitors (71). Similarly, structural studies of farnesyltransferase enzymes from *A. fumigatus* confirmed structural differences from the human enzyme that are sufficient for species-specific targeting (74). Although much of the work with

farnesyltransferase inhibitors has focused on their impacts on Ras localization and signaling, mapping the fungal farnesylome may also uncover novel drug targets for future antifungal development. One example is the Ras-related protein RhbA in *A. fumigatus*, which is important for fungal pathogenesis and vegetative growth *in vitro* and for virulence in an *in vivo* model of infection (75).

Calcineurin

A principal regulator of cellular stress responses in all eukaryotes is the Ca^{2+}-calmodulin-activated protein phosphatase calcineurin (76, 77). In pathogenic fungi, calcineurin regulates myriad physiological processes including cell cycle progression, cation homeostasis, morphogenesis, virulence, and antifungal drug responses (76, 77). Calcineurin is required for survival at physiological temperatures in *C. neoformans* but is dispensable for growth in *C. albicans* and *A. fumigatus* (77). Hence, the calcineurin signaling pathway has a conserved role in fungal biology and virulence yet also possesses unique specializations across the fungal genera.

Pharmacological inhibitors of calcineurin function, including the natural products cyclosporin A and tacrolimus, have potential therapeutic indications. For example, these agents are deployed in the clinic as immunosuppressants to prevent graft rejection in transplant recipients (77). Their immunosuppressive activity is due to inhibition of calcineurin-dependent activation of a key transcriptional regulator termed the nuclear factor of activated T cells (NFAT), which is involved in T cell activation. In fungi, calcineurin inhibitors have diverse effects on cellular stress responses and virulence. Pharmacological inhibition of calcineurin in *C. neoformans* abrogates growth at 37°C (78), potentiates the activity of both azoles and echinocandins in *C. albicans* (79–83), and renders the fungistatic azoles fungicidal against multiple *Candida* species (84). Further, cyclosporin A and tacrolimus act synergistically with azoles against *C. albicans* biofilms both *in vitro* and *in vivo*, implicating calcineurin as a key modulator of azole resistance during biofilm growth (85). In *A. fumigatus*, calcineurin inhibitors enhance echinocandin activity and transform the fungistatic activity of caspofungin to fungicidal (86, 87). Calcineurin inhibitors also show potent activity against azole- and echinocandin-resistant strains of *A. fumigatus* (88). Recently, it was shown that calcineurin orchestrates dimorphic transitions, antifungal drug responses, and virulence of the fungal pathogen *Mucor circinelloides* (89, 90). Thus, targeting calcineurin provides a logical strategy for combating fungal disease caused by evolutionarily diverse fungi.

Therapeutic exploitation of calcineurin as a target for antifungal drug development requires fungal-selective agents. Nonimmunosuppressive cyclosporin A and tacrolimus derivatives retain antifungal activity against *C. neoformans*, including azole-resistant strains (91). These nonimmunosuppressive analogues also retain synergistic activity with azoles against *C. albicans* (84). Chromofungin, a synthetic vasostatin-I-related peptide, acts as a calcineurin inhibitor and also displays *in vitro* activity against *A. fumigatus* (92). Development of effective antifungal therapeutic agents that target calcineurin signaling will require crystal structures of calcineurin from fungal pathogens coupled with structure-guided drug design to enhance potency and fungal-selectivity of calcineurin inhibitors or development of agents targeting fungal-specific calcineurin effectors (77).

Hsp90

Hsp90 is an essential molecular chaperone that regulates the form and function of diverse client proteins (93, 94). As a consequence of its role in stabilizing key signal transducers, Hsp90 modulates the relationship between genotype and phenotype by acting as both a capacitor and a potentiator for the storage and release of genetic variation (95–97). In pathogenic fungi, targeting Hsp90 function as an antifungal strategy holds considerable promise given that it orchestrates crucial cellular responses to drug-induced stress (98–100). In *S. cerevisiae* and *C. albicans*, genetic depletion or pharmacological inhibition of Hsp90 impairs the evolution of azole resistance and abrogates resistance that has been acquired through diverse molecular mechanisms (82, 83). Compromise of Hsp90 function also transforms azoles from fungistatic to fungicidal (82). Pharmacological inhibition of Hsp90 in *C. neoformans* and *C. gattii* inhibits growth and potentiates azole activity *in vitro* (101). Moreover, in *C. albicans*, *C. glabrata*, and *A. fumigatus*, Hsp90 enables basal tolerance and resistance to the echinocandins. Thus, Hsp90 has a profound impact on resistance to multiple antifungal classes in diverse fungal pathogens (81, 102–104).

Hsp90 regulates responses to antifungal-induced stress through its downstream effectors calcineurin and protein kinase C signaling (81, 105). In a series of clinical isolates recovered over time from an HIV-infected patient treated with fluconazole, the basal fluconazole resistance phenotypes of isolates recovered early during treatment were dependent on Hsp90, calcineurin, and Pkc1 function (82, 105). This dependence gradually evolved toward independence of Hsp90, calcineurin, and Pkc1, corresponding with upregulation of multi-

drug transporters (82, 105, 106). Biochemical analysis confirmed that Hsp90 stabilizes the catalytic subunit of calcineurin and the terminal MAP kinase of the Pkc1 cell wall integrity pathway, Mkc1 (81, 105). Hsp90 is one of the most highly connected hubs in cellular networks, interacting with an estimated 10% of the yeast proteome (107, 108). Chemical genomic studies in *C. albicans* identified a multitude of Hsp90 genetic interactors important for cellular responses to azoles and echinocandins (109), suggesting that Hsp90 may have pleiotropic effects on circuitry governing drug resistance.

Hsp90 is also a powerful therapeutic target given its function in orchestrating central virulence traits such as fungal morphogenesis. In *C. albicans* the ability to transition between distinct morphological states is correlated with virulence (50) and is tightly regulated by diverse environmental cues coupled with elevated temperatures of at least 37°C (7). Genetic or pharmacological inhibition of Hsp90 function induces filamentation by relieving its repression on Ras1-protein kinase A signaling (110, 111). Elevated temperatures similarly relieve Hsp90-mediated repression of filamentation as the chaperone becomes overwhelmed with global protein misfolding in the cell (110, 112). To add additional complexity, Hsp90 also regulates *C. albicans* morphogenesis through the cyclin Pcl1, the cyclin-dependent kinases Pho85 and Cdc28, and the transcription factor Hms1 (113, 114). Intriguingly, genetic depletion of Hsp90 in *A. fumigatus* has the opposite effect in that it decreases hyphal growth and leads to severe defects in germination and conidiation (102). Given its intimate and complex role in governing fungal morphogenesis in multiple species, targeting Hsp90 holds promise as an antivirulence strategy to combat fungal infection.

The impact of Hsp90 inhibition on fungal virulence and antifungal efficacy has been explored using a variety of *in vivo* infection models. In *Galleria mellonella* models of fungal pathogenesis, combination therapy with Hsp90 inhibitors that have been in clinical development for cancer, such as 17-AAG (Fig. 2), with either caspofungin or fluconazole improves survival upon infection with *A. fumigatus* or *C. albicans*, respectively (115). Furthermore, in murine models of *C. albicans* disseminated disease, genetic compromise of fungal *HSP90* expression reduces virulence (110) and enhances the therapeutic efficacy of fluconazole and caspofungin (81, 115). Similarly, genetic compromise of *A. fumigatus* Hsp90 abrogates virulence in a murine model of invasive aspergillosis (104). In a *Caenorhabditis elegans* model of cryptococcal infection, Hsp90 inhibition enhances the activity of fluconazole (101). Finally, in an *in vivo* rat catheter model of infection, 17-AAG transforms fluconazole from ineffective to highly efficacious without host toxicity in the context of this localized infection and drug delivery (116). In the context of systemic fungal infections, toxicity associated with inhibition of host Hsp90 precludes the use of current Hsp90 inhibitors as antifungals and demands the development of fungal-selective Hsp90 inhibitors or agents that target fungal-specific regulators of Hsp90 function.

Acetyltransferases and Deacetylases

Lysine deacetylases (KDACs) and lysine acetyltransferases (KATs) catalyze the removal or addition of acetyl groups from the ε-amino group of lysines. Such modifications in core histones result in changes in chromatin structure and gene expression (117, 118). Consequently, KDACs and KATs have pleiotropic effects on cellular signaling and stress responses in fungi. The broad-spectrum KDAC inhibitor trichostatin A potentiates azole activity in *C. albicans* (119, 120). Further, *C. albicans* clinical isolates are sensitive to nicotinamide, an inhibitor of NAD^+-dependent KDAC complexes, and nicotinamide reduces fungal kidney burden in a mouse model of disseminated candidiasis (121). Nicotinamide is also active against other *Candida* species and against *A. fumigatus* and *Aspergillus nidulans*, suggesting broad antifungal properties (121). Further, a molecule thought to inhibit the KDAC Hos2, MGCD290 (Mirati Therapeutics, San Diego, CA), displays synergistic activity with azoles and echinocandins against diverse *C. albicans* drug-resistant clinical isolates (122, 123). These studies were restricted to *in vitro* analysis, but *in vivo* studies coupled with preliminary clinical trials have supported the use of MGCD290 in combination with fluconazole to treat *C. albicans* infections (124). Thus, these findings suggest considerable promise for the use of KDAC inhibitors in combination with current antifungals in combating invasive fungal disease.

In addition to their roles in modifying histones, KDACs also deacetylate a spectrum of nonhistone proteins, such as Hsp90. Acetylation of Hsp90 provides a mechanism of posttranslational control that governs the emergence and maintenance of Hsp90-dependent azole resistance (120). In *S. cerevisiae*, Hsp90 is acetylated on lysine 27 and 270, residues that are regulated by KDACs Rpd3 and Hda1 (120). Genetic or pharmacological inhibition of both Hda1 and Rpd3 blocks the physical interaction between Hsp90 and calcineurin, thereby impeding calcineurin function (120). Deletion of both *HDA1* and *RPD3* does not increase global Hsp90 acetylation levels, suggesting that additional

KDACs orchestrate Hsp90 deacetylation. One candidate KDAC is Hos2, which interacts genetically with Hsp90 under diverse environmental conditions in *C. albicans* (109). In *A. fumigatus*, Hsp90 lysine residues important for drug resistance and virulence are conserved with those identified in *S. cerevisiae* (120, 125). Thus, by influencing gene expression through histone modification and controlling the function of key signal transducers, KDAC inhibitors hold promise as antifungal therapeutics.

KATs also modulate azole resistance. Genetic impairment of *C. albicans ADA2*, which encodes a component of the Spt-Ada-Gcn5-acetyltransferase (SAGA) coactivator complex, confers hypersensitivity to fluconazole due to impaired upregulation of the efflux pumps Cdr1 and Mdr1 (126). Further, deletion of the *C. albicans* KAT gene *RTT109* confers hypersusceptibility to macrophages, altered metabolic gene expression, and induction of a weaker inflammatory response, culminating in attenuated virulence in a murine infection model (121, 127). Deletion of *RTT109* also confers increased sensitivity to echinocandins and to other genotoxic stresses such as hydroxyurea and methyl methane sulfonate (121).

Other Antifungal Targets

The TOR protein kinases are global regulators of cellular growth in response to nutrient cues, including amino acids (128). In *S. cerevisiae*, inhibition of TOR signaling has a multitude of effects including induction of autophagy, inhibition of translation, and repression of ribosomal gene expression, as well as upregulation of genes involved in the retrograde response, nitrogen catabolite response, and stress response (128–130). TOR can be inhibited pharmacologically by the immunosuppressant rapamycin (sirolimus). Rapamycin is a natural product of the bacterium *Streptomyces hygroscopicus*, originally identified in a screen for antimicrobial activity against *C. albicans* and later found to have potent immunosuppressive activity (131). Pioneering genetic studies in *S. cerevisiae* identified FKBP12, Tor1, and Tor2 as the direct targets of rapamycin (132). Rapamycin inhibits growth of diverse fungi, including *C. neoformans*, *C. albicans*, *A. fumigatus*, *Fusarium oxysporum*, and *Penicillium* spp. (133, 134) and abrogates *erg3*-mediated azole resistance (135). Analogues of rapamycin with reduced immunosuppressive activity retain antifungal activity *in vitro* (136).

There are several other antifungal agents in development that target a variety of other cellular processes. Parnafungins inhibit poly(A) polymerase and display potent broad-spectrum activity against clinically relevant *Candida* species and therapeutic efficacy in murine models of candidiasis (Fig. 2) (45). Inhibitors of leucine tRNA synthases, such as tavaborole (AN2690), are highly selective against *Trichophyton* species (137, 138) and are in clinical development to treat onychomycosis (14). Finally, inhibitors targeting the 26S proteasome (fellutamides, Fig. 2), translation elongation (yefafungin), cyclic AMP homeostasis (campafungin), and microtubule dynamics (12-deoxy-hamigerone) are all unexploited areas that may represent the next breakthrough in novel antifungal scaffold (14, 44, 46). While it is impossible to predict which, if any, of the targets highlighted above will prove to be the next clinically exploited antifungal target, the portfolio of distinct prospects provides renewed hope for the development of novel antifungal treatments.

COMBINATION THERAPY TO EXPAND THE REPERTOIRE OF DRUG TARGETS

Although advances are being made to improve our current antifungal arsenal and to identify novel drug targets, the rate at which antimicrobials are being produced is vastly outpaced by the rate at which resistance is emerging (139, 140). A promising strategy for combating drug-resistant fungi is through combination therapy. Drug combination therapy has benefits such as enhanced efficacy and specificity when compared to individual drug treatments and can impede the evolution of resistance (141, 142). Further, by carefully selecting specific drug combinations, microbial drug resistance may be not only neutralized but also reversed through a process called selection inversion (143). Combination therapy provides the foundation for treatment of other infectious diseases such as HIV (144), tuberculosis (145), and malaria (146). Despite the therapeutic potential, there is only one combination that has been well validated in clinical trials for fungal infections: the combination of amphotericin B and flucytocine as the gold standard to treat cryptococcosis (12). Combination therapy also has the potential to unveil myriad additional antifungal targets given that fungal biology is controlled by a highly interconnected and functionally redundant network of biological interactions (147, 148). The yeast deletion project revealed that only ~1,000 of the ~6,000 genes in the *S. cerevisiae* genome are essential for viability (149). However, a tour de force systematic analysis of ~5.4 million pairs of gene deletions identified ~170,000 negative genetic interactions, including 10,000 synthetic lethal interactions (148). Synthetic lethality represents an extreme negative genetic interaction in which two mutations, causing little to no fitness defect individually, result in a lethal

double mutant phenotype (150). The potential for harnessing synthetic lethality provides a new avenue for antimicrobial drug discovery through the use of combination agents.

There is precedent for leveraging the power of genetic interactions to predict combination drug therapy. In *S. cerevisiae*, *FKS1* and its paralog *FKS2* encode the biosynthetic enzyme for (1,3)-β-D-glucan synthesis and the molecular target of the echinocandins. *FKS1* and *FKS2* are synthetically lethal, in keeping with echinocandin efficacy. *FKS1* is also synthetically lethal with *CHS3*, a chitin synthase required for the synthesis of the cell wall component chitin (148), and inhibitors of chitin synthases, such as nikkomycin, are synergistic with caspofungin against numerous fungal pathogens (151, 152). *FKS1* is also synthetically lethal with *CNB1*, the regulatory subunit with calcineurin, and as highlighted above, calcineurin inhibitors exert potent synergy with echinocandins against diverse fungi (77). While these examples support the fact that genetic interactions underpin the network response to compound combinations, the complexities of chemical action and genetic network density seem to preclude the prediction of synergism on a genome-wide scale (153). Thus, additional factors must be employed to identify effective antifungal combinations.

In addition to leveraging genetic interaction landscapes to predict chemical synergy, target-specific inhibitors may be screened *ad hoc* for synergistic activity against specific antifungal agents. We explored many of these examples above, as with the capacity of inhibitors of Hsp90 (98, 99), calcineurin (77), KDACs (120, 123), and TOR (136), to potentiate antifungals against fungal pathogens. Other notable examples include potentiation of azole activity by pharmacological inhibition of ADP-ribosylation factors (154), protein kinase C (105), and protein translation (155). Further, tamoxifen and other triphenylethylene-based estrogen receptors have antifungal activity against *C. neoformans* (156) and potentiate the activity of azoles, polyenes, and echinocandins in diverse fungal species (157). Tamoxifen inhibits the *C. neoformans* calmodulin protein Cam1, which activates calcineurin (158). Given that Cam1 is fungal-specific, optimization of the triphenylethylene scaffold provides a promising path for antifungal drug development.

Small molecules that target resistance determinants can be effectively paired with currently available antimicrobials to combat drug-resistant isolates. Examples of such drug combinations in the clinic include drugs such as amoxicillin, a β-lactam antibiotic, with clavulanic acid, an inhibitor of β-lactamase drug-resistant enzymes (140). A recent study with *C. glabrata* identified a small molecule (iKIX1) (Fig. 2) that inhibits azole efflux pump expression by disrupting the interaction between the mediator complex and the transcriptional activator Pdr1 (159). Follow-up *in vivo* studies supported the use of iKIX1 to potentiate fluconazole efficacy against fluconazole-resistant *C. glabrata* in both metazoan and mammalian models of infection (159).

A complementary approach to identify synergistic drug interactions employed in both academia and industry utilizes high-throughput screening of large compound collections. Molecules that enhance the activity of established antifungals against *S. cerevisiae* have been identified by chemical biology screens (160, 161) and computational methods (162–164). Recent large-scale screening efforts have extended the strategy of chemical synthetic lethality to the fungal pathogens *C. albicans* and *C. neoformans*. Two such studies examined the potential of drugs approved for other therapeutic indications to potentiate current antifungal agents (157, 165). Compounds that increase azole efficacy were found to often target membrane function or sphingolipid biosynthesis (165). One such example is the antimycobacterium compound clofazimine, which induces cell membrane stress in fungi (157). A combination of clofazimine and caspofungin was efficacious *in vivo* against *C. albicans* in a *G. mellonella* model of infection (157). These studies illustrate the potential of combining current antifungal treatments with repurposed medications.

CHEMICAL GENOMICS TO LINK BIOACTIVES TO CELLULAR TARGETS

A variety of genetic and genomic approaches have been developed to uncover the molecular target for a compound whose mechanism of action remains elusive. Traditionally, forward chemical-genetic approaches have been used to identify targets by selection of resistant mutants coupled with plasmid-based library complementation, as well as gene and whole-genome sequencing (166).

More recently, reverse chemical-genetic approaches have become widely used to identify the mechanism of action of bioactive agents. In *S. cerevisiae*, haploinsufficiency profiling screens were developed to identify targets of bioactive compounds *de novo* based on the principle that reducing the dosage of a drug target confers hypersensitivity to the drug. In these assays, a genome-scale collection of heterozygous deletion strains are pooled, grown in the presence of compound, and sampled over time (167, 168). Each heterozygous

strain has a unique barcode sequence that enables deconvolution of strain identity in pooled screens (169). Quantitative analysis of strain fitness can be achieved by next-generation sequencing or microarray technology to monitor barcode abundance (167, 168). Homozygous deletion profiling (HOP) provides a complementary assay to investigate the mode of action of compounds that lack an essential protein target (for example, DNA or lipids) or for those compounds with redundant protein targets (166). Further, HOP reveals the genes important for buffering the cellular response to a drug. For example, compounds that target DNA generate HOP profiles that identify nonessential DNA-repair genes and complexes required for surviving DNA damage (170).

Large chemogenomic screening efforts have unveiled chemical-genetic interaction maps for thousands of small molecules and revealed how eukaryotic cells respond to cellular perturbations. An intensive study with 1,144 haploinsufficiency profiling and 418 HOP experiments identified growth phenotypes for mutants covering 97% of the *S. cerevisiae* genome (171). This expands our knowledge of yeast physiology and suggests that most genes are conditionally essential with functions that can be probed by small molecules. Chemogenomic profiles generated for 3,250 compounds in *S. cerevisiae* revealed that the cellular response to small molecules is largely restricted to a network of 45 chemogenomic signatures (172). These signatures highlight the fundamental small molecule response system in eukaryotic cells and provide a resource for the exploration of relationships between genes, biological processes, and chemical structures (172). Using chemical-genomic datasets, researchers recently developed a machine-learning-based prediction algorithm capable of predicting chemical synergies from large chemical libraries (153). This algorithm achieves a 6-fold enrichment in predicting synergistic chemical pairs with activity against fungi compared with chance selection alone, providing an effective platform for identifying antifungal chemical combinations.

Enabled by the development of powerful functional genomics resources, analogous tools for chemical biology are now available for the fungal pathogens *C. albicans* (173, 174) and *C. neoformans* (175). It is becoming abundantly clear that gene essentiality and chemical-genetic responses diverge rapidly over evolutionary time (175, 176), underscoring the importance of performing chemical genomic analyses directly in fungal pathogens.

In addition to chemogenomic profiling, the development of a functional variomics tool provides a complementary approach to elucidate drug mode of action (177). This technology applies plasmid-based, high-complexity random mutagenesis (or variomic) libraries covering ~90% of the *S. cerevisiae* genome. Screening this library against test compounds allows for systematic discovery of resistance-conferring mutations, thereby defining residues critical for drug binding and identifying potential mechanisms of resistance (177). Research combining chemogenomic and variomic tools has led to the identification of two novel antifungal geranylgeranyltransferase I inhibitors, highlighting the importance of an integrated platform for drug target identification (178).

OUTLOOK

It is clear that creative and focused efforts are urgently needed to bolster the antifungal pipeline and improve clinical outcome for the millions of people with life-threatening fungal infections worldwide. There are new strategies on the horizon to expand the development opportunities beyond targeting essential genes or cellular functions. A complementary approach is to target proteins that are required for pathogen growth in the host or for virulence. Identifying nonessential virulence factors opens new opportunities for chemical diversity in therapeutic drugs, because the cognate inhibitors are not typically explored by conventional screening approaches. Although the potential utility of targeting nonessential genes has only recently been appreciated, there are already examples of antibiotics that target essential structures rather than essential proteins, as with daptomycin and the Gram-positive cell wall (179). Further, the diphtheria and tetanus vaccines, as well as the antitoxin for botulinum toxin, are examples of life-saving treatments targeting nonessential virulence factors (180, 181). Targeting virulence factors offers many benefits including expanding the repertoire of antifungal targets, minimizing effects on the host mycobiome, and reducing selection pressure for the evolution of drug resistance (182, 183). With advances in genomics technologies and structure-guided drug design, as well as having antifungals now granted "orphan status" by the FDA and a priority in the GAIN act (H.R. 2182) to facilitate clinical trials (184), there is great potential to foster stronger relationships between academia and industry to accelerate antifungal drug discovery.

The Insect Pathogens

45

Brian Lovett and Raymond J. St. Leger

INTRODUCTION

Estimates of the number of arthropod species vary between 1,170,000 and 10 million, accounting for over 80% of all known living animal species. One arthropod subgroup, insects, is the most species-rich member of all ecological guilds in land and freshwater environments (1). As arthropods were emerging as the dominant animals they are today, fungi were also colonizing the land. Over the past 400 million years fungi and insects have coevolved a wide array of intimate interactions (2, 3). These interactions include mutualistic endosymbiosis (4); fungi as obligate food sources, such as those found in fungus-gardening ants (5); sexually and behaviorally transmitted parasites, such as *Laboulbeniales* (6); and the most common disease-causing agents of insects (7). Entomopathogenicity has evolved independently and repeatedly in all the major phyla of the Kingdom Fungi (3). The heterogeneity of entomopathogenic fungi probably derives from both they and their hosts having short generation times, i.e., rapidly driving new diversity with each generation, and from their occupation of a wide range of habitats, with near ubiquity in the soil and on plants. Interactions among fungi, hosts, and the environment are therefore diverse and dynamic, which complicates comparisons between different fungi infecting different insects since their interactions may be necessarily disparate. Historically, this quandary was dealt with by intensively studying the host pathogen interactions of a couple of experimentally tractable fungal species, and then extrapolating these results to distantly related species. Consequently, most of what we know about the biochemical and molecular basis of interactions between fungi and insects has been determined with the experimentally tractable hypocrealean ascomycete genera *Metarhizium* (family *Clavicipitaceae*) and *Beauveria* (family *Cordycipitaceae*). *Metarhizium*, in particular, has also emerged as an excellent model to explore a broad array of questions in ecology and evolution, host preference and host switching, and the mechanisms of speciation.

Comparative genomics offers a way forward for assessing poorly characterized species. Already, comparative genomics has facilitated the identification of fungal fitness traits and the selective forces that act upon them, improving our understanding of how entomopathogenic fungi interact with insects and the environment. In particular, sequence data have provided crucial information on the poorly understood ways that these organisms reproduce and persist in the environment, identified the genes involved in ecologically relevant traits, and illuminated the nature, timing, and architecture of the genomic changes governing the origin and processes of local adaptation. Alongside the recent availability of genomic resources, the wide array of experiments that can be performed with entomopathogenic fungi makes them ideal models for answering basic questions on the genetic and genomic processes behind adaptive phenotypes (a "Holy Grail" in biology). In addition, Meyling and Hajek have described how insects and their fungal pathogens could be used as model species for exploring metapopulation theory via experimental and predictive models: consideration of the interactions insect pathogenic fungi have with their host and the broader community enables ecological questions to be probed from a unique perspective (8).

There are a lot of detailed reviews dealing with entomopathogenic fungi and their development as microbial control agents, including those from Lacey et al. (9), Vega et al. (10), and several chapters in Lovett and St. Leger (11). Relevant chapters in Roy et al. (12) detail the crucial roles fungal entomopathogens play in natural ecosystems, and for methods and techniques used to study these pathogens consult the chapters in Stock et al. (13). Studies on the evolutionary genetics of insect immunity and on insect-pathogen coevolution

Department of Entomology, University of Maryland, College Park, MD 20742.

are reviewed by Hu and St. Leger (14), and entomopathogen genomes are reviewed by Wang et al. (15). This review highlights recent advances in our understanding of insect pathogenic fungi deriving in large part from a plethora of genome sequences that have illuminated the nature of adaptive differences by which novel pathogens emerge and form. These studies have increased the utility of these fungi as important model and applied organisms, allowing us to focus attention on their convergent evolution, pathogenic strategies, and host specificity, which frequently involves manipulation of host behavior.

THE UTILITY OF INSECT PATHOGENIC FUNGI

Early interest in insect pathogenic fungi grew mostly from economic concerns. For example, Agostino Bassi described *Beauveria bassiana* in 1835 as the cause of the devastating muscardine disease of silkworms, and it was instrumental in his development of the germ theory of disease (16). There is still considerable research interest in protecting beneficial insects, particularly bees, from highly potent fungal pathogens, such as the causative agent of chalkbrood, *Ascosphaera apis* (17). The research interest in insect pathogens has also been propelled by the enormous ability of insects to negatively impact human society. It is estimated that insects destroy approximately 18% of the world's annual crop production, and vector-borne diseases kill millions every year (18). Since populations of most insects are regulated by density-dependent factors, the diseases, pathogens, and immune responses of insects have been a long-standing research interest. In 1880, the pioneer immunologist Elie Metchnikoff was among the first to propose practical methods of microbial biological control of an insect crop pest, initiating trials of the fungus *Metarhizium anisopliae* against grain beetles (19). Entomopathogenic fungi are particularly well suited for development as biopesticides because, unlike bacteria and viruses that have to be ingested to elicit disease, fungi are contact insecticides and typically infect insects by directly penetrating the surface of the insect (cuticle) and multiplying in the insect body cavity (hemocoel) (Fig. 1). Approximately 170 pest control products have been developed based on at least 12 species of fungal entomopathogens (20).

Killing the host slowly is adaptive for many entomopathogenic fungi because it allows them to replicate in large numbers in the living host, but this is a severe limitation in modern agriculture or when attempting to control a disease vector. Insect pathologists have been trailblazers in utilizing genetic engineering to improve the efficacy of beneficial fungi by improving their

(154).

tolerance to environmental stresses and increasing their virulence (21, 22). Up until now, most "useful" genes for strain enhancement have come from pathogens themselves, from host insects, or from arthropods, such as spiders, that produce insect-specific toxins (Fig. 2A) (23–27, 155). Each of these sources provides a vast array of biologically active metabolites. In addition, a *Metarhizium* strain has been engineered that expresses a single-chain antibody fragment that blocks transmission of malaria parasites (27). Recombinant antibodies provide an additional vast array of potential anti-insect effectors that could target, for example, hormone receptors. The efficacy of *Metarhizium* strains expressing arthropod toxins or antimalarials is currently being tested in a purpose-built "Mosquito Sphere" (a compartmentalized facility with double-walled mosquito netting designed to test experimental fungi and insects in a natural ecosystem) in the malaria endemic region of Soumousso, Burkina Faso. The desire to use these new tools safely has driven studies on monitoring and mitigation methodologies for confinement of genetically engineered (GE) *Metarhizium*; development of bioconfinement strategies; survivability profiles and fitness of GE *Metarhizium* in the wild; studies of transgene stability over many generations; and the "evolvability" of transgenic strains if they escape containment (28). A review of future prospects for biocontrol highlights the application of transgenic *Metarhizium* to mosquitoes as providing GE biopesticides with the high profile necessary for widespread acceptance as safe and sustainable alternatives to chemicals (29).

As well as their direct benefit to agriculture and vector control as insect pathogens, *Cordyceps/Ophiocordyceps* spp., in particular, are medicinally valued because they are generally prolific producers of enzymes and diverse secondary metabolites with activities against insects, fungi, bacteria, viruses, and cancer cells (30–34). Enzymes from *Metarhizium* and *Beauveria* spp. are frequently exploited as industrial catalysts (35, 36), even though the responsible genes for these products are rarely identified. The study of infection and immunity in insects has achieved considerable prominence with the appreciation that their host defense mechanisms share many fundamental characteristics with the innate immune system of vertebrates (14). Studies on the highly tractable model organism *Drosophila,* in particular, have led to a detailed understanding of conserved innate immunity networks, such as Toll (37).

The recent discovery (38) that common entomopathogenic fungi, including *B. bassiana* and *Metarhizium* spp., have epiphytic interactions with plants has generated a plethora of promising avenues of research investigating commonalities and distinctions between these two lifestyles (28, 39, 40). The same molecular and genetic tools developed to probe and manipulate these fungi to better kill insects are quickly allowing development of fungi with altered persistence in the environment and that can function as biofertilizers (40–42).

EVOLUTIONARY RELATIONSHIPS OF ENTOMOPATHOGENIC FUNGI

Fungal-insect pathogens represent lifestyle adaptations that have evolved numerous times, and there are significant differences in host range and pathogenic strategies between the major groups (Fig. 3). Ascomycetes, the most speciose phylum, and *Entomophthoromycota* are known to infect a diverse array of insects, Basidiomycota infect mostly *Hemiptera*, and the basal zoosporic groups that produce motile spores that swim to reach their hosts (e.g., aquatic chytrids and blastoclads) usually infect *Diptera* (3). Araújo and Hughes (3) emphasize that, despite their ecological importance and potential applications, fungal-arthropod associations remain an understudied area of fungal biodiversity and likely harbor one of the largest reservoirs of undocumented taxonomic, functional, and genetic diversity within the Fungi.

The best-studied entomopathogenic fungi are the *Entomophthoromycota* and three ascomycete families

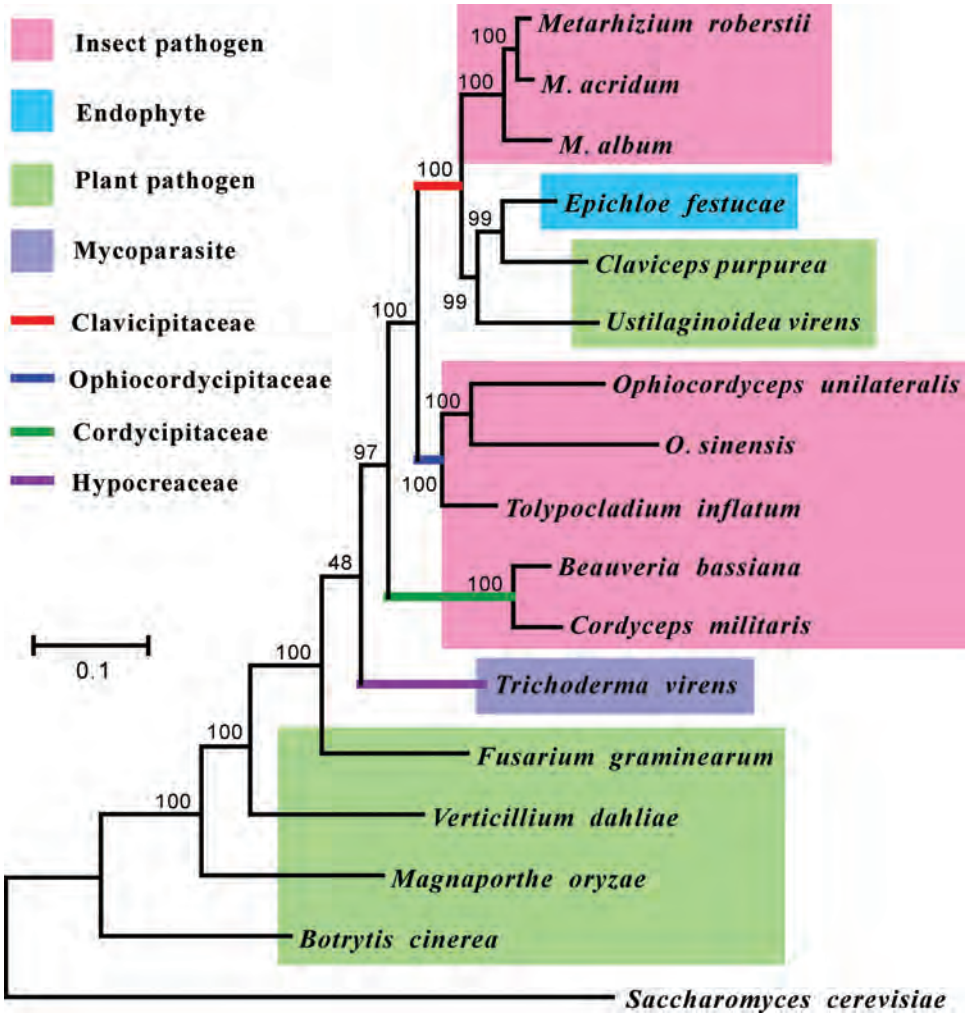

Figure 3 A phylogenetic tree representing relatedness of entomopathogenic fungal taxa. Important entomopathogenic groups are indicated in parentheses. (From reference 15, with permission.)

within the order *Hypocreales* (*Cordycipitaceae*, *Clavicipitaceae*, and *Ophiocordycipitaceae*). In terms of pathogenic strategies, the ascomycetes are characteristically hemibiotrophic, switching from a parasitic, biotrophic phase in the hemocoel to a saprophytic phase colonizing the host cadaver. Conidia are produced on the cadaver, but, unlike the *Entomophthoromycota*, are not actively discharged. In some genera of *Entomophthoromycota*, if the forcibly discharged primary infective spores (ballistospores) miss their aerial targets, they have evolved the ability to form secondary sticky spores (capillispores), thereby creating "minefields" around cadavers to entrap crawling targets (3, 156).

Both *Entomophthoromycota* and *Hypocreales* produce resting structures for persistence in the absence of new hosts or under adverse environmental conditions. The *Hypocreales* have both sexual (teleomorph) and asexual (anamorph) forms, although most research has focused on the anamorphs, which tend to be more amenable to *in vitro* techniques and have greater practical applications. Species in the *Entomophthoromycota* are characteristically biotrophic (exhibiting no somatic growth after death) with a narrow host range and are common among foliar arthropods in temperate environments. Eilenberg and Pell (43) list a number of host-pathogen systems in which the ecology of *Entomophthoromycota* has been studied.

Entomopathogenicity evolved independently in the *Cordycipitaceae*, *Clavicipitaceae*, and *Ophiocordycipitaceae*, and these hypocrealean genera cluster among closely related phytopathogens, endophytes,

and mycoparasites. These ancestral associations are consistent with repeated transitions (host switching) between plant, fungi, and insect hosts (4). Their teleomorphs are the most common fungi encountered in association with arthropods in tropical forests (Fig. 2) (43). Most appear to have a very restricted host range; e.g., the zombie-ant fungus, *Ophiocordyceps unilateralis* species complex (carpenter ant-specific teleomorphs), may have a level of specificity of one fungal species per insect species (Fig. 4) (44–46). In contrast, their anamorphic counterparts are often generalist pathogens with broad host ranges and the ability to pursue both pathogenic and saprophytic lifestyles (47). However, even within anamorph genera, there is considerable variation: thus, *Metarhizium robertsii* can infect hundreds of insect species spanning different orders, while *M. album* and *M. acridum* are specific to hemipterans (true bugs) and acridids (locusts and grasshoppers), respectively (48). In terms of the evolution of fungal host specificity, the study of *Metarhizium* species with different host ranges has shown a directional trajectory of speciation from being specialists to becoming generalists, and the specialists may have cryptic sexual stages (48). As discussed later, this raises the basic question of what is driving the host specificity of the sexual forms to a degree not observed in asexual forms of the same species. Other basic questions that remain unanswered include: why do teleomorphic ascomycetes not occur widely in temperate habitats, and are the teleomorphic ascomycetes utilizing the functional niches in the tropics that *Entomophthoromycota* occupy in temperate zones (49)?

Researchers studying the *Entomophthoromycota*, which are difficult to mass-produce, have focused on the ecology of these organisms and their role as causative agents of mass epizootics. Hajek and Delalibera (50) conclude that they have been used more frequently than other types of pathogens in classical biological control and provide a sustainable avenue for controlling arthropod pests, especially the increasing numbers of invasive species. As of February 2016, 10 strains of entomophthoromycotans have sequencing projects listed on the Genomes OnLine Database (GOLD): three are *Entomophthoraceae*, three are *Basidiobolaceae*, and four are *Ancylistaceae*. Leveraging the full power of genomics in the study of *Entomophthoromycota* will be shortly forthcoming, but currently the only complete genome in this collection is that for a strain of *Conidiobolus coronatus* (all others are draft genomes or incomplete). Studies on anamorphs within the *Ascomycota*, particularly the genera *Beauveria* and *Metarhizium* (family *Cordycipitaceae* and *Clavicipitaceae*, respectively), dominate the entomopathogen literature because they have been developed as

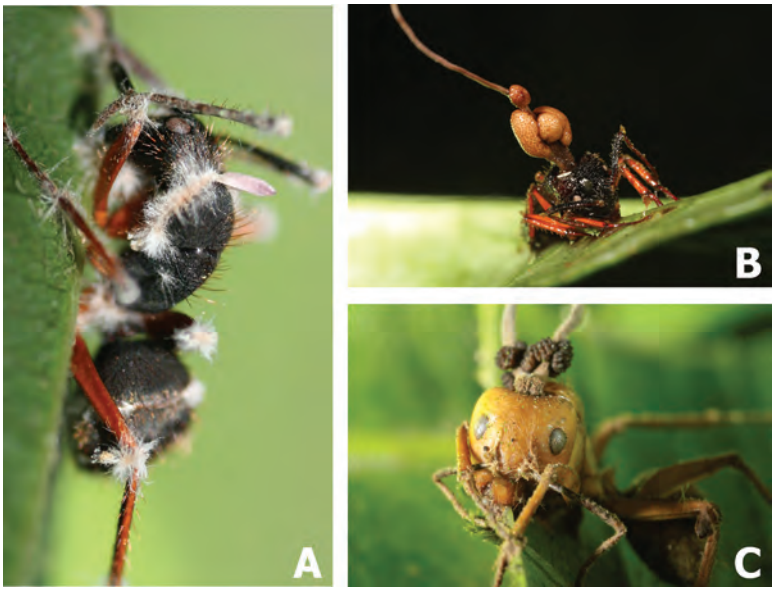

Figure 4 (**A**) A Brazilian carpenter ant *Camponotus rufipes* biting a leaf with *Ophiocordyceps camponoti-rufipedis* just beginning its growth out of the ant's body. (**B**) *Ophiocordyceps unilateralis* fruiting body emerging from the head of the Thai carpenter ant, *Camponotus leonardi*. inundative control agents, which can be applied *en masse* to control a pest population. To date, there is much more genomic information on ascomycete insect pathogens relative to the *Entomophthoromycota* because sequences are available from nine *Metarhizium* strains (48, 51–53), *B. bassiana* (54), *Cordyceps militaris* (32), *Ophiocordyceps sinensis* (anamorph, *Hirsutella sinensis*) (33), *O. unilateralis* (55), *Tolypocladium inflatum* (57), and *Hirsutella thompsonii* (56).

The comparative genome analysis of seven *Metarhizium* genomes (48) confirmed it is a monophyletic lineage that diverged from clavicipitacean plant pathogens and endophytes about 231 million years ago (MYA) and placed the hemipteran-specific *M. album* as basal in the *Metarhizium* clade with an estimated divergence time about 117 MYA (48). It has been suggested that the close physical proximity of the plant-associated ancestor of *M. album* to plant-sap-sucking hemipteran bugs may have facilitated this particular host switch to insects (3, 48).

Several *Metarhizium* spp. retain complex relationships with plants and endophytically colonize plant roots and the rhizosphere (the layer of soil influenced by root metabolism) (38, 39, 57, 58). *B. bassiana* also forms intimate endophytic relationships with a broad range of plant species, although it usually colonizes the aerial parts of the plant (59–62). Field trials showed that a rhizosphere competent, avirulent mutant *M. robertsii* strain survived better in grassland soil than an insect pathogenic mutant unable to adhere to root surfaces, providing experimental evidence for the importance of plant roots in maintaining populations of *M. robertsii* (28). Stress may play an important part in adaptive evolution to soil and root conditions (63). Cell wall and stress response genes evolved at an accelerated rate, increasing the fitness of field isolates, whereas virulence determinants were unaltered (28). *M. robertsii* trades insect-derived nitrogen (64) for plant-derived carbohydrates from its plant host (65). Moonjely et al. (39) suggest that, rather than shifting hosts, many of these fungi broadened their host range to exploit insects as a nitrogen source while maintaining mutualistic plant endosymbiosis. They hypothesize that the coupling of these dual lifestyles was the driving force behind this evolution: as conduits of insect-derived nitrogen, these fungi become an indispensable partner underground. As shown by their antagonism to plant pathogenic fungi (66), ability to survive exposure to lead and other heavy metals (67), and pathogenicity to soil amoebae (68), at least some *Metarhizium* isolates have additional unexpected flexibility in their trophic capabilities.

THE FUNGAL INFECTION CYCLE AND HOST SPECIFICITY

Cumulative evidence suggests that genes involved in the specificity of some entomopathogens to a narrow range of insects could control adhesion to the cuticle surface; exploitation of cuticle surface conditions (nutrients, humidity, specific recognition factors); ability to overcome structural and chemical barriers to penetration; and toxin production (48, 51, 69). Much research has been directed at identifying determinants of specificity and virulence, because a major goal in the development of fungal insect pathogens as biocontrol agents is to be able to control these parameters.

Attachment and Penetration of the Insect Cuticle

Although fungal entomopathogens are highly diverse taxonomically, they all produce infective spores that attach to, germinate, and penetrate the cuticle (or digestive tract) of their host. In most cases, spores landing on the epicuticle (the surface layer of the cuticle) undergo a stereotyped series of changes that include producing appressoria (sticky holdfasts that attach to the cuticle) that in turn produce infection pegs that breach the cuticle using a combination of mechanical pressure and cuticle-degrading enzymes (Fig. 1) (70). The nature of the inductive triggers for production of appressoria varies with the entomopathogen; while the protein and chitin composition of insect procuticle appears similar in all insects, the overlying epicuticular components are extremely heterogeneous, even within the same insect genus, and therefore allowing different pathogen responses to particular insects (70).

The insect epicuticle comprises a heterogeneous mixture of long-chain alkanes, wax esters, and fatty acids, and represents the site of adhesion and the first barrier against fungal attack. Hydrophobic interactions initially drive host adhesion, with *B. bassiana* and *Metarhizium* spp. conidia being covered with a proteinaceous layer formed by hydrophobins that contribute variously to cell surface hydrophobicity and mediate adhesion to the similarly hydrophobic epicuticle (71–75). Following nonspecific adhesion via hydrophobins, a specific adhesin-like protein (MAD1) mediates spore attachment in *M. robertsii* (40), and growing germ tubes and appressoria produce a sticky mucilage that also functions to localize secreted cuticle-degrading enzymes in the vicinity of the fungus (Fig. 1C through E) (78).

The transition from polarized hyphal growth to germ tube expansion (appressoria) in *M. robertsii* is linked to a reduced displacement rate or dispersal of

the Spitzenkörper (the vesicle-generating apparatus at the hyphal tip), redirecting cell wall synthesis from the apical tip to the entire cell surface, and is regulated by several signaling cascades including cAMP and Ca^{2+}-dependent phosphorylation events, with mitogen-activated protein (MAP) kinase regulating the organization of microtubules for vesicle transport (70, 76). The inability of the locust specialist *M. acridum* to infect cicadas is determined at the stage of appressorial formation. *M. acridum* adheres and germinates on cicada cuticle, but only forms few, small appressoria, suggesting different stimuli are on the locust and cicada cuticles. These stimuli are likely to be chemical, rather than physical, because locust cuticle extract is sufficient to stimulate abundant appressorial formation against a flat surface (70). Nutrient levels are one of the interactive phenomena that enable isolates of *Metarhizium* spp. to determine whether they are on an appropriate host cuticle (71, 77). For example, endogenous nutrients on homopterans are supplemented by sugar-rich insect secretions, while available nutrient levels on beetles are very low. Consistent with this, coleopteran-derived isolates produce appressoria against a plastic surface only in the presence of low levels of complex nitrogenous nutrients, while many lines isolated from homopterans also produce appressoria in glucose medium (71). Strains with very narrow host ranges showed the least plasticity and require host-derived supplements to stimulate germination and differentiation (70, 78). Despite their different, presumably selectable, responses to host-related stimuli, the ultimate physiological and morphological responses of these isolates (in terms of appressoria formation, enzyme biosynthesis, etc.) are very similar. This suggests host recognition may be determined by regulatory controls that allow modulated expression of pathogenicity genes by these fungi when they are on a suitable host; conversely, these regulatory controls preclude the expression of pathogenicity genes when not on a suitable host. Current evidence suggests the power to differentiate between hosts depends on G-protein-coupled receptors (GPCRs) that sense extracellular cues. *Beauveria* mutants defective in the GPCR3 gene showed reduced virulence consistent with a role for GPCRs in initial infection stages (79). Compared with the specialists *M. album* and *M. acridum*, there was a major expansion of GPCR-related proteins in the broad-host-range *Metarhizium* spp., consistent with these being able to recognize and respond to many more environmental triggers, with particular expansion in the subfamilies that are developmentally upregulated early in germination and formation of infection structures on host cuticles (48, 51). *M. acridum*, but not *M. robertsii*, transcribed different *Pth11*-like GPCR genes on locust and cockroach cuticles, indicating a role in coordinating a response to specific hosts, or at least that these genes have a function that varies between strains with different host ranges (51).

M. acridum utilizes hydrocarbons and long-chain fatty acid components of the epicuticle during its prepenetration growth, but the epicuticle also contains growth-stimulating peptides, free amino acids, and sugars (80). These induce extensive growth and appressoria formation by *M. acridum*, whereas the fungus is largely unresponsive to the nonpolar lipid fraction (a mixture of long-chain *n*-alkanes) that makes up the bulk of the locust epicuticle (79, 81). Thus, it seems that simple polar compounds are required to stimulate germination before the fungus can make effective use of a complex mixture of nonpolar lipids (80). At high levels, a polar extract of locust epicuticle produced extensive hyphal growth at the expense of appressorial production (81). This is consistent with observations on *M. robertsii* that suggest that a primary role of the appressorium is to establish a nutritional relationship with the host and is not necessary in the presence of a sufficiency of nutrients (82). *M. robertsii* and *B. bassiana* upregulate cytochrome P450 (CYP) subfamily CYP52 enzymes (for metabolism of insect epicuticular lipids) and lipase genes as they germinate on the cuticle surface (51, 54). Conidia harvested from insect cadavers contain high levels of cuticle-degrading enzymes and display higher virulence (83). Growth on insect lipid extracts can also result in conidia displaying higher virulence (84), presumably due to priming of lipid assimilatory pathways (85). However, individual targeted gene knockouts of the eight *B. bassiana* cytochrome P450 enzymes demonstrated a role for only one of these (Cyp52X1) in targeting cuticular waxy layer components (85, 86).

Following initial germination and growth of the fungal germling on the epicuticle, it proceeds to penetrate the protein/chitin insect procuticle. This involves the sequential expression of different degradative enzymes in combination with mechanical pressure. Mechanical pressure in *M. robertsii* appressoria is exerted by breakdown of endogenous lipids to glycerol; this process increases turgor pressure and is mediated by the expression of Mpl1 (perilipin) (87). Genes specifically induced by cuticle included a plethora of cuticle-degrading enzymes and transporters for cuticle degradation products. Although *M. robertsii* has specific responses for different cuticles, the most highly expressed cuticle-degrading enzymes are a large combination of subtilisin proteases

(88). These differ in regulation (88), as well as structure and function (89). Thus, the broad-range subtilisin Pr1A is expressed by appressoria (90) as part of a general response to nutrient deprivation and functions in concert with the exopeptidases to generate host degradation products. These products allow the fungus to "sample" the cuticle and then respond with the secretion of an arsenal of cuticle-induced proteins, including proteases that require cuticle for induction, have different specificities, and have specialized roles in breaching host barriers (88, 89).

Comparative genomics has shown that diverse entomopathogens have more proteases, particularly subtilisins and trypsins, than plant pathogenic fungi (48, 51); this is consistent with niche-specific traits, i.e., traits shared by fungi that occupy the same niche irrespective of their phylogenetic position (91). The expansion of proteases is dramatic in *B. bassiana* and broad-host-range *Metarhizium* species, and less marked in more specialized pathogens, e.g., *M. acridum* and *Cordyceps* species. Similarly, entomopathogens have greatly expanded families of chitinases, lipases, fatty acid hydroxylases, and acyl-CoA dehydrogenases (for β-oxidation of fatty acids), compared with plant pathogens, and the generalists overall have more of these enzymes than the narrow-host-range species (32, 51, 54). The basal *M. album* genome, in particular, highlights the early expansion of genes involved in cuticle degradation, because it has 3-fold or more trypsin genes than related plant endophytes and phytopathogens (Fig. 3) (48). However, compared with *M. album* (87 proteases) and *M. acridum* (116 proteases), there has been additional expansion of proteolytic capacity in other *Metarhizium* species (average 165 proteases). Therefore, the proliferation of proteases may reflect an adaptation to infect insects via the cuticle and, as with the GPCRs, is possibly influenced by host range. The abundance of chitinases in entomopathogens compared with plant pathogens is likely an adaptation to the abundance of chitin in the insect cuticle. For entomopathogens, the necessity of crossing the protein-chitin procuticle has, therefore, had a major impact on their evolution; this is also a testament to the critical role the cuticle plays as a defense against entomopathogenic fungi. Genetically engineering overexpression of chitinase and protease activities has led to the construction of more virulent strains of *Metarhizium* and *Beauveria* spp., suggesting that these enzyme activities may be (partially) limiting virulence in the wild type (92–95).

Clearly, there are factors specialists lack that limit their ability to cause disease in multiple insects, as demonstrated by an increased host range following transfer of genes from a generalist strain to the locust specialist *M. acridum* (96). Interestingly, the components of pathogenicity in specialists and generalists differ not only in how fast they evolve, but also in the ways in which they change. Thus, *M. acridum* has a large number of rapidly evolving genes (those with abundant nonsynonymous mutations), compared with generalists, showing that this specialist has not remained functionally static; rather, specialization has involved rapid evolution of existing protein sequences rather than the extensive gene duplication observed in generalists (48). The rapidly evolved genes are genes involved in specific locust to *M. acridum* pathogen interactions and, by evolving under pairwise coevolution, have been subject to strong balancing or directional selection. By contrast, generalist *Metarhizium* spp. interact with a wide range of hosts in multiple environmental conditions. Diffuse coevolution with many insect hosts offers an explanation as to why signatures of positive selection are observed less frequently in the genomes of *M. robertsii* and other generalists.

With the exception of *O. sinensis,* insect pathogenic ascomycetes have a 2- to 3-fold higher proportion of their genome (~17%) devoted to secreted products than other ascomycetes, including plant pathogens and mycoparasitic *Trichoderma* spp. (54). *O. sinensis*, which mummifies ghost moth larvae (*Thitarodes* spp.) exclusively in Tibetan Plateau alpine ecosystems, provides an extreme case of specialization. Touted as "Himalayan Viagra," the fungus' sexual fruiting body is highly prized because of its pharmaceutical activities and dwindling supply (33). *O. sinensis* infects caterpillars through their spiracles (breathing holes) or orally and has greatly reduced gene families encoding epicuticular degrading CYP52 enzymes, cuticle-degrading proteases, and chitinases (33). In addition, protein families involved in adhesion to cuticles and formation of appressoria are absent or reduced in *O. sinensis* (33). These gene losses are consistent with the inability of *O. sinensis* to breach intact cuticle. Hydrolytic enzymes, particularly proteases, can elicit host immune defenses (92). In which case, the reduced number of cuticle-degrading enzymes in *O. sinensis* might also be an adaptation to avoid immune system detection during the several years it spends latent in the host. Copy number reduction was also evident for genes encoding known pathogen-associated molecular patterns such as lectins, consistent with selection for "stealth" (avoidance of host defenses) as a major force driving *O. sinensis* evolution (33). Evidently, differences found among the insect pathogens in protein

family size are related to their *modus operandi* and host range.

The large secretomes of insect pathogens probably reflect the many habitats they must adapt to *in insecta*, including the cuticle and the hemolymph, as well as additional environmental habitats in the soil and with plants. These complex lifestyles are also reflected in the transcriptomes of insect pathogens; hundreds of different genes are induced during adaptation to host cuticle, hemolymph, or root exudate (54, 65, 70, 88, 97–99). Some of these genes have been knocked out to confirm involvement in virulence. These encode regulators such as adenylate cyclase, the key enzyme for production of cAMP (100), the cAMP-dependent protein kinase A (PKA) that controls expression of many secreted virulence factors (101), calcineurin pathways with roles in *B. bassiana* responses to environmental stresses and host signals (102), components of the MAP kinase pathways involved in fungal adhesion and penetration (103, 104), an osmosensor that signals to penetrant hyphae that they have reached the hemocoel (105), and perilipin, glycerol-3-phosphate acyltransferase, and cell autophagy-related proteins that regulate lipolysis, turgor pressure, and formation of infection structures (51, 87, 106).

Many of the signal transduction genes regulating virulence in *Beauveria* and *Metarhizium* have also been implicated in pathogenicity in plant pathogens, e.g., PKA, MAP kinase pathways, and GPCR genes. Thus, although the signals that induce germination and differentiation are different, similar signal transduction pathways may mediate these signals in plant and insect pathogens. This conservation of developmental circuitry has probably facilitated switching between very different hosts.

Some genes are highly adapted to the specific needs of *Metarhizium*, e.g., *Mcl1* (involved in immune evasion) with its collagen domain is so far unique to *Metarhizium* and is only expressed in the hemolymph (98). Mr-NPC2a is also expressed exclusively in the hemolymph; it was horizontally acquired from an insect and allows *Metarhizium* to compete with the host for growth-limiting sterols in the hemolymph (107). *M. robertsii* upregulates a specific plant adhesin in the presence of plants (Mad2) and a specific insect adhesin (Mad1) in the presence of insect cuticle, demonstrating that it has specialist genes for a bifunctional lifestyle (40). Other specifically regulated genes include a novel oligosaccharide transporter for root-derived nutrients required to colonize the rhizosphere and roots (65), an RNA binding protein that has important roles in both saprotrophy and pathogenicity (108), and an invertase that aids in the regulation of hydrolytic enzymes and provides a plant-derived signal restricting fungal growth (109).

Transcription of these genes is in part controlled by bZIP or C2H2-type transcription factors (TFs) (110, 111). *M. robertsii* has an array of 24 bZIP domain-containing TFs; a knockout of one of these (*MBZ1*) revealed that it contributes to negative regulation of subtilisin proteases, but positive control of adhesin *MAD1* (110), consistent with transcriptomic data showing little subtilisin production while spores are in the process of adhering to cuticle (51). Characterization of MrpacC, a *M. robertsii* homologue of the C2H2-type PacC TF (a pH-responsive transcription factor), showed that it was highly activated in alkaline conditions and impacts cuticle penetration and evasion of the host immune response, perhaps in part because it positively controlled chitinase genes (111). Cultures of *M. robertsii* always show a rapid increase in pH during production of chitinases (112), hydrophobin, and proteases (113, 114). *M. robertsii* alkalinizes a proteinaceous microenvironment, such as the insect cuticle, by producing ammonia from proteolytic degradation products (114). Digestion of cuticle proteins exposes the underlying chitin to enzymolysis (115), so linking alkalinization with chitinase production is adaptive for the fungus. It is likely that continuing the dissection of the roles of individual TFs in the manner of *MBZ1* and *MrPacC* will untangle the complexity and illuminate the interactions between what currently seem to be disconnected strands of biochemical and molecular data.

Immune Evasion and Growth Within the Hemocoel

Once within the host, entomopathogenic fungi proliferate as a progression of single- or multi-celled structures (protoplasts [fungal cells without a cell wall], blastospores [yeast-like budded cells], hyphal bodies [chains of budded cells]) thought to be important for dissemination of the pathogen. These exploit the nutritional resources of their hosts, and ultimately kill them through starvation or as a result of toxin production. In the majority of entomopathogenic fungi, the hyphae break through the cuticle only after death to produce either more infective conidia for immediate transmission or resting structures (sexual or asexual resting spores, chlamydospores, mummified hosts) for persistence in the environment. Species in the *Entomophthoromycota* are obligate pathogens and do not produce toxins of importance for the progression of the infection. They are characteristically biotrophic, keeping the host alive until all resources are utilized. This is in

contrast to the strategy used by the hypocrealean fungi, which are hemibiotrophic, switching from a biotrophic phase (parasitism) in the hemocoel to a saprophytic phase, colonizing the body after death. Host death is, for broad-host-range strains, usually achieved by the production of toxic secondary metabolites.

Once inside the insect's body cavity, a fungal pathogen faces a potent immune defense by which the host attempts to eliminate or reduce an infection. The antifungal immune response in *Drosophila* includes coagulation or melanization, phagocytosis, cellular encapsulation, and the release of antimicrobial peptides (AMPs) following activation of the Toll signal-transduction pathway (14). Utilizing *Metarhizium anisopliae* in a *Drosophila* mutagenesis screen has enabled investigations on how host genotypes differentially affect pathogen fitness, and how defense is interconnected with other aspects of host physiology in complicated trade-offs (116). Approximately 9% of *Drosophila* lines with random single minos element insertions had altered disease resistance and only 13% of these insertions were in genes encoding immune responses (coagulation, phagocytosis, encapsulation, and melanization) (116). The nonimmune genes impacted a wide variety of biological functions including basic cellular processes, nutrition, early development, and, particularly, behavior (116).

There is evidence that entomopathogenic fungi are capable of interacting with the innate immune system, to successfully infect their hosts. This involves immune evasion strategies that interfere with, disrupt, or manipulate immune defenses (14). *Diptera*-infecting members of the genus *Entomophthora* proliferate within the host insect as protoplasts; producing no cell wall avoids detection by a host immune system that is triggered by cell wall epitopes (117). This intricate mechanism may have been a contributing factor for the evolution of a generally narrow host range within this group (118). However, a narrow host range is not a prerequisite for a "camouflage strategy," as generalist *Metarhizium* spp. produce a hemolymph-induced, hydrophilic collagen (Mcl1) coat on cell surfaces to reduce immune detection of hyphal bodies (98). *Metarhizium* conidia can also be internalized and grow within arthropod phagocytic cells where they can avoid additional immune reactions ("anatomical seclusion" strategy), while dispersing through the insect body (119).

The *Drosophila* mutant screen implicated melanization as an effective defense in the fight against entomopathogenic fungi (115). This is consistent with fungal pathogens tightly regulating their own proteases so as not to activate this pathway (88, 120) and with the observation that many entomopathogenic fungi, including *B. bassiana*, have evolved antiphenoloxidase (anti-PO) activity (121) that may, in part, be mediated by secondary metabolites (99). At least some strains of *Metarhizium* and *Beauveria* are immune to drosomycin, the principal *Drosophila* antifungal AMP (116, 122), suggesting that successful adaptation to entomopathogenicity involved evolving multiple overlapping countermeasures to avoid or mitigate the antagonistic effects of responding host immune defenses.

Most hypocrealean insect pathogenic fungi produce large numbers of secondary metabolites (SMs) that are assumed to be part of the ongoing evolutionary arms race between fungi and insects. These compounds are often synthesized by nonribosomal peptide synthetases (NRPSs), polyketide synthetases (PKSs), and terpene cyclases (TCs). Some of the compounds produced by these SM gene clusters have been identified, such as destruxins and serinocyclins in *M. robertsii* (123). However, a multitude of biosynthetic pathways have been uncovered by the newly available *Metarhizium* genome sequences (123). These include pathways likely responsible for known chemistries (e.g., cytochalasins, ovalicin), pathways without candidate products yet known in *Metarhizium*, but similar to those in other fungi (ergot, diketopipearzine, resorcylic acid lactones), and pathways that are so unique that the molecules they produce cannot yet be predicted. These pathways highlight that the capacity of entomopathogenic fungi for secondary metabolite production is far greater than their known chemistry. Accordingly, we have a primitive understanding of how SMs are involved with the interactions of these fungi with other organisms (123).

There is also considerable variability in the number of SM genes among species in the genus *Metarhizium*. In terms of PKS genes and putative polyketides, generalist *Metarhizium* spp., such as *M. robertsii*, possess a greater potential for the production of secondary metabolites than specialist strains and other sequenced ascomycetes (48, 51, 123). Acting collectively with the secretome, the number and diversity of these effectors may contribute to the ability of generalists to infect and kill a much wider variety of insects than specialists. This also relates neatly with pathogenic strategies because *M. robertsii* kills hosts quickly via toxins and grows saprophytically in the cadaver. The destruxins (cyclic peptide toxins) produced by many broad-host-range *Metarhizium* spp. also play a specific role in resisting host immunity, as they have been shown to suppress AMP expression (124) and variously block phagocytosis (125). In contrast, like many specialists, including the *Entomophthoromycota*, *M. acridum*

causes a systemic infection of host tissues before the host dies, which suggests a much smaller role for toxins (54, 126). It seems likely that specialists will have evolved specific adaptations to evade the immune systems of their particular hosts, whereas generalists that lack these specific adaptations produce toxins to kill the host before it has time to mount a significant defense.

Thus far, no *Metarhizium* SM has been shown to be *sine qua non* for pathogenicity (54, 127), except ferricrocin, which is considered by many to not be an SM, as it functions to sequester intracellular iron like many primary metabolites in other organisms (128). This highlights the complexity of virulence and host range in *Metarhizium* spp: the effect of a single toxic SM is not enough to drive either phenomenon (123).

Members of *Clavicipitaceae* (e.g., *Metarhizium* spp.) share few SM pathways with entomopathogens in *Cordycipitaceae* (e.g., *B. bassiana* and *C. militaris*). *Beauveria* produces its own large array of biologically active secondary metabolites (e.g., oosporein, bassianin, tenellin, beauvericin, bassianolides, and beauveriolides) and secreted metabolites putatively involved in pathogenesis and virulence (e.g., oxalic acid) that have potential or realized industrial, pharmaceutical, and agricultural uses (129). As with *Metarhizium* spp., the natural function of most of these metabolites is unknown, but oosporein suppresses insect host immunity (99).

Many other entomopathogens produce SM compounds with pharmaceutical applications and/or roles in antibiosis, pathogenesis, and competitive interactions between organisms (15, 124). For example, *C. militaris* produces cordycepin and cordycepic acids, which have been linked to a variety of benefits from antiaging to sleep-regulating effects (130). *O. sinensis* encodes four terpenoid synthases and one terpenoid cyclase that are absent in other fungi, indicating that it produces novel terpenoids. However, many putative secondary metabolism clusters were conserved between *O. sinensis* and other insect pathogens, providing singular exceptions to the restructuring of the *O. sinensis* genome by repeat elements, and suggesting that physically linking secondary metabolite biosynthetic genes has strong adaptive significance for entomopathogenicity. *Toylypocladium inflatum* produces a range of insecticidal compounds: most notably cyclosporine, an immunosuppressant in humans, as well as in insects, that is exploited to prevent transplant rejection. Phylogenomic analyses revealed complex patterns of homology between the NRPS that encodes for cyclosporin synthetase and those of other secondary metabolites with activities against insects (e.g., beauvericin, destruxins), and demonstrated the roles of module duplication and gene fusion of distantly related NRPS modules in diversification of NRPSs (131).

CONTROL OF INSECT BEHAVIOR BY PARASITIC FUNGI

Entomopathogenic fungi provide many classic examples of pathogens manipulating the behavior of their hosts, the so-called fungal extended phenotype (132–134). In fact, the Fungal Kingdom stands alone in the range, extent, and complexity of their manipulation of arthropod behavior (3). This ability fascinates both scientists and nonscientists alike: it is fascinating because it inspires the macabre and touches on core philosophical issues, such as the existence of free will, and it is of enormous practical importance because parasites are ubiquitous and many have a predilection for the "immunologically privileged" site of the central nervous system. However, this location also provides a parasite with direct "access to the machinery" to alter host behavior, and a very large number take advantage of this. Unfortunately, the significance of such parasitic infections of the brain and "mind" is still underappreciated with limited information on their public health impact, and their overall impact in many areas of ecology, physiology, and evolution. Fungi probably represent a special case in this general field because of several peculiar features that usually include causing host death at the end of an infection cycle. At this stage, the pathogen depends on efficient transmission to maximize its fitness, so selection will favor positioning the dying host in time and space to achieve this. Numerous studies have documented that entomophthoralean fungi kill insect hosts during the late afternoon or evening (135, 136). This ensures that cadavers sporulate under the humid conditions of night to infect new hosts. Rapid transmission is required because the longer a cadaver is present in the field, the greater the chance that it will fall, be overgrown with saprophytic fungi, or be eaten by a scavenger (134). In many cases, the final interactions between a host and pathogen involve the pathogen directing the infected insect to seek an elevated position where wind currents and gravity can effectively disseminate conidia (the so-called "summit disease"). Summit disease has evolved multiple times within both the *Entomophthoromycota* and *Ascomycota*, and often involves an induced death-grip behavior involving the insect's legs and/or jaws with wings outstretched to allow spores to be discharged from the body (132). Carpenter ants (*Camponotus* spp.) are probably the

best known victims (132). An *O. unilateralis* infection transforms these ants into "zombie ants"; ultimately the fungus directs the ant to wander upward and, around noon (possibly after a solar cue), secure itself by biting down on foliage (twigs in temperate woods and leaf margins in rainforests) (Fig. 4) (136, 137). After the death of the host, the fungus sprouts a fruiting body (ascoma) from the back of its head and, after a few weeks of subsequent growth, this starts to rain sexual ascospores down on passing ants as they move on the forest floor or on branches below (132, 138). The *modus operandi* of *Pandora formicae*, an entomophthoromycotan infecting ants in the genus *Formica*, is very similar to the zombie-ant behavior manipulation seen in *O. unilateralis*: *P. formicae* manipulates ants to leave their nest, wander up onto vegetation, and use their mandibles to secure themselves so fungi are well placed for active discharge of conidia from the soft areas of the ant carcass (139, 140).

Very little is known about the mechanisms behind behavioral manipulation, and research has more often ruled out mechanisms than proved them. For example, adult flies killed by entomophthoromycotan fungi are often highly sexually attractive, facilitating spread of infectious propagules, but this is not due to the production of a sex pheromone (141). However, recent transcriptomic studies on ants infected with *Pandora* and *Ophiocordyceps* offer major insights into the mechanisms and extent to which fungi can manipulate their hosts (55, 142). The *in insecta* transcriptome of *P. formicae* elucidated the machinery that articulates its extensive morphological changes in the host, and revealed upregulation of catalases, which protect against host oxidative defenses, along with host-degrading subtilisin- and trypsin-like proteases (142). These proteases were similarly upregulated by *O. unilateralis* in the death-grip phase of infection, along with enzymes affecting oxidation-reduction processes and modulating serotonin and dopamine, thus, likely also modulating behavior (55). *O. unilateralis sensu lato* also secretes a plethora of putative compounds that have an effect on behavior, including, potentially, ergot, enterotoxins, alkaloids, polyketides, and nonribosomal peptides (55). Ergot famously causes serotonergic overstimulation of the central nervous system in humans and livestock (143), and polyketides, nonribosomal peptides, and alkaloids can be neuromodulatory agents (144). It has also been hypothesized that muscle atrophy seen during an *O. unilateralis* infection may be due in part to fungal enterotoxins (138). When incubated with the brains of two host and two nonhost ant species, *O. unilateralis* produced a different chemical cocktail for each ant species, in a manner that suggested it "knows" the brains of its target hosts and reacts accordingly (44). This goes some way to explaining why different *Ophiocordyceps* species seem to infect only certain ants.

Also of particular interest are potential commonalities for behavior manipulators across kingdoms (55). *O. unilateralis* upregulated the secreted enzyme protein-tyrosine phosphatase (PTP) by >110-fold in its ant hosts. In baculoviruses, PTP has been shown to cause the migration of caterpillars upward into plant foliage before death: a convergent viral approximation of the fungal summit disease (145, 146). The activity of PTP in fungal manipulations of ant behavior has not yet been experimentally confirmed.

Summit disease is not the only behavioral manipulation produced by insect pathogens. In possibly the most highly evolved interactions, as they indicate a very high level of adaptation of the pathogen to the host, the fungus keeps the host alive and controls its flight behavior so that the insect becomes an aerial vehicle for spore release. There are many examples reviewed by Roy et al. (134), but the entomophthoromycotan fungal genera *Strongwellsea* and *Massospora* are the best understood. In the case of *Strongwellsea castrans*, the hosts are adult flies (3). The fungus causes a large circular hole to develop on the host's abdomen, and conidia are ejected from the flying insect through this hole. *Massospora cicadina* also initiates sporulation when its cicada host is still alive (Fig. 5) (147, 148). Eventually, the abdomen is entirely consumed,

Figure 5 Live cicada with its abdomen replaced by sporulating *Massospora cicadina*: the insect host disseminates the fungus during this stage of the disease. Image courtesy of Mike Raupp.

leaving just the head and thorax of the living insect. The cicada's ability to fly is retained, increasing dispersion of spores in the environment, especially in the case of infected male cicadas, which attempt to attract and copulate with females and even continue to feed (3, 149).

EVOLUTION OF SEX IN ENTOMOPATHOGENIC FUNGI

Teleomorph hypocrealean states have much narrower host ranges than anamorphs, prompting the interesting question of how closely related fungi could differ so fundamentally in ecology depending on sexual state (49). Comparative genomics of entomopathogenic fungi has confirmed they exhibit diverse reproductive modes that often determine the rates and patterns of genome evolution and are linked as cause or effect with pathogenic strategies (15). The three modes of sexual reproduction in ascomycetous fungi, i.e., heterothallic, homothallic, and pseudohomothallic, are governed by the mating-type (*MAT*) locus (150, 151). The haploid genome of heterothallic species carries only one of the *MAT* loci, and, thus, they require a haploid partner with a compatible *MAT* locus to complete the sexual cycle. Homothallic species (self-fertile) have both loci in their haploid genomes, while the pseudohomothallic species are similarly self-fertile, but they contain two compatible haploid nuclei within their sexual spores (152). Most members of the three hypocrealean entomopathogen families (*Clavicipitaceae*, *Cordycipitaceae*, and *Ophiocordycipitaceae*) are heterothallic and are therefore potentially outcrossing fungi. Signs of sex in supposedly asexual species include footprints of Repeat Induced Point (RIP) mutations, a genome defense mechanism specific to fungi, occurring only during the sexual stages on repeated sequences. The consequences of RIP mutations are that repeated DNA segments, such as those that would result from the transposition of a retrotransposon or the duplication of a gene, are inactivated by mutations. Calculations of RIP indices indicated that RIP mutations occur in narrow-host-range species, *M. album* and *M. acridum*, but not in the broad-host-range species such as *M. robertsii*, which suggests retention of sexuality in specialists, although their sexual stages have not been verified (48). Intriguingly, therefore, asexuality in *Metarhizium* spp. is associated with broad host ranges and sexuality with narrow host ranges, consistent with the narrow host range of known teleomorph states. Unlike *C. militaris*, which is specific to lepidopteran pupae, the closely related *B. bassiana* has a wide host range. *B. bassiana*, like generalist *Metarhizium* spp., lacks the RIP mutations, consistent with the sexual cycle being rare (54). RIP is incompatible with gene duplication events, so its absence is consistent with expanded gene families and more transposable elements (TEs) in the *B. bassiana* and *M. robertsii* genomes, relative to *C. militaris* and *M. acridum*. It is possible, therefore, that losing sexuality, and therefore RIP, was a prerequisite for generalists expanding gene families.

In contrast to the other sequenced insect pathogens, which are all heterothallic, *O. sinensis* contains two compatible MAT loci in the genome and is sexually self-fertile, i.e., homothallic (33). It is likely that inbreeding is an adaptation by *O. sinensis* to its small population size resulting from a very specialized lifestyle and the extreme environmental conditions in its small geographical range. The *O. sinensis* genome size is approximately three times larger (~120 Mb) than other ascomycete insect pathogens, but, whereas they contain more than 9,500 protein-coding genes, *O. sinensis* has only 6,972 genes (33). The RIP mechanism is dysfunctional in *O. sinensis*, which has probably contributed to a massive proliferation of retrotransposable elements, and thus genome size inflation, and the large number of retrotransposed and fragmented pseudogenes in the genome implicates retrotransposition in most of the gene losses in *O. sinensis*. It has been proposed that plant pathogenic fungal lineages with large and flexible genomes are likely to adapt faster during coevolution with hosts (153). The massive proliferation of transposable elements in the inbreeding *O. sinensis,* may provide a trade-off between advantages of increased genetic variation independent of sexual recombination and deletion of genes dispensable for its specialized pathogenic lifestyle. As *O. sinensis* has lost many genes for expanding its host range, future transitions away from its current lifestyle seem unlikely, indicating that, while retrotransposition may facilitate rapid adaptation, it may also contribute to stable host interactions.

CONCLUSION

Nearly all fungal phyla have representatives that have convergently evolved pathogenicity to insects. Identifying commonalities and differences between these fungi is providing a comprehensive picture of the mechanisms they use for pathogenicity, and how new pathogens emerge with different host ranges. Bioinformatics and sequencing technology have already contributed greatly to the study of insect pathogenic fungi, particularly the hard to culture obligates, and promise further

breakthroughs in some of the more intractable aspects of this field, e.g., behavior manipulation and evolution of host specificity. Bolstered by this influx of information, entomopathogenic fungi are emerging as models for understanding how pathogens in general respond to and evolve in changing environments, initiate host invasion, colonize tissues, and counter host immune responses. These pathogens offer us a glimpse into the diverse answers fungi have to the question, how best to kill an insect?

Made for Each Other: Ascomycete Yeasts and Insects

46

Meredith Blackwell

INTRODUCTION

The classic work of Paul Buchner in the first half of the 20th century established the common occurrence of symbiotic associations between microbes and animals, often a fungus association hidden from view within an animal gut (see reference 1). Interest in the fungi associated with insects continues (2–9), and recently renewed interest comes from the molecular techniques available to study the interactions.

In the mid-1990s I was asked by a prominent ecologist how I would go about undertaking one of the trendy things in field biology at the time: conducting an all-taxon biological inventory of fungi (10). In addition to surfaces of everything, I suggested sampling the internal parts of every plant and animal within the boundary of the survey. As an entomologist, he recognized the enormity of such an inventory, a task probably not worth the effort with the methods available at the time. Soon after that conversation many new fungus-arthropod associates were discovered using the standard techniques of dissection and culturing internal insect parts, especially intestinal tracts, and with the aid of new DNA sampling methods, progress was faster. Often, newly discovered gut fungi were yeast-like in form (11), and new taxa and lineages of yeasts were found associated with insects. Boekhout (12) pointed out that only 6% of the yeast strains in the CBS-KNAW collection had come from insect sources, a percentage that is increasing today.

YEAST: A POLYPHYLETIC GROWTH FORM IDEAL FOR ANIMAL SYMBIOSIS

"Yeast" is a growth form, and yeasts have common morphological traits but do not form a monophyletic group (13–15). A simple description that covers the disparate taxa of fungi known as yeasts is that "yeasts bud" (Fig. 1). Any fungus that is characterized by production of budding cells in asexual reproduction has been called a yeast or yeast-like fungus (Fig. 1, Fig. 2). Alternative forms of asexual reproduction such as conidium formation also may occur in a budding individual. Pseudohyphae are connected buds that do not separate from each other, and the cells may elongate to look like filaments. True hyphae are developmentally different because they are formed by extension and elongation at the filament apex without budding.

Historically, one subphylum of Ascomycota, Saccharomycotina, has been known as "the yeasts." When yeasts in Saccharomycotina reproduce sexually, they lack specialized sex organs, and ascospores (Fig. 3) are produced in somatic cells converted into naked asci, that is, asci not amassed in a common structure, an ascocarp. Some members of Pezizomycotina (e.g., *Symbiotaphrina* spp. and unnamed obligate associates of planthoppers) have yeast growth and have been called yeasts but also yeast-like symbionts (YLSs), to distinguish them from Saccharomycotina yeasts. In addition to existing as budding cells, some fungi are dimorphic with an individual changing between budding and hyphal growth depending on environmental conditions. Changes occur when certain dimorphic fungi assume yeast morphology in association with an insect host (e.g., the mycangia of many ambrosia beetles) but undergo hyphal growth when they are free-living. A similar switch between growth forms is well known in certain animal pathogens (e.g., Onygenales).

Until recently yeasts have been difficult to identify and classify. Because single cells provide few morphological characters, 19th century workers relied on methods used by bacteriologists. The outcome was 2-fold: the availability of many phenotypic characters and the

DNA sequencing indicates it has arisen independently several times, not only in yeasts, but also in Pezizomycotina. Scale bar = 5 μm. Photograph courtesy of S.-O. Suh.

realization of the biochemical potential of yeasts. With the onset of DNA-based classification in the 1980s, DNA-DNA reassociation attempted to give a genetic basis for relationships, but methods for yeast identification plus phylogenetic assessment only came later with the development of PCR and the use of the D1/D2 region large subunit ribosomal DNA (rDNA) sequencing methods and a large database for making comparisons (16). A broad sampling of 500 species of ascomycete yeasts and the newly defined species limits acquired by this method were equilibrated with results derived from previous methods, including information on outcrossing. Kurtzman and Robnett (16) found that conspecific strains generally had fewer than 1% nucleotide substitutions in the D1/D2 region, and different species usually were separated by more than 1% substitutions. Beyond a means to separate species, the ability to perform phylogenetic analyses was an equally important outcome for yeast systematics and evolution. The paper marked the beginning of a new era in yeast systematics, and with that start yeast biologists have gone on to sequence many genes and entire genomes (e.g., http://genome.jgi.doe.gov/saccharomycotina/saccharomycotina.info.html).

As mentioned earlier, yeast growth at some stage in the life history is a trait of many fungi that are closely or obligately associated with arthropods, but not all yeasts are documented to be arthropod-associated. The yeasts discussed in this article are ascomycetes, members of Saccharomycotina and Pezizomycotina. The yeast growth form, however, is well established in certain members of other taxonomic groups (Table 1), few of which have insect associations beyond dispersal (e.g., Tremellales, Ustilaginomycotina, Pucciniomycotina, and in addition to the Saccharomycotina among the Ascomycota, the Taphrinomycotina and Pezizomycotina). In the past the assumption was that the yeast form probably arose independently on a number of occasions. Information derived from fungal genomes, however, indicates that not only was the genetic information to determine yeast growth present early in the divergence of the fungal lineage, but a conserved genetic toolkit for the yeast factor persisted in many fungal lineages. The sporadic occurrence of yeast forms by what was described as "latent homology and convergence regulatory evolution" possibly involves parallel diversification of Zn-cluster transcription factors known to regulate switches in yeast-filamentous growth (17). The explanation fits the observed pattern of yeast appearances and disappearances throughout much of the

Table 1 Some common insect-yeast and YLS associations[a]

Phylum: Subphylum	Examples of insect-associated yeasts and YLSs
Ascomycota: Saccharomycotina	Many clades, especially *Suhomyces tanzawaensis*, *Teunomyces kruisii*, cactophilic yeasts, *Ascoidea*
Ascomycota: Pezizomycotina	YLS *Symbiotaphrina* of anobiid beetles, YLS of planthopper, dimorphic ambrosia fungi in Ophiostomataceae and Ceratocystiaceae
Basidiomycota: Pucciniomycotina, Agaricomycotina	*Septobasidium*, sciricid wood wasp associates (*Amylostereum*), ambrosia beetle associates (*Entomocorticium*, *Phlebiopsis* cf. *gigantea*, *Peniophora*, *Flavodon*)

fungal tree of life. The triggers of the genetic switches, however, have not been identified.

WHY YEASTS AND INSECTS?

Insects, the most successful group of animals on Earth as measured by their species and individual numbers and the diverse habitats they occupy, lack the ability to synthesize sterols, many vitamins, and enzymes to degrade plant cell wall materials and toxic plant allelochemicals. Many insects depend on microbes, including fungi, for their success. Besides direct ingestion of fungi such as mushrooms, ambrosia fungi (see below), and hyphal gardens in Old World termite and New World ant galleries, many more insects benefit from enzymes used to degrade intractable carbon compounds (18, 19) and toxic plant metabolites. Yeasts provide essential amino acids, vitamins, and sterols and produce allelochemicals to attract the insect dispersers for targeted dispersal to a fresh environment (1). The very word "enzyme," derived from a Greek word meaning "leavened," denotes a process carried out by yeasts. A need for insect "probiotics" to acquire carbon is easy to imagine when one considers the diet of partially rotted wood ingested by some insects throughout their entire lives (see section on passalid beetles below).

Yeasts and other fungi provide sterols and vitamins, and although they do not fix atmospheric nitrogen as prokaryotes do, fungi have enzymes to recycle the nitrogen wastes of insects (see section on planthoppers below). Often, less is known about the symbiotic advantage for the fungus, but it is assumed to be a stable environment with a dependable food source and transportation to a new habitat when the old one is depleted. The general term "symbiosis" is often used to cover all types of interactions (e.g., reference 20). The term "endosymbiont" describes a microbial partner within the body of an insect host; "endocytobiont" indicates that the microbial symbiont is located within cells of the host. The examples discussed in this chapter all involve positive interactions for at least one partner, ranging from "horizontal" dispersal on the surface of insects to obligate associations between yeasts and their hosts, in these cases almost always accompanied by "vertical" transmission of microbes from a parent.

INSECT ADAPTATIONS FOR FUNGAL ASSOCIATIONS

Many arthropods are associated with eubacteria and archaea, but individuals of the same species usually have fungal associates (1). Moran, Dillon, and their colleagues (21–23) discussed the importance of beneficial prokaryotic microorganisms to the success of insects, and many of their ideas apply equally well to fungal associations with insects. Engel and Moran (23) summarized factors involved in initiation, retention, and transfer of insect-associated gut microbes: (i) microbial intake through food, the environment, or social interactions; (ii) appropriate physical conditions (pH, O_2 levels, available nutrients) in the gut; and (iii) microbial transfer by egg smearing, eating of frass (excrement), or feeding by offspring at mouth or anus of mature insects to acquire microbes. Modifications to retain and transmit symbionts are numerous, especially in the insect gut.

Insect intestinal tracts are divided into three chambers: foregut, midgut, and hindgut (Fig. 4); differences in the nutrition of the insects are reflected in the physiology and morphology of the gut regions. The gut varies within an individual over different life stages, especially in insects with "complete" (holometabolous) life cycles (having egg, larva, pupa, and adult stages). Physiological differences of the gut significantly affect microbial symbioses, such as fungi favoring the more acid or aerobic areas. In some cases larvae and adults use different food, and these differences are reflected in modified morphology and microbial communities in a single life cycle. Characteristics associated with symbionts include hindguts that are enlarged and differentiated into several regions as in the hindgut of some wood-ingesting insects (see section on passalid beetles below). In other insects midgut modifications including elaborate gastric caeca are evident (see section on anobiid YLSs below).

Major changes in the gut occur when the chitinous exoskeleton covering the soft bodies of immature insects is lost through molting. The cuticle extends inward, lining the inner surfaces of both foregut and hindgut. As long as the insect continues to grow, the cuticle continues to be shed, and associated foregut and hindgut microbes are lost and must be reacquired. In some cases midgut microbes may be affected when the "peritrophic" membranes lining the midgut are disrupted. Midgut caeca or crypts, however, may help to protect against such loss (23).

Other insect structures that house yeasts are gastric caeca and fat bodies. Gastric caeca are pockets that develop off the anterior midgut. Gastric caeca of roaches, stinkbugs, and some aphids are filled with bacteria, while other insects, especially beetles (e.g., anobiids, erotylids, cerambycids, and tenebrionids), contain yeasts. The fat body is a mass of fatty cells that surround the gut, and this major organ is involved in storage and

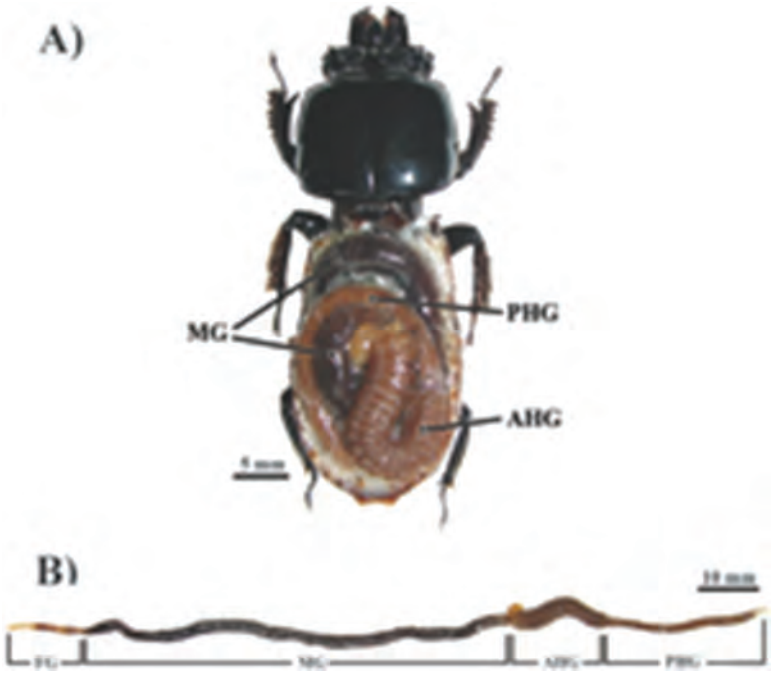

Figure 4 *Odontotaneus disjunctus* (Passalidae). (**A**) Partially dissected beetle shows the gut and its regions *in situ*. (MG, midgut; PHG, posterior hindgut; AHG, anterior hindgut. (**B**) Foregut (FG), MG, AHG, and PHG removed from the beetle. utilization of nutritional reserves, functioning somewhat like a liver. Fat body reserves maintain the insect during energy-depleting activities such as life stage transformations and egg laying. In some planthoppers and aphids the YLSs (see below) are packed into the fat body.

Some insects have invaginations in their exoskeletons that form "mycangia" (pockets) in which they carry fungal spores or yeast cells. Francke-Grosmann (24) discovered "skin glands" in female ambrosia beetles, later renamed "mycangia" (25). The mycangia they studied were glandular structures with secretions probably beneficial to the YLS carried within mycangia. Mycangia can be located on different parts of the insect body, including head, mouthparts, "pronotum" (the covering of all or part of the dorsal thorax) (Fig. 5), sternum, and even legs and wings (26). The use of mycangium has been broadened to include structures that vary in complexity from simple pits and crevices in the exoskeleton to the complex glandular structures that support growth and multiplication of the yeast cells within (27). The term also has been applied to fungus-bearing structures in other beetles (e.g., Lucanidae, Erotylidae), wood wasps (Siricidae), and even the saddlebag-like structures of mites that transport fungal spores in bark beetle habitats.

Insect behavior helps to determine how effective transfer of symbionts to new generations will be. The close contact of "eusocial" insects (those characterized by cooperative broods, overlapping generations, and division of labor into reproductive and nonreproductive types), such as bees, wasps, ants (Hymenoptera), and termites (Isoptera), ensures microbial transmission to the offspring. Other insects, while not considered to

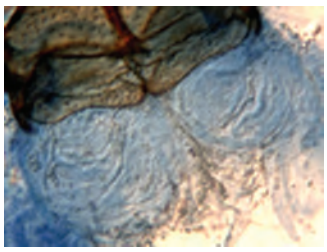

Figure 5 *Xylosandrus amputatus* (Curculionidae: Scolytinae: Xyleborini). Large, complex bilobed mesonotal mycangium (stained blue) with opening on the pronotum; spores of the mycangial symbiont *Ambrosiella nakashimae* at the edge of the pronotum. Fungi in Ceratocystidaceae, including *A. nakashimae*, have close associations with certain species of beetle and produce arthrospore-like cells rather than yeast-like budding typical of other ambrosial symbionts. Photograph courtesy of Chase G. Mayers.

Figure 6 *Pselaphacus nigropunctatus*, a species of beetle (Erotylidae) with parental care; red speckled adult beside a late instar larva (grub) on white basidiocarp of a wood-decaying fungus in Bolivia. Photograph courtesy of J.V. McHugh.

have a high level of social organization, do have parental care, including a surprising number of beetles (Erotylidae [e.g., *Pselaphacus* spp.; Fig. 6], Carabidae, and Curculionidae [Scolytinae, Platypodinae] [J. V. McHugh, personal communication, February 2016]), and many of these insects have microbial associates.

YEASTS IN INSECT HABITATS

Cactophilic Yeast Communities

Drosophila spp. lab stocks are fed yeast diets, so it should not be surprising that the flies are closely associated with yeasts in nature. Experimentation with appropriate yeasts as food for flies continues today (28, 29). In one example genetically modified *Saccharomyces cerevisiae* fed to *Drosophila suzukii*, an invasive pest of soft-skinned fruits such as cherries, may have potential as a RNAi pesticide. Flies fed on the modified yeast cells displayed reduced locomotor activity and other measures of reduced fitness (30).

An understanding of the interactions of cactophilic yeasts, their *Drosophila* dispersers that eat and breed in necrotic lesions of columnar cacti, the cacti, and cactus secondary metabolites comes from more than 40 years of study by William Heed, his students, and colleagues (31–39). The Sonoran Desert assemblages evolved in Arizona and adjacent Mexico under conditions of high stress. Based on their study, Starmer and his colleagues (36) suggested that "cactus chemistry, environmental extremes, and vector associations and interactions" were the likely strong selective factors involved in the origin of the community assemblages. Some of the yeasts detoxify cactus fatty acids and aromatic compounds toxic to the flies, and many of the yeasts have distributions limited by their dispersers (39). A pattern of disperser influence on yeast biogeography also has been seen for yeasts associated with insects in other habitats (e.g., ephemeral flowers and mushrooms; see below). For these reasons yeast populations of columnar cacti, such as senita and saguaro, are relatively stable in species numbers and composition over time and space. In addition to a core group of yeasts associated only with the Sonoran Desert, however, some yeasts are more widespread.

Phylogenetic methods have helped to settle some questions of the origin of the desert yeast communities, which likely are descended from local yeast communities in slime fluxes and fruit rots that evolved as the desert developed. Evidence comes from phylogenies indicating a pattern of many independent yeast origins, rather than diversification from a few common ancestors. Starmer and his colleagues (36) also estimated the age of the cactus-yeast community based on the current ideas of the origin of Cactaceae. Since that time, a more recent date of around 30 to 35 million years ago has been suggested, with current cactus diversity having evolved, perhaps, as recently as 5 to 10 million years ago (40, 41). Additional study of this system offers an opportunity to determine more precisely the rate at which multiple species of yeasts arise under strong selection pressure in desert environments.

Ephemeral Flower Communities

Sap beetles (Nitidulidae) and *Drosophila* spp. are geographically widely distributed, and certain lineages have evolved varied nutritional modes. For example, some nitidulid subfamilies use fermenting plant juices, decaying fruits, or mushrooms as food, while a distinct group visits ephemeral flowers. Lachance and his colleagues (42–47) isolated yeasts from ephemeral flowers (Convolvulaceae, *Hibiscus* spp., Cactaceae) and "insect walk plates" from the flower-visiting beetles in a number of noncontiguous regions, including Hawaii, Australia, Brazil, Costa Rica, Arizona, California, and the Great Lakes region of the United States.

In experiments with bagged morning glory flowers, ascomycete yeast communities did not develop in the flowers, indicating that insect dispersers were the source of yeasts. Many of the yeasts (e.g., *Metschnikowia* spp., *Kodamaea* spp., *Wickerhamiella* spp.) appear to be very specific to the flower habitat (43). The yeast communities isolated from flowers were distinct from those of nonflower tissues of the same plants. The flower-inhabiting yeasts varied in their physiological profiles,

but most had several properties in common (L-sorbose assimilation, lipid hydrolyzation, growth at high osmotic pressures), properties assumed to be correlated with the use of flowers and nectar. In Costa Rica when yeasts from honeybees were compared to those of beetles visiting the same flowers, the insects carried different yeast species, notably *Starmerella* spp., by bees. This study indicated that distinctive communities were determined largely by the dispersers (43, 47).

Mushroom- and Other Fungus-Feeding Beetles

Other yeast-insect associations include beetles that eat mushrooms and other fungi. Certain yeasts were recovered reliably from the gut of the beetles and drosophilids and less often from their habitats (48–50). Drosophilids collected from *Russula* spp. ingested species of *Suhomyces* and *Teunomyces*; the yeasts from the mushroom habitat were distinct when compared to those of other habitats, but the total diversity was low (51). Sexual reproduction is unknown in many of these species, and they appear to be tied to the beetle dispersers rather than the mushroom substrates (48). As mentioned above, cactophilic and ephemeral flower yeast communities also are more closely associated with the dispersers. Little information is available on the interactions between the yeasts and insects, but cultural studies using the standard battery of yeast physiological tests have shown that most of the yeasts produce a wide variety of B group vitamins, ferment glucose and trehalose, and assimilate a wide variety of the carbon sources used to characterize yeasts (52). The common yeast physiological attributes suggest a benefit to the beetles. The presumed absence of sexual reproduction in the yeasts, moreover, implies some degree of dependence of the yeasts on the insect host for transmission, resulting in "mutual beneficiality" discussed by Aanen and Boomsma (53) (see also reference 54).

Nakase isolated *Suhomyces tanzawaensis* in 1966, but he did not formally describe the species until 1988 (as *Candida tanzawaensis*), because he waited in vain to find a second strain. Thirteen years elapsed before any close relatives were discovered (55); eventually the species was recollected and 16 more close relatives were discovered in the habitats and guts of mushroom-feeding beetles (56). Members of the clade, now placed in *Suhomyces* (52), are not rare, only concealed in what was then an unexplored gut niche, especially of erotylid and tenebrionid beetles (Fig. 7). *Suhomyces* spp. have been isolated in the United States, Panama, Japan, The Netherlands, South Africa, and Thailand, almost always in beetle guts or beetle habitats. For example, in a month-long study in Panama, nearly 30% of over 600 yeast strains collected from mushroom-feeding beetles were members of the *S. tanzawaensis* clade (56). The gastric caeca located at the anterior end of erotylid midguts are packed with yeasts, and some of the beetles have parental care, increasing the possibility for transfer of yeasts to the offspring.

Figure 7 The name of the yeast genus *Suhomyces* recognizes Dr. Sung-Oui Suh for his studies of yeasts in the field and laboratory. Barro Colorado Island, Panama, July 2002. Photograph, M. Blackwell.

A trend toward specificity was observed with *Teunomyces* spp. (formerly *Candida kruisii* clade) (52) and mushroom-feeding beetles in Nitidulidae (Fig. 8). *Teunomyces* spp. were isolated not just from nitidulids, but often specifically from *Pallodes* spp. in both Central America and the United States (57). Several other yeast clades are associated with mushroom-feeding beetles, and while there is no strict species-species level specificity, certain patterns have been observed over several geographical regions as was seen in the ephemeral flower communities.

Although filamentous fungi and bacteria may have been present in the gut of the fungus-feeding beetles, none was reported in the studies relying on isolation of microbes on acidified agar medium. Furthermore, usually a single species of yeast was isolated from an individual beetle. A similar trend of low species diversity in drosophilids also was reported (51). Such low microbial gut diversity is unusual, and these observations

Figure 8 Four yeast biologists (l. to r. Drs. Marc-André Lachance, Clete Kurtzman, Jack Fell, and Teun Boekhout) at a coffee break at a meeting to celebrate the centenary of the CBS-KNAW Fungal Biodiversity Centre (since February 10, 2017, known as the Westerdijk Fungal Biology Centre), Utrecht, The Netherlands, in Amsterdam, April 2004. The genus *Teunomyces* recognizes the research of Dr. Boekhout; all the others also have yeast genera named for them and are cited in this chapter. Photograph M. Blackwell.

need to be confirmed. Are they due to artifacts of isolation, the gut physiological conditions, or perhaps the presence of killer strains of *Suhomyces* spp. as previously suggested (S. Lu and M. Blackwell, unpublished observations)?

Ambrosia Beetles Eat Fungi and Their Cultivated Fungal Symbionts

Ambrosia beetles tunnel into sapwood (conducting xylem) to inoculate fungi into the galleries. Some fungi are carried as yeasts in mycangial pouches (Fig. 5), often by female beetles (see above) (24, 25, 58, 59). By the time the eggs have hatched, the yeast-like fungal growth is ready to be larval food. Although described earlier by a forest pathologist, it was the work of Francke-Grosmann that created interest in the ambrosial fungi. Interestingly, Batra's curiosity about ambrosia beetles and their fungi was piqued when he observed ambrosia beetles attracted to beer at a picnic (Lictwardt, personal communication, June 1990).

Many ambrosia fungi are dimorphic, alternating between yeast-like and hyphal phases, growing as yeasts within mycangia and tended in beetle galleries as special hyphae (yeast-like sprout cells described by Batra in 1967) (59) or as more typical hyphae when untended in abandoned galleries. Beetles and fungi form assemblages that evolved independently multiple times, perhaps driven to the xylem to avoid competition in bark habitats (60). Ambrosia beetles are members of the weevil family (Curculionidae), mostly members of Platypodinae, but some also of the derived tribes (Corthylini and Xyleborini) of a second subfamily, Scolytidinae. The fungi, members of the Ophiostomatales, *Ophiostoma* clade (e.g., *Raffaelea* spp.) (61), and the Microascales, *Ceratocystis* clade (*Ambrosiella* and *Meredithiella*) (62, 63), include species associated with both beetle subfamilies. About 3,400 species of Scolytidinae and Platypodinae have an ambrosial habit, but incredibly, only about 35 species of ambrosia fungi (~1%) have been identified from the beetles;

even fewer ambrosia fungi have been given formal names (60).

The taxonomic problems caused by sexual and asexual species related to *Ophiostoma* and *Ceratocystis* are complex, because convergent morphological characters used to promote insect dispersal were previously used in taxonomy. Convergent evolution of many independently arising sexual and asexual taxa and the overwhelming numbers of these fungi require molecular characters for their revision. Great progress has been made when one considers that many of the unrelated fungi once were considered members of a single genus. Although some ambrosia beetles are associated with more than one fungal associate, one species is sometimes designated as the primary symbiont, although this may not always be appropriate. The work of Mayers and his colleagues (63), however, supports specificity of associations between insects with large complex mycangia and their fungal associates, underscoring the probability that many more ambrosia fungi await discovery and description.

An unusual behavior evolved independently on several occasions in some tropical lineages of ambrosia beetles (e.g., *Diuncus* spp.). The beetles lack mycangia to carry their own symbionts, but instead break into the brood chambers of host beetles of a different species to steal their fungal provisions. The behavior could be energetically efficient for the thieves but often is detrimental to the success of the invaded beetles (64). Ambrosia fungi also grow in association with Saccharomycotina yeasts, especially *Ambrosiozyma* spp. (65), and still other beetles are associated with a few basidiomycete yeasts that also are carried in mycangia (66–68).

Most ambrosia beetle-fungal associations do little harm to trees because they provision their galleries in sapwood, but some invasives do cause plant disease (60). The redbay ambrosia beetle, *Xyleborus glabratus*, was introduced relatively recently into the United States from Asia in wooden packing materials (69–71), and the beetle brought with it an aggressive mycangial fungus, *Raffaelea lauricola*, the agent of laurel wilt. Laurel wilt is a lethal vascular wilt disease of southeastern U.S. native redbay (*Persea borbonia*), a member of the laurel family (Lauraceae). Female beetles are attracted to healthy trees by the aromatic volatiles the plants produce, not by aggregation pheromones (or beer) as with other ambrosia beetles. Wilt symptoms occur after the beetle carries the fungus into water-conducting xylem tissues, where the tree reacts by producing "tyloses" (plugging structures) and gums in an attempt to seal off the fungus. Rather, the conducting cells become clogged and water movement upward in the tree is prevented. Symptoms in redbay, such as branch dieback (flagging), followed by rapid death of the tree, are typical of wilt diseases. The beetle and fungus have spread to the south and west, and they have infected additional New World native Lauraceae, including sassafras and several threatened or endangered species, as well as commercial avocado (*Persea americana*) plantings in Florida (69, 70). In the case of a lack of resistance, however, cooperation between fungus and beetle has begun a cascade that may lead to several extinctions in the New World environment. Two species of swallowtail butterflies, the palamedes and spicebush swallowtails, feed largely on three at-risk members of Lauraceae, and butterflies and native laurels are all imperiled (North Carolina Forest Service, http://www.ncforestservice.gov/forest_health/forest_health_laurelwiltfaq.htm).

A pattern of natural selection for resistance in the native region is common in plant and animal infections. For example, Lauraceae in Asia would not be expected to show disease symptoms where the fungus was also native. The same observation can be made in the southeastern United States, where an Asian native of the laurel family, the camphor tree (*Cinnamomum camphora*), was introduced in the late 19th century for commercial purposes that were unsuccessful. The camphor tree has resistance to *R. lauricola* that evolved in Asia and does not have disease symptoms in the New World, but the symptomless plants may act as a reservoir for the fungus (72).

The earliest of all fungus-growing beetles to evolve may have been cucujiform beetles in the family Lymexylidae (73). These beetles have sometimes been called ambrosia beetles, although they are better known as ship-timber beetles. Most species of lymexylids are uncommon, but a few species have caused periodic dramatic losses of living coconut palms as well as of trees and cut timber in southern Asia. In North America certain species have become relatively rare because ships are no longer built of wood, and one beetle has lost most of its specialized habitat to chestnut blight (73).

The ship-timber beetles and their interactions with fungi are poorly known compared to ambrosia beetles in Scolytidinae and Platypodinae. The females of several species are reported to carry yeast cells and eggs in a slimy matrix in vaginal pouches, considered to be mycangia, and to deposit them into weakened or decaying conifer and hardwood trees and building timbers; the movements of early instar larvae have a part in spreading the yeasts to eggs and other larvae in the galleries (58, 74). *Ascoidea africana* (Fig. 9) and *Ascoidea*

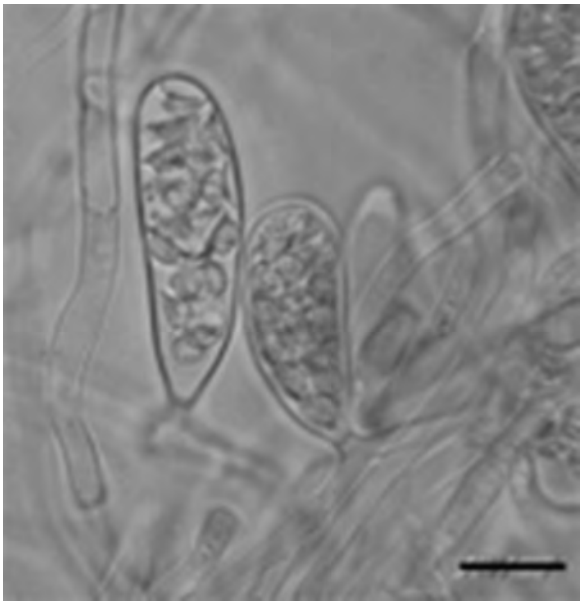

Figure 9 *Ascoidea asiatica* (NRRL Y-17632), an ambrosia fungus disseminated by insect vectors, was isolated from a beetle larva in wood. This species has been reported to be associated with lymexylid ship timber beetles. Asci with hat-shaped ascospores developed on agar, although budding cells and abundant hyphae are also produced under the cultural conditions. Hat-shaped ascospores are a convergent character (see Fig. 3). Scale bar = 10 μm. See reference 133. Photograph courtesy of Cletus Kurtzman.

hylecoeti (Saccharomycotina) have been reported as symbionts of several species of lymexylids, although the yeasts also are found to be free-living (75, 76).

Wood-Ingesting Passalid Beetles

The rich microbial communities of the gut of wood-ingesting beetles, *Odontotaenius disjunctus* and relatives (Passalidae), are separated in compartmentalized guts (Fig. 4) with marked oxygen and pH gradients, sometimes in close proximity (77, 78). Bacteria (e.g., methanogenic and nitrogen-fixing bacteria) as well as yeasts and other eukaryotes (cellulose-degrading flagellates related to those of termites) are partitioned within gut regions that are more anaerobic. Most of the yeasts are able to assimilate xylose (a component of hemicellulose, a plant wall polysaccharide) and some clades ferment xylose (79–81). For example, the xylose-fermenting yeast genus *Scheffersomyces* is attached to the hindgut wall by a holdfast (77), where thalli remain attached in adult and larval beetles as food passes through the gut (Fig. 10). Recently pupated adults reacquire the yeasts after the final molt from gallery walls, provisioned by adults with a mixture of wood and spore-containing frass. Lichtwardt and his colleagues (82) isolated *Scheffersomyces stipitis* (as *Enteroramus dimorphus*) from the hindgut of *O. disjunctus*, where it grew as a filamentous un-yeast-like fungus attached to the beetle gut wall. It was only after DNA sequencing that the fungus was identified as *S. stipitis* (83). In addition to the *Scheffersomyces* clade, members of the *Spathaspora* clade also contain xylose- and cellubiose-fermenting yeasts (81). Because of their ability to ferment xylose to ethanol, biotechnological interest in *Scheffersomyces* spp. and *Spathaspora passalidarum* continues to increase (84, 85). Several other yeasts with similar properties also have been found in rotting wood, and some of these may be efficient for ethanol or xylitol production from sugarcane bagasse (86).

Other yeasts present include additional ascomycete lineages but also several basidiomycete yeast groups, all common in the wood-inhabiting beetle gut in North and Central America, Thailand, and Australia. The yeast lineages usually assimilate xylose, but because many appear to be located in the hindgut, where absorption may be minimal, benefits to the beetle and yeasts are not clear. The yeast communities, however, are fairly stable and present in the gut of all larval and adult wood-feeding beetles that have been examined (80, 87, 88).

Saccharomyces cerevisiae in the Gut of Paper Wasps

In addition to the nutritional and antibiotic benefits of bacteria in the gut of insects, gut conditions in some insects were described as favorable for bacterial conjugation and therefore as "hotspots" for bacterial gene

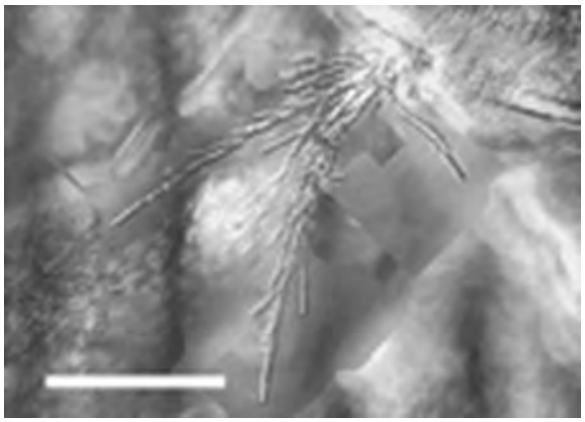

Figure 10 Water mount made without a cover slip of the interior hindgut of *Odontotaenius disjunctus* (Passalidae) showing several thalli attached along a furrow in the hindgut. Scale bar = 100 μm. See reference 77.

transfer (21). A similar phenomenon has been reported for *S. cerevisiae* and *Saccharomyces paradoxus* yeasts in the gut of social wasps (*Polistes* spp.). *S. cerevisiae* is one of the best known of all eukaryotic organisms. As a model organism and the basis of multibillion-dollar-a-year industries, it was the first eukaryotic organism to have its complete genome sequenced. We know, however, much less about its natural history, especially sexual reproduction in nature. On a number of occasions the yeast was isolated from the bark of forest trees, often oak (*Quercus* spp.) (e.g., references 50, 89). Some species of social wasps, also known as "paper wasps," chew wood and bark into a pulp, the paper with which their nest is built, and perhaps chewing on bark or feeding on rotting fruit as they are known to do could be the source of the yeasts in their guts (90) (see also reference 91). Stefanini and her colleagues (90) found interspecific hybrids between *S. cerevisiae* and *S. paradoxus* in the vicinity of their study area, a finding that led to experiments to determine the source of the hybrids. New data supported the presence of high levels of *S. cerevisiae* heterozygosity and interspecific hybrids between *S. cerevisiae* and *S. paradoxus* in the wasp gut. In their experiments Stefanini and her colleagues (92) fed genetically marked strains of the two yeast species to wasps, and hybrids were isolated at increasingly higher levels over time in hibernating wasps. The pure experimental strains of *S. paradoxus* chosen for the experiments could not survive gut passage, but the hybrids did, evidence that in addition to *S. cerevisiae*-*S. cerevisiae* crossing, hybridization with even higher levels of recombination was promoted in the wasp gut.

Anobiid YLSs: *Symbiotaphrina buchneri* and *Symbiotaphrina kochii*

Species of *Symbiotaphrina*, YLSs of beetles in the family Anobiidae, are housed in caeca at the anterior end of the insect midgut, and the female transmits yeast cells to the next generation by smearing them on her eggs. The larvae acquire the cells as they emerge from the eggs. Although the yeasts grow easily in agar culture and have been isolated as endophytes, host beetles have never been found without YLS in nature. Colonies of *S. buchneri* in culture are described as reddish-brown and mucoid, with clavate or pyriform cells having distinctive budding; mycelium is not formed and sexual reproduction is unknown (93).

The yeasts provide nutrients, including B group vitamins and sterols, to their hosts (e.g., reference 94). The yeasts also have attracted interest because the beetles live in processed plant material that contains toxic allelochemicals. *S. kochii* and its host, *Lasioderma serricorne* (cigarette beetle), have survived on tobacco shreds at the bottom of cigarette packs and on other plant materials known to be toxic to insects. Shen and Dowd (95) used the YLS-host system to test the ability of the yeast to survive a variety of plant toxins. The yeasts have broad-spectrum detoxifying enzymes, including ester hydrolase, glucosidase, phosphatase, and glutathione transferase, that they use to detoxify mycotoxins, insecticides, herbicides, and even the organophosphorus insecticide parathion; they used some of the compounds as sole carbon sources.

Escherich (96) first isolated yeast cells of *S. buchneri* from the drugstore beetle, *Stegobium paniceum*; much later, a related yeast, *S. kochii*, was isolated from the cigarette beetle, *L. serricorne* (97, 98). *S. buchneri* was considered a relative of *Saccharomyces* (96), but the placement was questioned because the yeast did not ferment glucose (99). Since that time the yeasts have been considered members of several different genera and higher taxa (see reference 100), but the taxonomic confusion at the higher taxonomic level was settled when small subunit rDNA placed both species within Pezizomycotina but not close to known taxa (100–102). A better understanding of the relationship of *Symbiotaphrina* spp. was to wait for the discovery of a new lineage, the Xylonomycetes. Gazis and her colleagues (103) discovered an endophyte, *Xylona heveae*, in sapwood of Peruvian rubber trees. Surprisingly, *X. heveae* was unrelated to common xylariaceous endophytes, and it lacked the ability to degrade cellulose and lignin, important traits for a plant-invading fungus. More recently, Gazis and her colleagues (104) used additional phylogenomic data to place *Symbiotaphrina* and *Xylona* in a clade within Xylonomycetes, a part of a major radiation of Leotiomyceta within Pezizomycotina. Furthermore, when enzyme profiles and other genome features were compared with those of ascomycetes with varied life styles, *X. heveae* was more similar to animal-associated taxa such as *S. kochii* than to other members of Pezizomycotina, especially those with plant associations (104). Fewer carbohydrate-active enzymes (CAZymes) to degrade plant cell walls were encoded, limiting the ability of *X. heveae* to enter plants by direct penetration. Based on genomic features and the discovery of GenBank sequences of two strains of *Symbiotaphrina* (KC215113, KC215110) that had been isolated as endophytes, Gazis and her colleagues (104) suggested that *X. heveae* could be insect-transmitted. Such a solution to the problem of entry into the plant in the absence of enzymes indicates that the life history of *Symbiotaphrina* may be more complex than previously appreciated.

Planthopper YLSs

Homopterans are sucking insects, including cicadas, planthoppers, leafhoppers, whiteflies, aphids, and scales, many of which transmit plant diseases and all of which harbor intracellular prokaryotes or in a few cases eukaryotic YLSs. A small group of closely related species of YLSs are obligate associates of planthoppers (Delphacidae) and aphids (Aphididae, Cerataphidinae). The fungi are located in "mycetocytes" (fungus-containing cells) in the fat body of planthoppers, and egg surfaces are infected by transovarial infection. The yeast cells are released by exocytosis from fat body cells to the hemocoel, then to cells surrounding the oocytes, and then they finally enter the mature eggs. Larvae become infected as they hatch (1), and the YLSs are present in all life stages of the insects (105). As mentioned earlier, unlike the YLS of anobiid beetles, the planthopper yeasts cannot be cultured on agar; however, a method for obtaining pure YLS cells for DNA extraction involving density gradient centrifugation has supported the research (106).

YLSs are important to the brown planthopper, *Nilaparvata lugens* (Fig. 11), for essential processes, including sterol utilization, nitrogen recycling, and amino acid synthesis (107, 108). Uric acid, an otherwise "waste" product stored by the planthopper, is broken down by the yeast uricase to recycle the nitrogen resource (107, 109–111). The brown planthopper survives on rice phloem sap, which is low in many required nutrients, and this low-quality diet led earlier workers to wonder if the insects might be associated with symbionts. The genomes of four tightly associated organisms (rice, planthopper, YLS, and a newly discovered prokaryotic endosymbiont) revealed the way in which genes of free-living organisms coevolve to the point that some of the organisms can no longer live independently. The reliance on associated organisms includes the eukaryotic YLS, but also the bacterial symbionts present in most of the other groups of Homoptera. The genes of the eukaryotic YLS have functions complementary to those of the planthopper for synthesis of essential amino acids, nitrogen storage and recycling, and sterol synthesis, all of which supplement the poor nutritional quality of rice phloem sap. *De novo* synthesis of essential amino acids occurs in the YLS to supplement the rice sap diet, and some enzymes used in nitrogen metabolism are shared, so that both YLS and planthopper are genetically complementary (112). Fan and colleagues (113) verified previous studies and provided more details of lost genes associated with nutrition and reproduction in the YLS. Strangely, the YLS of *N. lugens*, part of a well-studied model system, has never been validly described, although the name "*Entomomyces delphacidicola*" was suggested (112).

Figure 11 Brown planthopper, *Nilaparvata lugens*, feeding on a rice stem. The insect and YLS harbored in its fat body are obligately associated for essential nutritional resources. Photograph courtesy of Sylvia Villareal, International Rice Research Institute.

Phylogenetic studies indicated that planthopper and aphid YLS are members of the Pezizomycotina (101, 114). Later analyses placed the YLSs within a clade of largely necrotrophic insect pathogens in Ophiostomataceae, including *Ophiostoma sinensis* of medicinal notoriety, and *Elaphocordyceps* spp., parasites of hypogeous mycorrhizal ascomycetes, *Elaphomyces* spp. (115–117). Taxon sampling among Hypocreales has been limited, and only partial small subunit and large subunit rDNA were used in the analyses (115). More information on the position of the YLS among its closest relatives would help to understand the steps involved in the evolution of an obligate symbiotic life style from ancestral necrotrophic parasites.

The genomics of organisms in several symbiotic associations has begun to provide information to support hypotheses of symbiont changes with a change in an insect diet. Current evidence strongly supports the association of a bacterial symbiont similar to *Blattabacterium* in the common ancestor of roaches and termites; soon after the termite lineage diverged, the bacterium was lost in all but the earliest-diverging termite species. The change from prokaryotic to eukaryotic symbionts appears to have been driven by the inability of *Blattabacterium* to synthesize an array of amino acids and to degrade plant cell wall materials during the termite invasion of the woody habitat (118). Replacement of the *Blattabacterium*-like symbiont with hindgut bacteria and protists overcame the dietary deficiencies associated with the ingestion of wood as a sole source of nutrition. Among the homopterans, almost all taxa have bacterial symbionts, but a few lineages have had replacement by eukaryotic YLSs, and replacement of the prokaryotic symbionts by eukaryotic YLSs among several planthopper and aphid lineages probably involved changes in diet as described for the roach-termite symbiont switch. Another outcome of the *N. lugens* genome studies

indicated that a previously undiscovered prokaryotic symbiont was present, indicating the need for caution in the interpretation of symbiotic benefit (112).

ALONG FOR THE RIDE: PHORESY

Botryozyma

Although many yeasts are dispersed by insects, some dispersal (phoretic) associations are highly specialized and involve organisms with interwoven life histories. The term "hyperphoresy" refers to several layers of organisms that all depend on a single mobile organism for transport. Examples include yeasts attached to mites or nematodes, which are attached to the mobile insect. In nature *Botryozyma* spp. are associated with free-living nematodes (*Panagrellus* spp.) (Fig. 12), where they live in insect frass, slime fluxes in trees, and beetle galleries in wood. Kerrigan and Rogers (e.g., references 119, 120) isolated several species of *Botryozyma*, including a sexual state from galleries and frass of the long-horned beetle, *Saperda calcarata* (Cerambycidae), in trembling aspen, *Populus tremuloides*. The yeast has no known detrimental effect on the nematodes or beetles, except to use some energy for transport to fresh habitats. The yeast pseudohyphal filaments attach to nematodes by a bifurcate basal cell and often are present in large numbers.

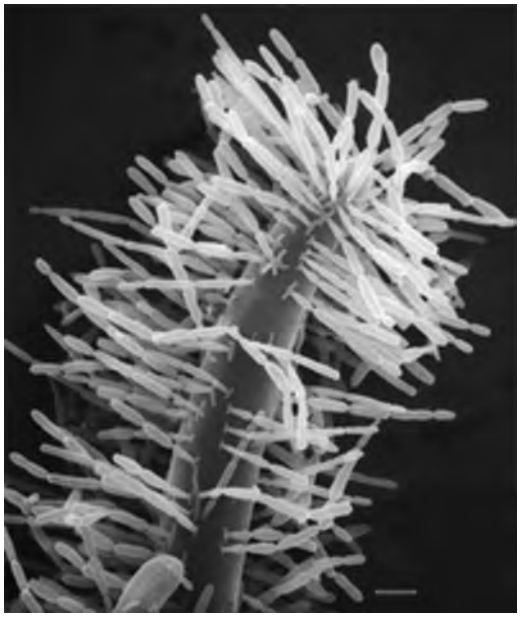

Figure 12 Yeasts are usually studied from isolations made in petri dishes, and their life histories in nature are largely unknown. The yeast described as *Ascobotryozyma americana* (CBS 8560) and the nematode *Panagrellus dubius* have a unique phoretic relationship with the poplar borer beetle (Coleoptera, Cerambycidae, *Saperda calcarata*) that would be unobserved in pure culture. The yeast uses its bifurcate basal cell as a holdfast to attach to the nematode, and they both fly away on a beetle to get to a fresh environment. Scanning electron micrograph, bar = 0.4 mm. See reference 120. Courtesy of J. Kerrigan.

The only other yeast holdfast known anchors *Scheffersomyces pichia* to the hindgut wall of passalid beetles (Fig. 10). The yeasts are not closely related, and the holdfasts are morphologically distinct. Is it possible that other yeasts attach to substrates in nature? We do not know, because yeasts are seldom observed *in situ*, but rather are isolated into culture without direct observation. In addition to *Botryozyma*, a similar dispersal association involves ascospores rather than yeast cells attached to phoretic mites attached to insects (see below).

Yeasts Spread on Substrates

Several other examples of hyperphoresy involve ascospores specialized for insect dispersal. Species in two genera (*Pyxidiophora*, *Kathistes*) of Pezizomycotina are specialized for life in ephemeral substrates such as dung, mushrooms, and rotting wrack strewn on beaches. The timing of maturation is precise, with ascospores, mites, and mobile insect maturing at the same time. The sticky attachment sites of *Pyxidiophora* ascospores become passively attached to phoretic mites, the mites actively seek out and attach to insects, the insects fly to a new substrate, and only after the ascospore reaches the new substrate does a yeast state develop. In cultural studies, ascospores placed on fresh agar produce yeast cells to multiply the number of propagules that then germinate by germ tubes (Fig. 13). The rapid movement of mites across a fresh substrate spreads the yeast cells, probably increasing the chance that the cells will contact hyphae of a suitable fungal host in the complex life history of *Pyxidiophora* spp. (121). In the case of *Pyxidiophora kimbroughii*, perithecia develop in the wood of pine trees, and attachment to a mite disperser is essential to ferry the mites to the bark beetles that undergo their last molt in the outer bark of trees (122, 123).

The ascospores of *Kathistes* spp. also stick to mites, but unlike *Pyxidophora*, they lack a highly specialized attachment region (124). The mites are phoretic on a blood-sucking muscid fly (*Haematobosca alcis*) that blankets the rump of the moose in large numbers (125). The flies spend most of their lives attached to the moose, where both males and females use the blood as their only food. The flies, cued by gasses released when a moose defecates, drop into the moose dung, where

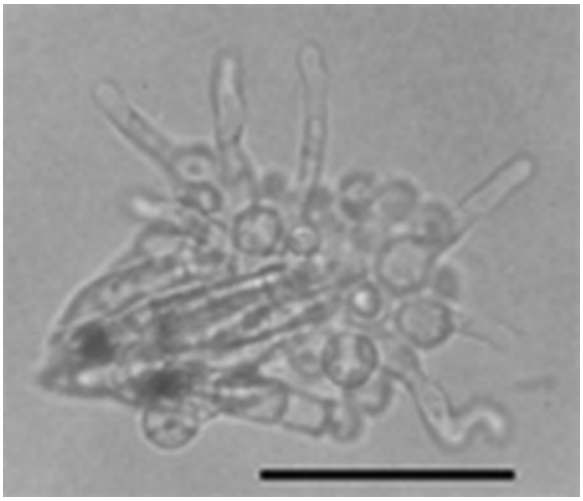

Figure 13 Ascospores of *Pyxidiophora* sp. photographed 24 h after being placed on agar. No cover slip was used, so it looks a little foggy. The ascospore produced several conidia at the ascospore tip, and these budded several times more to produce yeast cells before hyphae elongate. The yeasts are likely dispersed over the new substrate by the mite, improving the chance of finding a suitable fungal host in this complex life history. Scale bar = 50 μm. M. Blackwell.

they lay eggs. *Kathistes*-spore-laden mites hop on flies to return to the moose, and then to another dung pile to repeat the life cycle. The ascospores, aseptate at first, become up to six-septate and germinate by yeast-like budding. In agar culture they usually grow as yeasts. A variety of unrelated ascomycetes have spores that bud in a similar manner, all probably serving the purpose of multiplication of the meiotic products by yeast-like propagules.

EVOLUTION OF YEAST-INSECT ASSOCIATIONS

Because insects and fungi have lived together in terrestrial environments for millions of years (126, 127), it is not surprising that close associations have evolved. Thus far, fossils that could help to clarify steps in the evolution of yeast-insect symbioses have not been discovered. If fossil organisms known to harbor yeasts were found, however, they could provide useful calibration points as they have been used in previous molecular studies (126, 128).

The principle that accelerated evolution is a consequence of the "transition to mutualism" was established soon after the application of molecular methods to the study of fungal interactions (129). These transitions must be millions of years old, providing ample time for associations to develop and communities to assemble, including the polyphyletic assemblages of fungi and ambrosia beetles and cacti, cactophilic yeasts, and *Drosophila* spp., described above. Vega and Dowd (130) suggested three hypotheses of the origin of insect-yeast associations: (i) symbionts were derived from parasites or pathogens; (ii) symbionts were the descendants of plant pathogens or saprobes; or (iii) the insect feeding habitats led to development of the associations. More than one hypothesis may be needed to cover all examples.

Close contact in nature was suggested as the basis for the dramatic host shifts described as interkingdom jumps. In these cases the "host-habitat hypothesis" put forward to explain shifts from one host to another distantly related one states that opportunity for the host switch occurs when both hosts occupy the same immediate environment and rely on the same food source. Examples supported by ancestral character state reconstruction in phylogenetic analyses include host shifts by the YLS member of the Ophiocordycipitaceae jumping from underground cicada larval (insect) hosts to truffle (fungal) hosts and by several shifts in Hypocreales from animals to plants and plants to fungi (131, 132).

CONCLUSION

In this article we have seen examples of progress in the study of symbiosis: investigation of all members of an assemblage and their behavior *in situ* and over time; broad taxon sampling in phylogenetic analyses to pinpoint the closest relatives, then blanketing analyses with near relatives (a process that may rely on long-term searches for undiscovered relatives); examination of fossils by mycologists; and the use of molecular methods for environmental sampling and identification. Lastly, the impact of comparative genomics on our understanding of the evolution of strict associations between yeasts and insects enlightens us, and although many more explanations are needed, the progress shown thus far is encouraging.

Acknowledgments. *I thank Julia Kerrigan, Cletus P. Kurtzman, and Joseph V. McHugh for use of photographs, unpublished information, and fruitful discussions. Buyung Hadi kindly supplied the brown planthopper photograph. I appreciate helpful conversations with Fernando E. Vega, Margaret K. Thayer, Thomas C. Harrington, and Chase G. Mayers and the unpublished photographs graciously provided by Chase G. Mayers. Timothy James and Romina Gazis offered numerous editorial comments to improve the manuscript. Joseph McHugh and James A. Robertson were helpful collecting partners who could identify the insects. I am grateful to students and postdoctoral associates Nhu H. Nguyen, Sung-Oui Suh, Hector Urbina, and Ning Zhang for enlightening me about yeast biology, ecology, and techniques, and to*

many LSU undergraduates who worked tirelessly on yeasts over the years. Funding came from the Radcliffe Institute, Harvard University, and the Boyd Professor Research Fund, LSU. The U.S. National Science Foundation generously supported much of my research over my career.

Nematode-Trapping Fungi

47

Xiangzhi Jiang, Meichun Xiang, and Xingzhong Liu

INTRODUCTION

There are about 700 species of taxonomically diverse fungi that are be able to attack living nematodes (juveniles, adults, and eggs) and use them as a nutrient source (1, 2). The most important genera include *Purpureocillium*, *Pochonia*, *Hirsutella*, *Nematophthora*, *Arthrobotrys*, *Drechmeria*, *Fusarium*, and *Dactylellina* (3, 4). Among these nematophagous fungi, only a few species are obligate parasites of nematodes, but the majority are facultative saprophytes (5–7). Based on the mechanisms by which they attack nematodes, these nematophagous fungi are usually divided into four general groups: (i) nematode-trapping fungi that use specialized trapping structures differentiated from hyphae; (ii) endoparasitic fungi that use their spores; (iii) the opportunistic fungi that invade or colonize nematode eggs, females, or cysts with their hyphal tips; and (iv) toxin-producing fungi that immobilize nematodes before invasion (1, 8). Nematophagous fungi are important natural enemies of nematodes in soil ecosystems. In recent decades, environmental and health concerns over the use of chemical nematicides have greatly increased the demand for the development of biological control agents in plant protection. The reason for the growing interest in nematophagous fungi is mostly their potential as biocontrol agents against plant- and animal-parasitic nematodes. So far, a substantial number of myconematocides have been developed worldwide (3, 4, 6).

Nematode-trapping fungi are soilborne fungi that entrap free-living nematodes by using trapping structures. These fungi have evolved sophisticated trapping structures, including constricting rings and five types of adhesive traps (sessile adhesive knobs, stalked adhesive knobs, adhesive nets, adhesive columns, and nonconstricting rings) (9–12). About 380 species of nematode-trapping fungi have been reported from different regions of the world (2). Different fungal species can produce one or more types of different trapping devices (11, 12). Most nematode-trapping fungi can live both saprophytically on organic matter and as predators by capturing tiny animals (7, 13–16). Traps are not only the weapons that nematode-trapping fungi use to attack nematodes, but are also an important indicator of their switch from a saprophytic to a predacious lifestyle (10, 16). Nematode-trapping fungi are usually not host specific and can trap all soil-dwelling nematodes (1, 17, 18). With increasing discovery of the corresponding sexual-asexual morph connections, most nematode-trapping fungi are known as asexual morphs of *Orbilia* spp. within the Orbiliales (Ascomycota) (2, 19, 20). Recent analyses based on DNA sequences suggest that trapping devices provide the most relevant morphological features for taxonomic classification of predatory asexual Orbiliaceae (11, 21–23). These fungi have been classified into four genera: *Arthrobotrys* (adhesive three-dimensional networks), *Dactylellina* (stalked adhesive knobs and/or nonconstricting rings), *Drechslerella* (constricting rings), and *Gamsylella* (adhesive branches and unstalked knobs). However, given the new nomenclatural regulations that employ only one name per fungus, the names for these nematode-trapping fungi have to be revised (24, 25).

Previous studies of nematode-trapping fungi mainly focused on investigation of their species diversity and abundance in different regions and habitats, taxonomy and phylogeny, laboratory screening, and field trials for nematode control (4, 6, 15, 26–31). In recent years, more attention has been paid to the molecular mechanisms underlying the process of fungi trapping and infecting nematodes, the origin and evolution of trapping structures, genomics, and proteomics (10, 11, 32–37). Virulent factors, the role of proteases, chitinases and small chemical molecules, and the regulation of trap formation have been extensively studied with modern techniques (16, 37–40). There is an increasing body of evidence to illustrate that the predatory

lifestyle of nematode-trapping fungi has evolved among cellulolytic or lignolytic fungi as a response to nutrient deficiencies in nitrogen-limiting habitats. Based on molecular clock and fossil evidence, nematode-predatory Orbiliaceae were estimated to have originated as a result of mass extinctions in the Permian and Triassic (10). Recent studies also showed that nematophagous fungi can detect and respond to ascarosides, which are an evolutionarily highly conserved family of small molecules secreted by many species of soil-dwelling nematodes as molecular signal to recognize prey and trigger trap formation (37). By using comparative genomics and transcriptomics, scientists deciphered two genomic mechanisms leading to the evolution of parasitism in nematode-trapping fungi: the formation of novel genes through gene duplication and the differential regulation of existing genes identified by differential expression of orthologous genes (34, 35). Understanding the molecular and genomic basis of nematode-trapping fungi and nematode interactions provides crucial insights for developing effective biological control methods against plant-parasitic nematodes.

TAXONOMY AND DIVERSITY

Nematode-trapping fungi are a taxonomically heterogeneous group of organisms (distributed in Ascomycota, Basidiomycota, and Zygomycota) that can use these special structures (traps) to capture free-living nematodes in soil (1, 17, 41, 42). About 380 species of nematode-trapping fungi have been reported from different regions of the world (2), including species in the genera *Arthrobotrys*, *Cystopage*, *Dactylellina*, *Dactylella*, *Drechslerella*, *Hohenbuehelia*, *Hyphoderma*, *Monacrosporium*, *Nematoctonus*, *Orbilia*, *Stylopage*, *Tridentaria*, *Tripospora*, and *Zoophagus*. Orbiliaceous members represent the largest group of nematode-trapping fungi, which include about 96 species and are currently assigned to the asexual genera *Arthrobotrys* (53 species), *Dactylellina* (28 species), and *Drechslerella* (14 species) (17).

Molecular phylogenetic analyses indicate that the monophyletic classes Orbiliomycetes and Pezizomycetes are among the earliest diverging branches of Pezizomycotina, the largest subphylum of the Ascomycota (43–45). Orbiliomycetes is represented by a single order, Orbiliales, with the only family, Orbiliaceae, consisting of three accepted sexual genera, *Hyalorbilia*, *Orbilia*, and *Pseudorbilia* (46, 47). This family has about 288 described species (19). The members of Orbiliaceae are characterized by small, translucent, waxy, disk-shaped apothecia that are formed in soil and wood. Apothecia are produced without stromata and have an ectal excipulum of globose, angular, or prismatic cells. Small asci with truncate to hemispherical apices are intermixed with paraphyses that typically are swollen at their tips. Small hyaline ascospores usually possess an apical spore body that selectively stains in cresyl blue (48). About 10 asexual genera have been connected with Orbiliaceae (49), and all are hyphomycetous. Certain of these asexual genera are commonly known nematode-trapping fungi, and their evolution and phylogeny have been studied with nuclear and protein-coding genes.

The first nematode-trapping fungus, *Arthrobotrys superba* as the type species of *Arthrobotrys*, was described in 1839, but its nematode-trapping habit was unknown until the observation of *Arthrobotrys oligospora* by Zopf in 1888; the connection between *A. oligospora* and *Orbilia fimicola*, and its nematode-trapping lifestyle, was confirmed by Pfister in 1994, 155 years after the first nematode-trapping fungus was described (50). The characteristics of the genus *Arthrobotrys* were considered to be hyaline conidiophores producing conidia asynchronously on short denticles at swollen conidiogenous heads or clusters of pronounced denticles, the conidia being subhyaline, obovoid, or clavate and (0–)1(–6)-septate (50). Trapping devices were considered to be constricting rings, adhesive nets, hyphae, or adhesive knobs (50). This wide generic concept based on reproductive structures resulted in considerable confusion, although since 1930, nematode-trapping fungi have been mostly assigned to *Arthrobotrys*, *Dactylaria*, *Dactylella*, and some other genera.

The trapping devices of nematode-trapping fungi are developed from the vegetative mycelia. The known trap types include adhesive networks, adhesive knobs, constricting rings, nonconstricting rings, adhesive branches, undifferentiated or unmodified adhesive hyphae, stephanocysts, spiny balls, and acanthocytes (51–54) (Fig. 1). Members of the Orbiliaceae can produce the first five types of traps (9). *Zoophagus* species of Zygomycetes (55, 56) and *Nematoctonus* species of Basidiomycetes can also produce adhesive knobs (57). Traps of adhesive hyphae are restricted to the genera *Stylopage* and *Cystopage* of Zygomycetes (58), while stephanocysts are restricted to the genus *Hyphoderma* of Basidiomycota (51). Spiny balls and acanthocytes are only formed, respectively, by *Coprinus comatus* (53, 54) and *Stropharia rugosoannulata* (59) in Agaricales of Basidiomycota. The sexual morphs of most nematode-trapping species are now assigned to *Orbilia*, and their type of trapping apparatus can be used as robust indicators of generic delimitation. These fungi were

also classified according to their trap types with the support of genetic data as follows: *Arthrobotrys* (adhesive three-dimensional networks), *Dactylellina* (stalked adhesive knobs and/or nonconstricting rings), *Drechslerella* (constricting rings), and *Gamsylella* (adhesive branches and unstalked knobs) (17).

Fungal taxonomy has changed a lot in the past decades, from being based on only morphological observations to being a combined analysis of morphology and DNA sequence data. Morphology-based classification based on conidia was demonstrated to be inadequate in reflecting natural relationships among the nematode-trapping fungi. The first phylogenetic analysis of nematode-trapping fungi was conducted by Rubner in 1996. She used molecular data to rationalize the classification of nematode-trapping fungi based on types of rapping devices (60). Phylogenetic studies based on rDNA sequence analysis also found that trapping

devices are more informative than morphological characters in delimiting genera (11, 21–23, 61). Subsequently, in 1999 Scholler et al. classified nematode-trapping fungi into four genera using 18S and internal transcribed spacer (ITS) rDNA analysis. Li et al. (21) reevaluated the placement of nematode-trapping genera based on 28S, 5.8S, and β-tubulin analysis, and the establishment of *Gamsylella* proposed by Scholler et al. was criticized and rejected.

Although trapping devices have been shown to be vital in generic delimitation of nematode-trapping fungi, species in the same genus are mainly delimited from each other by the morphology of their conidia and conidiophores. With more and more connections between nematode-trapping fungi and Orbiliaceae being established (49, 50, 62–64), phylogenetic analysis including existing asexual species indicated that conidial morphology showed little correlation, while characters of their sexual morphs showed a high level of correlation. For example, *Arthrobotrys* belongs to series Auricolores, which is defined by the ability to form adhesive networks, while the asexual Trinacrium type belongs to species of *Hyalorbilia* and *Orbilia* subgenus *Hemiorbilia* and subgenus *Orbilia* (H.-O. Baral, personal communication). Further studies are needed to set up a natural classification system based on the connection of asexual and sexual nematode-trapping fungi. In 2012, the International Code of Nomenclature for algae, fungi, and plants was published, which no longer allows a single fungal species to have two names; the older name takes priority except in exceptional circumstances (24, 25). The asexual genus above that is linked to *Orbilia* sexual morphs may need to be allocated to *Orbilia* or, alternatively, to an asexual genus. Discussions are presently under way in the Orbiliomycetes working group of the International Commission on the Taxonomy of Fungi to adopt a single nomenclature for this group of fungi.

ECOLOGY AND EVOLUTION

Nematophagous fungi represent an important group of soil microorganisms that can suppress populations of plant and animal parasitic nematodes (3, 4, 26–28, 65–67). These fungi are broadly distributed in terrestrial and aquatic ecosystems, from the tropics to Antarctica (7, 13, 15, 29–31, 68–70). Efforts have frequently been made to control diseases caused by plant-parasitic nematodes by using nematode-trapping fungi, but results have been inconsistent. It has subsequently been pointed out that a fundamental knowledge of the ecology of these fungi is essential before the value of such biological control methods can be assessed. Environmental factors greatly affect the occurrence and activity of soil microorganisms. However, our knowledge about how the environment affects the abundance and activity of nematophagous fungi is still relatively poor (14, 31).

The effect of major biotic and abiotic variables such as soil moisture, organic matter, pH, nematode density, soil nutrients, and submerged water conditions on the distribution of nematode-trapping fungi has been extensively studied. Previous studies by Gray on the distribution of nematophagous fungi indicate that the occurrence of certain species and groups of fungi is associated with specific soil variables: in particular, pH, soil moisture, nutrients (N, P, K), heavy metal, and nematode density (15, 71). Gray revealed that soil nutrients such as N, P, and K were all positively correlated with nematode density. Based on his results, species with stalked, knobbed trapping devices (*Dactylellina*) and species with constricting rings (*Drechslerella*) were more frequently isolated from organically richer soils which contained a greater density of nematodes (31, 72, 73). However, net-forming species (*Arthrobotrys*) are largely independent of soil fertility, especially low K (74). In a recent survey, Mo et al. found that the diversity of nematode-trapping fungi was positively correlated with lead concentration (75). These soil variables are known to vary with depth, as are the densities of soil bacteria, fungi, and nematodes (76, 77), and a high level of nematode-capturing activity has been recorded from the rhizosphere area. However, there are also large variations depending on plant species and soil types (78). The species of nematode-trapping fungi vary with soil depth (79). Peterson and Katznelson (80) revealed that the greatest diversity occurred in the upper 10 to 30 cm of soils, and this was a positive correlation between the population density of nematophagous fungi and root-knot nematodes in peanut fields. Hao et al. (13) observed that the nematode-trapping fungi were not detected deeper than 4 m in a freshwater pond. Several studies have also been carried out on horizontal distribution (81). For example, Persson et al. (81) studied the growth and dispersion of *A. superba* under natural conditions determined by a radioactive tracing technique.

The number of nematode-trapping species present in a specific soil and their population densities can vary considerably. Application of chopped organic amendment and glucose to soil could increase the activity of nematode-trapping species perhaps because of the consequent increase in the number of free-living and microbivore nematodes (82–84). Although organic

amendments probably stimulated population densities, similar population densities of trapping fungi were found in plots with and without organic amendments. The effect of abscisic acid and nitric oxide on the nematode-trapping fungus *Drechslerella stenobrocha* AS6.1 was tested, and it was demonstrated that the trap development and nematode-trapping capability of *D. stenobrocha* were increased by abscisic acid but decreased by nitric oxide (85). It is apparent that the trapping fungi need a carbohydrate source for their proliferation, but other factors, such as those that cause fungistasis, are also important for their abundance and trophic state in soil. It is hypothesized that *Orbilia* species, the sexual morph of *Arthrobotrys* species, are weak wood decomposers and that nematode cadavers act as an important supply of nitrogen. Predaceous behavior of *A. oligospora* can be controlled either by physiologically active compounds (amino acids or vitamins) present in nematodes or by nitrogen sources.

The majority of nematode-trapping fungi colonize soil, waiting until passing nematodes touch them. Some fungi increase their trapping chances by producing secondary attractive compounds for nematodes, such as *A. superba*, which attracts second-stage juveniles (J2) of *Meloidogyne* species (86). Others grow in the rhizosphere and can even colonize plant roots (76, 80, 87), which gives them superior predatory activity to trap plant-parasitic nematodes on their way to roots. For example, *A. oligospora* was more abundant in the rhizosphere of tomato and barley plants because of its chemotropical attraction to the root tips. Plant species obviously influence the rhizosphere and external root colonization. The highest incidence and diversity of nematode-trapping fungi were detected in association with rhizosphere of peas, while *Dactylellina ellipsospora* and *Arthrobotrys dactyloides* were successfully colonized on tomato roots in a pot experiment (87, 88).

Carbon and nitrogen are two essential nutrients for fungal growth and reproduction. It has been proposed that the nematode-trapping lifestyle is an evolutionary response by cellulolytic or lignin-degrading fungi to nutrient deficiencies in nitrogen-limiting habitats. Because nitrogen is essential for fungal growth and is not freely available in dead wood or in soil where carbon is abundant, direct capture of nitrogen compounds from free-living nematodes or other small animals is advantageous (89). Many network-forming species do not produce a network trap spontaneously, and they are more saprophytic than other nematode-trapping fungi. Formation of network-trapping devices can be induced by the presence of nematodes or substances of animal origin known as nemin. The adhesive network is a primitive characteristic induced only by covering the hypha with a thin film of stick fibrils. Fungal species with other types of trapping devices, such as adhesive knobs (sessile or stalked) and constricting rings, produce trapping devices spontaneously. The spontaneous trap formers more effectively prey on nematodes than do nonspontaneous formers, such as species forming adhesive networks, which have the flexibility to become more predacious by induction of more traps (10).

Various hypotheses on the origin and evolution of nematode-trapping lifestyles in the Ascomycota have been proposed, but conflicts exist between molecular and phenotypic phylogenies (10, 11, 21, 61). The phylogenetic relationships between the different nematode-trapping species need to be known to understand the evolution of parasitism in nematode-trapping fungi. Many molecular phylogenetic studies have shown that the largest group of nematode-trapping fungi belongs to a monophyletic group in the order Orbiliales (Ascomycota). A recent study based on a comprehensive phylogenetic analysis of the nucleotide sequences of three protein-coding genes and rDNA in the internal transcribed spacer region demonstrated that the trapping mechanisms within the Orbiliales have evolved along two major lineages, one leading to species with constricting rings and the other to species with adhesive traps, including three-dimensional networks, knobs, and branches. Among those adhesive trapping devices, the adhesive network separated itself from other trapping mechanisms at an early stage. The adhesive knob evolved through stalk elongation and finally developed into nonconstricting rings. It was shown that the derived adhesive traps are at a highly differentiated stage, but in this study the evolution of the adhesive traps was still ambiguous, partly because the number of taxa representing each type of trapping device was uneven (11).

In a more recent study, data based on a phylogeny of five protein-encoding genes and molecular clock calibration based on two fossil records revealed that fungal carnivorism diverged from saprophytism about 419 million years ago (Mya), which was after the origin of nematodes about 550 to 600 Mya. Active carnivores (fungi with constricting rings) and passive carnivores (fungi with adhesive traps) diverged from each other around 246 Mya, shortly after the occurrence of the Permian-Triassic extinction event about 251.4 Mya. The major adhesive traps evolved around 198 to 208 Mya, which was within the time frame of the Triassic-Jurassic extinction event about 201.4 Mya (Fig. 2). However, more evidence, including additional

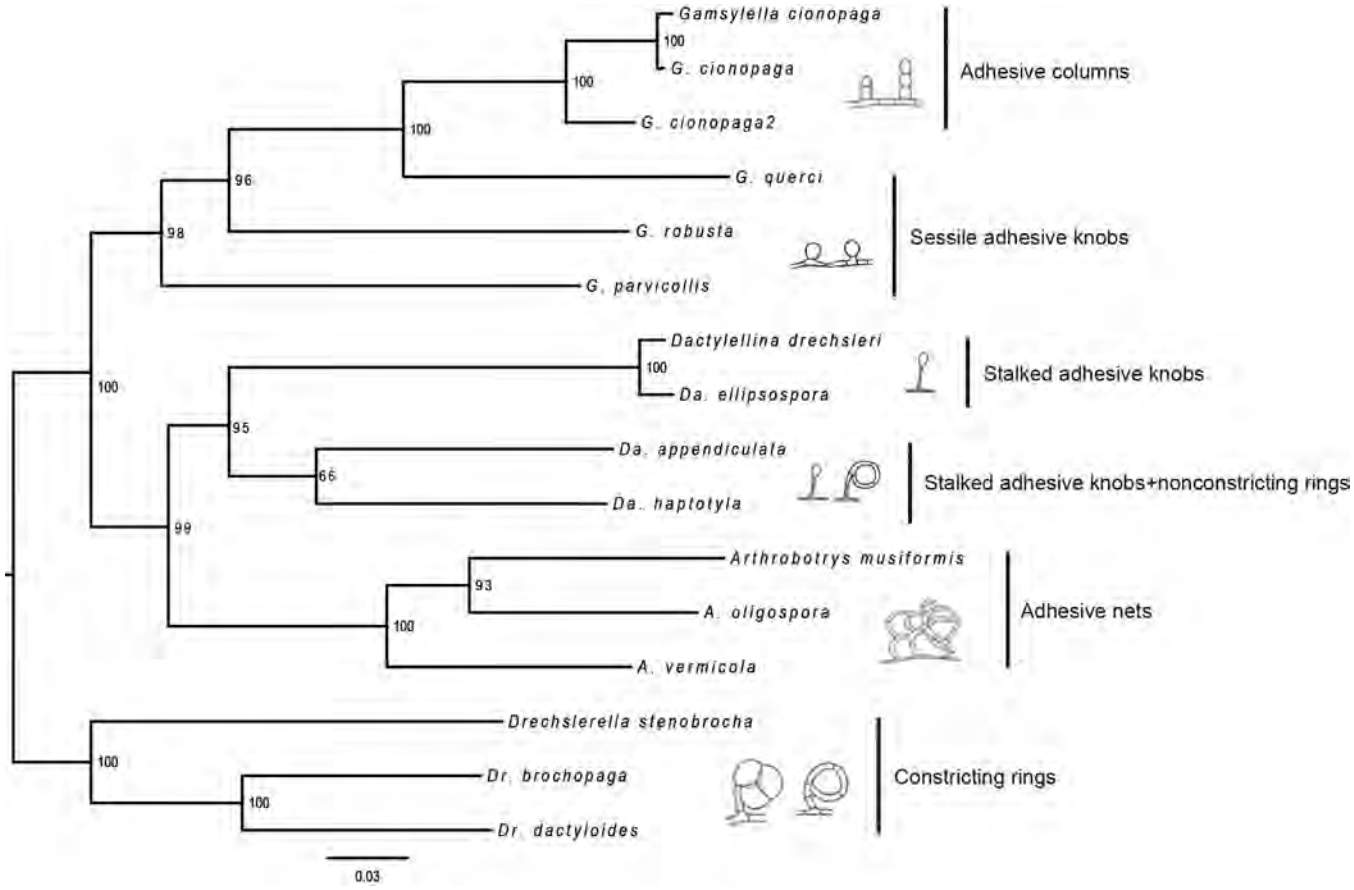

Figure 2 Phylogeny of carnivorous Orbiliomycetes constructed by RAxML using five protein-coding genes. The bootstrap supports are marked on the branch. Trapping devices are drawn on the left.

fossil records, is still needed to illustrate if fungal carnivore evolution was a response to mass extinction events. This study also illustrated a clearer route for the evolution of adhesive traps. Sessile adhesive knobs and an extinct trapping structure (unicellular ring) originated from the adhesive ancestor. Adhesive columns diverged from sessile adhesive knobs by the proliferation of adhesive knobs into a column, which increased the adhesive surface and predatory efficiency. The unicellular ring probably became extinct due to low predatory efficiency (the unicellular ring is morphologically similar to nonconstricting rings, which have the lowest predatory efficiency of existing trapping fungi). The unicellular ring evolved along two lineages to increase predatory efficiency. One formed adhesive nets by proliferating the ring into a network of rings. The other formed nonconstricting rings accompanied by stalked adhesive knobs, in which the single-celled rings developed into three-celled nonconstricting rings, unicellular knobs, and stalked adhesive knobs (10).

MECHANISMS OF FUNGI TRAPPING NEMATODES

Plant-parasitic nematodes cause significant damage to a broad range of vegetables and agricultural crops throughout the world. Understanding the molecular basis of microbe-nematode interactions could lead to the development of more efficient and reliable methods for biological control of parasitic nematodes (12, 90, 91).

Nematode-trapping fungi infect their hosts through a sequence of events (1). They use specialized trapping devices to catch and consume nematodes, and previous studies demonstrated that most fungal species do not produce traps constitutively but, rather, initiate trap formation in response to their prey (92–94). Recognition and adhesion were the first steps in nematode-

trapping fungi infecting their hosts. However, little is known about the molecular mechanisms of recognition and adhesion. Lectin has been reported to be involved in the recognition process (95–97). The finding of lectins in the role of nematode-fungi interaction came from an observation that the interaction between *A. oligospora* and nematodes was mediated by a GalNAc-(*N*-acetyl-D-galactosamine)-specific fungal lectin binding to receptors present on the nematode surface (97). Similar experiments have also indicated that lectins play a role in the adhesion to host surfaces by a number of parasitic and symbiotic fungi (98). However, after a gene encoding such a lectin was deleted in *A. oligospora* by homologous recombination, the deletion mutant showed little decrease in spore (conidia) germination, saprophytic growth, and pathogenicity (99). This result suggested that the fungus might be capable of compensating for the absence of the lectin by expressing other proteins with similar function(s) as the lectin in *A. oligospora*.

The recognition of molecular patterns associated with specific pathogens or food sources is fundamental to ecology and plays a major role in the evolution of predator-prey relationships. Recent studies have shown that nematodes could produce an evolutionarily highly conserved family of small molecules, the ascarosides, which serve essential functions in regulating nematode development and behavior. Interesting research revealed that nematophagous fungi could detect and respond to ascarosides. It was found that ascarosides, which are constitutively secreted by many species of soil-dwelling nematodes, represent a conserved molecular pattern used by nematophagous fungi to detect prey and trigger trap formation. Ascaroside-induced morphogenesis is conserved in several closely related species of nematophagous fungi and occurs only under nutrient-deprived conditions. It was demonstrated that microbial predators eavesdrop on chemical communication among their metazoan prey to regulate morphogenesis, providing a striking example of predator-prey coevolution (37).

Despite large variation in their morphology, adhesive traps share a unique ultrastructure that clearly separates them from vegetative hyphae. One common feature of traps is the presence of numerous cytosolic organelles called dense bodies (100, 101). These organelles always have catalase and D-amino acid oxidase activities, which indicate that they are peroxisome-like organelles. However, the function of these organelles is not yet fully understood. Another feature of traps is the presence of a fibrillar layer of extracellular polymers, which are believed to play an important role in the attachment of the trap cell to the nematode surface (9, 102). Following adhesion, a penetration tube forms and then pierces the nematode cuticle. At this stage, the nematode becomes paralyzed (killed), and the internal tissues are rapidly colonized by fungal hyphae (103).

After recognition and adhesion, the nematode-trapping fungi, like other pathogens, enter into the host through both enzyme degradation and mechanical pressure. The nematode cuticle is composed mainly of proteins including collagen, and several proteases have been isolated from nematophagous fungi that can hydrolyze proteins of the cuticle (104–107). Several extracellular hydrolytic enzymes including serine proteases and collagenases have been detected and partly identified from different nematode-trapping fungi. These studies suggested that extracellular hydrolytic enzymes are key virulence factors involved in the penetration process. Following penetration, the nematode is digested by the invading fungi. These fungi obtain nutrients from the nematodes for their growth and reproduction (108).

APPLICATION OF NEMATODE-TRAPPING FUNGI

In recent decades, concerns about the environmental hazards of using chemical nematicides and limited alternative crops for rotation have led to the development of biological control agents as a component of crop protection. Biological control is considered ecologically friendly and is a possible alternative in pest and disease management. Plant-parasitic nematodes cause significant damage to a broad range of vegetables and agricultural crops throughout the world. Yield losses worldwide to plant-parasitic nematodes have been estimated to range from 5 to 12% annually (3, 4, 6, 109). These losses, however, are influenced greatly by both the production systems and management options utilized. The continuous production of susceptible crops in the sandy soils of the southeastern coastal plains of the United States and other similar regions also often result in devastating losses to nematodes, especially *Meloidogyne* and *Heterodera* species (110).

As the natural enemies of nematodes, nematophagous microorganisms offer a promising approach to control the nematode pests. These biological control agents have an important effect in the regulation of plant-parasitic nematode populations, and numerous organisms including fungi, bacteria, viruses, nematodes, and other invertebrates have antagonistic activity against plant-parasitic nematodes. According to the

report from MarketsandMarkets, from 2009 to the present, the market for biological nematicides has grown nearly 20%, with most of the growth in field crops and biological products occurring in the United States. Sales of nematicides totaled just over $1 billion in 2014 and are expected to grow at a compound annual growth rate of 2.7% in the next 10 years to reach $1.3 billion in 2024. The ability to trap nematodes makes nematode-trapping fungi an attractive candidate agent for controlling parasitic nematodes of plants and animals. Indeed, two commercial biological nematicides, Royal 300 and Royal 350, have been developed based on the species *Arthrobotrys irregularis*, *A. oligospora*, and *Arthrobotrys robusta*. Fungal biological control is an exciting and rapidly developing research area, and growing attention is being paid to the exploitation of fungi to control nematodes (3, 4, 6, 109, 111). The relationship between nematodes and the fungi that infect them has been the subject of widespread mycological studies.

Lots of natural enemies attack nematodes and decrease their populations, but the number of organisms which could be practically employed for biocontrol is restricted (112). In other words, many soil types and their microorganisms all around the world show biological control activity, but their effect on nematode populations can range from insignificant to complete suppression. There have been advances in the biological control of nematodes, but field-scale exploitation of this tactic remains to be realized. Many fungi grow slowly in natural soil, and this can be attributed to inherent competition in the highly diverse communities of soil microfauna and microflora. For a fungus to overcome the competition of resident soil microflora, it must produce a resistant resting stage that is rich in food sources (113). Also, a number of organisms, including mites and possibly mycophagous nematodes, may feed on mycelium of these fungi. Some disadvantages such as complexity in the establishment in the soil, their limited capturing activity, and above all, nonspecific trapping of plant-parasitic nematodes reduce their potential for biological control. Some *Arthrobotrys* species have been formulated and applied under specific conditions, but the results were inconsistent. So there is still a long way to go in developing a highly efficient fungal agent to control nematode pests.

GENOMICS AND PROTEOMICS OF NEMATODE-TRAPPING FUNGI

Genomic and proteomic analyses provided comprehensive understanding of the evolution and infection process of fungi. Recently, the evolution of the nematode-trapping lifestyle and the infection process, including the differentiation of trap cells and the penetration and digestion of nematodes, have been examined using genomic and proteomic approaches.

So far, several genomes of nematode-trapping fungi have been *de novo* sequenced or are currently being sequenced, including *Arthrobotrys conoides*, *A. oligospora*, *Dactylellina appendiculata*, *Dactylellina drechsleri*, *Dactylellina haptotyla, D. stenobrocha*, *Gamsylella cionopaga*, *Gamsylella querci*, and *Orbilia auricolor*. Genomics or proteomics analyses of *A. oligospora* forming adhesive networks (36), *Monacrosporium haptotylum* forming adhesive knobs (35), and *D. stenobrocha* forming constricting rings (33) have been published and provided a new approach for obtaining a better understanding of the interaction between nematode-trapping fungi and their hosts.

Molecular phylogenies based on rDNA sequences strongly support that the nematode-trapping lifestyle evolved once in the Orbiliales. Subsequently, several distinct trapping types evolved. On the genomic level there are three compatible mechanisms that could account for such evolutionary patterns. First, parasitism has been associated with the presence of novel genes. Such genes could be acquired by gene duplication or horizontal gene transfer. Second, adaptations to the parasitic habit may result from the differences in the regulation of gene expression. Third, parasitism is associated with gene loss and deletions (114). By comparative genomics analysis of the knob-forming species *M. haptotylum* and the net-forming species *A. oligospora*, two genomic mechanisms have been determined to be important for the parasitic adaptation in these fungi. First, the expansion of protein domain families and the large number of species-specific genes indicated that gene duplication followed by functional diversification had a major role in the evolution of the nematode-trapping fungi. Gene expression indicated that many of these genes are related to pathogenicity. Second, the gene expression of orthologs between the two fungi during the infection process indicated that differential regulation was an important mechanism for the parasitic evolution in nematode-trapping fungi (35).

Comparative genomics analysis showed that *A. oligospora* shared many more genes with pathogenic fungi than with nonpathogenic fungi. Specifically, compared to several sequenced ascomycetous fungi, the *A. oligospora* genome has a larger number of pathogenicity-related genes in the subtilisin, cellulase, cellobiohydrolase, and pectinesterase gene families. Searching the pathogen-host interaction gene database identified 398

homologous genes involved in pathogenicity in other fungi. The analysis of repetitive sequences provided evidence for repeat-induced point mutations in *A. oligospora*. Proteomic and quantitative PCR analyses revealed that 90 genes were significantly upregulated at the early stage of trap formation by nematode extracts, and most of these genes were involved in translation, amino acid metabolism, carbohydrate metabolism, and cell wall and membrane biogenesis. Based on the combined genomic, proteomic, and qPCR data, a model was proposed for understanding the formation of the nematode-trapping device in this fungus. In the model, multiple fungal signal transduction pathways are activated by its nematode prey to further regulate downstream genes associated with diverse cellular processes such as energy metabolism, biosynthesis of the cell wall and adhesive proteins, cell division, glycerol accumulation, and peroxisome biogenesis (35, 36).

The trap of *M. haptotylum* consists of a unicellular structure called a knob that develops at the apex of a hypha. To better understand the cellular functions of adhesive traps, the trap cell proteome of the fungus *M. haptotylum* was characterized. In this research, 336 proteins were identified, with 54 expressed at significantly higher levels in the knobs than in the mycelia. The upregulated knob proteins included peptidases, small secreted proteins with unknown functions, and putative cell surface adhesins containing carbohydrate-binding domains, including the WSC (cell wall integrity and stress-response component) domain. A further phylogenetic analysis showed that all upregulated WSC domain proteins belonged to a large, expanded cluster of paralogs in *M. haptotylum*. Several peptidases and homologs of experimentally verified proteins in other pathogenic fungi were also upregulated in the knob proteome. Complementary profiling of gene expression at the transcriptome level showed poor correlation between the upregulation of knob proteins and their corresponding transcripts. It was concluded that the traps of *M. haptotylum* contain many of the proteins needed in the early stages of infection and that the trap cells can tightly control the translation and degradation of these proteins to minimize the cost of protein synthesis (115).

These genomic and proteomic studies will greatly facilitate the identification of pathogenicity-related genes and provide a broad foundation for understanding the molecular and evolutionary mechanisms underlying fungal-nematode interactions.

Host-Microsporidia Interactions in *Caenorhabditis elegans*, a Model Nematode Host

48

Emily R. Troemel

NEMATOCIDA SPECIES ARE NATURAL MICROSPORIDIAN PATHOGENS OF THE NEMATODE *C. ELEGANS*

The nematode *Caenorhabditis elegans* is a highly tractable organism that has been studied in the laboratory for several decades and has provided novel insights into questions of development, neurobiology, and cell biology, among other basic biological processes (1). Until recently, however, little was known about its natural ecology. Now, because of greatly increased sampling of *C. elegans* from the wild, we are learning more about its life outside the laboratory (2). In particular, it has become clear that *C. elegans* and other *Caenorhabditis* nematodes are commonly infected by microsporidia in the wild (3–5). Microsporidia comprise a phylum of over 1,400 species of fungal-related parasites that can infect nearly all animal hosts (6–8), so it is perhaps no surprise that these pathogens commonly infect the nematode *C. elegans*.

Microsporidia have been studied since the time of Louis Pasteur, and they have a very specialized obligate intracellular lifestyle that shares some similarities with protozoan parasites (Fig. 1) (6). The stage of microsporidia that survives outside the host cell is the dormant spore stage, which is characterized by a specialized infection apparatus called a polar tube. This tube is coiled inside the spore until it receives the proper cue, at which point it fires the tube and injects a parasite cell directly into the host cell. This cell then replicates intracellularly as a meront, which in most species is a multinucleated cell. Meronts eventually differentiate back into spores that are released from the host to transmit infection. In addition to this unique intracellular life cycle, microsporidia are distinguished by a lack of true mitochondria and smaller ribosomal rRNA genes, which led them to initially be proposed as ancient eukaryotes. However, with more genome sequence available, it has become clear that microsporidia are either close relatives of fungi, or true fungi (9, 10). Notably, microsporidia have the smallest known eukaryotic genomes, with the human-infecting species *Encephalitozoon intestinalis* genome only 2.3 Mb (11), which is smaller than many bacterial genomes.

ANALYSIS OF THE GENOMES FROM *NEMATOCIDA* AND OTHER MICROSPORIDIA SPECIES

The first and best-described microsporidian pathogen of *C. elegans* was obtained from a wild-caught *C. elegans* isolated from a compost pit near Paris, and it was named *Nematocida parisii* (nematode killer from Paris) strain ERTm1 (3). *N. parisii* causes a lethal intestinal infection in *C. elegans* (3), and it can also cause developmental arrest of *C. elegans* larvae (12). In the original study, two other *N. parisii* strains from wild-caught *C. elegans* in France were described (strains ERTm3 and ERTm4), as well as a related *Nematocida* species called *Nematocida* sp. 1 (strain ERTm2), which was found in a sister species of *C. elegans* called *Caenorhabditis briggsae* isolated from a park in India (3). Genome sequencing of *N. parisii* strain ERTm1 demonstrated a genome size of 4.1 Mb, containing 2,661 predicted genes, with expression of most of these genes confirmed by transcriptome analysis of several stages of the *N. parisii* life cycle (10). The *N. parisii* isolate ERTm3 genome had a similar size and predicted gene set, while an isolate of the sister species *Nematocida*

Division of Biological Sciences, Section of Cell and Developmental Biology, University of California, San Diego, La Jolla, CA 92093.

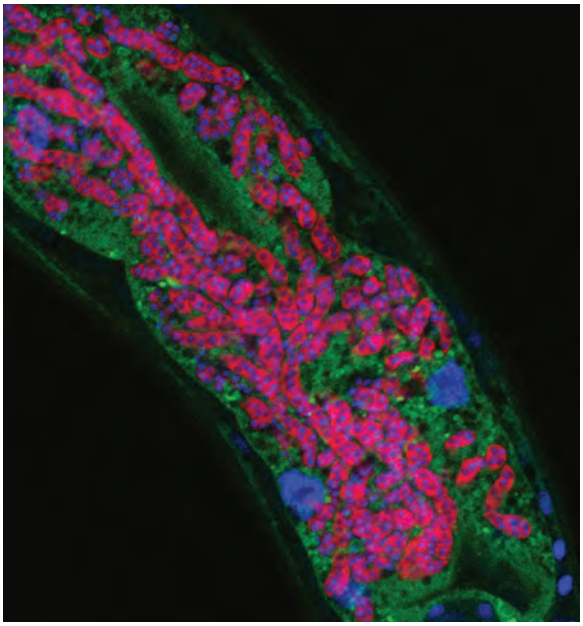

Figure 1 *N. parisii* microsporidia infecting the *C. elegans* intestine at the meront stage. *N. parisii* meronts are labeled with a fluorescent probe for rRNA in red, the *C. elegans* intestine is labeled with cytoplasmic GFP in green, and DNA is labeled with DAPI in blue. DAPI, 4′,6-diamidino-2-phenylindole; GFP, green fluorescent protein. (Image credit Susannah Szumowski.)

sp. 1 sequencing revealed a slightly larger genome of 4.7 Mb and 2,770 predicted genes. Thus, like other microsporidia species, *Nematocida* genomes are quite small, being smaller than many bacterial genomes.

Interestingly, genome sequencing indicated that *Nematocida* are diploid—the ploidy was unknown for any microsporidia species before this study. Most regions of the *Nematocida* sp. 1 genome were highly heterozygous, with one single nucleotide polymorphism every 82 bp (10). *N. parisii* was similarly found likely to be diploid, although with much less heterozygosity than *Nematocida* sp. 1 (strain ERTm2). Genome sequencing of a second *Nematocida* sp. 1 strain (ERTm6) isolated from a *C. briggsae* in Cape Verde indicated that it also is heterozygous, although not as heterozygous as ERTm2 (13). Subsequent studies of other microsporidia species have indicated that they too are diploid (14). Intriguingly, several chromosomal arms in *Nematocida* strains have a loss of heterozygosity (LOH), indicating there has been a rare or recent recombination event, consistent with a sexual cycle for microsporidia (10). Rare sexual cycles have been shown to be important for virulence in other fungal species (15). Passaging of *Nematocida* sp. 1 for 3 months in the laboratory did not result in a change in the pattern of LOH, suggesting that a sexual cycle did not occur under these laboratory conditions (10). It would be interesting to examine the patterns of LOH under more natural conditions to determine if or when a sexual cycle may occur for *Nematocida* species, and whether it is linked to virulence.

Using the *Nematocida* genome sequences described above, together with genome sequences of other microsporidian species that infect insects and humans, comparative analysis was performed to gain a global view of the microsporidia phylum (10). In particular, ten microsporidian genomes were analyzed to determine which genes were gained and lost in comparison with "true fungi." This phylogenomic analysis uncovered potential cancer-like strategies that microsporidia may use to replicate rapidly in host cells. These studies showed that all microsporidia have lost the retinoblastoma gene (RB), which encodes a cell cycle inhibitor lost in most human cancers. Evolutionary loss of RB perhaps enabled microsporidia to acquire a fast cell cycle to replicate quickly and outpace the host in the utilization of resources. Loss of RB should also lead to a mistake-prone cell cycle and accumulation of mutations, which might explain why microsporidia have "long branches" in phylogenetic trees. This long-branch length has led to controversy in the phylogenetic placement of microsporidia, but data from this study and another study analyzing 53 shared genes have firmly established microsporidia as the earliest branching group of the sequenced fungi (9, 10). Intriguingly, it was found that microsporidian hexokinases have gained secretion signal sequences, and in a functional assay these were sufficient to export proteins out of the cell; thus, hexokinase may be targeted into the host cell to reprogram it toward biosynthesis, similar to the "Warburg effect" in cancer cells (10). This study, together with previous studies (16, 17), showed that microsporidia horizontally acquired transporters that could import nucleotides and nucleosides to fuel their rapid growth. Thus, rapid growth using cancer-like strategies, together with a rare sexual cycle for diversity, provide potential explanations for the emergence and success of these diverse intracellular parasites (10).

Bolstered by the *Nematocida* genome data described above, *C. elegans* provides a convenient whole-animal host to study microsporidia infection because of its transparent body plan and the ease of culturing it in the laboratory. In particular, it provides an attractive model for intestinal infection, because its cells share similar structural features with human intestinal epithelial cells, with apically polarized microvilli anchored into a cytoskeletal structure called the terminal web (18–

20). In the laboratory, *Nematocida* can proliferate to occupy the entire intestine of *C. elegans*, which can be observed in intact animals by staining with fluorescence *in situ* hybridization probes for parasite rRNA (Fig. 1). Because of the convenient culturing and imaging of *C. elegans*, together with the powerful genetic and molecular tools, it has been possible to molecularly characterize different aspects of its life cycle in the intestine of live animals to determine how it molecularly interacts with the host; these studies are described below.

N. PARISII RESTRUCTURES *C. ELEGANS* INTESTINAL CELLS AND EXITS VIA APICAL EXOCYTOSIS

N. parisii infection causes extensive cytoskeletal restructuring in the *C. elegans* intestine as part of its exit process (21). Like most microsporidia, *N. parisii* survives outside of host cells in the transmissible spore form, and replicates exclusively inside of host cells in a form called a meront (3). Early during infection, when *N. parisii* is replicating inside the cell as a meront, there is a partial loss of cytoskeletal polarity of *C. elegans* intestinal cells (Fig. 2). Normally, the intestinal-specific isoform of actin called ACT-5 is restricted to the apical side of the cell. However, *N. parisii* infection at the meront stage causes ectopic expression of this host ACT-5 to the basolateral side of the cell (22). Soon after this redistribution of actin, gaps appear in the terminal web, which is a conserved cytoskeletal structure composed of actin and intermediate filaments (3, 22). This redistribution of actin may in fact trigger the formation of terminal web gaps, because reducing actin expression with RNA interference caused the formation of terminal web gaps in the absence of infection (22). Characterization of terminal web gaps indicated that they appear precisely when spores begin to form and exit from the cell. Once terminal web gaps form, there do not appear to be additional gaps that form later, although the existing gaps become larger probably because of distension of the lumen. These gaps appear to be specific to *N. parisii* infection, in that they do not appear in response to infection with other pathogens that cause lethal intestinal infections in *C. elegans*. Although the exact function of these gaps has not been established, it has been proposed that they serve to remove a physical barrier to exit for *N. parisii*, such that the spores are able to traverse this cytoskeletal structure to reach the apical surface of the intestinal cell for exit into the lumen.

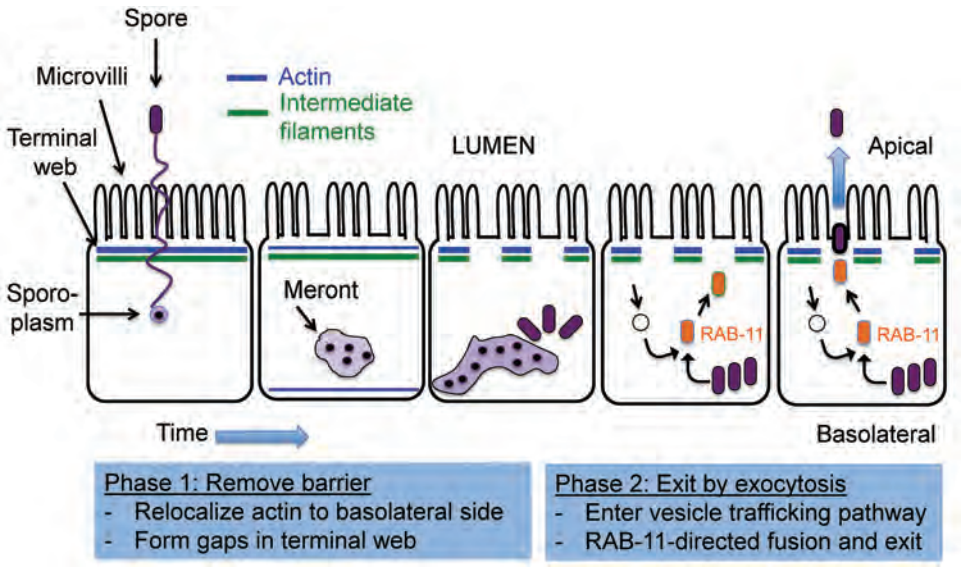

Figure 2 *N. parisii* restructures *C. elegans* intestinal cells and exits via RAB-11-directed apical exocytosis. *N. parisii* exit from *C. elegans* intestinal cells is a two-phase process. Phase 1: When *N. parisii* replicates as a meront inside *C. elegans* intestinal cells, the actin isoform ACT-5 is no longer restricted to just the apical side and instead appears to be ectopically expressed on the basolateral side of the cell. This relocalization may trigger gaps in the terminal web that occur just as spores begin to form in the intestinal cell. Phase 2: *N. parisii* spores are found in separate membrane-bound compartments, become coated in the host small GTPase RAB-11, which is required for spore-containing compartments to fuse with the apical membrane and allow spores to exit into the lumen.

Restructuring of the terminal web may remove a barrier to exit for *N. parisii* so it can reach the apical surface, but how does this pathogen actually traverse this membrane to exit from host cells? Initial studies of *N. parisii* indicated there might be a regulated form of exit, because animals infected with just a few spores were contagious to their neighbors (3). This transmission could happen from animals that were alive and seemingly healthy, suggesting that intestinal cells were not lysed to release pathogen. This nonlytic exit was confirmed through the use of cell integrity assays, and analysis of green fluorescent protein-labeled intestinal cells suggested that the exit was not due to budding off of membranes (22). Because *C. elegans* only has 20 nonrenewable intestinal cells, it is likely advantageous for *N. parisii* to exit from these cells nonlytically.

Further analysis with electron microscopy and molecular markers indicated that, after *N. parisii* meronts differentiate into spores, they are found in a separate membrane-bound compartment, suggesting a membrane fusion mode of exit (23). Indeed, using a marker for the apical side of intestinal cells it was demonstrated that *N. parisii* spore-containing compartments can fuse with the apical membrane and be released into the intestinal lumen to be defecated out and spread to new hosts for disease transmission (23). This exit appears to be highly directional, with exit only out of the apical side into the lumen with no evidence of exit basolaterally to spread into other tissues of the animal (22). Furthermore, this exit is prodigious, with 1 to 2,000 spores shed per worm per hour for several hours (22). Using a spore-shedding assay, researchers screened a small library of predicted small GTPases in *C. elegans* and identified the small GTPase RAB-11 as a critical host factor required for spore fusion, spore exit, and host contagiousness (23). RAB-11 localizes extensively to spores poised to exit into the intestinal lumen. Because RAB-11 directs recycling endocytosis to the apical side of the cell, by hijacking this pathway *N. parisii* can accomplish directional exit from the cell without causing a lysis event that would likely be very detrimental to its host.

In addition, there has been a recent report of the formation of actin coats around exocytosing spores (24). In this study, a genetic screen was performed to identify small GTPases required for formation of these coats, and hits included known actin regulators including Rac1/CED-10 and Cdc42/CDC-42. Analysis of CED-10- and CDC-42-defective animals, which lack these actin coats, indicated that actin coats are not required for spores to exit. However, it is possible that they facilitate exit, perhaps acting to stabilize the large spore cargo contained in an exocytic vesicle. Later during infection there are also large vesicles coated with actin that contain many *N. parisii* spores, and analysis indicates that these vesicles are due to compensatory endocytosis to maintain the membrane balance after the extensive exocytosis of *N. parisii* spores (24).

C. ELEGANS EXHIBITS A UBIQUITIN-MEDIATED RESPONSE TO *N. PARISII* INFECTION

In order to describe the *C. elegans* host response to *N. parisii* infection, RNAseq analysis was performed at five time points during *N. parisii* infection (25). These studies demonstrated that the *C. elegans* transcriptional response to this natural intracellular pathogen is distinct from responses to other previously described extracellular pathogens. However, there was a very strong similarity in the gene expression response to a natural viral pathogen, indicating that some similar feature of the infection caused by these two very distinct pathogens is eliciting a transcriptional response in the host (25, 26). This response was characterized by an upregulation of ubiquitylation components, and these had a functional role in protecting the host from infection, together with components of the autophagy pathway (25). For example, if components of the autophagy pathway were reduced in expression with RNAi, then animals were more susceptible to infection, whereas if the autophagy pathway was upregulated, then animals were more resistant to infection. Furthermore, there was localization of ubiquitin and autophagy components to meronts, suggesting that they are being targeted for destruction by ubiquitin-mediated autophagy, which is a common host defense strategy against intracellular pathogens. Interestingly, many of the microsporidia and virus response genes are also induced by inhibition of the ubiquitin-proteasome system (25). Thus, a trigger for transcriptional response to intracellular infection caused by microsporidia and virus may be perturbation of the ubiquitin proteasome system.

NATURAL VARIATION IN HOST RESISTANCE TO MICROSPORIDIA

Although the studies described above indicate that ubiquitin-mediated signaling in the N2 laboratory strain of *C. elegans* can provide some resistance against *N. parisii*, this host strain always ultimately succumbs to *N. parisii* infection. Interestingly, there is natural variation in *C. elegans* resistance against *N. parisii*, with a *C. elegans* strain from Hawaii that has the ability

to clear infection, demonstrating striking immune capabilities for epithelial cells (27). This capability is restricted to very young animals, and is lost rapidly as animals develop, even before attaining reproductive stage. Intriguingly, it is only at this young age that microsporidia impact the reproductive output of animals, and thus, from an evolutionary perspective, this is the most important life stage at which to have pathogen resistance. With quantitative genetics it was shown that this enhanced, early-life resistance of Hawaiian animals is a complex trait comprising at least four distinct genetic loci. By using near-isogenic lines it was confirmed that two of these loci confer resistance and act additively (27). Although the genes responsible for this resistance have not yet been identified, there are several exciting candidates in these regions, including F-box genes that can serve as ubiquitin ligase adaptors. Of note, these F-box genes are among the most rapidly evolving genes in the *C. elegans* genome, which might be a sign that they are part of an interface with a rapidly evolving pathogen, as part of a host/pathogen coevolutionary arms race (28). Further studies will investigate this possibility. This enhanced resistance of the Hawaiian strain of *C. elegans* enables them to outcompete the susceptible laboratory strain in just a few generations with selective pressure from pathogens. Altogether these findings indicate impressive abilities of epithelial cells in this wild *C. elegans* strain to clear intracellular infection by microsporidian pathogens.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The use of *C. elegans* as a model host for microsporidian infection has provided insight into the exit strategies of microsporidia and how they exploit host cell cytoskeletal and trafficking pathways to facilitate their life cycle. These studies have also provided insight into defense pathways and natural variation in host resistance. Sequencing of the genomes of several microsporidia species has provided intriguing hints about the evolutionary steps that have led to the emergence of this phylum, and identified several candidate effectors these pathogens use to manipulate hosts. However, studies of microsporidia infection in *C. elegans* and any other host are hampered by the lack of ability to transform and genetically manipulate these parasites. Developing these tools would greatly facilitate our understanding of the pathogenesis and life cycle of these ubiquitous parasites.

INTRODUCTION

From the saprotrophs that decay plant material to the pathogens and mutualists that shape plant population dynamics at local and regional scales, fungi are major drivers of ecosystem health, plant productivity, and sustainability in all major biomes (1–5). The ecological roles of such fungi are driven by their own genomic and epigenetic architecture, as well as that of their hosts, often with strong influences from the environmental context in which such interactions occur (1–9).

The environmental context of fungal biology has long been defined in terms of abiotic factors, including those that impact fungal growth and gene expression directly and those that influence the health, growth, structure, or defenses of hosts or substrates with which fungi interact (Fig. 1). Increasingly, however, it is clear that these environmental contexts also include biotic components—that is, additional, interacting species that directly or indirectly alter the outcomes of fungus-host associations. Foremost among these in terms of major effects are endohyphal microbial symbionts, including viruses and bacteria that occur within living fungal hyphae and can profoundly alter fungal phenotypes (i.e., endofungal microbes or microbial endosymbionts) (10–13).

Phenotypic modulation of fungi by endohyphal microbes can cause major shifts in fungal substrate use, enzyme production, thermotolerance, virulence, and the early phases of symbiotic establishment. Much like horizontal gene transfer (HGT) can alter diverse aspects of an organism's phenotype in ecological time, so too can acquisition (or loss) of a microbial symbiont change a virulent fungal pathogen to an avirulent lifestyle, alter the reproductive strategy of the fungus from sexual to asexual, increase fungal secretion of hormones and other signaling molecules relevant to plants, or broaden the niche space and competitive ability of fungi in ways that change the balance of fungal community dynamics (see references 11–19). In these ways endohyphal microbes are important not only in ecological time, but also in the evolution of fungi and reciprocal coevolutionary responses from their hosts (Fig. 1). Thus, understanding the mechanisms underlying symbiotic modulation of fungal phenotypes by microbes has the potential to inform not only fungal ecology but also the trajectory of fungal evolution, especially with regard to convergent phenotypes or ecological modes (e.g., endophytism) for which genomic markers and evolutionary shifts remain elusive. Such questions, paired with growing interest in applications of microbial endosymbionts of fungi, frame an exciting time as mycologists define myriad factors that shape fungal functional traits in short-term ecological snapshots and over evolutionary time.

Broadly defined under de Bary's conceptualization as "the living together of unlike organisms" (20), symbioses between fungi and endohyphal microbes encompass mutualistic, parasitic, and commensal interactions, many of which may be context-dependent in terms of their importance or effects. The best known microbes that occur as endohyphal symbionts represent two domains of life. The first are acellular microbes such as mycoviruses. Mycoviruses (viruses that infect fungi) usually are double-stranded RNA viruses (ca. 70% of known mycoviruses), positive-sense, single-stranded RNA viruses (ca. 30%), and rarely, geminiviruses (21).

[1]School of Plant Sciences; [2]Graduate Interdisciplinary Program in Genetics; [3]School of Natural Resources and the Environment; [4]Department of Ecology and Evolutionary Biology, University of Arizona, Tucson, AZ 85721.

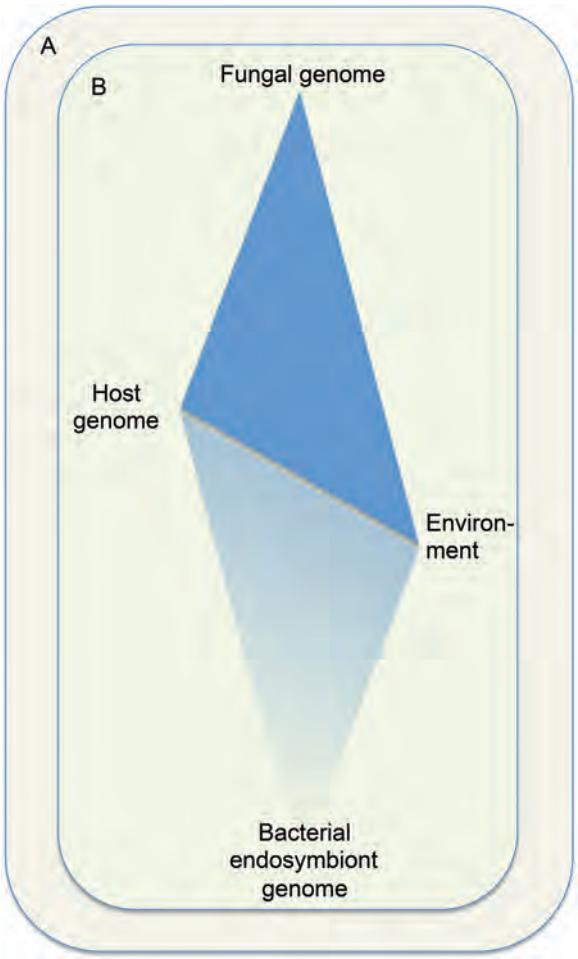

Figure 1 Fungal phenotypes result from direct and indirect interactions of fungal genomes, host genomes, substrate characteristics, and the environment, as well as the genomes of EHB. These often dynamic interactions occur in the context of biotic communities (**A**) that are shaped by an evolutionary and biogeographic context (**B**).

Viruses clearly are important in fungal biology (22–25). Their effects include hypovirulence of pathogens such as *Cryphonectria parasitica*, *Sclerotinia sclerotiorum*, *Botrytis cinerea*, and *Fusarium graminearum* (26–30); disease in various commercially important Agaricomycetes (31, 32); thermotolerance of plants via infection of the fungal endophyte *Curvularia protuberata* (33); and interference with the reproduction of other mycoviruses (34). Studies over the past 50 years have revealed that mycoviruses are ubiquitous in fungi (35, 36), with modes of transmission primarily via hyphal anastomoses and both sexual and asexual spores (but see reference 37 for an example of transmission via a mycophagous insect). Mycoviruses and their importance in fungi represent an exciting frontier for future research relevant to all aspects of fungal biology, and the themes structuring such research (i.e., effects on host phenotypes and gene expression, interaction with cellular defenses, modes of transmission, and roles in fungal ecology and evolution) are being investigated in parallel with studies of the other well-documented and diverse endosymbionts of fungi, in the domain Bacteria.

Much like other eukaryotes, fungi interact closely with bacteria. These interactions occur in the mycelosphere (the area around the mycelium with which the fungus interacts), on living hyphae (i.e., on the mycelo-plane), and within living structures such as hyphae (and in some cases spores; reviewed in reference 16). Those bacteria that occur within living hyphae are endofungal bacteria or endohyphal bacteria (EHB), broadly parallel to the concept of fungi occurring as endophytes of plants. These bacteria are grouped functionally based on their observation within hyphae, but their names do not imply obligate endosymbiotic lifestyles or proscribed benefits or costs to hosts. Instead, these phylogenetically diverse bacteria appear to have converged upon the capacity to infect fungal hyphae (38), together encompassing a spectrum of facultative to obligate associations, diverse localizations within fungal cells, and a range of outcomes of their associations.

Our thesis is that understanding the contributions of these EHB to fungal biology is a major frontier in studies of the fungal kingdom (16, 38–42). Their study is particularly exciting at present given the potential to explore new fungal strains and well-established model systems with high-throughput phenotyping and front-line molecular and computational methods in metabarcoding, genomics, and metatranscriptomics (19, 41–44). Our goals in this chapter are to provide a historical perspective on EHB as a means to frame a functional classification system for these bacterial associates of fungi, to summarize their functional importance and related genomic traits, and to highlight emerging methods by which EHB can be studied, pointing to emergent questions regarding the role of bacterial endosymbionts in fungal biology.

HISTORICAL PERSPECTIVES

Often present in symptomless mycelia, EHB inhabit diverse fungi representing at least the Mucoromycota (*sensu* reference 45: Mortierellomycotina, Mucoromycotina, Glomeromycotina) and Dikarya (Basidiomycota and Ascomycota) (38, 46–49). Most fungi documented as hosts of EHB are plant-associated, including arbuscular and ectomycorrhizal fungi, plant pathogens, saprotrophic fungi, soilborne fungi that interact with seeds,

and endophytes of tissues such as roots and leaves. Some clinically important fungi also harbor EHB, though they do not appear to play a major role in pathogenesis in human and animal systems (50–52).

Although it is not surprising that like many eukaryotes, fungi host bacterial endosymbionts, the discovery of their prevalence and their potential to shape major plant-fungi interactions has captured recent interest. The seminal discovery in 2005 that pathogenicity of a major plant pathogenic fungus, *Rhizopus microsporus*, was driven by an EHB (14) brought classical research on "bacteria-like organelles" (BLOs) (53) to the fore of plant pathology and mycology alike. Now, bacterial genomics, microscopy, and molecular biology are providing insights into the endohyphal lifestyle and the mechanisms by which such bacteria shape fungal traits.

EHB were first described in arbuscular mycorrhizal fungi in the 1970s (54, 55), although their status as bacteria was not confirmed until they were imaged by electron microscopy (53). Their discovery was complemented by the description of the cyanobacterium *Nostoc punctiforme* living within the fungus *Geosiphon pyriforme* (Glomeromycotina) (see 15, 56–59). Most classical mycology texts rarely mention bacteria except to differentiate them from fungi (e.g., 60–63, as also observed in reference 64). However, Wolf and Wolf frequently reference bacteria-fungi interactions, referencing "associative interactions" and characterizing fungi as gregarious in terms of their associations with prokaryotes (65). Notably, Wolf and Wolf also note that "pure cultures" of fungi in nature are "either non-existent or else occur as miraculous oddities" (65), speaking presciently to our current understanding of the complex associations that frame many aspects of microbial and fungal ecology.

In the 1970s several studies established that BLOs were present in diverse fungi. Mosse noted the presence of self-replicating bacteria in spores of *Endogone*, speculating that BLOs observed there might be spores of Actinobacteria (66). Protzenko also observed a bacterium or BLO in an endotrophic mycorrhizal fungus of pea, noting that the microbe's cell wall was located in close proximity to that of its host and stating that no morphological response of the fungus was observed (54). Microbial associates were observed in Ascomycota as early as 1973, when intracytoplasmic organisms ("probably bacteria") were recorded in *Scutellinia*, a genus of saprotrophs (67).

In most of these cases early observations were by microscopists, with MacDonald et al. noting that a major challenge in the further study of BLOs was that they appeared to be unculturable (68). Perhaps for this reason studies contemporaneous with the early description of BLOs focused on other bacteria-fungi associations despite compelling evidence of unusual microbial- or microbe-like structures in fungal hyphae. For example, the last decades of the 20th century were particularly rich in studies regarding mycorrhizal helper bacteria (reviewed in reference 69; see also reference 16), bacterial ectosymbionts of fungi (70, 71), interactions between cyanobacteria and lichen-forming fungi (72), bacterial pathogens of cultivated mushrooms (73, 74), the importance of mixed-microbial fermentations in foods (64, referencing 75), and antagonism between fungi and bacteria. Scannerini and Bonfante-Fasolo summarized the state of the field with respect to BLOs and endosymbiotic bacteria in fungi in general: "the available information remains scanty" (76).

Even so, Scannerini and Bonfante-Fasolo pointed to ca. 10 published and unpublished studies highlighting the structural classification of BLOs and endosymbiotic bacteria in arbsucular mycorrhizal fungi, providing evidence that these "endocytobionts" could be observed in spores, hyphae, arbuscules, and other structures (76). Moreover, they diagnosed the existence of two types of endocytobionts in fungal tissue: (i) rod-shaped bacteria with visible cell walls, nucleoids, and ribosomes, typically enclosed in vacuoles, observed in *Glomus* and an unidentified arbuscular mycorrhizal fungus (68, 77, 78), and (ii) BLOs, which lack cell walls, have a coccoid form, and are localized in the cytoplasm of diverse arbuscular mycorrhizal fungi. MacDonald and Chandler reported that such BLOs typically could be found near the nucleus or mitochondria of fungal cells, although their placement varied (53). Scannerini and Bonfante-Fasolo concluded that these BLOs resemble the vertically transmitted bacterial endosymbionts of some insects (76).

Enabled by these pioneering studies, a groundswell of interest in symbioses, and the combination of new analytical methods in visualization and molecular biology, a renewed focus on bacterial endosymbionts of fungi has emerged over the nearly 3 decades since Scannerini and Bonfante-Fasolo's review (76). Reconstruction of this phase in the study of bacterial endosymbionts is somewhat challenging because terminology has changed over time (i.e., endocytobionts, endocellular bacteria, endofungal bacteria, endobacteria, bacterial endosymbionts and endosymbiotic bacteria, and EHB). However, literature searches (e.g., in the Web of Science, early 2017, with these terms in Boolean arrays) point to a growth in publication rate from 1996 onward, especially over the past 10 years.

In 1996, one paper highlighted the presence of ca. 250,000 BLOs in a single spore of the arbuscular mycorrhizal fungus *Gigaspora margarita* and used 16S rRNA sequencing to identify bacteria within living fungi as members of the Gram-negative bacterial genus *Burkholderia* (*Betaproteobacteria*; now recognized as *Paraburkholderia* and hereafter referred to as such [46, 79]). By 2000, such studies included surveys of diverse arbuscular mycorrhizal fungi and revealed phylogenetic relationships among *Paraburkholderia* associated with various Gigasporaceae (80). Tools such as *in situ* hybridization further enabled visualization of symbiotic bacteria in spores and hyphae (e.g., of *G. margarita* [80]). Subsequent studies moved rapidly to address the functional significance of such bacteria, drawing from genomics to show that a *Paraburkholderia* in *G. margarita* has nitrogen fixation genes (81) and identifying regions coding for particular proteins (e.g., a methyl accepting chemotaxis protein [82]).

The first major papers on other fungal systems emerged with the 2005 study of *R. microsporus* (Mucoromycotina), wherein a strain of *Paraburkholderia* was shown to produce rhizoxin, a macrocyclic polyketide metabolite and phytotoxin critical to pathogenicity associated with rice seedling blight (14). By 2010, endohyphal *Burkholderiaceae* also were reported from Mortierellomycotina (83), highlighting the prevalence of this bacterial family across the Mucoromycota. Contemporaneously, *Alphaproteobacteria* were identified in plant-associated mycelium of the ectomycorrhizal basidiomycete *Laccaria bicolor* (84), demonstrating that diverse lineages of *Proteobacteria* can occur as endofungal symbionts and indicating that septate hyphae such as those in the Basidiomycota did not preclude establishment of EHB. A second *Alphaproteobacteria*, *Rhizobium radiobacter*, was identified subsequently as relevant to the establishment of endophytic symbioses by the basidiomycete *Piriformospora indica* (Sebacinales), which affiliates with roots of barley and other hosts (85).

Since that time, studies of EHB have widened in two main ways. First, the combined approaches of molecular biology, genomics, and computational biology have led to the identification of the coccoid BLOs in Glomeromycotina that had been observed for decades by microscopy alone. Now known as *Mollicutes*-related endobacteria and placed phylogenetically in the *Tenericutes*, these EHB are recognized as widespread symbionts of arbuscular mycorrhizal fungi (86, 87). They exhibit within-host genetic variation, small genomes, and complex genomic and evolutionary histories (41, 42, 88).

Second, the study of EHB now has extended to the Ascomycota, the most species-rich phylum of fungi. In the first studies evaluating phylogenetically diverse Ascomycota for EHB, fungi occurring as foliar endophytes were shown to harbor not only many lineages of *Proteobacteria* but also diverse Gram-negative and Gram-positive bacteria from the *Bacteroidetes* and *Firmicutes*, respectively (38, 49). As in other groups of fungi, visualization of these EHB was facilitated by LIVE/DEAD staining (i.e., LIVE/DEAD BacLight Bacterial Viability Kit, Invitrogen [38]) and by more precise methods such as fluorescent *in situ* hybridization (Fig. 2) and bacterial transformation for fluorescence (Fig. 3). Recent work has addressed the phylogenetic diversity of EHB (Fig. 4) (see 49), their significance with regard to fungal thermotolerance, production of plant hormones and activity of plant cell wall-degrading enzymes (Fig. 5) (11, 17), their alteration of fungal growth and plant tissue degradation (Fig. 6), their capacity to influence early stages of symbiotic establishment between endophytes and hosts (Fig. 7), their variation among closely related fungi that infect seeds as opposed to leaves (49), their ability to alter carbon substrate use by a

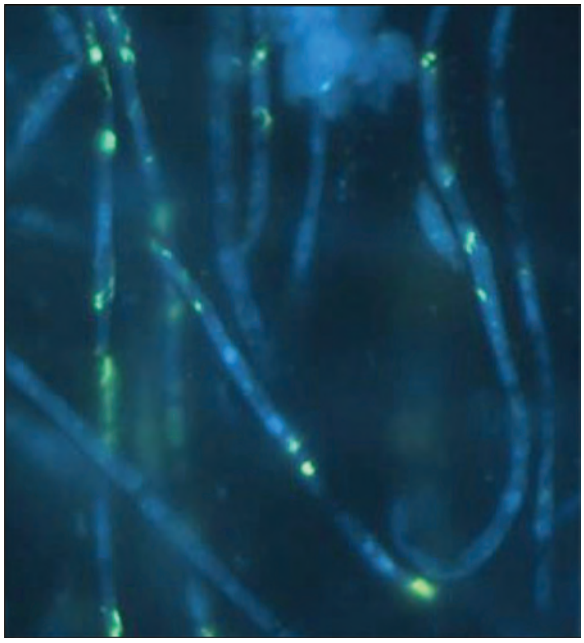

Figure 2 Fluorescent *in situ* hybridization microscopy showing endophytic *Pestalotiopsis* sp. 9143 harboring the class 3 endohyphal bacterium *Luteibacter* sp. 9143. The image shows the TAMRA fluorophore with the DAPI counterstain (blue), highlighting fungal nuclear and mitochondrial DNA in addition to bacteria (yellow/green). (Reprinted from reference 38).

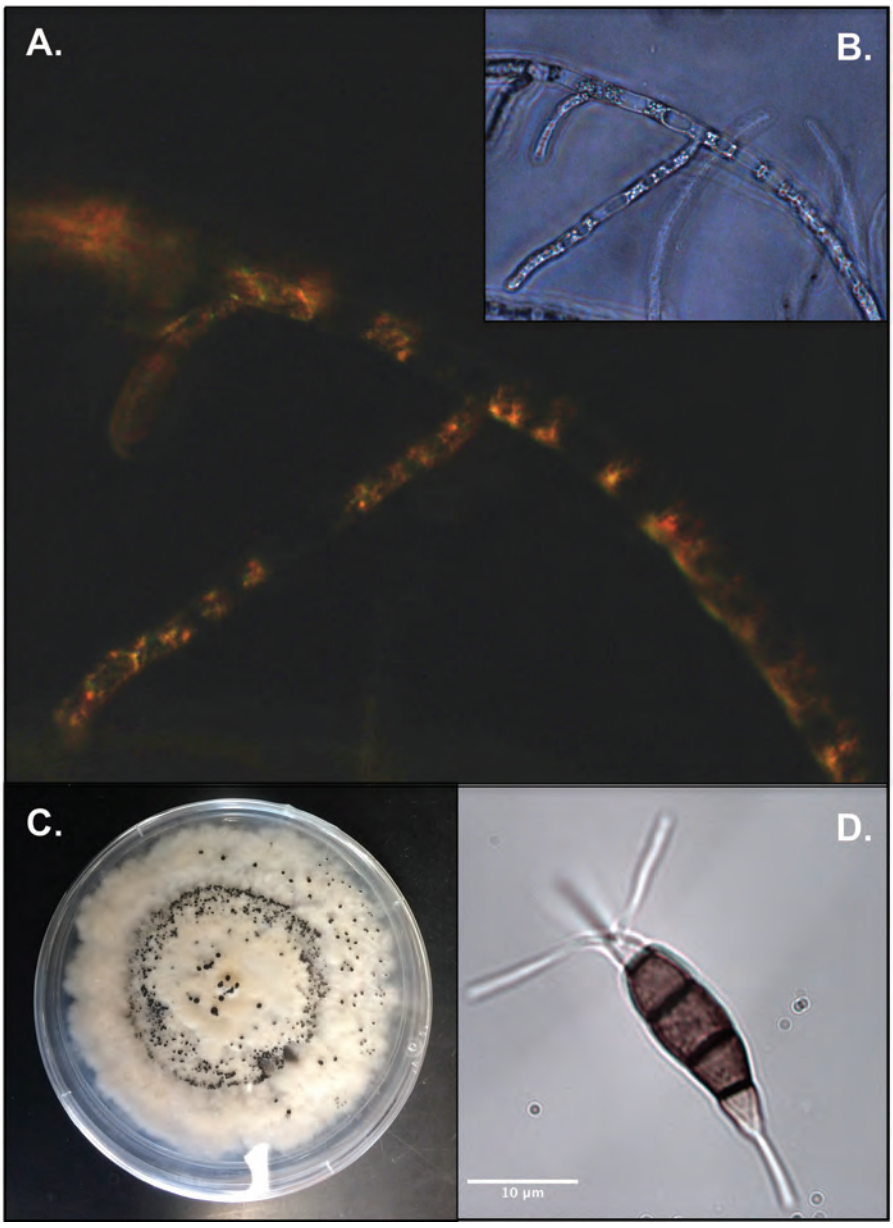

Figure 3 (**A**) Fluorescence microscopy (400×) reveals successful reintroduction of the class 3 EHB *Luteibacter* sp. 9143 with the tdTomato construct into hyphae of *Pestalotiopsis* sp. 9143. (**B**) The same image under phase contrast. (Images reprinted with modification from reference 48). (**C**) Healthy and apparently axenic colony of *Pestalotiopsis* sp. 9143 in which EHB are present but not visible without microscopy. (**D**) Conidium of *Pestalotiopsis* sp. 9143. Although EHB are widespread in the culture that produced such conidia, no conidial transmission (i.e., no vertical transmission) has been detected.

seed-associated fungus *in vitro* (19), and their genomic features (Fig. 8) (43).

Together, ca. 100 studies since 1996 have explored the biological, genomic, biochemical, evolutionary, ecological, and functional traits of EHB, painting a picture quite different than that encapsulated by the axenic approach to fungal biology (per reference 65): one of widespread, diverse, and important symbioses that frame fungal traits in cryptic ways. Emergent themes are that EHB are common in fungi, that they likely represent convergence in the general ability to live within fungi but do so in diverse ways with differing outcomes,

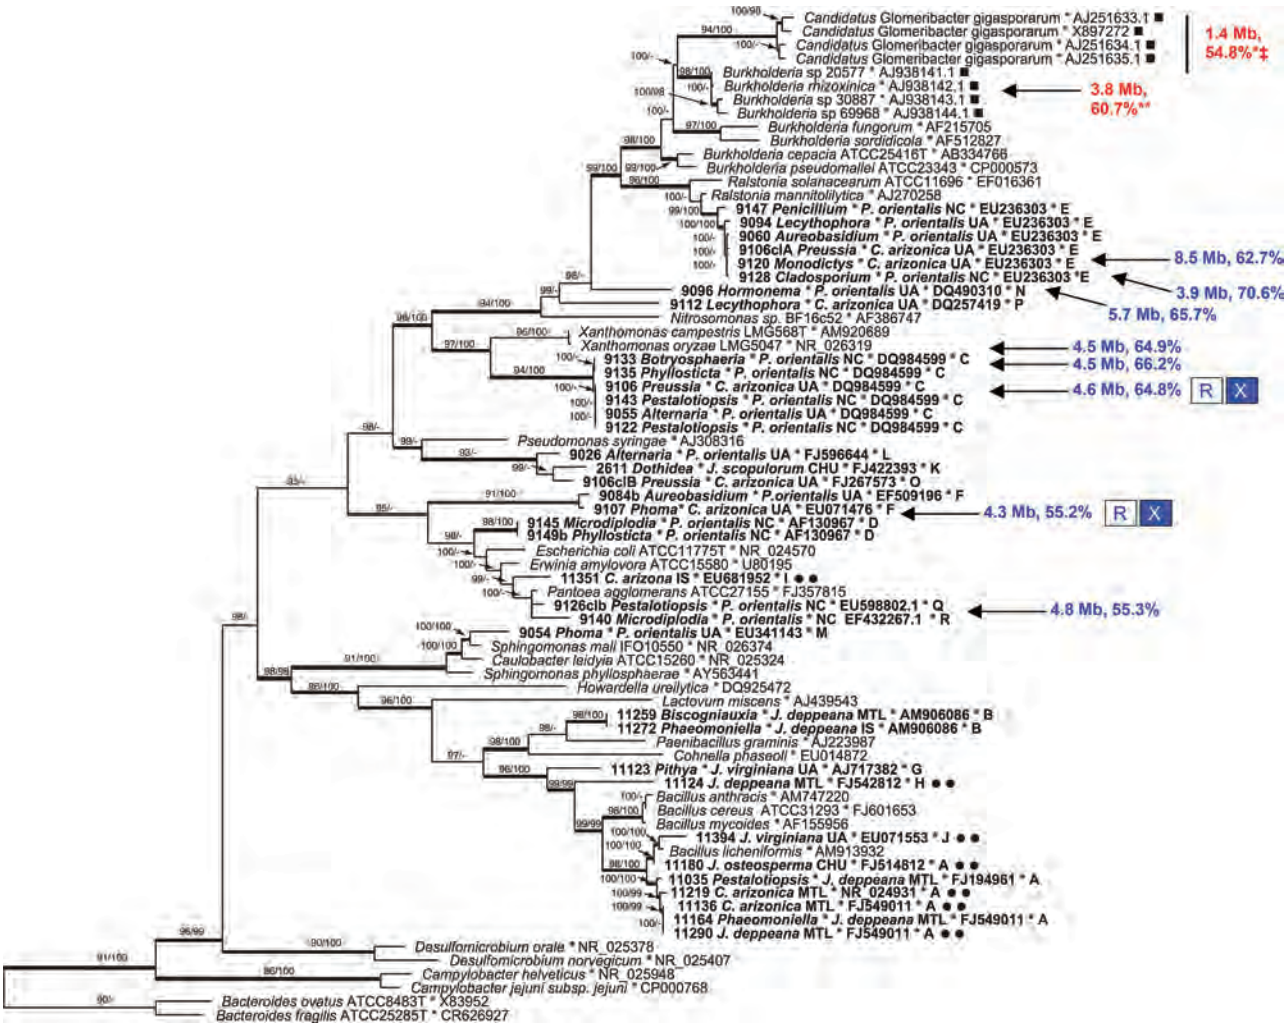

Figure 4 Phylogenetic relationships of selected class 2 EHB (black squares) associated with Mucoromycota, class 3 EHB (bold text) in the *Proteobacteria* and *Firmicutes* that associate with fungal endophytes in the Ascomycota, known bacteria (regular font), and bacterial endophytes (black circles). For fungal endophytes hosting class 3 EHB, taxon labels indicate the fungal genus, the plant species from which these fungi were obtained (*Cupressus arizonica*, *Juniperus deppeana*, *Juniperus scopulorum*, *Platycladus orientalis*), the location in which the host tree was growing (NC, North Carolina; UA, University of Arizona Campus Arboretum, Tucson, Arizona; CHU, M, and MTL, montane regions of Arizona), relevant GenBank accessions, and bacterial genotype groups (operational taxonomic units) based on 97% similarity of bacterial 16S rRNA (38). Colored labels indicate genome size and GC content for class 2 EHB (red) and class 3 EHB (blue), with the latter highlighting that members of the same 16S rRNA operational taxonomic unit can differ markedly in their genomic traits. Boxes containing R and X indicate class 3 EHB that have been reassociated with cured hosts under laboratory conditions (R) and transferred successfully and stably into novel fungal hosts (X). Labels for bacterial endophytes are similar to those of EHB in fungal endophytes but lack fungal hosts, because these bacteria occurred directly in plant tissues. Phylogenetic reconstruction from reference 38 depicts the results of a Bayesian analysis of 16S rRNA gene sequences. Branch support values indicate parsimony bootstrap values (≥70%; before slash) and Bayesian posterior probabilities (≥95%; after slash). Branches in bold indicate ≥70% neighbor-joining bootstrap values. Endohyphal *Burkholderia* listed here have since been reclassified as *Paraburkholderia* (79).

Figure 5 Context-dependence in the outcomes of interactions between class 3 EHB and foliar endophytes (rows) and meaningful phenotypic variation among symbiotic partners (columns). Cells reflect the significance and directionality of repeated-measures analyses of variance assessing growth of fungal strains containing EHB and clones that were cured of EHB by antibiotic treatment *in vitro* over 14 days on water agar (low nutrient), malt extract agar (high nutrient), lignin medium (with indulin as the sole carbon source), and cellulose medium (carboxymethylcellulose as the sole carbon source). Thermotolerance was assessed on two media at 36°C. Cellulase activity was measured as zone-of-clearing scaled by colony diameter. Orange cells indicate that the growth or cellulase activity of clones with EHB significantly exceeded that of cured clones. Blue cells indicate that the growth or cellulase activity of cured clones significantly exceeded that of clones with EHB. Gray boxes indicate no significant difference (ns) as a function of EHB status. Fungi in red differ only in the identity of their EHB, in that their fungal genotypes at the barcode locus are identical. The endohyphal *Burkholderia* listed here is now *Paraburkholderia* (79).

and that they vary reliably in suites of characteristics that can be used to place them into an operational classification. Below we define a preliminary classification for EHB before exploring in greater detail their functional significance. We then focus on one functional group to explore methods of study and research frontiers.

FUNCTIONAL CLASSIFICATION, TRAITS, AND SIGNIFICANCE OF EHB

When BLOs were first described from hyphae and spores of various Glomeromycotina, three interpretations were put forward with respect to their potential functional significance: (i) they might be obligate symbionts living in close and sustained relationships with their host fungi, (ii) they might be transient associates, repeatedly lost and reacquired by fungi, and/or (iii) they might be organelles of uncertain function and origin (68). Evidence now supports the first two interpretations for diverse EHB, albeit in different functional groups of fungi and bacteria. Here we assign a functional classification to EHB that references the phylogenetic classifications and functional traits of host fungi, genomic traits of EHB, and corresponding ecological and evolutionary traits of EHB such as transmission mode (Table 1). We identify three functional classes, here defined as class 1, class 2, and class 3 EHB.

Class 1 EHB

Class 1 EHB (Table 1) correspond to the EHB typically referred as *Mollicutes*-related endobacteria. These are consistent with the small, coccoid BLOs observed over the past half-century in arbuscular mycorrhizal fungi (41, 42, 68, 76, 87–90). These members of the phylum *Tenericutes* are closely related to various *Mycoplasma* species in the class *Mollicutes* (41, 42) and are thought to represent ancient associates of Glomeromycotina and related fungi (42, 87). Recently, a genus was erected to encompass these EHB (*Candidatus* Moeniiplasma) (91). They have not yet been isolated in culture (91).

Overall, class 1 is characterized by high intrahost genomic diversity, an apparently global distribution, and phylogenetic structure that mirrors species distinctions in their hosts (41, 42). They are considered heritable, although horizontal transmission coupled with recombination has been suggested to explain diverse intrahost populations (41, 88, 91). They have been observed in Mucoromycotina (e.g., *Endogone lactiflua* and close relatives) and Glomeromycotina (e.g., members of the Archaeosporales, Glomales, and Diversisporales [87, 90]), where they occur in the cytoplasm of fungal cells (89, 92). They typically are small (300 to 600 nm) and coccoid in appearance (89). Initially, the appearance of an electron-dense layer outside the plasma membrane led to the suggestion that they might have cell walls similar to those of Gram-positive bacteria, but this has since been refuted (41, 42, 91). They are not surrounded by host-derived membranes but instead are localized directly in the cytosol of living cells (87, 89).

The genomes of class 1 EHB are small relative to other known EHB (Table 1), but their genome sizes are consistent with those of horizontally transmitted

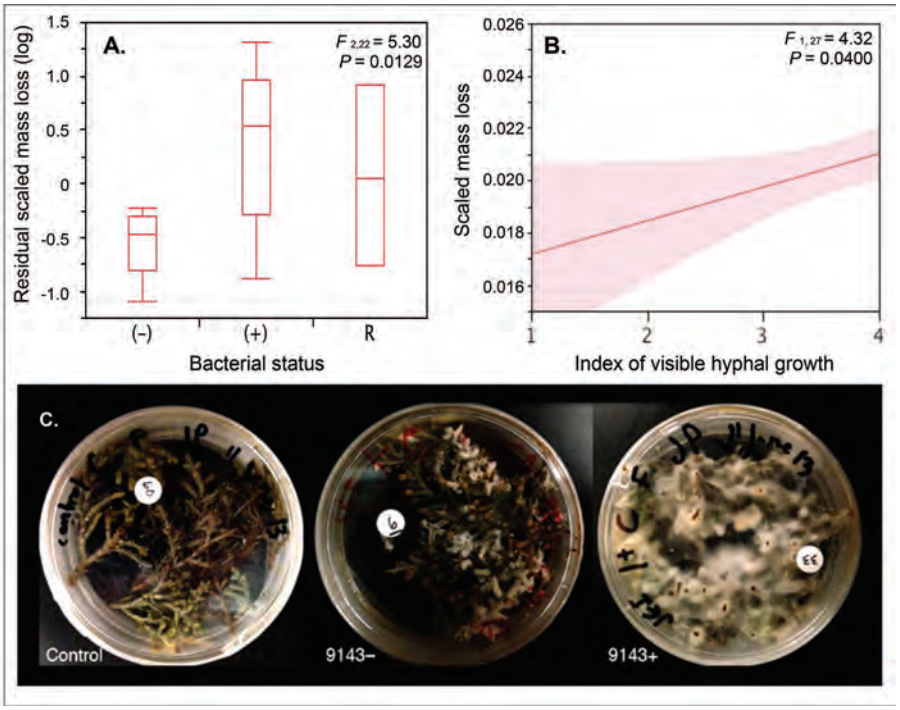

Figure 6 (**A**) Significantly more mass is lost from surface-sterilized, senescent leaves of a focal tree (*Cupressus arizonica*) following inoculation with *Pestalotiopsis* containing a class 3 EHB (*Luteibacter* sp. 9143, marked with +) versus treatment with clones of the same fungus cured of its EHB (–). Reassociation of the EHB and fungus following curing (R) led to mass loss that did not differ significantly from the original EHB-fungi association. Data reflect 14 days postinoculation in moist chambers. (**B**) Scaled mass loss is positively correlated with the quantity of visible hyphae on tissue (0 = no visible hyphae; 4 = 100% of foliage covered with fungal growth). (**C**) Hyphal coverage (white) after 14 days on surface-sterilized, presenescent foliage of *C. arizonica* in moist chambers. Controls (water only) had no visible hyphal growth. Hyphal coverage in *Pestalotiopsis* with EHB exceeded that of *Pestalotiopsis* without the EHB.

Mycoplasma (90). Genomes of *Mollicutes*-related endobacteria sequenced to date are characterized by low GC content (Table 1), low gene content, and proteins with domains involved in interactions with eukaryotic hosts, as well as genes acquired by HGT from arbuscular mycorrhizal fungi (41, 42). Genes acquired from their hosts include protein domains relevant to fungal programmed cell death, self/nonself recognition, and post-translational modification (summarized in reference 90). Their genomes also show evidence of intimate interactions with plectroviruses (*Inoviridae*, single-stranded DNA viruses affiliated with diverse *Tenericutes* [41]).

At present there is some debate regarding the functional roles of class 1 EHB. Their metabolic reliance on their fungal hosts is underscored by their limited biosynthetic capacity (summarized in reference 90). Genome analyses designed to infer function are hindered by the genetic distinctiveness of class 1 EHB, because functional annotation is lacking for >50% of genes (90). The conclusions of two contemporaneous papers differ with respect to the potential for class 1 EHB to be antagonists or mutualists with respect to their host fungi (41, 42, 88).

Class 2 EHB

In terms of host breadth, genome size, genomic traits, obligacy, and metabolic reliance on their hosts, the diverse assemblage here identified as class 2 EHB is intermediate between classes 1 and 3 (Table 1). These bacteria associate with diverse Mucoromycota and Ascomycota (Table 1). Members of class 2 demonstrate a capacity for transmission via spores as well as growth in vegetative hyphae and reproductive structures such as ascocarps (e.g., in the ectomycorrhizal fungus *Tuber borchii*) (15, 93, 94). They are best known in soilborne pathogens, seed-infecting fungi, ectomycorrhizal fungi, and the arbuscular mycorrhizae in which they were first characterized.

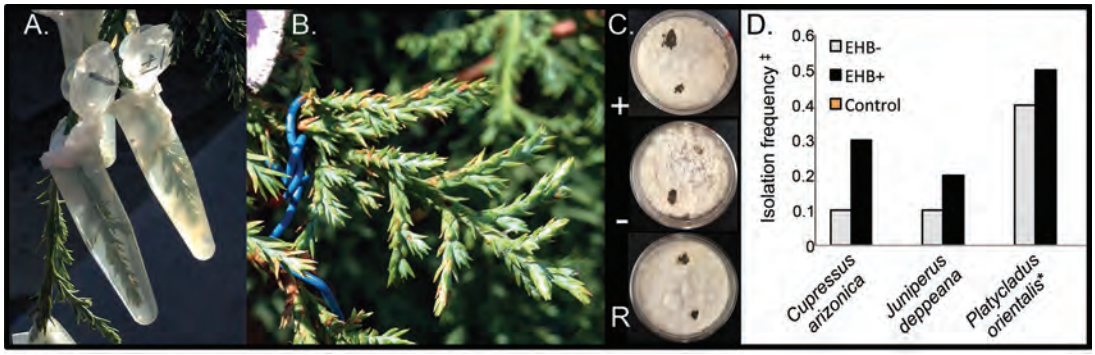

Figure 7 Class 3 EHB can modulate the establishment of endophytic fungi in healthy foliage. (**A**) Surface-sterilized foliage of the focal tree species, *Cupressus arizonica*, was immersed in a suspension containing axenic hyphae, a suspension containing hyphae with the EHB, or water only. Tubes were left in place for 24 h and then removed. (**B**) Inoculated branches were marked with colored wire according to treatment. After 2 weeks, tissue was surface-sterilized and evaluated for endophytes. (**C**) The foliar endophyte was reisolated from surface-sterilized, inoculated plant tissue (+, endophyte with EHB; –, axenic endophyte; R, reassociated EHB and endophyte). These strains do not differ in growth on standard media under laboratory conditions. (**D**) Successful inoculation by the axenic endophyte (EHB–, gray) and especially by the endophyte with EHB (EHB+, black); *y* axis shows percentage of 2-mm tissue segments from which the fungus was reisolated. The endophyte was never observed in untreated foliage (control, orange). *Host species from which focal symbiotic pair was first isolated.

Class 2 EHB have moderately sized genomes (ca. 1.4 to 3.8 Mb), moderate GC content (ca. 46 to 60%), a predominance (although with some exceptions) of vertical transmission, limited culturability or a high degree of fastidiousness, and in many cases, occurrence in fungal cells within membranes of host origin (Table 1) (15, 89). Some EHB in this class have yet to be isolated in culture (see 19, 93–95), but some can be cultivated outside of their hosts under laboratory conditions (93). Homogenizing mycelia and using genomics to predict substrate use or optimize growth conditions may greatly increase the success with which EHB in this functional group can be isolated in culture (96).

As presently defined (Table 1), class 2 EHB include members of the *Burkholderiaceae* (*Betaproteobacteria*) such as "*Candidatus* Glomeribacter gigasporum" in various Glomeromycotina (95, 97, 98), *Paraburkholderia rhizoxinica* and *Paraburkholderia endofungorum* in *R. microsporus* (Mucoromycotina [99–101]), and *Mycoavidus cysteinexigens* in *Mortierella elongata* (Mortierellomycotina [44, 96]). Also included here are intriguing examples of vertically transmitted and/or apparently unculturable associates of Dikarya, including the *Cytophaga-Flexibacter-Bacteroides* clade in ectomycorrhizal *T. borchii* (Ascomycota) (94, 102) and *Chitinophaga* sp. (Bacteroidetes) in a seed-associated *Fusarium keratoplasticum* (Ascomycota) (19, 49).

Such class 2 EHB illustrate the range of genomic and ecological traits that characterize this diverse functional group. Here we explore the four best known of these: "*Candidatus* Glomeribacter gigasporum," *P. rhizoxinica*, *M. cysteinexigens*, and *Chitinophaga* sp.

"*Candidatus* Glomeribacter gigasporum" (*Burkholderiaceae*) is an EHB affiliated with primarily Glomeromycotina such as *G. margarita*, *Scutellospora persica*, and *Scutellospora castanea* (97). It is vertically transmitted through spores and has not been grown in culture outside of its hosts (103), although it can be separated from host mycelium and maintained for several weeks under laboratory conditions (98). Consistent with vertical transmission and a high degree of metabolic dependence on its host, it has a relatively small genome (1.4 Mb with one plasmid [98]; 1.72 Mb with three plasmids [93]) and limited capacity for carbon catabolism, gluconeogenesis, phosphate transport, and the synthesis of essential amino acids. In addition to synthesizing diverse metabolites, including antibiotics, vitamin B_{12}, and molecules relevant to resistance against toxins (93), it influences the protein expression and lipid profiles of its host fungus, as well as spore morphology and hyphal growth in presymbiotic phases (104, 105). Like a related member of class 3 EHB (*Paraburkholderia* sp. 9120; see Fig. 8 and discussion below), it expresses type II and type III secretion systems (43, 93).

Figure 8 Genomic traits of class 3 EHB associated with foliar endophytes in the Ascomycota (blue font) compared with nonendohyphal relatives (black) and a model class 2 EHB (red), showing the bacterial habitat, genome size, gene count, and results of Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway searches to identify bacterial pathways involved in signaling between bacteria and eukaryotes (43). Boxes along the *x* axis indicate KEGG pathway identifiers (top) for constituent genes for each bacterial secretion system. Colored boxes indicate that at least one gene within the genome is present and classified according to that specific KEGG identifier. Numbers inside the colored boxes denote that more than one gene within that genome is classified according to that KEGG identifier. Boxes for EHB bacteria described first in reference 43 are shown in blue. Green boxes highlight a species that interacts with fungi but does not appear to occur endohyphally. Endohyphal *Burkholderia* listed here are now reclassified as *Paraburkholderia* (79).

Table 1 Functional classification of endohyphal bacteria into three operational classes based on host information, bacterial phylogeny, genomic traits, and associated traits relevant to bacteria/fungi interactions and ecology (references listed in text)

Class	Equivalency or example[a]	Fungal clade	Bacterial clade	Genome size (Mb)	GC content (%)	Transmission	Obligacy of bacterial association	Metabolic reliance on host	Localization	Cell wall	Proposed interaction with host
Class 1	*Mollicutes*-related endobacteria (MREs)*	Mucoromycota (Glomeromycotina, Mucoromycotina)	*Tenericutes*	0.7–1.2	32.0–34.3	Vertical	Obligate	High	Cytoplasm	No	Debated and presently unknown
Class 2	*Burkholderia* (*Paraburkholderia*) *rhizoxinica*‡ and *Paraburkholderia endofungorum*‡, "*Candidatus* Glomeribacter gigasporum"‡, *Chitinophaga* sp. EHB01‡, *Cytophaga-Flexibacter-Bacteroides*‡	Mucoromycota, soilborne Ascomycota	*Proteobacteria*, *Bacteroidetes*	1.4–3.8	46.1–60.7	Vertical but potentially horizontal in some species	Obligate to facultative	Moderate to high	Cytoplasm; some surrounded by membrane of fungal origin	Yes	Generally beneficial but can be context-dependent
Class 3	*Luteibacter* sp. 9143‡, *Erwinia* sp. 9145‡, *Pantoea* sp. 9140‡, *Pantoea sp*. 9133‡, *Massilia* sp. 9096‡, *Rhizobium* sp. 9140‡, *Curtobacterium* sp. 9128‡, *Paenibacillus* sp.‡, *Rhizobium radiobacter*‡	Diverse Ascomycota, Basidiomycota	*Proteobacteria*, *Firmicutes*, others	3.9–8.5	55.2–70.6	Horizontal	Facultative	Moderate	Cytoplasm; some surrounded by membrane of fungal origin	Yes	Mixed; highly context-dependent

[a]*, equivalency; ‡, example.

Ghignone et al. provide a model for tripartite interactions among "*Candidatus* Glomeribacter gigasporum," its fungal host, and the host plant with which these symbionts interact, highlighting energy fluxes in living cells, metabolic exchange, and the occurrence of the EHB in protein-rich vacuoles (93). This species is a model for studies of plant-arbuscular mycorrhizal-EHB associations.

Paraburkholderia rhizoxinica (formerly *Burkholderia rhizoxinica*) is affiliated with *R. microsporus* (Mucoromycotina), in which it is responsible for producing the toxins that have been identified as causal in rice seedling blight disease (14, 52). These include rhizoxin, a potent antimitotic agent, and rhizonin, a hepatotoxic cyclopeptide, both of which were previously thought to be mycotoxins produced by *R. microsporus* (52, 99, 101). Interestingly, the fungal host requires *P. rhizoxinica* for sporangium and spore development, tightly linking EHB with fungal reproduction and fitness (100). The same authors developed techniques for labeling and artificially introducing the bacterium into fungal structures, thus establishing a highly informative experimental system for studying EHB-fungi interactions (100). By studying resistance of fungi to the antimitotic properties of rhizoxin, Schmitt et al. suggested that the stable affiliation of *P. rhizoxinica* with *R. microsporus* represents a transition from parasitism to mutualism (106). Consistent with its close association with its fungal host, *P. rhizoxinica* has a 3.75-Mb genome with primary metabolism oriented to the acquisition and use of fungal metabolic products (107). Like many other EHB, and many non-EHB in the *Burkholderiaceae*, it is characterized by the presence of multiple plasmids in addition to its own chromosome. The biosynthetic gene cluster relevant to rhizoxin is located on the bacterial chromosome itself (107). Although it is transmitted via spores, evidence from a global population study suggests that past horizontal transmission events have shaped the genomic architecture of this species (47). *P. rhizoxinica* can be grown with limited success in culture under laboratory conditions (47, 52, 107). This EHB can actively invade fungal hyphae in part through use of a type II secretion system, which releases chitinolytic enzymes (107, 108). Strikingly, incursion into fungal cells occurs via softening of the fungal cell wall and leaves little detectable trace (108). In pure culture the EHB is motile, occurring in pairs or at times in clusters as short or coccoid rods ca. 1.2 to 2 μm long and 0.6 to 1.2 μm in diameter (107). This EHB was the first to be characterized as markedly altering the phenotype of fungi with respect to plant pathogenicity and toxin production (14), and it is a model system for genomics and the study of plant pathogen-EHB interactions. A close relative, *Paraburkholderia endofungorum*, was described in 2007 and shares many traits with *P. rhizoxinica* (109).

Mycoavidus cysteinexigens (*Burkholderiaceae*) is an EHB associated with the soil-inhabiting fungus *Mortierella elongata* (Mortierellomycotina) (44, 63, 110). This bacterium has been studied primarily via metagenomics (44) and genome sequencing of the bacterial fraction released from homogenized or macerated mycelium (110). Its 2.6-Mb genome reflects reduced function and considerable reliance on the fungal host (111). Detection of a potential cysteine dependency from genomic analyses led to its successful isolation (110), and treatment with antibiotics has revealed that it plays a major role in modulating host metabolism (44). The association between *Mortierella* and *Mycoavidus*, like that between other EHB and Glomeromycotina, is thought to be ancient, spanning in this case an estimated 350 million years (44).

Unlike the above examples, which encompass EHB in the *Burkholderiaceae* that occur in fungi in the Mucoromycota, *Chitinophaga* sp. EHB01 (*Bacteroidetes*) is affiliated with a member of the Ascomycota. It was isolated originally from *F. keratoplasticum* PS0362A, which in turn was isolated from a seed of a tropical tree (*Cecropia insignis*) after exposure to soil for several weeks in a lowland forest understory (19, 49). The genome of this EHB has not yet been sequenced, but the relevance of the *Chitinophaga-Fusarium* association has been evaluated using phenotypic microarrays. Since their development, phenotypic microarrays have been extended from evaluations with bacteria only to studies of yeasts and filamentous fungi. Shaffer et al. used phenotypic microarrays to compare growth of *F. keratoplasticum* with and without *Chitinophaga* on diverse carbon substrates (19). The fungus grew readily on standard growth media and on diverse substrates in the absence of the EHB, and on standard media, colony diameter and spore production were similar regardless of the presence of the EHB. However, global substrate use (i.e., growth across all substrates considered simultaneously) differed markedly between clones as a function of *Chitinophaga* infection. In particular, the axenic fungus grew to a higher density over the course of the experiment on 5 (of 95) carbon substrates (1 monosaccharide, D-arabinose; 2 stereoisomeric forms of one carboxylic acid, D- and L-malic acid; and 1 amide, succinamic acid). However, with its EHB, the fungus grew to a higher density on 59 of 95 substrates, including >75% of sugar-based substrates and most amino- and carboxylic acids and their derivatives (19).

Thus, *Chitinophaga* EHB01 is associated with increased breadth of substrate use and enhanced growth by its host on many substrates. Moreover, its improvement of fungal growth on substrates relevant to plant- and seed-fungus interactions is intriguing from an ecological standpoint. Much as genomic insights can be used to infer phenotypic traits, here phenotypic observations provide the basis for predictive genomics, currently a target for future work. Although vertical transmission of *Chitinophaga* has not yet been observed, we anticipate that challenges associated with isolating it in culture will correspond to a relatively small genome that is tightly integrated with host functional traits. This argues for its placement in class 2, much like the *Cytophaga-Flexibacter-Bacteroides* symbiont of the ectomycorrhizal ascomycete *T. borchii* (102). However, genomic data are needed for these strains, which stand out from other class 2 EHB by occurring in septate fungi within the Dikarya, rather than in the coenocytic Mucoromycota described above. These Ascomycota-associated *Bacteroidetes* may prove to be a unique functional group or may be moved to class 3 should cultivation be achieved and transmission by spores not be detected.

Class 3 EHB

Class 3 EHB are a diverse, nonmonophyletic assemblage of bacteria characterized primarily by horizontal transmission, partially free-living or otherwise non-endohyphal lifestyles, high phylogenetic diversity, and occurrence in the living hyphae of Dikarya (11, 17, 19, 38, 43, 48, 49, 85, 112). As a group these EHB represent the second scenario outlined by MacDonald et al.—that EHB may be transient associates of their hosts, with the capacity to be gained and lost repeatedly (68; see also 38, 48). Such gains and losses are easily detectable in the laboratory and speak to a facultative lifestyle in nature (17, 38, 48, 49).

Class 3 EHB as defined here occur in hyphae of Ascomycota and Basidiomycota affiliated with soil and above-ground plant parts. Hosts include ectomycorrhizal *Laccaria* (*Basidiomycota* [84]), growth-promoting root endophytes such as *P. indica* (*Basidiomycota* [85]), and diverse Pezizomycotina that occur in leaves and seeds of plants from tropical to arctic settings (38, 49). Together, class 3 EHB represent at least the phyla *Proteobacteria* (including *Alpha-*, *Gamma-*, and *Betaproteobacteria*; Fig. 4) and *Firmicutes* (e.g., *Paenibacillus* in *Laccaria* [112]; see also reference 38 for a report of *Paenibacillus* in *Phaeomoniella* and *Biscogniauxia* strains that occur as foliar endophytes).

The bulk of the diversity in this functional group appears to reside in the Proteobacteria, represented by genera such as *Paraburkholderia* (with large genome sizes compared to congeneric bacteria occurring as class 2 EHB [Fig. 4]); *Rhizobium* and *Acinetobacter*, associated with Sebacinales; and *Luteibacter*, *Pantoea/Erwinia*, *Sphingomonas*, and others (Fig. 4; Table 1). Generally, these bacteria are closely related to free-living or other non-EHB lineages (38, 43). They can be visualized using LIVE/DEAD staining and fluorescence *in situ* hybridization (Fig. 2). In some cases the number of bacterial cells per fungal cell can be quite low (e.g., 2 to 20 per fungal cell [113]). The few cases in which bacterial DNA has been quantified with respect to fungal genomic DNA reveal concomitantly low amounts of bacterial genomic material (e.g., 0.035 ng of bacterial DNA:100 ng of fungal DNA [114]).

Class 3 EHB typically can be cultured outside of their hosts, reintroduced to their axenic hosts, and moved into novel fungal strains (Fig. 3) (17), presenting a tractable set of experimental systems for tracking the relevance of EHB in modulating fungal phenotypes (11). At least some species are encapsulated in the cytoplasm of Dikarya by membranes apparently of host origin (M. Hoffman, personal communication). Individual fungi can harbor more than one class 3 EHB in different parts of the same mycelium (49), with EHB transformation allowing visualization of single- and multi-EHB infections (see Fig. 3).

Class 3 EHB appear not to have undergone significant reductions in genome size or content relative to their close relatives with other lifestyles. The genomes of these EHB generally are larger than those of class 1 and class 2 EHB (Table 1; Fig. 4), with higher GC content and a prevalence of genomic traits consistent with life phases outside of fungal hyphae (43). Their genome sizes range from ca. 3.9 to 8.5 Mb, with GC content exceeding 70% in some strains (Table 1; Fig. 8). Most have circular chromosomes and varying numbers of plasmids, but *R. radiobacter* has both a circular chromosome and a linear chromosome (together accounting for 4.9 Mb) as well as one plasmid (0.21 Mb) (114). GC content (ca. 59.3 to 59.4% in the bacterial chromosome) is similar to that of many other class 3 EHB (Table 1). Like other class 3 EHB, *R. radiobacter* is closely related to bacteria that do not occur as EHB (in this case, to plant-pathogenic bacteria [114]).

Preliminary evidence indicates profound effects of individual class 3 EHB on their fungal hosts with respect to altering phytohormone production, thermotolerance, substrate use, and the production of plant cell wall-degrading enzymes (Fig. 5) (see also references

11, 17). For example, *Luteibacter* sp. 9143 markedly increases production of indole-3-acetic acid in a foliar endophyte (*Pestalotiopsis* sp. 9143) (11). This increase in hormone production enhanced growth of seedlings treated with culture filtrates (11). However, few general rules apply with regard to the effects of these diverse bacteria on their hosts. For example, two closely related strains of endohyphal *Luteibacter* are associated with different phenotypic responses in different fungi (Fig. 5). Similarly, the same fungus differs markedly in its phenotype with respect to substrate use and thermotolerance when infected by different class 3 EHB (Fig. 5).

Overall, the emergent picture is one of facultative associations with context-dependent outcomes, which together translate to impacting plant-fungus symbioses in profound but as yet unpredictable ways. In this way, class 3 EHB in fungi such as endophytes resemble the facultatively symbiotic fungi they frequently inhabit, whose benefits for hosts are often context-dependent. Even so, class 3 EHB may play important roles in fungal niche differentiation, substrate use, and ultimately, ecological modes in nature: in the partnerships studied so far, certain EHB are associated with enhanced saprotrophy by some fungal endophytes (e.g., *Pestalotiopsis* sp. 9143), concomitant with enhancement of growth on cellulose-containing media and the production of cellulolytic enzymes (Fig. 5). In other cases symbiotic establishment with host plants can be influenced by class 3 EHB, in the context of both leaves (Fig. 6) and roots (113). Increasingly, it appears that EHB are important in the ecological diversification of fungi in the short term, potentially with lasting evolutionary consequences that may speak to the hyperdiversity of endophytic fungi and related functional groups of Dikarya (e.g., 115, 116).

Concomitant with their ecological and evolutionary diversity, class 3 EHB exhibit diverse genomic features relevant to bacteria-fungi interactions (Fig. 8). Closely related EHB often have similar genomic architecture with respect to secretion systems and enzyme-encoding genes, and often they resemble the genomic structure of their close relatives that occur in other ecological settings (Fig. 8). The diverse class 3 EHB for which genomes are sequenced demonstrate convergence on the endohyphal lifestyle, but apparently via different evolutionary pathways and with different mechanisms for communication with fungal cells (Fig. 8).

FRONTIERS FOR STUDYING EHB

The study of EHB was initiated when observations of fungal structures by microscopy revealed the presence of unexpected structures resembling bacteria in the cytosol (53, 66, 68, 76). Since that time inquiries into the existence, identity, and function of EHB have followed a trajectory that includes imaging; curing and, where possible, reinfection; phylogenetic characterization; and most recently, genomics and metagenomics that have in some cases facilitated culturing and in other cases illuminated the evolutionary history of uncultivable species (41, 42, 88). In the near future metatranscriptomes will be exciting for understanding gene expression, particularly in class 2 and class 3 EHB whose relationships with fungi can be manipulated. Variation in the outcomes of associations between class 3 EHB and different fungi (Fig. 5) sets up an especially compelling area of inquiry in which metatranscriptomic perspectives will be enlightening. Those fungus-EHB pairs that can be cured and reassociated, or that can be introduced easily into other fungi, might be promising targets for such work (see Fig. 3, Fig. 4, Fig. 5).

In the interim, current and traditional methods of evaluating fungi for EHB continue to be fruitful. The prevalence of class 3 EHB in the species-rich Dikarya argues for screening existing fungal collections and new isolates from diverse phylogenetic and functional groups to understand the scope and distribution of EHB symbioses. At the moment, most known EHB are in plant-associated fungi; EHB (class 2) have been detected in clinical isolates of *R. microsporus*, but the bacteria are not required for zygomycoses (47). Given the importance of such EHB as producers of toxins, however, an important area for future research relevant to human health certainly lies in food safety (e.g., in the context of *Paraburkholderia* affiliated with *Rhizopus* strains used for tempeh production; see references 47, 117).

In the earliest studies that detected EHB, transmission electron microscopy was key for diagnosing the presence of BLOs in hyphae of arbuscular mycorrhizal fungi (53). A decrease in the training of young mycologists in transmission electron microscopy and related methods (including ultrastructural analysis and other imaging approaches such as scanning electron microscopy) may limit visualizations that so richly complement -omics studies of EHB. In the case of class 3 EHB, resynthesis conditions have been published for the association between *Pestalotiopsis* and *Luteibacter*, outlining an approach for manipulating EHB and their partners that could be translated to microscopy and linked directly to genomics/metatranscriptomics analyses (48). In seeking to link structures with genes and gene expression, mycologists may benefit in some cases from collaborations: a survey of the literature reveals

that few papers on EHB have been published in mycological journals, suggesting untapped potential to link fungal biology with the work of microbial and genomic scientists outside the traditional scope of mycology.

At the end of the 20th century, intracellular *Paraburkholderia* (class 2) were described in the cytoplasm of Glomeromycotina through the combined approaches of PCR and fluorescence microscopy (e.g., 46). Staining spores of *G. margarita* with LIVE/DEAD (46) confirmed the viability of both the fungal and bacterial symbionts, a much-needed indication of symbiosis that should be established clearly when new EHB-fungi associations are described (see 15). Similarly, Salvioli et al. used SYTO BC dye, a nucleic acid stain component, in conjunction with confocal microscopy to detect "*Candidatus* Glomeribacter gigasporum" in spores of *G. margarita* (13). Such methods persist in more recent studies as effective approaches for validating the presence and placement of living bacteria in diverse fungi (38, 48, 49). However, methods such as LIVE/DEAD can lead to uncertain interpretations: fluorescence by ectohyphal bacteria and fungal nuclei and mitochondria cannot always be distinguished easily from EHB. In these cases, combining molecular analysis and more specific methods such as fluorescence *in situ* hybridization can be helpful. For example, Hoffman and Arnold used phylogenetic approaches based on 16S rRNA in conjunction with a TAMRA fluorophore to visualize and unambiguously confirm the identity of class 3 EHB (Fig. 2) (38).

Here, too, transformation of EHB can be of immense help in visualizing bacteria within fungal cells. For example, Partida-Martinez et al. used green fluorescent protein labeling to track vertical transmission of class 2 EHB (100). Similarly, Arendt et al. imaged tdTomato-tagged *Luteibacter* sp. 9143 in hyphae of its host (48). In the latter study, the *Luteibacter* strain was manipulated with transposon mutagenesis (Fig. 3) (48). In such cases, EHB that can be grown axenically, be manipulated, and be reintroduced to hosts can be especially tractable.

In general, class 3 EHB can be isolated from fungal hyphae after prolonged immersion in water, after heat treatment, or after macerating or otherwise damaging fungal mycelia (an approach that also has been useful in segregating some class 2 EHB for molecular analysis [96]). The emergence of EHB in culture, particularly from vouchers of fungi such as endophytes stored in sterile water, sometimes can be mistaken for contamination if their presence is unexpected (38). Occasionally, EHB may overcome fungi vouchered in water, making it impossible to regrow stored fungal strains. In such cases, fungaria may do well to voucher dual cultures: those grown on antibiotic-containing media and those grown on standard media (38). If fungi are originally isolated from the environment using antibiotic-containing media, EHB may be removed before downstream studies occur, and in such cases vital aspects of fungal traits—shaped by their EHB—might be overlooked. Because some fungi may harbor more than one EHB strain concurrently (49), future work should incorporate next-generation sequencing methods to evaluate the diversity and composition of EHB communities in individual mycelia.

More generally, a wealth of new or newly applied methods provides a compelling opportunity to address questions that are fundamental to understanding the traits and importance of EHB. Here we explore these with respect to molecular approaches, imaging, and questions of interdomain communication. In the following discussion we focus primarily on EHB that can be isolated and grown in culture, which are tractable for studying the initial phases of bacteria-fungi interactions, their chemical currency, their genetic and phenotypic responses to one another, the timeline of their associations, and—as demonstrated elegantly by Moebius et al. (108)—the dynamics of bacterial colonization into fungal hyphae. In this context, approaches used to study bacteria-fungi interactions in nonendofungal systems can shed light on principles of interdomain associations and their outcomes in the context of EHB symbioses. We explore several such avenues below, especially with regard to frontiers in the study of class 3 EHB, a ubiquitous group of symbionts with horizontal transmission that appears widespread in the most species-rich fungal clades.

Frontiers in Transcriptomics and Genomics

As the cost of high-throughput sequencing drops and more genomic data become available, opportunities will increase to understand the genetic underpinnings that shape bacteria-fungi interactions at stages ranging from first encounters to symbiont-driven modulation of fungal traits. In particular, transcriptomics tools have become increasingly important for understanding how genes are regulated during biotic interactions. For example, by comparing transcriptomes of the fungus *Aspergillus niger* and the bacterium *Bacillus subtilis* during coculture and axenically, Benoit et al. observed obvious metabolic changes upon attachment of the bacteria to fungal hyphae (12). Both *B. subtilis* and *A. niger* decreased their production of antifungal and antibacterial molecules, respectively. The majority of the genes downregulated during these *in vitro* inter-

actions were related to detoxification or secondary metabolite production and carbon metabolism, suggesting that an active physiological adaptation to the partner organism occurred in culture (12). Such dynamism may underscore facultative associations between class 3 EHB and their fungal hosts.

Similarly, Mela et al. used a dual transcriptomics approach to explore bacterial genes involved in mycophagy by *Collimonas fungivorans* and the fungal response to this attack (118). Their findings indicated a complex interaction involving antibiosis and nutrient competition in both organisms. On the bacterial side, chitinases and secondary metabolites played an important role. The fungal response was dominated by differential expression of genes related to cell wall and lipid degradation, nitrogen deficiency, and cell defense. Future studies could evaluate whether fungi exhibit similar responses when exposed to their native EHB (as opposed to EHB from other fungi) or when exposed to other bacteria that are closely related to EHB yet have other lifestyles (see 17).

Although there are commonalities in the fungal response to antagonism in both of these studies, common ground also exists between positive and negative interactions. A dual-transcriptomics microarray study of the interaction between *L. bicolor* and three bacteria (a helper strain, a commensal strain, and an antagonistic strain) revealed negative correlations in transcripts involved in primary metabolism between antagonistic and nonantagonistic interactions (119, 120). However, the fungus had a unique response to each bacterial strain. Although each bacterial strain responded differently to the fungus, all three bacteria demonstrated differences in the expression of genes involved with cell wall modification (119, 120). The relatively small size of microbial genomes and differences in mRNA processing between prokaryotes and eukaryotes make bacteria-fungi interactions ideal for transcriptome studies, with the potential to explain how EHB modulate the phenotypes of their fungal hosts in real time.

More broadly, the accumulation of genome-scale data from diverse EHB over the past 2 decades promises to accelerate as these associates of fungi, and their relevance, become better known. Comparative genomics for densely sampled clades that contain EHB has the potential to identify hypotheses regarding mechanisms of interactions between fungi and their endosymbionts. Variation in the presence of various protein secretion systems (e.g., Fig. 8) suggests that as a whole, EHB may communicate and interact with their fungal hosts in highly diverse ways. Chitinase has proved especially important for facilitating bacterial entry into living fungal hyphae (108), but it is striking that genomes of diverse EHB do not necessarily contain genes for chitinase production (Fig. 8) (43). Studies regarding alternative methods of entry into fungal hyphae merit further attention.

One related area of inquiry that also merits exploration is that of HGT between EHB and their fungal hosts. Illustrated clearly in the case of class 1 EHB (41), HGT contributes greatly to bacterial genome evolution in general (121) and has been detected, albeit at a lower frequency, in diverse fungi (122). Several genomic studies have suggested HGT between bacteria and fungi (123, 124), a process that could be accelerated or increased in frequency when fungi host EHB. We anticipate that HGT may be especially common in EHB with type IV secretion systems similar to that of *Agrobacterium*, which have been used to successfully transform fungi *in vitro* (125). Genes encoding for type IV secretion systems have been observed among diverse EHB in class 2 (e.g., plasmid-encoded in *P. rhizoxinica* [107]) and class 3 (Fig. 8) (43).

Frontiers in Metabolomics

Many new tools for studying signaling molecules relevant to bacteria-fungi interactions are increasingly available and can be applied to the study of EHB. One area of interest lies in the production and relevance of volatile organic compounds (VOCs) (see "Frontiers in Interdomain Communication," below). For example, recent advances in mass spectrometry (MS) acquisition and analysis have helped to elucidate VOCs used as novel communication signals of soilborne bacteria and fungi. Solid-phase microextraction devices are small filaments that can be inserted into the airspace of interest to adsorb VOCs and then be analyzed directly in gas chromatography MS. These devices have been used with cocultures as well as directly on substrates to identify compounds mediating intermicrobial interactions (126–128). Profiling of VOCs also is being advanced through tools such as the electronic nose, or e-nose, which does not provide specific identities of compounds in sampled air but provides entire profiles that allow researchers to make global comparisons between samples or to detect specific microbial profiles in the environment (129–132). To our knowledge, this method has not been used to examine specific bacteria-fungi interactions per se, though it has been used to profile the progression of truffle aromas over time (129), which are thought to be attributable to the fungus as well as its bacterial associates (133).

In turn, diffusible interactions are a related area of interest for exploring presymbiotic phases of EHB-

fungi interactions. Plating colonies in opposition, then extracting and assaying metabolites to examine outcomes (i.e., antibiosis, growth stimulation, chemotaxis) has been the "gold standard" in this area for some time. However, many recently developed techniques are extraction-free, which helps reduce inherent bias of extraction methods and gives a more complete picture of the molecular interplay of microbial interactions. Imaging MS is an especially promising platform, because it allows researchers not only to determine what compounds are in a sample, but also to map the location of those compounds to specific locations in coculture (134). One such method, matrix-assisted laser desorption imaging MS (MALDI-MS), is an extraction-free method that can assess the mass spectral patterns of interacting microbes on solid media. Matrix-assisted laser desorption imaging MS was used to identify ralsolamycin, the interdomain communication compound that induces formation of fungal chlamydospores (135), and to map metabolic interactions and conversion of bacterial phenazines by *Aspergillus fumigatus* (136). Finally, nanospray desorption electrospray ionization MS provides the ability to analyze metabolites directly from living environmental samples at the microscale (137, 138). When these techniques are combined with metabolic networking platforms, metabolic exchanges can be identified (139) that could inform presymbiotic and early interactions between EHB and their fungal hosts.

Frontiers in Imaging

Electron microscopy has a long and fruitful history with regard to illuminating how diverse bacteria interact with and occur in fungal hyphae (e.g., 68, 108). For example, Levy et al. used electron microscopy to explore colonization of *Gigaspora decipiens* spores and hyphae by a *Paraburkholderia* sp. (class 2 EHB) (140). Their work revealed previously undescribed fibrillar structures that were used to adhere to the hyphal surface. In parallel, improved spatial resolution has made confocal microscopy similarly indispensable for exploring close associations of bacteria and fungi, especially in conjunction with fluorescence *in situ* hybridization and related approaches (see 141). In both class 2 and class 3 EHB, interactions between bacteria and fungi can be temporally dynamic, such that monitoring these interactions as they progress is desirable (see 108). While traditional time-course studies have set the groundwork for understanding general processes in bacteria-fungi interactions (12), new tools can allow continuous, nondestructive monitoring of interactions through time. Stanley et al. recently used novel microfluidic devices to monitor interactions continuously between *Coprinus cinerea* and *B. subtilis*, showing dynamics in attachment, growth rates, and cell death resulting from these interactions (142). Such approaches provide an exciting new avenue for exploring microbial interactions over time at a microscopic level, including the dynamics of colonization by EHB, potential cell-sorting or selection of symbionts by fungi, and the abundance of colonists under particular conditions.

Frontiers in Interdomain Communication

Directed signaling between bacteria and fungi in environments such as soils often relies on VOCs (143). These compounds are generally lipophilic and have a low molecular weight, high vapor pressure, and low boiling point, which facilitates their movement through substrates via vapor diffusion and advection (i.e., matter transfer via fluid). Recent work demonstrates that VOCs are produced frequently by bacterial symbionts of plant-associated and soilborne fungi, with effects on fungal morphology, growth, and persistence in the environment (144). Such effects can be positive or negative and have strong impacts, especially at the spore germination and mycelial growth phases of fungal life cycles (145, 146).

In turn, some bacteria and fungi participate in two-way signaling. When the bacterium *Ralstonia solanacearum* was cocultured with a plant-pathogenic strain of *Aspergillus flavus*, conidiation by *A. flavus* decreased and aflatoxin production increased (127). At the same time, *R. solanacearum* showed decreased growth, decreased melanin production, and extracellular polysaccharide production (127). Sampling of the airspace of these cocultures and axenic cultures revealed VOC profiles that could influence autoinduction systems. We anticipate that further exploration of microbial signaling will show that VOCs contribute to subtler shifts in physiology than those described to date, which is potentially important in the early phases of communication between EHB and their fungal hosts.

As the above studies suggest, fungi are likely active participants in establishing interactions with EHB and, like many hosts that harbor microbial symbionts, play some role in filtering colonization by microorganisms. One particularly exciting area for future work with respect to such close interdomain interactions might focus on lectins. These proteins that react with sugars represent one of the few examples in which fungal activity is known to be influential in the early stages of interactions with bacteria. Lectins are widespread in fungi. They can mediate interactions between bacterial

and fungal pathogens and their hosts, including both plants and animals (147). Although reported primarily from Basidiomycota (148), lectins with relevance to bacteria-fungi interactions are known in some Ascomycota. For example, Díaz et al. showed that a glycosylated arginase acting as a lectin from the lichen-forming fungus *Peltigera canina* was involved in recruitment and attachment of cyanobacterial cells to the mycobiont (149). Given that both fungal and bacterial cell walls are extensively decorated with diverse carbohydrate moieties, lectins seem to be a reasonable area of focus for exploring the early signaling, chemical interactions, and attachment relevant to the establishment of EHB.

Similarly, oxalic acid is produced by members of diverse fungal phyla (150). Oxalic acid is continuously excreted from hyphal tips, sometimes in the form of oxalate crystals. Mycophagous *Collimonas* uses oxalic acid to locate hyphal tips (150). Bacterial motility experiments demonstrated that *Collimonas* can recognize and engage in directed growth based on concentrations of free oxalic acid (150). It is plausible that this and similar signaling molecules may be important in the initiation of EHB symbioses.

More generally, such observations speak to an important interplay of chemotaxis, extrahyphal localization, and early symbiotic interactions between bacteria and fungi (119). *L. bicolor* uses chemotaxis to attract the mycorrhizal helper bacterium *Pseudomonas fluorescens* (119), selecting for particular strains by exuding trehalose, a polyol compound that is a carbohydrate source in and around the mycorrhizal association. When trehalose is used as the sole carbon source in thin agar on glass microscope slides, fluorescent *P. fluorescens* bacteria accumulate onto and around the hyphae. This kind of attraction of the bacteria specifically to hyphae by the fungus indicates the potential for close interaction and communication, possibly signifying nutritional exchanges (119). Such signaling would be of interest in the case of class 3 EHB and in those cases in which *de novo* colonization occurs in fungal hyphae by class 2 EHB.

Once in proximity, bacteria and fungi typically communicate over shorter distances (micrometers to millimeters) via larger (>300 daltons), nonvolatile, and often specialized signals. These signals can be proteinaceous or nonproteinaceous and can diffuse through aqueous environments. We anticipate that proteinaceous signaling molecules are particularly important in pre- and early symbiotic phases of EHB-fungi associations. Fungi and many bacteria acquire nutrients via extracellular digestion, such that they secrete digestive enzymes into their local environment. These enzymes include cellulases, chitinases, glucanases, proteases, and lysozymes (151, 152). Although little has been documented about the roles of enzymes in direct bacteria-fungi interactions, chitinases have been indicated as important factors for bacterial mycophagy (152) and EHB entry into fungal cells (108).

Frontiers with Respect to Protein Secretion Systems

Bacteria rely on secretion systems to release large biomolecules into the local environment and neighboring cells. These systems can range from simple transporters to large protein complexes with specialized functions. In Gram-negative bacteria these multicomponent secretion systems have been catalogued into at least six types (type I to type VI), each differing in components and molecular mechanisms. These systems often are associated with virulence but have also been implicated in other symbiotic associations. They certainly are relevant in many EHB-fungal associations, but studies in this area are in an early phase.

Type I and type II systems secrete lipases, proteases, and beta-glucanases, which have been implicated in antifungal properties of different bacterial species (153, 154). Type II systems that secrete chitinases are essential for bacterial entry into fungal hyphae in the *Paraburkholderia-Rhizopus* endosymbiosis (class 2) (108).

Type III and type IV systems directly inject macromolecules such as proteins and DNA into host cells and have been implicated mostly in interactions with plants and animals, although there is a growing body of literature that suggests that these systems can also impact interactions with fungi. Specifically, type III secretion systems are essential for the maintenance of endosymbiotic bacteria in *Paraburkholderia-Rhizopus* interactions (107). Similarly, type III systems influence how the mycorrhizal helper bacterium, *P. fluorescens* BBc6R8, shapes colonization of pine roots by *L. bicolor* (155). In turn, *Agrobacterium tumefaciens* (syn. *R. radiobacter*) utilizes type IV systems to inject transformative plasmids into host plants (156). This transformation system has been adopted for biotechnological purposes to transform a number of fungi *in vitro* (125). Thus, type IV systems may have a yet undescribed function in mediating the transfer of genetic material from bacteria to fungi. While it is tempting to assume that some evidence of bacteria-fungi HGT may have been mediated by bacterial type IV secretion systems, particularly via EHB symbioses, the mechanisms of such gene transfer events have yet to be explored.

Type V and VI systems have received limited attention to date in EHB, although they may also play a role due to their implications in pathogenesis and interactions with eukaryotes. Type V systems secrete virulence factors and adhesins through the outer membrane, which can contribute to attachment and biofilm formation (157). These systems may be important for maintaining extracellular contact with fungi during early colonization and potentially matter for fungi-mediated translocation. Newly classified type VI secretion systems are important for virulence and are conserved across pathogenic (i.e., *Vibrio*, *Pseudomonas*), beneficial (i.e., *Rhizobium*), and environmental *Proteobacteria* (158). Because of the ubiquity and potential diversity in impacts of type VI systems, their potential roles in EHB associations are compelling for further exploration. Notably, genes for type VI secretion systems are widespread in diverse class 3 EHB (Fig. 8) (43).

Importantly, secretion systems are not the only elements relevant for EHB to enter fungal hyphae. The occurrence of *Firmicutes* and *Bacteroidetes* as EHB opens the door to exploring other means by which class 3 EHB and others with horizontal transfer via an extrasymbiotic phase can gain entry into the living cells of their fungal hosts. In the broad sense, these widespread and potent symbioses appear to be an extremely common feature in the biology of plant-associated fungi. We anticipate that future work will detect additional bacterial phyla and fungal clades involved in intimate interdomain relationships that impact the ecological modes of fungi and the hosts with which they, in turn, interact. Adopting the perspective of Wolf and Wolf (65) argues for assessing fungal holobionts—with their symbiotic bacteria taken into consideration—when exploring the phenotypes, gene expression, communication, and ecological activity of fungi. Together, these are exciting frontiers that have been enabled by a foundation of pioneering studies and the confluence of front-line methods in imaging, biochemistry, phenotyping, computation, and molecular biology.

Necrotrophic Mycoparasites and Their Genomes

50

Magnus Karlsson,[1] Lea Atanasova,[2]
Dan Funck Jensen,[1] and Susanne Zeilinger[2]

INTRODUCTION

Mycoparasitism is a lifestyle where a living fungus (host or prey) is parasitized by and acts as a nutrient source of another fungus (mycoparasite or predator). Mycoparasitic interactions are common among fungi and, similar to plant pathogens, comprise both biotrophic as well as necrotrophic relationships. Biotrophic mycoparasites obtain their nutrition from living fungal host hyphae, with which they can live in a balanced relationship for extended stages of their life cycles, and usually show a narrow host range (1). Because of their nature, however, only few species are studied in detail and applied as biocontrol agents. Examples are *Ampelomyces quisqualis* (Ascomycota, Pezizomycotina), a natural enemy of powdery mildews, whose genome sequence has recently been released, as well as haustorial biotrophs from the Zygomycota (2, 3). In contrast to biotrophs, necrotrophic mycoparasites are more destructive and often rather unspecialized (4). They usually have wide host ranges, often comprising fungal plant pathogens, and kill their fungal prey by invasion and secretion of damaging molecules followed by feeding on the released nutrients (5, 6). These traits render these fungi useful in agriculture for the biological control of plant diseases.

The diversity of mycoparasitic fungi and the variety of mycoparasitic relationships have been reviewed elsewhere (5, 7). We will here focus on necrotrophic mycoparasites. Certain species of particular genera of Hypocreales, especially *Trichoderma* but also *Clonostachys*, are among the best studied mycoparasitic fungi. Considering that the elucidation of the mechanisms involved in mycoparasitism is among the key factors for the development and purposeful application of biocontrol agents, it is not surprising that *Trichoderma* and *Clonostachys* are contained in many biocontrol formulations (4, 8).

While the mycoparasitic nature of *Trichoderma* has been known for over 80 years (9), and several *Trichoderma* species have since been well studied at the cellular, molecular, and genomic level (10), detailed studies on *Clonostachys* are on the rise. *Clonostachys rosea* was formerly classified as *Gliocladium roseum* (11), and the latter was described as a destructive mycoparasite in the 1960s (12). In recent years, *C. rosea* emerged as an effective biocontrol agent of several important plant diseases, and the interest in this mycoparasite recently resulted in the sequencing and analysis of its genome (13). Mycoparasitic *Trichoderma* spp. and *C. rosea* are not only antagonists of other fungi, but are also capable of colonizing and establishing on living plant roots, an ability termed rhizosphere competence (14–16). Root colonization often results in beneficial effects on the plants such as growth stimulation and elicitation of plant defense. Plant growth stimulation by *Trichoderma* spp. and *C. rosea* is a well-known phenomenon (17, 18). Induction of plant defense responses by *Trichoderma* spp. is also well documented, whereas only some cases have been reported for *C. rosea* (19–21). However, based on these, it seems likely that plant defense elicitation is an important biocontrol mechanism of *C. rosea* as well.

When directly applied to specific niches like flowers, wounds, and seeds, both *Trichoderma* spp. and *C. rosea* can exert biocontrol effects by being priority colonizers of such resources and thereby preventing colonization and plant infection by pathogens. Exploitation competition or interference competition via antibiosis might

[1]Department of Forest Mycology and Plant Pathology, Uppsala BioCenter, Swedish University of Agricultural Sciences, 75007, Uppsala, Sweden;
[2]Institute of Microbiology, University of Innsbruck, 6020 Innsbruck, Austria.

be important mechanisms that may precede a mycoparasitic interaction. Mycoparasitism in many such cases would come too late for efficient biocontrol of pathogens infecting via the same niches, because the pathogens in such cases might infect the plant and cause disease within hours, long before mycoparasitism is established (discussed in reference 22).

Concerning mycoparasitic activities, various *Trichoderma* species such as *T. virens*, *T. atroviride*, *T. asperellum*, species from *T. harzianum* complex, as well as *C. rosea* are highly efficient in overgrowing and killing their fungal prey. To this end, they apply a combination of mechanisms that may act simultaneously or sequentially and that may vary in a species-specific and prey-dependent way. *Trichoderma* species are invasive mycoparasites that, upon contact, attach to their prey, often followed by coiling around the prey hyphae and formation of appressoria-like infection structures aiding in penetration (23–25). *C. rosea* has similar mycoparasitic traits because it can coil around hyphae and spores and infect resting structures like sclerotia of other fungi. Hyphal swellings at the points of interaction have been observed with *Fusarium oxysporum* hyphae (13), but the formation of appressoria as a general trait in *C. rosea* mycoparasitism has, to our knowledge, not been verified (13, 26, 27). To be able to feed on the prey, the mycoparasite has to degrade the prey's cell wall (Fig. 1). Hence, hydrolytic enzymes and their respective genes, whose abundance in the genomes of *Trichoderma* mycoparasites is indeed increased relative to other fungi, are traditionally regarded as key features in mycoparasitism. Attack of the fungal prey can further be supported by secreted volatile and water-soluble secondary metabolites with inhibitory or toxic action (10).

While studies on the molecular aspects of mycoparasitism often relied on the analysis of single genes, the recent sequencing of the genomes of selected mycoparasitic *Trichoderma* spp. and *C. rosea*, as well as of additional mycoparasitic species in the order Hypocreales, i.e., *Tolypocladium ophioglossoides* and *Escovopsis weberi*, paved the way for high-throughput studies. Genome analyses revealed several gene families with a mycoparasitism-related expansion, but distinct differences also emerged between the different mycoparasites (13, 28–30). Furthermore, global transcriptome studies led to the identification of gene sets being specifically activated during the mycoparasitic interaction with living fungal preys or, in the case of *T. ophioglossoides*, isolated host tissue (31–34).

In this article, we will focus on mycoparasitic species in the order Hypocreales, mainly the well-characterized *Trichoderma* and *Clonostachys* mycoparasites, for illustration of biological principles and the molecular basis of necrotrophic mycoparasitism. We will describe the knowledge gained over the years on *Trichoderma* as a "model" mycoparasite and will compare its mycoparasitic strategies with the behavior and special features of *C. rosea* and, where applicable, with other hypocrealean mycoparasites.

HYPOCREALEAN NECROTROPHIC MYCOPARASITES: SYNOPSIS OF THEIR BIOLOGY AND GENOMES

The order Hypocreales (class Sordariomycetes) comprises major lineages of mycoparasitic fungi including the well-studied *Trichoderma* and *Clonostachys* biocontrol agents as well as the more specialized mycoparasites within the genera *Escovopsis* and *Tolypocladium*. Sung et al. (35) demonstrated that shifts to mycoparasitism occurred several times during the evolution of hypocrealean fungi. For example, mycoparasitic *Clonostachys* spp. (Bionectriaceae), which are closely related to plant pathogenic *Fusarium* (Nectriaceae), likely obtained this ability after diverging from a plant-feeding host, while ancestors of *Trichoderma* and *Escovopsis* likely evolved from animal pathogens (36). As another example, next phylogenetic neighbors of highly specialized *Tolypocladium* (Ophiocordycipitaceae), a parasite of ectomycorrhizal truffles, are all pathogens of insects (30).

In the genus *Trichoderma*, most species not only are capable of mycoparasitism, but also efficiently feed on dead fungal biomass, often depending on the type of *Trichoderma* strain itself, the type of interacting fungus, and the stage of the interaction. *Trichoderma* mycoparasites have wide host ranges including plant pathogens such as the basidiomycete *Rhizoctonia solani* (Cantharellales), ascomycetes like *Botrytis cinerea, Sclerotinia sclerotiorum* (Helotiales), *Alternaria alternata* (Pleosporales), and *Fusarium* spp. (Hypocreales), but also oomycetes like *Pythium ultimum* (10). The mycotrophic behavior (the use of fungi for food) is an ancestral lifestyle of *Trichoderma* (28). However, different species developed different ecological strategies (32, 37).

The recent sequencing of genomes of hypocrealean mycotrophic fungi other than *Trichoderma*, i.e., *C. rosea* (13), *E. weberi* (29), and *T. ophioglossoides* (30), has opened up new possibilities for the investigation of the molecular mechanisms of mycoparasitism. *C. rosea*, a ubiquitous soilborne ascomycete, is known for its mycoparasitic and nematophagous abilities (38, 39).

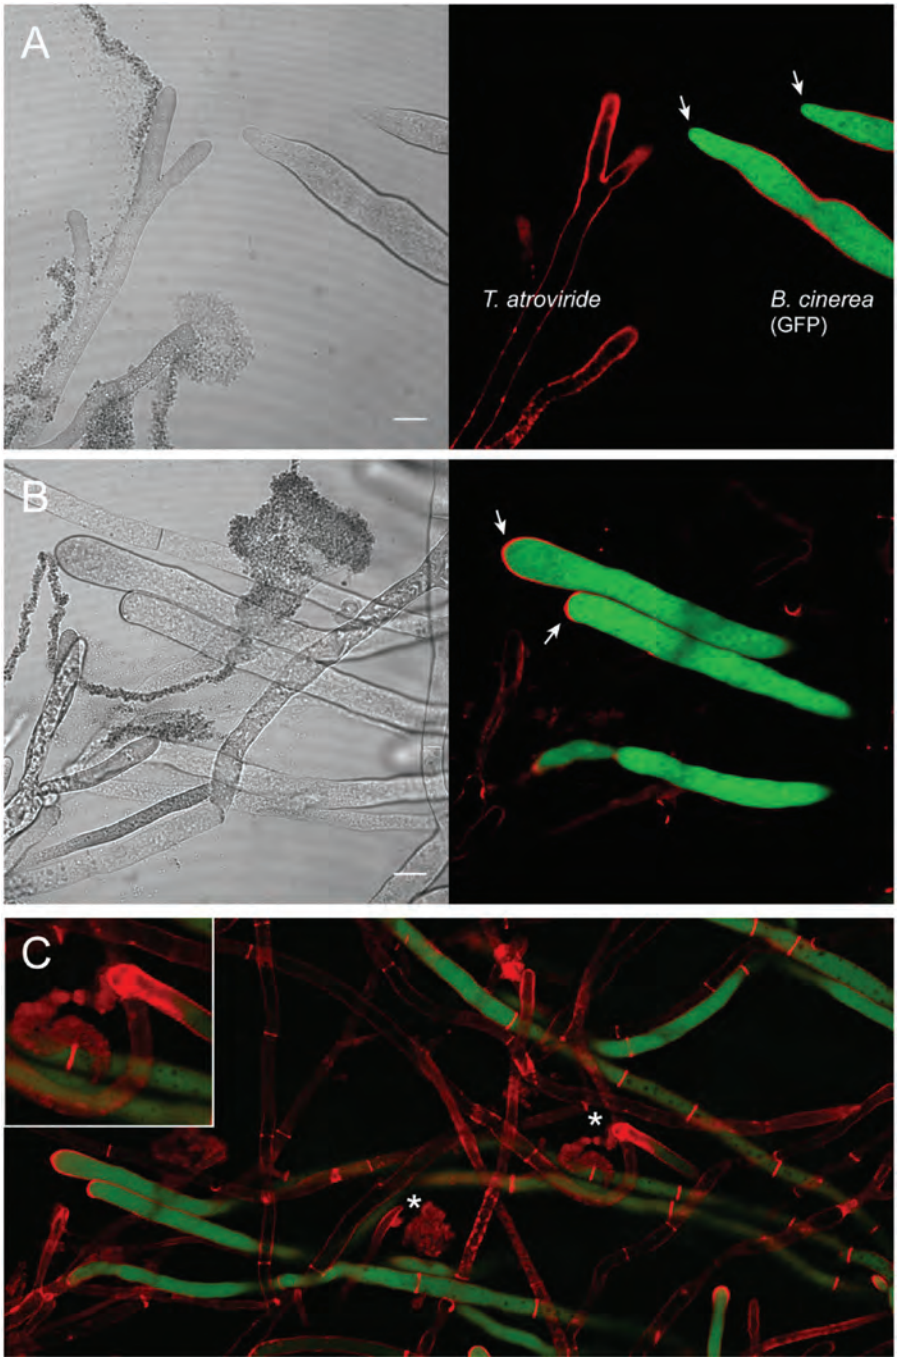

Figure 1 Interaction between hyphae of the mycoparasite *T. atroviride* and the fungal plant pathogen *B. cinerea*. (**A**) Before attack of *B. cinerea* (expressing cytoplasmic GFP) (188) by *T. atroviride*, the apical cell wall extends quickly and is only weakly stained with Congo red, a chitin-specific red fluorescent dye (arrows). (**B**) Mycoparasitic attack induces tip growth arrest in the prey hyphae, leading to tip swelling and increased chitin deposition in the apical cell wall (arrows). (**C**) Tip lysis of the prey hyphae results in cytoplasmic leakage (asterisks and inset) and use as nutrient substrate by the mycoparasite. GFP, green fluorescent protein. Scale bars: 20 μm (reprinted from *FEMS Microbiology Reviews* [189]).

Strain IK726, used for whole genome sequencing, has been isolated from barley roots infected with *Fusarium culmorum* and has proven to be highly efficient as a biocontrol agent (BCA) against a wide range of fungal and oomycete pathogens of agricultural and horticultural crops (13, 40).

In contrast to *Trichoderma* species and *C. rosea*, *Escovopsis* spp. are not generally aggressive fungi but highly selective mycoparasites with different species having different host ranges. *E. weberi* was isolated from the nests of fungi-growing leaf-cutting ants of the tribe Attini (Hymenoptera, Insecta) as a natural pathogen of *Leucoagaricus*, with which the ants share an obligate mutualism. Parasitism of *E. weberi* is specialized on the attack of leaf-cutting ant cultivated *Leucoagaricus* (Agaricales, Basidiomycota) fungi, in whose absence it grows poorly. *E. weberi* is hardly able to attack plant pathogenic fungi like *F. oxysporum*, *R. solani*, or *Sclerotium rolfsii* by which it is even agonized (29, 36). The mycoparasitic attack of *E. weberi* on *Leucoagaricus* spp. involves hook-like infection structures and penetration of the host hyphae and is further accompanied by secretion of enzymes and toxins (41, 42).

The genus *Tolypocladium* (Ophiocordycipitaceae, Hypocreales, Sordariomycetes) comprises insect pathogens as well as parasites of truffle fruiting bodies. The latter have a narrow host range restricted to the genus *Elaphomyces* (Eurotiales, Ascomycota), ectomycorrhizal fungi closely related to *Aspergillus* and *Penicillium*. The recently sequenced *T. ophioglossoides* is a commonly collected truffle parasite with a broad geographic distribution throughout many parts of the Northern Hemisphere (30).

The availability of sequenced and annotated genomes of mycoparasitic species, representing different families within the order Hypocreales, opens up new possibilities to identify key similarities and differences between their respective life strategies, which have direct bearing on the implementation of biological control in agriculture and horticulture. Genome size, structure, and gene content are heavily influenced by natural selection governed by the lifestyle and ecological niche of a species. Comparative analyses of gene content, or paralogous gene number gains or losses, are used extensively to identify genes (representing mechanisms) that are key determinants for ecological niche adaptation. The theoretical basis for this is that the long-term outcome of gene duplication and gene loss is highly constrained by the functions of the encoded proteins. Wapinski and coauthors (43) showed that genes encoding proteins involved in stress responsiveness, such as transporters, receptors, cell wall proteins, and carbohydrate-active enzymes, readily exhibit high interspecific copy number variation because this enables adaptation to diverse ecological niches. In contrast, genes encoding proteins involved in growth and cellular homeostasis show selection against copy number variation. One possible explanation is that many of these proteins are essential components of protein complexes and cellular machineries that require stoichiometric balance, i.e., the gene balance hypothesis (44).

So far, sequenced *Trichoderma* genome sizes vary between 31.7 Mbp and 39.0 Mbp and are similar to the genome size of the truffle parasite *T. ophioglossoides* (31.2 Mbp) (28, 30, 45, 46). It is notable that the species *T. longibrachiatum*, *T. reesei*, and *T. parareesei* (47) from the Longibrachiatum section have smaller genome sizes than species from Virens clade and section *Trichoderma* (Table 1). This reduction in genome size is accompanied by a lower number of protein-encoding genes. A similar but even more pronounced reduction in genome size and gene numbers occurred in *E. weberi*, whose genome with an estimated size of ~29 Mbp is among the smallest sequenced genomes of all Pezizomycotina (29). Primary metabolism-associated genes have been retained in the *E. weberi* genome, while it is depleted in carbohydrate-active enzyme-encoding genes, mainly those for plant degradation, a gene loss that is attributed to its specialization as a parasite of ant-cultivated *Leucoagaricus* spp. (29). For *C. rosea*,

Table 1 Genome sizes and gene numbers of mycoparasites in the Hypocreales order

Species	Family within Hypocreales	Genome size (Mbp)	Predicted gene number	Reference
Clonostachys rosea	Bionectriaceae	58.3	14268	13
Escovopsis weberi	Hypocreaceae	29.5	6870	29
Tolypocladium ophioglossoides	Ophiocordycipitaceae	31.2	10134	30
Trichoderma atroviride	Hypocreaceae, section Trichoderma	36.1	11863	28
Trichoderma hamatum	Hypocreaceae, section Trichoderma	38.2	12391	45
Trichoderma longibrachiatum	Hypocreaceae, section Longibrachiatum	31.7	9409	46
Trichoderma reesei	Hypocreaceae, section Longibrachiatum	34.1	9129	190
Trichoderma virens	Hypocreaceae, clade Virens	39.0	12427	28

the sequenced and annotated genome of strain IK726 (13) and the draft genome of strain 67-1 (48) were recently published. The genome size of *C. rosea* (55.4 to 58.3 Mbp) is comparable with that of some closely related *Fusarium* species, such as *F. solani* (51.1 Mbp [49]) and *F. oxysporum* (61.4 Mbp [50]).

While the draft genome of *T. ophioglossoides* has primarily been analyzed in regard to secondary metabolite biosynthetic genes and clusters, whose numbers are similar to those found in *Trichoderma* mycoparasites (28, 30), closer insights into the gene content of mycoparasitic *Trichoderma* species, *C. rosea*, and *E. weberi* are available from comprehensive comparative genome analyses. The *E. weberi* genome sequence shows a high degree of micromesosynteny with the genomes of *T. atroviride* and *T. virens*, pointing to a similar gene content but shuffled order and orientation. Of the 1,066 genes being unique to *E. weberi* relative to *Trichoderma* spp., most are of unknown function, and only 128 encode proteins with homology to proteins in other Pezizomycotina (29). Gene families exhibiting the largest expansions in *Trichoderma* spp. compared with other ascomycete fungi include Zn(2)Cys(6) transcription factors, major facilitator superfamily (MFS) transporters, short-chain alcohol dehydrogenases, S8 peptidases, and ankyrin-repeat proteins (28, 46). In *C. rosea*, the largest gene expansions compared with other fungi are among pectin/pectate lyases, glucose-methanol-choline oxidoreductases, lytic polysaccharide monooxygenases, ATP-binding cassette (ABC) transporters, polyketide synthases (PKS), and cytochrome P450 monooxygenases (CYP) (13). In the following sections, we will discuss specific gene families with relevance for the mycoparasitic lifestyle.

SENSING THE FUNGAL PREY AND ACTIVATION OF MYCOPARASITISM-RELATED SIGNALING PATHWAYS

The mycoparasitic fungus-fungus interaction is a complex, multistage process best studied in *Trichoderma*. *Trichoderma* is first being attracted by the prey, probably by chemotropism (6). Recognition of the fungal prey then leads to transcriptional reprogramming and expression of the "molecular weapons" involved in prey attack and lysis. Diffusible prey-released substances seem to induce the expression of a set of genes, including certain cell wall-degrading enzymes (CWDEs), before direct contact between the two fungi. Specific cell surface signaling mediated by prey-associated lectins mainly is responsible for attachment of *Trichoderma* to and its coiling around the prey hyphae (51–53). More recent genome-wide transcriptome studies confirmed the precontact induction of a distinct set of genes in *T. atroviride* and *T. virens* upon cocultivation with *R. solani* (31, 32). However, *T. virens* (strain Gv29-8, a gliotoxin-producing Q strain) mainly increased the expression of genes for gliotoxin biosynthesis, while *T. atroviride* strongly upregulated hydrolytic enzyme-encoding and certain secondary metabolism-associated genes (32). Studies with *T. atroviride* revealed that the contact-independent expression of CWDE-encoding genes such as *ech42* (endochitinase 42-encoding) and *prb1* (alkaline proteinase-encoding) is dependent on enzyme diffusion from the mycoparasite to its host (52–54). As a consequence of the actions of CWDEs on the fungal prey, oligosaccharides and oligopeptides are released by the prey that are then recognized by *Trichoderma* receptors and thereby act as inducers. The model is supported by the expression of several G-protein-coupled receptor (GPCR) genes in response to the host. These include members of the PAQR (progestin-adipoQ receptor), the Stm1-like (putative nitrogen sensors), and the PTH11-like (related to PTH11, which is required for appressorium formation and pathogenicity in *Magnaporthe oryzae*) families whereby differences in the transcriptional regulation between *T. atroviride* and *T. virens* are clearly evident in the latter two GPCR families (55). Two predicted PTH11-encoding genes are also induced in *T. ophioglossoides* during growth on truffle cell wall-containing media (34), emphasizing the importance of PTH11-type receptors in hypocrealean mycoparasites.

Heterotrimeric G-Protein Signaling

The heterotrimeric G-protein signaling pathway is conserved in eukaryotes and usually involves a GPCR, a heterotrimeric G protein (composed of the Gα, Gβ, and Gγ subunits), and an effector. In the classic paradigm, ligand binding to the GPCR causes the exchange of the GDP bound to the Gα subunit with GTP, which results in release of the Gβγ dimer. The released dimer and/or activated Gα then interact with downstream effectors, which in fungi often are mitogen-activated protein kinase (MAPK) cascades or the cAMP-generating adenylate cyclase (56). Of the three Gα proteins encoded in *Trichoderma* spp., two play essential roles in mycoparasitism, i.e., the adenylate cyclase-inhibiting (Tga1 in *T. atroviride*, TgaA in *T. virens*) as well as the adenylate cyclase-activating (Tga3 in *T. atroviride*) subunits (57–60). However, although *T. atroviride* Tga1 and *T. virens* TgaA are highly conserved at the amino acid level, quite different phenotypes emerged from deletion of the corresponding genes. While *T. virens*

TgaA does not affect the mycoparasitic activity against *R. solani* but governs the colonization of *S. rolfsii* sclerotia (58), *T. atroviride* Tga1 regulates growth and asexual sporulation and is essential for activating attack and overgrowth of different fungal hosts including *R. solani* (59). Similarly, Tga3 affects growth and conidiation in *T. atroviride* and impacts secondary metabolite production and extracellular chitinase activity. The avirulent phenotype of Δ*tga3* mutants further resulted from their inability to adhere to and coil around host hyphae, suggesting a role of the Tga3 protein in the transmission of signals that regulate prey recognition (60).

From the 65 and 76 putative GPCRs encoded in the *T. atroviride* and *T. virens* genomes, respectively (61), two *T. atroviride* members of the fungal cAMP receptor-like GPCR family have been functionally characterized so far. While silencing of the *gpr2* gene did not result in any phenotype (62), Gpr1 is essential for the antagonistic activity of *T. atroviride*. *gpr1*-silenced strains share several phenotypic alterations with Δ*tga3* mutants such as the inability to recognize and attack living fungal hosts (63). *gpr1* mutants are unable to respond to the presence of a living prey by expressing chitinase- and protease-encoding genes; consequently, prey hyphae remain completely intact and undamaged upon confrontation with the *gpr1*-silenced mutants (63). Although a physical interaction between Gpr1 and Tga3 could not be proven yet, their concerted action is further corroborated by reduced intracellular cAMP levels in both *tga3* and *gpr1* mutants and by the fact that addition of extracellular cAMP can rescue their defect in host adherence and infection structure formation (60, 63).

The cAMP Pathway

Upon stimulation by adenylate cyclase-activating Gα proteins, the membrane-bound adenylate cyclase enzyme synthesizes cAMP from ATP. cAMP then acts on a cAMP-dependent protein kinase (PKA), consisting of two regulatory and two catalytic subunits, that upon activation regulates gene expression by phosphorylating respective target proteins (64). Deletion of the single adenylate cyclase gene *tac1* in *T. virens* lowered the intracellular cAMP level to below the detection limit and resulted in mutants with strongly reduced growth on solid media and loss of biocontrol activity against plant pathogens such as *S. rolfsii, R. solani*, and *Pythium* spp. (65).

Application of exogenous cAMP stimulates coiling, whereas a reduced intracellular cAMP level as found in, e.g., *T. atroviride* Δ*tga3* mutants (60) results in a loss of infection structure formation. The synthesis of *N*-acetyl-β-D-glucosaminidase (NAGase) by *T. harzianum*, in contrast, is repressed by substances that increase the intracellular levels of cAMP (e.g., dinitrophenol, caffeine, aluminum tetrafluoride) (66). Accordingly, low cAMP levels and PKA activity elevate the transcription of *prb1* and *ech42* in *T. atroviride* (57), highlighting that multiple signals and effector pathways are involved in the regulation of mycoparasitic responses in *Trichoderma*.

MAPK Cascades

MAPK pathways, being among the most prominent signal transduction systems in fungi, contain a highly conserved core structure with a three-kinase module. Input signals lead to activation of the MAPK cascade by sequential phosphorylation from a MAP kinase kinase kinase (MAPKKK) across a MAP kinase kinase (MAPKK) to a MAP kinase (MAPK) that transmits it to downstream target proteins such as transcription factors, thereby generating a specific response (67).

Trichoderma spp. have MAPK members common in filamentous fungi that act in the pheromone response/pathogenicity (Tmk1/TmkA), the cell wall integrity (Tmk2/TmkB), and the osmosensing (Hog1/Tmk3) pathways (28). The functions of all three types of conserved MAPKs have been studied in mycoparasitic *Trichoderma* species. The *T. virens* and *T. atroviride* homologues (Tmk1/TmkA) of the yeast pheromone response MAPK are involved in mycoparasitism (68–70), a situation similar to plant pathogenic fungi where Fus3/Kss1 homologues have been described as effectors of virulence-associated processes (71). *T. atroviride* Tmk1 governs the production of CWDEs and antifungal metabolites such as certain peptaibols and 6-pentyl-α-pyrone (6-PP) as well as aerial hyphae formation and conidiation. Δ*tmk1* mutants have enhanced chitinase and antifungal activities, but nevertheless exhibit reduced mycoparasitic activity (70). Comparative analyses of Δ*tmk1* and Δ*ste12* mutants (missing the Ste12 transcription factor whose orthologue in yeast is a target of the Fus3 and Kss1 MAPKs) revealed an essential role of Ste12 in mediating the outcomes of the Tmk1 MAPK pathway, such as regulation of the mycoparasitic activity, hyphal fusion, and vegetative growth (72). In *T. virens*, the function of the Tmk1 homologue is strain specific. Respective deletion mutants in a gliotoxin-producing "Q" strain of *T. virens* have increased biocontrol activity against *R. solani* accompanied by an enhanced expression of mycoparasitism-related genes, the latter being similar to *T. atroviride* (68). In contrast, signaling through TmkA in a "P"

(gliovirin-producing) strain does not affect mycoparasitism of *R. solani* but stimulates antagonism against *S. rolfsii* (69).

Tmk2/TmkB, a homologue of the yeast cell wall integrity MAPK Slt2, is involved in cell wall integrity in both *T. reesei* and *T. virens* (73, 74). *T. virens* TmkB in addition has overlapping functions with TmkA (similar to Δ*tmkA* mutants, Δ*tmkB* mutants have a reduced ability to overgrow *S. rolfsii* while retaining their mycoparasitic activity against *R. solani*), suggesting shared downstream targets (73).

The Hog1 MAPK is a central component of the high osmolarity glycerol (HOG) pathway that mediates responses to hyperosmotic shock and other stresses in fungi (75). Accordingly, *T.* cf. *harzianum* Hog1 and the *T. atroviride* homologue Tmk3 participate in high-osmolarity resistance and the respective mutants are sensitive to osmotic and oxidative stress (76, 77). Hog1 positively affects the antagonistic activity of *T.* cf. *harzianum* against certain plant pathogens by neutralizing stress agents such as reactive oxygen species (ROS) produced by fungal preys (76).

The Global Regulators Lae1 and Vel1

The putative *S*-adenosylmethionine-dependent methyltransferase LaeA of *Aspergillus nidulans* forms a trimeric protein complex with VeA and VelB that serves as a global regulator of secondary metabolism and morphogenesis (78). In *T. virens*, Vel1 (VeA homologue) regulates not only conidia and chlamydospore formation, but also secondary metabolism and mycoparasitism (79). Similar functions have been reported for *T. atroviride* Lae1 (LaeA homologue) where *lae1* deletion mutants are completely avirulent, which is accompanied by a significant underexpression of several genes normally being induced during the mycoparasitic interaction. Δ*lae1* mutants are further unable to defend themselves against other fungi indicated by the finding that their growth is suppressed by the tested plant pathogens and that the mutants are more sensitive to oxidative stress (80). The overlapping functions of Lae1 and Vel1, together with the fact that Vel1 is highly conserved among *Trichoderma* species, make it likely that the Lae1-Vel1-Vel2 complex acts as a master regulator of *Trichoderma* mycoparasitism.

CELL WALL-DEGRADING ENZYMES AND THEIR ROLE IN MYCOPARASITISM

The fungal cell wall is a dynamic structure that protects the cell from environmental stresses while allowing it to interact with its environment (81). The exact biosynthesis and composition vary between fungal species and have been studied in very few systems, but the major constituents include covalently cross-linked chitin, glucans, mannans, and glycoproteins (81, 82). Production of hydrolytic enzymes that permeabilize and degrade the fungal cell wall is one of the key steps in the successful attack of the fungal prey by necrotrophic mycoparasites. Druzhinina et al. (83) showed that enzymes degrading poly- and oligosaccharides (carbohydrate-active enzymes or CAZymes), small secreted cysteine-rich proteins (SSCPs), and proteins with unknown function comprise more than 60% of the predicted secretomes of *T. reesei*, *T. atroviride*, and *T. virens*. In contrast, enzymes with hydrolytic activity on other polymers (proteases, lipases, nucleases, and phosphatases) and orphan proteins (proteins without orthologues outside the *Trichoderma* genus) are present in lower numbers.

Chitinases

Chitin is a β-1,4-linked *N*-acetylglucosamine homopolymer that provides structural rigidity to the fungal cell wall (82). Although chitin fibrils are mostly located in the inner layers of the cell wall close to the plasma membrane, chitin appears to be an important target for degrading enzymes during the mycoparasitic attack. Fungal chitinases are classified as glycoside hydrolase family 18 (GH18), which is divided into clusters A, B, and C and further subdivided into subgroups A-II to A-V, B-I to B-VI, and C-I to C-II based on the amino acid sequence of the GH18 module (84–87).

The importance of chitinases for *Trichoderma* spp. is reflected by the high number of GH18 genes present in their genomes (28, 45, 46). Comparative analyses with other filamentous ascomycetes revealed that the increased number of chitinase genes in *Trichoderma* spp. and the truffle-parasite *T. ophioglossoides* (Table 2) is specifically related to subgroups B-I/B-II and C-I/C-II (34, 88, 89), indicating that the corresponding enzymes play important roles in these mycoparasites. Interestingly, *C. rosea* differs substantially from mycoparasitic *Trichoderma* spp. because the genome contains only a few genes in these subgroups (two genes each for B-I/B-II and C-I/C-II) (13, 90). Finally, the *E. weberi* genome has a similar number of chitinases as *T. reesei* with many subgroup B-I/B-II but few subgroup C-I/C-II genes (29), indicating fundamental differences in the role of fungal cell wall degradation between the different mycoparasites.

Characterized *Trichoderma* cluster B chitinases show a preference for endoactivity (91–93) and possibly pro-

Table 2 Predicted number of glycoside hydrolase family 18 genes in mycoparasitic and nonmycoparasitic ascomycete fungi

Species	Cluster A	Cluster B	CHIT36[a]	Cluster C	ENGases	Total
Mycoparasitic species						
Clonostachys rosea	8	2	1	2	1	14
Escovopsis weberi	5	6	1	2	2	16
Tolypocladium ophioglossoides	7	6	–	10	1	24
Trichoderma longibrachiatum	7	6	1	3	2	19
Trichoderma reesei	7	6	1	4	2	20
Trichoderma virens	8	10	1	15	2	36
Trichoderma hamatum	6	10	1	5	2	24
Trichoderma atroviride	7	10	1	9	2	29
Nonmycoparasitic species						
Botrytis cinerea (plant pathogen)	3	4	–	1	2	10
Coccidioides immitis (animal pathogen)	4	2	–	2	1	9
Magnaporthe oryzae (plant pathogen)	9	2	–	2	2	15
Neurospora crassa (saprobe)	5	2	–	3	2	12

[a]CHIT36 represents a cluster B chitinase of bacterial origin transferred to fungi through horizontal gene transfer (84).

vide an initial attack on the cell wall chitin of the fungal prey (94). Many of these cluster B chitinase genes are induced during interactions with other fungi or by fungal cell wall material in *Trichoderma* spp. (86, 93, 95–97) as well as *C. rosea* (90, 98, 99).

Due to sequence similarity with the secreted killer toxin from certain yeast species (100), some cluster C chitinases are hypothesized to act in fungal-fungal interactions through a killer toxin-like mechanism to enhance the permeability of antifungal compounds into antagonist cells (86). Recent studies support this idea, because deletion of the killer toxin-like chitinase genes *chiC2-2* in *A. nidulans* and *chiC2* in the mycoparasite *C. rosea* resulted in lower fungal growth inhibitory activity of culture filtrates (90, 101). The growth inhibitory effect of the *chiC2* deletion in *C. rosea* was observed for both *B. cinerea* and *R. solani*, but not for *Fusarium graminearum*, which suggests some specificity in the action of CHIC2. Induced gene expression of cluster C chitinase genes in *Trichoderma* spp. and *T. ophioglossoides* during exposure to fungal cell wall material and during mycoparasitic interactions indicates a similar role, although some members are also regulated developmentally and by nutritional stimuli (34, 86, 102, 103).

The best studied chitinases in mycoparasitic fungi are Ech42 orthologues (Ech42 in *T. atroviride*, Chit42 in *T.* cf. *harzianum*, Chi18-5 in *T. reesei*, Cht42/Tv-Ech1 in *T. virens*, ECH42/CHI1 in *C. rosea*) that belong to cluster A. *T. atroviride* Ech42 was initially regarded as a key enzyme for mycoparasitism based on induced gene expression during fungal interactions and gene deletion studies (104–106). However, it is also induced during starvation and autolysis, suggesting a role in self- and non-self-cell wall degradation rather than mycoparasitism *per se* (107). A similar situation is seen for the two GH20 NAGase proteins NAG1 and NAG2 of *Trichoderma* spp. that were initially considered as specifically important for mycoparasitism. Now, expression and gene deletion data suggest that they cleave *N*-acetylglucoseamine dimers into monomers for nutritional purposes, irrespective of the chitin source (94, 107, 108). *Trichoderma* spp. contain two paralogous enzymes, Eng18A and Eng18B, in the GH18 subgroup B-V. They show endo-β-*N*-acetylglucosaminidase (ENGase) activity and are involved in deglycosylation of glycoproteins (109, 110). Eng18A is secreted and is hypothesized to be involved in *N*-deglycosylation of extracellular cellulases in *T. reesei* (110), while Eng18B functions in the endoplasmic reticulum-associated degradation of misfolded glycoproteins as shown for *T. atroviride* (109). Deletion of the *Eng18B* gene results in a severe secretion defect that abolishes the antagonistic ability of *T. atroviride* toward *B. cinerea* in confrontation assays (111).

Chitosanases

Chitosan is a totally or partially deacetylated derivative of chitin (112) and chitosanases are chitosan *N*-acetylglucosaminohydrolase enzymes that catalyze endohydrolysis of beta-linkages between D-glucosamine residues. While most fungi have only one or two chitosanase (GH family 75)-encoding genes, the mycoparasitic *Trichoderma* spp. and *C. rosea* have five (13, 28). Several studies showed an enhanced production of chitosanases by *Trichoderma* species (113, 114), but details regarding their transcriptional regulation or their enzymatic properties are lacking.

Glucanases

The major fibrillar polymer in fungal cell walls is β-(1,3)-glucan, or laminarin, which is degraded by β-1,3-glucanases. While chitin is arranged in regularly ordered layers, β-(1,3)-glucan fibrils, which represent more than 60% of the fungal cell wall, are ordered in an amorphic manner (82). In *T.* cf. *harzianum*, two distinct β-1,3-glucanases (BGN13.1 and LAM1.3) are induced during growth on media containing fungal cell wall polymers or from dual cultures with host fungi (115, 116). In *C. rosea*, β-1,3-glucanase activity and gene expression are induced during growth on media containing laminarin, *Pythium* sp. cell wall material, and homogenized cucumber roots (117). Similarly, two putatively secreted β-glucanase-encoding genes are upregulated in *T. ophioglossoides* cultured on media containing truffle tissue (34).

β-1,3-Glucanases have so far been attributed to the GH families 16, 17, 55, 64, and 81. Numbers of GH55- and GH64-encoding genes are increased in mycoparasitic *Trichoderma* spp. in comparison with other filamentous fungi (28), and four genes coding for GH16 members are strongly upregulated in *T. atroviride* during the mycoparasitic attack of *R. solani* (32).

Trichoderma spp. also produce β-1,6-glucanases that hydrolyze β-1,6-glucans, which constitute a minor portion of the fungal cell wall polymers. β-1,6-Glucanases belong to GH families 5 and 30, and are suggested to play an important role in mycoparasitism against a wide variety of oomycetes (whose cell walls are mainly composed of β-1,3- and β-1,6-glucans and cellulose) and fungi (115, 118, 119). In *T.* cf. *harzianum* CECT 2413, β-1,6-glucanase activity was detected during growth on chitin, pustulan, nigeran, and fungal cell walls, and three extracellular β-1,6-glucanases (BGN16.1, BGN16.2, and BGN16.3) have been purified from this strain (115, 118). BGN16.3 is expressed during the interaction of *T.* cf. *harzianum* CECT 2413 with *B. cinerea* (120). *Tvbgn3*, a β-1,6-glucanase-encoding gene from *T. virens*, is induced in the presence of the oomycete *P. ultimum*, indicating that this enzyme might be involved in mycoparasitism. Deletion and overexpression of *Tvbgn3* resulted in reduced or enhanced ability to inhibit the growth of the plant pathogen, respectively (119).

Cellulolytic Enzymes

As mentioned previously, a major fraction of oomycete cell walls consists of cellulose and hemicelluloses. Therefore, economically important plant pathogenic oomycetes, such as *Pythium* spp., may be combated using microbial agents that are able to produce cellulolytic enzymes. Cellulose is a polysaccharide consisting of a linear chain of several hundred to many thousands β-1,4-linked D-glucose units. Inglis and Kawchuk (121) tested 14 mycoparasitic and biocontrol fungi for their ability to degrade and utilize the cell walls of the oomycete *P. ultimum*. The authors showed that degradation of *P. ultimum* cell walls was successful by several *Trichoderma* species, but not by *C. rosea*. Upon direct interaction, *T. reesei* is able to produce holes characteristic of cell wall-degrading enzyme activity in *P. ultimum* cell walls (122). Thrane et al. (123) reported on *T.* cf. *harzianum* T3 having a significant ability to control *Pythium* damping-off of cucumber seedlings and that endo-β-1,3-glucanase and cellulase activities are induced by the presence of *Pythium*. Purified endo-β-1,3-glucanase and cellulase from *Trichoderma* were inhibitory to the germination and growth of encysted *Pythium* zoospores. However, a study using the *T. reesei* cellulase-negative mutant QM9978, which still is able to overgrow *P. ultimum* in plate confrontation assays as well as to protect plants, showed that cellulase gene expression seems not to be required for the observed antagonistic activity (124). In contrast to the diversity of carbohydrate-active enzymes produced by the broad-host-range mycoparasite *Trichoderma* spp., the specialized mycoparasite *E. weberi* lacks all cellobiohydrolases, xylanases, and auxiliary proteins like polysaccharide monooxygenases and swollenins while retaining chitinolytic enzymes. This suggests that *E. weberi* has lost the ability to feed on lignocellulosic plant material, possibly as a consequence of the specialization and coevolution of *E. weberi* with its host fungus (29).

Proteases

Many genes that encode proteases are expressed before and during contact with a prey in different *Trichoderma* spp. and some proteases, including aspartyl proteases, serine proteases, and subtilisin-like proteases, have been shown to be involved in mycoparasitic action (10, 125). Troian et al. (126) found that the aminopeptidase encoding gene *s9* is downregulated during the interaction of *T.* cf. *harzianum* 303/02 with *S. sclerotiorum*, whereas the trypsin-like protease-encoding gene *pra1* is upregulated during the interaction with host mycelia, sclerotia, and apothecia, and the serine protease gene *sprt* is slightly upregulated mainly in the presence of apothecia and mycelia. Hence, the trypsin-like and serine proteases may participate in the degradation of structural cell wall proteins to destabilize host cell integrity and facilitate penetration and colonization of *T.* cf. *harzianum* (126).

Trichoderma spp. have one of the largest sets of proteases among fungi (83). A total number of 383 (4.2% of all predicted protein-coding genes), 445 (3.75%), and 479 (3.85%) protease genes are predicted in the *T. reesei*, *T. atroviride*, and *T. virens* genomes, respectively, from which around 20% possess a signal peptide and are therefore entering the secretory pathway (83). Families such as the subtilisin-like proteases of the S8 family as well as dipeptidyl (S9) and tripeptidyl peptidases (S33) are expanded in *T. virens* and *T. atroviride* mycoparasites compared with *T. reesei* (28). Several extracellular proteases (mostly aspartyl and subtilisin-like proteases, dipeptidyl and tripeptidyl peptidases, and metalloproteases), but also transporters for oligopeptides and amino acids, are expressed by all three *Trichoderma* species during the attack of *R. solani* (31, 32). In *C. rosea*, 15 different protease genes are induced during growth on *S. sclerotiorum* sclerotia (33). The diverse substrate specificities of proteases produced by *Trichoderma* and *C. rosea* may act synergistically for efficient protein degradation.

THE ROLE OF SECONDARY METABOLITES IN THE MYCOPARASITIC INTERACTION

Secondary metabolites are low-molecular-weight compounds that are, unlike metabolites from primary metabolism, not directly essential for growth. Fungal secondary metabolites serve survival functions by supporting the fungus in competition against other microbes, in self-protection and defense, and have important roles in communication and interaction with other organisms (127, 128).

The mycoparasitism of *Trichoderma* and *Clonostachys* species is at least partly effective because of a strong ability of these fungi to produce and release a plethora of secondary metabolites of which several not only serve in chemical warfare against their competitors and fungal preys, but also exhibit plant-growth-promoting and plant-resistance-inducing activities (129). Secondary metabolites seem to play a crucial role in *E. weberi* as well. This specialized mycoparasite kills its ant-cultivated host fungi from a distance, thereby likely involving secreted toxins (29).

Since the discovery of gliotoxin in the 1930s (130, 131), numerous secondary metabolites have been reported from *Trichoderma* species. These comprise a diverse array of substances like nonribosomal peptides (such as peptaibiotics, epipolythiodioxopiperazines, and siderophores), polyketides, terpenoids, steroids, and pyrones; however, progress in elucidating the genes involved in their biosynthesis has been made only during recent years.

Genome analyses revealed that the sequenced mycoparasitic *Trichoderma* species and *C. rosea* are especially enriched in secondary metabolism-related genes, compared with most other filamentous ascomycetes (13, 28). Of these, nonribosomal peptide synthetases (NRPSs) are enriched in the sequenced *T. virens* strain Gv 29-8 genome, while PKSs are enriched in *C. rosea* strain CBS125111 (13), which may suggest fundamental differences between *Trichoderma* spp. and *C. rosea* in their secondary metabolite production spectra.

Secondary metabolism-related genes in *Trichoderma* spp., *C. rosea*, *T. ophioglossoides*, and *E. weberi* are mostly arrayed in multigene biosynthetic gene clusters reminiscent of bacterial operons, a situation typical for filamentous fungi (132). Usually all the genes necessary to synthesize, regulate, and self-protect the compound-producing fungus from the bioactive properties of a specific secondary metabolite are contained in a respective gene cluster (132). Interestingly, half of the secondary metabolism-related genes present in *T. atroviride* and *T. virens* are unique for the respective species and occur within nonsyntenic islands of the genome, indicating their origin by recent genome rearrangements (28).

Nonribosomal Peptides

Nonribosomal peptides (NRPs) are peptide secondary metabolites being synthesized independent of the ribosome by multimodular NRPS enzymes. NRPs constitute a diverse group comprising linear, cyclic, and/or branched structures of various lengths that usually contain both proteinogenic and nonproteinogenic amino acids (133). The major NRP groups produced by *Trichoderma* and *Clonostachys* species are peptaibiotics, epidithiodioxopiperazines, and siderophores.

Peptaibiotics are linear or, in a few cases, cyclic NRPs characterized by the presence of the nonproteinogenic amino acid alpha-aminoisobutyric acid (Aib). The majority of all known peptaibiotics have been described for *Trichoderma* spp. (134, 135) with suzukacillin and alamethicin having been the first substances described (136, 137). The antibiotic activity of peptaibiotics is based on their helical structures allowing them to insert into membranes and form ion channels and pores in a concentration-dependent manner resulting in perturbation of the membrane bilayer, as was recently shown for alamethicin (138, 139). Peptaibiotics contribute to the antagonistic action of *Trichoderma* mycoparasites, and synergism between CWDEs and these NRPs results in a combined enzymatic degradation of the host cell wall and membrane permeabilization resulting in efficient cell lysis and leakage (140, 141). In addition, peptaibiotics like *T. pseudokoningii*-derived trichokonins

induce apoptotic cell death in fungal hosts (142), and *T. virens* 18- and 20-mer peptaibols are able to induce systemic resistance responses in plants (143, 144). Similarly, a mixture of peptaibiotics was found to be produced by *C. rosea* that contribute to the antifungal activity toward the plant pathogen *S. sclerotiorum* (38). Three NRPSs with 7, 14, and 18 to 20 modules, that are responsible for the production of peptaibiotics, are encoded in the *Trichoderma* genomes (145). The genome of *C. rosea* also harbors several putative peptaibiotics assembly lines with the largest comprising 20 modules, whose specificity signatures correspond well to the structure of the antimicrobial peptaibiotics isolated from this fungus (13). Supporting the finding that peptaibiotics biosynthesis is a characteristic trait of mycoparasitic lineages of Hypocreales, three large peptaibiotic gene clusters have been identified in the *T. ophioglossoides* genome and two peptaibiotic synthases in the draft genome of *E. weberi* (29, 30).

Epipolythiodioxopiperazines (ETPs) are cyclic-peptide-derived toxins characterized by a diketopiperazine ring whose disulfide bridge can cross-link proteins via cysteine residues and generate ROS through redox cycling (146). Gliotoxin is the best studied ETP member, originally isolated from *T. virens* (130, 131). *T. virens* "Q" strains are gliotoxin producers, while "P" strains are incapable of gliotoxin biosynthesis but instead produce gliovirin, another ETP. In biocontrol tests, "P" strains were more effective against the oomycete *P. ultimum* because gliovirin is highly toxic to this pathogen, whereas "Q" strains gave better control of *R. solani* (147). Similar to peptaibiotics, gliotoxin was shown to exhibit synergistic action with an endochitinase in inhibiting the germination of *B. cinerea* spores (148). The *T. virens* gliotoxin gene cluster consists of eight genes with GliP, a NRPS dioxopiperazine synthase, being the core enzyme (149). Disruption of the *gliP* gene in *T. virens* Gv29-8 led to a loss of gliotoxin production and to an attenuation of the mycoparasitic activity against *P. ultimum* and *S. sclerotiorum*; however, mycoparasitism of *R. solani* was independent of *gliP* (150).

ETPs produced by *Clonostachys* spp. comprise verticillin A, the verticillin-type metabolites gliocladine A, C, D, and E, which have antinematodal activity, and the antimicrobial compound glioperazine (151). Analysis of the *C. rosea* genome revealed one putative ETP synthetase (NPS1) presumably involved in the biosynthesis of glioperazine or a related metabolite (13).

Polyketides and Terpenoids

Polyketides include substances with antibiotic activity implicated in the competition and communication between microbes. The biosynthesis of polyketides involves PKSs that perform successive decarboxylative condensations of simple building blocks such as acetyl coenzyme A (CoA) and malonyl-CoA (128).

The mycoparasites *T. atroviride* and *T. virens* are rich in PKS genes because 20 putative PKS gene clusters could be identified in their genomes in addition to the PKS clusters being responsible for conidial pigment biosynthesis (152). Deletion of *pks4* in *T. reesei* revealed the corresponding gene as being responsible for the green pigmentation of conidia and the nonmelanized structures of fruiting bodies, for conidial cell wall stability, and for the antagonistic abilities of *T. reesei* against other fungi. Pks4 also affects the expression of other *pks* genes of the fungus and the production of volatile organic compounds (VOCs) (153). Certain strains of *C. rosea* produce TMC-151-type polyketide antibiotics with antibacterial properties (154), which are unique to *Clonostachys* spp. (155). The truffle mycoparasite *T. ophioglossoides* has been reported to produce the polyketide ophiocordin. In total, 38 secondary metabolism-associated clusters were identified in the *T. ophioglossoides* draft genome sequence harboring 15 PKSs and two PKS-like genes, 15 NRPSs and 6 NRPS-like genes, three hybrid NRPS-PKS genes, and four terpene synthase genes (30). The 17 putative secondary metabolite clusters present in the small genome of *E. weberi* are predicted to mainly harbor terpene synthase genes, some of which are upregulated when *E. weberi* is growing toward its host (29).

Trichoderma-derived terpenoids, several of which have antifungal activity, include volatile terpenes, the diterpene harziandione, the trichothecenes trichodermin and harzianum A, and the triterpene viridin (156, 157). Their biosynthesis involves terpene synthases/cyclases as key enzymes, with seven and 11 respective genes being encoded in the *T. atroviride* and *T. virens* genomes, respectively (152). Characterization of the *tri* gene cluster responsible for harzianum A biosynthesis in *T. arundinaceum* revealed a role of this nonphytotoxic trichothecene in the antagonistic activity against *B. cinerea* and *R. solani* and in elicitation of defense-related gene expression in tomato plants (158, 159). The *C. rosea* genome encodes eight putative terpene synthases (13), but functional characterization is lacking.

Volatile Organic Compounds

VOCs are defined by having high vapor pressure at room temperature and low water solubility. In contrast to polar water-soluble substances, which remain more closely associated with the secreting fungus, VOCs are volatile and able to travel over longer distances.

Trichoderma-derived VOCs comprise pyrones, mono- and sesquiterpenes, alcohols, ketones, furans, alkanes, and alkenes whose production is species specific and coincides with certain developmental stages such as sporulation (157). One of the first VOCs isolated from *Trichoderma* is 6-PP. 6-PP has antifungal and plant growth-promoting activities and it is produced by certain *Trichoderma* species only; it is, for example, missing in the commercially used *T.* cf. *harzianum* strains T22 and T39 (160). The biosynthesis of 6-PP has been studied in *T. atroviride* IMI206040, revealing that it is derived from linoleic acid via the oxidation product 13-hydroperoxide-diene (13-HPOD) (161). Comparative genome analysis revealed a lipoxygenase gene in *T. atroviride* but not in *T. virens* and *T. reesei*, which is in accordance with the fact that 6-PP is one of the major secondary metabolites produced by *T. atroviride* but not the other two species (28). The lipoxygenase-encoding gene shows upregulation during the interaction of *T. atroviride* with *R. solani* (32) and, similarly, 6-PP production is elicited by the presence of *R. solani* or *B. cinerea* (161, 162). Production of 6-PP is correlated with the aggressiveness of *Trichoderma* toward its fungal prey. 6-PP is able to inhibit mycotoxin production in *Fusarium* by a still unknown mechanism and to stimulate plant growth and defense responses (129, 163).

TOLERANCE OF THE MYCOPARASITE TOWARD TOXINS, HYDROLYTIC ENZYMES, AND ROS

During the mycoparasitic interaction, the fungal prey is not a passive victim but responds to the attack by secreting secondary metabolites, enzymes, and ROS, and a successful mycoparasite must be able to cope with this counterattack (10). For example, *C. rosea* is able to tolerate the mycotoxin zearalenone (ZEA) when interacting with *F. graminearum*. Plant pathogenic *Fusarium* spp. such as *F. graminearum* and *F. culmorum* causing *Fusarium* head blight and foot rot in wheat are known producers of various mycotoxins. One of those, the polyketide ZEA, has strong antifungal properties and is hypothesized to provide *Fusarium* with a competitive advantage against other fungi (164).

Following screening of 150 fungal species for their ability to metabolize ZEA, *C. rosea* was shown in 1988 to be able to open the ring structure of ZEA and thereby detoxify this mycotoxin (165). Takahashi-Ando et al. (166) cloned and characterized the *zhd101* gene from *C. rosea* which encodes a zearalenone lactonohydrolase responsible for ZEA detoxification. The resulting cleavage product was highly reduced in toxicity and was similar to the compound previously characterized by El-Sharkawy and Abul-Hajj (165). Subsequently, *zhd101* was identified in 10 different *C. rosea* strains with the encoded zearalenone lactonohydrolase enzyme differing in only one amino acid between the strains (167). The *zhd101* gene is constitutively expressed but can be induced by exposure to ZEA in a concentration-dependent manner, which indicates that ZHD101 may have additional functions other than ZEA detoxification (167).

Deletion of *zhd101* significantly reduces the ability of *C. rosea* to detoxify ZEA (164, 167). When tested in confrontation assays against ZEA-producing *F. graminearum*, Δ*zhd101* mutants had clearly reduced antagonistic activities compared with the *C. rosea* wild type. However, when confronted with a *Fusarium* mutant unable to produce ZEA due to a knockout of the *pks4* gene, the antagonistic activities of *C. rosea* Δ*zhd101* mutants and wild type were similar (167). Biocontrol assays with wheat seedlings further showed that ZEA detoxification by *C. rosea* is at least, in part, important for the successful outcome of the biocontrol interaction. However, other biocontrol mechanisms are also involved (167).

The *zhd101* gene is also present in strains of *C. rosea* f. *catenulatum* and in *T. aggressivum*, a mycoparasite and pathogen of mushroom farms (168). Comparison of *zhd101* expression and the capability of ZEA detoxification between *T. aggressivum*, *C. rosea* f. *rosea*, and *C. rosea* f. *catenulatum* revealed clear differences in *zhd101* expression profiles and in duration required for ZEA breakdown (168). Studies with *C. rosea* IK726 showed a 1,000-fold increase in *zhd101* expression already 2 hours after exposure to ZEA, which at later time points, however, rapidly declined (169). Such differences could be important for the ability of different strains to effectively control ZEA-producing fungi in biocontrol interactions.

Transcriptomic profiling based on suppression subtractive hybridization revealed specific genes being expressed in *C. rosea* upon exposure to ZEA (169). Besides *zhd101*, these comprise two ABC transporters belonging to subfamily G (*abcG5*-group I and *abcG29*-group V) (13, 170), suggesting that these are involved in the tolerance of *C. rosea* to ZEA (169). Subfamily G of ABC transporters is classified as a pleiotropic drug resistance transporter and is known to contribute to drug resistance or fungicide tolerance in several fungi (e.g., reference 171). *C. rosea* IK726 *abcG5* deletion mutants have increased sensitivity to *F. graminearum* culture filtrates, to ZEA, and even to several chemical

fungicides based on iprodione and mefenoxam. In contrast, strains complemented with functional *abcG5* regained tolerance to ZEA and the fungicides mentioned (172). Results from confrontation assays further indicated a role of ABCG5 in the secretion of toxic secondary metabolites by *C. rosea* that might give this transporter an important active role in mycoparasitic or biocontrol interactions (172). Deletion of *abcG29* resulted in mutants with reduced biocontrol ability toward *B. cinerea* and *F. graminearum* and with low H_2O_2 tolerance, although they were not affected in their sensitivity to ZEA, fungicides, or osmotic stress (173).

In contrast, *T. atroviride* Taabc2, which belongs to subfamily G group V as well (13), has an important role in tolerance to toxins and fungicides (174). Accordingly, the *Taabc2* gene is upregulated in the presence of pathogen-secreted metabolites, specific mycotoxins, and some fungicides (benomyl and dicloran), and under conditions that stimulate the production of antagonism-related secondary metabolites and CWDEs in *Trichoderma* spp. *Taabc2* deletion mutants show increased susceptibility to inhibitory compounds either secreted by plant pathogenic fungi or *Trichoderma* itself and reduced biocontrol activity, suggesting that Taabc2 also has a role in avoiding autointoxication of the mycoparasite by endogenous compounds with inhibitory action that are secreted during antagonism (174).

The *C. rosea* IK726 genome encodes 86 ABC transporters and 620 MFS transporters, which are among the highest numbers found in any fungi sequenced today (13). The observed expansions in the ABC subfamilies B group III and subfamily G group I and V probably reflect the lifestyle of *C. rosea* as a mycoparasite of toxin-producing fungi. The gene expansion in ABC transporter subfamilies in *C. rosea* differs, however, from that identified in the *T. virens* genome (that has a larger set of ABC transporters than *T. atroviride* with an expansion in subfamily C), indicating different lifestyles of mycoparasitic *Trichoderma* spp. and *C. rosea* (13).

A mycoparasite must also protect itself against its own hydrolytic enzymes secreted during the antagonistic interaction. However, only limited information is available about the mechanisms involved. In *T.* cf. *harzianum*, the cell wall-bound protein Qid74 has been shown to play a role in cell protection, and mutants with a disrupted *qid74* gene are more sensitive to lytic enzymes than the wild type (175). In addition, Qid74 is involved in adherence to hydrophobic surfaces, a function similar to hydrophobins. A high number of hydrophobic cell wall proteins are encoded in *T. atroviride* and *T. virens* mycoparasites. and the *qid74* gene is present in their genomes as well (28, 107). However, it has been found in only very few other fungi and is missing in *C. rosea* (M. Karlsson, unpublished data). In contrast to the high number of hydrophobins (up to 11 genes) in *Trichoderma* spp. (176, 177), only three hydrophobins are encoded in the *C. rosea* genome. Deletion of the *Hyd1* and *Hyd3* genes results in increased growth rate, which in turn leads to enhanced *in vitro* antagonism and biocontrol (16).

Epl-1, a protein of the cerato-platanin family, has been characterized in detail in *T. atroviride* and *T.* cf. *harzianum*. *T. atroviride* Epl-1 self-assembles at air/water interfaces and forms protein layers on surfaces including chitin, thereby increasing their polarity (178). In *T.* cf. *harzianum*, Epl-1 is predominantly present in the cell wall of the mycoparasite under confrontation conditions and has been suggested to have protection function or act as a recognition molecule to identify its own and/or host hyphae while avoiding self-degradation (179).

Carbohydrate-binding proteins could be involved in cell wall protection as well, as suggested by Gruber and Seidl-Seiboth (107). They could bind to short oligosaccharides and influence the induction of CWDEs or even bind to chitin and mask and protect it from degradation as reported for fungal-plant interactions (180).

The Role of Oxidative Stress in the Mycoparasitic Interaction

Fungal NADPH oxidase enzymes, responsible for the catalytic one-electron transfer of oxygen to generate superoxide or hydrogen peroxide (H_2O_2), play an important role in the development of fungal sexual structures and appressoria (181), as well as in ROS production during defense against other fungi. Overexpression of *nox1* in *T.* cf. *harzianum* resulted in elevated ROS formation during direct contact with *P. ultimum*, accompanied by an increased expression of protease, cellulase and chitinase genes (182).

Exposure of fungal spores or mycelia to H_2O_2 promotes oxidative stress (183). *T.* cf. *harzianum* ETS 323 secretes an L-amino oxidase (Th-LAAO) during mycoparasitism that is responsible for H_2O_2 production (184). Th-LAAO is a flavoprotein that catalyzes the oxidative deamination of an L-amino acid substrate into the corresponding α-oxoacid together with production of H_2O_2 and ammonia. Monomeric Th-LAAO induces hyphal lysis and apoptotic cell death in *R. solani*, whereas it has a stimulatory effect on hyphal density and sporulation of *T.* cf. *harzianum* itself. The antagonistic activity of Th-LAAO seems to be closely interrelated with its interaction with *R. solani* cell wall

proteins and their subsequent structural alterations (184, 185).

Interestingly, the *C. rosea* genome contains a high number of genes encoding members of two H_2O_2-producing enzyme classes, the aryl-alcohol oxidase and glucose oxidase, whereas *Trichoderma* spp. genomes only encode few respective enzymes (13). In addition, a high number of group B-III-type ABC transporters are encoded in the *C. rosea* genome including a homologue of *M. oryzae* Abc3 that is involved in resistance against ROS (186). Deletion of the ABC transporter gene *abcG29* in *C. rosea* resulted in delayed conidial germination in the presence of H_2O_2, which implies a function of ABCG29 in oxidative stress resistance (173). A possible functional connection between the high gene numbers of H_2O_2-producing enzymes and ABC transporters putatively involved in oxidative stress protection in *C. rosea* remains to be investigated. A novel strategy for oxidative stress protection found in *C. rosea* involves the secreted serine protease PrC that acts upon nematode cuticles to produce degradation products that protect against oxidative stress by scavenging ROS (187).

CONCLUSIONS

Mycoparasitism is a quite prevalent fungal lifestyle, and *Trichoderma* spp. and *C. rosea* share the ability for necrotrophic mycoparasitism as part of their broad environmental opportunism. From a comparative genomics perspective, the mycoparasitic lifestyle results in common features such as high numbers of genes encoding carbohydrate-active enzymes, proteases, membrane transporters, and proteins involved in biosynthesis of secondary metabolites. However, there are also several differences in the expansion of gene families of these well-studied fungal mycoparasites, indicating ecological differences. The low number of genes encoding chitin and glucan catabolic enzymes in *C. rosea*, compared with the expanded gene sets in *T. atroviride* and *T. virens*, suggests that degradation of the cell wall of the fungal prey is an important feature of mycoparasitism in *Trichoderma* spp. but not in *C. rosea*.

Recent genome analyses of additional hypocrealean mycoparasites confirmed that the biosynthesis of peptaibiotic secondary metabolites is a characteristic trait of these fungi. In addition, toxin-like substances play crucial roles in the specialized mycoparasite *E. weberi*. The dependence of *T. virens* on toxic metabolites (e.g., gliotoxin) that poison the fungal prey is reflected in several unique adaptations, i.e., high numbers of secondary metabolism-associated genes, of multidrug resistance-associated ABC transporters involved in toxin export, and of killer toxin-like chitinases that presumably permeabilize the cell wall of the fungal prey to facilitate toxin entry. In the case of *C. rosea*, the unprecedented numbers of ABC and MFS transporters involved in drug resistance emphasize the importance of toxin tolerance in this species.

Another observation is that many mycoparasitism-related genes appear to share certain characteristics not present in genes involved in endogenous functions, such as high interspecific copy number variation and specific expression during fungal-fungal interactions (e.g., killer toxin-like chitinases, pleiotropic drug resistance transporters, hydrophobins, and reducing-type PKSs). Parallels with the effector concept in plant-pathogen interactions may be drawn where the coevolutionary arms race between the pathogen and the plant host results in effectors/effector targets that exhibit similar characteristics.

Although the data available so far allow first insights into the multitude of genes and biological processes contributing to the mycoparasitic interaction, many questions remain open such as how the fungal prey is sensed and recognized by the mycoparasite and how biotic and abiotic interactions affect the mycoparasitic activity, issues that are important for the efficient, reliable, and tailor-made application of mycoparasitic fungi as biocontrol agents. Our knowledge concerning mycoparasites' genomics so far is based on a single genome (individual) per species. An important future topic will be to study within-species variation that will address the long-standing axiom of strain variation of biocontrol-relevant mycoparasitic traits. Recent advances also point out the importance of assessing and delineating the ecological niche(s) and life histories of mycoparasites to better interpret data emerging from comparative genomics and to allow highly targeted application of respective strains.

The emergence of genomic and large-scale transcriptomic and proteomic data and their comparative analyses beyond the genus boundaries can offer further important clues to our understanding of the molecular basis of mycoparasitism. In addition, transcriptomic and proteomic studies examining the reactions of both interacting fungi, the mycoparasite and its fungal prey, will provide further insights into mycoparasitism-related processes such as attack, counterattack, and defense contributing to this pathosystem. Several processes essential for the mycoparasitic fungus-fungus interaction such as host sensing and signaling, transcriptional reprogramming, and secretion of effectors, enzymes, and secondary metabolites are likely to be

shared with pathogens of plants and animals. On the other hand, however, sensing and signaling events as well as mycoparasitic responses depend on the host fungus showing that the mycoparasitic interaction is complex and fine-tuned. Therefore, more studies characterizing gene functions are essential to complement the basis provided by genomics.

Lene Lange

THE ROLE OF FUNGI IN CONVERSION OF PLANT BIOMASS

The Increasing Importance of Fungi in Biotechnology

Fungi are now widely used in industrial biotechnology, for example, as production hosts for technical and food and feed processing enzymes, as gene donors for such enzymes, as production hosts for organic acids and cholesterol-lowering drugs (the statins), and as starter cultures and probiotics (1). Around half of the industrial enzymes used globally are of fungal origin; the other half are of bacterial origin. However, this balance is now moving toward the use of more enzymes from a wider spectrum of families of the fungal kingdom. There are several reasons for this. Fungal enzymes are efficient, compatible, and suitable for industrial processing: they have sufficient protein stability to give the enzyme products an acceptable shelf life; they provide customer solutions, meet regulatory approval demands, and fulfill end user needs.

The driver for this increased importance of fungi and fungal enzymes is the development of the new bioeconomy, where crop residues, industrial by-products, and organic waste streams are used as a basis for producing more bio-based products, obtaining more from biological resources, and wasting less (see Fig. 1). The potential is huge. Currently, there is a global loss of 30 to 50% (2) of all agricultural production, when summing up losses through the value chain from field to end user. Because of this, it is predicted that fungal enzymes will be vital for moving from a fossil-based to a renewables-based world economy, where upgrade of lignocellulosic biomass leads to production of not only biofuels, but also bio-based materials and bio-based chemicals, as well as new and healthier feed and food ingredients (3, 4).

Development toward a bioeconomy places fungi and mycology in a central position in relation to mitigating climate change; improving resource efficiency; replacing fuels, chemicals, and materials based on fossil resources; and contributing to feeding a growing global population. The next generation of products from biomass will utilize the intact structural complexity of the fresh biomass for health-promoting food and feed ingredients.

Fungal Enzymes, the Choice for Biomass Conversion: For Bioenergy and Beyond

Fungi have three roles in making value from plant biomass:

- As gene donors for large-scale production of enzymes
- As industrial production hosts for biomass-degrading enzymes and metabolites
- As producers of biorefinery end products (e.g., bioethanol, organic acids, biochemicals, or single-cell proteins) resulting from their growth on sugars from the enzymatic conversion of plant biomass

One of the most significant lifestyle characteristics of filamentous fungi is that they secrete enzymes. Secretion occurs primarily from the tip cells of the growing hyphae (5, 6). In nature, a large proportion of the secreted enzymes break down the substrate (e.g., plant tissue) that the fungus invades. In natural habitats, such

Technical University of Denmark, Department of Chemical and Biochemical Engineering, Center for Bioprocess Engineering, 2800 Kgs. Lyngby, Denmark.

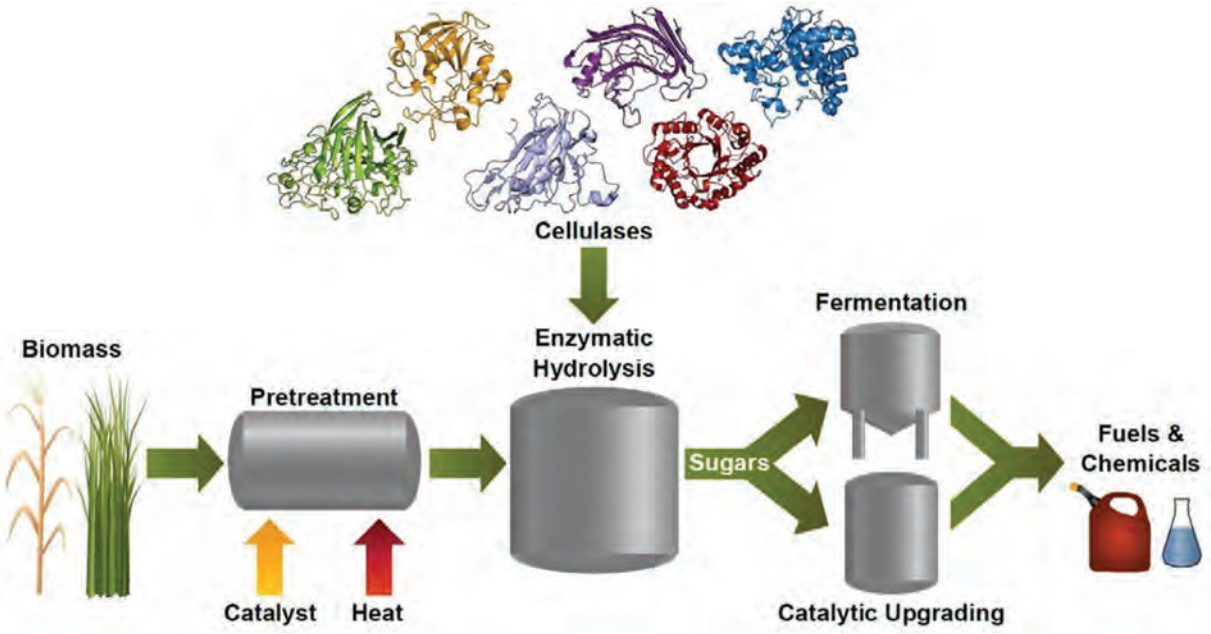

Figure 1 A schematic overview of a biorefinery. The product portfolio from biorefineries is not only fuels and chemicals but also includes higher-value products such as food and feed ingredients, cosmetics, skin care, and new functional biomaterials; it is also expected that many types of biorefineries will be developed for improved resource efficiency: the yellow (straw, stover, and wood chips), the green (fresh grass, clover, leaves), the blue (seaweed and fish bycatch and waste), the gray (agroindustrial side streams), and a biorefinery for upgrade of household waste and sludge (the brown biorefinery). Adapted from reference 16 with permission.

enzymatic biocatalysis of the substrate results in a conversion of the plant biomass into smaller building blocks suitable for hyphae to absorb for further growth of the fungus.

Through evolution, the growth of filamentous fungi has been adapted for efficiency in substrate utilization. The main adaptive traits are that (i) secreted fungal enzymes have a complement of activities for breaking down the substrate polymers, (ii) the enzymes are also stable outside the fungal cell, and (iii) the enzymes are available and are actively degrading the substrate at the time when the fungal hyphae have reached the area into which the enzymes have diffused. This allows the fungus to take up nutrients quickly after the degradation products have become available. Enzymatic breakdown thus primarily benefits the growth of the fungus itself rather than merely making substrate available for competitors such as bacteria or other fungi.

Almost all commercialized enzymes for industrial purposes (for example, in the detergent, textile, juice, paper, or baking industries) are enzymes (with a signal peptide for secretion) that in nature are secreted from the fungal cell which produces them. The reason for this is that secreted enzymes in general are more stable and significantly cheaper to produce because they can be recovered directly from large-scale fermentation broth without the necessity of opening the fungal cells.

Secreted, stable proteins suitable for large-scale, cost-efficient production can match the cost structure and price window of the industrial processes in question. Such proteins fulfill the primary industrial requirements, namely, high enzyme yields, easy recovery from fermentation broth, and good protein stability—all in all, giving lasting performance and end user benefits.

Overview of Secreted Enzymes from Filamentous Fungi

In the fungal kingdom a large spectrum of secreted enzymes has evolved to predigest organic structures into smaller molecules suitable for uptake by the fungal cell. Through evolution, fungal enzymes have been developed to break down almost all organic substrates available on earth (see the CAZy database [7]). The greatest diversity of enzyme activities described is related to the breakdown of plant cell wall structures. The CAZy database is described on its homepage as "a specialist

database, dedicated to the display and analysis of genomic, structural and biochemical information on Carbohydrate-Active Enzymes (CAZymes)." The CAZy database includes well-curated information about the following types of enzymes derived from all parts of the biological kingdoms: glycoside hydrolases (GHs) (hydrolysis and/or rearrangement of glycoside bonds), glycosyl transferases (formation of glycosidic bonds), polysaccharide lyases (nonhydrolytic cleavage of glycosidic bonds), carbohydrate esterases (hydrolysis of carbohydrate esters), and auxiliary activities (AAs) (redox enzymes that act in conjunction with CAZymes) (www.CAZy.org). In nature, fungal enzymes have been described that belong to all of these five groupings (GHs, glycosyl transferases, carbohydrate esterases, and AAs). Efficient conversion of biomass involves enzymes of all these major groups of carbohydrate active enzymes; GH cellulases and hemicellulases play the biggest role.

Biomass Conversion Enzymes Found Throughout the Fungal Kingdom and in Many Habitats

Genes encoding secreted enzymes are found in all divisions of the fungal kingdom. Based on the fungal enzymes included in the CAZy database, the richest portfolio of enzymes are in the *Ascomycota*, followed by the *Basidiomycota*, and lastly, the *Zygomycota*, whose members primarily produce enzymes suitable for releasing sugar molecules from already partially degraded products. Preliminary studies of the *Chytridiomycota* and *Neocallimastigomycota* document that at least selected species of these early-lineage fungi also have a wide portfolio of lignocellulosic polymer-degrading enzymes (8).

The most complex organic structures in plants and fungi are their cell walls. A huge number of different types of enzymes are needed for total breakdown of the plant cell walls of both monocots and dicots. Fungi specializing in degrading plant biomass in nature thus have a very broad portfolio of plant cell wall-degrading enzymes. Analysis and clustering of a broad spectrum of genome sequences of secretome enzymes from *Ascomycetes*, *Basidiomycetes*, and *Zygomycetes* gave a surprising result (9, 10): the clustering into being a good lignocellulose degrader or not was a more prominent trait than the fungal phyla to which the enzyme-producing fungi belonged. Thus, the phenotypic characteristic of the enzyme secretome portfolio overruled the taxonomic position.

Plant cell wall-degrading enzymes can be found in a vast spectrum of fungal habitats and life forms (Table 1). The most studied are white rot, brown rot, and soft rot fungi, as well as saprophytic fungi on dead herbaceous and wooden plant materials (11); interesting enzymes are also found from extremophiles (fungi growing in extreme environments) (12).

Table 1 A selection of well-studied lignocellulose degraders across the fungal kingdom

Fungal phyla	Fungal species	Fungal order	Physiology and habitat
Basidiomycota	*Phaenerochaete chrysosporium*	*Polyporales*	White rot
	Schizophyllum commune	*Agaricales*	Putative white rot
	Postia placenta	*Polyporales*	Brown rot
	Gloeophyllum trabeum	*Gloeophylales*	Brown rot
	Ganoderma applanatum	*Polyporales*	Heart rot
	Termitomyces spp.	*Agaricales*	Termite symbiont
	Leucoagaricus gongylophorus	*Agaricales*	Leaf cutter ant symbiont
Ascomycota	*Thermoascus aurantiacus*	*Eurotiales*	Saprotrophic
	Penicillium chrysogenum	*Eurotiales*	Saprotrophic
	Talaromyces leycettanus	*Eurotiales*	Saprotrophic
	Aspergillus niger	*Eurotiales*	Saprotrophic
	Myceliophthora thermophilae	*Sordariales*	Thermophilic, saprotrophic
	Neurospora crassa	*Sordariales*	Saprotrophic
	Melanocarpus albomyces	*Sordariales*	Saprotrophic
	Trichoderma harzianum	*Hypocreales*	Saprotrophic
	Fusarium oxysporum	*Hypocreales*	Necrotrophic
	Podospora		Coprophilic
Zygomycota	*Mucor circinelloides*	*Mucorales*	Saprotrophic
	Rhizopus stolonifera	*Mucorales*	
Chytridiomycota	*Rhizophlyctis rosea*	*Spizellomycetales*	Saprotrophic, soil
Neocallimastigomycota	*Piromyces communis*	*Neocallimastigomycetales*	Saprotrophic, rumen symbiont

Plant cell wall-degrading enzymes are also produced by plant pathogenic fungi (5) and by ectomyccorhizal fungi (13). Another biomass conversion habitat is that of coprophilic fungi, which grow on animal dung. Very prolific cellulase producers include *Podospora* spp. (14, 15). Coprophilic cellulase producers also typically secrete a range of bioactive metabolites and are found to be a better source of antimicrobial metabolites than most other cellulose-producing fungi: for coprophiles, substrate becomes available all at once, and the limiting factor for gaining access to the substrate is to outcompete other microbes present in the dung materials. In contrast, competition for access to substrate is not the primary parameter for plant pathogens. The infection process is very complex and depends primarily on breaking host resistance barriers.

PLANT CELL WALL-DEGRADING ENZYMES FROM FUNGI

The Recalcitrance of Lignocellulose and How To Overcome It

Lignocellulose is a highly complex and varying polymeric structure. It is the basic structure and major component of plant cell walls and has been developed through evolution to resist both biotic and abiotic stress, such as microbial pathogens and damage from wind and weather (16). Lignocellulose is composed of four major components: cellulose (20 to 50%), hemicellulose (15 to 35%), lignin (10 to 30%) (16), and pectin (often a rather low percentage). The lignocellulosic structure is highly recalcitrant to degradation, due to close packing of very complex, interlinked components. The branched hemicellulose coats the cellulose microfibers, the lignin encapsulates the polysaccharide components (cellulose, hemicellulose, and pectin) like a matrix around all polymeric structures, and the crystalline cellulose fibers themselves form a very recalcitrant structure, adding to inaccessibility and robustness. Due to this structural complexity and the interwoven, closely packed components, enzymes cannot readily access the plant cell wall components. Therefore, prior to industrial enzyme hydrolysis, a chemical/physical pretreatment is performed, which breaks down the lignocellulose structure sufficiently to allow enzymatic degradation.

Attempts have been made to develop more gentle pretreatment processes, for example, by using biocatalysis. The cellobiohydrolase enzyme family GH7 and laccases have been suggested for this purpose (17, 18) along with the use of family GH45-like proteins named expansins (19, 20), swollenins (21), and loosenins (16); lactic acid bacteria fermentation can also be used (16). Such gentler pretreatment could cut down energy costs and result in a hydrolyzed biomass that is more suitable as a base for upgrading, and it would not have the negative consequences of harsh pretreatments (e.g., artifacts, relocated lignin, and antinutritional factors).

Nature's biomass conversion processes have inspired research into the development of gentler pretreatment procedures. For instance, several *Ascomycetes* and *Basidiomycetes* can grow directly on and in a beech tree trunk; *Hypoxylon fragiforme* and *Schizophyllum commune* attack freshly fallen branches and trunks of deciduous trees, and *Fomes fomentarius* and *Ganoderma applanatum* cause heart rot on deciduous trees such as beech (22). Apparently, no pretreatment (physical or chemical) takes place. The fungi establish and grow, breaking down lignocellulose to fulfill their requirement for carbon. Time is obviously a factor, and changes over time in environmental conditions (humidity, temperature, light) play a role. However, molecules including the expansins, swollenins, and loosenins (16, 19–21) most likely also play a role. In addition, as yet undescribed synergies between chemical (reactive oxygen, photons, or metals) and biocatalytic reactions are probably involved. Interestingly, pretreatment is not required when aquatic biomass is used as biorefinery feedstock, because aquatic biomass has no or very little lignin in the cell walls.

Enzymatic Decomposition of Lignocellulose

Lignocellulose

Collective action among several enzymes is required to break down the complicated lignocellulosic structure. The most important group of enzymes for these activities is glycohydrolases, GH enzymes which cleave glycoside linkages (7). Such linkages are dominant in both cellulose and hemicellulose. Furthermore, polysaccharide esterases (carbohydrate esterases in the CAZy database [7]) assist the hydrolysis of GH enzymes by removing the methyl, acetyl, and phenolic esters. Polysaccharide lyases may also play a role in depolymerization. Several types of fungi, from a broad variety of habitats and taxonomic groupings, have all the enzymes needed for complete breakdown of lignocellulosic plant cell wall structures (see Table 1, above, and Fig. 3, below) (5, 16, 23–29).

Cellulose and cellulases

Depolymerization of cellulose fibers requires the following enzymatic activities: an endoglucanase acting on

cellulose (EC 3.2.1.4), two types of cellobiohydrolase (exoglucanases), one of which acts on the reducing end of the polymer (EC 3.2.1.177) and the other on the nonreducing end (EC 3.2.1.96), one β-glucosidase which cleaves the dimeric cellobiose to monomer C6 sugar/glucose (EC 3.2.1.21 β-glucosidase), plus the action of the lytic polysaccharide monooxygenases (LPMOs) (see Fig. 2A).

The occurrence of several β-1,4 endoglucanase-active enzymes (EC 3.2.1.4, of GH5, GH9, GH45) in a fungus is interpreted as reflecting a robust degrader whose enzymes contribute to improved fitness. This is because as a result, the fungus has built-in flexibility and can produce the enzymes most suitable for several types of environmental conditions (humidity, temperature, pH, etc.) (9).

Cellulases are divided into processive and nonprocessive; endoglucanases (EC 3.2.1.4) belong to the latter, and the cellobiohydrolases, GH6 and GH7, to the former. Furthermore, the hydrolytic activity can belong to the inverting (one-step) or the retaining (two-step) process (16). Among the active enzymes of the EC 3.2.1.4 class, GH45 is the only one of the inverting type.

Another prominent feature of cellulases in both nature and under industrial conditions relates to whether they are closely associated with the substrate, not just through interaction at the active site but also with a carbohydrate binding domain (CBM). The CBM can be located at either the N- or the C-terminal end (or in rare cases both) (30). CBMs can affect the efficacy and speed of enzyme activity; fungal CBMs primarily belong to the CBM1 family. Furthermore, whether the linker region that spans the catalytic domain and CBM is short or long also affects the behavior of the enzyme (27). CBM and linker modifications are such powerful tools for the design of enzymes and enzyme processes that they have been the basis of several patents and research and development (R&D) business strategies.

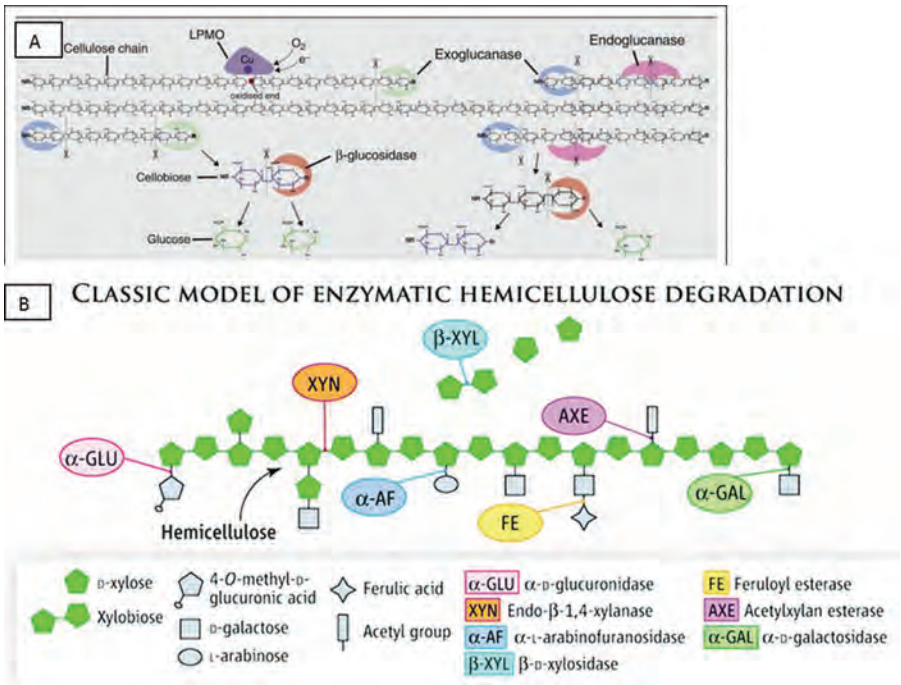

Figure 2 (**A**) Enzymatic breakdown of cellulose polymer includes several glycohydrolases (at least one endoglucanase, at least two cellobiohydrolases, reducing end and non-reducing-end active, and at least one β-glucosidase). Further, the activity of a lytic polysaccharide monooxygenase acts in synergy with the endoglucanase in breaking down the crystallinity of the cellulose polymer. Adapted from reference 24 with permission. (**B**) Hemicellulose is a very complex, highly branched and substituted polymer. The figure shows seven types of sugar components and lists the seven types of enzymes needed to break the linkages to such sugar moieties. However, enzyme hydrolysis of lignocellulose may not need the presence of all these seven hemicellulases because most of the standard pretreatment procedures will lead to the breakdown of several of the hemicellulose bonds. Adapted from reference 37 with permission.

Figure 3 "Fungal Hall of Fame" illustrating the five most important players in industrial lignocellulose biorefinery processing and in research. (**A**) *Aspergillus oryzae*, along with (**B**) *Aspergillus niger* and *Aspergillus nidulans*, are the most widely used monocomponent enzyme production organisms. (**C**) *Trichoderma reesei* is included due to its exceptional secretion capacity; it is the preferred production host for enzyme blends specifically designed for efficient biomass conversion. (**D**) *Saccharomyces cerevisiae* is the organism of choice for production of ethanol from the biomass conversion-derived sugar platform. *Pichia pastoris* is the expression host most often used for producing laboratory-scale volumes of newly discovered enzymes to facilitate characterization and evaluation of the new enzymes for industrial potentials. (**E**) *Myceliophthora thermophilae*, along with another thermophilic fungus, *Thermoascus aurantiacus*, represents alternatives to production of enzymes by species of *Aspergillus*. Hemicellulose and hemicellulases

The depolymerization of heavily branched and substituted hemicellulose structures also requires an entire complement of enzymes. At least one kind of endoxylanase (e.g., GH10 or GH11) is needed (7, 31) to break the xylan backbone. The endoxylanase activity (EC 3.2.1.8) is assisted by a range of other hemicellulases, usually by synergistic activity among the following types of enzymes: acetyl xylan esterase, arabinofuranosidase, and ferulic acid esterase (32–37) (Fig. 2B).

The reason why many of the hemicellulase enzymes have not been included in commercialized enzyme blends for lignocellulose decomposition is that many of the linkages cleaved by such enzymes are already broken during the pretreatment processing.

Lignin

Lignin is a very different type of polymeric substance compared to cellulose and hemicellulose, because it is a heterogeneous alkyl-aromatic polymer. Lignin degradation by white rot basidiomycetous fungi has been more studied than any other type of fungi (38). The most prominent types of enzymes active in lignin degradation are laccases and peroxidases (both types are oxidative enzymes) (17, 39–41). However, such enzymes do not react independently, and mediators are

needed. Brown rot fungi such as *Coniophora puteana* and *Serpula lacrymans* do not have prominent lignin-degrading enzymes, but such fungi do modify (through the action of specialized reactive metabolites) the lignin surface structure, thus freeing the cellulosic components from the lignin. The modified lignin structure remains for years in nature without much further degradation. Research on lignin degradation has led to many new efforts in studying not only the classical brown rot and white rot fungi, but also many other fungal species in many habitats. From such new studies it appears that throughout the range of lignin-degrading fungi, there exists a continuum of biomass degradation regimes, with varying degrees of similarity to white rot and brown rot fungi (38).

A recent development in understanding the fungal decomposition of lignocellulosic structures is the discovery of a new type of enzymatic activity, which has a function significantly different from all of the biomass conversion enzymes mentioned above. The new kind of enzyme activity was revealed by applying enzyme discovery approaches that are independent of sequence or function similarity to known enzymes. Two approaches were used: (i) use of culture broth fractionation followed by estimation of lignocellulose decomposition potential of the various fractions and (ii) use of transposon-assisted signal trapping (TAST) screening, a technique discussed later in this article (42). Both techniques demonstrated that a significant and novel type of enzyme, hitherto not associated with cellulose breakdown, was present in the most active fractions and was highly expressed and secreted in all fungi that degraded lignocellulose (43).

The enzyme responsible for such activity was first described as a glycohydrolase and was assigned to the protein family GH61 (10, 44). Further studies showed that this new GH61 type was widespread in the fungal kingdom, typically present in high numbers in the genome, and was not a GH enzyme but a monooxygenase (45, 46). As a consequence, such members of GH61 were recategorized as AA enzymes, were categorized as AA9, and were named LPMOs. Since the first article describing AA9 was published, knowledge of the LPMOs has grown explosively (47–49). Now several types of LPMOs are described under the following classifications: AA9 (45), AA10 (50) (bacterial, primarily chitin degrading), AA11 (51, 52), and AA13 (53). Furthermore, LPMO activity has been described on substrates including starch (53), hemicellulose (54), and keratin (55). An interesting feature of genes encoding fungal LPMOs is that they are often found in very high numbers in the fungal genome (51).

How Can Nature's Effective Fungal Lignocellulose Degraders Be Recognized?

Fungal genome sequencing has shown that genes encoding cellulose- and hemicellulose-degrading enzymes are found in a very broad spectrum of fungi. However, many of such fungi may not necessarily functionally be effective biomass degraders, even though they have the spectrum of genes of relevance for lignocellulose decomposition.

The most efficient fungal lignocellulose degraders can often be recognized up-front by knowing their physiology and ecology: Does the species in nature always grow in habitats where biomass decomposition takes place? Is it a strong competitor on such substrates? Classical mycological expertise, such as knowledge about fungal habitats and substrate associations, can provide answers to such questions and is particularly relevant and valuable for developing more efficient biomass conversion processes. At the DNA level, genome sequencing gives information about whether the species in question has the full complement of cellulase and hemicellulase genes. However, to predict the potential of a fungal species, we need to know not just which families of enzyme genes are present on the genome but also for which enzyme function the genes code. Assigning genes to a given enzyme family is not enough to identify its function because most enzyme protein families include several types of function (7). Since gene sequences which are very distantly related may share the same function, blast searches and alignment are not sufficient to predict the function. Based on this analysis and reasoning, efforts were made to develop a new sequence analysis method which could more accurately predict function from sequence.

As a result, a new non-alignment-based sequence analysis method was invented (56); it was later developed into a versatile and fast peptide pattern recognition (PPR) technology platform (9, 10, 51, 57). PPR can identify short peptides which are conserved among enzymes with shared function. Based on this, groups of proteins with the same enzyme function can be identified. With this approach, enzyme discoveries can be made, mining sequence databases efficiently and predicting enzyme function directly from sequence.

Different Mechanisms in the Fungal Breakdown of Cellulose

The enzymatic breakdown of cellulose in nature follows three or four models (16, 58–61): (i) fungal enzymatic breakdown where enzymes with different functionalities (endoglucanase, CBHs, betaglucosidase, and LPMO) are produced by separate genes, which results in individual

enzymes acting in synergy; (ii) cellulose breakdown, such as by brown rot fungi, where redox-acting enzymes give rise to ions needed for Fenton chemistry reactions to occur, which are capable even of breaking down the crystalline cellulose; and (iii) the bacterial model, where the genes needed for cellulose breakdown are placed sequentially in one reading frame and the proteins are placed in one huge molecular structure, the cellulosome, which processes the entire cascade of enzymatic reactions needed for breaking down cellulose; (iv) recently, a new category has been recognized, where enzyme hydrolysis is achieved by multimodular enzymes (*viz.*, enzymes with multicatalytic domains [59, 62]). Such multimodular enzymes have been described and are expected to be found in more fungi degrading plant biomass. Recent studies also suggest that in some habitats, such as anaerobic environments, most of the secreted xylanolitic and cellulolytic enzymes are found as free enzymes and are not organized in cellulosomes; they are, however, to a large extent encoded by multimodular genes (Wilkens C, Busk P, Pilgaard B, Kirkegaard R, Albertsen M, Zhang W-J, Nielsen P, Lange L, in press).

Interestingly, fungal enzymatic breakdown of cellulose (category [i], above) follows very closely the bacterial enzymatic breakdown of chitin (*viz.*, endo-acting chitinase plus reducing- and nonreducing-end, exo-acting chitinases (50). Moreover, bacterial decomposition of chitin also involves LPMO activity—the bacterial AA10 family (45). The resemblance of cellulose decomposition by fungi to chitin decomposition by bacteria is remarkable in evolutionary terms.

Recently, a new mode of action of fungal enzymatic degradation of the proteinaceous polymer keratin has been described (64). Fungal breakdown of alpha keratin can involve three types of proteases: endo-acting, exo-acting, and oligopeptide-acting (65); this pattern is thus also similar to fungal cellulose decomposition. Furthermore, keratin-degrading fungi (including the dermatophytes) also have LPMO genes (of type AA11) in their genomes (51). Such new knowledge could be applied to develop new technology for degrading chicken feathers and pig bristles, which so far are almost totally unexploited protein-rich waste.

YEAST FERMENTATION: FROM SUGAR PLATFORM TO BIOETHANOL

Fungal Yeasts: The System of Choice for Producing Bioethanol

Yeast cultures have been used to produce ethanol since ancient times. Even after centuries of industrial and academic practice, development, and research, *Saccharomyces cerevisiae* is still the biological production system of choice. This yeast is easy to control in industrial settings, and the robustness of wild-type *S. cerevisiae* against the cell toxicity of ethanol is acceptable. Increased ethanol tolerance can also be achieved through strain development, by mutation, or by genetic modification.

The primary focus of most of the research to improve the efficiency of ethanol fermentation from the sugar platform has been on using a larger range of the sugars of the biomass or, more precisely, to improve yeast fermentation to exploit not only C6 sugars (cellulose-derived glucose) but also C5 sugars (hemicellulose-derived xylose). Some progress has been achieved (see below). Further progress may be achieved by following one of three approaches: (i) make bioethanol only from the cellulose C6 sugars and reserve the hemicellulose C5 monomer and oligo sugar for making higher-value products such as food or feed ingredients; (ii) improve the efficiency of ethanol-fermenting yeast strains for fermenting both C5 and C6 sugars to ethanol; or (iii) develop new fermentation systems that produce a new generation of biofuels (66).

Higher-value products from hemicellulose (C5) sugars can be achieved, for example, by producing food and feed ingredients, based on the complexity (branching and substitutions) of the native hemicellulose polymers. These products can be refined to even higher value by making food and feed ingredients that have health-promoting effects such as prebiotic stimulation of the healthy gut flora of humans and nonruminant animals (67, 68). The resulting yeast biomass can also be upgraded to health-promoting ingredients, beta-glucans, nutraceuticals, or even drugs, based on the specialized fungal cell wall structure properties.

Development of Improved Yeast Fermentation Strains

In nature, yeast is primarily specialized to ferment C6 sugars. Until now, no wild-type microbe (yeast or bacteria) has been found which readily fulfills industrial demands such as efficient fermentation (high yields, rapid processing) of C5 sugars to ethanol and high tolerance to ethanol content in the fermentation broth.

Interesting attempts have been made to develop the bacterium *Thermoanaerobacter mathranii* (typical habitat is hot springs in North Atlantic areas) into an efficient ethanol production strain using both C5 and C6 sugars. High temperature tolerance makes recovery of the ethanol possible by skimming from the top of

the fermentation culture, so the critical ethanol concentration detrimental to the production strain is never reached (69). So far, a similar approach for a thermophile yeast has not been developed.

Improved yeast strains have been developed by several small companies, for example, Terranol. An *S. cerevisiae* strain that efficiently ferments C5 sugars and yeast strains that also grow on and utilize glycerol were developed (70, 71). For such progress, the key genes to control were Gut1p (glycerol kinase) and Gut2p (mitochondrial glycerol-3-phosphate dehydrogenase) originating from *S. cerevisiae* (72, 73). The next goal is to develop yeast strains capable of producing advanced biofuel (see below), as well as relevant chemical building blocks. The latter pave the way for renewable production of plant biomass-based chemicals, substituting for the current production of fossil-based chemicals. In the years to come the fuel- and chemical-producing organisms will be fungal, probably refined strains of *S. cerevisiae* (and in certain cases also strains of filamentous fungi), in versatile roles producing increased value from biomass. The core technology for this is enzymatic hydrolysis of the plant cell wall biomass, releasing free sugars from the plant polymers; this is followed by fermentation of fungi on the plant biomass-derived sugar platform.

BIOREFINERIES

Advanced Biofuels, Integrated Biorefineries, and On-Site Production of Enzymes

The terminology around different types of biofuels is very confusing. There are not only first- and second-generation biofuel, but also third- and fourth-generation, and a clearly defined term is needed. The European Biofuel Technology Platform (http://biofuelstp.eu/) has suggested and defined "advanced biofuels" as the term of choice. Advanced biofuels are defined as (i) being produced from lignocellulosic feedstock (not directly from starch, lipid, or sugar), (ii) having low CO_2 emission or high greenhouse gas reduction, and (iii) achieving zero or low indirect land use change impact.

Most of the advanced biofuels involve fungal enzymatic breakdown of biomass and fungal production of the advanced biofuel, but alternative systems are also being developed which do not involve fungi or fungal enzymes. These include advanced biofuels from algae or the use of physical and chemical processes, e.g., bio-dimethyl ether, biosynthetic natural gas, and bio-oil (75).

Integrated biorefineries (76) are not yet sufficiently cost-effective to be commercially viable. However, improved consolidated efficiency may be achieved by developing fungal strains which can produce the enzymes needed for biomass conversion and also produce ethanol. Alternatively, fermentation conditions may be created which allow two types of fungi to work in parallel under conditions controlled by changes in pH or another flexible parameter.

Enzymes may be produced on-site (77) directly in the production plant. The required enzymes are, for example, produced on a side stream of the feedstock, and the entire content of the enzyme-producing seed tank is then added to the main tank to start the enzymatic biomass hydrolysis. Intellectual property and technology protection issues, restrictions on the use of genetically modified organism (GMO) strains in industrial-scale biorefineries, or suboptimized on-site enzyme blends for efficient biomass conversion have so far blocked such development. However, when biorefineries are developed in which several higher-value products are produced from the feedstock, efficiency may be measured in terms different from the current emphasis on quantification of free sugars.

DISCOVERY AND PRODUCTION OF FUNGAL ENZYMES FOR BIOMASS CONVERSION

Production of Fungal Enzymes by Heterologous Expression in Fungal Production Hosts

The most classic and impressive example of development of an enzyme production strain is the early industrial use of cellulases. The history of the development of *Trichoderma* into a production host for cellulases (16) highlights the application of mycological knowledge to solve an industrial problem and to contribute to more sustainable agroindustrial processing.

In general, the fungi chosen as expression and production hosts have primarily been filamentous ascomycetous species such as *Trichoderma reesei* (78), *Aspergillus oryzae* (79, 80), *Aspergillus nidulans* (81), and *Aspergillus niger* (82, 83). Efficient production strains of *Fusarium venenatum* have also been developed (84). Further, attempts have been made to develop *Thermoascus aurantiacus* into a production host for heterologously expressed genes of thermotolerant enzyme proteins (85). Yeasts have also been developed as production hosts, e.g., *S. cerevisiae* (86) and *Pichia* spp. (87), but in yeast the yield is in general significantly lower than what can be achieved with filamen-

tous fungi. Yeasts are inferior with regard to protein secretion capabilities compared to filamentous fungi. This is an inherent characteristic of the yeast unicellular life form, with budding propagation and growth, because yeasts would not benefit from secreted enzymes that diffuse into the surrounding substrate. Figure 3 displays the five most prominent fungal species used in biomass conversion.

The company Dyadic has taken an interesting approach to the design of production hosts. Production strains of *Myceliophthora thermophilum* were developed in which the background of its native enzymes provided added value to the enzyme product; for instance, the native *M. thermophilum* cellulases boost the effect of the cellulases of a GMO construct (*M. thermophilum* with inserted cellulase genes, derived from other organisms) (88).

The latest significantly new type of application of GMO constructs of *T. reesei* is that it is used as a production strain for producing not just one enzyme but blends of recombinantly produced plant biomass-converting enzymes (e.g., Novozymes CellicCTec3: http://www.bioenergy.novozymes.com/en/cellulosic-ethanol/CellicCTec3/Pages/default.aspx) (90–92). Several genes are inserted into the genome, and the fermentation is developed to give an optimized blend, designed for efficient biomass conversion. It is noteworthy that for blends, most of the cellulase genes of *Trichoderma* have been replaced with superior cell wall-degrading enzymes from other fungi. Thus, the unique capability of *Trichoderma* to produce and secrete enzymes, and not the qualities of the *Trichoderma* enzymes, make this fungus the system of choice for biomass blend production.

Yeast production of industrial enzymes in bulk is still only barely commercially viable at a large scale, even though fermentation technologies leading to high yeast cell density (93) have to a certain degree compensated for the lower yield. However, at the laboratory scale, heterologous expression systems based on *Pichia* spp. and *S. cerevisiae* are commonly used as the system of choice for production and characterization of novel eukaryote proteins. The low level of glycosylation that takes place in these expression host systems can, however, be a drawback (87).

Interestingly, *Ascomycetes* spp., for instance, *Trichoderma* spp. and *Aspergillus* spp., also function well as production hosts for a broad spectrum of enzyme genes derived from other parts of the fungal kingdom (from species of *Basidiomycota*, *Zygomycota*, and even *Chytridiomycota*). However, production, for example, of basidiomycete genes in ascomycetous hosts may still result in lower yields compared to ascomyceteous genes (94). Codon-optimized synthetic genes may solve or at least minimize this problem.

Plant enzymes that also are of importance for biomass conversion have proven difficult to produce in filamentous fungi. Interestingly, the only effective expression of plant enzymes in fungi has been in yeasts and not in filamentous species (95, 96). Studies have been conducted to understand why successful expression of plant enzymes in filamentous fungi is blocked. Hamann and Lange found that filamentous fungal expression strains of *A. oryzae* misread the sequence of the plant enzyme gene as splicing sites, leading to production of fractionated mRNA and therefore to the lack of production of functional plant proteins (97).

Details about how to construct the most efficient fungal production hosts and which level of yield is achievable are primarily found in patent literature (giving a basis for the patent claims) or are more commonly kept as company-confidential. To be competitive in the industrial biotech industry, it is essential to have a very cost-efficient and cost-competitive enzyme production and enzyme recovery system, and the relevant details are considered strictly confidential.

An important part of developing a production host system is to modify the production strain by deletion of genes. Modifications may include abolishing end product inhibition and knocking out protease genes, which may break down the enzyme protein produced, and finally also to knock out the background of secreted enzymes which may interfere with the final enzyme product.

Another important issue is to have the fungal production strain approved by regulatory authorities, preferentially as a GRAS (generally recognized as safe) organism (98). This is needed for approval of the production plant and production process and is of special importance if food-grade enzymes are to be produced.

Fungi as Gene Donors: Discovery of New Industrially Relevant Fungal Enzymes

The technologies used for the discovery of new and improved fungal (and bacterial) enzymes have undergone significant development since the start of large-scale commercialization of microbial enzymes. The knowledge and experience gained during the different stages of industrial biotech are also relevant to future development of the bioeconomy. Several chapters of the new segment of industrial biotech (the circular bioeconomy, where local bioresources such as crop residues and agroindustrial side streams are upgraded to higher value in nearby biorefineries) lie ahead: big biorefineries will

be supplemented by smaller, decentralized and specialized use of bioprocessing; the need for new blends of enzymes for conversion of new types of complex biomass will grow. The use of microbial consortia may, in special instances, supplement the current pure culture fermentations, and new types of enzymes will be needed and new mechanisms of biocatalysis synergy may be discovered. This development will involve the increased use of a diversity of fungal (and bacterial) enzymes.

The inspiration for such development will be through a technology push, where new methods pave the way for new solutions. Likewise, studies of nature's own biomass conversion will also inspire and drive discoveries. Combining the two could prove to be a powerful strategy. Such developments inherently imply that discovery technologies should also be modified and developed to function efficiently at the metagenomics and meta-transcriptomics level, including the unculturable part of the microbiomes (99).

Enzyme Discovery from Nature

From the start of the industrial use of enzymes, the goal of discovery of fungal enzymes has been to find fungal isolates with a high level of activity on relevant defined or complex substrates. The enzyme protein should be stable and have pH and temperature profiles that match industrial process conditions. By this approach the discovery is based on experimental laboratory evaluation of the fungal strain and its enzymes, handling as one sample the entire multienzyme culture broth, with enzyme concentrations given by the fermentation physiology. Such screening and evaluation conditions favor the discovery of enzymes produced in high concentrations by their wild-type fungus and preferentially detect enzymes with good stability and high specific activity. However, with this approach it is easy to overlook enzymes for which no assays have been developed or cases in which several enzymes are needed from more than one organism (100).

A large spectrum of enzyme products relevant for industrial biotechnology was developed in the 1960s, 1970s, and first half of the 1980s based on such an enzyme discovery strategy. The strategy tapped into the microbial diversity available from culture collections and from the pool of naturally occurring microorganisms. Two examples are amylases for the detergent industry (bacterial, e.g., from *Bacillus* spp.) and cellulases for the textile industry (fungal, e.g., from *Trichoderma* spp. [101]). These examples relate to two very different industrial processes: (i) high pH and specific temperature stability and activity requirements and (ii) low pH and a broad spectrum of acceptable temperature activity profiles.

Exploitation of the early cellulase enzyme discoveries depended on more than the activity of the enzyme. The native fungal producer needed to grow well under submerged, aerated, fermentation conditions and to produce a good yield of the enzyme protein under such conditions. Basically, developing enzyme manufacturing systems with low production and recovery costs laid the foundation for industrial biotechnology. A realistic value proposition could be presented, which could convince industrial decision makers that biological processing could compete with chemical processing in cost, as well as in robustness and performance. The new biological processing also meant changing to a sustainable process technology, with less polluting chemicals in the wastewater and less energy use for high pressure and high temperature used in chemical processing. The emerging development of such competitive biological processing that was able to replace chemical processing (102) opened the way for setting environmental requirements to obtain regulatory approval of production facilities. This in turn meant that new environmental standards could be set, drawing up limits for acceptable negative impacts on the environment. The third type of driver for the development of gentle and competitive biological processing was to make improved use of the raw material, i.e., to obtain more product from the same raw material. Fungal cellulases were developed for treatment of, for example, fruit pulp after initial juice processing. A cellulase treatment could result in significantly higher yield of juice (and wine) simply by breaking down more of the plant cell walls to allow more juice to be extracted (103).

Next, the textile industry needed an enzyme for stone washing of jeans (104) and enzymes for the detergent industry for more gentle, color-protecting washing powder (105). Both of these commercial targets facilitated investments in significant R&D efforts to find new and interesting fungal cellulases. An important discovery was the GH45 protein, produced by the thermophilic fungus *Humicola insolens* (*Ascomycota*, *Sordariales*) (106). The enzymes of *H. insolens* are active at rather high pH (pH 8) and stable at elevated temperatures, with the maximum at ca. 45°C (104, 105).

During this period the foundation was laid for developing biocatalysis to replace many of the previously chemistry-based processes. But in the following period, the 1980s and 1990s, huge steps were taken to build the basis for understanding the complexity of plant cell wall-degrading enzymes. This knowledge was later used to develop the blend of cellulases needed for converting lignocellulosic biomass into biofuel (89, 106).

Monocomponent Enzymes Produced by Fungal GMO Production Strains

Analysis of the efficiency of enzyme production, e.g., productivity per tank year or enzyme yield per liter of fungal culture broth produced, revealed that much of the production capacity of the fungus and of the fermentation tanks was used to produce enzymes which did not add direct value for the customers (107).

Around the same time, in the 1980s, GMO technology was in its infancy, primarily focusing on making GMO constructs of plant cultivars (108) and in *Escherichia coli* (109, 110). From this research it became apparent that both prokaryote and eukaryote cells were able to produce much higher yields of single proteins than had been observed in wild-type strains. The use of a range of different promoters and of methods for selection of the highest-yielding transformants also inspired further development of microbial industrial biotechnology.

In 1988 the first GMO strain of an industrial enzyme was produced. It was a recombinant, monocomponent lipase enzyme for the detergent industry, expressed in *A. oryzae* (111). It was produced in Novo's facility in Japan because Danish legislation for industrial handling of GMO strains was not yet developed (112). This success inspired a new strategy among the leading industrial biotechnology companies (Novo and Danisco in Denmark, DSM in The Netherlands, and Genencore in the United States). Dialogue with, e.g., the Danish Environmental Protection Agency authorities (http://eng.mst.dk/) was very constructive, and both industry and authorities wanted strict regulation. Many years later, this proved to be a very wise decision. The strict requirements and regulatory conditions for approval of GMO strains and GMO production facilities, processes, and products laid the foundation for public acceptance of this new technology. The production vehicle was GMO-based but biologically confined to the fermentation plant, with no living GMO present in the end product and therefore no GMO organism reaching the end user. A new era of industrial biotechnology had begun.

Discovery and Optimization of Genes for Production of Monocomponent Enzymes

The initial step was finding a fungus with enzyme activities of interest and the necessary protein stability under industrially relevant pH and temperature conditions. This step was the same as for discovery of the classical non-GMO enzymes. But after this initial step, the entire discovery process was radically different. The first attempts to separate the wanted enzyme out of the complexity of the culture broth were tedious, costly, and slow; even if successful, discovery of the specific gene which could be inserted in the production host was far from easy. After a promising fungal isolate with interesting enzyme characteristics had been identified, the obvious next step was to focus on the genes, not the protein, and a strategy was developed as follows: (i) isolate the mRNA (which as a pool represents all expressed proteins), (ii) use this pool of mRNA to identify the cDNA of interest, and then (iii) insert this cDNA into the (heterologue expression) production host. By using cDNA, the uncertainty about whether the heterologue expression host could cope with the splicing of a foreign gene was circumvented, because cDNA has no introns. Only the coding part of the reading frame is transformed into the production host (100).

The next step was to efficiently develop (and screen) high-quality cDNA libraries to identify specific enzyme activities of interest. This process was developed to perfection in industry. During this period cDNA library screening became the single most used molecular technology in enzyme discovery, and it has resulted in the vast majority of new fungal enzyme discoveries commercialized over a period of 10 to 20 years. To date, a major proportion of commercially available fungal industrial enzymes have been found by cDNA screening technology (100).

The principles of high-throughput fungal cDNA technology screening (114) are as follows. (i) Prepare fungal biomass which has been exposed to the substrate components of relevance for the enzymes of interest. This is usually done by growing the selected fungal strain on its native substrate or on a well-defined medium containing the substrate of relevance for the enzyme activity of interest. (ii) Prepare total RNA followed by a polyA (tail) column separation of the mRNA fraction of the total RNA. (iii) Make the cDNA on the basis of the mRNA. (iv) Insert the cDNA in an *E. coli* library for propagation of the cDNA. (v) Insert the cDNA in a yeast expression host. For this, an *S. cerevisiae* strain was chosen with very limited background enzyme activity, and a substrate-induced promoter was included which only opened for gene expression if galactose was present in the growth media. The resulting yeast cDNA library was then screened for activity on multiple substrates by replica plating. Stock cultures and plates were maintained without promoter-inducing galactose to avoid fatigue of the selected transformants with promoter turned on all time. Such series of transformants were screened by measuring the activity obtained in small-scale fermentation, leading to selection of the transformants with the highest yield. The result of such

cDNA screening (100) was a yeast clone harboring the gene of interest that was known to be expressed and secreted; the gene found was full length and gave rise to a secreted, functional protein with the relevant activity.

The patent strategy for enzyme discovery and for product and process technology protection improved dramatically, along with development of monocomponent enzymes, GMO production strains and production processes, and value-added, end-product uses. It was of particular interest to extend the product patent coverage, which provided a basis for and resulted in protection significantly broader than just for the enzyme found. As a consequence, with patent protection as a driver, a series of new technologies were developed. These included approaches for the identification of conserved areas of the genes of interest to construct primers for PCR screening, thereby allowing for the discovery of nature's variants of the same gene (115). Patent examples based on such discoveries were a basis for broader claims of variation in sequence identity and for patent claims covering immunological recognition. One of the largest such efforts is Novozyme's GH45 patent claiming nature's variants of the GH45 gene across all fungal kingdom phyla (116).

Protein Engineering to Improve Enzymes for Conversion of Plant Materials

Three significant activities led to the development of molecular biotechnology R&D as a prominent field in its own right: (i) discovery of monocomponent protein backbones, (ii) sequencing of the enzyme proteins discovered becoming accessible and affordable, and (iii) elucidation of three-dimensional enzyme protein structures. Protein engineering (PE) became a scientific discipline and an important part of industrial biotech R&D. Both random mutagenesis and targeted mutagenesis were applied with a high level of success. The efficiency of particular enzymes with robust activity could be significantly improved through random or targeted mutation schemes to modify the optimum pH and temperature to match industrial needs. Another target of protein engineering was to change enzyme stability and robustness toward chemical and biochemical process agents. Generally, PE developed into a complex operation in which many rounds of different technologies eventually were merged together in one process, named artificial evolution. Along with such methodological progress, the use of high-throughput, automated laboratory screening by robotics was developed to build on not just smartness in thinking but also number-crunching power as a basis for selection of the superior enzyme activity (117–119).

A dedicated nonevolutionary technology—shuffling technology (*viz.*, cutting the gene to pieces, shuffling the gene parts, and reassembling them into new sequences)—was also developed as part of the artificial evolution. This was the basis for improving function to a level hitherto not achievable through mutations and selection (120, 121).

Protein engineering R&D efforts became so successful that for a period it appeared that discovery of new wild-type enzymes from nature's diversity might not be needed in the future. The diversity needed to satisfy industrial needs and end user demands was predicted to be met by engineering already known protein DNA backbones. However, it became apparent that finding activities radically different from known enzymes was most efficiently achieved by screening wild-type microorganisms and then using PE to optimize on such a backbone.

Next-Generation Sequencing Revolutionized Enzyme Discovery

The next-generation sequencing technologies paved the way for a new generation of microbial discovery strategies (63, 122). Initially, the technology was a shortcut to the integrated use of sequencing of, e.g., PCR bands identified in PCR screening searching for more variants of a lead enzyme gene, and for dynamic and fast sequencing of the new genes discovered by, e.g., cDNA screening to allow fast and efficient priority patenting. In short, the new-generation sequencing technology became a game changer: sequencing was much faster, prices dropped, and sequencing capacity, availability, and accessibility increased. Whole-genome sequencing became part of a standard enzyme protein discovery procedure which generated new sequences and mined sequences which had been placed in the public domain by other scientists with insufficient knowledge of the enzymes coded for by such deposited genes. Efficient enzyme discovery was now *de facto* tripartite: (i) discovery of new wild-type enzyme backbones from nature's diversity, (ii) discovery from man-made diversity (PE variant and mutagenesis libraries), and (iii) discovery by *in silico* mining of deposited sequences. The three approaches could strategically be placed sequentially: identifying interesting organisms by determining interesting habitats and by activity profiling such organisms, sequencing the genome of the selected organisms, and mining the new genomes along with other related genomes and genes and selecting the most promising genes for expression for further characterization of the enzyme protein. If gene expression was successful and the protein had promising activities,

automated screening of variant libraries would generate fast and improved versions of the new enzyme.

The limiting factor and pitfall for such new, sequence-based enzyme discovery is 2-fold. There may be a rather high risk of unsuccessful expression of the selected gene, and the limited number of available enzyme activity assays fails to precisely detect the desired novel type of activity.

Two new types of technologies, TAST and PPR, were developed to optimize exploitation of the overwhelming amount of sequence data available from new-generation sequencing of both eukaryote and prokaryote organisms (42, 74). Both technologies aimed at optimizing the possibilities of finding novel and improved types of enzyme activities from enzymes which are also expressed as functional proteins in nature, therefore with optimized perspectives for good expression in industrial production hosts.

The basic principle of TAST (42) is reflected in the construction of the transposon: a β-lactamase gene without its signal peptide is inserted (together with other marker genes) into the transposon. When a new gene is inserted in the *E. coli* screening host along with the transposon, the transformant cell, when screened on ampicillin-holding plates, will survive only if the gene has a signal peptide. This is because the β-lactamase protein is transported across the cell membrane and therefore correctly folded only if the β-lactamase gene on the transposon is fused with a signal peptide (from the new enzyme gene), making the β-lactamase active and thus protecting the transformant cell against ampicillin. Surprisingly, TAST screening could be used for discovery of novel genes and proteins from all groups of prokaryotes and eukaryotes even though the determining screening criterion is transportation over the *E. coli* cytoplasmic membrane. Enzymes with totally novel enzyme sequences and enzymes for which we did not have any assays available could now be found by TAST (42, 97).

A convincing example of the significance of the new TAST technology was the discovery of a new type of enzyme (GH61), which was found as being expressed in high numbers in almost all TAST screening projects performed with cellulose- and lignocellulose-degrading fungi (43). GH61 (now known as LPMO, AA9) is now a standard component of commercialized plant biomass-degrading enzyme blends.

TAST, however, was not an easy technology to exploit. Most laboratories which tried it did not succeed. New and improved methods were needed for finding secreted enzymes. Further, a need arose for making it possible to find also the sequence commonality among even distantly related proteins sharing the same function. Based on this, a new protein discovery technology, PPR, was invented.

PPR is a non-alignment-based, sequence analysis method which identifies conserved n-mer peptides and enables the assembling of a group of proteins sharing more than a set number of conserved peptides from a given list (56). Such PPR groupings have been validated to correlate to the enzyme function (10) and can be used (through application of additional PPR technology platform software programs) to predict function directly from sequence (9). PPR is faster and more efficient than other methods in mining even very large data sets. PPR can also be used to efficiently mine huge databases of metagenomic as well as metatranscriptomic sequences.

PPR enables discoveries of functions where screening assays have not been developed and facilitates the discovery of sequences of very distantly related genes with low shared sequence identity but the same function. It is currently superior to other sequencing analysis methodologies because it predicts the function directly from the sequence, which is especially valuable if discoveries are sought from microorganisms or habitats where annotated genome sequencing is not available. PPR can also be used efficiently to find new discoveries from poorly annotated sequence databases and to find more members of described families than have been found before (leading to *in silico* expansion of protein families). PPR brings order out of chaos.

The low cost of synthetic genes—codon optimized to the expression system of choice (for fungal genes, e.g., *Pichia pastoris*)—has made *in silico* discoveries (combined with PPR sequence analysis) a shortcut to the discovery of novel enzymes, e.g., for efficient conversion of new types of feedstocks.

FUTURE PERSPECTIVES: UPGRADING MORE ORGANIC FEEDSTOCKS TO EVEN HIGHER VALUE AND NEW BUSINESS MODELS

Exploitation of enzymes for the bioeconomy upgrade of complex organic residues, by-products, and waste streams has ushered in a new era of biological production. Earlier, monocomponent enzymes produced in GMO production hosts were commercialized following the business model of one gene, one enzyme, one product. However, the new production technology and business model for biomass conversion enzymes builds on several different genes transformed into one and the same production strain (for example, *T. reesei*), leading to production of a designed composite blend of enzymes (89, 90).

The next steps are to design enzyme blends for processing of more types of biomass, such as new types of plant feedstocks and agroindustrial by-products, biomass of fungi (e.g., vinasse, the spent microbial biomass from biorefineries), and of macroalgae (primarily brown and red), as well as to develop upscaled methods for valorization of organic fractions of household waste and sludge. The focus will broaden from being confined to the breakdown to monomer sugars to include recovery of selected structural components of the biomass for higher-value products (e.g., health-promoting prebiotics).

Systems for "on-site production" of enzymes may also be developed, for example, by growing fungi that produce blends of enzymes directly on the organic fraction of household waste and using this enzyme blend for hydrolysis and liquefaction of the organic part of the mixed waste stream. Development of hydrolysis and liquefaction processing of organic household waste has already been accomplished (see http://www.renescience.com/en). Similarly, fungal starter cultures could be developed for direct "on-farm" upgrade of crop residues (e.g., from vegetable production) to a protein-rich and bioaccessible animal feed.

Another future approach is to promote the use of fungal enzymes and fungal starter cultures in developing countries at the village level for upgrading organic waste to fuel, feed, and fertilizer. Such decentralized use of enzymatic biomass conversion could be promoted further if local scientists, mycologists, agronomists, and plant pathologists could more readily access the cultures and the knowledge of biomass conversion. A vision has been formulated for an open access biology (1) administered by international culture collections, where the essential strains and knowledge could be accessed. Strains earmarked for open access biology should be safe, efficient production hosts, gene donors, or starter cultures that are available in the public domain with freedom to operate royalty free.

MYCOLOGICAL PERSPECTIVES: FUNGAL SECRETOME, EVOLUTION, AND DYNAMICS

The enzyme composition of the secretome of filamentous fungi provides a basis for efficient biomass conversion and valorization. More research into the evolution and dynamics of the fungal secretome, put in evolutionary perspective, is essential for understanding biomass conversion in nature and for developing biomass conversion even further. In nature, evolutionary pressure is on the secretome and on the enzyme functions, proteins, and genes, because increased fitness is achieved through efficient enzymatic breakdown of available organic materials (89, 113). The mechanisms for adaptation of fungal secretome composition and enzyme functions are gene copying, followed by gene loss or gene retention, similar to the process of speciation, but faster. Evidence is growing of the prevalence of an additional mechanism: horizontal gene transfer. This occurs in special habitats such as cow rumen and gut channels but is expected to be found more widely among fungal habitats, including other biomass conversion hot spots. Studies of such habitats can pave the way for interesting, new conceptual understandings of relevance for both mycology and applied use.

The fungal gardens of termites and leaf cutter ants can be seen as nature's prototype for the yellow and the green biorefineries (28). In the garden, fungal biomass is used to feed entire colonies. Similarly, new higher-value products derived from fungal biomass could be the next important new step in the bioeconomy for improving the health of both humans and livestock (68).

Fungal Ligninolytic Enzymes and Their Applications

52

Miia R. Mäkelä,[1] Erin L. Bredeweg,[2] Jon K. Magnuson,[3,4] Scott E. Baker,[2,3] Ronald P. de Vries,[1,5] and Kristiina Hildén[1]

INTRODUCTION

Lignin is an aromatic polymer with a heterogeneous structure. Varied, nonhydrolyzable linkages between subunits present a significant constraint to efficient exploitation of plant lignin. The different types of biomass and pretreatment used in biomass conversion processes result in a large variety in the molecular weight, structures, modifications, amount, and aqueous solubility of the lignin in the remaining product side streams. While polysaccharides are deconstructed biologically mostly by glycoside hydrolase and esterase hydrolysis, the ether and carbon-carbon bonds of lignin are attacked by fungal oxidative enzymes and small-molecule oxidative species, adding heterogeneity to the products.

Lignin is the second most abundant renewable biopolymer on Earth, after cellulose, and accounts for 26 to 32% and 20 to 25% of the dry weight in softwoods and hardwoods, respectively (1). In gramineous plants, lignin content varies across plant species and tissues, such as 15 to 21% of the dry weight in corn stover and 5 to 17% of the dry weight in wheat straw (2). Cross-linking of lignin to hemicellulose provides strength to the plant (3), aids in water transportation, and protects the plant cell from microbial attack (4). Lignin consists of three monolignols synthesized through the phenylpropanoid pathway: sinapyl, coniferyl, and *p*-coumaryl alcohol (5, 6). Lignin contains various C-C and C-O bonds, but the β-O-4 aryl ether linkage is most abundant (30 to 40% in softwood and 40 to 50% in hardwood) (7). The mix of woody components by tissue and species also may determine carbon-active enzyme activity (8). Recent analysis of genome content in metagenomes and diverse wood decay fungi has unearthed new candidate lignin-interacting enzymes (9–12).

Research has built a detailed picture of the biosynthesis and structure of lignin. Genetic modification of the lignin pathway in plant systems has enhanced the digestibility of cell walls due to (i) lower lignin content, (ii) increased access to cellulose and hemicellulose, and/or (iii) more easily digested bonds in lignin itself (13–15).

BIOMASS PRETREATMENT AND ITS EFFECT ON LIGNIN

Pretreatment broadly covers the thermochemical processes that open the structure of biomass so that it becomes susceptible to subsequent enzymatic hydrolysis of polysaccharides and enzymatic oxidative deconstruction. Until recently, pretreatment research focused on polysaccharide exposure, with little concern about lignin other than as a component for removal or alteration to avoid inhibition of enzymatic hydrolysis. Changes in the chemical structure of lignin due to pretreatment may make the resulting lignin less suitable for interaction with fungal enzymes, because it is then no longer a natural substrate. A diverse range of biomass pretreatments are used, and these generate differences in quantity and structure, as well as solubility of lignin breakdown products. The amount of lignin is also dependent on the feedstock substrate, and therefore the choice of pretreatment is also dependent on the ultimate product.

PRETREATMENT METHODS

In alkaline pretreatments, strong bases (e.g., sodium, calcium, or ammonium hydroxide) are used to partially degrade (open) the (hemi-)cellulose structure, but they also result in structural changes in lignin (16, 17). Up to 60% of lignin can be solubilized and separated from cellulose by alkaline treatment. Under alkaline conditions the phenolic alkyl-aryl ethers in lignin are cleaved, resulting in a more soluble lignin (18).

Acid pretreatment is usually performed using dilute sulfuric acid (19, 20), though processes using hydrochloric acid are also used. This pretreatment removes the hemicellulose (21), but not lignin. However, it does alter the structure of lignin, cleaving β-O-4 ether linkages and generating a β-ketone or an aldehyde group on one lignin molecule and a free phenolic group on the other (22). Drawbacks of the process are condensation of lignin (23) and side products that reduce sugar to ethanol efficiency (e.g., furfural and hydroxymethylfurfural) (24).

Ionic liquids are salts that are in liquid form at room temperature and have a high dissolving capacity for lignocellulose (25). The advantage of using ionic liquids is that they largely leave the various polymers intact, resulting in more native substrates, including lignin, for subsequent enzymatic depolymerization (26, 27).

Steam explosion pretreatments are a short exposure of the feedstock to high temperature (190 to 270°C) and pressure (0.7 to 4.8 megapascal) followed by rapid pressure reduction, resulting in disruption of the fiber structure (28). Dilute acids are often used to facilitate the process (28). Lignin is partially removed or redistributed during the steam explosion, resulting in modified lignin (29), caused by cleavage of acid-labile linkages such as the predominant β-O-4 ether linkage (30).

Similar to steam explosion, liquid hot water is an autohydrolysis process that uses liquid water at high pressure and elevated temperatures (160 to 240°C) (31). Liquid hot water pretreatment results in cosolubilization of hemicellulose and lignin and in separation of this product stream from the solid cellulose-rich fraction. Solubilization of lignin together with hemicellulose is more efficient at lower temperatures (32). The treatment can result in an increase of the ratio of acid-insoluble to acid-soluble lignin due to an altered lignin structure (23).

In ammonia fiber explosion, the feedstock is exposed to liquid anhydrous ammonia at high pressure and moderate temperatures (60 to 100°C) followed by rapid pressure reduction, in a process similar to steam explosion (33–35). Rapid expansion of the ammonia gas results in swelling of the feedstock, which breaks lignin-hemicellulose linkages. However, ammonia fiber explosion does not remove lignin, but deposits it on the surface of the feedstock (34) and alters its structure significantly (36).

In ammonia recycle percolation, 5 to 15% aqueous ammonia is fed through a packed bed reactor containing the lignocellulose feedstock at temperatures between 140 and 210°C (37). This process differs from ammonia fiber explosion in that it removes 75 to 85% of lignin and solubilizes 50 to 60% of hemicellulose (38). In organosolv pretreatment, delignification is less pronounced compared to organosolv pulping. It is performed at high temperatures (100 to 150°C) using a variety of solvents that cause breakage of internal bonds of the lignin polymer (36). Lignin is removed in varying degrees depending on the solvent (39) and can be separated containing a high amount of aromatic rings (40).

Ozonolysis treatment of biomass efficiently removes lignin due to an electrophilic attack followed by a hydroxylation reaction of the aromatic ring (41). This results in a partial conversion of acid-insoluble to acid-soluble lignin, enabling the removal of a significant proportion of the lignin (42). While ozone also reacts with carbohydrates, these reactions are about 106 times slower than with lignin, resulting in specific lignin removal (41).

Supercritical fluid pretreatment uses materials that can be in either a gaseous or liquid state and are used under temperature and pressure conditions where both states coexist. They therefore can penetrate the crystalline structure of lignocellulose (43). No removal of lignin has been reported for this treatment.

LIGNIN-MODIFYING FUNGI

Basidiomycetous species are the only organisms able to efficiently mineralize lignin into CO_2. Lignin-modifying basidiomycetous species have been traditionally divided into two groups based on the visual appearance of the wood residue. White rot fungi (e.g., *Phanerochaete chrysosporium*, *Dichomitus squalens*, *Trametes versicolor*) degrade all the major polymers in plant cell wall including lignin. As a result, the decayed wood is characteristically white, and it includes fiber-like cellulose-enriched material (44). Litter-decomposing fungi are also able to cause white rot-type decay. Brown rot fungi (e.g., *Gloeophyllum trabeum*, *Postia placenta*) depolymerize cellulose in the early stage of wood decay, whereas lignin is only modified, e.g., by demethoxylation. The remaining brown wood residue has decreased strength (45, 46). However, a more nuanced classification of wood-rotting fungi has been suggested.

The more diverse mechanisms of wood decay have been revealed by analysis of the basidiomycete genomes, which reflect a spectrum of lifestyles between brown and white rots and ectomycorrhizal associations (47, 48). Wood-colonizing ascomycete fungal species such as *Xylaria* spp. have potential in mineralizing lignin, although to a lesser extent than wood-decaying basidiomycetes (49). Soft rot, which can attack the softer parts of the wood that have lower lignin content, is often a characteristic of the ascomycetes, though there are reports that soft rot characteristics are present in some Basidiomycota (48).

Brown rot fungi lack class II peroxidase enzymes, which encompass lignin-active AA2-type peroxidases. Phylogenetically, brown rot lifestyles have evolved at least five times from white rot lineages (48). Brown rot fungi have also lost many carbohydrate active enzymes (e.g., GH6, GH7, AA9) and oxidoreductases, enzymes that may be energetically costly to exploit lignin as a carbon source. Brown rot genomes have an expansion of both GH5 and GH28 gene families, which target cellulose and hemicellulose. Active fluidity between lifestyles is observable through phenotyping and genome characterization, reflected by pseudogenization of peroxidases in *Fistulina hepatica*, a relative of the white rot *Schizophyllum commune* (50).

Lignin decay takes place both enzymatically through the activity of enzymes and through nonenzymatic radical-based breakdown. The current paradigm of nonenzymatic rot activity is that fungi lower their environmental pH and secrete protective and iron-sequestering oxalate, other iron chelators, and enzymes that produce oxygen radicals (51). Hydroxyl and hydroperoxyl radicals generated by electron exchange between iron and hydrogen peroxide, as well as iron-reductant phenolates diffuse into the wood, continuing to reduce iron for reactivity with hydrogen peroxide, and both react with lignin elements which are then released (52). These diffusion reactions are a first foray into breakdown in both white rot and brown rot fungi, because decay of the plant cell wall takes place at a distance from the fungal hypha (53). Differences between lignin utilization (by white rot fungi) and lignin modification or repolymerization (by brown rot fungi) may be due to efficiency differences of nonenzymatic Fenton reaction-based wood penetration (52). The large size of many white rot lignin-active enzymes is thought to prevent access to portions of the wood (54).

Wood growth experiments (50, 52) have shown that enzyme production and activity on a single biomass type varies, which suggests that optimization of overall or specialized enzyme activity for industrial deconstruction may benefit from knowledge of the many new genomes of fungi being sequenced and phenotypically characterized (11, 48, 50, 55). Additionally, small molecule reactivity and Fenton chemistry intermediates can be investigated *in vitro* (56), leading to lignin byproducts and modifications that may be useful for extraction or lignin bioproduct manufacture. As with cellulosic enzyme mixtures, inclusion of different accessory enzymes and nonhydrolytic proteins (57–59), chemistries (52, 56), or timing of enzyme activity (60) may improve industrial manipulation of lignin. For instance, higher molecular weight products from lignin can be produced from laccase enzyme-producing fungi, while peroxidase activity is correlated with smaller molecular weight wood components (60).

STRUCTURE AND ACTIVITY OF LIGNIN-ACTING ENZYMES

Enzymes involved in lignin depolymerization include oxidative enzymes that catalyze nonspecific reactions (Table 1). Several of these enzymes are catalogued in the Carbohydrate-Active enZymes Database (CAZy; http://www.cazy.org/) as a family of auxiliary activities (AAs) (61).

Fungal class II heme-containing peroxidases, i.e., lignin peroxidases (LiP), manganese peroxidases (MnP), and versatile peroxidases (VP), classified in the AA2 family, are the key enzymes for lignin degradation (44). By using H_2O_2 as a cosubstrate, they catalyze oxidation of high-redox aromatic substrate molecules. Genes encoding lignin-acting peroxidases have been found exclusively in genomes of basidiomycete white rot fungi (47, 62, 63). The overall architecture of lignin-acting peroxidases from primary to tertiary structure is well conserved, including Ca^{2+}-binding sites, heme-pocket residues, and four disulfide bridges (64).

LiPs were the first heme peroxidases shown to be associated with ligninolysis (65, 66). LiP enzymes have been reported only from a few white rot fungal genera such as *Bjerkandera*, *Phanerochaete*, *Phlebia*, and *Trametes* (47, 62, 67). The redox active residue needed for LiP catalysis is a solvent-exposed tryptophan (Trp-171 in *P. chrysosporium* LiP H8 [68]), which facilitates the oxidation of lignin and other bulky aromatic substrates by long-range electron transfer to a heme cofactor (69, 70). A similar solvent-exposed tryptophan is conserved in VPs (71). LiPs and VPs are also distinguished from the other lignin-acting peroxidases by their high redox potential (1.4 to 1.5 V) that facilitates direct oxidation of nonphenolic lignin substructures (72). LiP catalyzes one-electron oxidation of a broad range of

Table 1 Fungal oxidoreductases involved in modification of lignin and lignin-derived compounds

Enzyme	CAZy family[a]	Systematic name/EC no.	Reaction	Characterized enzymes from fungi
Laccase	AA1_1	Benzenediol oxygen oxidoreductase/ 1.10.3.2	4 Benzenediol + O_2 ⇒ 4 benzosemiquinone + 2 H_2O	Widely distributed in ascomycetes and basidiomycetes
Manganese peroxidase (MnP)	AA2	Mn(II):hydrogen-peroxide oxidoreductase/1.11.1.13	2 Mn(II) + 2 H^+ + H_2O_2 ⇒ 2 Mn(III) + 2 H_2O	White rot wood and litter-decomposing fungi (e.g., *Dichomitus squalens*, *Agaricus bisporus*, *Agrocybe praecox*)
Lignin peroxidase (LiP)	AA2	(3,4-Dimethoxyphenyl)methanol: hydrogen-peroxide oxidoreductase/ 1.11.1.14	(3,4-Dimethoxyphenyl)methanol + H_2O_2 ⇒ 3,4-di-methoxybenzaldehyde + 2 H_2O	Some white rot fungi (e.g., *Phanerochaete chrysosporium*, *Phlebia radiata*, *Trametes versicolor*)
Versatile peroxidase (VP)	AA2	Reactive-Black-5:hydrogen-peroxide oxidoreductase/1.11.1.16	(1) Reactive Black 5 + H_2O_2 ⇒ oxidized Reactive Black 5 + 2 H_2O (2) Donor + H_2O_2 = oxidized donor + 2 H_2O	Only in some white rot species (e.g., *Pleurotus ostreatus*, *Bjerkandera adusta*)
Dye-decolorizing peroxidase (DyP)	na	Reactive-Blue-5:hydrogen-peroxide oxidoreductase/ 1.11.1.19	Reactive Blue 5 + 2 H_2O_2 ⇒ phthalate + 2,2′-disulfonyl azobenzene + 3-[(4-amino-6-chloro-1,3,5-triazin-2-yl)amino] benzenesulfonate + 2 H_2O	Common in ascomycete and white rot and litter-decomposing basidiomycetes (e.g., *Geotrichum candidum, B. adusta, Auricularia auricula-judae*)
Chloroperoxidase (CPO)	na	Chloride:hydrogen-peroxide oxidoreductase/1.11.1.10	RH + chloride + H_2O_2 ⇒ RCl + 2 H_2O	Litter-decomposing basidiomycetes (e.g., *Agaricus bisporus*)
Unspecific peroxygenase (UPO)	na	Substrate:hydrogen peroxide oxidoreductase (RH-hydroxylating or -epoxidizing)/1.11.2.1	RH + H_2O_2 ⇒ ROH + H_2O	Litter-decomposing basidiomycetes (e.g., *Agrocybe aegerita*)
Cellobiose hydrogenase (CDH)	AA3_1	Cellobiose:acceptor 1-oxidoreductase/ 1.1.99.18	Cellobiose + acceptor ⇒ cellobiono-1,5-lactone + reduced acceptor	Ascomycetes and basidiomycetes (e.g., *Myceliophtora thermophila*, *D. squalens*)
Aryl-alcohol oxidase (AAO)	AA3_2	Aryl-alcohol:oxygen oxidoreductase/ 1.1.3.7	Aromatic primary alcohol + O_2 ⇒ aromatic aldehyde + H_2O_2	White rot fungi (e.g., *Pleurotus eryngii*)
Glucose oxidase (GOX)	AA3_2	β-D-Glucose:oxygen 1-oxidoreductase/ 1.1.3.4	β-D-Glucose + O_2 ⇒ D-glucono-1,5-lactone + H_2O_2	Ascomycetes and basidiomycetes (e.g., *Aspergillus niger, P. chrysosporium*)
Methanol oxidase (MOX)	AA3_3	Alcohol:oxygen oxidoreductase/ 1.1.3.13	A primary alcohol + O_2 ⇒ an aldehyde + H_2O_2	Some ascomycetes and basidiomycetes (e.g., *Penicillium amagasakiense*, *P. chrysosporium*, *Gloeophyllum trabeum*)
Pyranose 2-oxidase (P2O)	AA3_4	Pyranose:oxygen 2-oxidoreductase/ 1.1.3.10	D-Glucose + O_2 ⇒ 2-dehydro-D-glucose + H_2O_2	Some basidiomycetes (e.g., *P. chrysosporium*, *Trametes ochracae*)
Vanillyl-alcohol oxidase (VAO)	AA4	Vanillyl alcohol:oxygen oxidoreductase/ 1.1.3.38	Vanillyl alcohol + O_2 ⇒ vanillin + H_2O_2	Ascomycetes, *Penicillium simplicissimum*
Glyoxal oxidase (GLX)	AA5_1	na/ 1.1.3.–	RCHO + O_2 + H_2O ⇒ RCOOH + H_2O_2	White rot and brown rot basidiomycete species (e.g., *P. chrysosporium*)
Galactose oxidase (GAO)	AA5_2	D-Galactose:oxygen 6-oxidoreductase/ 1.1.3.9	D-Galactose + O_2 ⇒ D-galacto-hexodialdose + H_2O_2	Some ascomycetes (e.g., *Fusarium graminearum*)
Benzoquinone reductase (BQR)	AA6	NADPH:*p*-benzoquinone oxidoreductase/1.6.5.6	NADPH + H^+ + *p*-benzoquinone ⇒ $NADP^+$ + hydroquinone	Some white rot and brown rot basidiomycetes (*P. chrysosporium*, *G. trabeum*)

[a]na, not available.

substrates such as phenols, aromatic amines, aromatic ethers, and polycyclic aromatics generating cation radicals (73, 74). This results in C_α-C_β cleavage, aromatic ring oxidation, and cleavage of the dimeric lignin model compounds (75, 76). One example of nonphenolic high-redox-potential aromatic substrates of LiP is veratryl alcohol (3,4-dimethoxybenzyl alcohol), which is converted to veratraldehyde by LiP catalysis (77, 78).

Like LiPs, VPs directly oxidize high-redox-potential aromatic compounds and recalcitrant dyes. These include compounds such as Reactive Black 5, which LiP can oxidize only in the presence of redox mediators (79, 80). VPs also possess Mn-oxidizing activity, combining catalytic properties of both LiP and MnP. The best-characterized VPs are from the white rot fungal genera *Pleurotus* and *Bjerkandera* (79, 81) (see Table 1). Interestingly, LiP of *Ceriporiopsis subvermispora* is able to directly oxidize both veratryl alcohol and Reactive Black 5, and its VP lacks the ability to oxidize Mn^{2+}. This suggests that *C. subvermispora* enzymes represent an intermediate evolutionary state between LiPs and VPs (82).

MnPs are the most prevalent lignin-acting enzymes in wood- and litter-decomposing white rot fungi. They specifically catalyze oxidation of Mn^{2+} to Mn^{3+}, which diffuses from the enzyme and oxidizes phenolic substrate. Mn-binding sites of MnPs consist of three acidic amino acid residues (Glu-35, Glu-39, and Asp-179 in *P. chrysosporium* MnP1) that hexacoordinate the Mn^{2+} ion. Mn^{3+} ions are chelated by dicarboxylic acids, e.g., oxalic acid, into a more stable form. This facilitates the diffusion of the chelated Mn^{3+} into the intact lignified secondary cell wall with micropores <6 nm in diameter, which are inaccessible by large enzymes (53, 83). However, due to their lower redox potential (1.0 to 1.2 V), MnPs cannot directly oxidize nonphenolic lignin structures (72). MnP activity on lignin is mediated by lipid peroxidation, whereby reactive intermediates, i.e., peroxyl radicals, are generated from lipids, resulting in the MnP-lipid system, which is powerful enough to attack bonds in nonphenolic lignin substructures (84–86). In addition, gene models encoding atypical MnP and VP enzymes have been reported (50, 62), based on conserved Mn-binding sites and a solvent-exposed tryptophan residue.

Two new superfamilies of secreted fungal peroxidases have been described, i.e., dye-decolorizing peroxidases (DyPs) and heme-thiolate peroxidases, which are involved in degradation or modification of lignin. DyPs are phylogenetically unrelated to LiPs, VPs, and MnPs. Numerous DyP-encoding gene models are present in the genomes of fungi, bacteria, and archaea (88), but only a few of the enzymes have been biochemically characterized (89). DyPs are interesting enzymes from a biotechnological standpoint, since they oxidize various dye compounds, carotenoids, and phenolics (90, 91). Also, a low-level oxidation of veratryl alcohol and nonphenolic lignin model compounds has been reported for DyPs (92, 93), whose redox potential (1.2 to 1.5 V) is comparable to even that of high-redox-potential LiPs and VPs (72). Recently, the first fungal DyP able to efficiently oxidize Mn^{2+} was characterized from the white rot basidiomycete *Pleurotus ostreatus* (94). However, the biological role of DyPs is still unclear.

The heme-thiolate peroxidase superfamily includes nonspecific peroxygenases (UPOs). UPOs are catalytically versatile enzymes that, unlike peroxidases, catalyze the addition of oxygen atoms into aromatic and aliphatic compounds (95, 96). While the physiological role of heme-thiolate peroxidases is unclear, their catalytic diversity indicates a putative function in conversion of lignin-related compounds. For instance, UPOs cleave nonphenolic β-O-4 lignin model dimers (97). UPOs have been biochemically characterized from the litter-decomposing fungi genera *Agrocybe*, *Coprinellus*, and *Marasmius* (98).

Laccases, in the CAZy family AA1_1, belong to the diverse multi-copper oxidase superfamily (99). Typically, laccases contain four copper atoms. Laccases catalyze four consecutive one-electron transfer reactions from various phenolic compounds, aromatic amines, and dye molecules (see Table 1) (100). The redox potential of fungal laccases is low (0.5 to 1.0 V), but in the presence of suitable low molecular weight redox mediator compounds such as 1-hydroxybenzotriazole and 2,2-azinobis(3-ethylbenz-thiazoline-6-sulfonate) their substrate spectrum is expanded to nonphenolic compounds and larger organic polymers (101). Laccase and multi-copper oxidases display a highly conserved three-dimensional structure with four substrate binding loops and four highly conserved signature sequences which contain amino acids that act as copper ligands. Phylogenetically, multi-copper oxidases can be divided into subfamilies including *sensu stricto* laccases and Fe^{2+}-oxidizing Fet3-like ferroxidases, the latter associated with pigment formation and putative ascorbate oxidases (102). Fungal laccases are thought to participate in lignocellulose decay, morphogenesis, plant pathogen interactions, and stress defense (100, 103). However, some lignin-degrading white rot fungi lack genes encoding *sensu stricto* laccases (e.g., *P. chrysosporium* and *Phanerochaete carnosa*).

Extracellular generation of H_2O_2 is important for catalysis by all heme peroxidases and for generation of

highly reactive hydroxyl radicals via Fenton chemistry (73, 104, 105). Various oxidases have been associated with biodegradation of wood and lignin as providers of extracellular H_2O_2. These include the glucose-methanol-choline oxidoreductase superfamily and copper radical oxidases. Other methods of H_2O_2 production, such as Mn(III)-mediated oxidation of fungal-secreted organic acids, also exist (106).

Glucose-methanol-choline superfamily members such as cellobiose dehydrogenase (CDH), glucose oxidase (GOX) (107), aryl-alcohol oxidase (AAO) (108), pyranose 2-oxidase (P2O) (109), and methanol oxidase (also known as ethanol/alcohol oxidase) (110, 111) are classified in AA3. All glucose-methanol-choline superfamily members share similar structural features and catalytic activity, oxidation of an alcohol moiety to the corresponding aldehyde. They are flavoproteins that contain a conserved flavin-adenine dinucleotide-binding domain (112, 113) and two conserved histidines (His-497 and His-541 in *Bjerkandera adusta* AAO) at the active site (114, 115). In P2O, methanol oxidase, and CDH, the second histidine is replaced by asparagine.

CDH has been classified in the CAZy subfamily AA3_1. CDH is a heme-containing flavocytochrome which oxidizes cellobiose and cello-oligosaccharides to the corresponding lactones using a wide spectrum of electron acceptors such as dioxygen, quinones, and phenoxy radicals (116–118). CDH enzymes have been suggested to generate hydroxyl radicals through Fenton chemistry, potentially oxidizing lignin substructures (116). Typically, white rot species possess only a single CDH-encoding gene (67).

GOX and AAO are structurally related and belong to the subfamily AA3_2. GOX oxidizes the hydroxyl group at the C1 position of sugars concomitantly producing H_2O_2, while AAO generates H_2O_2 by oxidizing aromatic primary alcohols to their corresponding aldehydes (114). AAO has been mostly studied in *Pleurotus* species such as *Pleurotus sajor-caju* (119), *Pleurotus eryngii* (108), and *P. ostreatus* (120) and in *B. adusta* (121). Redox cycling of aromatic fungal metabolites such as anisaldehyde (*Pleurotus* spp.) and 3-chloro-p-methoxybenzaldehyde (*B. adusta*) provides a continuous source of H_2O_2 to peroxidases (122–124). Copper radical oxidases such as glyoxal oxidase (GLX) have broad substrate specificity for the oxidation of simple aldehydes such as glyoxal and methylglyoxal to the corresponding carboxylic acids with the reduction of O_2 to H_2O_2 (125). GLX is a copper metalloenzyme containing an unusual active site free radical-coupled Cu similar to the structure in galactose oxidase (125). GLX is the most studied member of the copper radical oxidases and is physiologically linked to LiP in *P. chrysosporium*, making H_2O_2 to aid LiP activity (126).

Knowledge about conversion of lignin-derived monomeric intermediates, e.g., quinones, hydroquinones, and benzaldehydes, by intracellular enzymes is scarce. Benzoquinone reductases (CAZy AA6 family), vanillyl alcohol oxidases (CAZy AA4 family), cytochrome P450 mono-oxygenases, glutathione *S*-transferases, and *O*-methyl transferases have been implicated in fungal aromatic metabolism (127).

INDUSTRIAL APPLICATIONS OF LIGNIN-ACTING ENZYMES

While a major application of fungal lignin-acting enzymes is the depolymerization of lignin to facilitate the conversion of lignin to value-added products, other uses have been developed. Laccases are widely exploited due to their diverse substrate range, which can be even further extended using redox mediators, though mediator costs can be an obstacle for application (128, 129). Laccases are used for degradation of pollutants and xenobiotics (130–138) and for decolorization and degradation of chemical dyes commonly used in the textile industry (139–142). Other environmental applications involve the treatment of effluents (142–144), bleaching (145), and waste removal (146, 147) in the pulp and paper industry. Laccases polymerize catechol to polycatechol, a redox polymer used for production of chromatographic resins and thin films for biosensors (148). Laccase produces the polymer poly(1-naphthol) (149–151), found in wood composites, resins, fiber bonding, coatings, and adhesives (149).

Laccases have been used to produce a variety of pharmaceutical compounds, such as in the conversion of 4-methyl-3-hydroxyanthranillic acid to actinocin, an anticancer drug (152). It can also couple katarantine and vindoline to form vinblastine, which is used in leukemia treatment (129). Other pharmaceutical compounds produced using laccase are herbamycin derivatives and other aminoquinones (153, 154), oxidized catechins (155, 156), and hormone derivatives (157, 158).

In other applications, DeniLite, a fungal laccase, has been used to produce amine-derivatized platinum electrodes for detection of phenols, which have a very fast response time and long stability (159). Similarly, recombinant laccases are used for graphite-electrode-based phenol biosensors (160).

Lignin-related enzymes other than laccases are exploited in several applications (161). MnP from the white rot fungus *T. versicolor* has been explored for the bleaching of wood pulps (162), while a VP from

the white rot fungus *Pleurotus sapidus* has carotenoid-degrading activity (163). Transformation of a range of pharmaceutical compounds was reported with a VP from another white rot species, *B. adusta* (164). DyP from the litter-decomposing basidiomycete *Marasmius scorodonius* is able to degrade β-carotene (165), a role that has potential for the food industry.

APPLICATIONS OF LIGNIN AND LIGNIN PRODUCTS

Lignin applications and products use the highly versatile properties of lignin polymers and their functional groups, either alone or complexed with other molecules or templates (166). Its ability to scavenge radicals makes lignin a natural antioxidant (167). Biobased polymers like lignin are attractive alternatives to chemical polymers due to their eco-friendly and biodegradable characteristics. Lignin-based polymers include phenol-formaldehyde adhesives (168), phenolic resins (169), and polyurethane foams (170). Similarly, lignosulfonates are broadly applied for sequestration of heavy metals, binders, and emulsifiers (166).

The high aromatic content and amorphous character of lignin make it particularly suited for the production of graphene structures such as carbon fibers. However, this process demands a high purity of lignin as well as a narrow molecular weight distribution (171). Lignin-based hydrogels, polymer-based networks that swell when in contact with water or aqueous solvents, have been prepared (172) using graft copolymerization or chemical cross-linking. Evaluation of a lignin-grafted copolymer, specifically, lignin-*graft*-poly(methyl methacrylate-*co*-butyl acrylate), revealed improved thermoplastic elastomeric properties (173) compared to polymer without the lignin and an elastic strain recovery of close to 70%.

Nanotubes synthesized from lignin using alumina membrane templates have very promising features, such as ease of functionalization, auto-fluorescence that allows easy detection, and flexibility. Based on cytotoxicity studies, human cells have a high tolerance for lignin-based nanotubes, which made them highly efficient vehicles for gene delivery into human cells (174).

When lignin nanocrystals were confined on reduced graphene oxides as an electrochemical energy storage material, they showed excellent capacitive characteristics, demonstrating the potential of lignin for development of advanced renewable electrodes for energy storage (175).

Vanillin is a high-value compound of food, beverages, pharmaceuticals, and fragrances. While the initial process of obtaining this from lignosulfonates created a significant environmental burden, a new process has been developed by Borregaard in Norway that is more eco-friendly (176). More recently, a procedure for obtaining vanillin from Kraft lignin has been developed (87).

CONCLUSIONS

Fungi promise to provide a valuable source of lignin-acting enzymes for deconstruction and conversion. As the technologies developed to liberate sugars from biomass for subsequent fermentation into specialty biofuels and bioproducts become increasingly efficient, more attention is being given to the lignin fraction as a source for high-value products. Valorizing lignin as more than a burning fuel to generate heat will not only further develop a renewable biorefinery, but will also add significantly to the economic sustainability of second-generation biofuel plants. However, to achieve this, pretreatments that leave a convertible form of lignin will need to be further refined. Even more importantly, biological, thermochemical, and hybrid processes must continue to be developed to convert lignin streams into useful products. These processes will have to enable economically viable conversion of the carbon in lignin to specialty fuels and chemicals. However, it should not be forgotten that fungal lignin-modifying enzymes and chemistries have developed over millions of years to deal with the native lignin present in plant biomass. Emerging fungal genomes, and characterization of both endogenous and exogenous enzymes, hold great promise for utilizing lignin.

Fungi as a Source of Food

53

Joëlle Dupont,[1] Sylvie Dequin,[2] Tatiana Giraud,[3] François Le Tacon,[4] Souhir Marsit,[2] Jeanne Ropars,[5] Franck Richard,[6] and Marc-André Selosse[1,7]

INTRODUCTION

Since ancient times, humans have used fungi as food sources (1, 2). The edible sexual structures of basidiomycetes and ascomycetes (e.g., truffles), the so-called mushrooms, are produced mostly in wood because many fungi are tree symbionts or decayers of tree tissues. These fruiting bodies represent a rich source of proteins, with low fat content and otherwise nutritionally quite poor. In some soils, they accumulate pollution (heavy metals and radioactivity) and should only be eaten in moderate quantities. Some mushroom species are considered delicacies (e.g., truffles, boletus, morels), but cultivation attempts have been unsuccessful, with a few exceptions (e.g., *Morchella rufobrunnea*). Only a few saprobic species can be industrially produced, such as *Agaricus bisporus* (3), *Lentinus edodes* (shiitake), and *Pleurotus ostreatus*, with production having mainly taken place in Asia for thousands of years (4). Some other fungi, while not really cultured, are inoculated on trees grown in appropriate natural habitats to increase the production of fruiting bodies, such as for shiitake and oyster mushrooms, with, however, sometimes unpredictable success, as is the case for truffles (5).

A few plant-pathogenic fungi are also eaten, for example, the corn smut fungus, *Ustilago maydis*, which produces black tumors on maize. These tumors are considered a delicacy in Mexico, where it is called *huitlacoche* (6). These fungi can have great cultural significance (7), as do hallucinogenic mushrooms in many traditional cultures (8).

Fungi are also used for the production of fermented food and beverages in all traditional and indigenous cultures in the world. Examples include cheeses, bread, beer, wine, cider, rice, and soy sauce. Humans have exploited the natural abilities of fungi to ferment fruits and grains to produce alcoholic beverages and bread since as early as 6000 BCE (9–11) and for cheese since at least 7500 BCE (12). Yeasts are used for the fermentation of bread, wine, and beer, while filamentous fungi are used for the maturation of cheeses and soy sauce (from soybeans using *Aspergillus oryzae*) (13) and the production of alcohol from rice (yielding sake, also using *A. oryzae*) (14). In the south of France and other regions, a plant pathogenic fungus, *Botrytis cinerea*, is used to concentrate sugar in grape berries before collection, yielding "noble rot," which is a sweet and expensive wine (15). Some other filamentous fungi and yeasts are used to ferment and preserve meat from food spoilage, in particular *Penicillium nalgiovense*, which forms the white crust on salamis (16).

Before Louis Pasteur's research, microorganisms and their importance were not recognized. Humans thus unintentionally used the ability of fungi to ferment and produce alcohol, which inadvertently led to artificial selection of the most effective fungal strains, thus modifying species such as beer yeasts and cheese fungi (17–19). Because these species have acquired new adaptive traits compared to their wild ancestors (17–24), they can be considered domesticated species. They thus constitute excellent models for studying rapid and recent adaptation (18).

FUNGI AND CHEESE: DOMESTICATION OF *PENICILLIUM* FUNGI

Cheese making by early Neolithic farmers was a major advance in food processing, allowing milk to be preserved in a nonperishable, transportable form and making it more digestible for adults, because cheese contains much less lactose than fresh milk does (25). The earliest evidences of cheese making date from the 6th millennium BCE in Poland, with findings of the presence of milk fat in sieve vessels (12), and from the early Bronze Age (ca. 3,800 years ago), with the discovery of residues of old cheese in tombs (26). The earliest cheeses were simple, made by adding lactic acid bacteria (LAB) to fresh milk to provoke milk curdling and then draining in sieve vessels. The use of different mechanical processes to drain the curd, i.e., carving, brewing, pressing, grinding, heating, and the maturing of these cheeses, appeared later and gave rise to the large variety of cheeses known today (soft cheeses, blue-veined cheeses, hard cheeses, uncooked firm cheeses, and cooked firm cheeses). Microorganisms play a major role in the cheese-making process, from the initial milk curdling by LAB to the maturation step by fungi (including yeasts and molds). Indeed, during ripening, microbiological and biochemical changes directly influence the development of the texture and flavor that make each kind of cheese unique. Primary biochemical changes include (i) lipolysis, in which LAB are the main actors by metabolizing lactose into lactate; (ii) proteolysis, which has a direct influence on flavor through the production of short peptides and amino acids, originating from six primary sources (e.g., the coagulant, the milk, starter LAB, nonstarter LAB), secondary starters (molds such as *Penicillium roqueforti* in blue cheeses), and Gram-positive bacterial microflora on the surface of smear cheeses (27); and (iii) metabolism of residual lactose, lactate, and citrate. Secondary biochemical changes include metabolism of fatty acids and of amino acids by molds such as *P. roqueforti* in blue cheeses and *Penicillium camemberti* or *Geotrichum candidum* in soft cheeses such as Camembert and Brie. Microbial interactions within a cheese are thus crucial to produce a cheese with the desired texture and flavor, making the cheese substrate a complex but very interesting ecosystem in which to study microbial community interactions (28, 29).

Besides the emblematic cheese-making species *P. camemberti* and *P. roqueforti*, cheese producers widely use other important filamentous Ascomycota within the classes of Eurotiomycetes and Sordariomycetes (30). *Penicillium* species (Eurotiales) are used for the production of blue cheeses such as Roquefort and Fourme d'Ambert (*P. roqueforti*) and soft cheeses such as Camembert and Brie (*P. camemberti*). *Sporendonema casei* (Onygenales) is used for the production of firm cheeses such as cantal and Salers. Some *Scopulariopsis* species (*Scopulariopsis candida*, *Scopulariopsis flava*, and *Scopulariopsis fusca*, Microascales) are found in uncooked hard cheeses, including Tomme des Pyrénées and Ossau-Iraty, while *Fusarium domesticum* (Hypocreales) is inoculated for the production of Saint Nectaire and Reblochon. Along with Ascomycota, several Mucoromycotina species from the genus *Mucor*, including *Mucor racemosus*, *Mucor circinelloides*, and *Mucor lanceolatus*, are used for the production of uncooked hard cheeses such as Saint Nectaire and Tomme de Savoie (31). From an ecological point of view, some species are specific to the cheese environment (e.g., *F. domesticum*, *P. camemberti*, *S. casei*, *S. flava*, *M. lanceolatus*) while others are ubiquitous (e.g., *P. roqueforti*, *S. fusca*, *S. candida*). This leads to the questions of whether and how these species have adapted to this particular man-made, nutrient-rich ecological niche.

P. camemberti and *P. roqueforti* are ideal models for studying parallel adaptation because they are distantly related and have completely different domestication histories (32). *P. camemberti* is a human-created species, being a clonal lineage selected in the late 19th century for its white color and its fluffy, downy texture. It is thought to be derived from the blue-gray mold *Penicillium commune*, a species complex now split into *Penicillium biforme* and *Penicillium fuscoglaucum* (32, 33). *P. camemberti* is found only in the cheese environment and is inoculated in soft cheeses such as Camembert and Brie; no genetic or morphological diversity has been found in this species so far. In contrast, *P. roqueforti* is a common food spoilage agent in refrigerated stored foods, meat, and wheat products because of its ability to tolerate cold temperatures, low oxygen concentrations, alkali, and weak acid preservatives; it also occurs in silage and even in forest soil and wood (34, 35).

P. roqueforti has occurred in blue cheeses since at least antiquity (36–38). The fungus was originally not inoculated during blue cheese production but appeared spontaneously. At the beginning of the 19th century, environmental spores of *P. roqueforti* were collected from rotten bread left on purpose to rot on shelves in caves. Later, breads were inoculated with *P. roqueforti* spore powder kept from previous inocula, and strains that yielded good cheese were selected. For the past 30 to 40 years, the inoculated strains have been much more carefully controlled. Inoculated spores now mostly come from sterile *in vitro* conditions and derive from monospore isolations. Such controlled cultivation aims

to avoid sanitary issues and to render the cheese maturation process more repeatable and reliable (36–38). In contrast to *P. camemberti*, *P. roqueforti* shows substantial within-species genetic and phenotypic diversity, as well as genetic subdivision (39, 40). In particular, different genetic clusters of *P. roqueforti* seem to have been independently domesticated (41), and subclusters correspond exclusively to particular designation of origins, notably the Roquefort cheeses (41).

Recent studies compared the genomes of the two emblematic cheese species *P. camemberti* and *P. roqueforti* to eight other *Penicillium* species, four of which were isolated from the cheese environment but considered as contaminants by producers (*Penicillium paneum*, *P. fuscoglaucum*, *P. biforme*, and *P. nalgiovense*) (17, 19). The study also included a *Penicillium* species isolated as a contaminant in the meat environment (*Penicillium carneum*), the penicillin-producer *Penicillium rubens* and its close relative *Penicillium chrysogenum*, and the necrotrophic pathogen *Penicillium digitatum*, which is specialized to citrus. The genomic comparison revealed multiple horizontal gene transfers (HGTs) likely involved in cheese adaptation (17, 19). HGT is the process whereby genetic material is transferred between species by means other than vertical descent. In particular, two genomic regions of several hundreds of kilobases, named *Wallaby* (17) and *CheesyTer* (19), were shown to share a nucleotide identity of almost 100% among all cheese *Penicillium* species while being absent from noncheese species. These horizontally transferred regions (HTRs) were unique when compared to other HTR cases cited in the literature by (i) their size (*Wallaby* is ca. 600 kb long, encompassing 2% of the genome of *P. roqueforti*, and *CheesyTer* is 80 kb long), (ii) their eukaryotic origin (likely among cheese-associated *Penicillium* species), (iii) the number of species in which the same regions have been horizontally transferred, and (iv) the very recent date of the transfers, likely associated with the human history of cheese production (17, 19, 32, 42). These HTRs are flanked by copies of a particular family of transposable elements, namely, the *i* non-long terminal repeat (LTR) retrotransposons, that are always found clustered around putative HTRs in *P. roqueforti*. In contrast, the other transposable element families such as *copia* or *gypsy* LTR retrotransposons are widespread along the *P. roqueforti* genome (19). This supports the idea that *i* non-LTR retrotransposons may be involved in the horizontal transfer of these regions.

The gene content of these HTRs suggests that *Wallaby* and *CheesyTer* may play a role in the cheese adaptation. Indeed, two genes in *Wallaby*, named *paf* and *Hce2*, encode proteins previously described to be involved in interactions with other microorganisms (17). Genes coding for a lactose permease and a beta-galactosidase were found in *CheesyTer*, suggesting a role in the metabolism of the cheese substrate (19). These genes were found to be overexpressed during the first days of cheese maturation in an industrial Canadian Camembert-type cheese (19, 43). Experiments of growth and competition on different media using *P. roqueforti* strains have further supported a role of these HTRs in adaptation to cheese. Indeed, *P. roqueforti* was found to display polymorphism regarding the presence of *Wallaby* and *CheesyTer*: strains isolated from other environments than cheese did not carry either of the two HTRs, and among cheese strains, only a subset of strains carried the HTRs, and always either both *Wallaby* and *CheesyTer* or neither of them. Strains carrying the two HTRs grew significantly faster on cheese medium and significantly more slowly on minimal medium (19). Furthermore, strains carrying the HTRs showed a significant competitive advantage, both against *P. roqueforti* strains lacking the HTRs and against other *Penicillium* species also lacking the HTRs (19).

In conclusion, *Penicillium* fungi show footprints of rapid adaptation through frequent HGTs that have occurred under selection in the human-made cheese environments. This shows the importance of HGTs, in particular in the food environments. Now that we know about the ability of microorganisms to exchange genes through nonvertical descent and even between distant species, the use of genetically modified organisms in the food chain should be avoided.

Finally, domestication of cheese fungi has impacted their mode of reproduction. Indeed, industrial companies replicate their strains exclusively clonally, without sex. This together with bottlenecks and strong selection may contribute to the degeneration of cheese strains in the form of reduced fertility as occurs in domesticated plant and animal species (44–47). Investigations of premating (i.e., prevention of syngamy between individuals) and postmating fertility (i.e., syngamy occurs but the progeny is not viable or fertile) between and within genetic clusters of *P. roqueforti* have suggested reduced fertility of cheese strains (48). This degeneration has occurred independently in two cheese lineages, representing convergent evolution on a very short timescale.

YEASTS IN THE WINERY, BAKERY, AND BREWERY

Humans have used *Saccharomyces* yeasts for thousands of years for brewing, baking, and wine making.

Because yeasts are able to convert sugars into alcohol, they were used primarily as effective ways to preserve the quality and safety of foods and beverages, because high concentrations of ethanol are toxic for most other microbes. During food fermentation, yeasts convert sugars to ethanol and carbon dioxide under both anaerobic (fermentation) and aerobic conditions (known as the Crabtree effect) (49, 50).

Saccharomyces species are ascomycetous yeasts (51) that are model systems for ecology, genetics, and evolution (52), particularly at the genomic level (53). Studies have focused primarily on domesticated forms: besides the famous *Saccharomyces cerevisiae*, other closely related species belonging to the *Saccharomyces sensu stricto* complex and several important interspecific hybrids have been isolated from fermented food (bread) and beverages (beer, wine, cider, and sake). Their relationships are shown in Fig. 1. The abundance and variety of hybrids in fermented products are intriguing (54) and suggest that such hybrids could have selective advantages over parental species (55). It is possible that stressful conditions in fermentation processes promote hybridization events (52). The persistence of these hybrids in the long term has been questioned (56), but there is some evidence that they undergo progressive genome stabilization (54). Comparative genomic studies of hybrids and ideally of the progenitors of the hybrids are essential to unravel the process of domestication and the impact of domestication on genome architecture and function (57). The discovery of progenitors is sometimes challenging, as it was for the lager beer hybrid *Saccharomyces pastorianus*. This organism has been known to be an interspecific hybrid for more than 3 decades (see below for more details), but the second progenitor was only recently identified as *Saccharomyces eubayanus* (58). The fact that new food-associated *Saccharomyces* species are still being discovered points to our still-limited knowledge about the diversity of yeasts.

The origin and the natural environment of the baker's yeast *S. cerevisiae* have long remained a mystery. Given their ability to ferment sugars, *Saccharomyces* yeasts have been sought in mature and rotted fruits, in sugar-rich plant exudates, and in nearby soils (59). It seems that oak trees in the Northern Hemisphere (59–63) and *Nothofagus* trees in the Southern Hemisphere (58) could be important in the natural life cycle of *Saccharomyces* yeasts. Currently, *S. cerevisiae* seems to have a global distribution in wild and human-associated environments (56). In contrast, other species such as *Saccharomyces paradoxus* and *Saccharomyces kudriavzevii* seem to be more limited in their

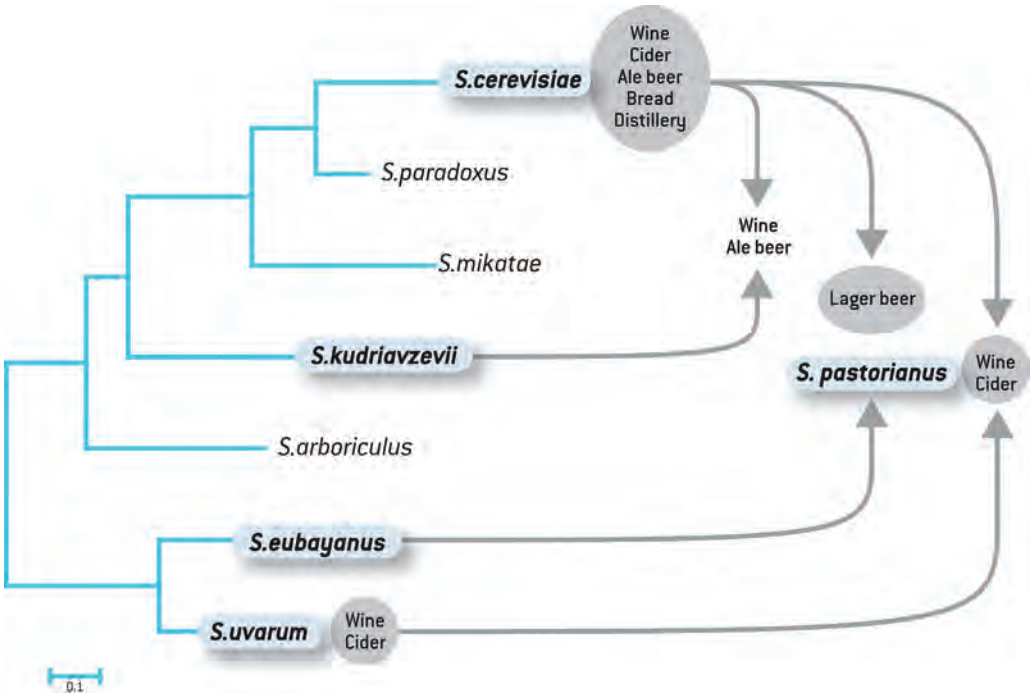

Figure 1 Relationships between *Saccharomyces* species and their industrial hybrids. Tree topology was obtained using a subset of 25,000 single nucleotide polymorphisms selected after genome alignment.

geographical distribution, with strong spatial genetic subdivision between populations suggesting limited dispersal (56). Recently, extensive field surveys conducted in China revealed substantial and novel genetic diversity among wild isolates, suggesting East Asia as a possible center of origin of *Saccharomyces* yeasts (59, 63).

The life cycle of *Saccharomyces* yeasts is well documented in the laboratory (52), but little is known about their life cycle in natural populations. This is true even for the well-studied *S. cerevisiae*; how strains disperse and how and where they reproduce are unknown (64). Recent data have confirmed the importance of insects in their dispersal, e.g., fruit flies for *Candida* species, which are members of the same family (65). Social wasps host *S. cerevisiae* in their intestine and disperse them in the wild (66). More importantly, the wasp intestine provides environmental conditions favoring mating and outbreeding of *Saccharomyces* yeasts (67), an important finding that may explain the high levels of variability and mosaicism observed in *S. cerevisiae* populations. Genotyping and population genomic studies have indeed revealed a complex population structure of *S. cerevisiae* (68–72), with, on the one hand, well-delimited lineages of particular geographical or technological origins (wine, sake, beer) and, on the other hand, mosaic lineages, with recombinant genomes likely originating from admixture after human-associated dispersal. The mosaic lineages include clinical isolates (73), wine strains (74), bakery isolates, and some laboratory strains (64, 70). Strains also cluster according to their ploidy level and type of mating compatibility (75).

Altogether, these results suggest different domestication histories for beer, bread, and wine strains. The following sections focus on recent progress made in understanding the origin and the impact of domestication of *Saccharomyces* yeasts in different fermentation usages.

Wine Fermentation

The first evidence of wine production by humans is dated to the Neolithic period. The presence of tartaric acid and terebinth resin was detected in a pottery jar dated to 5400 to 5000 BCE in Hajji Firuz, Iran (10). Evidence was also provided that the yeast *S. cerevisiae* was responsible for wine fermentation in Egypt by at least 3150 BCE (76). Wine fermentation technologies expanded from Mesopotamia toward Europe and subsequently spread to the New World (77).

Wine alcoholic fermentation is a complex process involving many yeast genera and species that are part of the grape berries' microflora (78). The first stage of wine fermentation involves mainly non-*Saccharomyces* yeasts. However, due to its outstanding fermentative abilities in anaerobic conditions and to its high tolerance to ethanol, *S. cerevisiae* rapidly dominates alcoholic fermentation and is responsible for the degradation of the majority of sugars in alcohol. In the 1970s, the practice of inoculation with selected pure cultures of *S. cerevisiae* in the form of active dry yeast became widespread, and this has enabled better control and reliability of the fermentation process, contributing to the improvement of wine quality. In addition to *S. cerevisiae*, other *Saccharomyces* species and a growing number of interspecies hybrids involved in wine fermentation have been recently identified and characterized.

The fermentation of grape juice exposes yeast to a variety of stresses, including high osmolarity reflecting high sugar concentrations (180 to 260 g/liter), low pH (3 to 3.5), the presence of added sulfites (40 to 80 mg/liter), anaerobiosis, limiting amounts in nutrient (nitrogen, lipids, and vitamins), and ethanol toxicity. During this process, the majority of hexoses are converted into ethanol and CO_2, and a small fraction of sugars is used to synthesize the anabolic precursors required for biomass formation. Various by-products, including glycerol, carboxylic acids, aldehydes, higher alcohols, esters, carbonyl compounds, and sulfur compounds, are also formed, deriving from the degradation of sugars, amino acids, and fatty acids. Moreover, yeast can also convert nonaromatic grape precursors into aromas (monoterpenes and thiols). These metabolites play a crucial role in the organoleptic balance of wines (79).

Wine fermentation comprises mainly a lag phase and a short growth phase followed by a stationary phase, during which most of the sugar (between 50 and 80%) is fermented. Nitrogen is the main limiting nutrient responsible for cell proliferation arrest, although the availability of other micronutrients such as lipids and vitamins can also be a limiting factor (80). Nutrient imbalance affects yeast fermentation capacity, resulting in stuck or sluggish fermentations, and can also affect the production of volatile compounds and the organoleptic balance of wine.

Today, more than 200 wine strains of *S. cerevisiae* are used to inoculate grape musts. These strains have been selected from spontaneous fermentations or selected in the vineyard environments according to particular fermentative capacities, tolerance to stresses, particularly ethanol and sulfites, and the limited production of undesirable compounds such as H_2S and acetate.

Diversity of wine yeasts and evidence of adaptive evolution to the wine environment

In the past decade, various studies based on multigene sequencing (59, 66, 68), microsatellite analyses (69),

tiling array hybridization (81), low-coverage whole-genome sequencing (70), or restriction-site-associated sequencing (Rad-seq) (82) have provided deep insights into the population structure and evolutionary history of *S. cerevisiae*. Genome analyses of *S. cerevisiae* isolates from different sources have led to the identification of five distinct lineages based on their technological and geographic origin (West African, Malaysian, North American, sake, and European/wine). Strains with mosaic genomes resulting from crosses between these lineages have also been identified (70, 81). These studies and earlier findings (68–70, 81–83) have shown that wine yeasts belong to a distinct phylogenetic group with low diversity and have suggested an initial domestication event followed by an expansion of the population favored by human activity. A recent study increased the number of collections of natural lineages, especially oak-associated wild isolates, and used population genomics analyses to analyze a balanced number of anthropic and natural *S. cerevisiae* strains (84). This study identified a new Mediterranean oak population that seems to be the closest wild relative to the wine lineage known to date. The estimated divergence time between the two populations is consistent with the first historical evidences of wine making. Furthermore, three horizontally acquired regions largely widespread in wine yeasts and containing genes relevant to wine making (24) are absent in the wild Mediterranean oak group. These results suggest that the common ancestor of these two populations provided the wild genetic stock that underwent domestication and gave rise to wine yeasts (84, 85).

An increasing number of studies in the past decade have focused on the understanding of the genetic and functional underpinnings of human-driven selection of wine yeasts over millennia. Wine yeast strains demonstrate better resistance to chemical compounds such as copper (86, 87) used in vineyards or sulfites (88, 89) added in grape must. Several wine yeast strains also have the ability to use xylose as a carbon source (90) or different types of di-tripeptides as nitrogen sources (22, 91, 92), and recent data suggest that they might produce more fruity aromas than do strains from other origins (93). Identifying the variations contributing to the properties of wine yeast and deciphering the mechanisms that participate in these evolutionary processes remain major challenges. Several molecular mechanisms may have contributed to the adaptive evolution of wine yeast genomes, including single nucleotide polymorphisms, chromosomal rearrangements, gene copy number variations, introgressions, HGT, and interspecific hybridization (21, 94–96). A hallmark of adaptation has been detected in the genome of so-called flor yeasts. Flor yeasts are closely related to wine strains but have distinct capacities such as the ability to form a biofilm on the surface of wine after fermentation and to develop oxidative metabolism in the presence of a high ethanol concentration and a low amount of fermentable sugar, mainly fructose (97). Flor strains have acquired two mutations in the promoter and the coding regions of the gene *FLO11* encoding a glycosylphosphatidylinositol-anchored cell surface glycoprotein (flocculin) required for pseudohyphal growth and biofilm formation (98, 99), resulting in enhanced cell adhesion. In addition, flor strains possess a fructophylic allele of the *HXT3* hexose transporter previously identified in an industrial strain (100) and a high-affinity fructose transporter, *FSY1*, which may provide an adaptive advantage after alcoholic fermentation when traces of fructose remain in the fermented must but glucose is exhausted (101).

A striking example of yeast adaptation to current wine-making environments is the response of these fungi to chemicals used in the vineyard and winery environments. Elevated copper tolerance in the European wine and sake lineages has been associated with a copy number variation of *CUP1*, which encodes a copper-binding metallothionein (87). The recent resequencing of the genome of 100 yeast strains revealed that some strains of the wine/European cluster could possess up to 18 copies of the *CUP1* gene (102). The acquisition of this trait can be associated with the use of copper sulfate in vineyards, which has been used as a fungicide against powdery mildew since the 1880s (86).

Genomic variations have also been gained by wine yeasts as a response to the use of sulfite. Two reciprocal translocations, between chromosomes VIII and XVI or XV and XVI, have been detected among wine yeasts. These translocations result in the overexpression of *SSU1*, encoding a sulfite pump and thus conferring a high level of sulfite resistance (89, 103, 104).

Several signatures of introgressions with potential adaptive roles have been identified in wine yeasts. A large *S. paradoxus* introgressed region, identified in commercial *S. cerevisiae* wine yeast strains (105), contains the *S. paradoxus SUC2* gene, which encodes sucrose-hydrolyzing invertase, and a gene similar to *S. cerevisiae HPF1*, which encodes a glucan alpha-1,4-glucosidase that, when overexpressed, reduces protein haze formation in white wines (106). The cryotolerant species *Saccharomyces uvarum* is also found in wine fermentation. A recent study of the population structure and diversity of this species revealed multiple introgressions from other *Saccharomyces* species, especially

from *S. eubayanus* (107). These introgressed regions are enriched in functions involving nitrogen metabolism, suggesting that these regions might confer an advantage under nitrogen-limiting wine fermentation conditions.

Horizontal gene transfer also significantly contributes to the adaptation of wine yeasts. Three large genomic regions, called A, B, and C, acquired through independent HGT events from distant yeast species were identified in the genome of the commercial *S. cerevisiae* wine yeast EC1118 (24) and were furthermore shown to be widespread among wine yeasts and some mosaic genomes (24, 71, 108). These genomic islands contain 39 genes encoding potentially important metabolic functions in wine making (sugar and nitrogen metabolism), suggesting a role in adaptation to the wine environment. The yeasts *Zygosaccharomyces bailii* and *Torulaspora microellipsoides* were identified as the donors of regions B and C, respectively (22, 24). For region C, the transfer was dated to approximately 2,000 years ago (22). Evidence was provided of an initial insertion of a 158-kb genomic fragment from *T. microellipsoides* into the *S. cerevisiae* genome, followed by several rearrangements including gene losses and gene conversion between two tandemly duplicated *FOT* genes encoding oligopeptide transporters (22). Interestingly, *FOT* genes are strongly conserved in wine yeasts. These genes confer a strong competitive advantage during grape must fermentation by increasing the amount and diversity of oligopeptides that yeast can utilize as a source of nitrogen, thereby improving biomass formation, fermentation efficiency, and cell viability (22).

Thus, the acquisition of *FOT* genes has favored yeast adaptation to the nitrogen-limited wine fermentation environment. Furthermore, *FOT*-mediated uptake of peptides rich in glutamate substantially affects central carbon and nitrogen metabolism, resulting in decreased acetic acid production and increased ester formation, which might improve the organoleptic balance of wines (109).

Wine hybrids: characterization and advantages

An increasing number of interspecific hybrids have been identified in the wine environment, including *S. cerevisiae/S. kudriavzevii* (110–117), *S. cerevisiae/S. uvarum* (113, 118–120), and *S. cerevisiae/S. kudriavzevii/S. uvarum* (23, 110). These hybrids present several advantages in wine fermentation such as increased tolerance to various stresses and robustness compared with the parents (54, 114, 115, 121–123). *S. kudriavzevii* and *S. uvarum* are better adapted to growth at low temperatures compared to *S. cerevisiae*, whereas *S. cerevisiae* is more alcohol- tolerant. The natural hybrids between these species have adapted to growth under ethanol and temperature stress through the inheritance of competitive traits from one or another parental species (124). These hybrids have potential value under conditions of fermentation of white wines at low temperatures (10 to 15°C) that minimize the loss of aromatic volatile compounds. Hybrids of *S. cerevisiae* × *S. kudriavzevii* produce more esters, fusel (>2 carbon) alcohols (112, 115, 121), and thiols derived from non-aromatic precursors present in grapes than *S. cerevisiae* does (125, 126). The abundance of these hybrids could reflect an adaptive advantage, but it is also possible that stressful conditions trigger hybridization events (52).

Improvement of wine yeast

Although many benefits to wine production have been gained through the selection of strains with suitable properties, efforts can still be deployed to improve wine yeasts for various traits, e.g., improvement of stress tolerance, fermentative performance, aroma properties, or low ethanol production. Non-genetically modified organism strategies based on rational genetic strategies to exploit existing natural diversity have proven successful in the past decade to develop strains with improved traits. These strategies build on the identification of desired traits in the yeast genome by quantitative trait locus analyses. Quantitative trait loci controlling the formation of acetic acid, aroma compounds, SO_2 production, nitrogen utilization, or ethanol resistance have been identified (127). Once quantitative trait loci have been identified, the desired alleles can be transferred into a new strain by breeding using marker-assisted allele transfer. In addition, several strains with improved phenotypes have been developed using adaptive laboratory evolution approaches, which involve the propagation of a microbial population under defined selective conditions for prolonged periods of time and the selection of better-fitted mutants. These strategies have allowed the development of wine yeast strains overproducing esters, which are major determinants of the fruity character of wines (128) and strains with reduced ethanol yield (129, 130). The construction of interspecific hybrids to generate new combinations of genes conferring new properties has also been performed (131, 132).

Baker's Yeasts

S. cerevisiae is also known as baker's yeast. Bread-making scenes have been discovered on reliefs in several tombs dating from ancient Egypt, and the analysis of pottery containing remains of cereals and bread has allowed the investigation of ancient Egyptian baking

methods (11). However, the origin and expansion of the process of leavened bread is poorly documented, and it is unclear whether yeasts came from cereals or from the process of fermenting beer (133). In countries that produce beer, ale yeast was used in bread production, and a portion of the yeasted dough was recycled by blending it with fresh water and flour for formation of the next dough. The production of baker's yeast exclusively for bread dough production has been dated from the late 19th century. Initially, this was done by production of distiller's yeast on mashed grains, and later with the less expensive source of assimilable sugar, molasses (134).

Most of the bread consumed today is leavened with the commercial baker's yeast, *S. cerevisiae*. However, the consumer demand for sourdough bread is increasing, and some bakers use sourdough containing natural lactic bacteria and yeasts as an alternative to commercial yeasts (see reference 135 for a review). The diversity of yeast strains is high in French natural sourdoughs, with *Kazachstania* species dominating and *S. cerevisiae* being an uncommon species (136). This suggests that *S. cerevisiae* does not compete well with other sourdough and yeast species.

Baker's yeast provides the gas required to leaven the dough through the alcoholic fermentation of sugars, in particular maltose, but yeast also influences the bread texture and taste. In contrast to beer and wine, bread dough is a solid fermentation occurring in a reduced level of free water, and the cellular physiology of the yeasts is likely different than in liquid fermentation. The study of the yeast transcriptome throughout the bread dough fermentation process has revealed three phases during which protein- and RNA-coding genes are differentially expressed (137). At the onset of fermentation, expression of glucose-regulated genes changes dramatically, and the osmotic stress response is activated. The middle fermentation phase is characterized by the induction of genes involved in amino acid metabolism. Finally, in the last phase, cells suffer from nutrient depletion and activate pathways associated with starvation and stress responses. Altogether, the results have shown that cells embedded in a solid matrix such as bread dough suffer severe osmotic stress.

Baker's yeasts have lower genetic diversity and a higher number of chromosomes than other *S. cerevisiae* lineages used for wine, sake, and beer fermentations (138). But unlike brewing yeasts, which are allotetraploid, baking yeasts are autotetraploid, displaying four complete chromosome sets arising from the same species. Usually transitory, the autotetraploid status may have occurred very recently and/or may have been maintained by human selection because of metabolic benefits for fermentation (75). The genome analysis of three bread strains has shown the mosaic nature of their genomes, with some regions very similar to those present in wine strains; some others being more related to sake, oak, or palm wine yeast genomes; and some that were unique (70, 138). This suggested that baker's yeasts have arisen from crosses between wild lineages that had appropriate fermentation properties (138).

Improvement of Baker's Yeast

The evolution of bakery technologies has highlighted a need to improve yeasts for their tolerance to various stresses, including high sugar concentration (in sweet dough), drying, and freezing (in relation to the increase of production of dry and frozen dough, respectively), as well as for their performance in the fermentation of dough sugars and for their growth rate and biomass yield relevant to the production of the baker's yeast itself (138, 139). Different genetic engineering strategies have been applied, in particular manipulation of the small osmolyte pathways, including those of glycerol, proline, and trehalose (137, 138). Experimental evolution has been used to enhance the freeze-stress tolerance of industrial baker's yeast cells by generating adaptations to growth at low temperature (140). Two new baker's yeast strains obtained by hybridization between commercial baker's yeasts have shown improved fermentation abilities and cryoresistance (141).

Brewing Yeasts

Beer is the most widely consumed alcoholic beverage in the world, with a total consumption volume of 176.4 billion liters in 2014, corresponding to total revenues of $464.4 billion (142).

Water, hops, malt, and yeasts are the four main ingredients for manufacturing beers (143). Hops give beer its typical bitterness and aroma. Malt is obtained by inducing the germination of grains, mainly barley grains, for a period of time necessary for enzymes to degrade complex molecules, such as starch and proteins, into forms that can be assimilated by yeasts. To stop the process, water is removed by fresh air or heating, to obtain green to pale or dark dried malts, respectively. This manipulation of the process impacts the beer's characteristics, in particular the color of pale to dark beers. Barley or malt is roasted to make the typical dark stout beers.

Generally, the yeasts used for beer production belong to the *Saccharomyces* genus. Depending on their physiological characteristics, and on the quality of other ingredients, two main types of beers are produced, i.e.,

ale or lager-style beers. Ales are brewed at a relatively high temperature (15 to 26°C) with top-fermenting *S. cerevisiae* strains, which rise to the surface of the fermenting wort after cell aggregation during the flocculation process. Lager beers are brewed at lower temperature (5 to 14°C) with bottom-fermenting yeasts that have a tendency to sediment after flocculation and sink to the bottom of the fermenters. Ales have been brewed since ancient times, possibly as early as 6000 BCE (144). In contrast, lager beer production was limited to cool seasons but expanded with the invention of the refrigerating machine by Linde in 1871, allowing the necessary cool temperatures for bottom fermentations to be achieved during all seasons. Another major advance was the development of pure cultures of yeasts. Previously, brewmasters selected best batches and yeasts were reutilized from batch to batch. At the time, problems in the end product such as bitter taste and bad odor frequently occurred. In 1883 E. C. Hansen, who worked at the Carlsberg Laboratory in Copenhagen, developed an effective technique to obtain pure cultures of yeasts. This technique was essential to standardize beer production by selection of desirable yeasts and to the standardization of yeast cultures all over the world (145). Today lager beer production dominates the market.

A fascinating and ongoing research story began when the lager yeast, whose current name is *S. pastorianus* (syn. *Saccharomyces carlsbergensis*) (146), was discovered to be an interspecific hybrid showing high similarity in nucleotide sequence to both *S. cerevisiae* and *Saccharomyces bayanus* (147). A microsatellite analysis suggested that the ancestral *S. cerevisiae* parent of the hybrid came from the ale-brewing process, because ale and lager beer yeasts clustered together and were distinct from bread and wine yeasts (69). This result was confirmed by sequence data (148, 149). The second parental species was suggested to be closely related to *S. bayanus* (23, 150, 151) until the discovery of a better candidate, the cryophilic species *S. eubayanus*, first isolated in Patagonia (58) and recently also in China (63). *S. pastorianus* strains have greater mitochondrial DNA sequence similarity to the Tibetan strain BaiFY1 than to the type strain CBS12357 isolated in Patagonia (152), in agreement with previous genomic data (63). These data suggest a common origin of the domesticated *S. pastorianus* strains with the wild Tibetan strains and support a scenario of continental migration of *S. eubayanus* from China to Europe along the Silk Road (153), rather than by overseas transport from Patagonia to Europe as originally suggested (58). It is thought that the hybridization event probably occurred quite recently, about 500 years ago (153). To elucidate the date and circumstances of the process, more isolates from more diverse origins in the world and particularly along the hypothesized migration routes are needed for population genomics studies.

The genetic diversity in *S. pastorianus* populations is much lower than that in ale yeasts (154). Two groups were identified in *S. pastorianus*, called Saaz (or group I) and Frohberg (group II), after the locations in Bohemia and Germany in which original strains were derived (145). Each group has specific brewing abilities and produces different flavors. Saaz strains have a greater cold tolerance than Frohberg strains but relatively poor fermentation performance due to their inability to utilize maltotriose (155, 156). This deficiency may have contributed to favor the use of Frohberg strains in modern brewing companies (155). Not surprisingly, genetic differences were found between the two groups, including genome rearrangements, copy number variations, ploidy differences, mitochondrial and nuclear DNA sequence polymorphisms (148, 152), and transposon distribution (157). More precisely, the genomic content inherited from hybridizing ancestral species appeared different in the two *S. pastorianus* groups. Saaz strains are triploid, containing less than one haploid genome of *S. cerevisiae* and more than a diploid *S. eubayanus* genome (156), while Frohberg strains are tetraploid, containing one full diploid *S. cerevisiae* genome and one full diploid *S. eubayanus* genome (149, 152, 156, 158).

To date, it is not known whether the Saaz and Frohberg lineages arose from single or separate hybridization events. The differences between the two groups suggest separate hybridization events, in particular the high level of variation in telomeric sequences and LTR-transposon copy number and location (157), the difference in ploidy (148) and in single-nucleotide variants (152), the different rates of evolution in the two subgenomes since hybridization (159), and the pattern of presence/absence variation of the lager-specific genes that are located in the subtelomeric regions (160). Baker et al. (159) suggested that hybridizations may have involved nearly identical *S. eubayanus* parents but more diverse *S. cerevisiae* parental strains. Two classes of *S. cerevisiae* parental strains were identified as a Foster-O-like ale yeast and a stout yeast, respectively, for the groups I (Saaz) and II (Frohberg) hybrid lineages (160). The main argument favoring a single hybridization event at the origin of the two groups is that the two lineages share at least three chromosomal translocations between *S. cerevisiae* and *S. eubayanus*

genomes, with identical breakpoints at the nucleotide level (152, 156).

Okuno et al. (152) proposed two scenarios with at least one common hybridization event to reconcile all the data (Fig. 2). Scenario A proposes hybridization between diploid parental strains as suggested in references 144 and 156 and chromosomal deletion to explain the massive reduction of the *S. cerevisiae* genome in the Saaz type. Scenario B involves a hybridization event between haploid *S. cerevisiae* and diploid *S. eubayanus* leading to a triploid hybrid ancestral Saaz group. To explain the tetraploid Frohberg type, an additional hybridization between the F_1 hybrid and another *S. cerevisiae* strain was suggested, as proposed by Baker et al. (159) and Monerawela et al. (160). The instability in the nascent allopolyploid hybrid genome may have contributed to rapid evolution of the yeast to tolerate the conditions prevalent in the brewing environment (153), particularly the fermentation temperatures, and to the selection of new biochemical activities (85). As a result, amplification and deletion of genes and/or pseudogenization would have occurred at rearrangement breakpoints on different chromosomes in lager hybrids. An increase in the number of copies of genes involved in maltose utilization has been observed on chromosome II. Several breakpoints have led to changes in flocculation genes, particularly the elimination of the *S. cerevisiae* copy of the *FLO5* gene, but the apparent retention of the *S. eubayanus* version of the gene known as Lg-*FLO1* (148, 161). The Frohberg genome was shown to carry inactive copies of both *S. cerevisiae* and *S. eubayanus SUL1* sulfate transporters while retaining functional versions of the two *SUL2* genes, which are more efficient under fermentation conditions (58), sulfite formation being important in lager brewing because it is an antioxidant and flavor stabilizer (139).

The impact of domestication has also been investigated in terms of selective pressure that may have occurred on genes, and particularly on metabolic genes that are important for brewing (159). A global increase

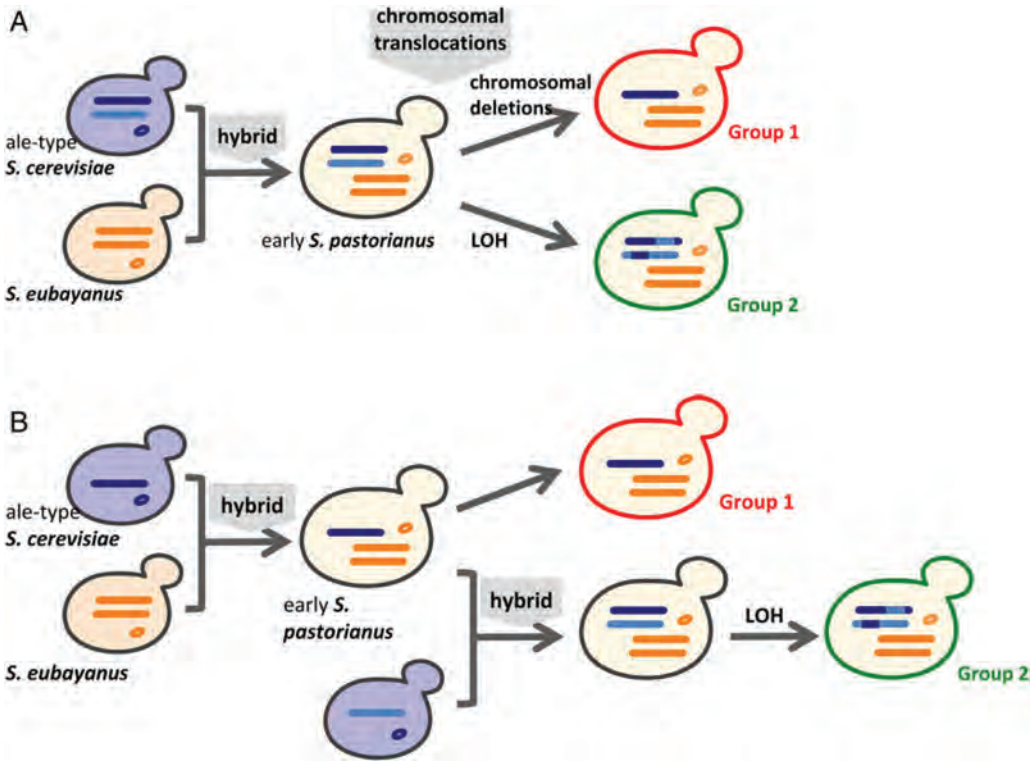

Figure 2 Two hypotheses regarding origins of *S. pastorianus* based on shared chromosomal translocations and differences in ploidy between groups 1 and 2. (**A**) Hybridization between diploid Sc and Se types occurred before chromosomal translocations, whereas chromosomal deletions occurred only in ancestral group 1 strains. (**B**) After hybridization between haploid Sc and diploid Se types and chromosomal translocations, ancestral group 2 strains gained another Sc type (i.e., a second hybridization event occurred). Chromosomal deletion or loss of heterozygosity (LOH) explains single nucleotide polymorphisms observed when comparing reference genomes.

in the fixation of nonsynonymous substitutions in the hybrid *S. eubayanus* subgenome of *S. pastorianus* in comparison to the genome of a wild strain of the parental *S. eubayanus* species was observed and was interpreted as a relaxation of purifying selection during domestication (159). Some genes showed footprints of positive selection, with particularly high rates of protein sequence evolution in both Saaz and Frohberg lineages. However, different nonsynonymous changes have been acquired in the two lineages, indicating convergent adaptations to the same environment (159). Examples include genes encoding global transcription factors or factors required for the expression of enzymes specialized for ethanol oxidation rather than fermentation, as well as genes involved in the regulation of other genes related to the utilization of ethanol (159).

Novel lager brewing yeasts

The recent discovery of *S. eubayanus* opened up the possibility of using this species alone as a lager brewing strain (153, 155) and to create novel artificial hybrids (162, 163). The best of these novel hybrids have shown growth at a broader range of temperatures, a high fermentation capacity in laboratory-scale lager beer fermentations, and desirable aromatic profiles that were significantly different from the profiles produced by the currently exploited lager yeasts. Hybrids previously obtained by breeding lager yeasts with *S. cerevisiae* ale strains have shown improved stress resistance, as seen in the ale parent, including improved survival at the end of fermentation (164).

A. oryzae in Japanese fermentations

A. oryzae has been used for hundreds of years in Japanese fermentations to produce traditional alcoholic drinks, sauces, and condiments. It is one of the most potent secretory producers of proteins among filamentous fungi, and its use is now extended to the commercial production of enzymes in modern biotechnology (165, 166). In Japan, it is used to prepare koji, a starter for secondary fermentations, using solid-state cultivation, a process thought to have originated in China 3,000 to 2,000 years ago (167). The commercialization of koji dates back to the 13th to 15th century, in Heian and Muromachi periods (167). The long history of extensive use in the food industries placed *A. oryzae* on the FDA list of Generally Recognized as Safe (GRAS) organisms in the United States (168). For making koji, *A. oryzae* spores are spread onto steamed rice. After ~2 days of growth, the resulting *A. oryzae*-rice mixture (koji) is mixed with soybeans or additional steamed rice and water and fermented mainly by yeasts to produce miso, shoyu, and sake (169, 170). The fungus has an important role in the degradation of proteins and starch contained in the raw material for fermentation and contributes to the color, flavor, and aroma of the fermented foods. Starch is converted into simple sugars by a biochemical process called saccharification.

A. oryzae was first isolated from koji in 1876 by H. Ahlburg. It appeared morphologically almost indistinguishable from *A. flavus* (171) and nearly identical when analyzed by DNA/DNA hybridization (172). Unlike *A. flavus*—which produces the toxic and carcinogenic aflatoxins, a serious problem worldwide in agricultural commodities such as maize, peanuts, tree nuts, and cotton seeds (173)—*A. oryzae* is a nontoxigenic species (174). However, using multilocus genotyping and sequencing analysis, *A. oryzae* strains were shown to form a monophyletic clade nested within *A. flavus*, closely related to atoxigenic *A. flavus* strains. This finding suggests that *A. oryzae* may have evolved by domestication from a single lineage of *A. flavus* selected for its particular properties (173, 175). This hypothesis is in agreement with previous studies based on SNPs and evolutionary analyses (168, 174). The close evolutionary relationship is reflected in their genomes, which are nearly identical in size and gene content (176, 177). These two genomes are larger than those of *A. fumigatus* and *A. nidulans* due to the expansion of metabolic gene families that may have been acquired by HGT (13).

Genes in expanded families include those encoding secretory hydrolases, transporters, and primary and secondary metabolism. These latter families represent the most expanded gene classes, and they are involved in the degradation of the vast amount of compounds to which the fungi are exposed during fermentation for *A. oryzae*, or in the fields for *A. flavus*, and in the excretion of toxic compounds (13, 167). The fact that these expanded gene families are present in both *A. oryzae* and *A. flavus* indicates that they expanded before domestication (167). *A. flavus* and *A. oryzae* also share the aflatoxin biosynthetic gene cluster, but in *A. oryzae* the gene cluster sequences contain deletions, frameshift mutations, and base pair substitutions (166, 178). No sequence derived from aflatoxin biosynthetic genes was found in the large-scale collection of expressed sequence tags obtained from cDNA libraries from nine biologically or industrially important cultures of *A. oryzae* (179). This indicated the lack of transcription of the *aflR* gene, which encodes a transcription factor positively regulating expression of aflatoxin biosynthetic genes in *A. flavus*. A comparison of the transcriptomes and proteomes of *A. oryzae* and *A. flavus* when grown

on rice showed a global downregulation of biosynthetic genes for secondary metabolites in *A. oryzae*, and particularly of the aflatoxin pathway (166), explaining its inability to produce the toxin. Interestingly, aflatoxin is toxic to *S. cerevisiae* (180), suggesting that the toxicity loss of *A. oryzae* might have been driven by its cooperation with yeast during fermentation for making sake and/or by selection by humans of nontoxic strains (166). Putative adaptations to a starch-rich diet were also found in *A. oryzae*. Several genes involved in carbohydrate primary metabolism, such as those encoding for α-amylase or maltase glucoamylase involved in the catabolism of starch, were significantly upregulated in *A. oryzae*.

Domestication is an artificial selection process that can leave footprints of selective sweeps in genomes as a reduction in polymorphisms in genomic regions encompassing the selected variants. Selective sweeps have been detected in *A. oryzae*, mainly on genes and pathways involved in primary and secondary metabolism. The most relevant genes within selective sweeps are involved in protein and peptide degradation and in carbohydrate metabolism, including a glutaminase gene that catalyzes the hydrolysis of carbon-nitrogen bonds of l-glutamine to produce glutamic acid, a widely used enhancer of food flavor found in considerable quantities in sake (166). The transition to domestication has often been associated with a relaxation of selective constraints and population bottlenecks (46) leaving footprints in the genomes, such as an excess of nonsynonymous substitutions (often deleterious). Surprisingly, this has not been observed in *A. oryzae*; in contrast, the ratio of nonsynonymous to synonymous substitutions and the percentage of estimated deleterious substitutions are lower in *A. oryzae* than in *A. flavus*, and this observed lack of selective relaxation has been discussed with regard to population genetics and the ecology of domestication events (181).

In conclusion, *A. oryzae* is probably the result of a single domestication event from an atoxigenic lineage of *A. flavus*, which sake makers may have selected as a safe mutant, allowing yeast growth in fermented products (57). In *A. oryzae*, the genomic mechanisms of adaptation during domestication appear to have involved mainly changes in secondary metabolism.

TOWARD THE DOMESTICATION OF THE BLACK TRUFFLE (*TUBER MELANOSPORUM* VITTAD.): A GLIMPSE INTO A 2-CENTURY-LONG SAGA

True truffles are hypogeous fungi belonging to the genus *Tuber* (Ascomycota, Tuberaceae), which contains the most famous and prized edible mushrooms (182). The Piemont white truffle (*Tuber magnatum* Picco) and the Périgord black truffle (*T. melanosporum* Vittad.) are the most valuable, the black truffle being the most anciently cultivated in the Western part of the Mediterranean basin (183). Unfortunately, the production of *T. melanosporum* drastically declined during the 20th century, and there are still difficulties in increasing production, despite a sustained planting effort since the 1970s.

The mutualistic biology of truffles requires their association with a plant for accomplishing their sexual reproduction, and in particular for producing the edible fruiting body that results from a mating event (184, 185). Vegetative life depends on the edification of short-lived structures called ectomycorrhizae that connect mycelia to shrubs or trees from various families (e.g., *Fagaceae*, *Salicaceae*, and *Betulaceae*) (186). In spontaneous truffle grounds, the Périgord black truffle mainly associates with oaks but also with Mediterranean shrubs in the *Cistaceae* (187), while it naturally establishes and fruits in early forest stages during secondary succession, mainly in the opened vegetation called "garrigue" (188).

The worldwide notoriety of *T. melanosporum* has fueled the development of unprecedented planting efforts and the introduction of the species in America, Australia, New Zealand, and other countries. As a consequence, truffle growers stimulated the development of highly inventive, but often empirical, techniques to induce truffle production in a wide range of ecological contexts. However, the obligate association between *Tuber* mycelia and trees of few compatible species, combined with the impossibility of producing fruiting bodies *ex situ*, has made the management of truffle growth complex. When remaining aloof, truffle growers act as blind gardeners who indirectly work on truffles through arboriculture practices (e.g., pruning) and agriculture (e.g., tillage or sowing) management methods, over years, with particularly uncertain outcomes.

Here we present a three-step history of the attempts to cultivate truffles, with a focus on the Périgord black truffle. We first deliver a comprehensive assessment of the 2-century-long empirical approach developed in spontaneous truffle grounds since the beginning of the 19th century, with special attention paid to the diversity of practices. Furthermore, we present the tremendous contribution provided by the agronomic approach developed in the 1970s, based on the use of inoculated plants and irrigation practices. We finally discuss the recent development of a global truffle-growing method that includes the input of metagenomics tools and ecological modeling.

The Early Attempts: Empiricalism and Observation in Spontaneous Truffle Grounds

It is likely that the truffle was first gathered as a wild product, although direct reports are lacking. An understanding of its exact ecology was probably delayed by the inconspicuous nature of its vegetative stage. Truffles were harvested and much appreciated by the Romans, although the identity of the species collected 2 millennia ago remains unclear. Pliny the Elder, for example, stated in his *Naturalis Historia* (*Natural History*) that the most valued truffles came from Africa (making a possible reference to the distantly related genus *Terfezia*) and that truffles were formed "when there have been showers in autumn, and frequent thunderstorms,… thunder contributing more particularly to their development; in some places the formation of them is attributed to waterstorms" (189). Yet empirical methods, as in many uses involving microbes, took into account the subterranean link to trees well before any idea of mycelium or mycorrhizae was reached (Table 1).

The emergence of the concept of mycorrhizae itself is tightly linked with truffles. After the Prussian minister of agriculture commissioned a mycologist and botanist, A. B. Frank, to study the origin of truffles to promote their cultivation, Frank in 1885 described the morphology of the relationship of the fungus with tree roots and coined the word *mycorrhiza* (190, 191). He also pointed out the need for "an underlying limestone," i.e., the clear calcicolous ecology of the fungus. Before and after this discovery, many empirical methods already used inoculations on trees (Table 1), but without an established protocol.

Agronomy Considerations: Controlled Inoculation and Irrigation in Planted Truffle Grounds

The first prerequisite to optimize the chance of successfully producing truffles is the production of seedlings with a mycorrhizal relationship with the right fungus. The first successful attempt to synthesize truffle

Table 1 Two centuries of domestication of the Périgord black truffles and production in France

1564: Alphonso Ciccarello, following the ideas of the Arab philosopher Almadel, suggests inoculating trees with crushed fruiting bodies.
1726: Richard Bradley suggests the same method, but for *Tuber aestivum* (Wulfen) Spreng.
Before 1750: Georges Louis Leclerc, Comte de Buffon, inoculates the roots of adult hornbeams in Montbard (Côtes d'Or) with crushed ascocarps of *Tuber melanosporum* and gets truffles 2 years later.
About 1750: Jean-Pierre-François Ripert de Monclar sows acorns in Saint-Saturnin-les-Apt (Vaucluse) and gets black truffles 10 years later.
1790: Pierre II Mauléon sows acorns (*Quercus pubescens* Willd) in Grand-Ponçay (Vienne) and harvests truffles 10 years later.
Between 1808 and 1815: Joseph Talon has the same idea and sows acorns in his fields at Saint-Saturnin-les-Apt (Vaucluse).
Around 1830: 100 to 200 hectares of artificial truffle orchards in the Vienne department and between 300 and 400 hectares in the Drôme and Vaucluse departments are created.
1847: Auguste Rousseau sows acorns (mainly *Quercus ilex*) in a 7-hectare (ha) area near Carpentras (Vaucluse) in previously cultivated soil and irrigates his orchard. He obtained large harvests reaching 70 kg/ha in the best years.
From 1860: 380,000 ha of eroded and overgrazed lands are reforested in southeast France. The Périgord black truffle naturally occurred in these plantations. The Mont Ventoux and the Lubéron mountain became the largest "truffle orchard" in the world.
1866: Bedel creates the "truffle sylviculture," a sylviculture on poor soils with low tree density allowing small-scale production of Périgord black truffles, probably less than 0.5 kg/ha.
From 1863: Beginning of the *Phylloxera* crisis, which destroyed French vineyards, and then in the late 19th century, disease of the silkworm. Numerous vineyards or fields of mulberry trees were replaced by managed truffle orchards, mainly in southeast France. Acorns were also replaced by seedlings cropped under productive trees or produced in nurseries and more or less having mycorrhizal associations with *T. melanosporum* ascospores, using crushed ascocarps but without soil disinfection. In the Drôme and Vaucluse departments, deep soils are used, allowing production reaching several kilograms per hectare in good years.
1885: Discovery and description of the ectomycorrhizae by Albert Bernard Frank.
1894: Dangeard describes ectomycorrhizae of *T. melanosporum* on *Quercus pubescens*.
1900s: Peak of French truffle production, between 500 and 1,000 tons per year.
1914–1918: First World War. National production decreases.
1920–1939: Production is stabilized around 300 tons.
1939–1945: Second World War. Another decrease in production.
1945–1946: Only 66 tons produced.
1947–1960: Stabilization at around 200 tons per year.
1960–1980: Gradual decrease of production, probably resulting from rural exodus.
1980 to present: Stabilization of production around 50 to 60 tons per year.

ectomycorrhizae was realized by Bruno Fassi, Mario Palenzona, and Anna Fontana in Italy (192–196). In 1970–1971, a collaboration started between these Italian scientists and two French scientists, Jean Grente and Gérard Chevalier (197). In 1972, Grente and Chevalier extended this inoculation technique on a large scale and contributed to the creation of the AGRITRUFFE society, exploiting a know-how license INRA/ANVAR. In 1973, AGRITRUFFE put on the market about 10,000 seedlings mycorrhizally colonized with *T. melanosporum* (198). Nowadays in France, 300,000 seedlings (oaks, hazel, hornbeams, pines, etc.) mycorrhizal with *T. melanosporum* are produced in 18 nurseries, and their quality is controlled by INRA or the CTIFL (Centre Technique des Fruits et Légumes) (199). This large-scale inoculation technique was developed first in France and then spread to Italy and Spain and is now used worldwide. At the same time, many truffle growers still use home-made inoculations.

The development of efficient techniques to control *T. melanosporum* inoculation is not the only agronomic contribution of the past decades. Water management during the first 3 or 4 years following planting is crucial for the seedlings and the mycorrhizae (200, 201). To favor the formation of new roots and good development of the *T. melanosporum* mycorrhizae, it is necessary to irrigate the seedlings during summer and to eliminate weed competition by manual hoeing, soil tilling, or mulching (200, 201).

There is increasing evidence that inoculation of the trees with ascospores throughout the truffle orchard life can increase the production of fruiting bodies. During the first years, such inoculations may allow the renewal of *T. melanosporum* mycorrhizae and decrease the chance of dominance of other ectomycorrhizal (ECM) fungi on roots of the host. Three to 5 years after planting, inoculation with ascospores may enhance sexual reproduction, which may be limited by exclusion of one mating type by the other at the mycorrhizal level (202–204) (see below). The current view is that truffle spores added by dispersal of fruiting body pieces act as male contributors to initiate reproduction and thus fruiting body formation: the so-called truffle-trapping designs, mixing spores with soil, often enhance the production of fruiting bodies (205), although the mechanisms, either genetic or linked to soil disturbance, remain unclear.

The Time for a Global Approach: from Metagenomics to Ecological Modeling

Since the early 1990s, the development of metagenomics tools and the *in situ* use of isotope (e.g., ^{13}C and ^{15}N) labeling experiments has opened up new research perspectives on fungal biology and ecology. The below-ground description of truffle grounds based on the barcoding of ECM root tips provided valuable insights into the understanding of the fungal compartmentation in truffle grounds. During the past decade, the sequencing of root apices has been widely applied to truffle plantations and spontaneous systems to provide comprehensive views of below-ground distribution of truffles in *Tuber aestivum* (206), *Tuber borchii* (207), *Tuber macrosporum* (208), and *T. magnatum* (209) grounds. Molecular tools have been developed that are aimed at determining the distribution of *T. melanosporum* in soils and the abundance of black truffle mycorrhizae within ECM communities in planted orchards (e.g., 5, 210) and in its typical habitat (188), where *T. melanosporum* is part of diversified ECM communities, with clear vegetative affinities for oaks as compared to companion shrubs (*Arbutus unedo*, *Cistus* spp.).

In situ labeling experiments have clarified the nutrition of *T. melanosporum* and answered a controversial question debated in handbooks until the 2010s regarding truffle cultivation. The natural abundance of ^{13}C and ^{15}N in tissues of the host and the fungus (211) reflects that *T. melanosporum* behaves like a true ECM fungus that does not exhibit a saprotrophic strategy during the development of its ascocarps, as speculated by some authors (see reference 183 for a review). Subsequently, a labeling experiment of tree photosynthates unambiguously demonstrated sugar transfers from host leaves to fine roots that act as a conduit and transfer carbon to *T. melanosporum* mycorrhizas and finally to the ascocarp, which accumulates host carbon 200 days after the labeling (212). A soil labeling experiment confirmed that *T. melanosporum* did not exhibit saprotrophic capacity for carbon and that carbon used by ascocarps is mainly provided by the host (213). These discoveries will pave the way for the development of pruning calendars that take into account the periods of carbon storage in the wood of the host (winter) and avoid any harmful management practice in periods of carbon demand by the fungus (summer).

The sequencing of the 125-Mb-long genome of *T. melanosporum* (214) was another essential step on the road to truffle domestication. One of the most striking features of this sequencing was the analysis of the region that governs the fungal sexual cycle, showing that *T. melanosporum* is a heterothallic species with two alternative genes at a single *MAT* locus. The provision of these genes revealed the unique population structure of *T. melanosporum* in planted orchards (202). Indeed, the black truffle shows markedly segregated patterns of

spatial distribution of individuals based on their mating type, with long-lived maternal individuals vegetatively established in truffle grounds and paternal individuals remaining cryptic before fecundation (203), leading to the idea that germinating spores (and not mycelia) may be paternal individuals (185, 215, 216). This finding suggests that competition occurs between mycelia of different mating types at the establishment stage and highlights possible mechanisms explaining the absence of fruit body production in large parts of the orchards. Further research is needed to identify paternal reproductive structures in *Tuber* spp. and to detect the ephemeral dikaryotic structure derived from parental mating.

Toward a Domestication of Truffles?

For a long time, the domestication of truffles has been a critical issue for the economy of rural Mediterranean societies (217), and complete control of the life cycle of the fungus is not achieved yet. It is now a spatial planning challenge for stakeholders in many regions of the world who aim to implement a truffle-based development of landscapes (218). Current harvests of Périgord black truffle in its natural Mediterranean habitat are well below production levels in the early 20th century, perhaps as a result of marked changes in landscapes and rural desertification. Exceptional production levels obtained in plantations outside Europe, mainly in Australia, are promising for those who invest, but these countries are too remote to supply the world demand because of the impossibility of controlling all the factors involved during the truffle biological cycle. However, the unprecedented rhythm of scientific knowledge accumulation and the extremely efficient toolbox developed by laboratories give great hope that the synergy between truffle growers and researchers will lead to increasingly understood and controlled practices in the coming years.

CONCLUSION

Fungi have been used safely in food production, even unconsciously, for thousands of years since early agricultural practices, and there is also a long and notable tradition of wild edible fungi in different cultures all over the world. However, only a fraction of edible mushrooms are eaten, and a minute portion of fungi are used in food processing. Fungal biodiversity is evidently a resource pool for food but also for more value-added uses. Fungi are gaining popularity in the context of a global need for new sources of food, and some species are already exploited to supply new-generation bio-based products in proteins or dietary fibers. Moreover, fungal enzymes have huge potential to produce higher-value products as food and feed ingredients from biological raw materials and agro-industrial waste. In addition, they are valuable as good models for studying the genomic processes of adaptation and domestication, with their often small genomes and experimental tractability (18).

Biologically Active Secondary Metabolites from the Fungi

54

Gerald F. Bills[1] and James B. Gloer[2]

INTRODUCTION

Fungi, plants, and bacteria are the major kingdoms of life with well-developed secondary metabolism. About 500,000 secondary metabolites (also referred to as natural products) have been described to date. About 100,000 of these are derived from animals, 350,000 are from plants, and 70,000 are from microbes (1, 2). Roughly 33,500 bioactive microbial metabolites have been described (2). Of these 33,500 microbial metabolites, about 12.5% (4,200) are metabolites of unicellular bacteria and cyanobacteria, 41% (13,700) are products of Actinomycete fermentations, and about 47% (15,600) are of fungal origin (1). Furthermore, the rate of discovery of new fungal metabolites has accelerated significantly in the past two decades relative to the rate of discovery in the actinomycetes, filamentous bacteria that traditionally have been the richest source of microbial natural products (2). This complex and rich secondary metabolism is highly developed in the filamentous Ascomycota and Basidiomycota, while it is underdeveloped in the unicellular forms of the Ascomycota and Basidiomycota and in the Zygomycota, Blastocladiomycota, and Chytridiomycota (Fig. 1). The diversity of fungal species, particularly in the Ascomycota and Basidiomycota, and the accompanying diversification of biosynthetic genes and gene clusters points to an almost limitless potential for metabolic variation. In fact, one can argue that much of the ecological success of the filamentous fungi in colonizing virtually all habitats on the planet is owed to their ability to deploy arrays of secondary metabolites in concert with their penetrative and absorptive life forms. This dependence of the fungi on secondary metabolites to conquer diverse habitats and sustain their existence within them is evidenced by the facts that most species make multiple types of secondary metabolites, their expression is orchestrated with the life cycle and environment, and significant portions of their genomes are devoted to encoding and regulating the production of these products.

Secondary metabolites display an incredibly broad range of biological activities. Some have afforded society-changing benefits, while others are associated with serious, almost intractable problems. This dichotomy is indicative of the diversity of natural products that fungi can produce. Fungal metabolites with the greatest negative impact include mammalian toxins commonly known as mycotoxins. As many as 1,000 fungal compounds have been afforded this label, with the most widely known including aflatoxins, trichothecenes, fumonisins, ochratoxin, cytochalasins, and various indole-terpene tremorgenic compounds (3, 4). Organisms in all domains of life produce toxins, including many that are more toxic than those from fungi, but mycotoxins tend to be more problematic because of their widespread occurrence as contaminants of food for humans and livestock, as well as mold-contaminated indoor environments (5). Understanding mycotoxin chemistry is essential to improving the ability to monitor and reduce the levels of exposure to such compounds. Fungi that produce mycotoxins and phytotoxins associated with crop diseases can cause considerable economic losses and require significant investment in their control. Metabolites that function as phytotoxins and small-molecule virulence factors produced by plant pathogenic species are responsible for many of the damaging effects of plant diseases (6).

On the other hand, many important pharmaceuticals have been discovered through studies of fungal chemistry (Table 1). Natural products continue to be among

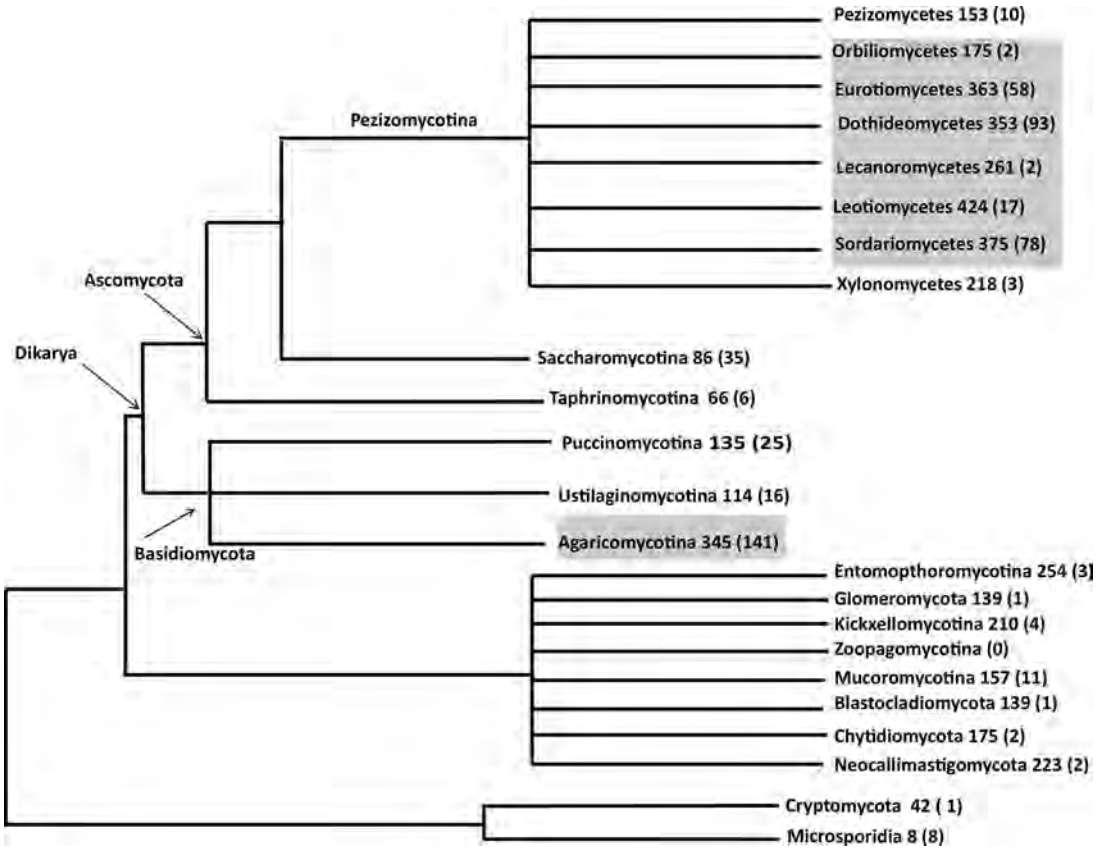

Figure 1 Simplified phylogeny of the phyla and classes of the Fungi. Numbers after phylum or class indicate the average number of secondary metabolite, transport, and catabolism genes recognized by the Clusters of Orthologous Groups of Proteins Classification (KOGs) from sequenced genomes (number in parentheses) of fungi at the Joint Genome Institute's Mycosm Project (January 15, 2016). Taxa shaded in gray are known to produce secondary metabolites with high frequency. Branch length reflects relatedness of taxa.

the most important therapeutic agents and lead compounds in medicine and have been particularly important in the development of effective therapies for cancer, malaria, bacterial and fungal infections, neurological and cardiovascular diseases, and autoimmune disorders (7). Many agricultural chemicals are also natural product-derived (8, 9). Fungi are particularly prolific sources of bioactive secondary metabolites (10) and have contributed in spectacular and indispensable ways to improvements in human and animal health (Table 1). The best known examples are the β-lactam antibiotics, which include penicillins and cephalosporins (Table 1). It is difficult to overstate the tremendous effect these compound classes have had on global health because of their effectiveness against bacterial infections. Moreover, the success of penicillins effectively spawned the development of major technological advances in microbiology, chemistry, biochemistry, and engineering and contributed in many ways to the establishment of the modern pharmaceutical industry. Many other fungal metabolites with valuable activities are known (Table 1), and further examples are incorporated into the discussion below.

One ongoing question regarding the dimensions of fungal biodiversity relates to judging the potential for discovery of even more novel and useful secondary metabolites, as well as the likelihood of further applications for those that are already known. Often one reads provocative statements such as "To date, fewer than 7% of the more than 1.5 million species of fungi thought to exist have been investigated for bioactive components" (11). Such statements are based on the number of metabolites described in the literature and the number of species from which those metabolites have been reported (12). Ultimately, no one really knows what percentage of the total number of species has been tested for biologically active compounds, but it is in all probability much higher. Our experience and

Table 1 Fungal metabolites that have been developed into pharmaceutical, agrochemical, and cosmetic products

Metabolite	Source species	Structural classification	Commercial product(s)	Mode of action	Indication(s)
Penicillins G and V	*Penicillium rubens*, *Penicillium chrysogenum*	Nonribosomal peptide	Benzylpenicillin and phenoxymethylpenicillin; 6-aminopenicillanic acid derived from penicillin G is acylated to make semisynthetic penicillins with diverse side chains, e.g., piperacillin, amoxicillin, and ampicillin	Interferes with biosynthesis of cell wall peptidoglycans	Deep-seated infections caused by Gram-positive and some Gram-negative bacteria
Cephalosporin C	*Acremonium chrysogenum*	Nonribosomal peptide	The 7-amino cephalosporanic acid core is used to produce numerous derivatives, including cephalothin, cephalexin, cephradine, and cefadroxil	Interferes with biosynthesis of cell wall peptidoglycans	Treatment of Gram-positive and some Gram-negative bacterial infections
Pleuromutilin	*Clitopilus passeckerianus*, other *Clitopilus* spp.	Diterpene	Precursor for the partial chemical synthesis of topical antibiotic retapamulin (Altabax) and animal antibiotics tiamulin and valnemulin (Econor)	Targets peptidyl transferase center of bacterial ribosome	Topical treatment of infections from Gram-positive bacteria, treatment of Gram-positive bacterial infections in livestock
Fusidic acid	*Acremonium fusidioides*	Triterpene	Usidin, Fucidin, Fucicort, Fucibet, Taksta, and others	Prevents translocation of the elongation factor G from the ribosome	Topical antibiotic for Gram-positive bacterial infections including methicillin-resistant *Staphylococcus aureus*; under development for prosthetic joint infections
Strobilurins A–D and other strobilurins and oudemansins	*Strobilurus tenacellus*	Polyketide with benzoyl CoA starting unit	Templates for synthetic family of β-methoxyacrylate strobilurins including azoxystrobin, fenamidone, fluoxastrobin, kresoxim methyl, and trifloxystrobin	Targets the mitochondrial cytochrome b and interferes with respiratory electron transport	Fungicides for broad range of plant pathogenic fungi
Griseofulvin	*Penicillium griseofulvum*, *Penicillium aethiopicum*, *Penicillium Coprophilum*, and other *Penicillium* spp.	Halogenated polyketide	Fulcin, Fulsovin, Grisovin, and others	Inhibits mitosis by binding to tubulin and preventing tubulin polymerization	Treatment of fungal infections of the skin, hair, and nails
Pneumocandin B_0	*Glarea lozoyensis*	Nonribosomal peptide acylated to polyketide	Precursor of the partial chemical synthesis of caspofungin (Cancidas)	Inhibits β-1,3 glucan synthase and cell wall biosynthesis	Treatment of systemic fungal infections
FR901379	*Coleophoma cylindrospora* (= *C. empetri*)	Nonribosomal peptide acylated to fatty acid	Precursor of the partial chemical synthesis of micafungin (Mycamine, Fungiguard)	Inhibits β-1,3 glucan synthase and cell wall biosynthesis	Treatment of systemic fungal infections
Echinocandin B	*Aspergillus pachycristatus* and other *Aspergillus* spp. of section *Nidulantes*	Nonribosomal peptide acylated to fatty acid	Precursor of the partial chemical synthesis of anidulifungin (Eraxis)	Inhibits β-1,3 glucan synthase and cell wall biosynthesis	Treatment of systemic fungal infections

(Continued)

Table 1 Fungal metabolites that have been developed into pharmaceutical, agrochemical, and cosmetic products *(Continued)*

Metabolite	Source species	Structural classification	Commercial product(s)	Mode of action	Indication(s)
Enfumafungin	*Hormonema carpetanum*	Triterpene glycoside	Precursor of the partial chemical synthesis of experimental drug Scy-078 that is in phase II clinical trials	Inhibits β-1,3 glucan synthase and cell wall biosynthesis	Treatment of systemic fungal infections
Lovastatin (monacolin K)	*Aspergillus terreus*, *Monascus purpureus*, also occurs in basidiomata of *Pleurotus ostreatus*	Polyketide, product of two highly reducing polyketide synthases	Mevacor Simvastatin (Zocor, Simvacor, Simvastin, and other brand names) is made by semisynthesis from lovastatin	Inhibits 3-hydroxy-3-methylglutaryl-coenzyme A reductase, prevents conversion of mevalonate into cholesterol	Treatment of hypercholesterolemia to reduce risk of cardiovascular disease
Compactin (Mevastatin)	*Penicillum citrinum*, *Penicillum solitum*, and other *Penicilium* spp.	Polyketide, product of two highly reducing polyketide synthases	Although recognized as the first statin, never approved as a drug. Used for biotransformation or partial chemical synthesis from mevastatin (Pravachol, Selektine, Lipostat, and other brand names)	Inhibits 3-hydroxy-3-methylglutaryl-coenzyme A reductase, prevents conversion of mevalonate into cholesterol	Treatment of hypercholesterolemia to reduce risk of cardiovascular disease
Cyclosporin A	*Tolypocladium inflatum*	Nonribosomal peptide	Cyclosporine A (Sandimmune, Neoral, Restasis, Gengraf, and other names)	Binds to cyclophilin A, resulting in calcineurin inhibition, which activates transcription of interleukin 2. Also inhibits lymphokine production and interleukin release	Prevention of organ transplant and tissue graft rejection
Mycophenolic acid	*Penicillium brevicompactum* and other *Penicillium* spp.	Meroterpenoid	Used to produce mycophenolate mofetil (Cellcept), mycophenolate sodium (Myfortic)	Inhibits inosine monophosphate dehydrogenase (IMPDH). T and B lymphocytes are heavily dependent on the activity of IMPDH to make DNA to proliferate	Prevention of organ rejection following kidney, liver, or heart transplants
Myriocin (ISP-I)	*Isaria sinclairii*	Amino acid lipid	Structural template for synthesis of fingolimod (Gilenya)	Activated form binds to extracellular G protein-coupled receptors and prevents release of lymphocytes that enter the CNS	Treatment of multiple sclerosis
Ergotamine	*Claviceps purpurea*, *Claviceps fusiformis*, and *Claviceps paspali*	Prenylated nonribosomal peptide	Ergotamine tartrate (Ergomar, Migril, and others), dihydroergotamine mesylate (Migranal), or combined with caffeine (Cafergot, Cafetrate, and other names), dihydroergotamine (DHE 45)	Neurotransmitter mimic, agonists of 5-OH tryptamine (5-HT2) receptor 1B, dopamine, norepinephrine, and serotonin receptors	Vasoconstrictor used as antimigraine agent, also combined with belladonna and phenobarbital for relief from menopausal hot flashes

Ergometrine (ergonovine)	*C. purpurea*, *C. fusiformis*, and *C. paspali*	Prenylated nonribosomal peptide	Ergometrine maleate (Ergotrate, Ergovin, and others); Methylergometrine is a synthetic version, sometimes combined with oxytocin (Syntometrine) for veterinary usage	Serotonin antagonist, activating (or blocking) 5-HT2 receptors	Treatment of postpartum haemorrhage
			Used for partial chemical synthesis of lysergic acid diethylamide, LSD-25, LSD (Delysid)		Hallucinogen, treatment of psychosis and depression
Ergocryptine	*C. purpurea*, *C. fusiformis*, and *C. paspali*	Prenylated nonribosomal peptide	Partial chemical synthesis of bromocriptine (Parlodel and other names)	Agonist of dopamine D_2 receptors and various serotonin and adrenergic receptors	Treatment of reproductive disorders, e.g., galactorrhoea, prolactindependent mammary carcinoma, amenorrhoea, acromegaly or anovulation, complications, e.g., osteoporosis. Bromocriptine is also used in the treatment of Parkinson's disease
Mizoribine	*Penicillium brefeldianum*	Imidazole nucleoside	Bredinin and other names	Competitive inhibitor of IMPDH	Immunosuppressant used for renal transplants in Japan, Korea and China
Kojic acid	*Aspergillus oryzae*. *Aspergillus tamarii*, *Aspergillus flavus*	Pyrone derived from glucose	Often formulated as kojic dipalmitate to increase stability and shelf life	Inhibits tyrosinase and suppresses melanogenesis	Antioxidant in cosmetic products, used to lighten skin color and treat abnormal hyperpigmentation
PF1022A	*Rosellinia* sp.	Nonribosomal peptide	Emodepside is the bis-paramorphonyl-derivative of PF1022A	Disrupts target nematode neuromuscular function due to interactions with the latrophilin-like HC110-R G-protein coupled and SLO-1 potassium channels	Combined with praziquantel, another anthelmintic drug, to treat roundworm, hookworms, and tapeworms in cats as Profender
Fumagillin	*Aspergillus fumigatus*	Meroterpenoid	Bicyclohexyl ammonium fumagillin	Inhibits methionine aminopeptidase2 (MetAP2)	Control of nosema disease in honey bees caused by *Nosema apis*
Gibberellic acid (GA)	*Fusarium fujikuroi*	Diterpene	Produced by fermentation of *F. fujikuroi*	GA signaling promotes plant growth by overcoming DELLA-mediated growth restraint	Plant growth hormone for plant tissue culture and applications for certain high-value crops
α-Zearalanol (Zeranol)	*Fusarium* spp., including *Fusarium culmorum*, *Fusarium sporotrichioides*, *Fusarium equiseti*, and *Fusarium semitectum*	Polyketide, product of a highly reducing and a nonreducing polyketide synthase	Produced by fermentation of zearalenone, then hydrogenation to form α-zearalanol, formulated as Ralgro implants	An estrogen mimetic that binds to mammalian estrogen receptors α (ER α) and ER β	An anabolic agent used to increase the rate of weight gain and feed conversion in cattle in North America

that of our colleagues who have worked in the pharmaceutical and agrochemical industries tells us that far more species have been surveyed for secondary metabolites of interest over the decades in discovery screening programs than the literature would indicate, because inactive, strongly toxic, redundant, or unproductive fermentation extracts and products are rarely pursued, let alone published or otherwise documented (13, 14). Recognition of already known compounds in fungal fermentations—a process referred to as dereplication (15, 16)—is a vital step in natural product discovery processes. The high frequency of encounters with known compounds in screening programs represents a substantial resource cost that generally affords little value. Although improvements in the efficiency of dereplication processes continue to develop with advances in relevant analytical technologies (16), the costs in time and effort associated with "rediscovery" of known metabolites pose a significant obstacle to natural product discovery efforts. Such findings generally result in disinterest, and certainly not in publication. Other phenomena, such as compound decomposition or loss during separation efforts or the possibility that mixtures may exert effects not detected in purified/individual metabolites, may ultimately prevent identification of secondary metabolites that may be present.

Fermentations of most strains in major service collections have probably been examined for biologically active compounds at some level (17), yet most of this work likely is undocumented. For example, in the past, pharmaceutical companies would routinely buy strains from major service collections when the collection staff made routine transfers of their stock collections. It is impossible to know how many fungi have really been screened or how many compounds have been produced, detected, purified, and partially or fully characterized but then discarded for lack of potency and target specificity in the assays being employed for screening. To complicate such speculation even further, the window of desired biological activity in a given screening program often may be quite narrow, e.g., inhibition of bacterial type II topoisomerases, and negative data from these efforts are seldom considered worthy of publication. What is clear is that the numbers of possible applications for fungal metabolites in medicine, agriculture, cell biology, and consumer products are limitless and constantly evolving. Even well-known metabolites, previously discarded for one application, e.g., an antibiotic, can suddenly become recognized for new and exciting biology. In our opinion, exploration of fungal chemistry with the aim of finding new applications is likely to be far more productive than surveying what one believes are new fungi using dated screening methods, e.g., growth inhibition of typical model strains of human pathogens, and certainly more productive than simple chemical screening with no biological detection method at all.

No example illustrates the unforeseen value of "ordinary" fungal metabolites better than mycophenolic acid (MPA) (Fig. 2a, Table 1) (18). MPA was discovered by Bartolomeo Gosio from *Penicillium brevicompactum* in 1893, and it has the distinction of being the first antibiotic to be purified in crystalline form (19). It inhibited the growth of *Bacillus anthracis*, but quantities were insufficient for further investigation. Its medical application as an antibiotic was later investigated by C. L. Alsberg and O. M. Black in 1912 (20) and by Howard Florey's team at Oxford in 1946 (21), but it was discarded as a potential antibiotic due to its toxicity. During the 1960s and 1970s, MPA was recognized to have remarkable biological activities against viruses and certain tumor types, and its mode of action as an inhibitor of inosine 5′-monophosphate dehydrogenase, an enzyme required for the biosynthesis of guanine, was elucidated. Depletion of the cellular guanine derivative pool, therefore, accounted for many of MPA's effects. These mechanistic studies led to explorative studies of MPA as an oral treatment for psoriasis (22). Inhibition of this critical metabolic pathway in more susceptible human T and B lymphocytes was later exploited in the development of the immunosuppressive agent mycophenolate mofetil, marketed under the names CellCept (Hoffmann LaRoche) and Myfortic (Novartis).

Beyond its impact as the precursor for this important new class of immunosuppressant drugs, MPA illustrates the current transformation underway in modern natural product research. The complete biosynthetic pathway has been characterized in two producing fungi, *P. brevicompactum* (23, 24) and *Penicillium roqueforti* (25). MPA production is catalyzed by interaction of MpaA, a prenyl transferase, with a polyketide synthase (PKS), MpaC, producing 5-methylorsellinic acid, and MpaDE, which is a newly recognized hybrid enzyme,

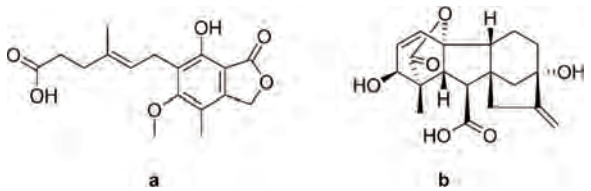

Figure 2 Structures of (**a**) mycophenolic acid and (**b**) gibberellic acid.

fusing a cytochrome P450 domain and a hydrolase domain, catalyzing the production of 5,7-dihydroxy-4-methylphthalide (23). By reconstituting the entire gene cluster in a heterologous host, *Aspergillus nidulans*, the functions of the genes encoding and regulating MPA biosynthesis have been characterized, and the feasibility of employing *A. nidulans* as a microbial cell factory for MPA has been established (23).

This review will briefly summarize general aspects of fungal secondary metabolism and recent developments in our understanding of how and why fungi make secondary metabolites, how these molecules are encoded, and how their encoding genes are distributed across the Fungi. Readers seeking in-depth and detailed works on fungal metabolites and their biosynthesis should consult information from more comprehensive works (3, 26–31) and a new database on functionally characterized secondary metabolite gene clusters (32). In addition, we will illustrate the breadth of fungal secondary metabolite diversity by highlighting recent information on the biosynthesis of some of the most important fungus-derived metabolites that have contributed to human health and agriculture, as well as those that have negatively impacted crop production, food distribution, and human-built environments.

WHAT ARE SECONDARY METABOLITES AND THEIR FUNCTIONS?

Classical definitions of secondary metabolites convey the idea that these compounds are not essential for growth or survival of the producing organism. While primary metabolism is generally shared by most organisms, a general characteristic of secondary metabolites is that they have a biased phylogenetic distribution due to multiple factors that have driven extinction and diversification of their encoding genes and gene clusters along narrower evolutionary lineages. In the laboratory, genes encoding the primary catalytic enzymes for secondary metabolite synthesis can often be silenced by gene disruption with relatively minor effects on vegetative growth or sporulation (33–35). However, the essentiality of secondary metabolism is frequently contextual, and some secondary metabolites that appear to fall into this category are indispensable to survival in nature, e.g., pigments, sunscreens, siderophores, and pheromones. What is clear is that their importance to the organisms that produce them is underestimated because of their incomplete inventory and their unidentified or misunderstood functions. It has been argued that secondary metabolites and other small bioactive molecules of biogenic origin are so vital to the organisms that produce them that they should form the fourth pillar of "the central dogma of biology" along with DNA, RNA, and proteins (36). The line between secondary and primary metabolism can be blurry, and sometimes primary metabolites may behave like secondary metabolites, e.g., oxalic acid (37–39). Depending on their perceived essentiality and functions, secondary metabolites can include simple molecules derived directly from primary metabolism, such as alcohols, sugars, and organic acids. As an example, the discovery and characterization of quorum-sensing molecules and related systems in bacteria, and more recently in yeasts, have changed popular notions of the roles of low-molecular-weight compounds in microbial communities (40).

Fungi can release their secondary metabolites from cells as volatiles, excrete them into the environment, or incorporate them into structural elements of the cell, or they can remain cell-bound. The term "extrolites" has been suggested as an alternative descriptor for such compounds based primarily on the fact that their biological functions are assumed to be outwardly directed (41), but because the functions and sites of cellular biosynthesis for so many remain unknown, because some have self-directed functions, and also for the sake of continuity, we prefer to employ the classical term "secondary metabolite."

From a chemical standpoint, secondary metabolites are on one end of a continuum of metabolites and are categorized as compounds biosynthesized by pathways that employ primary metabolites as building blocks to assemble more complex molecules, such as polyketides, terpenoids, nonribosomal peptides, nuclear-encoded ribosomal peptides, and molecules of mixed biogenic origin arising from hybrid pathways. These categories, representative examples of each, and related recent developments are discussed in separate sections below. Thousands of secondary metabolites are known and catalogued in various compendia and databases (12). Many of them have been encountered and identified because of their association with a biological activity or phenomenon detected outside of laboratory settings (e.g., mycotoxins, phytotoxins, pigments). In a few groups of fungi, secondary metabolite profiles of fungal reproductive structures or cultures have been characterized and correlated with taxonomic and phylogenetic classifications (42–46). However, much of our knowledge of such chemistry has arisen through extensive screening programs conducted in the pharmaceutical and agricultural industries, as well as in academic laboratories, in search of small molecules with potentially useful effects. Bioassays of various kinds are typically

used to guide the isolation of secondary metabolites from complex fermentation extracts using various chromatographic methods, and they are identified using spectroscopic techniques, most commonly nuclear magnetic resonance, mass spectrometry, and X-ray crystallography. These tools, along with databases that store spectral and other physical data, have grown rapidly in their capabilities, greatly expanding the ability to purify and identify such compounds and to detect and quantitate them in various samples.

Secondary metabolites that have been reported from both fungi and plants are not common. Of course, differences in secondary metabolism would be expected from these two domains of eukaryotic organisms due to differences in their basic metabolism and evolutionary origins of their respective biosynthetic pathways. Some of these differences stem from initial steps in biosynthetic processes that influence the prevalence of certain precursors. For example, decarboxylation of amino acids is much more common in plants than in fungi, affording amine precursors that are ultimately incorporated into many classes of plant alkaloids that have not been encountered among the fungi. The phenylpropanoid pathway so common among plants is not as prevalent among fungi. Similarly, secondary metabolic differences also occur between fungi and other microorganisms. For example, polyketide production in fungi generally involves poly-1,3-dicarbonyl precursors generated from acetyl and malonyl CoA. Bacteria also produce polyketides but can also utilize propionyl and butyryl CoA in such processes, leading to different kinds of end products. The dominant type of PKSs in plants are type III PKSs, such as chalcone synthase, a well-known plant type III PKS that catalyzes the first committed step in flavonoid biosynthesis.

Some secondary metabolites are made by both plants and fungi, such as gibberellins, diterpenoid plant hormones that can also be produced by certain fungi, albeit via different enzymatic pathways. The intensively studied gibberellic acids (GAs) (e.g., Fig. 2b) represent the best known unequivocal case of convergent secondary metabolites between plant-inhabiting fungi and plants. They are based on the tetracyclic *ent*-gibberellane terpenoid skeleton and are produced by plants, as well as the plant pathogen *Fusarium fujikuroi*, and are occasionally reported from other fungi (47, 48). In plants, the GAs are a major family of hormones that promote and regulate plant growth. The commercial manufacture of GAs via fungal fermentation has enabled the development of these natural plant hormones into high-value plant growth regulatory hormones for plant tissue culture, horticultural, and biotechnological applications (Table 1). In *F. fujikuroi*, the GA gene cluster contains a pathway-specific geranylgeranyl diphosphate synthase gene (ggs2) that seems to form geranylgeranyl diphosphate exclusively for GA biosynthesis. In addition, a bifunctional CPS/KS (copalyl diphosphate synthase, CPS/*ent*-kaurene diphosphate synthase, KS)-encoding gene, *cps/k*s, catalyzes the cyclization steps to *ent*-kaurene, and four P450 monooxygenase-encoding genes and a desaturase gene carry out the oxidative steps and introduce a double bond, respectively.

The question of whether endophytic fungi may biosynthesize secondary metabolites in physiologically relevant quantities in living plants has received considerable attention. Ergot alkaloids are mycotoxins characteristically produced by fungi in the Clavicipitaceae that form biotrophic infections of grasses and some species of the *Convolvulaceae* (morning glories and relatives). The fungi and their metabolites can increase host plant resistance to herbivores and cause toxicity to consuming livestock (49). Some species of *Convolvulaceae* are infected by endophytic clavicipitaceous fungi (*Periglandula* spp.) that produce high concentrations of ergot alkaloids in seeds—up to 1,000-fold greater than in infected grasses. Swainsonine is an indolizidine alkaloid and is the toxic component that causes livestock poisoning upon consumption of locoweeds (*Astragalus*, *Oxytropis*, and *Swainsona* spp. of the *Fabaceae*) (50). It can also be found in certain species of *Ipomea* and *Turbina* (*Convolvulaceae*) and *Sida carpinifolia* (*Malavaceae*). In a manner analogous to ergot alkaloid production in grasses, the swainsonine in plant tissues results from infection by seed-transmitted endophytic fungi of the genus *Undifilum* (Dothideomycetes, Pleosporales) that produce swainsonine in living tissues of locoweeds. Swainsonine production in plants of the *Convolvulaceae* appears to be associated with an endosymbiotic fungus of the order Chaetothyriales (270).

Biosynthesis of secondary metabolites may be tightly regulated. Their expression is often triggered by chemical or environmental stimuli and coordinated with the development and morphogenesis of the producing organism (51–54). For example, early studies showing that certain bioactive secondary metabolites were strongly associated with *Aspergillus* sclerotia have been supported by more recent investigation of tissue-specific regulation of gene expression in sclerotia versus mycelia (52). Even so, details regarding their functions in nature remain elusive. In some cases, expression may be stimulated or repressed by association with other organisms (55, 56). Because some secondary

metabolites are products from pathways that are expressed in a particular context or life stage, our perception of secondary metabolism in the laboratory depends on whether the context-dependent stimulus or life stage can be artificially replicated and whether pathways are expressed under typical laboratory environmental and nutritional conditions. Some products are easily produced in culture and thus are repeatedly encountered, while other pathways remain silent in artificially cultured strains. The long history of fermentation technology has documented that growing strains under varied nutrient and aeration regimes can profoundly change metabolite compositions and titers (57–59), e.g., plant-derived media versus defined media (60) or liquid versus solid media (61). Experimental efforts to capitalize on these phenomena have remained largely empirical. This knowledge gap has been a key rate-limiting factor in the identification of the natural functions of secondary metabolites, as well as in the discovery of new applications of secondary metabolites in medicine and agriculture.

Secondary metabolite gene clusters are the product of selection of complex traits over millions of years of evolution. Mechanisms contributing to the diversification of the end products include gene duplication, fusion, neofunctionalism, transposition, recruitment and loss of additional genes, and in some cases, horizontal gene transfer (HGT) (62, 63). During the past decade, apparent discontinuous distributions of many secondary metabolite pathways has been attributed to HGT, or in other words, the acquisition and stable inheritance of foreign genes by a recipient organism outside of the process of karyogamy. Although HGT is prevalent in prokaryotes and was responsible for the origin of eukaryotic mitochondria and plastids, through endosymbiosis, the degree to which HGT has impacted eukaryotic evolution remains controversial. In principle, the introduction of foreign DNA into fungal genomes might occur during unicellular or early developmental stages, when their nuclear DNA is relatively exposed to potential sources of HGT, but as of yet, the mechanisms of these proposed eukaryote HGT processes remain unknown. Nonetheless, if genes for a novel metabolic process move by HGT, they endow the recipient organism with the possibility of acquiring a new selective advantage that might promote the survival of the recipient and therefore also of the genes. Clustering of biosynthetic, regulatory, and resistance genes would favor dispersal of entire pathways. Evidence for HGT can be particularly strong because the putatively transferred gene carries a nucleotide composition of the donor genome at the time of transfer from the donor organism and is often easily recognized in the case of bacterial-to-eukaryotic HGT. For example, the partially reducing, 6-methylsalicylic acid (6-MSA)-type polyketide synthases that are widespread across the Fungi may have originated from Actinomycete ancestor proteins (64). However, in the case of hypothetical interascomycete transfers, the direction of transfer is usually not apparent.

The principal method for identification of HGT is phylogenetic incongruence as measured by strong statistical conflict between the phylogenies of the putatively transferred gene and of the background genes of the organism. These types of analyses are highly dependent on the availability of genomes and sampling of species. What at first seems to be HGT of a biosynthetic cluster between phylogenetically distant species may later be recognized as congruent as new gene cluster orthologues from newly sequenced genomes become available. An especially high-profile example was the report of a putative HGT of the sterimatocystin gene cluster from *A. nidulans* (Eurotiales) to *Podospora anserina* (Sordariales) (65). The authors of this report verified that sterigmatocystin genes were transcribed, but they never tested whether *P. anserina* produced sterigmatocystin. Subsequently, we have independently observed sterigmatocystin production in at least one freshly isolated strain of *P. anserina* (J. Gloer, G. Bills, unpublished data). A broader analysis of fungal genomes inferred that the donor organism of the *P. anserina* sterigmatocystin gene cluster may have been a species in the Dothidiomycetes, e.g., *Rhytidhysteron rufulum* (66).

Neither of these reports took into account the widespread reports of sterigmatocystins or their biosynthetic analogues in other fungi belonging to the Sordariomycetes, including *Chaetomium* spp. (Sordariales) (67), *Aschersonia coffeae* (Hypocreales) (68), *Monicillium nordinii* (Hypocreales) (69, 70), *Calcarisporium arbuscula* (Hypocreales) (71), or other fungi in the Dothidiomycetes, including an unidentified species in the Microthyriaceae (72). Furthermore, orthologues of genes in aflatoxin-sterigmatocystin gene clusters have been recently detected in the genomes of the causal agent of chalkbrood disease of bees, *Ascosphaera apis* (Onygenales) (73), the soil fungus *Ochroconis mirabilis* (Venturiales) (74), and the tomato pathogen *Cladosporium fulvum* (Capnodiales) (75). Thus, sterigmatocystin-aflatoxin pathway genes appear to be more widely distributed across the Dothidiomycetes, Eurotiomyctes, and Sordariomycetes than previously thought (67), and the gaps will likely continue to be filled in as more genomes are sequenced. One wonders

if new phylogenetic reconstructions based on the sterigmatocystin-aflatoxin pathway genes and associated housekeeping genes will eventually approach congruency once the analyses include data from the gene clusters from all of these fungi and others that have yet to be discovered. For the time being, our preference is to treat these putative discontinuous distributions as HGT hypotheses because unequivocal evidence is lacking and relatively few fungal genomes have been fully sequenced. As more fungal genomes become available, we predict that alternative evolutionary models will emerge that will explain these reticulate patterns of secondary metabolite distributions.

The events leading to secondary metabolite diversification are undoubtedly linked with speciation and niche radiation, but how selective pressures determine the genetic origins and distribution of these pathways, and their feedback on species fitness, remains obscure (76). Some secondary metabolites are critical to the ecological success of the Fungi because they mediate micronutrient acquisition and transport, virulence, intra- and interspecies communications, defensive mutualisms, protection against abiotic stress, and reproductive development and form pigments, among other functions (77). A puzzling aspect of the prevalence of secondary metabolism is that only a tiny fraction of secondary metabolites have a demonstrated effect that can be linked to a competitive advantage to the producer (78, 79). Design and interpretation of laboratory experiments to identify the natural function of a secondary metabolite discovered out of its natural context are notoriously difficult (79–81). Therefore, progress in dissecting the functions of microbial chemistry in nature has been limited to relatively few systems, such as plant and animal defensive mutualisms and host-pathogen relationships. Classic hypotheses regarding interference competition or defense have contributed explanations of the vast chemical repertoire of fungi and other microorganisms by incremental and reciprocal adaptations and counteradaptations between fungi and their symbionts, parasites, hosts, and predators, shaped by mutual selection (82–86). These hypotheses have underpinned fungal metabolite discovery projects since the discovery of the first antibiotics in the late 19th century and continue to guide modern fungal natural products research within the pharmaceutical and agrochemical industries.

Concepts of some secondary metabolites as agents of chemical defense or offense are further supported by observations that antibiotic resistance genes are common in nature and that the organisms that produce them often have complex self-resistance mechanisms (87–89). As in bacterial secondary metabolite gene clusters, evidence that fungal gene clusters can encode auxiliary target proteins to evade self-toxicity from their own metabolites is accumulating. One of the best examples of self-resistance genes for a fungal secondary metabolite occurs in the pathways for the hydroxymethylglutarate (HMG)-CoA reductase inhibitors, lovastatin and compactin (Table 1). These metabolites are weakly antifungal because they block production of mevalonate, which in turn affects steroid and terpene synthesis. The lovastatin and compactin gene clusters in the producing fungi carry an ancillary HMG-CoA reductase gene (*Aspergillus terreus*, *lvrA*; *Monascus pilosus*, *mokG*; *Penicillium citrinum*, *mlcD*) which confers resistance to the pathway product by producing the mevalonate precursor during compactin and lovastatin biosynthesis (90, 91). A strain of *P. citrinum* with mutated *mlcD* was 200-fold more sensitive to compactin and produced lower ergosterol levels than the parent strain (90). *Aspergillus fumigatus* produces the epipolythiodioxopiperazine gliotoxin from a bimodular nonribosomal peptide synthetase (NRPS) as an immunosuppressive virulence factor during pathogenesis (92). Disruption of the *gliT* gene, encoding a gliotoxin reductase, in the biosynthetic gene cluster resulted in reduced production of gliotoxin and sensitization of the mutants toward gliotoxin (93). The immunosuppressive metabolite MPA, discussed above, potently inhibits inosine-5′-monophosphate dehydrogenase (IMPDH). Characterization of the MPA biosynthetic gene clusters from *P. brevicompactum* and *P. roqueforti* revealed an auxiliary copy of an IMPDH-encoding gene (*mpaF*) embedded within the cluster that is resistant to MPA (24, 25). Self-toxicity also may be mitigated by tight regulation of product biosynthesis during the critical stages of the life cycle (53), by transport proteins specific for biosynthetic pathways, and by product-specific trafficking in specific cells and intracellular compartments (89, 94).

RUDIMENTARY SECONDARY METABOLITES: EVOLUTION OF THE FIRST BIOACTIVE SMALL MOLECULES

The origins of secondary metabolites are likely to coincide with the origins of self-replicating biological molecules (95–97). One can easily imagine how simple amino acids reacted with each other and other organic molecules to form new molecules that interacted with the earliest macromolecular processes; when these rudimentary secondary metabolites exerted positive effects on macromolecular processes and ultimately on

reproduction of the cell, they were retained as a new cellular process. Many consider that the early chemical and structural interaction sites of primordial amino acids, which gradually evolved into polypeptides, still retain some level of that specificity today (98). Indeed, the antagonistic activity of antibiotics, among their other varied small-molecule interactions, could simply be one facet of their primordial origins. And while not constituting proof of the role of secondary metabolites in nascent biochemical evolution, their ubiquity is consistent with the belief that bioactive small molecules have been critical to forging diversification of all organisms throughout molecular history (36, 96).

Many of these rudimentary metabolites (e.g., Fig. 3) are amino acid derivatives or by-products of amino acid biosynthesis. Given the importance of amino acids in cell composition and function and as building blocks of many secondary metabolites, the nonribosomal peptides may be the oldest secondary metabolites (97). One of the simplest fungal secondary metabolites is hadacidin (*N*-formyl hydroxyaminoacetic acid) (Fig. 3a), a compound found in *Penicillium frequentans* and other *Penicillium* spp. (99). Its name is based on its inhibition of human adenocarcinoma (100, 101). Furthermore, it potently inhibits plant growth (102). Hadacidin inhibits purine biosynthesis by inhibition of adenylosuccinate synthetase. Isotope labeling studies indicated that it is formed by *N*-oxygenation of glycine to yield *N*-hydroxyglycine, followed by *N*-formylation to give the hydroxamic acid. Another intriguing example of primitive secondary metabolites is provided by cyclic dipeptides (CDPs; diketopiperazines or dioxopiperazines) formed by the linkage of two amino acids. CDPs have been suggested to be among the most ancient classes of signaling molecules (98). These compounds are ubiquitous in biological systems and have even been found in extraterrestrial meteorites (103). In abiotic systems, CDPs are produced from unprotected linear dipeptides, and once formed, they remain relatively stable. The lack of free C- and N-terminal groups enables CDPs to resist human digestion, so they are attractive templates for the development of protein-based drugs.

Aside from spontaneous formation in primordial stews, they are produced by two major biosynthetic routes: as products of dedicated NRPSs (see below) or, more interestingly, by a recently discovered enzymatic process employing cyclodipeptide synthases (CDPSs) (104–106). CDPSs commandeer aminoacyl-tRNAs and employ them in the formation of a cyclodipeptide link from two aminoacyl transfer RNAs using a ping-pong mechanism that transfers an aminoacyl moiety of the first aminoacyl tRNA onto a conserved serine residue, yielding an aminoacyl enzyme. At the same time, CDPSs divert the flow of loaded tRNAs away from the ribosomal machinery (Fig. 4). The covalently bound

intermediate recognizes the aminoacyl-binding site of the cognate aminoacyl tRNA and reacts with the aminoacyl moiety of the second aminoacyl tRNA, forming a dipeptidyl enzyme. This novel enzyme family represents an interesting intermediate between amino acid tRNA-synthetase-based protein synthesis and other nonribosomal processes for peptide bond formation (Fig. 4). Genome mining indicated the presence of CDPS genes in more than 50 bacteria and in at least four *Fusarium* species (104), indicating the presence of a novel mode of fungal peptide synthesis in these fungi.

Many CDPs display biological activities such as inhibition of growth of fungi, bacteria, and human tumor cells. For example, a single fermentation of *A. fumigatus* can produce at least seven CDPs—cyclo (L-Leu-L-Pro) (Fig. 3b), cyclo(L-Phe-L-Pro) (Fig. 3c), cyclo(Gly-L-Pro), cyclo(L-Pro-L-Pro), cyclo(L-Pro-L-Val), cyclo(L-Leu-L-trans-4-OH-Pro), and cyclo(L-Phe-L-trans-4-OH-Pro)—most of which had antibacterial activity. Cyclo(L-Phe-L-Pro), a phytotoxin from *Rosellinia necatrix* (107), attenuated the development of physical dependence on morphine (108). CDPs also provide structural cores for a number of complex fungal secondary metabolites that incorporate diketopiperazine units, including chaetocin, gliotoxin, verticillin B, and many more.

Another simple amino-acid-derived metabolite is dipicolinic acid (pyridine-2,6-dicarboxylic acid) (Fig. 3d), a by-product of the lysine biosynthetic pathway. The synthesis of dipicolinic acid in fungi is thought to be similar to that in bacteria and may occur by condensation of aspartyl-β-semialdehyde with pyruvate to form 2-keto-6-aminopimelic acid, followed by cyclization to form 3,5-dihydro-4-hydroxyl-dipicolinc acid, a hypothetical precursor to dipicolinic acid (109, 110). It is a major component of bacterial endospores, and it is also found in *Penicillium* spp. and various entomopathogenic fungi of the Hypocreales (111). Its role as an extracellular metabolite in *Penicillium* spp. is thought to involve scavenging of external metal ligands, e.g., Mg^{2+}, while in hypocrealean fungi, it may act as an insect toxin (111).

The nonproteinogenic amino acid L-3,4-dihydroxyphenylalanine (L-DOPA) (Fig. 3e) can function as a

secondary metabolite and a virulence factor in fungi. *Cryptococcus neoformans* causes invasive infections in patients with immune systems impaired by AIDS, cancer chemotherapy, or immunosuppressive drug treatments. The fungus produces melanin by transforming shikimic acid to aromatic amino acids, resulting in the formation of L-DOPA. Melanization occurs during growth in its natural habitat in bird excrement and during host infection by the action of a laccase on a variety of precursors, including L-DOPA, D-DOPA, dopamine, and norepinephrine (112). Disruption of genes essential for melanin production in *C. neoformans* caused a reduction in fungal dissemination and lethality in murine infection models (113, 114). Tyrosol (Fig. 3f) is another amino acid-derived metabolite produced by *Candida albicans*, presumably through the decarboxylation of tyrosine; it acts as a quorum-sensing molecule by stimulating the yeast-to-hypha conversion (115).

3-Nitropropanoic acid (3-NPA) (Fig. 3g) has been widely found in some leguminous plants (116) and in some fungi, including *Penicillium* (117) and *Aspergillus* (118) spp. and as a necrotrophic toxin from *Septoria cirsii* (119). Consumption of moldy sugar cane contaminated with 3-NPA produced by *Arthrinium* spp. has led to human deaths in China (120, 121). Its cell toxicity is caused by irreversible inhibition of mitochondrial succinate dehydrogenase (122). Current proposals regarding its biosynthesis are based on the incorporation of ^{14}C-, ^{15}N-, and ^{18}O-labeled substrates into 3-NPA and its derivatives in cultures of *Penicillium atrovenetum*. These experiments showed that ^{14}C is incorporated when the fungus is fed L-[4-^{14}C]aspartate and that an ammonium ion rather than nitrate is involved in forming the nitro group of 3-NPA. The process possibly occurs through a series of oxidations resulting in conversion of the amino group of aspartate to a nitro group with concomitant loss of the aspartate C1 as CO_2. *Phomopsis* species and other endophytic strains excrete high levels of 3-NPA in their culture media, thus raising questions about whether 3-NPA accumulation detected in living plant tissues could be of fungal origin (123).

To resist high-intensity ultraviolet (UV) radiation, cyanobacteria and fungi have evolved biosynthetic pathways to produce hybrid amino acid-containing metabolites called mycosporines to protect vital macromolecules from degradation (124, 125). Mycosporine-like amino acids, e.g., mycosporine serinol (Fig. 3h), were first identified in fungi because of their role in mediating UV-induced sporulation (126). Mycosporine-like amino acids are small (<400 molecular weight), colorless, water-soluble compounds composed of a cyclohexenone or cyclohexenimine chromophore that is derived from a pentose phosphate pathway intermediate, e.g., sedoheptulose 7-phosphate, conjugated with the amino group of an amino acid or its imino alcohol. They are widespread in both the Ascomycota and Basidiomycota (127). Along with melanins, mycosporines absorb UV light, providing photo-protection for the organism. They may also play roles in osmotic regulation (11) and defense against oxidative stress (12). Recently, the biosynthetic pathways for mycosporine and mycosporine-like amino acid formation have been elucidated in cyanobacteria (128) and Actinomycetes (11). Genomic analysis revealed that orthologous biosynthetic potential exists in fungi, suggesting that fungal mycosporines are likely to be encoded by similar gene clusters (128).

Quorum sensing is a means of cooperative intercellular communication via accumulation of small messenger molecules in the environment. As the number of cells increases, the production of messenger molecules increases, and when messenger concentration reaches a threshold, the behavior of the population changes. Quorum sensing was first discovered in various bacteria, but more recently it has been recognized in fungi and has been shown to be relevant for the control of virulence factor expression in *C. albicans*. Supernatants from 2-day cultures of *C. albicans* inhibit the switch from yeast to hyphal growth in new cultures (129). Farnesol (Fig. 3i), a linear sesquiterpene alcohol derived from mevalonate, is the causative agent. *C. albicans* continuously releases farnesol into the environment during growth so that its concentration in the medium is roughly correlated with cell density (129). Farnesol is thought to be secreted by the cells to inhibit germ tube formation in the late stage of biofilm development where there is a high density of interwoven filamentous cells, and therefore, it promotes the dispersal of yeast cells to colonize new environments. Not only is morphological switching essential to *C. albicans* pathogenesis, but farnesol can act as a virulence factor of *C. albicans* by negatively affecting innate immune cells to promote inflammation and a nonprotective and dysfunctional response that fails to activate T cells and produce Th1-promoting cytokines (130). Farnesol can modulate the activity of a transcriptional regulator in *Pseudomonas aeruginosa* when applied as a pure compound or when produced during *C. albicans* coculture, resulting in decreased production of the secondary metabolites pyocyanin and *Pseudomonas* quinolone signal (2-heptyl-3-hydroxy-4-quinolone) while diminishing swarming (131, 132). Farnesol has also recently been implicated in mediating the yeast-hyphal transition

in *Ophiostoma piceae* (133). Additionally, farnesol can induce apoptosis in *Aspergillus* and mammalian cells and inhibits conidial germination and growth in a broad array of fungi and bacteria. Although farnesol is derived from farnesyl pyrophosphate, a central metabolite in steroid and terpene metabolism, the enzyme responsible for hydrolysis to farnesol remains uncharacterized. However, enzyme extracts from *C. albicans* can catalyze formation of farnesol (134).

Nucleoside analogues further exemplify modified primary metabolites that function like secondary metabolites. Cordycepin (3′-deoxyadenosine) (Fig. 3j) is a naturally occurring toxic adenosine analogue and one of the bioactive constituents isolated from *Cordyceps militaris* (135) and *Ophiocordyceps sinensis* (136). Cordycepin enters the cell and is converted to 3′-dATP, which functions as both an RNA chain terminator and a competitive inhibitor of polyadenylate polymerase via interference with subunits of the cleavage and polyadenylation complex (137, 138). A putative biosynthetic pathway for cordycepin was recently proposed based on transcriptome analysis of *O. sinensis*. The analysis identified a putative adenosine kinase, an adenylate kinase, and a 5′-nucleotidase that mediate phosphorylation and dephosphorylation in the process, followed by reduction of adenosine diphosphate to 3′-dADP by a putative ribonucleotide reductase and dephosphorylation to cordycepin (139).

Kojic acid (Fig. 3k) was one of the earliest fungal metabolites to be characterized. It was first isolated from solid-state koji cultures of *Aspergillus oryzae* on rice (140). Kojic acid is a weak, broad-spectrum antibacterial (141), antioxidant, and tyrosinase inhibitor, but its role in the fungal life cycle remains obscure. Early isotope labeling studies suggested that glucose was converted directly to kojic acid by only two or three enzymes and that polyketide or amino acid pathways were not involved (142–145). Recently, its biosynthetic genes were identified by statistical analysis of comparative gene expression profiles (146). Biosynthesis was associated with a small coregulated gene cluster consisting of an oxidoreductase (*kojA*), a transporter (*kojT*), and a transcription factor (*kojR*).

STRUCTURAL CLASSES OF SECONDARY METABOLITES

Shikimate-Derived Metabolites

Shikimate is the deprotonated form of shikimic acid—a trihydroxy cyclohexenecarboxylic acid that provides the carbon skeletons for the aromatic amino acids L-tryptophan, L-phenylalanine, and L-tyrosine via a multistep process leading through chorismate (the shikimate pathway) (147). Thus, any metabolites that incorporate aromatic amino acids in their construction are effectively shikimate-derived. The shikimate pathway is well studied because these essential aromatic amino acids are not produced by mammals and thus constitute important dietary requirements (148). This ancient eukaryotic pathway is highly conserved, because it is found in fungi, bacteria, and plants, and is to a substantial degree an important process involved in primary amino acid metabolism. However, the pathway has undergone diverse evolutionary processes leading to branches that produce a considerable array of secondary metabolites as well, many of which are aromatics and quinones. As noted above, shikimate is also involved in the formation of melanins, as well as mycosporine and mycosporine-like amino acids. Chorismate and subsequent products formed via the shikimate pathway are precursors for the biosynthesis of important isoprenoid quinones such as ubiquinones and menaquinone, which serve important roles in electron transport and as antioxidants. Secondary metabolic products of the pathway are particularly common in plants (flavonoids, coumarins, phenylpropanoids). Fungi tend to display somewhat different kinds of preferences among their shikimate-derived secondary metabolic products (149), because the enzymatic process in fungi is somewhat different from that in plants and bacteria. For example, in fungi, a single complex (AroM) performs five consecutive reactions of the seven basic steps in the pathway, converting 3-deoxy-D-arabino-heptulosonate-7-phosphate (initially formed from phosphoenol pyruvate and D-erythrose-4-phosphate) to 5-enol pyruvyl-shikimate 3-phosphate, which is converted to chorismate in the final step (150).

Simple aromatics often encountered among the fungi, such as benzoic acid derivatives, are commonly derived from this pathway and could be considered as further examples of rudimentary secondary metabolites. *Para*- and *ortho*-hydroxylation patterns tend to occur among shikimate-derived aromatics, in contrast with the *meta*-hydroxylation patterns typical of phenolics arising via the polyketide pathway, and can help in deducing the likely biosynthetic origin of an aromatic compound or unit. More complex shikimate-derived metabolites have been implicated in a variety of roles. For example, involutin (Fig. 5a), a diarylcyclopentenone secreted by the ectomycorrhizal fungus *Paxillus involutus*, reportedly plays a key role as an Fe^{3+} reductant in Fenton-based decomposition of organic matter by mobilizing embedded nutrients,

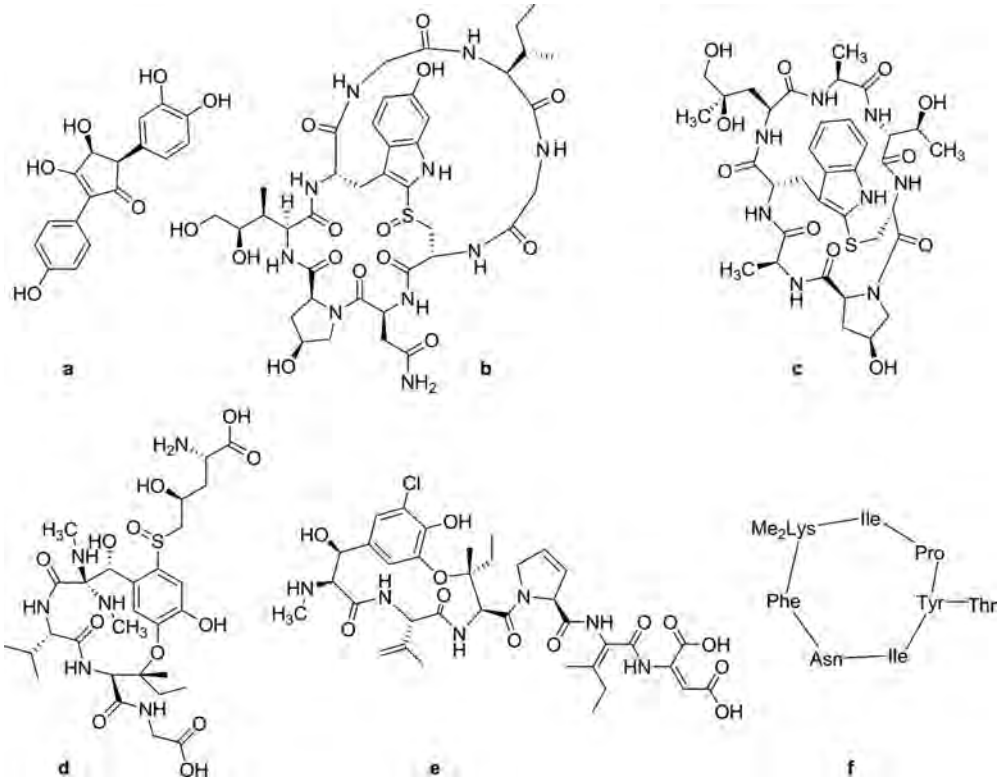

Figure 5 Some fungal metabolites derived from the shikimic acid pathway and ribosomally synthesized and posttranslationally modified peptides (RiPPs). (**a**) Involutin. (**b**) α-Amanitin. (**c**) Phalloidin. (**d**) Ustiloxin A. (**e**) Phomopsin A. (**f**) Epichloëcyclin A.

thereby increasing their accessibility to the host plant (151, 152). Structurally related metabolites, including aryl benzyl lactones such as pulvinic and vulpinic acids, and diaryl quinones, such as polyporic acid, are often encountered as lichen or basidiomycete metabolites (42, 153). *A. terreus* builds related products from *p*-hydroxyphenyl pyruvic acid, e.g. butyrolactones and aspulvinones, from indole pyruvic acid, e.g., asterriquinones (154), and from phenyl pyruvic acid, e.g., phenguignardic acid (155). These types of compounds serve as pigments and antioxidants and can show other bioactivities. Compounds of mixed biogenetic origin that incorporate simple aryl substituents such as phenyl groups (e.g., the antifungal strobilurins, Table 1) are also commonly constructed in part from shikimate-derived precursors.

RiPPs: Ribosomally Synthesized and Posttranslationally Modified Peptides

The influx of sequenced fungal genomes during the past decade has revealed that certain fungal peptide toxins are encoded directly in precursor proteins that are ribosomally synthesized and posttranslationally modified to create toxic peptides (RiPPs). RiPPs are produced in the *Eukaryota*, *Bacteria*, and *Archaea*. Their biosynthetic genes are ubiquitous in genomes, and their products exhibit a vast structural diversity (106, 156, 157). Many RiPPs have cyclic structures that confer the advantage of evading degradation by exopeptidases while increasing structural rigidity that enhances accuracy for binding to their molecular receptors, leading to high binding affinity and biological activity. Furthermore, cyclic RiPPs can often resist denaturation upon heating; thus, their activity is often unaffected by cooking.

The amatoxins and phallotoxins are infamous mushroom toxins produced by various species in the genera *Amanita*, *Galerina*, *Lepiota*, and *Conocybe* (Agaricomycotina) (158–160). They consist of N-to-C cyclized peptides of eight and seven residues, respectively, that also contain several other posttranslational modifications including an unusual 2′-indole thioether bond between the Cys and Trp residues, resulting in a unit referred to as tryptathionine that forms an inner ring structure. The genes (*AMA1* and *PHA1* in *Amanita bisporigera*) encode proproteins of 35 and 34 amino

acids, respectively, in which the amino acid sequences found in the mature toxins are flanked by conserved amino acid sequences. The proproteins are processed by proteolytic cleavage to produce linear peptides comprising the amino acids found in the mature toxins (161). The precursor peptides contain a 10-residue leader peptide, an 8- or 7-residue core peptide for amatoxins and phallotoxins, respectively, and a C-terminal recognition sequence. The tryptathionine in the amatoxin α-amanitin (Fig. 5b) is oxidized to the sulfoxide and hydroxylated on the indole. Other subunits displaying posttranslational modifications include a bishydroxylated isoleucine and *cis*-4-hydroxy proline. Despite their similar structures, the biological activities of amatoxins and phallotoxins are surprisingly different. Amatoxins are potent inhibitors of RNA polymerase II. Phalloidin and phallacidin bind to F-actin (162); thus, they have been developed into commercial kits in which they are conjugated with fluorescent dyes to visualize the cytoskeleton.

RiPPs are well known in other organisms, but several recent studies point to their widespread occurrence in the Ascomycota. Ustiloxins (e.g., ustiloxin A; Fig. 5d) are toxic cyclic peptides from rice false smut, a rice disease caused by *Villosiclava* (=*Ustilaginoidea*) *virens* (163), and also have been identified in *Aspergillus flavus* strains cultured on maize (164). They are generally constructed of a Tyr-Val/Ala-Ile-Gly tetrapeptide sequence and cyclized via an ether linkage of the side-chains of modified tyrosine and isoleucine units. It was long thought that ustiloxins A and B were biosynthesized in *V. virens* by a nonribosomal peptide synthetase (165). Analysis of coregulated transcripts in *A. flavus* identified a 15-gene cluster. The cluster's core gene, *ustA*, encoded UstA, a peptide with 16 repeats of a Tyr-Ala-Ile-Gly tetrapeptide unit that is converted into the cyclic moiety of ustiloxin B (164, 166). This highly repetitive sequence for the core peptide indicates that the *ustA* gene might have undergone selection for increased production of ustiloxin B. Adjacent to *ustA* in the gene cluster are gene(s) that encode a peptidase (*ustP1* and *ustP2* as a putative single gene), indicating that a peptide sequence served as the enzyme's substrate. Norvaline is then transferred to the activated aromatic ring of the ustiloxin tyrosine residue by a glutathione S-transferase (UstS). Sequence similarity searches with the ustiloxin biosynthetic gene cluster from *A. flavus* were used to probe the genome of *V. virens* (167) to identify a 15-gene cluster containing a gene encoding a precursor protein with five Tyr-Val-Ile-Gly and three Tyr-Ala-Ile-Gly repeats for ustiloxins A and B, respectively.

Phomopsins (e.g., phomopsin A; Fig. 5e) comprise a family of cyclic hexapeptide mycotoxins produced by *Diaporthe leptostromiforme* that infects lupins (*Lupus* spp.) (168). Phomopsins are comprised of a 13-membered macrocyclic ring formed by an ether bridge linking an isoleucine residue to the aromatic ring of a highly modified tyrosine unit. Lupin forage contaminated with phomopsins causes lupinosis, a liver disease of sheep and cattle. Phomopsins are potent microtubule inhibitors, and their toxicity is caused by their binding of the phomopsin tripeptide side chain to the vinca domain of tubulin, resulting in potent antimitotic activity (169). The ustiloxins contain a similar modified-tyrosine-containing macrocycle. The putative precursor peptide sequence (YVIPID) was used to search the genome of *D. leptostromiforme*, resulting in the identification of a precursor peptide gene, *phomA*, whose product contained five repeats of short peptides with the sequence YVIPID. The Phom gene cluster also included a copper-containing tyrosinase (PhomQ), an S41 family peptidase (PhomP1), an *S*-adenosylmethionine-dependent methyltransferase (PhomM), and other functionally unknown proteins (170). Disruption of PhomQ, the tyrosinase responsible for formation of the cyclic scaffold of phomopsins, abolished phomopsin biosynthesis.

A combination of two functionally unknown genes (*ustYa* and *ustYb*) and the *ust B* precursor gene were used to search genomes of other *Aspergillus* spp. At least 94 sets of precursor candidates were computationally identified and classified, indicating that RiPPs are likely to be widespread in the Ascomycota. Furthermore, one of these newly identified candidate RiPPs with two types of repeated sequences was identified by gene inactivation in *A. flavus* and found to be a novel bicyclic peptide that was named asperipin-2a (171). Similarity searches with the PhomA, PhomQ, and PhomM homologous proteins identified an additional 27 gene clusters similar to that involved in phomopsin biosynthesis in a variety of ascomycetes (170). Furthermore, Phom-like gene clusters were recognized in strains of *Beauveria bassiana* and *Metarrhizium aniosipliae*, leading to the fermentation, purification, and characterization of new phomopsin A analogs from *B. bassiana* (phomopsin Z) and *Metarhizium anisopliae* (metarisin A and B).

One of the most highly expressed *in planta* fungal transcripts in *Epichloë* endophyte-infected grasses, designated *gigA* (for grass-induced gene), was identified from tall fescue and perennial ryegrass associations (172). The protein sequence encoded by *gigA* was predicted to be a variable 27-amino acid repeat with an

N-terminal signal sequence, indicating that it should be translocated into the Golgi apparatus. The region adjacent to *gigA* contained a kexin protease gene for processing GigA for the liberation of multiple cyclic nonapeptides, the epichloëcyclins, into the host plant. The structures of epichloëcyclins A to E (e.g., epichloëcyclin A; Fig. 5f) were determined in part by the sequences of individual repeat units within the GigA protein, which differed between fungal strains and within the proprotein itself. Such processing of a single protein into multiple different small peptides is a remarkable and novel mode for generating chemical diversity. Gene deletion of *gigA* led to the elimination of all epichloëcyclins, with no conspicuous phenotypic impact on the host grass (172). The *gigA* gene cluster has also been identified in other plant-symbiotic Clavicipitaceae including *Periglandula ipomoeae* and *Atkinsonella hypoxylon*, suggesting a possible widespread bioactive role in plant-fungus symbioses.

Polyketides

Polyketides are the largest and most structurally diverse group of fungal secondary metabolites. Their carbon scaffolds share a common biosynthetic origin and are derived from the polymerization of short-chain carboxylic acid units (e.g., acetate, malonate). Polyketides are biosynthesized by large multifunctional enzymes called polyketide synthases (PKSs) and can be classified into four main types according to the catalytic domains and enzymatic mechanisms involved in their formation (173). Fungal PKS enzymes are closely related to fatty acid synthases. In the Ascomycota and Basidiomycota, the prevalent types of PKSs belong to the iterative type I class in which the domains act repetitively on the growing polymer during each chain extension cycle. The carbon backbones are assembled by repetitive decarboxylative Claisen condensation catalyzed by β-ketoacylsynthase domains and employ malonyl thioesters as extender units. An acyl carrier protein domain acts as an anchor where the growing polyketide chain is covalently tethered. After each chain-extension step, the polyketide backbone is increased by one "ketide" unit. Additional domains including β-ketoreductases, dehydratases, and enoylreductases can selectively modify the newly formed polyketide. Unlike fatty acid synthases, in which most or all of the β-keto positions are completely reduced to methylenes, resulting in a fatty acyl product, the tailoring domains in PKSs act in preprogrammed patterns at each β-position, resulting in products of varied oxidation states. Furthermore, one or more methyl groups may be introduced at the α-position of the growing chain by C-methyltransferase domains. Finally, the fully extended chain is usually offloaded or cyclized by a thioesterase domain, or in other cases, a terminal acyl carrier protein domain transfers the tethered product to an acyl transferase or other protein that shuttles it and covalently links it with another biosynthetic product. Thus, the collection of domains functions in an iterative fashion and follows integral programming rules that determine chain length, cyclization, reductive tailoring, and other structural features (174, 175).

Fungal iterative PKSs can be further grouped into three major subtypes: nonreducing (or aromatic) (NR-PKS), partial reducing (PR-PKS), and highly reducing (HR-PKS) PKSs, depending on the degree of programming and extent of α- and β-carbon processing. NR-PKSs are among the best-understood types of fungal PKSs. Griseofulvin (Fig. 6a, Table 1) was first characterized from *Penicillium griseofulvum* in 1939 and later was recognized for its antifungal effects, resulting in it being named the "curling factor" because it induced curling of fungal hyphae (176). Griseofulvin was developed at Glaxo Laboratories for the treatment of ringworm and other infections by dermatophytes. Genome scanning and gene deletion studies established that an NR-PKS, *gsfA*, encodes biosynthesis of the griseofulvin heptaketide backbone and that gsfI is the halogenase involved in chlorination of the final product (177, 178). Far fewer PR-PKSs have been characterized, with the 6-MSA (Fig. 6b) PR-PKS being a biosynthetically pivotal and widespread gene. The 6-MSA PR-PKS from *Penicillium patulum* was the first PKS to be purified and sequenced, and 6-MSA is an intermediate in the biosynthesis of the mycotoxin patulin (179). The *atX* gene from *A. terreus* and the *PKS2* gene from *Glarea lozoyensis* also encode for the 6-MSA PKS (180, 181). A fungal PR-PKS is responsible for the synthesis of the widespread metabolite (*R*)-mellein (Fig. 6c) in *Parastagonospora nodorum* (182) and probably many other fungi. It was proposed that biosynthesis of (*R*)-mellein was highly parallel to that of 6-MSA, requiring an additional chain elongation and keto reduction. These PR-PKS genes are likely important in encoding the biosynthesis of other dihydroisocoumarins and possibly the mycotoxin ochratoxin (183). Phylogenetic analyses have shown that the 6-MSAs and other uncharacterized PR-PKSs are more distantly related to the NR- and HR-PKSs and more closely resemble bacterial modular type I PKSs, suggesting a common origin from bacteria (184). However, divergence between the 6-MSA- and mellein-type PR-PKSs likely occurred during the course of fungal radiation (182).

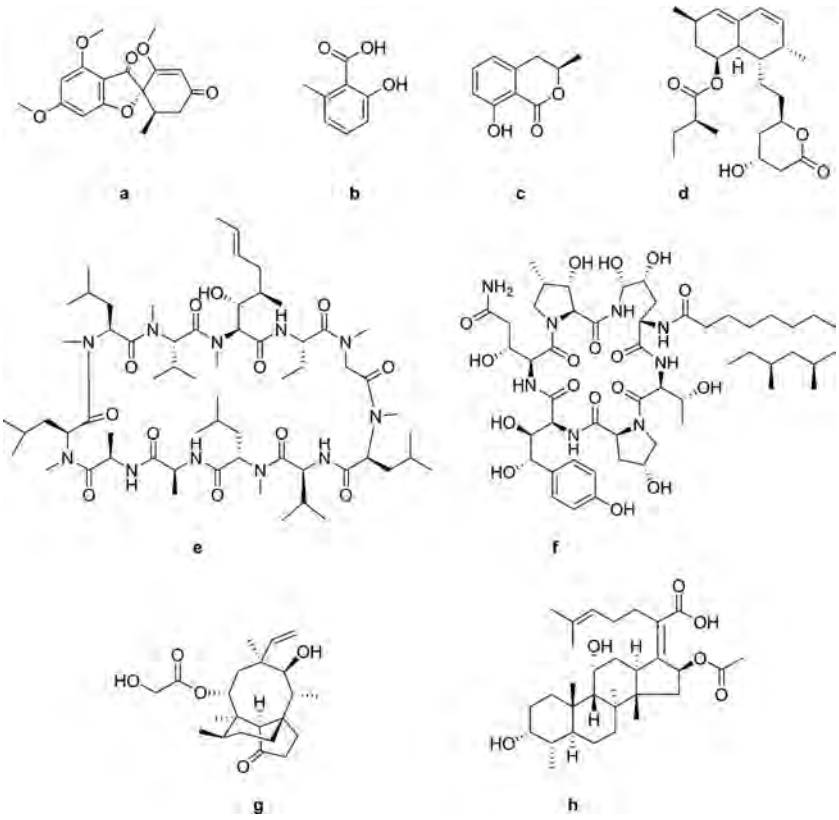

Figure 6 Some fungal polyketides, nonribosomal peptides, and terpenoids. (**a**) Griseofulvin. (**b**) 6-Methyl salicylic acid. (**c**) (R)-Mellein. (**d**) Lovastatin. (**e**) Cyclosporine A. (**f**) Pneumocandin A_0. (**g**) Pleuromutilin. (**h**) Fusidic acid.

The HR-PKSs have a higher degree of complexity in their programming relative to that of the NR-PKSs. T-toxin, the main virulence factor involved in southern corn leaf blight, a devastating disease caused by *Drechslera heterostrophus* race T that attacks maize, is a typical HR-PK. It consists of a linear polyketide whose biosynthesis is encoded by a nine-gene cluster that includes two cooperating HR-PKSs (185, 186). Fumonisins comprise a major group of mycotoxins produced by *Fusarium* spp. and certain black *Aspergillus* spp. (187). They act as ceramide synthase inhibitors. Coexpression of 15 contiguous genes defines a fumonisin biosynthetic gene cluster in *Fusarium moniliforme*, of which FUM1 is an HR-PKS that assembles the fumonisin backbone (19).

The compactin and lovastatin biosynthetic pathways are among the best-studied examples of HR-PKSs. These metabolites were among the first natural product enzyme inhibitors discovered for use in human health. As early as the mid-1960s, the biochemical pathway of cholesterol biosynthesis was fairly well understood, and the enzyme hydroxymethylglutaryl-CoA reductase (HMGR) was known to convert HMG-CoA to the intermediate mevalonate. Akira Endo at Sankyo in Japan developed a three-step assay (two phenotypic screens and a target-based assay) using liver tissues extracted from rats to screen fermentation broths for natural products that specifically inhibited HMGR (188). Using this approach, Endo discovered the compound ML-236B, later named compactin (Table 1), from a strain of *P. citrinum* (189). Although compactin was not developed as a drug, Endo and a group at Merck in the United States independently used strategies analogous to that used to find compactin to discover lovastatin, a methylated analog of compactin, from two fungi, *Monascus ruber* and *A. terreus*, respectively (188). Merck developed lovastatin (Fig. 6d), which became the first-in-class member of the statins (190), compounds that are widely and successfully used to treat hypercholesteremia. While this natural product was highly effective, a slight structural modification led to Zocor (simvastatin), a blockbuster drug product peaking at over $5 billion/year in sales during its patent lifetime. Using these compounds as models, chemists at

Warner-Lambert designed the chemically distinctive compound atorvastatin (Lipitor), which became the best-selling drug of all time, with more than $125 billion in sales over its patent lifetime. These and other second-generation synthetic derivatives or analogues of compactin and lovastatin continue to be among the world's best-selling drugs.

Closely related to the products of HR-PKSs are a broad range of hybrid polyketide-amino acid metabolites formed by fusion of an HR-PK to an amino acid-binding domain and known as iterative PKS-NRPSs (174, 191). Functionally characterized fungal iterative PKS-NRPS hybrid gene clusters have been linked to the biosynthesis of tetramic acid-containing metabolites such as equisetin, the actin-binding cytochalasins, the immunosuppressive agent pseurotin A, the nematocidal thermolides, and the mycotoxins fusarin C and cyclopiazonic acid, among others.

NRPs: Nonribosomal Peptides

The Fungi offer one of the richest and most highly elaborated pools of NRPs among all organism types. This diversity reaches its zenith in the filamentous Ascomycota (192, 193). The corresponding NRPS megaenzymes synthesize a wide range of biologically active natural peptide compounds. NRPS-derived siderophores are involved in iron transport, storage and homeostasis, and virulence toward plants and animals (194–196). NRPSs are responsible for the biosynthesis of the iconic natural product-based drugs penicillins, cephalosporins, cyclosporine A, and echinocandins (Table 1). NRPSs are similar to PKSs in their modular structure and share an assembly line thiotemplate mechanism to achieve peptide synthesis (197). Like PKSs, minimal NRPS modules have an analogous set of three core functional domains: adenylation (A) domains that recognize and activate a specific amino acid or amino acid derivative by adenylation with ATP, peptidyl carrier protein domains (also known as thiolation [T] domains) that bind the activated substrate to a 4′-phosphopantetheine with a thioester bond and shuttle the substrate, and condensation (C) domains that catalyze peptide bond formation between adjacent monomer units on the NRPS complex.

The selection of a highly diverse set of monomers for peptide synthesis, including a plethora of nonproteinogenic amino acids, contributes to the overall complexity of NRPs. Although exceptions occur, generally, fungal multimodular NRPSs follow the collinearity rule, in which a complete A-C-T module corresponds to one amino acid in the NRP amino acid sequence. Further structural diversification accrues during chain initiation, chain elongation, and chain termination of NRP biosynthesis. Some NRPSs, e.g., echinocandins, carry an N-terminal T and C domain (or starter C domain) before the first NRPS module to prime the synthesis of the peptide portion by addition of an aliphatic acyl chain. NRPSs may incorporate other catalytic domains which modify the substrate during biosynthesis, including (i) an epimerization (E) domain that inverts the chirality of the last amino acid in the growing peptide from the L- to the D-configuration, (ii) an *N*-methylation (M) domain (methyltransferase) that transfers a methyl group from an *S*-adenosylmethionine unit to the α-amino group of an amino acid substrate, and (iii) a specialized domain termed a cyclization (C) domain which catalyzes internal cyclization to oxazoline or thiazoline rings constructed from cysteine, serine, or threonine units. Often, additional tailoring enzymes may lie adjacent to the core NRPS and modify either the monomers or the final peptide product by acylation, glycosylation, hydroxylation, or halogenation. Offloading and release by macrocyclization is a common modality in fungal NRPSs and constrains the peptide backbone in a biologically active conformation. Fungal NRPSs characterized thus far universally terminate macrocyclic peptide synthesis with a condensation-like C_T domain that catalyzes the cyclization reaction.

The rapid development of therapeutic methods and industrial-scale processes for production of the β-lactam antibiotic penicillin during the 1940s were arguably the most significant milestones in the history of drug discovery research (198). Substantial increases in the human life span can be traced back to the introduction of the β-lactam antibiotics penicillin and cephalosporin and their modern derivatives (Table 1). The penicillin and cephalosporin biosynthetic gene clusters are among the best characterized of all NRPSs (199). Recently, the penicillin gene cluster from *Penicillium chrysogenum* was reconstituted as a single synthetic three-open reading frame polycistronic gene, and the construct was placed under the control of a single promoter (200). The open reading frames were separated by a sequence encoding the viral 2A peptide, which resulted in cotranslational cleavage, hence resulting in the formation of independent enzymes. After yeast-mediated homologous recombination, random genomic integration of this construct resulted in penicillin production in the heterologous host *A. nidulans* (200).

The introduction of the undecapeptide immunosuppressant drug cyclosporine A (Fig. 6e, Table 1) transformed and enabled the field of organ and tissue transplant methods. The genomic sequence of *Toly-*

pocladium inflatum and RNA-Seq transcriptome analysis has recently defined the complete gene cluster for cyclosporine biosynthesis (201). The formidable cyclosporine NRPS SimA, with its 11 amino acid-activating modules, seems to have evolved via duplication of simpler NRPSs that are apparently shared among other fungi of the Hypocreales. Several other NRPSs responsible for the biosynthesis of smaller cyclic depsipeptides in Hypocrealean fungi, such as enniatin, beauvericin, and bassianolide synthetases, and in part destruxin synthetase, appear to form a monophyletic lineage within the SimA clade (201). The biosynthetic pathways for the pneumocandins (e.g., Fig. 6f) in *G. lozoyensis* (202, 203) and echinocandin B in *Aspergillus pachycristatus* (204, 205), the starting metabolites for the semisynthesis of the lipopeptide antifungal drugs Cancidas and Eraxis, respectively (Table 1), have been mapped at the genetic level and functionally characterized to some extent. Phylogenetic studies from pathway gene clusters from multiple echinocandin-producing fungi have demonstrated that the echinocandin gene clusters have a common ancestor and formed a unique lineage among the families of fungal NRPSs (206).

Terpenoids

Fungi of the Ascomycota and Basidiomycota are prolific producers of terpenoids. In the Basidiomycota, terpenoids, especially diterpenoids and sesquiterpenoids, are the dominant biosynthetic class of secondary metabolites. In-depth information on the spectrum of fungal terpenoids can be found in recent reviews (26, 207, 208). Terpenoids are assembled from five-carbon precursor molecules: isopentenyl diphosphate and/or dimethylallyl diphosphate. In fungi, these two isomers are derived from acetyl-CoA via the mevalonate pathway (209). Condensation of isopentenyl diphosphate and dimethylallyl diphosphate monomers yields branched hydrocarbons in multiples of five carbons that are termed as being constructed of isoprene or prenyl units: geranyl pyrophosphate (C_{10}), farnesyl pyrophosphate (C_{15}), geranylgeranyl pyrophosphate (C_{20}), squalene (C_{30}), and phytoene/lycopene (C_{40}). These linear prenyl chains are further processed by prenyl transferases, terpene cyclases, and terpene synthases, resulting in a cascade of dephosphorylation, further condensations, and cyclizations which configure the carbon skeleton of the different classes of terpenoid natural products. Occasional loss of one or more methyl groups during biosynthesis results in norterpenoids. In addition, polyketide-, sugar-, or amino acid-derived elements are sometimes incorporated to yield molecules of mixed biosynthetic origin. For example, a hybrid terpenoid-polyketide is often referred to as a meroterpenoid. We mention only a few representatives from this vast class of fungal metabolites below.

The topical antibacterial antibiotic retapamulin is synthesized from the diterpenoid pleuromutilin (Fig. 6g; Table 1) produced by the mushroom *Clitopilus passeckerianus* and some related species (210, 211). A patent application from Sandoz AG first described the pleuromutilin pathway as consisting of six transcriptionally coregulated genes, including a labdane-type diterpene synthase gene, a putative geranylgeranyl diphosphate synthase gene, three cytochrome P450 monooxygenase genes, and a putative acyltransferase-encoding gene (212). The cDNA sequences of seven genes (*Pl-ggs*, *Pl-cyc*, *Pl-atf*, *Pl-sdr*, *Pl-p450-1*, *Pl-p450-2*, and *Pl-p450-3*) constituting the gene cluster in *C. passeckerianus* were cloned and placed under control of constitutive promoters for expression in *A. oryzae* (213). One of the *A. oryzae* transformants gave a remarkable 20-fold increase in pleuromutilin titers compared to the native host. This outstanding achievement represents the first successful heterologous expression of an entire basidiomycete secondary metabolite gene cluster in an ascomycete host and paves the way for further improvement of the pleuromutilin-producing *A. oryzae* strain through classical mutagenesis and other genetic manipulations (213).

Fusidic acid (Fig. 6h, Table 1) is a fusidane-type triterpenoid produced by *Acremonium fusidioides* that has long been used as an oral antibiotic for treatment of Gram-positive bacterial infections (214). Although labeled isotope studies have established that its precursor is squalene (215), its gene cluster has yet to be characterized. Nevertheless, its biosynthesis is likely to be initiated by an oxidosqualene synthase similar to that found in *A. fumigatus, Metarhizium anisopliae* (216), and *Sarocladium caerulens* (217), all of which produce the closely related helvolic acid. In *A. fumigatus*, the helvolic acid gene cluster has been characterized and comprises a gene for an oxidosqualene cyclase (*AfuOSC3*) that is colocalized with genes of cytochrome P450 monooxygenases, a short-chain dehydrogenase/reductase, and an acyltransferase, which presumably function in triterpene-tailoring steps (218, 219).

The genetic basis of the biosynthesis of trichothecene-type mycotoxins, which share a common tricyclic 12,13-epoxytrichothec-9-ene core structure, has been identified in fusaria and other species of the Hypocreales (220, 221). The trichothecene family also illustrates the incompleteness of our knowledge of the distribution of fungal biosynthetic gene clusters; trichothecolone acetate was recently discovered in the

apple sooty blotch fungus *Microcyclospora tardicrescens* (222). Indole-diterpenoid metabolites have been investigated intensively because of their neurotoxic and other biological effects. They are distributed sporadically among fungi of the Sordariomycetes and Eurotiomycetes. These metabolites consist of a diterpene backbone derived from geranylgeranyl diphosphate and an indole moiety derived from indole-3-glycerol phosphate (223). The biosynthetic gene clusters for paxilline (224, 225), aflatrem (226, 227), the lolitrems (228), penitrem (229), and terpendole E (230) have been functionally characterized. Finally, the heterologous expression of the products of several synthetic ascomycete monoterpene and sesquiterpene synthases has been achieved (231, 232), resulting in *in vitro* production of potentially valuable terpenoids, e.g., eucalyptol, pinenes, guaiene, caryophyllene, chamigrene, and gurjunene, for use as fuel additives, fragrances, and other commodities.

READING THE SECONDARY METABOLITE MENU AND BIOINFORMATICS-BASED DISCOVERY OF NATURAL PRODUCTS

Knowledge of microbial secondary metabolites is highly advanced due to the resources invested in controlling microbial toxins, crop virulence factors, and discovery of their chemical applications in medicine and agriculture. Studies of natural products produced by fungi have provided powerful probes for cell biology and drugs useful in medicine. Their importance is evidenced by their prominence as reagents and metabolic blockers for cellular metabolism and for labeling cell macromolecular structures. Understanding the biosynthetic logic of the principal pathways and how they operate can often enable straightforward recognition of the biogenetic origin of a given secondary metabolite. The metabolic precursors of metabolites can also be identified by feeding strains isotopically labeled precursors. Previous work in this area has served as the foundation for modern genetic biosynthetic studies (27, 233). Computational methods for decoding secondary metabolite pathways from sequenced genomes have transformed natural products research and have begun unfolding the roadmap to secondary metabolite biosynthetic genes and their regulation. Rapid advances in technology for genome sequencing and analysis are accompanied by parallel advances in relevant aspects of analytical chemistry. Applications of new techniques and informatics tools to mass spectrometric analysis are effectively expanding the field of metabolomics to encompass secondary metabolites (234, 235). These techniques are also fostering efforts to explore the significance of secondary metabolites, e.g., by detecting and localizing them *in situ* during interspecies interactions (236). Similarly, nuclear magnetic resonance capabilities continue to improve in terms of sensitivity, speed, pulse sequence development, automated interpretation, and amenability to mixture analysis (237). For example, the gene clusters and essential biosynthetic steps have been characterized for most major mycotoxins and fungus-derived drugs. The tools are sufficiently accessible that discoveries of important new microbial metabolites are now accompanied by characterization of the corresponding encoding gene clusters (238, 239). Within the next few years, we expect to see a near complete catalogue of gene clusters of most of the important fungal secondary metabolites (32).

Until recently, discovery of fungal metabolites was largely an empirical process that was supported by ecological, phylogenetic, and physiological clues to what fungal strains were most likely to produce secondary metabolites and by knowledge of which laboratory conditions would most likely produce metabolite-rich fermentations. The universe of known fungal metabolites has been further expanded from studies of fungi of the Basidiomycota and Ascomycota that produced large or numerous fruiting structures that could be collected in the field and then extracted directly for chemical studies. Metabolites characterized directly from fruiting bodies of ectomycorrhizal fungi in many genera, e.g., *Cortinarius*, *Boletus*, *Lactarius*, *Hydnellum*, *Cantharellus*, and those directly extracted from lichenized fungi have provided a vast catalogue of secondary metabolites from species that have proven to be unculturable in the laboratory (42, 240). While the prokaryotic biology community sensationalized their realization of the "uncultured majority" in the 1980s and 1990s (241), fungus biologists have been aware of vast numbers of unculturable fungi since axenic cultures were introduced in the 1800s (242) and have generally assumed that unculturability was a normal phenomenon. Thus, issues of unculturability of fungi were acknowledged early on in the history of fungal chemical research and differ significantly from those associated with prokaryotic organisms. Unlike most prokaryotes, fungi can often be seen by eye or by low magnification microscopy, and their cells and tissues harvested for their DNA and chemistry. Consequently, the issue of unculturability has had less impact on efforts to evaluate biodiversity and chemical diversity in fungi, even though it remains a significant hurdle in the experimental study of biosynthesis and for practical scale-up of metabolite production.

Secondary metabolite gene clusters are among the most diverse and rapidly evolving features of fungal genomes and can be used to follow mechanisms of adaptive evolution, including evolution of pathogenic species (44, 243, 244). During the past decade, the search for fungal metabolites, like that for other microorganisms, and their corresponding biosynthetic genes has entered a transformative new era. The search for new and useful microbial metabolites is shifting from being an experience-guided empirical process to being a genomics-guided process in which identification of the biosynthetic genes precedes and informs isolation of the secondary metabolite. By examining historical data retrospectively, it is now possible to rationalize why a strain's genetic makeup dynamically interacts with fermentation methods to yield fluctuating patterns of bioactive molecules during screening and why the pool of new drug-like metabolites from certain kinds of common fungi appeared to have been depleted. The numbers of biosynthetic gene clusters in every filamentous genome examined to date is thought to exceed the number of detectable metabolites under a given set of laboratory conditions, indicating the existence of numerous unexpressed or poorly expressed pathways possibly encoding the biosynthesis of undescribed metabolites. These unexpressed gene clusters are commonly called "orphan" or "cryptic" gene clusters because their silence is likely an artifact caused by our inability to simulate the environmental conditions or chemical signals required for their expression, or even to grow the organism at all (245, 246). Regulation of secondary metabolism remains poorly understood across the diversity of secondary metabolite-producing organisms, and identification of a low-abundance discrete predicted metabolite from within a crude metabolome is a nontrivial challenge. Recognition that transcription and translation of these repressed genes can sometimes be induced has spawned an entirely new area of natural products research dedicated to finding chemical and genetic tools to break pathway silence and induce homologous expression in the native organism (71, 245, 247–249).

Genome sequencing has moved beyond model fungal species, major pathogens, and industrial organisms to encompass the full spectrum of fungal diversity. Consequently, as in other microorganisms, a global picture of the phylogenetic distribution of secondary metabolites encoding genes and gene cluster architecture in fungi is emerging. In principle, conceptual barriers no longer impede the future unlocking of cryptic secondary metabolic gene clusters. The complex secondary metabolism of a given fungus can easily constitute 20 to as many as 80 different core secondary metabolite-encoding genes or gene clusters. On the other hand, fungi that have little history of secondary metabolite production, e.g., chytrids, yeasts, powdery mildews, vesicular-arbuscular mycorrhizae, and truffles, are now known to lack or have few secondary metabolite gene clusters because (i) they diverged prior to the evolution of secondary metabolism or (ii) during their descent from fungal groups with rich secondary metabolism, their genomes underwent a concurrent loss and reduction in unnecessary secondary metabolism due to stable environments provided by obligate parasitism (e.g., rusts, smuts, powdery mildews) (250). However, other biotrophic fungi, e.g., lichenized fungi, mycorrhizal mushrooms, and plant-associated Clavicipitaceae, have retained a rich secondary metabolism that is highly related to that of their metabolite-rich sister phylogenetic lineages. It is hypothesized that these fungi have retained their secondary metabolic capabilities in part because of the need for defense and the interorganism interactions of their conspicuous and often long-lived vegetative (lichens) or reproductive (mushrooms) structures, or to maintain their mutualistic relationships with host plants (Clavicipitaceae) (44, 240, 251–253).

Reading the biosynthetic menu for secondary metabolites from sequenced fungal genomes is a complex process, but it can be assisted by several computational tools that can identify signature motifs and genes associated with secondary metabolite biosynthetic gene clusters or, minimally, the primary catalytic backbone genes (254). A full range of software packages can be found at the Secondary Metabolite Bioinformatics Portal (http://www.secondarymetabolites.org). These software packages organize searches and categorize results so that identified genes and gene clusters are associated with their nearest known orthologues. In some instances, these searches can propose a hypothesis for a secondary metabolic product of a cluster through close homology with gene clusters that have been experimentally linked to a secondary metabolite.

The most widely used software tool is the Antibiotics & Secondary Metabolite Analysis Shell (antiSMASH, http://antismash.secondarymetabolites.org) (255). This Web-based tool enables users to easily identify and annotate pathways with typical repetitive domain structures directly from DNA or protein sequence data. Two complementary tools are designed to aid in organizing the results of AntiSMASH analyses. One is the ClusterMine360 database that stores the antiSMASH annotation of known gene clusters and links them to its own repository or to sequence references in the NCBI GenBank as well as to the structure

of the natural product encoded by the gene cluster (256). The other is the recently released Minimum Information about a Biosynthetic Gene cluster (MIBiG), a Web-based community-annotated database which has cataloged about 200 unique natural product pathways including those corresponding to most classes of fungal metabolite. This effort is vital to guiding future genome mining and synthetic biology efforts aimed toward discovering novel fungal enzymes and metabolites. Other computational tools useful for fungi include Secondary Metabolite Unknown Regions Finder (SMURF, http://jcvi.org/smurf/index.php) (257); Cluster Assignment by Islands of Sites (CASSIS), a method for biosynthetic gene cluster prediction in eukaryotic genomes, and Secondary Metabolites by InterProScan (SMIPS), a tool for genome-wide detection of key secondary metabolite backbone enzymes (anchor genes), e.g., PKSs, NRPSs, and dimethylallyl tryptophan synthases (https://sbi.hki-jena.de/cassis/cassis.php) (258); ClustScan (http://bioserv.pbf.hr/cms/) (259, 260); and natural product searcher (NP.searcher, http://dna.sherman.lsi.umich.edu/) (261).

Currently, for fungal gene clusters, *de novo* structure prediction from gene cluster DNA sequence data may provide a structure hypothesis when the targeted genes exhibit high homology to a functionally characterized gene cluster of a known chemical product. Detailed manual prediction of structure from gene cluster data can often provide a reasonable estimate for the core structure encoded by a PKS or NRPS, but automated structure prediction is not yet possible.

More recently, alternative methods have been developed to identify clusters for which the genes are cooperatively regulated at transcriptional levels, thus allowing for the identification of novel gene clusters even when sets of canonical core genes are unrecognizable (254, 262). The cases of kojic acid and ustiloxin B, mentioned above, demonstrated that different computational techniques can be applied to identify biosynthetic gene clusters that do not contain any known types of core scaffold-synthesizing enzymes. Discovery of the corresponding gene clusters employing the MIPS-CG algorithm has been applied to two or more transcriptional data sets from producing and nonproducing conditions to identify chromosomally adjacent clusters of coexpressed genes over a 3- to 30-gene frame in a fungal genome. The advantage of this approach was that no assumptions were made regarding the patterns of the genes that would be identified which can help recognize hypothetical new classes of biosynthetic gene clusters. The expanding use of these tools has led to the observation that most newly identified biosynthetic pathways are not readily associated with a known PK, NRP, terpenoid, or other product. The assignment of potential products to these orphan pathways is thus a major unaddressed challenge, as is the basic question of whether these newly recognized biosynthetic gene clusters are even functional (254).

A global overview of secondary metabolite gene cluster evolution and diversification in the Fungi is now emerging, and significant progress has been made in developing predictive frameworks for classifying fungal NRPSs, PKSs, and terpene synthases. Previously, the frequency of isolation of bioactive metabolites and the chemical complexity of organic extracts were used to measure the chemical potential of different fungal taxa. The genetic capacity of different groups of fungi can now be explored directly from genomic sequences to ask which taxa have the highest potential to produce large numbers of complex secondary metabolites with drug-like properties and which taxa have moderate or poor potential. Because most drug or drug-like metabolites are polyketides, nonribosomal peptides, or terpenoids or incorporate derivatives of dimethylallyltryptophan, the numbers of iterative PKS, NRPS, terpene synthase, prenyl transferase, and dimethylallyltryptophan synthase genes per genome can serve as a measurement of the potential to produce secondary metabolites. On this basis, the dikaryotic filamentous fungi are clearly the most productive sources of secondary metabolites compared to the basal fungal lineages. This conclusion correlates very well with historical data on how the numbers of known secondary metabolites are distributed across the Fungi.

The highest complexity of secondary metabolite pathways is concentrated within the filamentous Ascomycota, especially in the higher lineages of the Eurotiomycetes, Dothideomycetes, Sordariomycetes, Leotiomycetes, and Lecanoromycetes, while secondary metabolism is limited or absent altogether in the obligate biotrophic Erysiphales, the basal lineages of the Pezizomycetes, the Saccharomycotina, and the Taphrinomycotina (Fig. 1). All genomes of the higher ascomycete lineages examined to date have roughly a minimum of 5 to 10 core secondary metabolic pathways (pigments, siderophores) and may have as many as 80 (263), thus rivaling the complexity and richness of the Actinomycete genus *Streptomyces*. In particular, gene clusters for biosynthesis of polyketides and nonribosomal peptides have undergone significant expansion, and many of these pathways are ascomycete-specific. Furthermore, few of these core biosynthetic genes are fully conserved across ascomycete and basidiomycete fungi; therefore, when one takes into account

the potential numbers of fungal species, the capacity for encoding chemical diversity in the Ascomycota seems limitless. The situation in the Basidiomycota appears to be nearly as complex, but with the chemistry and diversification of gene clusters skewed toward terpenoids. The Agaricomycotina have genomes that are often rich in terpene pathways, are moderately rich in PKSs, and incorporate only a few NRPSs (240, 264–266), while other Basidiomycota lineages have little or no secondary metabolism due to evolutionary contraction as a consequence of biotrophy and parasitism (6, 267, 268).

CONCLUDING REMARKS

There is an urgent a need for the development of new drugs to combat multidrug-resistant pathogens and for molecular templates for targeted cancer therapeutics. The capacity for sequencing microbial genomes is outpacing the ability to identify natural product gene clusters and, most importantly, to convert this sequence information into collections of testable molecules. Therefore, unlocking small-molecule chemodiversity encoded in microorganisms, including the Fungi, will be crucial for next-generation drug development. Genome sequencing projects covering the whole spectrum of environmental fungi are providing fertile ground for directed secondary metabolite discovery. A variety of new approaches have revitalized the field of fungal natural product discovery, particularly in the fields of elucidation of biosynthetic mechanisms, identification of biosynthetic gene clusters and their connections to new and known fungal secondary metabolites, induction of homologous expression of repressed pathways in the native organisms, and heterologous expression of pathways in genetic model hosts. A valuable approach would be to focus community resources on generating high-quality sequenced genomes of all fungi that produce biologically important and structurally distinctive secondary metabolites and to connect these secondary metabolite clusters to their corresponding annotated gene cluster. Such a collective community project would streamline the recognition of orthologous pathways in new genomes and enable mapping of widely and narrowly distributed families of fungal metabolites. Concurrently, the discovery of novel secondary metabolite pathways would be accelerated. It would be logical to assume that at some point these new platforms for fungal natural product discovery would be introduced into industrial pharmaceutical and agrochemical discovery. Efforts to build industrial-scale genome-mining platforms for Actinomycetes are already under way (269). However, to the best of our knowledge, parallel efforts on the Fungi at an industrial scale have yet to be organized.

Index

1000 Fungal Genomes Project, 166

A

Acanthamoeba, 58, 59
Accessory chromosomes, 787, 796
Acetyltransferases and deacetylases, new antifungal target, 912–913
Adaptive cell therapies, immune-based therapy, 896
Adaptive immunity, dermatophytes, 859–860
Adaptive potential, 787
Adhesins, 276
Agaricomycotina, 24–26, 147, 946
  genome size and gene count, 622
  genomic organization, 154
  phylogeny of, 150
Agriculture
  fungal model systems, 704–706
  impact of fungal pathogens on, 703–704
  threats from emerging fungi, 804
AGRITRUFFE society, 1076
Agrobacterium tumefaciens, 998
Agrocybe gibberosa, 350
Agro-ecosystem, 787
AIDS (acquired immunodeficiency syndrome), 97, 98, 819, 829, 1099
Aisworth & Bisby's Dictionary of the Fungi, 81
Albaconazole, 907, 908
Albendazole, 98
Aleurodiscus, 25
Allomyces, 7, 8, 62, 239
Allomyces reticulatus, 444
Alsberg, C. L., 1092
Alternaria alternata, 133, 393, 510, 776
Amanita bisporigera, 47
Amanita muscaria, 49, 82
α-Amanitin, 1101, 1102
Amatoxins, 1101–1102
Amblyosporidae, 103
Amblyrhynchus cristatus, 408
Ambrosiella nakashimae, 948
Ameson michaelis, 105
Amino acid biosynthesis, 58
Aminocandin, 907, 908
Amoeboaphelidium protococcarum, 67
Amoeboaphelidium, 7
Amoebochytrium, 68
Amphibian chytridiomycosis (*Batrachochytrium dendrobatidis* and *B. salamandrivorans*), 792–793
Amphotericin B, 906–907
Anamorphic, 187
Aneuploidy
  changes during *in vivo* evolution, 610–611
  in context of experimental evolution, 608–611
  fungal genetic variation, 638–639
  impact of cancer biology, 612
  methods for detection of, 600
  molecular detection of, 601
Animal diseases, *see also* Fungal disease
  amphibian chytridiomycosis, 792–793
  azole-resistant aspergillosis, 795
  bat white nose syndrome (WNS), 793–794
  human cryptococcosis, 794–795
  Malassezia species and skin disease, 863–864, 865
Animals, as long-distance dispersal vector, 317, 319
Anisogamy, 166
Anopheles gambiae, 927
Antagonism, 300
Antagonistic mechanisms
  energy expenditure during, 304
  morphological changes, 301
  oxidative enzyme activity, 302–303
  reactive oxygen species (ROS) accumulation, 301–302
  secondary metabolite production, 301, 302
Antibiotics & Secondary Metabolite Analysis Shell (antiSMASH), 1108
Antifungal drugs
  acetyltransferases and deacetylases, 912–913
  azoles, 904, 905, 906, 907
  calcineurin, 911
  chemical-genetics approaches, 914–915
  classes of, in clinical use, 904–906
  combination therapy, 913–914
  compounds with antifungal activity, 908
  development of improved agents, 906–907, 908
  echinocandins, 905, 906, 907
  farnesyltransferase, 910–911
  fungal sphingolipids, 909–910
  GPI anchor biosynthesis, 910
  Hsp90, 911–912
  mechanisms of action, 905
  new targets in development, 909–913
  outlook for, 915

Antifungal drugs *(Continued)*
parnafungin A, 908, 913
polyenes, 904, 905, 906–907
pyrimidines, 904, 905
target space for, 907, 909
Antigens, diagnostic, 283–284
Aphelids, 67–68
Apophysomyces, 13
Aquatic environmental sequencing, 65
Aquatic Phycomycetes, 399
Arabidopsis thaliana, 446
Arbuscular mycorrhizae, 48, 49
biological features of, 730
classification and phylogeny of, 728–730
colonization process, 731–734
common mycorrhizal network, 737–738
first genome project dedicated to, 730–731
fluorescence micrographs of life cycle stages, 729
genetics of, 730
genome organization of, 730
host cell colonization, 733–734
impact of symbiosis on aboveground organs of host plant, 736–737
presymbiotic signaling, 731–733
root colonization, 728, 732
transfer of nutrients, 734–736
Archaeorhizomyces, 82, 87
Archaeorhizomycetes, 88
Architecture of network, *see* Mycelial network architecture
Armillaria spp., 47, 295
Armillaria mellea, 248, 388
Armillaria ostoyae, 346
Arthoniomycetes, lichen fungi, 753–754, 758
Arthrobotrys, 18, 963, 964
Arthrobotrys dactyloides, 501
Arthrobotrys oligospora
fungal sense of touch, 487, 488, 489, 491, 495
nematode-trapping fungi, 964, 968, 969
structures of traps in, 965
Arthrodermataceae sp., 856, 857
Ascobolus, 18
Ascobolus immersus, 690
Ascobolus pulcherrimus, 252
Ascoidea asiatica, 953
Ascomycetes
images of sexual reproduction, 121
mating signaling in filamentous, 133–134
pheromones and receptors, 134
phylogeny of, 117, 118
role for sexual signaling in, 135
sexual development in filamentous, 127–133
transcriptional analysis of mating, 134
Ascomycete yeasts and insects
ambrosia beetles, 951–953
anobiid yeast-like symbionts, 954
Botryozyma spp., 956
cactophilic yeast communities, 949
common associations, 946
ephemeral flower communities, 949–950
evolution of associations, 957
insect adaptations for fungal associations, 947–949
mushroom- and fungus-feeding beetles, 950–951
phoresy, 956–957
planthopper yeast-like symbionts, 955–956
Saccharomyces cerevisiae in gut of paper wasps, 953–954
symbiosis, 947
wood-ingesting passalid beetles, 953
yeasts spread on substrates, 956–957
Ascomycota, 4, 5, 6, 14–20
diversity of, 15
lignocellulose degraders, 1031
lineage infecting humans, 814
opportunistic of humans, 824–828
Pezizomycotina, 17–20
phylogenetic relationships, 573, 620
reverse ecology of populations, 646–647
reverse ecology of species, 647–648
Saccharomycotina, 16–17
Taphrinomycotina, 14, 16, 117, 118
Ashbya gossypii, 17, 38, 233, 243, 501, 609, 610, 623
Ash die-back, *Hymenoscyphus fraxineus*, 800, 802–803
Aspergillus spp., 18, 45, 47–48, 193
mating-type loci, 196, 197
opportunistic of humans, 826
production strains, 1038–1039
sclerotia formation in *A. niger*, 202
sex in, 203–204
Aspergillus flavus, 997, 1102
Aspergillus fumigatus, 98, 133, 195, 252–253, 815–816
antifungal drugs, 903–905, 909–915
azole-resistant aspergillosis, 795
biofilms of, 270, 876–878
cell wall, 268, 269
cell wall salvage pathways, 277, 278
circadian rhythm, 515, 517
contact sensing, 495, 499, 500
fungal sensing, 889
genetic variation, 635, 637
human infection, 817
light response, 454
polysaccharides, 272, 272–274
stress, 467–468, 471
target of rapamycin (TOR), 542
Aspergillus nidulans, 36, 38, 43, 129, 130, 132, 195
biofilms, 878
carbon sensing, 421
cell cycle checkpoints, 560, 561, 562
cell cycle landmarks, 554–556
cell cycle of, 559–560
cell cycle proteins, 552–553
DNA damage checkpoint, 560, 562
fungal exocytosis, 234–241
genetics, 571, 635, 637
hyphal growth, 233–234
mitosis, septation and cytokinesis in, 554
morphogenesis checkpoint, 566
mycophenolic acid (MPA), 1093
photoreceptor proteins, 441, 443
phytochrome functions in light regulation in, 450, 451, 452
polysaccharides, 272
production strains, 1038–1039
reboot regulation, 566
spindle assembly and position checkpoints, 565
stress, 466
target of rapamycin (TOR), 542
Aspergillus niger, 248, 995
biorefinery processing, 1034
phosphates, 376
target of rapamycin (TOR), 542
Aspergillus oryzae, 251, 353
biorefinery processing, 1034
in Japanese fermentations, 1073–1074
Aspergillus sydowii, long-distance dispersal, 311, 313, 321
Aspergillus versicolor, 510
Atorvastatin (Lipitor), 1105
Aureobasidium pullulans, 37, 40
Auricularia auricular-judae, 37
Automixis, 167
Azole-resistant aspergillosis (*Aspergillus fumigatus*), 795
Azoles
albaconazole, 907, 908
antifungal drug class, 904, 906, 907
isavuconazole, 907, 908
mechanism of action, 905
structure of, 905

B

Bacillus anthracis, 1092
Bacillus subtilis, 995
Bacteria, *see also* Endohyphal bacteria
bacteria-like organelles, 893
participation in lichen thalli, 760
Baker's yeasts, 1069–1070
Barberry Eradication Program, 22
Basal fungi, 178
Basidiobolus, 12, 239
Basidiobolus ranarum, 818
Basidiomycetous species, lignin-modifying, 1050–1051
Basidiomycota, 4, 5, 6, 13, 20–26
Agaricomycotina, 24–26, 147
diversity of, 21, 147
genomic organization of, 154, 156
homeodomain transcription factors, 152
homothallism in, 163–165
lignocellulose degraders, 1031
lineage infecting humans, 814, 822–824
molecular determinants of mating type, 151–152
opportunistic of humans, 824
pheromone/receptor sensing system, 151–152
phylogenetic relationships, 147, 150, 573, 620
Pucciniomycotina, 22–23, 147
reverse ecology of populations, 647
reverse ecology of species, 648
sexual development and cell type identity, 147, 149, 151
tetrapolar systems, 152–153, 155
tetrapolar systems with multiple alleles in Agaricomycetes, 155, 157, 159–160
Ustilaginomycotina, 23–24, 147
Bassi, Agostino, 926
Batrachochytrium dendrobatidis, 9, 68, 319, 321, 402, 403
amphibian chytridiomycosis, 792–793
aneuploidy, 602, 639
frog populations, 814
gene family, 624
ploidy variation, 602

RNA interference (RNAi), 658
Batrachochytrium salamandrivorans, 792–793
Bat white nose syndrome (*Pseudogymnoascus destructans*), 793–794
Beauveria, 18, 925, 927
Beauveria bassiana, 926, 928
evolution of sex, 937
infection cycle, 930–935
Beetles
ambrosia, eating fungi, 951–953
mushroom- and fungus-feeding, 950–951
Symbiotaphrina spp., 954
wood-ingesting passalid, 953
Behavioral fever, 814
Berberis, 22
Biochemistry, *Malassezia* species, 864–865
Biodiversity hot spots, 88–89
Bioethanol, fungal yeasts for, 1036
Biofilms
adherence of, 874–877
agglutinin-like sequence (Als) structure, 875
cell walls, 270
confocal imaging of *C. albicans* biofilms, 874
conserved features of, 882
dispersal of cells, 878
drug resistance and persistence, 878–879
extracellular matrix material, 873, 877–878
future research, 882–883
gene expression, 879–881
gene regulation, 881–882
infection and, 873
inside of, 873
Biological clocks, *see* Circadian rhythms
Biologically active metabolites, *see* Secondary metabolites
Biomass conversion
discovery and optimization of genes for, 1040–1041
discovery and production of fungal enzymes for, 1037–1042
enzyme discovery from nature, 1039
enzymes in Fungi kingdom, 1031–1032
fungal enzyme production by heterologous expression, 1037–1038
fungal enzymes for, 1029–1030
fungi as gene donors, 1038–1039
future perspectives for, 1042–1043
monocomponent enzymes by GMO production strains, 1040
mycological perspectives, 1043
next-generation sequencing revolutionized enzyme discovery, 1041–1042
protein engineering to improve enzymes for, 1041
role of fungi in, 1029–1032
schematic of biorefinery, 1030
Biomass recycling
inclusion in continuum models, 354–355
mycelial network, 345–346
Biomineralization, 374
Biopolymer, *see* Lignin
Biorefinery
advanced biofuels, 1037
future perspectives, 1042–1043
lignocellulose processing, 1034
schematic overview of, 1030
Biotechnology
cDNA library screening, 1040–1041
enzymes by GMO production strains, 1040
fungi as gene donors, 1038–1039
importance of fungi in, 1029
Biotrophs
effectors, 714–715, 770–771
plant pathogenic fungi, 708–709
Bioweathering, 373–374
Bipolar breeding systems
Basidiomycota, 160–165
Cryptococcus spp. and *Trichosporon*, 161–162
homothallism in Basidiomycota, 163–165
Malassezia, 161
Microbotryum, 162–163
Bipolaris maydis, 19
Bipolarity, 167
Black, O. M., 1092
Black truffles
agronomy considerations, 1075–1076
domestication of, 1074–1077
global approach to, 1076–1077
history of domestication, 1075
Blakeslea, 13
Blastocladia, 10
Blastocladiella, 8
Blastocladiella emersonii, 444
Blastocladiomycota, 4, 5, 6, 8
Blastomyces dermatitidis, 39, 40
cell walls, 269, 280
stress, 464
Blattabacterium, 955
Blumeria graminis
contact sensing, 491
fungal pathogen effectors, 770, 774
Boekhout, Teun, 951
Botryllus schlosseri, 215
Botryobasidium spp., 44
Botryobasidium botryosum, 150, 159
Botryozyma, 956
Botrytis spp.
fungal model system of *Sclerotinia* and, 704–705
fungal pathogen effector, 773
Botrytis cinerea, 45
fungal pathogen effector, 773
noble rot, 1063
RNA interference (RNAi), 665
stress, 468
Breeding system, 167
Brewing yeasts, 1070–1074
Brumeria graminis, 468
Buller, A. H. Reginald, 252
Burkholderia (*Betaproteobacteria*), 984, 989, 990, 991, 992
Burnet, F. MacFarlane, 887

C

Cadophora, 48
Caenorhabditis elegans, 97, 535
analysis of genomes, 975–977
future directions, 979

Zygomycota, 177, 178
  lignocellulose degraders, 1031
  lineage infecting humans, 814
Zygomycotina, 118, 128
Zygophore, 187
Zygorhizidium planktonicum, 408
Zygorrhynchus moelleri, 512
Zygosaccharomyces bailii, 472, 1069
Zygospore, 187
Zymoseptoria, chromosomes, 585–586
Zymoseptoria pseudotritici, hybridization, 644
Zymoseptoria tritici, 19, 241, 246, 254, 580, 581
  fungal model system, 706
  fungal pathogens, 768
  gene family, 624
  wheat pathogen, 796, 798
