The Complexity of Fungal Vision

20

Reinhard Fischer,[1] Jesus Aguirre,[2]
Alfredo Herrera-Estrella,[3] and Luis M. Corrochano[4]

INTRODUCTION

Sunlight, harvested by photosynthetic organisms (plants, algae, and some bacteria) and used to synthesize energy-rich molecules (sugars) from carbon dioxide and water, provides the energy required to sustain life on Earth. In addition, sunlight properties such as intensity, duration, polarization, and spectral composition are used as sources of information (1). Indeed, all forms of life are continuously obtaining and decoding information from their environment. In fungi sunlight, ranging from ultraviolet (UV) to infrared wavelengths, regulates a diversity of biological processes including circadian rhythms, morphogenesis, tropism, and synthesis of pigments, among others (reviewed in reference 1). UV light can be harmful, since DNA modification products of photochemical reactions may be transmitted to the next generation as a mutation. Visible light appears not only to provide early warning of the presence of impending UV radiation and further damage, but also seems to contribute to the capacity of these organisms to deal with abiotic stress in general (2–5). Thus, the ability of most fungi to perceive and respond to light has very likely contributed to their survival and fitness.

Light responses in fungi, some of which can be extremely rapid (e.g., phototropism), were observed more than 150 years ago, and light-induced alterations in fungal morphology have been described for hundreds of fungi (6, 7). Responses may be triggered by very low light and require only nanoseconds to minutes of exposure with a rate of photons that could be only 10^{-10} mol of photons m^{-2} (8–10). Long-term effects of light rely mainly on genetic reprogramming of the fungal genome and usually involve major changes in gene expression patterns. A major question is how such coordinated activation and repression of hundreds of genes is achieved. Photoreceptors are proteins that contain light-sensing chromophores that modulate their biological activity after photoreception (10). The first step of light perception is a physical reaction, the absorption of photons by an organic molecule followed by conformational protein changes and transduction into biochemical reactions such as phosphorylation events.

Few physical and many genetic, molecular biology, and biochemical analyses have provided detailed information on the mechanisms of fungal vision. Although many open questions remain, it becomes clear that light sensing is a rather complex and multifaceted process with a strong impact on most aspects of fungal life. Hence, although most results rely on studies of a few model organisms, foremost *Neurospora crassa* but also *Aspergillus nidulans*, *Phycomyces blakesleeanus*, and *Trichoderma atroviride*, the strong impact of light in these organisms prompted studies of other fungi with pathogenic or symbiotic lifestyles or with biotechnological potential. All these studies continuously improve our knowledge of light regulation and help to unravel common principles but also species- or lifestyle-specific impacts of light. As a consequence of the growing number of publications combined with a long history of the field, it would be impossible to give a comprehensive overview and discuss all papers related to fungal vision. Instead we will concentrate on recent findings and refer to older publications when necessary. For more information the reader is referred to references 10 through 17.

FUNGAL VISION: THE PHENOMENON

Light represents only a small fraction of the electromagnetic radiation produced by the sun that organisms use for photosynthesis, photomorphogenesis, or orientation

[1]Karlsruhe Institute of Technology (KIT), Institute of Applied Biosciences, Department of Microbiology, D-76131 Karlsruhe, Germany; [2]Departamento de Biología Celular y del Desarrollo, Instituto de Fisiología Celular, Universidad Nacional Autónoma de México, Mexico City, Mexico; [3]Laboratorio Nacional de Genómica para la Biodiversidad, CINVESTAV-Irapuato, Irapuato, Guanajuato 36821, Mexico; [4]Department of Genetics, University of Seville, 41012 Seville, Spain.

in the environment. Human vision, for instance, detects wavelengths between roughly 400 and 700 nm. However, shorter wavelengths such as UV and X rays (which are rare in nature) are also important, due to their damaging effects. Thus, the reaction of organisms to light can be divided into reactions to damaging irradiation and reactions to visible light (as defined by the human eye). Whereas the sensing and reaction to damaging radiation seems obligated for life on Earth, the reaction to visible light could be optional. However, one important function of light sensing may be the adaptation to harmful irradiation because visible light is a reliable indicator of the presence of UV radiation during the day.

Most fungi are able to sense and respond to light, with only a few exceptions that lack any indication of genes for sensing light (Fig. 1). Those organisms include the yeasts *Schizosaccharomyces pombe* and *Saccharomyces cerevisiae* and some dermatophytic pathogenic fungi such as *Microsporum*. An exception appears to be the fission yeast *Schizosaccharomyces japonicus*, in which a blue-light effect and the presence of blue-light photosensors have been reported. However, it has to be considered that *S. japonicus* is a dimorphic fungus, which can switch between yeast and hyphal form (18). It has been speculated that light sensing may be of special interest for multicellular fungi that constantly need to adapt to changing environments (16). Most fungi respond in one or another way to light, and it is important to mention that only in some cases have the analyses of light responses been done using defined wavelengths (i.e., light-emitting diodes or monochromatic filters) and strict control of fluence rates (19–23).

Development of Basidiomycetes fruiting bodies depends on, among other factors, light or light-dark cycles (24). Scientists noted 60 years ago that under laboratory conditions the mushroom *Cyathus stercoreus* required light to initiate fruiting body development (25). Later it was shown that *Coprinus macrorhizus* primordia formation and stalk development, as well as the timing of meiosis, were all light dependent (26, 27). Some mushrooms not only produce meiotically derived spores in their caps, but are also able to generate different asexual spores, named oidia or chlamydospores. Oidia formation occurs in monokaryons and dikaryons of *Coprinus cinereus* and is blue-light dependent in dikaryons but not in monokaryons (28). In the basidiomycetous dimorphic yeast *Cryptococcus neoformans*, blue light controls growth, development, and virulence (29, 30).

In ascomycetes, light also has a strong impact in morphological and physiological processes, including the regulation of conidial germination, hyphal branching, sexual and asexual development, and secondary metabolism. Blue light induces sporulation in many ascomycetes, such as *T. atroviride*, *Aspergillus ornatus*, and *Penicillium isariiforme* (31). In contrast, *Alternaria solani* and *Botrytis cinerea* produce conidiophores under starvation conditions and after induction with UV light, which—if kept in the dark—produce conidia. Blue light inhibits the last step, conidia formation (31, 32). Furthermore, the inhibitory effect of blue light can be reversed by red-light illumination, which again can be reversed by far-red light (33). These complicated photoconidiation experiments suggested the presence of several photoreceptors in *B. cinerea*. In *A. nidulans*, conidiation is also induced by blue and red light, which together reach the level of white-light induction (34). Hence, light controls the balance between asexual and sexual development in this fungus (35). In *Trichoderma reesei* sexual development occurs in light (36), whereas in *N. crassa* fruiting bodies can be produced in the dark, although the number of protoperithecia is greatly increased upon exposure to blue light (37). Additionally, the position of the perithecium neck is also light dependent (38), with necks oriented to the light source but randomly oriented in the dark (39). Light is also required to obtain the maximum number of conidia in *N. crassa*, with a 4-fold increase in the number of conidia obtained in the light over the number obtained in the dark (40).

Germination, growth, and secondary metabolism are also affected by light. In *A. fumigatus* and *A. nidulans* light inhibits spore germination (41, 42), whereas it promotes hyphal branching in *N. crassa*, *Tuber borchii*, *T. atroviride*, and the plant pathogen *Colletotrichum trifolii*. Therefore, colonies look more compact in the presence of light (40, 43–45). In *N. crassa* and *Fusarium fujikuroi*, light activates the biosynthesis of carotenoids in vegetative mycelia, resulting in hyphae with a deep-orange color (46, 47). In *A. nidulans* sterigmatocystin (an aflatoxin precursor) and penicillin production are regulated by light (34, 48, 49). The study of the circadian clock in *N. crassa*, a light-regulated phenomenon, led to an enormous stimulation of the entire research field (15, 50–52). Conidiation in *N. crassa* is governed by a circadian clock that can be entrained by light (53), and it turned out that a main component of the clock system is the blue-light photoreceptor WC-1 (50, 54, 55).

Within zygomycetes, light regulates many aspects of the biology of *P. blakesleeanus*, *Mucor circinelloides*, and *Pilobolus crystallinus*, including growth and growth direction of fruiting bodies (phototropism), the development of sexual and asexual reproductive structures, and the biosynthesis of the beta-carotene pigment (56). Light effects have also been described in

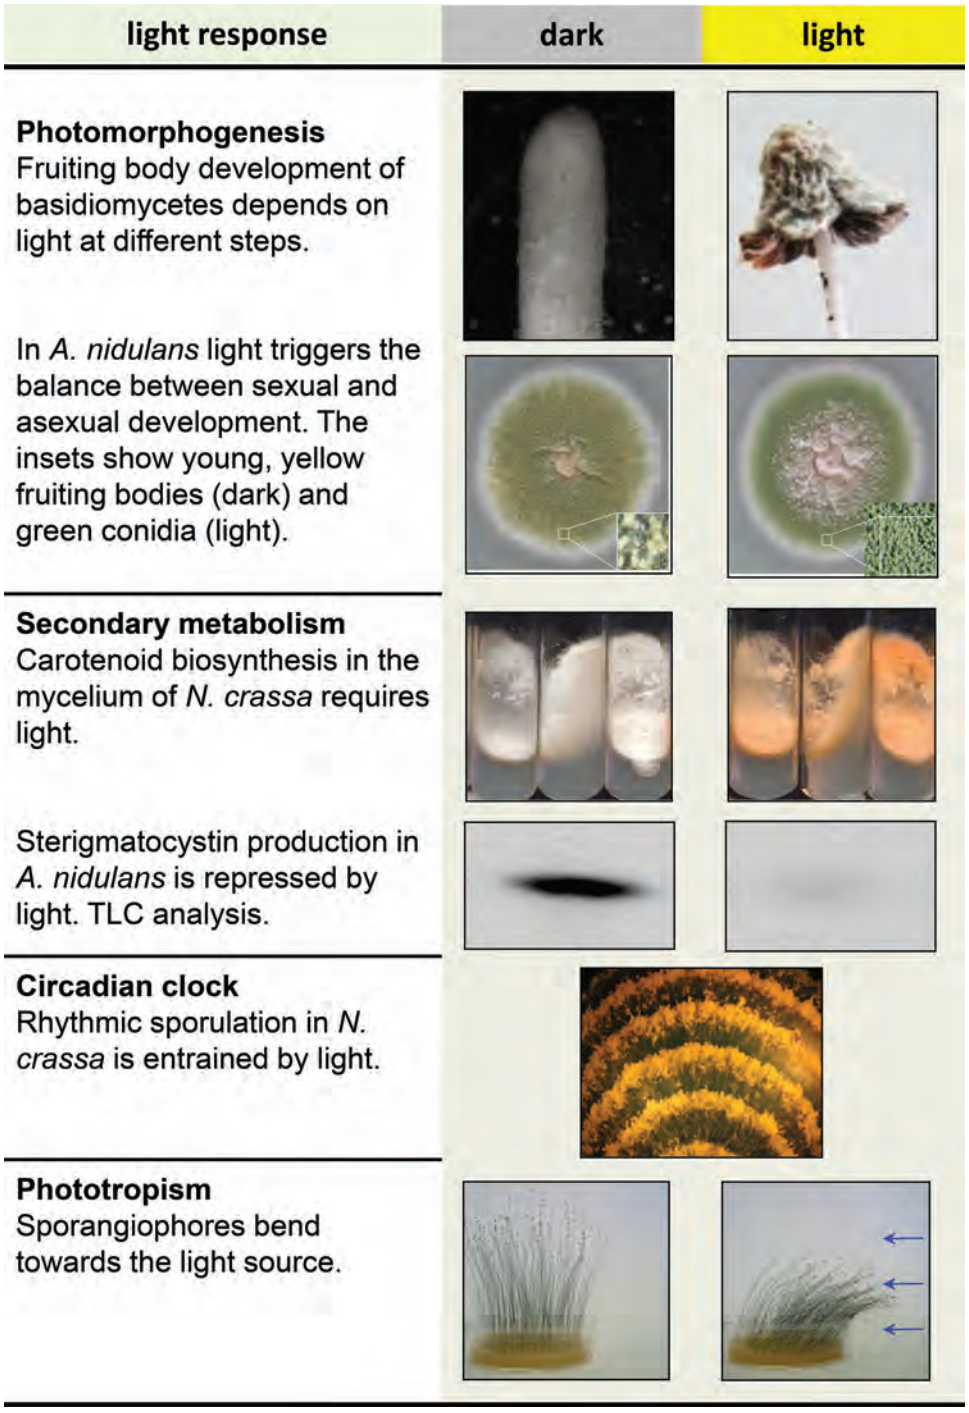

Figure 1 Phenomena of fungal responses to light. Light has a large impact on fungal morphology and physiology. The pictures of *Coprinus cinereus* were provided by Shanta Subba and Ursula Kües (University of Göttingen).

other basal fungi, including the regulation of zoospore mobility in the chytridiomycete fungus *Allomyces reticulatus* (57) and phototaxis in *Blastocladiella emersonii* (58). All these phenomena illustrate well the broad distribution of fungal vision and support the early evolutionary appearance of this feature.

The great variety of phenomena observed in response to light suggests that illumination causes a large reprogramming of the genetic machinery in fungal cells. Indeed, many genome-wide expression studies in various fungi show that hundreds of genes representing a significant fraction of the genome (5 to 10%) are differentially regulated by light (59–66). Whereas in animals one type of photoreceptor, rhodopsin, is used to sense blue, green, and red light, microbial eukaryotes and bacteria employ different classes of photoreceptors, each perceiving a narrow spectrum of light in the blue, green, or red part of the rainbow (Fig. 2). Here, we summarize the main properties of the classes of photoreceptors present in fungi.

PHOTOSENSORY PROTEINS AND THEIR MODES OF ACTION

The Flavin-Based White Collar Photoperception System

The search for components of the light perception machinery in fungi was first approached in *P. blakesleeanus*

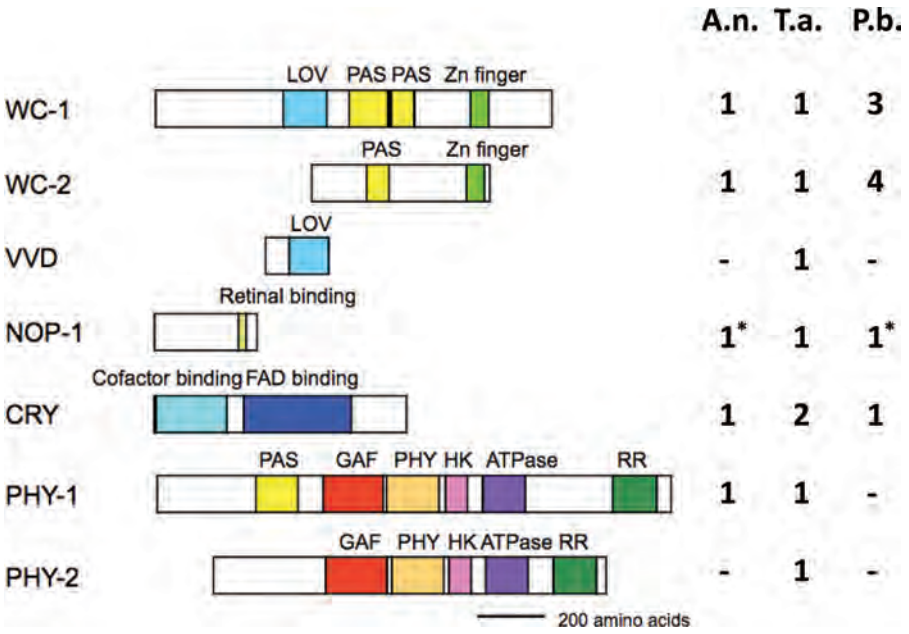

Figure 2 Schemes of the *Neurospora crassa* photoreceptor proteins and their presence in *Aspergillus nidulans*, *Trichoderma atroviride*, and *Phycomyces blakesleeanus*. The figure shows the set of *N. crassa* photoreceptors and a comparison of the presence of homologous genes in other model fungi, including the LOV-domain photoreceptors WC-1 and VIVID (VVD) together with WC-2, the protein that interacts with WC-1 to form the WC complex. Other photoreceptors identified in the *Neurospora* genome are a rhodopsin (NOP-1), a cryptochrome (CRY), and two phytochromes (PHY-1 and PHY-2). LOV-domain photoreceptors contain the flavin chromophore-binding domain (LOV) and may also contain the protein-interaction domains (PAS) and the Zn finger domain. Rhodopsins contain the retinal-binding domain. Cryptochromes contain the FAD chromophore-binding domain and the domain for binding the antenna cofactor. Phytochromes contain an amino-terminal sensory domain and a carboxy-terminal output domain. The sensory domain involved in binding the bilin chromophore is composed of three domains (PAS, GAF, and PHY). The output domain is composed of the histidine kinase domain (HK), the ATPase domain found in ATP binding proteins, and the response-regulator domain (RR) that is likely involved in relaying the light signal to other proteins. The number indicates the presence and number of photoreceptor protein encoding genes in the genomes of *A. nidulans* (A.n.), *T. atroviride* (T.a.), and *P. blakesleeanus* (P.b.). The * indicates that the protein is present but lacks the critical lysine residue required for retinal binding.

and *Trichoderma viride* (67–70). Max Delbrück and his research group described in detail the properties of *Phycomyces* responses to light and initiated the genetic study of the signal transduction pathways (68). Eventually, it was concluded that in both fungi the most likely receptor for blue-UV light was a flavoprotein (69–71). More than 30 years later the *T. atroviride* blue-light regulator gene (*blr1*) was cloned, corroborating the original conclusions reached based on action spectra (45). Blr1 belongs to a family of fungal blue-light receptors, whose founding member is the white collar-1 (WC-1) protein of *N. crassa* (72, 73). In *A. nidulans* the WC proteins are also conserved, although their role appears to be different because red light and phytochrome play dominant roles in light sensing (34, 74). Fungal photoreceptors belonging to the WC-1 family contain three PAS domains, the first of which is a LOV (light, oxygen, voltage) domain (55). LOV domains are specialized domains belonging to the PAS (Per Arnt Sim) superfamily and are present in proteins that sense UV-blue light in plants and fungi. They are about 110 to 120 amino acids in length and adopt a conserved α/β-fold that binds flavin dinucleotide (FAD) or flavin mononucleotide. Upon absorption of blue light, LOV domains undergo a photocycle, transiently forming a covalent flavin-thiol adduct with a conserved cysteine residue present in the LOV domain (75). The other two PAS domains are involved in protein-protein interactions (76). These photoreceptors also contain GATA zinc finger DNA binding domains, nuclear localization signals, and activation domains in several cases (10). However, there are exceptions to the presence of the activation domains, suggesting the involvement of additional proteins for the control of gene expression (1). The *N. crassa* WC-1 protein dimerizes with its partner, the WC-2 protein, which contains a PAS, a GATA zinc finger domain, and an activation domain to form the WC complex (WCC). Through Chip-Seq experiments, WCC has been found to directly control gene expression, functioning as a transcriptional factor (77). Only WC-2 is required for binding the WCC to DNA, whereas the zinc finger of WC-1 is needed for clock-related DNA regulation and DNA binding of the WCC. This suggests different mechanisms of gene regulation for light or clock-related processes (78). Mutants in either *wc-1* or *wc-2* are affected in all known blue-light responses. Similarly, mutants in the orthologs of these genes in other fungi are clearly affected in blue-light perception (1, 17).

As a product of genome duplication events, multiple WC genes are found in the *M. circinelloides* and *P. blakesleeanus* genomes (66). In *M. circinelloides*, three *N. crassa* WC-1 orthologous genes (*mcwc-1a*, *mcwc-1b*, and *mcwc-1c*) have been identified, all encoding LOV-domain proteins. *mcwc-1a* regulates phototropism, whereas *mcwc-1c* regulates photocarotenogenesis (79). The *mcwc-1b* gene product is also involved in carotenoid synthesis and is regulated by ubiquitylation by CrgA (80). In *P. blakesleeanus* three *wc-1* genes and four *wc-2* genes have been described (81, 82). The main key players in *P. blakesleeanus* photobiology are MadA and MadB, orthologs of WC-1 and WC-2, respectively, which form the main photoreceptor complex (81). Whole-genome transcriptome analysis carried out in *P. blakesleeanus* led to the proposal that the stage-specific transcriptional response to light relied on the expanded set of photoreceptors and other light-dependent transcriptional regulators that arose after genome duplication (66). In this regard, whole-genome duplication in vertebrates has resulted in specialization of genes for signal transduction that are part of their visual system (83). Thus, expansion of photoreceptors or downstream signal transduction genes has resulted in more elaborate photoperception systems in both vertebrates and fungi.

Some fungi contain secondary photoreceptors (Vivid and/or Envoy), consisting of a LOV domain and a few extra amino acids, and bind either FAD or flavin mononucleotide as a chromophore (84–86). These photoreceptors are important for photoadaptation under constant light and for responding to changes in light intensity. In *Neurospora*, vivid (VVD) fine-tunes light responses by interacting with the WCC through the WC-1 LOV domain by quenching these responses (87, 88).

Phytochrome: A Linear Tetrapyrrole-Containing Histidine Kinase

Phytochromes, first discovered in land plants, were later also found in algae, diatoms, bacteria, and fungi and are absent in animals (89–93). Phytochromes are composed of a multidomain protein with a linear tetrapyrrole covalently attached to the protein. The protein moiety consists of an N-terminal PGP or photosensory domain, which combines domains named PAS (found in Per, Arnt, and Sim), GAF (named for vertebrate cGMP-specific phosphodiesterases, cyanobacterial adenylate cyclases, and the transcription activator FhlA), and PHY (phytochrome-specific PAS-related). The chromophore attaches autocatalytically to a cysteine, located in most bacterial and fungal phytochromes in the PAS domain and in the GAF domain in the case of plants. The chromophore, a linear tetrapyrrole, absorbs red light and undergoes a conformational change,

which in turn changes its spectroscopic properties, and the absorption maximum is shifted toward far-red light. The conformational changes are reversible, and thus the chromophore interconverts from the red-light-absorbing Pr form to the far-red-light-absorbing Pfr form. The photosensory domain has been crystallized from bacterial phytochromes and recently from *Arabidopsis thaliana* (94–96).

The PGP domain is followed by a histidine-kinase domain, which consists of an ATP-binding and a substrate domain with a critical histidine residue. In plants this histidine residue is replaced by an arginine or glutamate, and thus the enzyme is not catalytically active. In contrast, in bacteria and fungi the histidine is conserved and phosphorylation activity has been demonstrated (91, 97, 98). In some bacteria and in fungi the histidine-kinase domain is followed by a response-regulator domain. Unlike plant phytochromes, *A. nidulans* FphA possess an N-terminal extension of 172 amino acids, which was shown to stabilize the Pfr form (97). The sequence similarities suggest a bacterial two-component signaling module as the origin of phytochrome and hence phosphorylation events as part of the signaling cascade (99, 100). In *A. nidulans*, *in vitro* experiments showed that the protein can become autophosphorylated at histidine number 770 and that it is capable of intermolecular phosphotransfer to the aspartate residue number 1181 of the response-regulator domain of a second phytochrome molecule (97). While autophosphorylation was stimulated by red light and shown to be dependent on the chromophore, transphosphorylation was independent of the chromophore and also found with apo FphA as the substrate. Autophosphorylation was stimulated with red light. In addition to the autophosphorylation activity of FphA, it was shown that aspartate 1181 serves as a substrate for YpdA, a histidine-containing phosphotransfer protein, *in vitro* (101). Hence, phosphorylation events are likely to play crucial roles in signal transduction in fungi and perhaps the interconnection with other pathways.

An open question concerns the nature and production of the chromophore. Although *in vivo* data are not yet available, it was shown that *A. nidulans* phytochrome incorporates biliverdin *in vitro* and, with less efficiency, phycyanobilin (74). Linear tetrapyrroles are normally generated by heme oxygenases. This is also how active phytochrome can be expressed in *Escherichia coli*, namely the coexpression of phytochrome along with a cyanobacterial heme oxygenase (74). However, heme oxygenase candidates were not found in the genome of *A. nidulans*.

Many fungi contain phytochromes, and sometimes even two or three genes can be found in their genomes (13, 102) (Fig. 2). However, functional studies remain to be conducted for most fungi. *N. crassa* contains two phytochrome genes, and it was only very recently that a role in the timing of sexual development could be assigned to one of them. Both phytochromes, though, affected the expression of a large number of genes (103). Thus, our knowledge of fungal phytochrome functioning is largely based on the results obtained in *A. nidulans*, and it is highly desirable that the light response of other fungi with pronounced red-light effects be studied at the molecular level. No phytochrome genes have been detected in the genomes of *P. blakesleeanus*, *M. circinelloides*, or other Mucoromycotina fungi, but a candidate phytochrome gene has been found in the chytrid *Spizellomyces punctatus* (Fig. 2) (17).

Cryptochrome and Photolyases

Cryptochromes are plant blue-light photoreceptors very similar to photolyases, enzymes required for blue-light-dependent DNA repair. They bind noncovalently the flavin chromophore FAD and other, probably secondary, chromophores (pterin or deazaflavin) and do not show photolyase activity (104, 105). Cryptochrome genes have been described in the genomes of several fungi, but their role in light sensing or DNA repair has been investigated only in some species (Fig. 2).

Neurospora CRY belongs to the cryptochrome-DASH subfamily, and the gene is induced by light in a WC-1-dependent manner and by the circadian clock (106). The *Neurospora* cryptochrome binds the blue light-absorbing chromophores FAD and MTHF (methenyltetrahydrofolate) when the gene is expressed in *E. coli* and shows DNA binding activity *in vitro* (106). A role has been proposed for CRY in the regulation of the activity of the WCC for the activation of some light-induced genes such as *con-10* (107). However, genome-wide activation of transcription by light is not significantly altered in the *Neurospora cry* mutant (106), suggesting a very limited role of CRY in the regulation of transcription by light. CRY also plays a marginal role in the regulation of the *Neurospora* circadian clock as a component of a secondary oscillator (108).

F. fujikuroi cryptochrome CryD is also a member of the CRY-DASH family and participates in the regulation of secondary metabolism and the development of conidia (109). In the ascomycete *Sclerotinia sclerotiorum*, deletion of the CRY-DASH gene results in minor developmental defects, suggesting that, as in *Fusarium*, this protein may have a sensory role in this fungus (110).

A. nidulans CPD photolyase CryA is phylogenetically related to cryptochromes and has dual roles as DNA repair enzyme and photoreceptor. CryA provided DNA repair activity in *E. coli*, and deletion of the *cryA* gene reduced the sensitivity in the near-UV/blue region of the spectrum for the inhibition of sexual development, supporting its role in this process (19). A similar dual role has been proposed for *T. reesei* Cry1, a member of the 6-4 photolyase family. Cry1 provides DNA repair activity in conidia of *T. reesei*, and its biochemical characterization shows that it can bind and repair DNA lesions *in vitro* or in *E. coli* cells expressing *cry1* (111). The changes in the pattern of light-dependent transcription in the *cry1* mutant suggested a sensory and regulatory role in the regulation of light-induced transcription (64).

A role in DNA repair has been proposed for a cryptochrome in *P. blakesleeanus*. This fungus shows a blue-light-dependent photoreactivation that is typical of photolyases despite the absence of a photolyase gene in the genome (112). Indeed, cryptochrome-DASH (CryA) provides DNA repair activity *in vivo* when expressed in *E. coli* and can bind and repair single-stranded and double-stranded DNA *in vitro*, suggesting that CryA acts as a photolyase for DNA repair in *P. blakesleeanus* (113). As such, CryA seems to represent an early step in the evolution of cryptochromes from DNA repair enzymes to sensory photoreceptors. It is tempting to speculate that proteins homologous to CryA in fungi related to *P. blakesleeanus* play similar roles as DNA repair enzymes despite being identified as cryptochromes by their amino acid sequences (113).

Opsins

Rhodopsins are membrane-embedded seven-transmembrane helix photoreceptors composed of a retinal chromophore bound to an opsin apoprotein (114–116). Despite their ubiquitous role as photoreceptors for animal vision, the opsin genes described in several fungi and their role in fungal photobiology are only starting to be appreciated.

Neurospora NOP-1, the first example of a fungal opsin, shows a slow photocycle and long-lived intermediates, consistent with a role as a sensory photoreceptor (117–121). However, the inactivation of *nop-1* did not result in a blind phenotype (120). *nop-1* mRNA accumulates during asexual or sexual development, with a large amount of the mRNA observed during late conidiation but not during early vegetative growth (120). A regulatory role for the NOP-1 protein has been suggested based on changes in mRNA accumulation of light and conidiation-regulated genes (122).

A rhodopsin gene has been isolated from *Leptosphaeria maculans*, the fungus responsible for blackleg disease of *Brassica* species. The *Leptosphaeria ops* gene seems to be constitutively expressed, unlike its *Neurospora* homolog (123), and is active as a light-driven proton pump when expressed in yeast membranes (124). The capacity of *Leptosphaeria* rhodopsin to act as a proton pump seems to require specific amino acids and the presence of hydrogen-bonded water molecules (119). However, the role of a light-dependent proton pump in the biology of *L. maculans* remains to be clarified.

Two opsin genes, *carO* and *opsA*, have been identified in the genome of *Fusarium* species. The gene *carO* was identified in a cluster of genes for carotene biosynthesis, suggesting a common regulation. Indeed, *carO* was induced after light exposure and was overexpressed in carotene-overproducing strains, like other neighboring *car* genes (125). Since the synthesis of the retinal chromophore requires a regular supply of carotenes, the coregulation of the opsin apoprotein gene with the genes involved in carotenoid biosynthesis may ensure that opsin apoproteins are not wasted in the absence of retinal molecules. CarO is a light-driven proton pump that is abundant in conidia and retards germination under light, suggesting a role for CarO in the regulation of fungal germination (126). The other opsin gene, *opsA*, is not linked to the *car* cluster and is subject to a different regulation: mRNA levels are moderately induced by light, and *opsA* is not overexpressed in carotene-overproducing strains (127).

In *A. nidulans* an opsin homolog can be found in the genome as well. However, the critical lysine residue for retinal binding is absent, and thus it is not yet clear if it is a chromoprotein and plays any role in light regulation. A similar opsin-like gene has been identified in the genome of *T. atroviride*, but its role remains to be identified. Opsin genes have not been detected in the genomes of *P. blakesleeanus* or *M. circinelloides* (Fig. 2) (17).

A detailed characterization of the role of an opsin as a fungal photoreceptor has been described for *B. emersonii*. The photoreceptor for phototaxis in this fungus is a fusion protein containing an opsin domain and a guanylyl cyclase catalytic domain, suggesting a role for the cGMP signaling pathway in vision as it has been described in vertebrates (58). It is tempting to speculate that this is an ancient mechanism of vision that was lost in most fungi and is still observed in vertebrates.

The absence of obvious phenotypes in most fungal strains lacking a functional rhodopsin gene is puzzling.

However, the use of action spectroscopy and chromophore replacements with retinal analogs indicated that rhodopsins are the most likely photoreceptors that guide zoospore motility in the chytridiomycete fungus *A. reticulatus* (57). It is possible that rhodopsins play a key role in zoospore motility in other members of the Chytridiomycota.

BLUE-LIGHT SENSING: THE WC SYSTEM

In *N. crassa*, which is considered the model fungus for the study of blue-light responses, it has been found that most blue-light responses are controlled by WC-1 and WC-2 (128). In the dark a WCC composed of a WC-1/2 heterodimer is formed (54) that binds to light response elements in the promoters of light-responsive genes. However, this complex appears to be unable to trigger transcription *in vivo* (77, 129, 130). It is believed that upon exposure to light, structural changes in the WC-1 LOV domain take place, resulting in changes in the quaternary structure of the WCC that make it active (54). Upon activation by light, the WCC transiently binds to the light response elements of early light-responsive genes. Subsequently, transcriptional initiation takes place, which has been associated with transient phosphorylation events of WC-1 preceding removal of WC-1 from light response elements (130–133) (Fig. 3). This mechanism is assumed to be similar in many

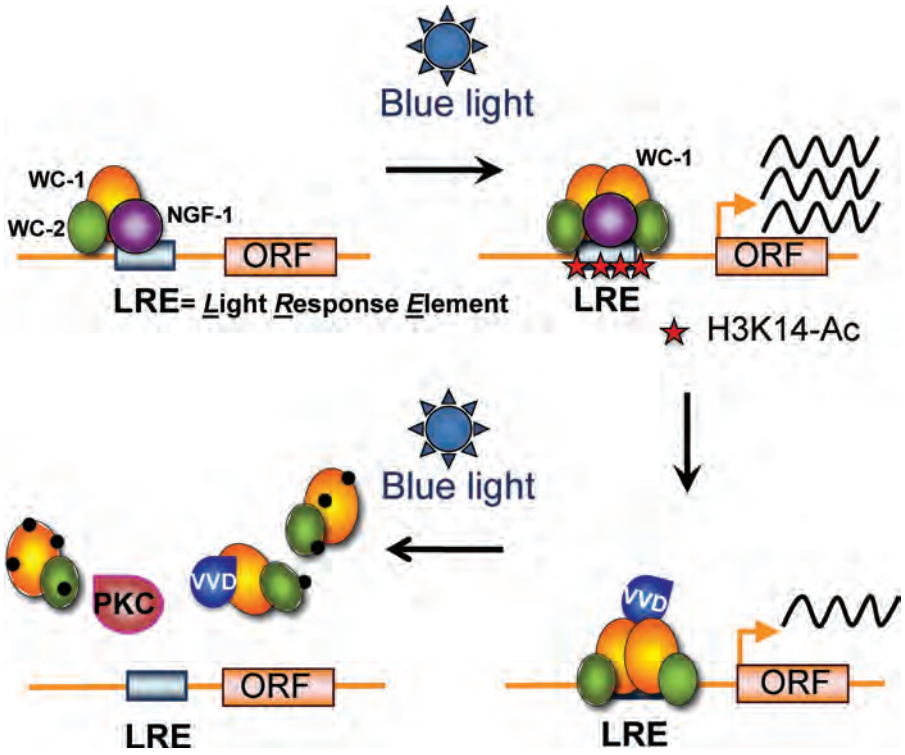

Figure 3 Model for WCC-dependent light signaling in *Neurospora crassa*. A simplified model for the activation of transcription by light and photoadaptation. Light reception by the FAD chromophore of WC-1 should trigger the formation of a flavin-cysteinyl adduct, causing a conformational change that leads to WCC dimerization, chromatin remodeling through the histone acetyltransferase NGF-1, and the activation of gene transcription. The modified histones are shown by stars at the site of promoter binding. Light exposure stimulates the transcription of *vvd*, *frq*, and other light-induced genes. Newly synthesized VVD competes with the light-activated WC-1 and disrupts the formation of WCC dimers, reducing WCC binding to the promoter. The WCC bound to VVD is not transcriptionally active, and it results in the attenuation of the response to light. Different fractions of the light-activated WCC are stabilized by FRQ (not shown) and transiently phosphorylated (black dots) and partially degraded, probably through an interaction with the protein kinase C (PKC) and other kinases and phosphates, some of them not yet identified (not shown).

other fungi that respond to light using WC orthologs, although in most cases this has not been proven (1).

Chromatin modifications are also involved in the photoinduction of gene expression regulated by the WCC (Fig. 3). Light-induced acetylation of promoter histone H3-K14 appears to be essential for the activation of light-induced genes (134, 135). Furthermore, a strain expressing a mutant allele of H3 (*hH3K14q*) that cannot be acetylated at K14 behaves like a *wc-1* mutant strain (135). Such histone acetylation is carried out by the acetyltransferase NGF-1, which directly interacts with WC-1 (134). Recently, H3K9me3 DNA methylation by the methyltransferase DIM-5 has been found to be involved in the repression of light-induced gene expression (136). Thus, there are at least two levels of control of WCC light-induced expression of genes at the chromatin level.

Organisms must be capable not only of perceiving the presence or absence of light but also of detecting subtle changes in its intensity to elicit adequate behavioral and developmental responses. Consequently, they have evolved mechanisms to adapt to prolonged exposure to light while retaining sensitivity to changes in its intensity. After prolonged exposure to light, gene expression undergoes photoadaptation in *Neurospora* and *Trichoderma*, returning to basal levels after 1 to 4 h of exposure to light (137, 138). To remain sensitive to an additional increase in ambient light intensity, both fungi are able to adapt to various levels of light intensity (137–139).

In *N. crassa*, VIVID (VVD) is a small LOV domain-containing blue-light photoreceptor that functions downstream of the WCC to negatively regulate the light responses initiated by the WCC. In light VVD forms a rapidly exchanging dimer in solution, suggesting the possibility that the LOV domain of VVD could interact with other PAS domains, including those found in the WCC proteins (84). Indeed, it was shown that there is a physical interaction between VVD and the WCC that results in a reduction of the transcriptional response, which could explain photoadaptation (87, 137, 140, 141) (Fig. 3). Further, a data-driven mathematical model proposes that VVD allows *Neurospora* to detect relative changes in light intensity. In this model VVD acts as an inhibitor of WCC-driven gene expression and as a positive regulator that sustains the responsiveness of the photosystem. The authors of that model suggest that this function is carried out by a futile cycle involving the light-induced sequestration of the active form of WCC by VVD and the replenishment of the activatable WCC pool through the decay of the photoactivated state (142).

RCO-1 and RCM-1, the *Neurospora* homologs of the corepressor complex Tup1-Ssn6 in yeast, play a role in photoadaptation. RCO-1 and RCM-1 accumulate in *Neurospora* nuclei (107) and interact to form a repressor complex similar to that observed in yeast (143). When exposed to five hours of light, the *rco-1* and *rcm-1* mutants show a sustained expression of light-induced genes, suggesting that the RCO-1/RCM-1 complex is involved in photoadaptation. The absence of the RCO-1/RCM-1 repressor complex leads to a reduction in the amount of VVD that is available for the regulation of the WCC. The reduction in the amount of VVD results in increased WCC binding to the promoters of light-regulated genes in the dark and after long exposures to light, leading to the modification of photoadaptation that has been observed in *rco-1* and *rcm-1* mutants. These results indicate that the photoadaptation phenotype of mutants in the RCO-1/RCM-1 repressor complex is, at least in part, an indirect consequence of the reduction of *vvd* transcription and the resulting modification in the regulation of transcription by the WCC (144).

Photoadaptation has been observed in other fungi too. In *P. blakesleeanus* the activation of *hspA* gene expression by light was transient, which suggested the presence of a photoadaptation mechanism similar to that described for *Neurospora* and *Trichoderma*. However, photoadaptation of *hspA* was not prevented by changes in light intensities or dark incubations, unlike photoadaptation in *Neurospora* (145). Photoadaptation has been observed for the light-dependent transcription of the developmental regulator *brlA* in *A. nidulans* (59). The differences in the sensitivity to changes in light intensities, and the absence of a *vvd* homolog in the genomes of *P. blakesleeanus* or *A. nidulans* (Fig. 2), suggests the operation of a molecular mechanisms for adaptation in these fungi that is different from that described for *N. crassa*.

In addition to the central blue-light perception system constituted by the WCC, biochemical and molecular data suggest the participation of at least two light perception systems that regulate photoconidiation in *T. atroviride* (64, 146, 147). One of the proposed signal transduction pathways participating in this alternative light perception system involves cAMP, given that protein kinase A activity increases and induction of gene expression have been observed after a pulse of blue light in Δ*blr1* mutant strains (147). Additionally, as mentioned above, members of the cryptochrome/photolyase family have functions as regulators of gene expression in several fungi (1, 19, 111, 148, 149).

RED-LIGHT SENSING AND THE INTERPLAY WITH BLUE-LIGHT AND STRESS-SENSING SYSTEMS

In *A. nidulans* light can have activating and repressing functions. Whereas asexual sporulation occurs in light, sexual development is repressed and occurs in the dark. Interestingly, both red and blue light stimulated asexual sporulation, and for full induction, both light qualities were required (34, 150). This suggested the involvement of both FphA and the blue-light-sensing WC system (LreA and LreB). However, whereas deletion of *fphA* caused a reduction of conidia production, deletion of *lreA* and *lreB* caused a slight increase in conidia formation, suggesting a positive function for FphA and a negative function for LreA (34). Red light inhibits cleistothecia formation more effectively than blue light, but the combination of the two wavelengths increases the inhibition to the level of white light. Deletion of the phytochrome gene caused a slight increase, and deletion of *lreA* caused a decrease in the number of cleistothecia. The latter effect suggests a function of LreA independent of light. To analyze the effects of the light regulators at the molecular level, light-regulated genes were identified in genome-wide analyses (59). Two of those genes, *ccgA* and *conJ*, were chosen for further analysis, because the orthologs were known to be light regulated in *N. crassa*. In contrast to the effect of light on sporulation, both genes were highly upregulated by red but not by blue light (34, 150). Because *ccgA* and *conJ* do not play any obvious role in asexual development, it is possible that the regulation of the two genes is distinct from the regulation of genes involved in conidiation. In addition, it has to be considered that sporulation or cleistothecia formation involves hundreds of differentially expressed genes. Some of these genes may be regulated like *ccgA* or *conJ*, but others may be regulated differently. Therefore, *ccgA* and *conJ* will be discussed as models to understand the effects of light at the molecular level.

Because FphA, LreA, and LreB were found within the nuclei, direct interactions of those proteins with the two promoters were feasible. Indeed, LreA was detected bound to the *ccgA* and *conJ* promoters in the dark and was released after illumination (150). Phytochrome, however, could not be detected at the promoters of these genes (Fig. 4). Thus, LreA/B could have a repressing effect and FphA an activating function without interacting directly at the promoter level, raising the question of how the information from FphA could be transmitted to the promoters. One key protein could be VeA (velvet A), another well-known fungal regulator involved in the light response (151–153). VeA contains a domain with structural similarity to NF-κB, a well-known transcription factor (154). It localizes to nuclei, and we found a physical interaction between VeA and FphA within nuclei (34). It was demonstrated that it is a multiphosphorylated protein, and a phosphorylation code has been postulated to explain the involvement of the protein in many different pathways (155, 156). The localization and accumulation of VeA in nuclei appears to be dependent on the phosphorylation of certain amino acids, where it binds to the *ccgA* and *conJ* promoters. However, this was independent of the illumination conditions, and therefore the exact role of VeA is still unclear. Apparently, VeA is required for LreA binding to the promoters (150). In summary, it appears that only FphA has an essential function in gene induction and that other proteins studied so far serve minor functions, probably allowing the integration of different regulatory cues. A breakthrough for the understanding of signal transduction from FphA to the gene expression level was achieved using a classical mutant-screening approach, where SakA, the stress-activated kinase, was identified (4). This indicates a link between light and stress signaling and a role for the transcription factor AtfA as a central component of light-dependent gene induction (157) (discussed below). In agreement with these recent findings connecting phytochrome signaling stress, mitogen-activated protein kinase (MAPK) signaling has been studied in *Beauveria bassiana*, in which phytochrome was shown to be involved in multistress tolerance (158). However, a mechanistic link between light sensing and other stresses has not yet been established in *B. bassiana*.

Besides a role of phytochrome in triggering the activity of transcription factors, a role in chromatin remodeling in *A. nidulans* is also likely (Fig. 4A). The acetylation level of the *ccgA* and *conJ* promoters changed upon illumination, and this change depended on LreA and FphA (150). It was also found that LreA interacts with the acetyltransferase GcnE and the histone deacetylase HdaA. Since FphA interacts with the WCC, it could be that FphA indirectly modulates the activity of these enzymes, but there is also some evidence that FphA directly interacts with the two enzymes (150). Hence, phytochrome-dependent gene regulation appears to occur at transcriptional and chromatin-structural levels. Unfortunately, the interplay between LreA, LreB, and phytochrome in this process is not yet well understood.

Phytochrome interacts with several other proteins, and these interactions could be indicative of its function as well. It is possible that some of the interaction partners modulate or control the phosphorylation

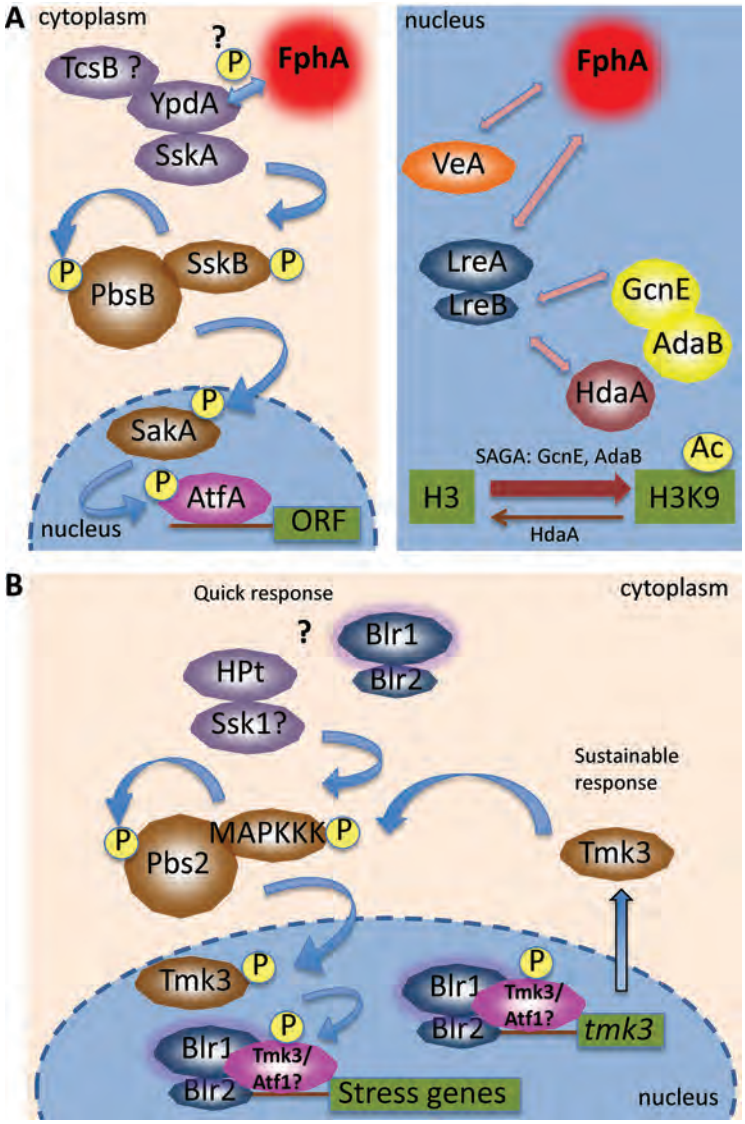

Figure 4 Phytochrome functions in light regulation in *Aspergillus nidulans* and the link of light and stress sensing in *A. nidulans* (A) and *Trichoderma atroviride* (B). (**A, left panel**) There is good evidence that the light signal is perceived by FphA in the cytoplasm and transmitted into the nucleus by activating the SakA stress signal pathway. SakA becomes phosphorylated, shuttles into the nucleus, and activates the transcription factor AtfA. (modified after 177) (**A, right panel**) Light signaling also involves chromatin remodeling of the promoters of light-regulated genes such as *ccgA* or *conJ*. It was shown that the acetylation level of lysine 9 of histone H3 increases upon illumination, that LreA interacts with the acetyltransferease GcnE and the histone deacetylase HdaA, that deletion of the SAGA/Ada complex component AdaB causes reduction, whereas deletion of *hdaA* causes induction of the photoinduction, and that changes of lysine 9 in histone H3 phenocopy the phenotypes of *adaB*- or *hdaA*-deletion strains. VeA is always bound to the *ccgA* or *conJ* promoter, whereas LreA leaves the promoter upon illumination. Hence, LreA could keep GcnE inactive and stimulate HdaA in the dark. The situation would be reversed after illumination, and the acetylation level of the lysine residue 9 of histone H3 would increase. There is evidence that GcnE is further activated through FphA. Lysine 9 acetylation was dependent on FphA, but an interaction between the two proteins was only shown by split YFP and could not be verified by Co-IP. The arrows indicate protein interactions verified by different methods. It should be noted that the current models rely solely on the results obtained with two light-regulated genes, *ccgA* and *conJ*. (**B**) The link between light and stress regulation in *T. atroviride*. In a quick response light causes phosphorylation of the MAPK Tmk3, which requires the MAPKK Pbs2. Nevertheless, it is still unclear where the WCC is linked to the Tmk3 MAPK pathway. At the promoter of a set of light-regulated genes the WCC could interact either with Tmk3 or with a not-yet-identified AtfA ortholog. Light also stimulates the transcription of the *tmk3* gene, giving rise to higher levels of Tmk3, which may aid in keeping a sustained response.

activity of FphA. Indeed, it was shown that the autophosphorylation activity increased if inactive phytochrome was added (97). New insights and hypotheses into red-light signaling in fungi may also come from the comparison with red-light signaling in plants (159).

The current model for phytochrome-dependent gene regulation in fungi mostly relies on findings in *A. nidulans*, and it will be interesting to compare the sys tem with other fungi in which phytochrome is likely to play a role. For example, conidiophore production in *B. cinerea* is induced by UV light, but conidia formation then occurs in the dark. Blue- but also red-light illumination inhibits spore production (33, 160). The molecular basis for red-light sensing in this fungus has not been investigated in detail yet, although three phytochrome-encoding genes were identified in the genome (102). In *Trichoderma*, red light provokes a reduction in mycelial growth and also has an impact on the transcriptional regulation of some genes, indicating the participation of a phytochrome in these responses (45, 161). However, expression of the set of genes that respond to red light is also controlled by blue light (64). These observations suggest that blue and red light photoreceptors act together to regulate expression of these genes. In this regard, it has been suggested that in *N. crassa* the photoreceptors CRY-1, NOP-1, and PHY-2 modulate the activity of the WCC, presumably through the light-dependent activation of a putative repressor of the WCC (162). Furthermore, expression analysis of a small set of genes in the Δ*blr1*, Δ*phr1*, and Δ*cry1* mutants of *T. atroviride* showed that the three potential blue-light photoreceptors are involved in the control of gene expression in both blue and red light (64).

LIGHT SIGNALING TO STRESS MAPKs

Most of recent research in fungal photobiology has focused on the identification and characterization of the WC photoreceptor complex and other photoreceptors, but little attention has been paid to the components of the signal transduction pathway that relies on the light input into the cell. The key role of the transcription factor and blue-light WC photoreceptor complex in *N. crassa* and other fungi suggests a prominent role for light-dependent gene regulation in fungal photobiology. However, it is possible that the WCC and other photoreceptors regulate other aspects of fungal biology at the posttranscriptional level through the action of a signal transduction pathway that starts with the reception of light by the photoreceptor. As mentioned earlier, a connection between light sensing and MAPK signaling has been established in some fungi, which could constitute a more general aspect of fungal photobiology.

Indeed, many environmental signals are transmitted through conserved three-tiered phosphorylation cascades composed by a MAPK, a MAPK kinase (MAPKK), and a MAPKK kinase (MAPKKK). Active MAPKs phosphorylate multiple targets including other enzymes and usually translocate from the cytoplasm to the nucleus to phosphorylate nuclear targets such as transcription factors. Stress-activated protein kinases (SAPKs) are MAPKs that are specialized in transducing stress signals. In fungi, SAPK input involves the participation of phosphorelay signal transduction systems composed by different sensor histidine kinases (HK), a phosphotransfer protein (HPt) Ypd1, and a response regulator (163) (RR) (Fig. 4).

The first report connecting light to MAPK signaling in fungi showed a circadian rhythmic activation of the SAPK OS-2 in *N. crassa*, which was dependent on WC-1, the clock component FRQ-1, and the RR RRG-1 (164). Notably, OS-2 phosphorylation induced by osmotic stress required RRG-1 but not the WC-1/FRQ-1 oscillator, indicating that OS-2 regulation by osmotic shock and circadian clock occurs through different pathways, upstream of RRG-1. Later it was shown that WC-1 mediates SAPK light input by binding to the promoter of the *os-4* gene, encoding MAPKKK OS-4, both in response to light and in a rhythmic fashion under constant darkness. Deletion of *os-4* WC-1 binding sites disrupts *os-4* mRNA and OS-2 phosphorylation rhythmic oscillations. Since WC-1 is also indirectly required for antiphase rhythmic expression of the HPt gene *hpt-1*, it was proposed that such WC-1-mediated antiphase expression of positive (OS-4) and negative (HPT-1) SAPK regulators is coordinated to enhance the rhythmic activation of the OS-2 pathway (5). The negative relationship between phosphotransfer HPt proteins and SAPKs has been indicated by the fact that the elimination of HPt proteins is lethal in wild-type backgrounds in *A. nidulans* (165) and *N. crassa* but is viable in an *os-2* null background (166). Furthermore, the transcription factor ALS-1, also reported as ATF-1 and proposed to act downstream of OS-2 (167), is required for the circadian rhythmic oscillation of OS-2 responsive genes *bli-3*, *ccg-1*, *cat-1*, *gcy-1*, and *gcy-3*, in the absence of osmotic stress (168).

More recently, it has been shown that transcript levels of the *T. atroviride tmk3* gene, which encodes SAPK Tmk3, are increased after blue-light exposure, and this depends on the WC homolog Blr1. Likewise, light-induced conidiation and the induction of the

blue-light-regulated genes *blu1* and *grg2* is drastically reduced in mutants lacking Tmk3 or the upstream MAPKK Pbs2 (3). Although it is not known if transcription factor Atf1 is required for light induction of these genes, these data show that through Blr1, light regulates SAPK signaling at the transcription or mRNA stability levels. Because the *tmk3* promoter contains putative Blr2-binding sites, the authors propose a model in which the Blr1/Blr2 photoreceptor complex could regulate *tmk3* expression and also mediate light input to the SAPK pathway upstream from Pbs2 and/or interact with Tmk3 in the nucleus to promote the transcription of stress and light-responsive genes (Fig. 4, B). It seems possible that Blr1/Blr2 could also regulate the expression of MAPKKK and Hpt1 proteins, as in *N. crassa* (5). In addition, Blr1 is required for Tmk3 transient phosphorylation after mycelia exposure to a light pulse or constant illumination. One possibility is that *T. atroviride* Blr1/Blr2 forms a complex with the HK equivalent to phytochrome FphA, as it occurs in *A. nidulans* (34, 155), and transduces direct phosphorylation signals to the SAPK pathway (4). Alternatively, Blr1/Blr2 could feed the pathway downstream of Tmk3. As in *S. pombe* (169) and *A. nidulans* (170), Tmk3 is required for resistance to different types of stress (3), and SAPK activation by heat shock (171) and nutrient limitation (172) in *S. pombe* occurs downstream of Spc1/Sty1 through inhibition of specific tyrosine phosphatases.

As mentioned before, red-light sensing has recently been connected to MAPK signaling in *A. nidulans* through the phytochrome FphA (4), which is a hybrid HK (34, 155). This fungus contains 15 HKs, and the function of most of them is unknown. Genetic evidence indicates that the HK NikA transmits osmostress and fungicide signals to the phosphotransfer protein YpdA and to the response regulator SrkA, which is coupled to the SAPK SakA (170), as well as to the SAPK-independent RR called SrrA (165). SakA was also identified as HogA and shown to be involved in gene regulation in response to osmotic stress (173). Upstream, MAPKK PbsB and MAPKKK SskB regulate SakA (174), which is phosphorylated in response to multiple types of stress, including osmotic, oxidative (170), nutrient starvation (157), and hypoxia (Sánchez and Aguirre, unpublished). Stress-activated SakA translocates to the nucleus, where it interacts with transcription factor AtfA, which is required for induction of several genes, including catalase genes *catA* and *catB*, and both Δ*sakA* and Δ*atfA* mutants are sensitive to oxidative stress (157). Both SakA and AtfA are also required for osmotic-induced gene expression (175). It is worth mentioning that SakA also interacts with MAPK-activated protein kinase SrkA and that both show H_2O_2-induced interaction with other proteins involved in SAPK signaling, cell-cycle regulation, DNA damage response, and mitochondrial function (176), because such interactions might become relevant to the light-sensing process. In addition, SakA and AtfA play important roles during development, repressing sexual development and being activated during asexual development (170). Δ*sakA* intact conidia progressively lose their viability, and this is consistent with the fact that SakA accumulates in asexual spores (conidia) in an AtfA-dependent manner. SakA becomes phosphorylated during conidia development and needs to be dephosphorylated for germination to take place, indicating that this SAPK plays essential roles in the transition between growth and differentiation (157).

Yu et al. isolated "blind" mutants by using a light-responsive promoter fused to a nutritional marker (4). By genomic sequencing, these authors found that different mutants carried inactivating mutations at the MAPKKK (SskB), MAPKK (PbsB), or MAPK (SakA) components of the SAPK pathway. Indeed, several lines of evidence support the involvement of this pathway in red-light and, to a minor extent, blue-light sensing. First, blind and Δ*sakA* mutants show the same phenotypes in terms of asexual/sexual development. Second, deletion of FphA upstream (SskA, SskB, PbsB) or downstream (AtfA) SAPK components results in failure to induce *ccgA* and *conJ* genes in response to light. Third, FphA physically interacts with the HPt protein YpdA, as shown by BiFC and coimmunoprecipitation. Fourth, light induces increased SakA phosphorylation and its nuclear localization in a way that depends on FphA but is independent of blue-light receptors LreA and LreB. Somewhat unexpectedly, blue light partially induces SakA nuclear localization, not as strongly as red light, and this response depends only on FphA. Notably, FphA-mediated regulation of SakA is not required for osmotic stress-induced activation of SakA.

Under certain conditions, FphA histidine kinase is able to autophosphorylate and transfer the phosphoryl group to the response regulator of a second interacting FphA molecule *in vitro* (97). Both phosphorylation sites in FphA, the histidine in the histidine-kinase domain and the aspartate in the response regulator domain, are essential for function (150). *In vitro* experiments showed that FphA autophosphorylation activity was higher in light than in dark (97), and the phosphotransfer from YpdA to FphA has been shown *in vitro*, using a truncated version of FphA lacking the first 677 amino acids (101). Taken together,

these results clearly support the role of FphA as a light-sensitive histidine kinase connected to the SakA-AtfA pathway at the YpdA level. However, they tell little about the actual phosphotransfer dynamics *in vivo*. Nevertheless, it is clear that *in vivo* red-light illumination results in the activation of the MAPK SakA and the regulation of red-light-responsive genes through the AtfA transcription factor.

Discussing these results, Yu et al. considered that FphA had a higher kinase activity in the dark, when actually it shows red-light-induced autophosphorylation *in vitro* (97). This led to a proposed model in which under dark conditions the HK FphA phosphorylates and associates with the HPt protein YpdA, and this leads to phosphorylation of the response regulator SskA and inactivation of SakA. Light would cause YpdA dephosphorylation and activation of the SakA pathway (4, 177). Such a model is consistent with the fact that light inhibits the germination of conidia in an FphA-dependent way (42), because it is known that high levels of phosphorylated SakA prevent spore germination (157). However, the exact mechanism by which red light activates SakA remains to be demonstrated.

LIGHT: A STRESS, A SIGNAL, OR BOTH?

The presence and functioning of different photoreceptors in fungal cells and the low threshold for some responses to light suggests that light is used as a source of environmental information, because it clearly occurs during the phototrophic reaction of Phycomyces. The connection between light, photoreceptors, and the stress MAPK can be interpreted as a mechanism that uses the light cue to activate the SAPK pathway to anticipate and prepare the cell for later stress (164). In this scenario, light is a reliable signal about incoming changes in temperature, osmotic stress, oxidative stress, and damaging UV radiation. Such alarm signaling can occur many times during the day as hyphae grow in and out of their substrate or in circadian rhythms as an alarm system that every morning prepares fungi for the stress of the day. However, recent evidence suggests that excessive light can also directly cause cell stress (i.e., the production of H_2O_2 and other reactive oxygen species [ROS]), which in turn might activate photoreceptors and SAPKs. The fact that the replacement of key cysteine 196 by threonine in *T. reesei* ENV1 (138), a homolog of *N. crassa* VVD, abolishes adaptive responses to both light and oxidative stress *in vivo* (85) suggests that light and ROS signals perceived by a single protein could be transmitted to SAPK or other signal transduction pathways.

Additional, less direct evidence connecting light irradiation and ROS production has been reported in other fungi. In *B. cinerea*, constant light impairs growth of a wild-type strain, and this is more drastic in mutants lacking the WC homolog BcWCL1. Notably, this can be enhanced and reversed by adding H_2O_2 and antioxidants, respectively (102). In *N. crassa*, deletion of the superoxide dismutase *sod-1* gene results in circadian rhythmic conidiation (178). Microarray analyses of the light response of *A. nidulans* and *N. crassa* revealed that stress-related genes are activated by light (59, 137). Similarly, transcriptome analyses of this response in *T. atroviride* showed that a significant proportion of the light-induced genes are related to oxidative and other types of stress responses (64). Furthermore, a recent proteome analysis of the *Penicillium verrucosum* response to light indicated that many of the induced proteins are involved in responses to stress (179). In *A. fumigatus* exposure to light results in enhanced resistance to acute UV and oxidative stresses and an increased susceptibility to cell wall perturbation (41), and in *B. bassiana* the putative phytochrome (*Bbphy*) is not only a photoreceptor essential for asexual development, but it also acts as a regulator of the fungal responses to a variety of stresses, including oxidative stress (158).

Evidence linking light and ROS production has also been reported in animal systems. In zebra fish light induces H_2O_2 production, while external H_2O_2 induces cryptochrome *zCry1a* and period *zPer2* gene expression and the subsequent circadian oscillation of *zPer1*. Notably, the expression of the catalase gene *zCat* shows antiphasic oscillation to *zCry1a* and *zPer2*, and consistent with this, *zCat* overexpression causes reduced induction of *zCry1a* and *zPer2* by light (180).

All these results clearly show a connection between light, circadian rhythms, and redox metabolism, which is consistent with the idea that monitoring ROS levels is essential in triggering cell differentiation (181). Such interesting relationships can now be studied from the perspective of the established connections between light, stress, and SAPK signaling.

WHY SO MANY PHOTORECEPTORS?

Although the effect of light on fungal development and physiology was recognized long ago, the molecular analysis reveals a complex picture of light sensing. It appears that light is an important environmental cue mainly to adapt fungal biology to stressful or harmful conditions. One of the open questions, however, is why several photoreceptor and light-sensing systems were established during evolution if their role was only to

detect light or darkness. Although normally one photoreceptor system appears to dominate the light response in a given species, such as the blue-light-sensing system in *N. crassa* or the red-light response in *A. nidulans*, there is very good evidence that the additional systems also play certain roles. It could be that the different photosensing systems evolved for the sake of robustness in light sensing. However, one system does not seem to substitute for the lack of the other, suggesting that sensing different light qualities provides an advantage. Although monochromatic light is rare in nature, the composition of daylight may vary significantly. For instance, blue light penetrates deeper into water than red light, red light is more present in the evening, plants absorb the blue and red range of the spectrum, and fungi living in the shade of plants are exposed to more green light. Fungi are able to sense these spectral differences as additional environmental cues to adapt to their lifestyles accordingly. The existence of several photoreceptors and their relative conservation during evolution also suggests that the light stimulus needs to be transduced to different biological processes, which might be more difficult with a single photoreceptor. In *B. bassiana* phytochrome appears to be also involved in sensing the length of the illumination period. Whereas a wild-type strain grown for 7 days produced the maximum amount of conidiospores with 3 h of white light illumination (21 h darkness), the phytochrome mutant required 16 h of light (8 h darkness) (158). Although such adaptive changes may be rather subtle in other fungi and hard to detect under laboratory conditions, they might be important for fitness and survival in nature.

In addition to our improved understanding of photoreceptors in light responses, it appears that some of these proteins also serve functions in the dark. One prominent example is the WCC in *N. crassa*. This is the positive element in the circadian clock system, and it enables its entrainment by light. However, one of the conspicuous features of the clock is its free running in the absence of external stimuli (53). As germination is delayed in the dark in the absence of phytochrome in *A. nidulans* (42), phytochrome also appears to have functions in the dark. A still open question is, Which was the ancestral function of photoreceptor proteins? We think that initially, fungal vision originated as a mechanism to anticipate the stress and damage caused by light. Alternatively, it is possible that the fungal ancestor, being a motile cell living in the ocean, could use low and different colored light as a guide, explaining the large number of different photoreceptors in all fungi. Once fungal ancestors changed their living habitat to soil and plant surfaces, the primordial light detection system was adapted as a protective system to predict excess light.

CONCLUDING REMARKS

Fungal genome projects have allowed the identification and characterization of several photoreceptor genes, many of them unexpected. The identification of the WCC in *N. crassa* has served as a model for other fungi, and in most cases mutants in the homologs of the WCC result in blind phenotypes. On the other hand, *A. nidulans* displays a pronounced red-light response, and phytochrome has been characterized in some detail. Recently, also in *N. crassa*, a role for phytochrome was assigned. In addition, opsin may be a new player in photosensing. When all this is taken together, it becomes evident that fungi employ several photoreceptors, and we are just at the beginning of unraveling their functions and interlinked signaling cascades. Given the broad impact of light on fungal growth, development, and physiology, the understanding of the roles of and interactions among fungal photoreceptors will be a major avenue of fungal research in the near future.

INTRODUCTION

Planet Earth plays host to an extravagantly diverse range of fungal species. Recent estimates suggest the probable existence of as many as 3 million fungal species (1), and the *circa* 75,000 of these that have been characterized to date display a wide range of lifestyles. Many fungi occupy specific niches within natural environments, playing essential roles in nutrient scavenging and recycling. Some thrive in close harmony with species from other kingdoms, a superb example being the mycorrhizal fungi, which display mutualistic interactions with plants. Other fungi are pathogenic, causing devastating infections of plants or animals. Indeed, the global threats that fungi pose to human health and food security are being increasingly recognized (2). Fortunately, a relatively small number of fungal species cause infections in humans (circa 400 species are described in the *Atlas of Clinical Fungi* [3]). Some of these fungi normally occupy environmental niches but are capable of colonizing and damaging human (or animal) tissues, whereas other fungi appear to be obligately associated with their host.

These diverse fungal niches are dynamic in that they display fluctuations in local parameters such as temperature, water balance, pH, or the levels of particular compounds such as nutrients and reactive oxygen and nitrogen species. These fluctuations are often capable of perturbing cellular homeostasis and causing molecular damage, thereby imposing stress on the fungal cell. Consequently, fungal cells must be able to adapt to these dynamic changes if they are to survive, grow, and colonize any niche. This stress adaptation is dependent on three fundamental principles. The first is the ability to detect environmental signals, i.e., the changing inputs from the local environment. The second is the ability to transduce these signals to regulate the cellular processes that mediate the stress adaptation. The third represents the adaptive responses themselves that allow cells to survive the stress. These adaptive processes either counteract or detoxify the initial stress and repair or remove the molecular damage caused by that stress. These fundamental principles must apply to all fungi.

Given the elemental nature of environmental stresses, it is not surprising that there are fundamental similarities across the fungal kingdom (and beyond) with regard to the basic cellular processes that mediate adaptation to specific stresses. For example, evolutionarily divergent ascomycetes and basidiomycetes induce protein refolding mechanisms in response to changes in temperature (4, 5) and the synthesis of antioxidants following exposure to oxidative stresses (6, 7). However, different niches exert different evolutionary pressures, and this has led to considerable diversity between fungal species with regard to the robustness of specific stress responses. For example, the yeast *Debaryomyces hansenii*, which is found in hypersaline waters, can tolerate higher levels of salt than *Saccharomyces cerevisiae* (8), which seems to have evolved to grow on fruit and to be disseminated by wasps (9). Also, *Candida glabrata*, which is a fungal pathogen of humans that is relatively resistant to phagocytic killing (10), displays extremely high levels of oxidative stress resistance compared to other yeasts (11). This evolutionary tuning of stress resistance to the local niche has led to some divergence between fungal species in the regulation of the cellular processes that mediate adaptation to some stresses.

This chapter summarizes our current understanding of the mechanisms underlying fungal stress adaptation and the regulation of these responses. We focus on those

stresses that have been perceived to be the most relevant and hence have been most studied to date and the experimentally tractable model fungi in which stress adaptation mechanisms are best characterized. Also, we compare and contrast these outlooks on stress sensing to those from other fungi which have provided fascinating insights into niche-dependent stress adaptation.

ADAPTING TO INDIVIDUAL STRESSES

Heat Shock

Temperature modulates diverse facets of biology and disease (Fig. 1). Organisms across the tree of life must contend with changes in temperature that can manifest across a multitude of scales, from global climate change, to seasonal environmental change, to abrupt change associated with transitions in environmental niches. For microbial pathogens, temperature can signal the successful infection of a host and serves as a central cue governing proliferation, developmental programs, and virulence (12). As an example, fever is a ubiquitous response to infection, with elevated febrile temperatures thought to serve as an adaptive host response to restrict microbial proliferation. In a broader context, mammalian endothermy may have evolved as a strategy to minimize infections caused by fungal species, most of which have a diminished capacity to proliferate at elevated temperatures (13). Of the ~3 million fungal species estimated to exist, less than 0.1% are able to cause disease in mammals, and this can largely be attributed to most rapidly losing their capacity for growth above ambient temperature (14).

Thermal transitions have a profound impact on fungal development and virulence. For example, virulence of the dimorphic fungal pathogens is controlled by a temperature-dependent change in morphology (15). *Blastomyces dermatitidis*, *Coccidioides immitis*, and *Histoplasma capsulatum* are key species that exemplify the characteristic response to temperature of the dimorphic fungi: these species grow as filamentous molds in the soil in response to ambient temperature and convert to growth as yeast cells in response to host temperature upon inhalation of spores into mammalian lungs. The polymorphic fungus *Candida albicans* is another fungal pathogen for which temperature induces a dramatic morphological change (16). In contrast to the dimorphic fungi, *C. albicans* proliferates in the yeast form at ambient temperatures, and elevated temperature promotes a transition to filamentous growth. A temperature of 37°C is required to enable filamentation in response to diverse cues such as serum, and a further increase in temperature to 39°C is sufficient to induce filamentation in the absence of other cues (17). Beyond morphogenesis, temperature exerts a profound influence on diverse aspects of *C. albicans* biology, including mating, phenotypic switching, and drug resistance (17). In addition to the phenotypic consequences of growth at sustained elevated temperatures, fungi also have a profound response to acute but temporary increases in temperature that is referred to as a heat shock response. Strikingly, a transient heat shock can activate

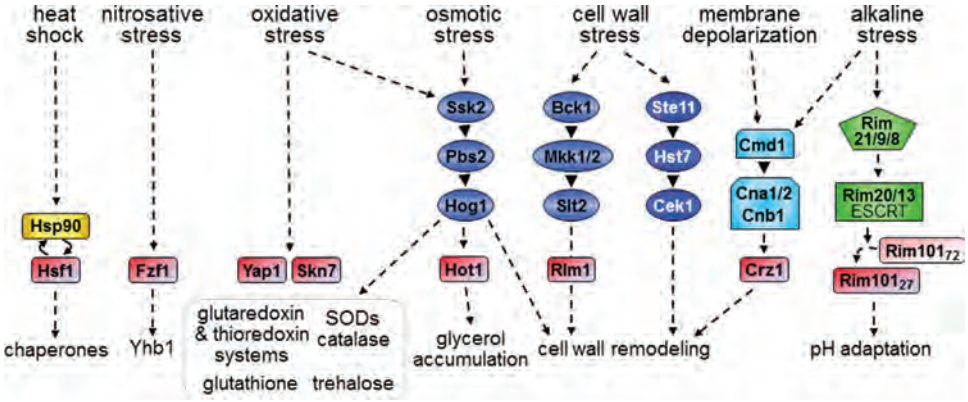

Figure 1 Cartoon summarizing stress pathways in the model fungus *S. cerevisiae*. See text. This figure summarizes some, but not all, of the known components of these signaling pathways. Components of MAPK signaling modules are highlighted in blue, transcription factors in pink, components of the calmodulin-calcineurin pathway in cyan, Rim pathway components in green, and the molecular chaperone Hsp90 in yellow. Note that the *C. albicans* Cek1 MAPK pathway, which contributes to cell wall remodeling in this fungus, is included (dark blue ovals with white lettering).

a *C. albicans* transcriptional program that is associated with increased host cell adhesion, host cell damage, and virulence (18).

Fungi have evolved complex molecular machinery and regulatory circuits to respond to the stress induced by sustained or transient responses to elevated temperature, with the heat shock response being one of the most evolutionarily conserved stress responses in nature. Core to the heat shock response is a global arrest of translation elongation and transcriptional activation of genes encoding heat shock proteins, which include molecular chaperones that promote folding and refolding (19). In *C. albicans* and the model yeast *S. cerevisiae*, ~10 to 20% of genes in the genome are induced in response to heat shock (20, 21). This transcriptional response is orchestrated in large part by the heat shock transcription factor Hsf1. In *C. albicans*, Hsf1 binds to 49 targets constitutively and an additional 55 targets in response to heat shock, with targets enriched for functions in protein folding and entry into the host (18). Hsf1 typically binds at nucleosome-depleted regions in the promoters of target genes and recognizes three motifs with distinct binding affinities (18). Hsf1 is activated by phosphorylation, and this activation is required for virulence in *C. albicans* (19, 21).

Complex functional relationships influence mobilization of cellular responses to thermal stress. Hsf1 promotes the basal expression and thermal induction of genes encoding the molecular chaperone Hsp90 (Fig. 1). Hsp90 in turn physically interacts with Hsf1, thereby exerting a repressive effect on activation of the heat shock response (19). As a consequence, perturbation of Hsp90 function by small molecules, mutations, or elevated temperature causes activation of Hsf1 and induction of the heat shock response in the absence of thermal stress. In contrast, Hsp90 is required to mobilize a rapid transcriptional response to thermal stress, such that depletion of Hsp90 causes delayed induction of the transcriptional program induced by heat shock (18). Hsp90 influences transcriptional programs not only via effects on Hsf1, but also by modulating chromatin remodeling, nucleosome removal, and RNA polymerase II stalling (22–24).

As a molecular chaperone, Hsp90 regulates the stability and function of diverse client proteins, which include many core cellular regulators beyond Hsf1. For many client proteins, Hsp90 stabilizes otherwise metastable regulators, thereby enabling their activation in response to stress or other cues (25, 26). In the context of thermal adaptation, Hsp90 stabilizes the Hog1 stress-activated protein kinase, as well as the mitogen-activated protein kinases Mkc1 and Cek1 (27–29). In this context, Hsp90 enables signaling required for cell wall remodeling and adaptation to heat shock. Classical genetic screens and chemical genomic approaches to identify mutants that are hypersensitive to Hsp90 inhibition under distinct stress conditions have provided powerful strategies to identify novel Hsp90 client proteins and key regulators of thermal adaptation (27, 29, 30).

The circuitry underpinning thermal adaptation can be activated by a remarkable diversity of temperature-sensing mechanisms. For example, Hsp90 function is exquisitely sensitive to elevated temperature because the global problems in protein folding that arise for thermal stress create an elevated cellular demand for Hsp90 that exceeds its functional capacity to engage with client proteins (30). In the broader context, DNA, RNA, proteins, and lipids can all serve as thermosensors that sense changes in temperature to initiate crucial cellular responses and developmental programs (12).

Osmotic Stress

Managing changes in water balance is another fundamental challenge for fungi in most environments. The classic experimental model for this has been the imposition of hyperosmotic shock through addition of sorbitol or salts such as NaCl (31). This results in a sudden decrease in the intracellular turgor pressure that is required for fungal growth. The fungus must restore its turgor pressure before it can resume growth, and to achieve this, it activates the synthesis and accumulation of intracellular osmolytes such as glycerol (Fig. 1).

S. cerevisiae responds to osmotic stress by increasing the flux from glycolysis to glycerol. This is achieved by inducing the genes encoding glycerol-3-phosphate dehydrogenase (*GPD1*) and glycerol-3-phosphate phosphatase (*GPP1*). *S. cerevisiae* can also assimilate glycerol from the growth medium, although this uptake is repressed by glucose (32), which is in contrast to the response of some other yeasts (33, 34). However, the intracellular accumulation of glycerol is also dependent on restricting glycerol efflux from the cell through the plasma membrane-based aquaglyceroporin, Fps1 (35). Following the imposition of a hyperosmotic stress, the intracellular accumulation of glycerol and the restoration of turgor pressure take about 30 minutes (36), after which growth may resume.

This type of response, which involves signaling, gene regulation, and subsequent changes in metabolism, is too slow to protect the fungal cell against hypo-osmotic shock. This stress causes the immediate accumulation of water and rapid increases in cell volume which, if not countered quickly, would cause a yeast cell to burst

(37). In *S. cerevisiae*, this rapid rise in turgor pressure is alleviated by swift opening of the Fps1 aquaglyceroporin, the activity of which is regulated by protein phosphorylation. Mutations that inactivate Fps1, and hence block rapid glycerol efflux, confer hypo-osmotic stress sensitivity on the yeast cell (38). Clearly, responses to hyper- and hypo-osmotic shocks occur over differing timescales that reflect the relative imminence of potentially irreversible damage to the fungal cell.

Regarding the regulation of osmotic stress responses, the activation of Hog1 in *S. cerevisiae* has formed the paradigm of osmotic stress activation of fungal stress-activated protein kinases (SAPKs) (39). Like all mitogen-activated protein kinase (MAPK) modules, the Hog1 MAPK module comprises three tiers of kinases; the MAPKKK(s) at the top of the pathway phosphorylates and activates a downstream MAPKK, which then phosphorylates and activates the terminal MAPK. The central importance of this MAPK module in fungal stress sensing is illustrated by its involvement in diverse environmental responses in diverse fungi, which even include light sensing in *Aspergillus nidulans* (40). In *S. cerevisiae*, two functionally redundant pathways converge at the MAPKK Pbs2 to relay osmotic stress signals to Hog1. These are the Sln1 two-component signaling pathway and a pathway that contains the SH3-domain-containing Sho1 transmembrane protein. In the first pathway, loss of turgor pressure, induced by high osmolarity, inactivates the transmembrane histidine kinase Sln1 and thus halts phosphorelay through the phosphorelay protein Ypd1, leading to a rapid dephosphorylation of the Ssk1 response regulator (41). Dephosphorylated Ssk1 activates the MAPKKKs Ssk2/22 in a two-step mechanism (42), leading to phosphorylation and activation of the Pbs2 MAPKK. In the second pathway, the Ste11 MAPKKK phosphorylates Pbs2 when stimulated by osmotic stress signals received from the Sho1 branch of the Hog1 pathway (43). Many proteins are involved in the osmotic stress signaling from Sho1 to Ste11-Pbs2, including Cdc42, Ste20, Cla4, Ste50, and Opy2 (43, 44). Sho1 was originally thought to function as the osmosensor at the top of the pathway (45). However, two functionally redundant osmosensensors have since been identified: the mucins, Msb2 and Hkr1 (46). As different signaling mechanisms are employed by Msb2 and Hkr2 (47, 48), the Sho1 branch is now divided into the Hkr1 and Msb2 subbranches. While Msb2 and other Sho1 branch components also participate in the filamentous growth MAPK pathway, Hkr1 plays a specific role in Hog1 signaling (49), and this is mediated through the newly discovered scaffold protein Ahk1 (50).

Because the SAPKs are among the most evolutionarily conserved stress signaling proteins in fungi (11), it is remarkable that the mechanisms underlying the osmotic stress regulation of *S. cerevisiae* Hog1 have significantly diverged. For example, in the distantly related model yeast *Schizosaccharomyces pombe*, two-component signaling functions to relay H_2O_2, but not osmotic, stress signals to the Sty1 SAPK (51), and an orthologue of Sho1 is seemingly absent from the fission yeast genome (11). In *C. albicans*, although Sho1 pathway components have been identified and characterized, they are not required for the relay of osmotic stress signals to Hog1 (52, 53). Consistent with this, Hog1 in *C. albicans* is regulated by a single MAKKK, Ssk2, with the Ste11 MAPKKK—predicted to function downstream of Sho1—having no obvious role (54). In contrast, the available evidence does support the involvement of two-component signaling in the activation of *C. albicans* Hog1 by osmotic stress, because close homologues of the Sln1-Ypd1-Ssk1 pathway are present in *C. albicans*, and Hog1 is hyperactivated in cells lacking Sln1 (53). However, the observation that osmotic stress-induced Hog1 activation is not notably impaired in cells lacking the Ssk1 response regulator (55) suggests the presence of a novel osmotic stress-sensing pathway in this fungal pathogen. In certain *C. glabrata* isolates, only the Sho1 branch functions to relay osmotic stress signals to Hog1. This is due to a truncated *ssk2* allele which prevents signaling through the Sln1 branch (56). Intriguingly, gain of function mutations have been identified in the related Ssk2 MAPKKK in *Cryptococcus neoformans* (57), which are responsible for high basal levels of Hog1 activation in serotype A strains (58).

Hog1 has been shown to play a central role in the regulation of osmoadaptation in *S. cerevisiae*. This MAPK regulates accumulation of glycerol via transcriptional activation of *GPD1* and *GPP1* in response to osmotic stress via the transcription factors Hot1, Msn2, and Msn4 (59) and by controlling the activity of the Fps1 acquaglyceroporin (60). It should be noted that additional TORC2/Ypk1-dependent signaling mechanisms do contribute to the regulation of Fps1 and hence to survival in the face of hyperosmotic stress (38). However, Hog1 also mediates the transient delay in cell cycle progression following hyperosmotic shock by phosphorylation of Sic1 and Hsl1, and by downregulating G1 and G2 cyclins (61). Once osmo-adaptation is achieved, the yeast cell has essentially achieved a new homeostatic state in which turgor pressure has been restored in the face of the external osmotic conditions (62). Consequently, the input signal has been

dampened, Hog1 becomes deactivated, the block to cell cycle progression is released, and growth can resume.

Oxidative Stress

Reactive oxygen species (ROS) are highly damaging, reduced forms of oxygen, which include the superoxide anion O_2·, hydrogen peroxide (H_2O_2), and the hydroxyl radical (·OH). These reactive molecules damage proteins, DNA, and lipids and can trigger programmed cell death (63). All fungi that grow aerobically are exposed to superoxide anions generated as a by-product of aerobic respiration in the mitochondria (64). Environmental fungi are also exposed to ROS generated following exposure to UV light or to drugs/xenobiotics found in the environment (63). In addition, pathogenic fungi are exposed to superoxide and hydrogen peroxide ROS, which are generated by plant (65) or animal (66) host defense systems as a major antimicrobial defense mechanism. Significantly, other toxic chemicals are subsequently derived from the host-generated ROS (66).

Oxidative stress occurs when the levels of ROS exceed the antioxidant capacity of the cell which functions to maintain the intracellular redox environment in a reduced state. In response to oxidative stress, fungal cells mount a wide range of defense and repair strategies. One well-characterized and conserved response involves the rapid induction of mRNAs that encode oxidative stress detoxification and repair proteins (Fig. 1). Transcript profiling studies indicate that a set of core antioxidant genes are induced in fungi following exposure to H_2O_2 (20, 67–71). These include catalase (*CAT1*), glutathione peroxidase (*GPX*), and superoxide dismutase (*SOD*) antioxidant encoding genes, in addition to genes encoding components of the glutathione/glutaredoxin (*GSH1*, *TTR1*) and thioredoxin (*TSA1*, *TRX1*, *TRR1*) systems. An additional and very rapid response to oxidative stress, which precedes transcriptional activation, is the dynamic redirection of the metabolic flux from glycolysis to the pentose phosphate pathway. This metabolic switch is triggered by the oxidation and inactivation of the glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase, which functions to promote the generation of reducing power in the form of NADPH (72). Yeast cells also transiently delay cell cycle progression following exposure to ROS to allow DNA damage repair. For example, H_2O_2 causes a G2 cell cycle arrest in *S. cerevisiae* by activating the Rad53 DNA damage checkpoint (73). For more details on activation of DNA damage checkpoints in *S. cerevisiae*, readers are directed to the recent excellent review in reference 74. In the pathogenic fungus *C. albicans*, exposure to H_2O_2 also triggers Rad53-mediated cell cycle arrest. Interestingly, in this fungus, such genotoxic-induced cell cycle arrest promotes the formation of a filamentous hyperpolarized bud growth form (75, 76).

Orthologues of transcription factors that are vital for oxidative stress-responsive gene induction in *S. cerevisiae*, the AP-1-like bZip factor Yap1 and the Skn7 response regulator, have now been studied in many fungi (66). The elegant mechanism underlying activation of *S. cerevisiae* Yap1 is well characterized. Following exposure to H_2O_2, specific cysteine residues located within two distinct cysteine-rich domains become rapidly oxidized (77). This oxidation event, which requires the thiol peroxidase Gpx3 (78) and the Yap1 binding protein Ybp1 (79), triggers a conformational change within Yap1 that masks a nuclear export sequence (80). Consequently, Yap1 accumulates in the nucleus, resulting in the induction of Yap1-dependent genes (78). In the human fungal pathogen *C. albicans*, Cap1 oxidation is similarly regulated by Gpx3 and Ybp1 (81). However, in the model yeast *S. pombe*, Pap1 oxidation depends instead on the 2-Cys peroxiredoxin Tpx1 (82), and in the fungal symbiont *Epichloe festucae*, redox regulation of the analogous YapA factor is independent of both Gpx3 and Tpx1 (83). Thus, multiple mechanisms may exist to regulate the oxidation of fungal AP-1-like factors. Interestingly, AP-1-like factors have been found to be dispensable for the virulence of the human fungal pathogens *Aspergillus fumigatus* (84), *C. neoformans* (85), and *C. albicans* (81, 86) but are required for the virulence of a number of plant pathogens (87–89).

In *S. cerevisiae*, Yap1 collaborates with Skn7 to regulate many oxidative stress-response genes, and this may be conserved, because similar findings have been reported in *C. glabrata* (90) and *S. pombe* (91). Little is known about Skn7 activation following oxidative stress, but a study has reported a DNA-independent interaction between Yap1 and Skn7 in *S. cerevisiae* (92), and in *C. glabrata*, Yap1 and Skn7 cooperatively bind to the upstream region of core oxidative stress genes (90). In *S. pombe*, a role for two-component mediated phosphorylation of the Skn7 homologue in responses to high levels of H_2O_2 stress has been uncovered (93). A recent review summarizes the functions of Skn7 and its roles in fungal virulence (94).

In addition to Yap1 and Skn7 are the bZip factors of the ATF/CREB family. The best characterized is the Atf1 transcription factor in the model yeast *S. pombe*. In response to oxidative stress, Atf1 is hyperphosphorylated by the Sty1 SAPK (95). This stabilizes this transcription factor, which is vital for its function in

oxidative stress-induced gene expression (96, 97). Analogous transcription factors shown to play roles in oxidative stress-mediated gene expression include Atf1 in *C. neoformans* (98), Moatf1 in *Magnaporthe oryzae* (99), and AtfA in *A. nidulans* and *A. fumigatus* (100, 101). Moreover, there is emerging evidence to support the general concept that such transcription factors are targets of fungal SAPK pathways (101, 102).

Although the Hog1 SAPK in *S. cerevisiae* is dispensable for oxidative stress responses (20, 103), homologues play important roles in oxidative stress tolerance in many other fungi. These include the model yeast *S. pombe* (104); the filamentous fungus *A. nidulans* (101); a number of human pathogenic fungi including *C. albicans* (105), *C. neoformans* (58), and *A. fumigatus* (106); and the plant pathogens *Bipolaris oryzae* (107) and *Fusarium graminearum* (108). The Sty1 pathway in the model yeast *S. pombe* has provided key insight into the oxidative stress-mediated activation of such pathways. Sty1 is robustly phosphorylated in response to oxidative stress and plays a major role in the regulation of the oxidative-stress-induced transcriptome (91). In *S. pombe*, a two-component signaling system operates to relay H_2O_2, and not osmotic, stress signals to the Sty1 SAPK module. The Mak2 and Mak3 histidine kinases contain redox-sensing PAS and GAF domains, which are essential for the relay of H_2O_2 signals to Sty1 (93). In addition, protein oxidation also regulates the H_2O_2-induced activation of Sty1.

The redox-sensitive peroxiredoxin enzyme Tpx1 is essential for H_2O_2-mediated Sty1 activation and, because intermolecular disulfide bonds are formed between conserved cysteine residues in Sty1 and Tpx1 following H_2O_2 stress, it appears that Tpx1 may regulate Sty1 function directly (109). Mechanisms underlying H_2O_2-mediated SAPK activation have also been explored in *C. albicans*. *C. albicans* Hog1 is robustly activated following exposure to H_2O_2 (70), and *hog1*Δ cells are sensitive to a range of ROS (105, 110), despite a limited transcription role (70). Similar to that in *S. pombe*, oxidative stress-induced Hog1 phosphorylation is drastically reduced in cells lacking the Ssk1 response regulator (55), although no similar roles have been found for the upstream histidine kinases (53, 111). Both the redox-sensitive peroxiredoxin Tsa1 and thioredoxin Trx1 enzymes are vital for H_2O_2-induced Hog1 activation in *C. albicans* (75). Thus, protein oxidation appears to be an important mediator of both *C. albicans* and *S. pombe* SAPK activation following oxidative stress. Mechanistic details regarding oxidative-stress-mediated SAPK activation in other fungi are lacking, although in *A. nidulans* it has been shown that the SskA response regulator is essential for oxidative stress-induced activation of the SakA SAPK (112).

Nitrosative Stress

Fungal cells experience nitrosative stress when they are exposed to relatively high levels of reactive nitrogen species (RNS). These RNS include nitric oxide (·NO) and its derivatives peroxynitrite ($ONOO^-$, which is formed by the reaction of nitric oxide with superoxide, $O_2^{\cdot -}$), nitrite (NO_2^-), nitrogen dioxide ($\cdot NO_2^-$), and nitrate (NO_3^-). Fungi are confronted by RNS in the soil, as well as in mammalian hosts, where these reactive molecules are components of the phagocytic armory used to combat microbial infection (113–115). Therefore, the protective responses of fungal pathogens against nitrosative stress are important for pathogenicity and have been examined in some detail, for example, in *C. albicans* and *C. neoformans* (116, 117). In contrast, for plant pathogens such as *Blumeria graminis*, *Botrytis cinerea*, and *M. oryzae*, NO has been shown to promote the spread of infection in plant hosts. These effects might be mediated by the action of NO as a developmental signal (118–120) but could also be due to the influence of fungus-derived NO on the behavior of the plant host (121).

Excess RNS damage proteins by reacting with thiols, metal centers, and tyrosine residues. Fungi protect themselves by buffering RNS with antioxidants such as glutathione and by inducing mechanisms to detoxify the RNS and repair the damage they cause. NO reacts with glutathione (GSH) to generate S-nitrosoglutathione (GSNO). To restore redox homeostasis, fungi recycle this GSNO to GSH via glutathione disulfide. This is achieved through the evolutionarily conserved enzymes GSNO reductase (GSNOR: Fdh3) and glutathione reductase (122–124). NO detoxification to nitrate is mediated by nitric oxide oxidoreductases (e.g., *S. cerevisiae* Yhb1), which are conserved enzymes that are members of the flavohemoglobin family (125).

While the processes that protect against RNS are evolutionarily conserved, the regulatory mechanisms that induce these processes in response to RNS appear to have diverged. For example, while RNS exposure triggers global changes in the expression profiles of *S. cerevisiae* and *C. albicans* that include the induction of Yhb1 and glutathione synthesis (116, 126), seemingly unrelated transcription factors drive these changes. In *S. cerevisiae*, *YHB1* expression is induced by the transcription factor Fzf1 (126) (Fig. 1), whereas Cta4 activates *YHB1* in *C. albicans* (127). Nevertheless, the outcomes are similar: these transcription factors both

promote Yhb1 and glutathione expression and, hence, nitrosative stress resistance in these fungi. For the fungal pathogen *C. albicans* the deletion of *YHB1* or its activator *CTA4* attenuates virulence slightly (116, 127, 128). Similarly, inactivation of the nitric oxide oxidoreductase (Fhb1) or the GSNOR (Gno1) in *C. neoformans* attenuates the virulence of this pathogen (129). NO production by the host does not seem to be a major factor in limiting fungal virulence (116). Nevertheless, the available data suggest that RNS detoxification does contribute to fungal virulence.

Cell Wall Stress

The fungal cell wall is a dynamic structure that is continually remodeled during cell growth and division. The cell wall represents ~25% of the yeast cell dry weight, underscoring the extensive metabolic commitment to support this elaborate structure, which provides the key interface for mediating interactions with the environment (130). Fungal cell wall architecture involves layers of polysaccharides and glycoproteins, although the specific composition varies across species. Typically, a matrix of chitin, β-1,3-glucan, and β-1,6-glucan constitutes the core inner layer, with mannans and other mixed glycans and glycoproteins prevalent in the outer layer. Cell walls provide crucial protection against changes in external osmotic potential and can confer resistance to infection and to degradation by soil predators such as amoebae and protists. These adaptive advantages may contribute to the emergence and maintenance of cell walls in the fungal kingdom (131). Cell walls serve not only as a protective shell, but also as a means to modulate immune recognition. Fungal cell wall glycans, glycolipids, and proteins that are absent from mammals activate a wealth of immune recognition mechanisms, and the dynamic exposure of such pathogen-associated molecular patterns can modulate immune recognition (132). As a consequence, perturbation of fungal cell wall architecture can potentiate immune responses and induce lethal cell wall stress. Molecules that potently inhibit fungal cell wall biosynthesis have been elaborated in nature as with the echinocandins and exploited in modern medicine, with semisynthetic derivatives now a front-line treatment for fungal infections (133).

Fungi have evolved complex cellular circuitry to sense and respond to cell wall stress. Although details vary among fungi, the core architecture is broadly conserved. Cell wall stress is typically sensed at the plasma membrane via cell surface sensors, which include Wsc1, Wsc2, Wsc3, Mid2, and Mtl1 in *S. cerevisiae* (130). This stimulates nucleotide exchange on the small G-protein Rho1, which orchestrates cell wall integrity signaling. Downstream effectors of Rho1 coordinate synthesis of β-glucans, transcriptional control of cell wall genes, polarization of the actin cytoskeleton, and targeting of secretory vesicles. The most well-established pathway through which cell wall integrity signals are transduced from Rho1 is the MAPK cascade that includes Pkc1, Bck1, Mkk1/2, and Mpk1/Slt2 in *S. cerevisiae* (17). Although this cascade provides a powerful mechanism to amplify cell surface signals and coordinate highly sensitive responses, additional robustness is integral to ensure maintenance of cell wall physiology and is achieved by complex genetic interaction networks. These networks can enable compensatory responses to cell wall perturbations. For example, activation of chitin synthesis suppresses the antifungal activity of echinocandins (134–136), which inhibit biosynthesis of β-1,3-glucan. The highly connected genetic networks that control cell wall stress response circuitry can be activated by diverse environmental stresses, providing a powerful strategy to rapidly mobilize protective mechanisms.

Environmentally contingent hubs of cellular signaling are crucial for orchestrating cell wall stress responses. An excellent example is the molecular chaperone Hsp90. Hsp90 modulates the stability and function of diverse regulators of cellular signaling, thereby enabling responses to a myriad of stresses, including perturbation of the cell wall (29, 137, 138) (Fig. 1). Hsp90 enables responses to cell wall stress at least in part by modulating cell wall integrity signaling. Hsp90 stabilizes the terminal MAPK in the cell wall integrity pathway, Slt2 in *S. cerevisiae*, and Mkc1 in *C. albicans* (139–141). Hsp90 also stabilizes an additional MAPK that is implicated in cell wall remodeling: Cek1 (29). Compromise of Hsp90 function leads to depletion of these kinases and hypersensitivity to cell wall stress. Additional Hsp90 client proteins important for cell wall remodeling are the protein phosphatase calcineurin and kinase Hog1. Signaling through the cell wall integrity pathway, Hog1, and calcineurin coordinately regulates the synthesis of chitin in response to stress induced by perturbation of the cell wall or cell membrane (142). Chitin levels are dramatically increased in response to echinocandins, which provides protection that enables cells to cope with cell wall damage (134). Cell damage induced by various genetic or environmental insults can also be buffered by activation of other core cellular signaling pathways such as the cyclic AMP protein kinase A cascade (17). Although the molecular details have been explored in the greatest depths in *S. cerevisiae*, many conserved principles of coordinate control

of cell wall stress response are emerging from studies in diverse fungi (143–146).

There is broad therapeutic potential of targeting core regulators of cell wall stress responses as a strategy to enhance the efficacy of antifungal drugs that target the cell wall, as with the echinocandins. This potential is illustrated by the discovery that inhibition of Hsp90 of calcineurin enhances the efficacy of echinocandins against diverse fungal pathogens in multiple models of infection (137, 144, 147). The therapeutic challenge of exploiting these conserved eukaryotic cellular regulators as targets for antifungal drug development lies in the development of molecules that can distinguish the pathogen from the host. Achieving this goal can be facilitated by structure-guided drug design (148). As a complementary approach to targeting regulators of cell wall stress response, systematic screens for molecules that potentiate the activity of echinocandins provide a powerful strategy to enhance the efficacy of our limited arsenal of antifungal drugs and thwart the emergence of drug resistance (149).

pH Stress

Alkaline pH imposes several stresses on fungi. One of the most significant relates to nutrient acquisition. At high extracellular pH, the establishment of electrochemical gradients across the plasma membrane for nutrient transport and ATP synthesis is more difficult (150). Moreover, the solubility and biological availability of essential elements such as iron are dramatically reduced at high pH. The finding that the addition of micromolar concentrations of copper or iron ions significantly improves the growth of *S. cerevisiae* at high pH suggests that these two elements are limiting factors for growth under alkaline pH conditions (151).

An important aspect of pH regulation is the ability to regulate gene expression in response to ambient pH, which allows fungi to synthesize the environmentally appropriate gene products, particularly secreted proteins. This ability has practical implications, for example, in the production of secondary metabolites or for fungal pathogenicity on plant and animal hosts (152, 153). Environmental pH also has profound effects on fungal development. For example, in *C. albicans* a shift from acidic to neutral-alkaline pH promotes the transition from yeast to filamentous growth (152).

The best-known alkaline pH-responsive signal transduction mechanism in fungi is the Pal/Rim pathway (Fig. 1). This pathway has been extensively studied in *A. nidulans* (Pal) and *S. cerevisiae* (Rim). In *A. nidulans*, the Pal pathway sequentially involves the proteins PalH, PalI, PalF, PalC, PalA, and PalB. Moreover, the pathway encompasses a number of co-opted components of the multivesicular body and endosomal sorting complexes required for transport (153). Activation of the pathway by alkaline pH leads to proteolytic activation of the zinc finger transcription factor PacC/Rim101 (154, 155). PacC undergoes two successive C-terminal proteolytic cleavages from the full-length 72-kDa to the processed 27-kDa active form, the first of which is pH-dependent and carried out by the signaling protease PalB (153).

PalH/Rim21, a seven-transmembrane-domain plasma membrane protein, is thought to function as a pH receptor. PalH forms a complex with the arrestin-like protein PalF/Rim8, which is ubiquitinated in an alkaline pH-dependent manner and recruits endosomal sorting complexes required for transport-I Vps23, thereby creating multiple docking sites for the downstream signaling components (156–159).

An unanswered question is how PalH/Rim21 senses alkaline ambient pH. The membrane potential of the yeast plasma membrane is mainly generated by differences in proton concentration between the inside and outside of the cell. External alkalization therefore leads to impaired phospholipid flipping and plasma membrane depolarization by collapsing the proton electrochemical gradient. Interestingly, it was shown that the Rim101 pathway in yeast can be activated in a pH-independent manner by either protonophore treatment or depletion of phosphatidylserine in the inner leaflet of the plasma membrane, both of which cause plasma membrane depolarization similar to external alkalization. This activation is dependent on Rim21, suggesting that plasma membrane depolarization is a key signal sensed by Rim21 (159). Moreover, a recent study suggests that alterations in lipid asymmetry cause changes in lipid composition and local charge on the inner leaflet, leading to dissociation of the Rim21 complex from the plasma membrane and recruitment of downstream proteins (160). Thus, Rim21 senses external alkalization, as well as altered lipid asymmetry. It was proposed that Rim21 uses its flexible C-terminal cytosolic tail like an antenna to monitor the status of membrane lipid asymmetry (160).

To achieve infection, pathogenic fungi must adapt to wide variations in the ambient pH of host tissues, which in humans, can vary from 2 to >8 depending on the niche. Early studies of *C. albicans* revealed that genes encoding two functionally redundant cell wall β-glycosidases, *PHR1* and *PHR2*, display divergent pH-dependent expression patterns and virulence functions in cell wall remodeling. While *PHR1* is expressed preferentially at neutral-alkaline pH and is required for

systemic infection, *PHR2* is expressed preferentially at acidic pH and is required for vaginal infection (161). These pH-dependent expression patterns are dependent on PacC/Rim signaling (162). More recently, multiple roles for the PacC/Rim pathway during human colonization and infection have been established in *C. albicans*, including filamentation, adhesion to host cells, tissue invasion, iron acquisition, and protease secretion (152). The role of PacC/Rim101 in mammalian infection is conserved in filamentous ascomycetes such as *Fusarium oxysporum* and *A. fumigatus* (163, 164). In the basidiomycete human pathogen *C. neoformans* the RIM pathway is also involved in pathogenicity (165), although the function of PalH/Rim21 appears to be carried out by a distinct membrane protein (166).

Alkaline pH signaling is also relevant in other fungus-host interactions. For example, deletion of PacC in the nematophagous fungus *Clonostachys rosea* and the insect pathogen *Metarhizium robertsii* results in attenuated virulence (167, 168). In plant pathogens, the role of PacC in virulence varies depending on the pathogen-host system. While it contributes to virulence in the rice blast fungus *M. oryzae* and the fruit pathogen *Penicillium expansum*, it appears to function as a negative virulence regulator in the vascular wilt fungus *F. oxysporum* (169–171).

Besides the Pal/Rim pathway, additional cell signaling pathways function in fungal adaptation to neutral/alkaline pH. The calcium-dependent protein phosphatase calcineurin and its downstream transcription factor Crz1 are required for growth at alkaline pH and for fungal virulence on animal and plant hosts (172–176). Crz1 also mediates tolerance to high cation concentrations (177). Mds3, a negative regulator of the TOR pathway, promotes adaptation to neutral/alkaline pH as well as virulence-related morphogenesis in *C. albicans* (178). Moreover, mutations in the cell wall integrity MAPK cascade confer sensitivity to alkaline stress, and alkalinization results in rapid and transient phosphorylation of the Slt2 MAPK in *S. cerevisiae* (179). This suggests that alkaline pH stress profoundly affects the composition of the fungal cell wall.

Recently, a novel signaling pathway was identified which is required for resistance to alkaline pH and cation stress in *A. nidulans* (176). This pathway, which appears to be specific to filamentous fungi, is defined by the transcription factor SltA and the serine protease SltB. Activation of SltA requires proteolytic cleavage and removal of the N-terminal domain by SltB and phosphorylation of the functional C-terminal moiety (180). Interestingly, while the SltA pathway is conserved in filamentous fungal pathogens, its role in infection remains to be determined.

Weak Acid Stress Response

The weak acid stress response has been largely studied in the context of food spoilage, but it is likely to be highly relevant to environmental and pathogenic fungi that occupy acidic niches or that are exposed to phagocytic attack. Weak organic acids such as acetic, propionic, sorbic, and benzoic acids impose stress on fungal cells when the environmental pH lies below the pK_a of the acid in question (i.e., below pH 4.8 for acetic acid). Below its pK_a, a weak acid is in its associated nonpolar form and is better able to cross the plasma membrane. Acetic acid enters the *S. cerevisiae* cell via the aquaglyceroporin Fps1, whereas propionic, sorbic, and benzoic acids appear to diffuse passively across the plasma membrane (181). Once they enter the higher pH of the cytoplasm, they dissociate into the free acid anion and proton (H^+). The equilibrium of this reaction drives the accumulation of the acid anion and protons and, consequently, acidification of the cytoplasm. Weak acid stress is imposed partly by this cytoplasmic acidification and partly by the accumulation of the organic anion, which can impose toxic effects on yeasts and molds (182, 183). For example, sorbic acid appears to exert membrane-active antimicrobial effects in *S. cerevisiae* (182).

Fungal cells respond to weak acid stress by attempting to maintain their intracellular pH and by exporting the organic anion. In *S. cerevisiae* these tasks are executed by Pma1 and Pdr12, respectively (184, 185). Pma1 is the plasma membrane H^+-ATPase proton pump. This pump is essential for growth and for the restoration of cytoplasmic pH, which is an energy-demanding process (186). Pdr12 is an ATP-binding cassette transporter that mediates efflux of the organic anion from the yeast cell. Pdr12 is also important for the restoration of cytoplasmic pH during sorbic and benzoic acid stress (187).

In *S. cerevisiae*, resistance to acetic acid stress is dependent on Hog1 signaling. Hog1 downregulates the Fps1 aquaglyceroporin, thereby reducing acetate accumulation (181), and activates the Haa1 transcriptional regulon, which includes genes encoding membrane stress proteins (188). Meanwhile, resistance to propionic, sorbic, and benzoic acids depends on the induction of *PDR12* (184) via the transcription factor War1 (189, 190). War1 is potentially regulated by direct binding of the organic anion, thereby precluding a requirement for upstream signaling.

Analogous regulatory mechanisms appear to exist in some yeasts. For example, Hog1 mediates sorbic acid

resistance in *C. glabrata* (191), and resistance to this weak acid in *C. albicans* is dependent on a War1 orthologue (192) as well as the Msn2/4-like transcription factor Mnl1 (193). However, alternative mechanisms seem to mediate weak acid stress resistance in other yeasts, most notably the food spoilage organism *Zygosaccharomyces bailii*, which displays high levels of weak acid stress resistance. In this species, survival in the face of weak acid stress appears to be dependent on population heterogeneity: a proportion of cells that display low cytoplasmic pH, and therefore reduced weak acid accumulation, give rise to a population of resistant cells (194). Rather than inducing a Pdr12-like weak acid exporter, *Z. bailii* degrades sorbate and benzoate, exploiting them as a carbon source (184).

Core Stress Response

In the preceding sections we discussed fungal responses to individual stresses. Here we describe how exposure to different types of stress can lead to similar responses via what has been termed the core stress response (CSR). Genome-wide transcript profiling studies first revealed the existence of CSRs in the model yeasts *S. cerevisiae* (20, 67) and *S. pombe* (68), in the pathogenic fungus *C. glabrata* (71), and to a lesser extent in *C. albicans* (69, 70). Formally, the CSR describes a set of genes that are commonly regulated in response to diverse types of stress (Fig. 2).

In *S. cerevisiae*, between 200 and 300 genes were found to be upregulated in response to diverse stresses including heat shock, osmotic stress, oxidative stresses, increases or decreases in pH, and amino acid starvation (20, 67). In addition, between 300 and 600 genes were commonly downregulated following exposure to these diverse stress treatments (20, 67). Thus, in *S. cerevisiae*, the CSR involves approximately 10 to 14% of the yeast genome. Similar numbers of genes were reported to be regulated in the closely related, but pathogenic, yeast *C. glabrata* following exposure to glucose starvation and osmotic, oxidative, and heat stresses (71). Furthermore, in the divergent yeast *S. pombe*, approximately 140 genes are commonly upregulated and 100 downregulated in response to a range of stresses including osmotic, oxidative, heavy metal, DNA damage, and heat stress (68). Common processes were represented in the induced core stress gene sets such as carbohydrate metabolism, protein folding and degradation, redox regulation, and DNA repair. In contrast, repressed genes were associated with energy-consuming and growth-related processes, including RNA processing, transcription and translation, and biosynthesis of ribosomes and nucleotides. Interestingly, the pathogenic fungus *C. albicans* mounts a significantly smaller CSR than those described above, because only 24 and 37 genes were commonly induced or repressed, respectively, by osmotic, oxidative, and heavy metal stress (70). Despite this, the CSR genes in *C. albicans* do belong to some of the same functional categories as those in *S. cerevisiae*, *S. pombe*, and *C. glabrata*, suggesting that some of the processes involved in the CSR are evolutionarily conserved.

In *S. cerevisiae*, different signaling pathways and transcription factors converge to control a common set of stress genes, although the functionally redundant Msn2 and Msn4 $(C_2H_2)_2$ zinc finger transcription factors play a major role (20, 67). Consistent with this, many of the CSR genes carry a stress response element within their promoters, to which Msn2 and Msn4 bind (20, 67). This Msn2/4-mediated CSR forms the basis of the previously characterized general stress response in *S. cerevisiae*, which is composed of an Msn2/4-stress response element regulon that is activated in response to diverse stresses (195). Msn2/4 rapidly accumulate in the nucleus following a range of nutrient and stress conditions (196, 197) and are subject to complex regulation by several pathways (198). However, a number of other factors also regulate the CSR in *S. cerevisiae*. In response to osmotic stress, the Hog1 SAPK contributes to the regulation of CSR genes (20), likely through the Hot1 transcription factor (59), whereas the Yap1 AP-1-like transcription factor contributes to CSR gene induction postoxidative stress (20). In addition, the Mec1 DNA-damage specific pathway contributes to CSR gene regulation in response to DNA damaging agents (199).

Recently, it has been shown that the Msn2 transcription factor also makes a major contribution to the regulation of CSR genes in *C. glabrata* (71). Consistent with this, in this pathogenic yeast, Msn2 rapidly localizes to the nucleus following glucose starvation and in response to osmotic, oxidative, or heat stress (71). In stark contrast, homologues of Msn2 and Msn4 do not have the same broad stress-protective roles in *C. albicans* (193, 200), which may contribute to the relatively small CSR seen in this fungus (70). Moreover, in *S. pombe*, which lacks close homologues of Msn2/4, the CSR is regulated by a different mechanism. In this yeast, the Sty1 SAPK is activated in response to diverse stress conditions including osmotic, oxidative, and heat stress; nutrient limitation; UV light; and cold stress (201). Following activation, Sty1 accumulates in the nucleus, where it phosphorylates the Atf1 transcription factor, leading to its activation and stabilization (95–97). Sty1 and, to a lesser extent, Atf1 are the major

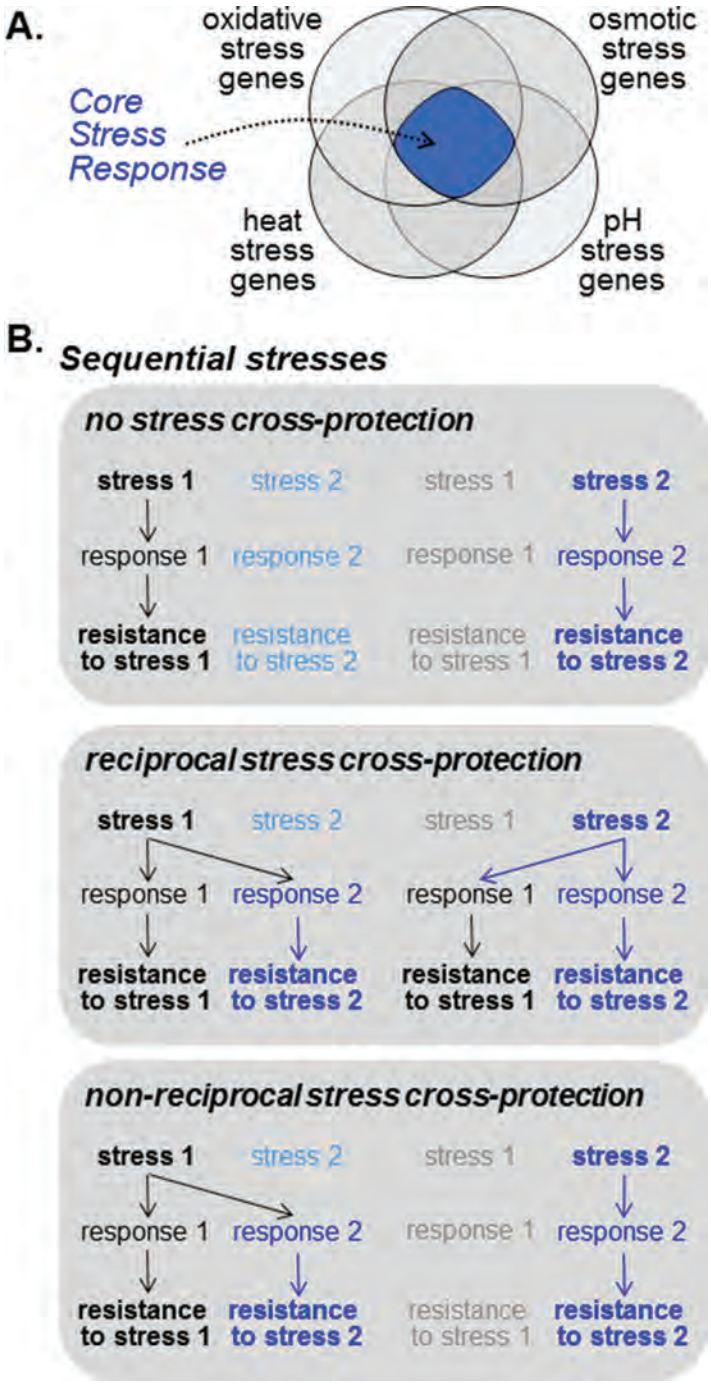

Figure 2 The CSR can lead to stress cross-protection. (**A**) CSRs, which have been defined by genome-wide transcriptional profiling, represent the set of genes that is commonly up- or downregulated by different types of stress (see text). This Venn diagram illustrates the conceptual overlap between these sets of genes, highlighting the core stress genes. (**B**) A CSR can lead to stress cross-protection during exposure to sequential stresses; i.e., cells that are exposed to one type of stress can then display elevated resistance to a subsequent stress of a different type (see text). In some cases no cross-protection is observed. In other cases it is observed, but this cross-protection can be reciprocal or nonreciprocal. This can depend on the nature and dose of the initial and subsequent stress.

regulators of the CSR in *S. pombe* (68). It is interesting that CSR genes implicated in stress defense are dependent on Sty1 and Atf1, whereas CSR genes with regulatory functions are induced by Sty1 independently of Atf1 (68).

Similar to the Sty1 SAPK in *S. pombe*, the Hog1 SAPK in the fungal pathogen *C. albicans* is activated in response to diverse stresses (110). Significantly, a CSR was only observed after treating cells with three stress conditions—osmotic, oxidative, and heavy metal stress—that activate Hog1 (69, 70). Intriguingly, however, Hog1 regulated the transcriptional responses to osmotic and heavy metal stresses, but not to oxidative stress, and this was reflected in the role of Hog1 in the regulation of *C. albicans* CSR genes. Instead, the Cap1 AP-1-like transcription factor regulated the *C. albicans* CSR following oxidative stress (70). Thus, the *C. albicans* SAPK pathway functions in parallel with other pathways to regulate the core transcriptional response to stress. Hence, although aspects of a CSR are conserved across the fungal kingdom, the mechanisms underlying its regulation have diverged significantly.

What is the physiological role of a CSR? Earlier studies in *S. cerevisiae* revealed a phenomenon called "stress cross-protection," in which exposure to a nonlethal dose of one stress provided significant protection from the subsequent exposure of a potentially lethal dose of a second unrelated stress (202) (Fig. 2). Such stress cross-protection was impaired in the presence of cycloheximide, illustrating a role for new protein synthesis (202). The Msn2/4-mediated general stress response in *S. cerevisiae*, together with the identification of the CSR, probably accounts for the observed stress cross-protection in several fungi (68, 71, 110). Interestingly, subsequent studies have revealed that the CSR triggered by the initial low stress dose is not required to survive this stress but instead provides protection against the second stress (203). Furthermore, the actual genes and processes necessary to acquire resistance to the same severe stress are different depending on the nature of the initial mild stressor. In other words, the mechanism of stress cross-protection is determined by the initial stress (204). This probably underlies previous findings that stress cross-protection is context dependent and not always reciprocal (203) (Fig. 2).

But why might stress cross-protection have evolved? Some microbes occupy reasonably predictable niches in which one environmental input is generally followed by a second input. In such cases, fungi that have evolved to anticipate the second input following exposure to the first would have a fitness advantage (205). Domesticated brewing yeasts provide an excellent example of this "adaptive prediction" because, as they ferment sugars, they become exposed to increasing ethanol concentrations (input 1) and then, when the sugars are exhausted, they switch to respiratory metabolism and become exposed to oxidative stress (input 2). Presumably, as a consequence of this environmental predictability, *S. cerevisiae* has evolved to activate oxidative stress genes following exposure to ethanol (206). Asymmetric adaptive prediction appears to have evolved in other fungi such as *C. albicans* (207, 208). Unlike *S. cerevisiae*, this pathogen displays increased resistance to acute oxidative stress following exposure to glucose (209), which possibly reflects anticipation of phagocytic attack after entry to the bloodstream. Therefore, it is conceivable that CSRs have evolved as a result of adaptive prediction.

ADAPTING TO STRESS IN NATURAL ENVIRONMENTS

Combinatorial Stress Responses

Our understanding of stress responses in yeast has been shaped largely by the study of individual stresses or, as discussed in the previous section, how the prior exposure to one stress can provide stress cross-protection against a second unrelated stress. However, the diverse environments that fungi occupy are complex and dynamic, and it is conceivable that fungi will often be exposed to multiple stresses. At times these stresses may be imposed sequentially, in which case stress cross-protection may facilitate survival. However, at other times, a fungus may be exposed simultaneously to multiple stresses, termed "combinatorial stress." Recent studies have revealed that certain combinations of stresses are particularly potent in terms of their ability to kill functionally divergent model (*S. cerevisiae*, *S. pombe*) and pathogenic (*C. albicans*, *C. glabrata*) yeasts (210, 211). Notably, all of these species are acutely sensitive to combinations of cationic and oxidative stresses (210). Pathogenic fungi encounter this combination of stresses following phagocytosis; microbes are exposed to high levels of ROS generated by the respiratory burst (212), and the resulting accumulation of anionic charge is compensated for by a rush of potassium (K^+) ions into the endocytic vacuole, which simultaneously imposes a cationic stress (212).

Strikingly, studies investigating the mechanistic basis underlying the exquisite sensitivity of *C. albicans* to such combinations of stress have revealed that exposure to cationic stress prevents this pathogen from mounting an oxidative stress response. The oxidative

stress regulon in *C. albicans* is largely regulated by the Cap1 AP-1-like transcription factor (213), and Cap1 fails to be activated following exposure to combinatorial oxidative and cationic stress (210, 214). This phenomenon, which has been termed "stress pathway interference" (210) (Fig. 3), contrasts starkly with that of stress cross-protection in which exposure to one stress protects against the subsequent exposure to a different stress (103). Exposure of *C. albicans* to H_2O_2 triggers the rapid oxidation of Cap1, and this masks the nuclear export sequence, resulting in the rapid nuclear accumulation of Cap1 and the induction of Cap1-dependent genes. However, cationic stress inhibits this Cap1-mediated oxidative stress response in two ways. First, cations inhibit catalase activity, which triggers significant increases in intracellular ROS levels following combinations of cationic and oxidative stresses (210). Such high levels of ROS trap Cap1 in a partially oxidized form that fails to induce target antioxidant-encoding genes (214). Second, cations stimulate the interaction of Cap1 with the nuclear export factor Crm1, which results in significant delays in the H_2O_2-induced nuclear accumulation of this transcription factor. Importantly, the cationic stress-mediated inhibition of oxidative stress responses contributes to the fungicidal potency of human neutrophils, because effective killing of *C. albicans* is dependent on the combinatorial effects of the oxidative burst and cationic fluxes (210). These findings may also explain the lack of expression of *C. albicans* oxidative stress genes in certain host niches, such as during systemic infections of the kidney, despite the presence of neutrophil infiltrates (215).

Although to date, studies have focused on combinatorial oxidative plus cationic stress, it is feasible that other stress combinations will influence stress outputs (207). Indeed, we have found that pH has drastic effects on the oxidative stress tolerance of a number of fungi (J.Q., A.J.P.B., unpublished). This is an exciting new area in the field of stress responses that is likely to be of broad relevance across the fungal kingdom due to the complexity of natural environments.

Dynamics of Stress Responses

Our perspectives of fungal stress responses and stress resistance have been shaped largely by our experimental approaches. For example, plate assays, which are widely used to examine stress resistance, often do not differentiate between the ability of a strain to survive immediately following exposure to an acute stress and its ability to adapt and resume growth in the longer term. Also, the availability of powerful molecular genetics and genomics approaches has led to major advances in our understanding of fungal stress responses at the gene and protein levels, but the metabolic changes that underlie stress adaptation have received less attention. Yet these changes play vital roles in fungal stress resistance.

The resistance of yeast cells to stress is enhanced by increases in metabolic flux toward the generation of antioxidants such as glutathione and stress protectants

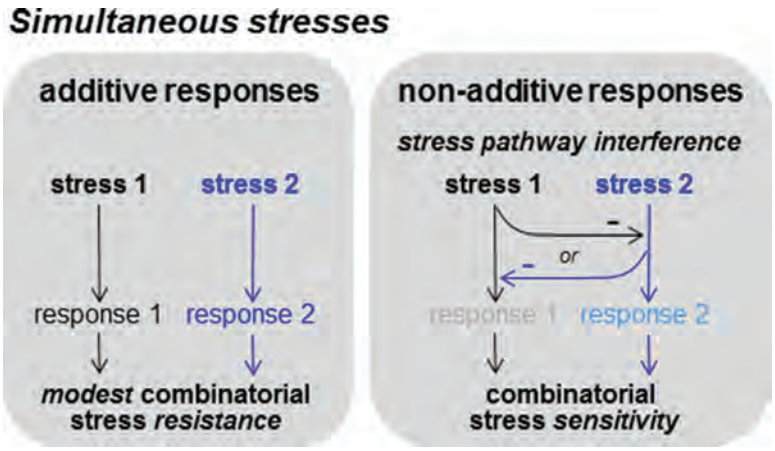

Figure 3 Exposure to combinatorial stresses can yield nonadditive outputs. Simultaneous exposure to some combinations of stress (i.e., certain combinatorial stresses) can yield additive outputs if there are no significant interactions between the stress pathways that mediate these responses. However, for some combinatorial stresses (see text), stress pathway interference can block the normal response to one of the imposed stresses, leading to combinatorial stress sensitivity. We are unaware of any examples of the opposite effect, where stress pathway enhancement might lead to elevated levels of combinatorial stress resistance.

such as trehalose (122, 216–219). Like the accumulation of glycerol in response to hyperosmotic stress (36), these increases in glutathione and trehalose levels are mediated in large part by changes in gene expression and enzyme synthesis and hence are slow. Other metabolic responses are much faster. For example, there is a rapid shift in metabolic flux from lower glycolysis toward the pentose phosphate pathway upon exposure to oxidative stress (72). This metabolic shift, which is mediated through the sensitivity of glyceraldehyde-3-phosphate dehydrogenase to oxidative inactivation (220), increases the NADPH synthesis and hence the availability of protective reducing equivalents (72). This metabolic response to oxidative stress occurs within seconds, preceding transcriptional responses to oxidative stress (221).

Clearly, different aspects of a fungal adaptive response take place over different timescales (36) (Fig. 4). Initial metabolic and biophysical responses can occur within seconds to minutes (37, 221). Signal transduction is activated rapidly, within minutes, and often remains active for tens of minutes (36). This triggers changes in gene expression: transcript levels often rise within 5 minutes and, depending on the stability of the mRNA, can remain elevated for tens of minutes. Resultant changes in enzyme levels are often observed in tens of minutes and can last for hours, depending on the stability of these proteins. Consequently, the accumulation metabolites such as glycerol can take tens of minutes to an hour.

While these general principles hold, the dynamics of a stress response are strongly influenced by the dose. Large single doses are often applied to experimentally dissect a stress response *in vitro*. However, in reality, that stress response might have evolved to maintain

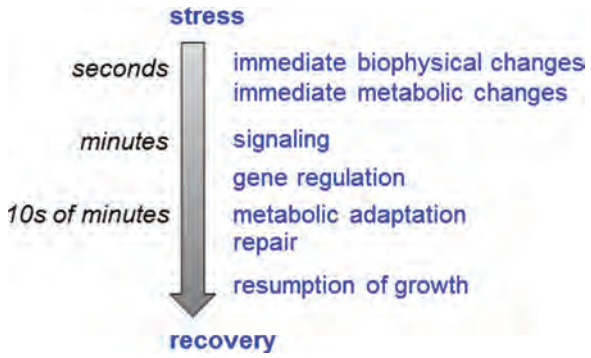

Figure 4 Different aspects of stress adaptation occur over different timescales. This generic figure summarizes this principle of an environmental insult such as osmotic stress (see text). However, some stresses may include adaptation mechanisms that occur over other timescales.

cellular homeostasis in the face of less acute but multiple challenges. For example, researchers often use large acute heat shocks to study thermal adaptation, although many fungi encounter less dramatic thermal fluctuations in the wild. Also, researchers generally examine the impact of a single dose, and yet fungi can face repetitive doses of certain stresses in some habitats (e.g., repetitive hypo-osmotic shock during rainfall). The mathematical modeling of stress responses permits the analysis of the vast theoretical space represented by variations in the dose, exposure time, and frequency of a stress. Indeed, mathematical modeling is already improving our appreciation of the dynamics of stress responses, the influence of stress dose, and their impact on stress adaptation in fungi (36, 62, 222, 223). These dynamics are significant because they influence the length of time for which the molecular memory of a stress is retained and hence the period over which stress adaptation provides protection against a subsequent stress (224) (see "Core Stress Response," above).

Impact of Growth Conditions on Stress Resistance

Historically, the dissection of fungal stress responses has largely been performed under a relatively small set of experimental conditions to facilitate comparison between studies. This has influenced our perceptions of stress adaptation. For example, it is well known that changes in carbon source exert dramatic effects on stress resistance in *S. cerevisiae*. Yet stress adaptation in *C. albicans* has largely been examined using glucose-rich media, although this fungus generally inhabits glucose-poor niches. Temperature also affects stress responses (29).

A shift from glucose to a nonfermentative carbon source increases stress resistance in *S. cerevisiae*, partly through activation of the CSR. Glucose inhibits the CSR through Msn2/4 phosphorylation, which is mediated by Ras-cAMP-protein kinase A signaling (225). Phosphorylation of Msn2/4 prevents the nuclear accumulation of these transcription factors, thereby blocking their activation of core stress genes (196). Glucose also regulates *YAP1* (the AP1-like transcription factor central to the transcriptional response to oxidative stress) and *ENA1* (a P-type ATPase Na^+ pump required for cationic stress resistance) (226, 227).

Changes in carbon source also affect stress resistance in *C. albicans*. Exposure to glucose increases oxidative stress resistance by upregulating oxidative stress genes in this yeast (209). In contrast, growth on glucose decreases the resistance of *C. albicans* to osmotic and cell wall stresses, in large part through carbon source-

dependent changes in the preadapted state of the cell wall (37, 228). Consequently, as different host niches contain different carbon sources, the nature of a niche must determine the ability of *C. albicans* to counteract stresses in that niche. Not surprisingly, the virulence of this pathogen is influenced by the carbon source (228).

CONCLUSIONS AND PERSPECTIVES

It is clear that major advances have been made in our understanding of fungal stress adaptation over the past decades. However, much remains to be learned with regard to how cells respond to stress in their natural environments. Several issues should be addressed.

First, many gaps remain in our understanding of stress signaling pathways and of stress responses themselves, even for individual stresses in model fungi. Just one example is our understanding of how nitrosative stress responses are regulated, which is rudimentary compared to oxidative and osmotic stress signaling even in *S. cerevisiae*. The situation is worse for model ascomycete and basidiomycete pathogens such as *C. albicans* and *C. neoformans*. Their lifestyles differ markedly from *S. cerevisiae* and *S. pombe*, and differential evolutionary pressures appear to have driven regulatory rewiring and niche-specific tuning of stress responses, yielding different stress sensitivities and different patterns of stress cross-protection.

Second, our understanding of the dynamics of stress adaptation needs to improve, incorporating the immediate and long-term contributions of metabolic responses and biophysical changes alongside those driven by transcriptional and posttranslational gene regulation. This needs to be considered alongside the issue of population heterogeneity. The molecular basis for the differential stress sensitivity of genetically identical cells experiencing the same environmental conditions needs to be better understood. To achieve this we require experimental approaches that provide dynamic views of cell-to-cell variation at high resolution.

Third, more consideration needs to be given to the nature of the stresses that are encountered by a fungus in its natural habitat and the nature of the microenvironment(s) in which it must respond to these stresses. How acute is the stress, how long is the exposure, and how frequently is it encountered? This is significant because some fungal stress responses may have evolved to maintain cellular homeostasis in the face of modest but repetitive challenges rather than single acute doses (see "Dynamics of Stress Responses," above). Is the stress imposed in combination with other environmental insults? This should be considered because certain combinations of stresses can yield unexpected stress responses (see "Combinatorial Stress Responses," above). What is the temperature of the niche, and what nutrients are available? These factors are important because they strongly influence the preadapted state of the fungus and hence its ability to counteract the stress (see "Impact of Growth Conditions on Stress Resistance," above).

If these issues are addressed, there will be a paradigm shift in our understanding of fungal stress responses and their relevance to survival in natural environments.

Thigmo Responses: The Fungal Sense of Touch

22

Mariana Cruz Almeida and Alexandra C. Brand

INTRODUCTION

The growth and development phases of most fungi take place on a two-dimensional surface or within a three-dimensional matrix. The fungal sense of touch is therefore critical for fungi in the interpretation of their environment and is often involved in the switch to a new developmental state. Contact sensing, or thigmo-based responses, include thigmo differentiation, such as the development of invasion structures by plant pathogens; thigmonasty, where contact with a motile prey rapidly triggers its capture; and thigmotropism, where hyphal growth direction is guided by physical features in the environment. Like plants and some bacteria, fungi grow as walled cells. How do fungi, as walled organisms, not only sense contact, but also interpret the signal in a developmental context?

The fungal sense of touch was first observed in 1937, when Drechsler recognized the role of thigmonasty in the predaceous activity of the nematode-trapping fungus, *Arthobotrys oligospora* (1). This fungus forms a specialized hyphal stalk ending in a loop comprising three "capture cells" that form an aperture of approximately 20 μm (Fig. 1A). When a migrating nematode enters the loop, the capture cells sense contact with the prey and dramatically inflate to three times their normal size within a tenth of a second (Fig. 1B). The constriction immobilizes the nematode, which is subsequently penetrated and digested by hyphae that develop from the encircling capture cells (1, 2). Over a century later, the fungal sense of touch was found to be essential for the recognition, exploration, and invasion of host surfaces by plant pathogens using thigmotropism, or contact-induced directional growth (Fig. 1C and D). Studies using inert materials patterned to mimic host-leaf topography showed that highly defined three-dimensional surface features elicited pathogenic behaviors, including host-specific directional growth responses and the morphological development of specialized invasion structures (thigmo differentiation) (Fig. 1E) (3, 4). More recently, the contact-induced behavior of the human pathogen, *Candida albicans*, has been investigated. Although the characteristics of the external signals received by the fungus *in vivo* are not fully understood, the loss of normal hyphal touch responses correlated with attenuated tissue penetration, damage, and virulence (5–7). Fungal contact sensing has been primarily recognized and studied in the context of predation and pathogenesis, but it is involved in many other fungal behaviors including interactions with "self," such as mating and anastomosis (e.g., fusion between specialist cells or vegetative hyphae), and with "non-self," such as the symbiotic association of mycorrhizal fungi with plant roots. There are likely to be many other contact-dependent behaviors that are so far unappreciated because of the highly varied, and mainly unseen, lifestyles of the estimated 3 to 5 million fungal species (8).

The study of contact-dependent behavior by fungi presents several challenges. First, a link must be observed between a specific stimulus and a consistent response output. Fungal cells are microscopic, but their activity is often observed at the population level when they cause visible harm to valued macro-organisms such as food crops, livestock, and humans. Next, an experimental system must be devised that captures and defines the relevant stimulus so that fungal responses can be studied. Bespoke microscopy methods coupled with molecular tools, microfabrication, and laboratory-based host model systems have provided considerable insights as to the stimuli sensed by fungi that induce

MRC Centre for Medical Mycology, University of Aberdeen, School of Medicine, Medical Sciences & Nutrition, Institute of Medical Sciences, Foresterhill, Aberdeen, Aberdeenshire AB25 2ZD, United Kingdom.

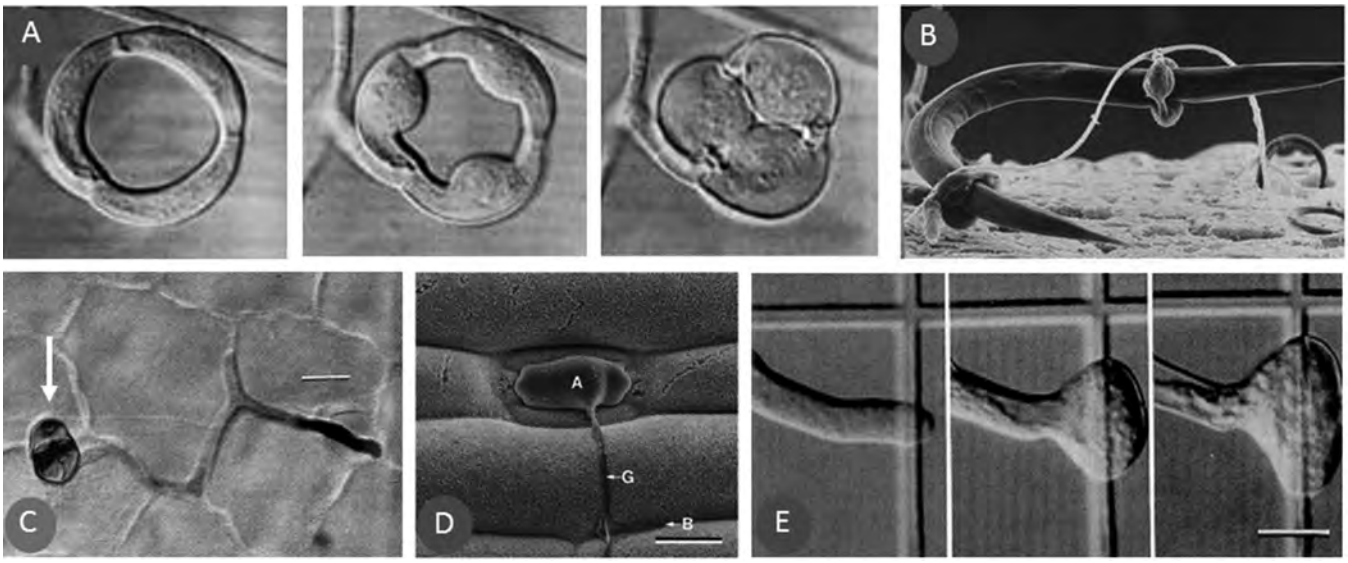

Figure 1 Thigmo responses play crucial roles in the fungal lifestyle. (**A**) Thigmonasty: On sensing exudate from nearby nematode prey, *Arthobotrys oligospora* hyphae produce a lateral peg and three consecutive capture cells that grow round until they contact the peg, with which they fuse to form a capture loop (1, 2) (reprinted from taxusbaccata.hubpages.com with permission of the author). (**B**) Contact with a nematode entering the aperture of the loop causes immediate swelling of the capture cells to immobilize the prey (reprinted from apsnet.org with permission of the author). Invasive hyphae then germinate from the contact zone of the capture cells to penetrate and digest the nematode. (**C**) Thigmotropism: Hyphae of the sooty blotch fungus, *C. trifolii*, follow interepidermal cell depressions on the surface of the host plant, *T. repens* (white clover), to locate a stoma, over which a penetrative appressorium is formed (arrow) (bar, 10 μm) (reprinted from *Mycological Research* [23] with permission of the publisher). (**D**) Germ tubes of the cereal rust fungus, *Puccinia hordei*, grow perpendicularly across depressions in the surface of its host barley leaf to locate stomata, which are arranged in staggered arrays, and form appressoria (G, germ tube; A, appressorium; B, branch; bar, 20 μm) (reprinted from *Planta* [148] with permission of the publisher). (**E**) Thigmo differentiation: the differentiation of appressoria by *U. appendiculatus* is induced by topography alone when the fungus is grown on an inert polymer with topographical features that precisely mimic the surface of the host plant (bar, 11.8 μm) (reprinted from *Experimental Mycology* [4] with permission of the publisher).

specific growth responses. Once an experimental system is in place, the next challenge is to define the mechanism of contact sensing at the molecular level. Mammalian cells sense the physical environment through direct contact between the extracellular matrix (ECM) and adhesive proteins that are embedded in the viscoelastic plasma membrane that surrounds the cell. In fungi, the plasma membrane and its embedded proteins are encapsulated by a semirigid polymeric cell wall that separates them from the outside world. It is therefore hard to imagine how these organisms can not only sense contact but also can recognize the size of features in the substrate topography on which they grow. Recent works suggest that the internal organization of the growing fungal cell may play a role in this type of sensing (7). However, for most contact-dependent responses, contact alone is insufficient to induce fungal responses and an additional chemical signal is required, suggesting that contact sensing in fungi constitutes a chemomechanical-coupled system that requires optimal chemical interactions at the fungus-substrate interface in addition to mechanical stimulation. What is more, the developmental stage of the cell enables the fungus to interpret the contact signal within that context. The output, or behaviors, contact recognition elicits in cells is critical to understanding the lifestyle of the fungus, its evolution, and its adaptation. Response behaviors result from the activation of hard-wired signaling pathways that are poised to deliver context-relevant responses. We currently have some understanding of the importance of contact sensing for fungi but can only point to potential mechanisms for mechanosensing at the

molecular level. Thanks to constant advances in technology, we now have a growing catalogue of observed behavioral outputs and the genetic tools with which to test new hypotheses about how contact is sensed. This review will emphasize the importance of contact sensing for fungi and describe the diverse contexts in which specific responses are induced. We discuss the molecular mechanisms that may be involved in generating intracellular signals, with reference to their counterparts in plants, bacteria, and mammalian systems. Some concepts involved in mechanosensing appear to be conserved across these three domains of life.

THE IMPORTANCE OF CONTACT SENSING IN FUNGAL LIFESTYLES

Fungal Contact in the Environment

Contact sensing stands at the threshold of many developmental aspects of the fungal lifestyle and, in most cases, there is a requirement for an additional chemical signal. For other responses, such as the circumnavigation of obstacles, it is not yet known whether chemical signals are involved. Although the molecular mechanism through which contact is sensed has not been elucidated, a number of chemical inputs have been identified that are required for generation of a complete response. The requirement for two stimuli suggests that fungi use a logic gate, where IF there is a physical signal AND there is a relevant chemical signal, THEN a specific response at the cellular and developmental level is generated (Fig. 2).

Initial Contact and Host/Prey Recognition

Many phyto- and entomopathogenic fungi are dispersed as windborne spores where contact with a host heralds the transition from a resting state to growth. Fungal interactions with host plants have been well studied because they constitute the first step in the disease process that can devastate important food crops. To function as a signal that induces new growth and differentiation, the interaction between a spore and its substrate/food source must be quickly stabilized. In plant and insect pathogens, this is achieved through adhesion, but in *A. oligospora*, the nematode-trapping fungus, it is equally well accomplished by the constricting rings formed by capture cells. Both systems require the correct reciprocal chemistry between the fungus and its target (Fig. 3A). In plant and insect pathogens, the spore coat comprises an outer layer of amphipathic proteins called hydrophobins, which have been identified only in filamentous fungi (9, 10). At air-water interfaces, hydrophobins self-assemble to facilitate the growth of aerial structures, but they also mediate adhesion to hydrophobic surfaces through passive, nonspecific interactions (11–13). The chemistry of the outer spore wall therefore establishes adhesion through its compatibility with the hydrophobic epicuticle of the host. Studies of

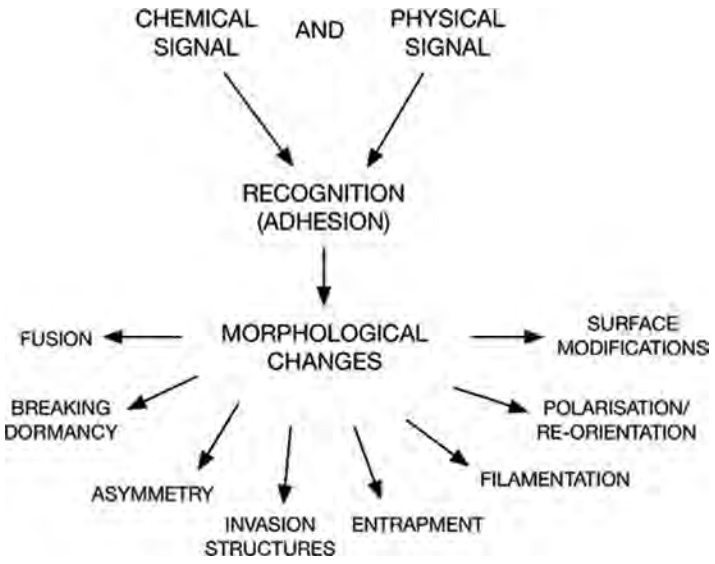

Figure 2 Contact sensing stands at the threshold of a diverse range of morphological and growth transitions relevant to specific fungal lifestyles. Most transitions require a supporting chemical signal for complete induction of a normal response while, in others, this aspect has not been fully investigated.

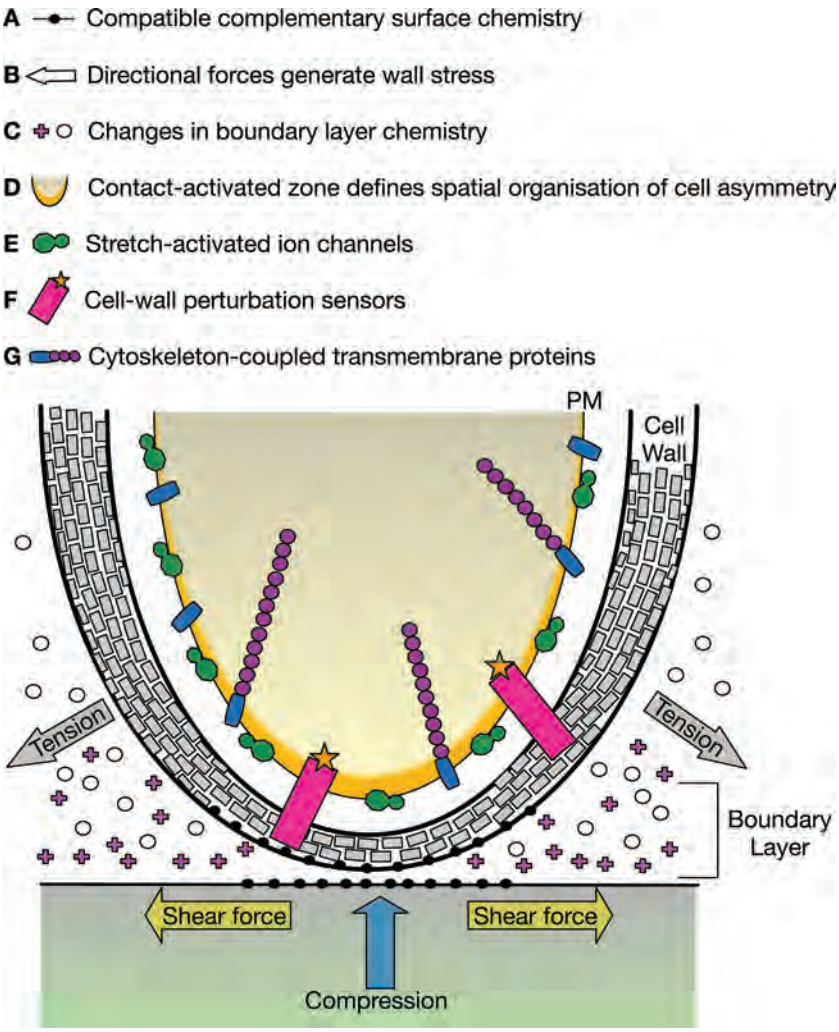

Figure 3 Mechanisms involved in fungal contact resulting in recognition and/or adhesion. (**A**) Compatible surface chemistry between fungal and substrate surface promotes adhesion. (**B**) Directional forces generate cell wall stress. (**C**) Chemical changes sensed within the boundary layer, sometimes as a result of fungal enzyme activity against host exudate. (**D**) Contact-activated zone defines spatial organization of cell asymmetry. (**E**) Stretch-activated ion channels. (**F**) Plasma membrane (PM)-associated cell wall perturbation sensors coupled to intracellular signaling pathways. (**F**) Sensors of cell wall perturbation. (**G**) Cytoskeleton-coupled transmembrane proteins.

hydrophobins show that the arrangement of rodlets differs between fungal species, but they all present an undulating, regularly patterned surface at the plant interface. Some fungi employ additional adhesion mechanisms. The elongated conidia of the rice blast fungus, *Magnaporthe grisea*, attach to surfaces through the release of mucilage from the spore tip after moisture is absorbed, where hydration of the fibrous material causes it to expand and burst through the cell wall (14). There is no evidence that host-specific receptors are recognized by spore surface proteins in plant and insect pathogens, so the avidity of multiple hydrostatic and van der Waals interactions appears to be sufficient to anchor spores to the host (12).

For fungal spores, contact with a suitable substrate is a prerequisite for breaking dormancy, but how is the substrate sensed through the cell wall? The requirement for adhesion suggests a mechanism whereby vibration, wind, or rainfall generates shear stress at the spore-host interface, and this perturbation is somehow transmitted through the cell wall (Fig. 3B). The further requirement for surface hardness by fungal spores supports this idea

because a viscoelastic surface would absorb the energy from external strain, thereby dampening the mechanical signal, potentially to below a threshold level. In addition to shear stress, there is evidence that contact is sensed chemically through changes in the local ionic concentration or chemical species present within the aqueous boundary layer at the interface between plant and fungus (Fig. 3C) (15).

The requirement for two external signals to operate as a simple "AND" logic gate increases the likelihood that a suitable host has been located before resources are committed to the next developmental stage. *Blumeria graminis* and *Uromyces viclai-fabae* carry lipases, cutinases, and esterases on their spore surface so that contact with the cognate host generates specific breakdown products from the long-chain waxes that coat the host leaf surface (16–18). Production of these moieties, or their addition *in vitro*, stimulates spore differentiation so it is likely that they act as a positive-feedback mechanism for host recognition by the fungus (16). While host surface hydrophobicity is required for spore adhesion via fungal hydrophobins, it also facilitates the generation of a chemical signal that is sensed by the fungus. In *M. grisea*, contact with a hydrophobic surface, whether it be a leaf or an "inert" plastic, allows the lipophilic surface-borne inhibitor, pyriculol, to diffuse away from the spore wall, thereby relieving inhibition and permitting germination (19). Chemical signals also play a role in host/prey recognition in the nematode-trapping fungus, *A. oligospora*, but here the logic gate becomes more complicated because the chemical signal is temporally separated from the sensing of contact, and it must come first. Capture cells are induced by the recognition of prey exudates in the environment so that the fungus does not commit these resources unless prey is nearby. There is interspecies variation in the ability of exudate from parasitic nematodes to induce these loop structures but, once generated, capture-cell activation is entirely contact driven and independent of nematode species (20). In all the examples described here, contact involving thigmo- and chemo-sensing drives host/prey recognition. Just as importantly, they also spatially define the zone of the fungal cell surface at which contact has been made (Fig. 3D). This information will determine the direction of asymmetrical cell development in the next stages of gene expression, development, and growth.

Contact Sensing and Plant Pathogenesis

For most plant pathogens, breaching of the tough host-leaf cuticle is a challenge that requires the generation of specialized penetration structures called appressoria. The function of appressoria is to produce a specialized peg that has the capacity to penetrate through the protective cuticle into the tissue below. Appressorial structures vary by fungus and can be dome shaped or appear as swollen hyphal tips, known as infection cushions. Correct orientation of the penetration peg in relation to the host leaf is essential for function and is probably determined by sensing the zone of contact with the host leaf to generate an internal landmark signal that specifies the site of new growth. The majority of biotrophic phytopathogens, including the rice blast fungus, *M. grisea*, form appressoria after a short polarized growth stage on the surface plane of the leaf. The secretion of adhesive material around the zone of contact anchors the base of the appressorium to the host to provide an opposing force against which the penetration peg can push. Sensing of the contact zone also orients the penetration peg toward the underlying leaf and, in *M. grisea*, excludes this site from the process of cell wall melanization and strengthening that is required for the accumulation of solutes and for withstanding the resulting turgor pressure of up to 8 MPa (80 bar) (21). The corn pathogen, *Colletotrichum graminicola*, also uses the zone of contact to define a point adjacent to the leaf surface from which the new germ tube emerges (22). After emergence, the germ tube adopts a flattened morphology against the leaf surface and remains in close contact before the appressorium is generated. Together, these examples demonstrate that surface contact influences cell shape and the direction of polarization. Fungi such as the white clover pathogen, *Cymadothea trifolii*, and the rusts, *Puciinia graminis, Puciinia hordei*, and *Uromyces appendiculatus*, produce exploratory hyphae that search the host leaf to locate epidermal pores called stomata, which are ideal penetration sites. Thigmotropic sensing by hyphal tips appears to be differentially programmed in these fungi to accommodate the host-specific arrangement of stomata within the leaf structure. In the white clover, *Trifolium repens*, stomata are located at epidermal cell boundaries. The hyphae of *C. trifolii* search out these stomata by growing along the meandering depressions between the host cells (Fig. 1C) (23). In contrast, stomata of the maize plant are laid out in a staggered grid, where hyphae of the rust fungi, such as *U. appendiculatus*, grow perpendicularly across parallel host leaf depressions to locate them (Fig. 1E) (23–26). Sensing of the topography of host stomata induces thigmo differentiation, whereby hyphal extension ceases and an appressorium develops over the pore structure. By growing these hyphae on inert plastics featuring ridges of defined heights and spacing, it has been observed

that the exploratory hyphal tips were asymmetrically biased toward the substrate and only responded to topographies that precisely mimicked the stoma dimensions of the host plant (Fig. 1D) (4, 22). The inductive ridge height was optimal at a perpendicular elevation of 0.5 μm, representing 0.06 to 0.1 of the hyphal diameter, and required the presence of two acute angles, suggesting that the hypha was tuned to detect this shape (Hoch et al [25]). Thigmo differentiation, germ tube emergence sites, the orientation of penetration pegs, and the shape of exploratory hyphal tips are morphological responses that are induced by fungal recognition of an external zone of contact with the host plant. This sense of contact then determines the spatial organization of intracellular asymmetry and growth that is required for the next stage of host tissue invasion by phytopathogens.

Contact Sensing and Fungal Mutualism

The antagonistic relationship between fungi and plants is countered by the endophytic and mycorrhizal fungi that support the growth of plants by developing intimate relationships with their host, in general, to their mutual benefit. The processes that establish and maintain these interactions are not well understood because of the paucity of available genetic methods and the challenges involved in imaging the host-fungus interactions in real time *in vivo*. Endophytes such as *Epichloë* and *Neotyphodium* spp. live as hyphae within grasses, permeating through intercellular spaces and extending along the length of the leaf between the host cells (Fig. 4A). Endophytes confer resistance to a variety of external host stresses, such as insect predation and attack by downy mildew, by producing toxic alkaloids and other compounds (27). Endophytes grow synchronously with their host plant, elongating each hyphal compartment as its host's leaves enlarge. It is thought that the tight attachment of hyphae with the host extracellular matrix stimulates hyphal elongation through a sense of stretch (Fig. 4B). Unlike vegetative hyphae that grow by extension at the apex, the hyphae of endophytes extend by incorporating new material into the cell wall, known as intercalary growth (28). As hyphal compartments elongate, new septa are laid down between existing septa instead of forming sequentially as they do during apical growth. The mechanism through which stretch is sensed by endophytes has not yet been established. It seems likely that the shear force along the wall is transmitted to the plasma membrane underneath to signal sites where new wall material is required to relieve the strain. The mechanism of sensing stretch is better characterized in plants, where cells undergo shear stress during the expansion of adjoining cells. The cell wall is linked to the plasma membrane in a punctate manner via structures called Hechtian strands, but these have not been demonstrated in fungi (29). Intercalary growth has been observed previously in the developmental programs of mushrooms, rhizomorphs, water molds, and others (reviewed in reference 30) but the stimulus is unknown in these cases. In endophytes, it is the fungal sensing of contact with the host through adhesion that acts as the important regulatory factor in the rate and spatial control of hyphal extension (28).

The role of contact with an external host is also important in the development of arbuscular and ectomycorrhizal mutualism, whereby formation of close intracellular or extracellular associations with plant roots delivers phosphate and nitrogen, respectively, in exchange for photosynthesis-derived carbon. Location of the host's root apex by the fungus is driven by chemotropic growth toward CO_2 and volatiles present in root exudate (31–33). Recognition and contact with the host drives the development of specialist structures that permit the exchange of nutrients between organisms. Arbuscular mycorrhizae cause an internal rearrangement of the host's cortical cells, which produce a specialist membrane that surrounds the intruding hyphal arbuscules and expresses symbiosis-specific transporters (Fig. 4C) (34). Ectomycorrhizae do not penetrate host cells, instead forming a fungal sheath surrounding the root cortex and a network of hyphae, known as a Hartig net, that surrounds each root cell (Fig. 4D) (35). The genes that drive the development of these fungal structures are being identified, but their functions are as yet unknown. The formation of root-associated structures partially depends on chemical signaling gradients from the host, but it seems likely that these signals are integrated with contact sensing if the fungus is to adapt its own cell wall to fit around the host cell surface, between cortical cell layers, and within host-cell cavities.

Contact Sensing During Cell Fusion

An important feature of the fungal lifestyle is to undergo cell fusion, which can occur with "self" or as "nonself" fusion, which in turn can occur in an intra- or interspecies manner. The process is carried out in two stages, and the pivotal point that marks the end of one stage and commencement of the other is defined by cell-cell contact. During the first stage, the presence of a partner is recognized through secreted chemical signals, and the cells grow chemotropically toward each other along a concentration gradient, a process

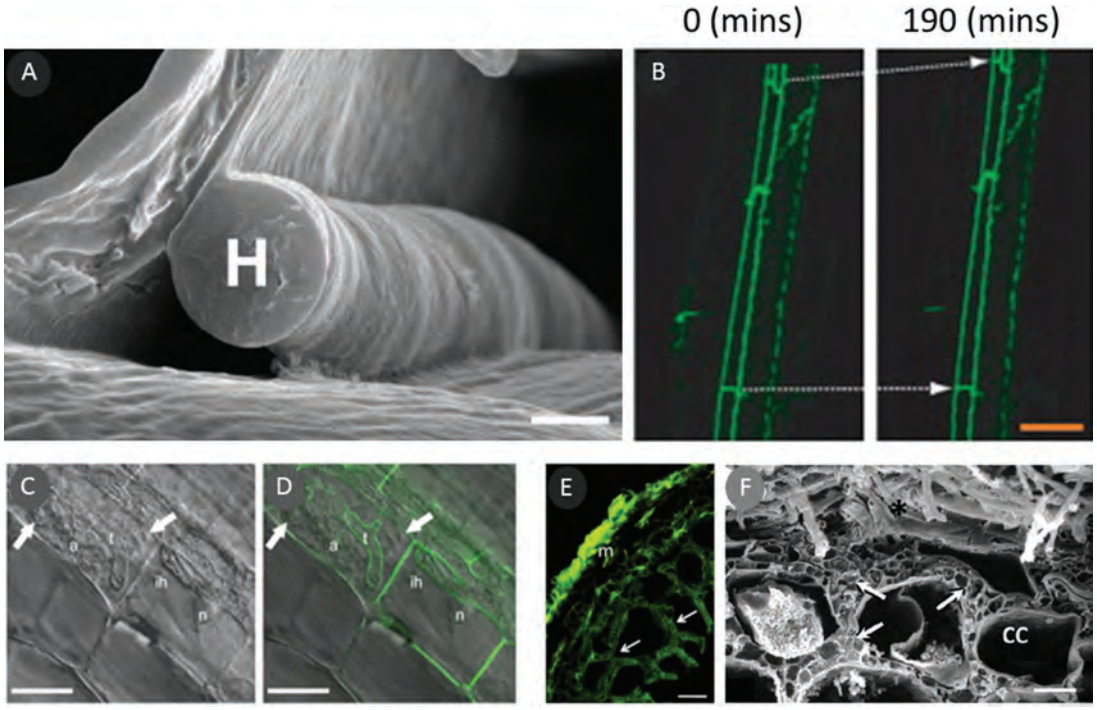

Figure 4 Tight contact between fungus and host during fungal mutualism. (**A**) Host-plant cell growth is thought to be sensed by the endophyte, *Neotyphodium coenophialum*, through its strong adhesion to the host intercellular matrix (H, hypha; bar, 1 μm) (reprinted from *Fungal Genetics and Biology* [28] with permission of the publisher). (**B**) The sense of stretch induces intercalary growth of the endophyte, *Epichloë fesctucae*, so that it elongates at the same rate as the host. Arrows indicate the lateral branches that have moved further apart as a result of intercalary growth (bar, 100 μm) (reprinted from *Fungal Genetics and Biology* [28] with permission of the publisher). (**C, D**) Arbuscular mycorrhizae form intruding hyphal arbuscules within the root cells of *Medicago truncatula*. Host GFP-Mtcp1 localizes to the cell plasma membrane and its derivative that surrounds the arbuscule trunk, but is not expressed in host membrane surrounding arbuscule branches (arrows), which is thought to be involved in nutrient exchange (a, arbuscules; t, arbuscule trunk; ih, intracellular hyphae; n, nucleus; bar, 20 μm) (reprinted from *Plant Physiology* [34] with permission of the publisher). (**E**) *Hebeloma cylindrosporum* ectomycorrhizae, labeled with wheat germ agglutinin-fluorescein isothiocyanate, grow as a dense outer fungal sheath or mantle surrounding the "Hartig net" (arrows) of hyphae growing between outer cortical cells of hazelnut, *Tuber melanosporum* (m, fungal mantle; bar, 15 μm) (reprinted from *Frontiers in Plant Science* [149] with permission of the publisher). (**F**) *H. cylindrosporum* forms a fungal sheath surrounding the Hartig net (arrows) of hyphae that intercalate between the cortical root cells of *Pinus pinaster* (CC, cortical cells; black asterisk, fungal sheath; bar, 10 μm) (reprinted from *Molecular Plant-Microbe Interactions* [35] with permission of the publisher).

that has been termed "homing." Contact between the cells marks the spatial and temporal point at which growth ceases and the second phase commences, during which the cell walls are dissolved and the plasma membranes are reorganized to allow the mixing of cytoplasmic material. Cell fusion generally occurs between specialist fungal structures, and the response to cell-cell contact is specified by this developmental context. The best characterized example of non-self-cell fusion is the mating response in *Saccharomyces cerevisiae*, where cells of opposite mating types form blunted, polarized mating projections called "shmoos." The chemical signaling molecules, **a** and α pheromone (peptides), have been identified (36, 37) and the shmoo tips grow chemotropically toward each other until contact is made, whereupon the cell walls dissolve, the plasma membranes fuse, and nuclear fusion takes place (Fig. 5B). The mechanism for sensing contact in this process remains elusive and it has been generally understudied, given its pivotal role.

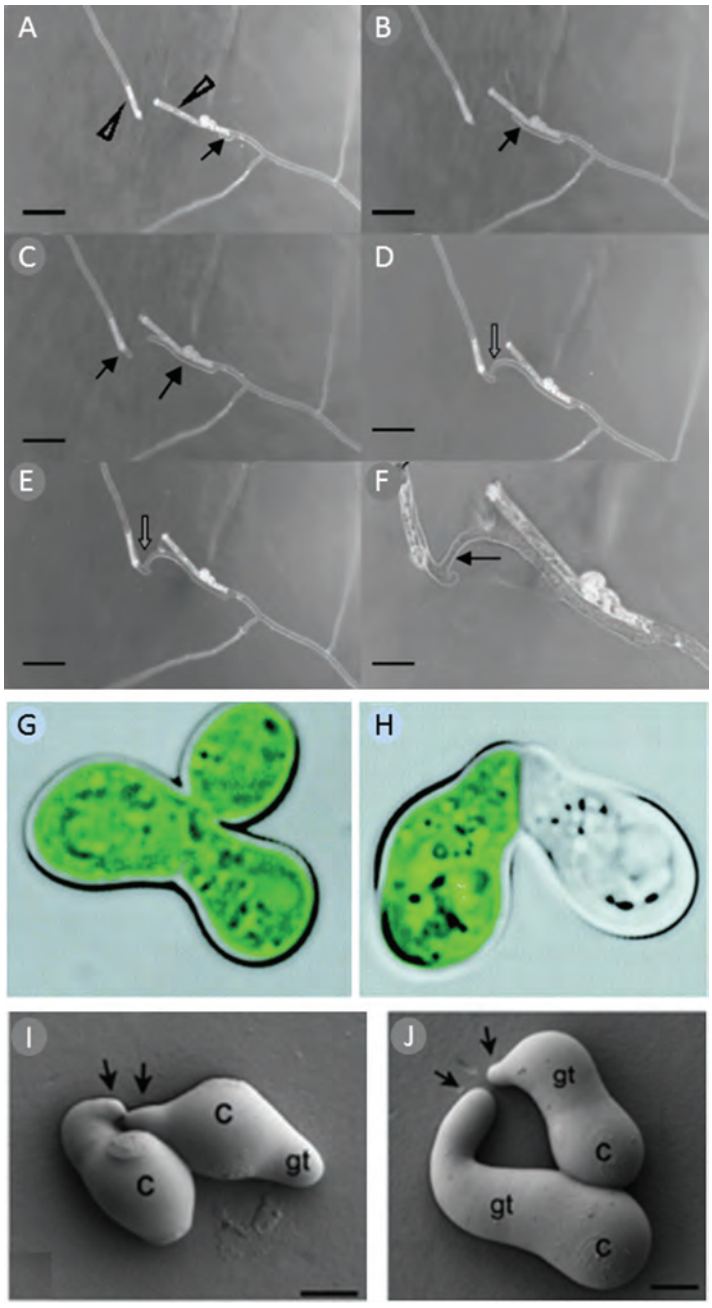

Figure 5 Cell-cell contact marks the developmental tipping point between "homing" and fusion. (**A to F**) Healing process between the ends of a severed hypha in mycelia of the arbuscular mycorrhiza, *Gigaspora margarita*. (**B, C**) Severed hyphal compartments (open arrows) are sealed off by the formation of new septa. New hyphae emerge from behind the septa and grow chemotropically toward each other (closed arrows). (**D to F**) Hyphal wall contact and fusion (open arrows) permits cytoplasmic flow to be reestablished (open arrowhead). (Bars, 80 μm) (reprinted from *New Phytologist* [39] with permission of the publisher). (**G**) Mating cells of yeast *S. cerevisiae*, where the shmoos of two wild-type cells expressing soluble GFP have fused by degrading the cell wall and fusing the plasma membrane. A daughter cell has emerged (top). (**H**) In the *prm1*Δ null mutant, which lacks a multispanning transmembrane protein, shmoo-shmoo contact triggered cell wall degradation but not membrane fusion, stalling the mating process (reprinted from the *Journal of Cell Biology* [150] with permission of the publisher). (**I**) Conidial anastomosis tubes (CATs) emerge from conidia of *N. crassa* and "home" toward each other (c, conidia; gt, germ tube; bar, 6 μm). (**J**) CATs emerge from germ tubes prior to contact and fusion (bar, 5 μm) (reprinted from *FEMS Microbiology Letters* [44] with permission of the publisher).

Filamentous fungi generate spreading branched networks that form interconnections, called anastomoses, between vegetative hyphae or between specialized fusion filaments. In soil fungi that scavenge for resources in heterogeneous environments, anastomosis improves colony resilience by creating efficient routings for the distribution of nutrients (38). The imperative to maintain colony integrity is evidenced by the arbuscular mycorrhizae, *Gigasporaceae* and *Glomeracea*, which use anastomosis in an elaborate wound-healing process that rejoins the two ends of a severed hypha (Fig. 5A). This is achieved by first forming a septum either side of the wound to stem cytoplasmic leakage. A new branch then emerges from each sealed compartment and grows toward the other to fuse, thus restoring normal hypha function and nutrient flow (39). Mycorrhizal fungi undergo intraspecies anastomosis between extraradical mycelia that are already symbiotically associated with plant roots and compatible germlings that are not (40). Not only does this maximize nutrient scavenging for the host plant, but it benefits the fungus in two ways. First, it enhances species survival by providing germlings with host-derived carbon before they have formed their own mutualistic association and, second, it improves species fitness through the exchange of nuclear material (41).

Intrahyphal fusion that relies on the formation of a lateral hyphal peg is a mechanism used for the formation of clamps in basidiomycetes such as *Coprinus cinerea* and *Schizophyllum commune* and for trap formation in the nematode-trapping fungus, *A. oligospora*. Hyphal clamps ensure the correct distribution of dikaryotic nuclei through the formation of a lateral peg that acts as a homing device for the tip of a hook-shaped cell that protrudes just ahead of it. After formation of a septum that divides the hypha between the two structures, the hooked clamp cell fuses with the peg to deliver a daughter nucleus to join its genetically different partner (42). Hyphal trap formation involves anastomosis between a lateral hyphal peg and the distal end of the three specialized trap cells in order to form a complete loop. An exchange of cytoplasm takes place before a septum is formed at the site of fusion and the trap is complete (43). The lateral peg mechanism is consistent with the overall theme of fungal fusion, whereby sensing, homing, and fusion require highly defined apical zones in which the function-specific molecular machinery is confined. The intriguing nature of the signaling systems during anastomosis has been investigated in the homing of conidial anastomosis tubes (CATs). Twenty-one genera and 73 species of filamentous fungi, primarily *Aspergillus* spp. and *Penicillium* spp., form CATs, which are short, thin hyphae that home toward each other and fuse (Fig. 5C) (44). The nature of the extracellular signaling molecules and their receptors remains to be identified but, in *Neurospora crassa*, CAT signaling involves the oscillatory antiphase recruitment of the proteins, MAK-2 and SO, to the two homing tips in a process termed the "ping-pong" mechanism of call and response (45, 46). Although CATs form between various types of conidia of the same species, they also emerge from mature hyphae, and even interspecies fusion has been observed, which can produce stable heterokaryons (47). Since nutrient limitation increases the frequency of germling fusion, and clonal, rather than sexual, replication dominates among filamentous fungi, nutrient sharing and the exchange of genetic material appear to be the most common benefits to fungi in the evolution of cell-fusion mechanisms (48, 49). As with all the examples of fungal fusion highlighted here, recognition that tip contact has been achieved is an essential component of the process.

Fungal Contact with the Human Host

Every day, humans inhale hundreds of airborne spores produced by environmental fungi, yet very few fungal species cause infections, and then mostly only in patients with immune deficiencies or specific underlying medical conditions, such as HIV infection. Most environmental fungi are unable to survive the relatively high body temperature of mammals and they are efficiently cleared by the host immune system. The inhaled spores of *Cryptococcus neoformans*, *Aspergillus fumigatus*, and *Pneumocystis jirovecii* comprise three of the top four causes of fatal fungal infection, with mortality rates of 20 to 90% (50). Other fungi that afflict the human population are transmitted through direct contact with a colonized surface. These include *C. albicans*, a commensal yeast of the mucosa that is primarily transmitted from passage through the birth canal (51), the dermatophytes of keratinized skin such as *Trichophyton rubrum*, which transfers through surface contact and causes "athlete's foot," and dermatophytes of the glabrous skin, such as the zoonotic fungus, *Microsporum canis*, which produces the circular lesions known as "ringworm" and is transmitted through person-to-person contact or between people and animals (52).

For the inhaled spores of environmental fungi, the dominant signal for contact with a human host is likely to be the sustained rise in temperature and ambient moisture. Human surfaces present an extremely complex landscape of chemistries, are highly variable by

body site, and, in general, are not amenable to *in vivo* study so our understanding of contact-dependent interactions requires reductionist methods. Studies of human pathogenic fungi that are acquired by direct transmission often have a complex fibrillar outer surface composed of glycoproteins, unlike the smoother hydrophobin coat of conidia from environmental fungi (53, 54). The advantage to fungi of glycoprotein fibrils is that they can present diverse surface chemistries simultaneously to maximize the likelihood of achieving adhesive interactions with host surfaces. The fibrils of the dermatophytes *T. rubrum* and *Trichophyton mentagrophytes* include lectin-like adhesins that bind host-surface carbohydrates, while *C. albicans* expresses a large number of glycoprotein adhesins that enable cells to bind to RGD moieties in extracellular matrix proteins (e.g., collagens and fibronectin), surface carbohydrates, specific receptor proteins, and implanted medical plastics (55–60). Of particular note is the *C. albicans* hypha-specific cell wall protein, Hwp1, which is covalently cross-linked to keratinized cells through its N-terminal domain by host transglutaminase (58). Whether this linkage acts as a signal through the Hwp1 C-terminal of Hwp1, which is covalently bound to cell wall β-glucan, is not known. To date, although numerous types of interaction take place between the host and extracellular fungal fibrils, none is known to directly act as part of a trans-cell wall protein signaling pathway to indicate that host binding has occurred. As with phytopathogens, contact is more likely to be sensed by general cell wall perturbation across the zone of adhesion that activates stretch sensors in the underlying plasma membrane. A role for chemical sensing of the host environment to support contact-induced signals could occur in the form of nutrients that are released from the host. *C. albicans*, for example, carries surface-mounted aspartyl proteases that function at different pH optima. Their activity may indicate not only that adhesion has been achieved, but also identify the site of adhesion by virtue of the chemical profile of host-related products that is generated (61).

Contact with a compatible surface that facilitates adhesion is the critical first step in host colonization and a signal for the initiation of new fungal cell growth. In filamentous pathogens, this is usually accompanied by cell asymmetry, polarization, and differentiation before transferring from surface growth to embedded growth in a tissue matrix. The outer cornified epidermal layer to which dermatophytes adhere is subject to continuous abrasion and cell loss. To counter this, the arthroconidia of *T. rubrum* and some *Malassezia* species produce filamentous hyphae that undergo anastomosis and intercalate between the keratinized cell layers to form a subcutaneous mycelial network that can withstand the loss of the outer epidermal cells. In *T. rubrum*, HexA, the primary component of the Woronin body that seals off hyphal compartments on wounding, is upregulated during growth on keratin, suggesting that this is important for the integrity of the mycelium in the elastic milieu of the epidermis (62, 63). *C. albicans* produces hyphae when immune surveillance is locally deficient or is compromised because of medical interventions. Hypha production may be a stress response that does not occur in the commensal environment of the gastrointestinal tract, where there is immune cell tolerance and sufficient access to nutrients. Upon adhesion to the oral or vaginal mucosa, hyphae invade the underlying epithelial layers, causing localized inflammation. Serum is a powerful inducer of morphogenesis and yeast cells that access the bloodstream through surgery or by nosocomial transmission soon generate penetrative hyphae that facilitate escape of the fungus into underlying solid organs. *C. albicans* yeast readily adheres to medical plastics, where hyphae germinate to form resilient three-dimensional biofilm networks, often containing other *Candida* species and bacteria (64). Adhered hyphae can apply sufficient force to penetrate soft medical silicones such as voice prostheses, causing the material to swell and stiffen, leading to failure of the device (65). In the lung, *Aspergillus* conidia swell, fragmenting their hydrophobin coat prior to hypha formation, which results in tissue distribution patterns that are dependent on the underlying disease and immune status of the host. As seen for plant pathogens, contact with a compatible host facilitates cell adhesion and the induction of downstream developmental pathways. In some host-fungus relationships, this leads directly to disease and, in others, to compatible responses, immune tolerance, and fungal commensalism. In all cases, the fungal sense of contact is inextricably linked to mechanisms that maintain the association of the fungus with the host.

THE MOLECULAR BASIS FOR CONTACT-INDUCED DIRECTIONAL GROWTH RESPONSES

Despite its important role in the fungal lifestyle, the molecular basis for contact sensing by fungi is unknown. In contrast, the downstream signaling pathways for the developmental phases triggered by the sensing of contact are reasonably well defined in a number of fungi. In part, this imbalance is due to the difficulties of study-

ing contact at the level of individual cells, especially resting conidia, and differentiating between defective input versus output pathways. Progress has recently been made using growing hyphae of *C. albicans*, in which there is an increasing availability of molecular tools that can be exploited in imaging systems using microfabricated surfaces and fluorescence live-cell imaging. These approaches are helping to characterize contact-dependent responses that can be disrupted by gene deletion or mutation. Studies of actively growing hyphae showed the effect of contact events with topographical features that perturb the direction of growth and induce specific growth responses. Over the decades, imaging has consistently shown that hyphae growing on a surface adopt an asymmetric tip morphology with the tip pressed to the substrate (66). This is particularly striking in *Uromyces* hyphae as they explore the host leaf surface in search of the small topographical cues indicative of stomatal penetration sites (Fig. 1D). *C. albicans* hyphae also become asymmetric during growth on surface, where they can respond to topographical ridges of less than half the hyphal diameter by reorienting their growth axis to follow the contour (67). The basis for this morphology and the role it plays in sensing surface features has been partially elucidated (7). Green fluorescent protein (GFP) labeling of cell polarity proteins including myosin light chain 1 (Mlc1) and Spa2, markers for the Spitzenkörper and polarisome, respectively, demonstrated that the molecular complexes involved in polarized growth were also asymmetrically skewed toward the point of hyphal tip contact (Fig. 6A). Thus both the tip shape and the intracellular polarity complexes within are biased toward the substrate. When growing hyphae encountered channels and ridges, the Spitzenkörper translocated across the hyphal apex to the new point of contact (7). This asymmetric, contact-mediated positioning was crucial for generating thigmotropic behaviors in *C. albicans*, which included contour-following, gap penetration, and the maintenance of an overall growth trajectory, even after circumnavigating small obstacles (Fig. 6A through D). Deletion of the internal landmark GTPase, Rsr1/Bud1, abolished tip asymmetry and affected the stable localization of the Spitzenkörper and the ability of hyphae to steer normally in response to obstacles (Fig. 6E through G). These findings suggest that Rsr1 mediates outside-in signaling that locates the growth zone at the point of contact, and, in this way, very small changes in topography can be sensed. The upstream signal that localizes Rsr1 activity at the point of contact in *C. albicans* is not known, but, in *S. cerevisiae*, Rsr1 is localized to the

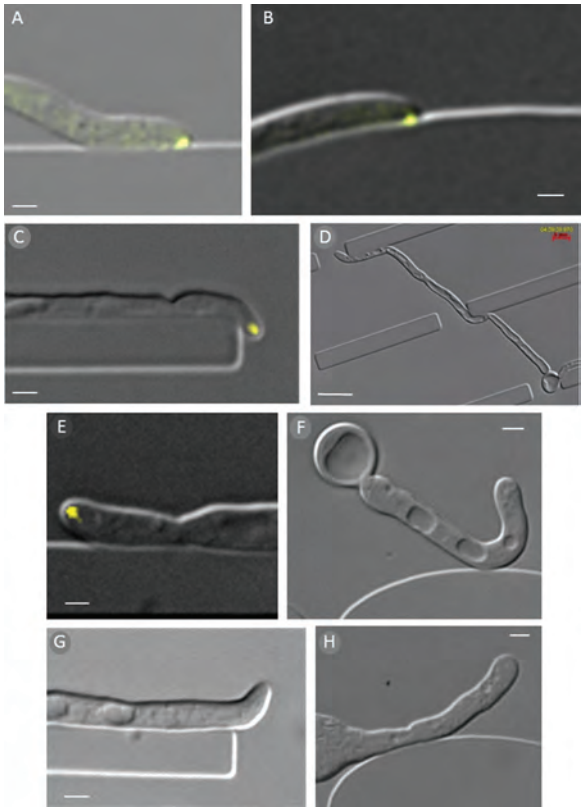

Figure 6 Contact-induced hyphal tip responses in *C. albicans* (7). (**A**) Tip and Spitzenkörper asymmetry induced by contact of a hyphal tip with an obstacle in control cells expressing Mlc1-YFP (bar, 2 μm). (**B, C, and D**) Hyphae exhibit contour following, gap penetration, and trajectory maintenance. (B, C, bars, 2 μm; D, bar, 10 μm). (**E to H**) In hyphae of the *rsr1*Δ mutant, the Spitzenkörper tends to be centrally positioned with the apex, hyphal tips do not become asymmetrical on contact or respond normally to substrate topography by following contours or penetrating gaps (bars, 2 μm) (reprinted from *Cellular Microbiology* [7] with permission of the publisher).

poles of the cell by Rax2, a single-pass transmembrane protein that binds the Rsr1 activator, Bud5. Deletion of Rax2 in *C. albicans* hyphae did not severely affect contact-dependent tip reorientation responses, so does not appear to act as the sensor that localizes Rsr1 activity during growth on a surface (68). Deletion of *RSR1* in *C. albicans* severely attenuated virulence and the ability of hyphae to penetrate and damage host cell layers *in vitro* (5, 6). Together with observations from *Uromyces*, it would appear that the contact-induced asymmetrical organization of the growing hyphal tip plays an important role in host invasion by a range of plant and human fungal pathogens. In *C. albicans*, it was observed that perpendicular contact of a hyphal tip with an obstacle temporarily stalled tip extension until

a new growth direction was determined. During this period, the fungus exerted a force of approximately 8.7 μNagainst the obstacle before reorienting, which theoretically is sufficient to penetrate a human cell plasma membrane without the use of enzymes (7). However, the force generated was influenced by carbon source. Growth of cells in lactate at concentrations reflecting physiological levels at body sites such as the urogenital and gastrointestinal tracts generated a thinner hyphal cell wall with a higher Young's modulus (69, 70). Lactate-grown hyphae reoriented more readily on contact and applied approximately half the force of glucose-grown cells (D. D. Thomson and A. C. Brand, unpublished data). This indicates that nutrient availability influences contact-induced hyphal growth behavior by altering cell wall properties, and this may be relevant to disease development by *C. albicans* at specific body sites. This observation also poses the question as to how hyphae with a thin, stiff cell wall respond more quickly to contact than cells with a thick, soft cell wall.

Potential Mechanosensing Systems in Fungi

To date, no protein or complex has been definitively shown to be a contact-induced mechanosensor in fungi, although there is good evidence that calcium ion (Ca^{2+}) influx is important for signal propagation (71–73). The importance of a sense of touch in fungal decision making suggests that a definable molecular mechanism does exist in fungi. It may be a discrete system that awaits discovery, or it may co-opt other signaling pathway sensors where signal integration indicates that contact has occurred. Here, we speculate on the systems that could be involved in contact sensing, starting with the most likely candidates that have either been linked to contact-induced behavior in fungi, or they bear similarities to mechanosensing systems in mammalian, bacterial, or plant cells. We then discuss other signaling proteins that might be predicted to act as sensors because they function in fungal cell wall integrity surveillance, maintenance, and remodeling processes. Last, we move to the possibility that fungi use as-yet-unidentified functional analogues of mechanosensing systems in animals. The proteins and their downstream signaling pathways discussed below are shown in Fig. 7.

Mechanosensing Ion Channels

Ion channels that are activated by membrane stretch have been identified in all kingdoms of life. They have been best characterized in bacteria, where the MscS (small conductance) and MscL (large conductance) channels are required for resistance to hypo-osmotic stress by releasing solutes from the cell (74, 75). The precise gating mechanisms of these multimeric protein complexes are still unknown but are thought to involve force transmitted from the lipid bilayer, differential partition of components within the bilayer, and the nanoscale properties of water within the pore (76–78). In whole cells, membrane interactions with the cytoskeleton and the presence of a cell wall also influence the pressure required to open mechanosensing channels (79, 80). Mechanosensing channel activity similar to that in bacteria has been identified in some fungi by using patch clamping (Fig. 3E). *S. cerevisiae*, *C. albicans*, *N. crassa, U. appendiculatus*, and *Schizosaccharomyces pombe* exhibited conductance from one or two channels using this method, and in *S. cerevisiae* it was confirmed that the mechanosensing channel was regulated by membrane tension and not by outward pressure (67, 79, 81–83). In *S. pombe*, two channels, Msy1 and 2, localized to the endoplasmic reticulum and protected the vacuole and nucleus from hypo-osmotic shock (84). Single, nonselective channels were observed in *S. cerevisiae* and *U. appendiculatus* and were calculated to occur at a density of 4–6 and 2 channels per μm^2, respectively (79, 82). Whether this channel density is sufficient to sense membrane tension in the tip of *U. appendiculatus* during contact with inductive ridged topographies is not known, but localization has not been determined and channels may cluster at the growing apex. Alternatively, these channels may be sparsely dispersed but transmit a potent signal. Channels in both fungi were found to be relatively selective for entry by calcium ions. Ca^{2+} is a signaling molecule involved in many stress-related pathways so the resting cytoplasmic calcium concentration is maintained at levels of ~0.1 to 0.2 μM in fungi, establishing a steep electrochemical gradient across the plasma membrane. It was calculated that only two stretch-activated Mid1 channels in *S. cerevisiae* would need to open for 0.59 s to accumulate sufficient cytoplasmic Ca^{2+} to activate calmodulin and the phosphokinase C pathway, demonstrating how few channels may be required for localized contact sensing, signaling, and cell development (85).

The role of Ca^{2+}-influx in mechanosensing was established through studies of the *S. cerevisiae* protein, Mid1 (Mating-induced death 1) (86, 87). Deletion of *MID1* reduced calcium uptake and stalled the mating process after shmoo formation, ultimately leading to cell death. The phenotype could be rescued by the addition of exogenous $CaCl_2$. When expressed in Chinese hamster ovary cells, ScMid1 conferred a response to mechanical stress by inducing a rise in intracellular

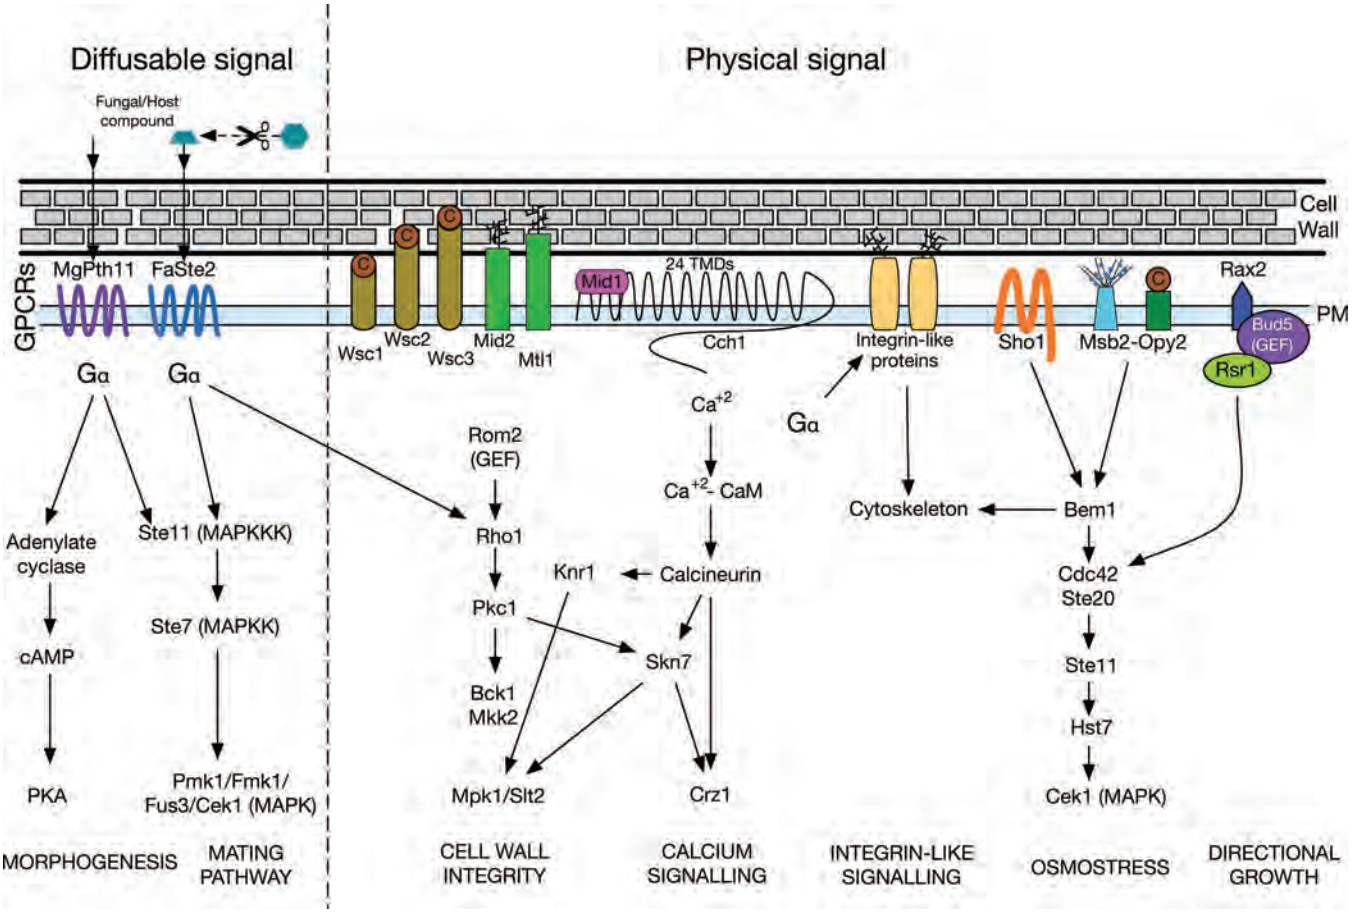

Figure 7 Sensing and signaling pathways that have the potential to be involved in mechanosensing in fungi. For details and references, see the text. PM, plasma membrane.

Ca^{2+}, suggesting it was a stretch-activated Ca^{2+} channel (88). In *C. albicans*, Mid1 is involved in Ca^{2+} uptake and was required for normal contact-dependent hyphal tip reorientation (72). In other fungi, Mid1 was generally found to be involved in calcium homeostasis but other deletion phenotypes differed from *S. cerevisiae*. In *N. crassa*, turgor pressure and growth rate were reduced but mating was unaffected, and the *mid1*Δ mutant in *A. fumigatus* was hypervirulent (89–92). ScMid1 was predicted to contain four transmembrane domains and localized to the endoplasmic reticulum and the plasma membrane (85). The identification of ScCch1, a homolog of the α-subunit of mammalian voltage-gated L-type Ca^{2+} channel (VGCC), ultimately led to the view that Mid1 was not a channel but a subunit, and potentially a regulator, of the Cch1 high-affinity calcium uptake system (HACs) (93–96). In *C. albicans*, where Cch1 has high similarity in its pore-forming and voltage-sensing domains to human CaV1.2 voltage-gated Ca^{2+} channels, the Mid1 peptide sequence is cysteine rich and contains a potential ω-site at Ser^{537}, suggesting that it is glycosylphosphatidylinositol (GPI) anchored and the bulk of the protein is extracellular. This overall topology is similar to the α2δ regulatory subunit of mammalian VGCCs, which also contain a cysteine-rich C terminus and are GPI anchored (97). Other Mid1-like proteins with cysteine-rich C terminals but no GPI anchors have been identified in animals, where they control the activation threshold of cation channels (98). In animals, VGCCs are also regulated by γ subunits. Several proteins have been identified as potential homologs of γ subunits in *S. cerevisiae* but only two, Ecm7 and Fig1, have been examined by gene deletion. Fig1 is upregulated in *S. cerevisiae* and *C. albicans* during mating, where it localizes to membranes that are destined to fuse (99, 100). Its deletion in *S. cerevisiae* did not inhibit fusion but produced aberrant zygotes with incomplete clearance of membrane or wall at the fusion site (101). Thus, Ca^{2+} is again linked with a cellular process that

involves contact-dependent responses, but the sensing mechanism that triggers Ca^{2+} influx into the cytoplasm is not known.

Cell Wall Integrity Pathway Sensor

Five single-pass transmembrane proteins in *S. cerevisiae* are specifically involved in sensing perturbation of the cell wall by virtue of N-terminal head groups that are embedded within the matrix of the wall, making them candidate mechanosensors that could mediate contact-dependent responses (Fig. 3F). The head groups of Mid2 and Mtl1 are large, branched *N*-glycans, while those of Wsc1, 2, and 3 comprise eight cysteine residues in cysteine-rich domains (CRDs) through which they are thought to cluster (reviewed in reference 102). Representatives of the two protein families are found in *Candida glabrata*, *A. fumigatus*, and *Cryptococcus neoformans* (reviewed in reference 103). Compounds that bind and disrupt hydrogen bonding between the structural cell wall β-glucan or chitin polymers, such as Congo red and calcofluor white, or echinochandin antifungals that inhibit glucan synthase, activate the cell wall integrity (CWI) signaling pathway via Rho through the Slt2/Mpk1 mitogen-activated protein (MAP) kinase cascade to upregulate cell wall biosynthesis. The computed live cell extension length of CWI sensors varies from 61 nm (Mid2) to 106 nm (Wsc3), where the cell wall in *S. cerevisiae* has been measured at 102 nm. These CWI proteins may partially span the cell wall in *S. cerevisiae* but seem too short to act as direct sensors for external cell wall contact. In *C. albicans*, cell wall thickness varies by at least 50% in a carbon-source-dependent manner (70) so Wsc1 and Mid2 family proteins, with their transmembrane domain, cell wall-embedded head group, and potential extracellular reach, could constitute functional mechanosensors. In support of this idea, in *C. albicans*, although not in *S. cerevisiae*, growth on a surface activates Mpk1, the MAP kinase of the CWI signaling cascade (104). However, the nano-spring structure of Wsc1 that enables it to stretch (105), CWI activation through treatments that weaken the cell wall, and the role in sensing hypo-osmotic stress (106) suggest that Wsc1/Mid2 function is to sense outward cell wall tension rather than contact-induced compression. Cell wall tension indeed occurs during some contact events, for example, at either side of the hyphal tip during perpendicular contact with an obstacle (7). However, an argument against the involvement of Wsc1/Mid2 in contact sensing is that activation of the CWI pathway leads to Rho-mediated depolarization of the cytoskeleton and redistribution of the wall biosynthesis machinery (107), which is inconsistent with the observation that most contact events in fungi induce the development, or retention, of cell asymmetry.

Sensors of Osmotic Stress

Hyperosmotic shock, such as exposure to 1 M NaCl, causes *C. albicans* yeast cells to shrink to half their volume before recovering via the high-osmolarity glycerol (HOG) signaling pathway, which comparative genomics has shown is generally well conserved across a sample of 38 fungi (70, 108). The sensors that trigger the response are localized in the plasma membrane and activate Hog1 through the histidine kinase, Sln1, or through two Sho1-based pathways, both of which signal through Cdc42 and Ste20. Proteins of the *SHO1*-related pathways (Msb2, Opy2, and Hkr1) form large, planar oligomers where the mucins, Msb2 and Hkr1, which are highly *O*-glycoslyated, and Opy2, with its cysteine-rich domain, are activated by conformational change (109, 110). If cell contact is signaled by cell wall changes that result in mechanical perturbation of the cell membrane, these structures could potentially act as mechanosensors. The Msb2 mucin-like protein is a particularly intriguing protein because it is strongly linked to fungal pathogenesis through extracellular and intracellular functions. In *C. albicans*, all the functions of Msb2 rely on its cleavage to shed the large glycosylated extracellular domain (111). In mammalian cells, mucin cleavage is autoproteolytic through the activity of an internal 120-amino-acid SEA domain (112). This domain is lacking in *C. albicans* Msb2 and it is thought that Msb2 cleavage occurs through the activity of a dedicated protease, placing Msb2 downstream of the sensor protein. Release of the glycodomain protects the fungus by binding to host antimicrobial peptides. In *C. albicans*, Msb2 is involved in the detection of defective surface protein glycosylation and activates the CWI pathway (111), as it does in *Fusarium oxysporum* (113–115). In *Ustilago maydis* and *M. grisea*, Msb2 is required for detection of hydrophobic surfaces and cutin monomers, while in *Botrytis cinerea* it regulates the secretion of proteins (116–118). Given that contact sensing in fungi generally induces cell asymmetry, the strong links between Sho1-Msb2-Opy2 and their downstream effector, Cdc42, which also regulates cell polarity, hint that this signaling pathway may play a role in contact-induced responses.

G-Protein Coupled Receptors

G-protein coupled receptors (GPCRs) are seven transmembrane proteins that are coupled to the intracellular heterotrimeric subunits Gα, Gβ, and Gγ. GPCRs ex-

change GTP for GDP on Gα, which dissociates from Gβγ so that all three subunits can participate in multiple downstream signaling pathways. Six classes of GPCR have been classified in fungi where they are primarily involved in pheromone and nutrient detection (119). However, the nature of the binding ligand in fungal GPCR homologs varies by species and the downstream pathways are differentially wired. For example, Gpr1, the glucose-sensing GPCR in *S. cerevisiae*, appears to be activated by methionine in *C. albicans* where glucose is instead sensed via Cdc25 or Ras (120). Likewise, in *F. oxysporum*, plant exudate is sensed via the GPCR, Ste2, a functional homolog of the pheromone receptor in *S. cerevisiae* (121). Importantly, activated Gα subunits stimulate generation of the small cytoplasmic signaling molecules, cAMP and Ca^{2+}, which activate protein kinase A (PKA) and calmodulin, respectively. Activation of the PKA pathway is involved in cell morphogenesis and differentiation in many fungi, including budding growth in *U. maydis*, hypha induction in *C. albicans*, and appressorium formation in *M. grisea* (122–126). In the nematode-trapping fungus *Arthrobotrys dactyloides*, pressure applied by the nematode on the inner surface of the trap cells is thought to activate heterotrimeric G proteins without a chemical ligand (127). Experiments using calcium ionophores and a calmodulin antagonist in this organism suggested that the activated Gα subunit increased cytoplasmic calcium and activated the calmodulin pathway to open aquaporin water channels and inflate the capture cells. Although the GPCR has not been identified in this fungus, the assumption is that GPCRs can respond to pressure that is exerted against the cell wall and could therefore be mechanosensors in some species. In support of this, Pth11, a novel GPCR in *M. grisea*, is thought to sense inductive surfaces because deletion of the gene resulted in an 85% reduction in the number of appressoria produced, although those that were produced were functional (128, 129). The phenotype was similar to that observed when spores were exposed to noninductive surfaces, suggesting that Pth11 could act as a sensor at the top of the signaling pathway. In mammalian cells, GPCRs can function in a ligand-independent manner to sense membrane perturbation. In endothelial cells, studies using conformation-sensitive fluorescence resonance energy transfer showed that GPCRs are activated by the mechanical effects of shear flow (130), and, in neutrophils, shear stress is sensed by the formyl peptide receptor GPCR to alter cell shape and reduce pseudopod projection (131). However, in mammalian cells, GPCRs are exposed on the cell surface. In fungi, GPCRs are exposed instead to the inner surface of the cell wall, so, although their activity is certainly required for contact-induced responses, it remains to be determined whether they do indeed sense contact, perhaps via membrane perturbation, or whether they act as the receptor for the additional chemical signal that is required in the logic gate to induce a new developmental stage.

Integrin-Like Proteins

An important mechanosensing system in mammalian cells comprises single-pass transmembrane proteins called integrins, which function in focal complexes that link the cell-derived ECM to the cytoskeleton via the intracellular scaffolding protein paxillin. Integrins are type I transmembrane proteins that bind as heterodimers to secreted ECM proteins, such as fibronectin and vitronectin, to sense substrate stiffness and provide traction during cell migration (reviewed in references 132 and 133). The concepts underlying this mechanosensing mechanism could be applicable in fungi if the cell-derived secreted proteins of the cell wall are considered as analogous to the mammalian ECM. Another concept associated with integrins is their linkage to the cytoskeleton, where contact is signaled via deformation of the cytoskeleton. Some protein components of the focal complexes through which mammalian integrins function are conserved in fungi, although their function has not been elucidated. Paxillin is the central scaffold protein and orthologs have been identified in *S. pombe*, *S. cerevisiae*, and *Ashbya gossypii*, where they generally localize to sites of new cell wall deposition such as cell tips and septa (134–137). However, orthologs of vinculin and talin, the components that link integrins to the cytoskeleton in the mammalian complex, appear to be absent. Importantly, proteins with integrin-domain homology have not been identified in fungi, despite various attempts to find them. Experiments where anti-(human) integrin antibodies bound to fungal cells were ultimately unable to pinpoint candidate proteins (138). Integrins generally bind to RGD moieties in ECM proteins, and synthetic peptides containing RGD sequences were able to inhibit the formation of appressoria in *Uromyces*, suggesting that a potential signaling pathway through integrin clustering was blocked (139). Affinity purification using two different β-integrin antibodies isolated a 95-kDa protein, but this has not yet been identified. In *Candida* spp., antibodies against human αM, αX, α5β1, and αVβ3 were found to interact with moieties on the fungal cell surface (138, 140–142). However, these were not identified and later evidence suggested that the binding proteins may be wall-associated GAPDH and alcohol dehydrogenase

(143, 144). A cDNA probe encoding a region from the integrin transmembrane domain, but not the defining extracellular head groups, of human αM identified a *C. albicans* protein, Int1, as a single-pass transmembrane protein containing several motifs common to αM (145). CaInt1 localized to the cell wall where it appeared to be involved with adhesion, because its deletion reduced binding of *C. albicans* to epithelial cells by 39% (146). Int1 was also involved in morphogenesis in some media and colocalized with the intracellular septin, Cdc3 (147). Because of the thickness of the fungal cell wall, at 50 to 100 nm (in *C. albicans*), it seems unlikely that a protein with extracellular binding domains could signal contact with a ligand through the cell wall matrix. An alternative possibility is that Int1 is bifunctional and, like many cell wall proteins, can be exported and processed by the still-unknown cleavage mechanism to become a wall-linked adhesin. To date, its role in contact sensing has not been examined. If functional homologs of integrin-like proteins operate as mechanosensors in fungi, they do not seem to be identifiable through protein sequence homology. Nevertheless, proteins with a homologous function may have evolved separately in fungi to act as a linkage system between the cell wall and the cytoskeleton.

FUTURE PROSPECTS

Evidence of the importance of the fungal sense of touch abounds in studies of fungal growth and behavior. While we can observe the outcomes following contact events, no definitive contact sensor has been identified. Fungi are not the only system in which this subject is under scrutiny, and, in some ways, they are better placed than bacteria or plant cells for advancing our understanding because of the combined advantages of genetic methods and the ability to correlate cell behavior with outputs from reporter proteins using live-cell imaging. One of the immediate challenges is the current lack of a comprehensive model of cell wall dynamics, its spatial organization at the molecular level, and the regulation of its viscoelastic properties. In addition, the function of many of the proteins isolated in cell wall proteomes remains uncharacterized. A better understanding of these areas might enable us to assess the likelihood that contact is sensed through a cell wall-embedded mechanism. Studies of the effect of carbon source on the cell wall during osmotic stress, where the cell size reduces by 50% in approximately a minute without buckling, and live-cell imaging of thigmotropic growth, have forced us to move away from the "rigid" cell wall model to one whereby cell wall organization renders it capable of rapid change (7, 70). This might support contact-induced local remodeling that is somehow transmitted to spatially organized intracellular proteins to define a zone of contact.

Ion flux, particularly calcium transients, are well recognized as mediators of mechanosensing in mammalian cells and bacteria. The use of genetically encoded ion reporters is set to revolutionize our understanding of calcium flux in fungi, which has been previously hampered by the failure of fungi to retain calcium dyes in the cytoplasm of living cells. With the advent of a range of new molecular, genetic, and imaging tools, an understanding of how contact is sensed by fungi is at last within our grasp.

Melanin, Radiation, and Energy Transduction in Fungi

23

Arturo Casadevall,[1] Radames J. B. Cordero,[1] Ruth Bryan,[2] Joshua Nosanchuk,[2] and Ekaterina Dadachova[3]

INTRODUCTION

Melanins are dark pigments that are made by diverse fungi (1, 2). Even fungi that produce white colonies, such as *Candida albicans*, have the ability to make melanins (3, 4). Melanins have elicited considerable interest in microbial pathogenesis because they are important virulence factors for many pathogenic microbes, and their presence is associated with reduced susceptibility to antifungal drugs (5, 6). Melanins are multifunctional molecules that give cells structural strength as well as reduced susceptibility to temperature extremes, heavy metals, and molecules produced by the immune system such as oxygen- and nitrogen-derived oxidants and microbicidal proteins (2, 7–10).

Despite the importance of melanins in biology, their structure remains largely unsolved (11). Melanins are composed of covalently polymerized indole- and phenol-type compounds resulting in a material that is insoluble and acid resistant. Melanin structures exhibit local order with global heterogeneity, thus resulting in an amorphous material. Insolubility combined with an amorphous nature means that the structure of melanin cannot be solved with currently available analytical techniques such as X-ray diffraction. A remarkable property of melanins is that they are stable free radicals and manifest a distinctive electron spin resonance signature that is used in their identification (12). Despite the difficulties involved in working with melanin, considerable progress has been made in eliciting its structure by combining results from several techniques including solid-state nuclear magnetic resonance (11, 13, 14).

Melanin production in fungi is a result of three pathways known as the polyketide, 3,4-dihydroxyphenylalanine (L-DOPA), and L-tyrosine degradation synthetic pathways, which produce two chemically different compounds with similar properties (2, 7, 15, 16). Melanin synthesis involves free radical reactions with toxic intermediates. Consequently, melanin synthesis in both animals and fungi occurs in specialized structures known as melanosomes (17). Melanin can be located internally or in and on the cell wall, where it is closely associated with other cellular components such as lipids, carbohydrates, and proteins, although the nature of these associations is poorly understood due to the inherent difficulties in studying melanin structure. For *Cryptococcus neoformans*, one of the fungi in which the process of melanization is best understood, melanin synthesis is catalyzed by a laccase, and the pigment is exclusively 3,4-dihydroxyphenylalanine-melanin. *C. neoformans* melanin is synthesized in vesicles that are exported to the extracellular space and are assembled in the cell membrane into concentric layers, where the pigment is closely associated with polysaccharide and other cellular structures such as chitin and its derivatives (11–14).

Among the remarkable properties of melanin is its capacity for energy transduction (18). Melanin is unique among biological compounds in that its absorption spectrum reveals absorption of all wavelengths in the UV-visible-infrared spectrum. The capacity of melanin to absorb all these wavelengths is presumably a function of its complex molecular structure, which allows it to interact with these frequencies of light. The

[1]Department of Molecular Microbiology and Immunology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD 21205; [2]Departments of Medicine and Microbiology & Immunology, Albert Einstein College of Medicine, Bronx, NY 10461; [3]Fedoruk Center for Nuclear Innovation, University of Saskatchewan, Saskatoon, SK, S7N 0W8 Canada.

ability of melanin to absorb electromagnetic radiation extends into the range of X rays and gamma rays, such that it has a shielding capacity that is approximately half that of lead and twice that of carbon (19). Mice given fungal melanin are capable of surviving lethal doses of gamma irradiation, presumably as a result of the pigment protecting the digestive tract and associated lymphatic tissue (20). The ability of melanin to absorb and convert electromagnetic energy is associated with a variety of biological effects that give melanotic fungi tremendous resilience, which translates into their ability to survive in hostile environments.

MELANOTIC FUNGI INHABIT RADIATION-EXTREME ENVIRONMENTS

Melanotic fungi inhabit some of the most extreme environments known, and it is generally believed that the presence of melanin contributes to survival through a variety of mechanisms. For example, Antarctic black rock fungi include a large number of diverse melanotic species that colonize the rocks of one of the most extreme environments on Earth (21). For the purposes of this article we review the literature reporting melanotic fungi in high-radiation environments. The remarkable finding that the damaged reactor at Chernobyl and surrounding soils host a large population of melanotic fungal species is perhaps the best-known example of fungi living in a high-radiation environment (22–24). The Antarctic highlands, where many black rock fungi thrive exposed on the surface and interior of rocks, is also a high-radiation environment (21), especially during the long austral summer and considering the recent historical weakening of the atmospheric protection in the southern hemisphere through ozone depletion. Notably, black fungi recovered from Antarctica can survive in simulated Mars conditions (25). The melanotic fungus *Ulocladium chartarum* was able to grow under space flight conditions, with a rate of growth that exceeded that achieved on Earth (26).

MELANOTIC FUNGI RESPONSES TO RADIATION

Three lines of evidence indicate that melanotic fungi respond to radiation: kinetic attraction toward radioactive sources, faster growth, and metabolic changes. Although these lines of evidence are not completely independent (e.g., hyphal growth toward a radioactive source and enhanced colony growth both reflect cell growth, which in turn is associated with metabolic changes), they are sufficiently distinct to discuss separately.

Radiotropism

The term "radiotropism" refers to the ability of some fungi to grow toward radiation sources (27, 28). This phenomenon was first reported among fungal species colonizing the damaged reactor at Chernobyl and involved the migration toward and degradation of carbon containing "hot particles" (28). Radiotropism was triggered primarily by gamma radiation, but it is possible that both alpha and beta radiation could be "sensed" by the fungi as well. Although the mechanism and purpose of fungal cell migration toward a radioactive source remain unknown, the careful work documenting this phenomenon indicates that fungi respond to radiation and suggest intentional migration and attraction to this energy source.

Enhanced Growth

In 2007 our group reported differential growth effects on melanotic and nonmelanotic strains of *C. neoformans* and *Exophiala* (*Wangiella*) *dermatitidis* exposed to gamma radiation such that the melanin-containing strains grew faster than albino strains (29). This phenomenon was subsequently confirmed and expanded (see below) by another group (30). Enhanced fungal growth in melanotic fungi in response to high-energy electromagnetic radiation has also been reported for other fungal species. Large increases in colony-forming units (>100-fold) were observed for *Alternaria alternata* exposed to gamma radiation (31). Exposure of *Aspergillus versicolor* to radioactive nuclides increased hyphal length and spore germination, phenomena that were attributed to enhanced growth by radiation (24). Hence, enhanced growth of melanotic fungi in high-radiation environments has been observed for several fungal species by at least four independent groups. Analysis of the energy levels that triggered radiation-related fungal growth revealed that whereas low levels of radiation (150 peak kilovoltage [kVp]) enhanced the growth of both melanized and nonmelanized *C. neoformans*, higher levels (320 kVp) triggered enhanced growth only in the melanized cells (32).

Metabolic Changes

Analysis of wild-type and albino mutant *wdpks1 E. dermatitidis* strains' gene expression after exposure to high-energy radiation revealed differential expression of about 3,000 genes involving multiple pathways, such that genes for cell cycles of amino acid synthesis were downregulated, while stress response genes were upregulated (30). Of particular interest was the observation that the wild-type (melanotic) but not the albino *wdpks1* strain manifested ribosomal biogenesis genes'

upregulation to radiation exposure, leading the authors to suggest the possibility that melanin-derived energy was being used for protein synthesis (30). An experiment with three melanotic fungal species in a simulated Mars environment that included exposure to 200 nm UV radiation revealed some initial changes in protein expression followed by adaptation with resumption of normal expression, leading the investigators to conclude that these organisms could survive in that environment (33). An analysis of the response of *Hormoconis resinae* to chronic radiation resulting in cumulative doses of 2 to 3 Gy found that radiation was associated with enhanced synthesis of melanin and antioxidant enzymes (34).

INTERACTIONS OF MELANIN WITH HIGH-ENERGY ELECTROMAGNETIC RADIATION

For melanin to capture electromagnetic radiation in a manner that is suitable for conversion to biological energy, it must interact with it. Whereas melanin is known to absorb all UV, visible, and infrared frequencies, the phenomena of radiotropism and enhanced growth upon exposure to gamma rays depend on the ability of the pigment to interact with much higher-energy radiation. Such interactions have now been demonstrated by several methodologies. Irradiation of melanin with gamma rays resulted in changed electronic properties as measured by electron spin resonance spectra (20). A demonstration of the capacity of melanin to serve as an energy transduction molecule for high-energy electromagnetic radiation came from the observation that an electric current was produced by a melanin electrode placed in a gamma-ray beam (35).

IMPLICATIONS OF MELANIN-MEDIATED ENERGY TRANSDUCTION

The phenomenon of radiation-induced growth in melanotic fungi was called radiosynthesis in analogy to photosynthesis, by which plants convert light energy into chemical energy that they can utilize for biological processes (29). Supporting this designation was the observation that irradiated melanin was able to reduce NAD to NADH, thus providing a critical link for the conversion of electromagnetic energy into chemical energy that was immediately biologically useful. However, the analogy of radiosynthesis to photosynthesis is only partial, for the latter is understood to include a series of complex reactions that involve the fixing of carbon to synthesize new biologically useful molecules. For fungi, there are some suggestions that they can utilize CO_2 for

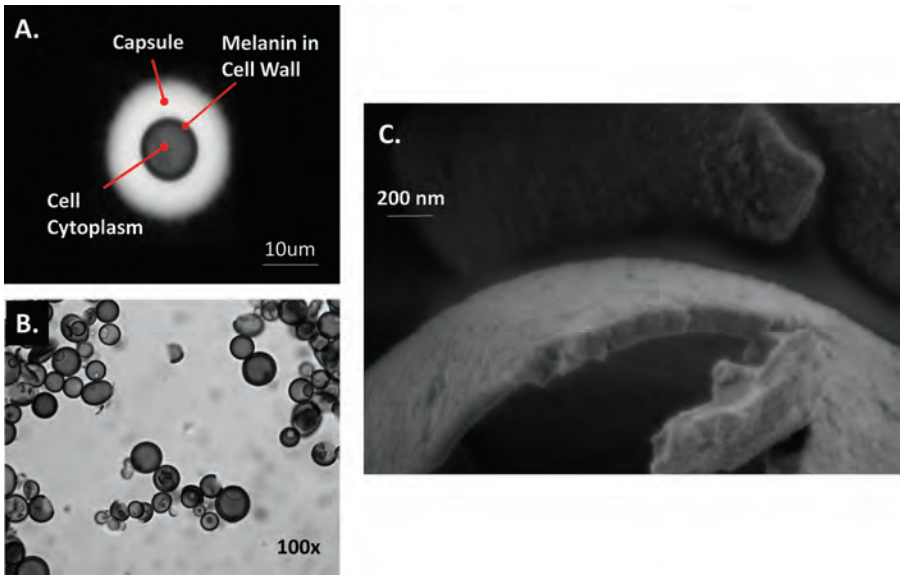

Figure 1 Melanized *Cryptococcus neoformans* and melanin "ghosts." (**A**) Melanized *C. neoformans* cell in India Ink suspension to illustrate the cellular location of melanin. The cell wall appears dark because of the presence of melanin. Note that melanin is external to the body of the cell. (**B**) Melanin ghosts prepared from melanized cryptococcal cells by strong acid digestion (38), which removes cellular components except for the cell wall-associated melanin. (**C**) Scanning electron microscopy of a melanin ghost showing its granulated surface structure, porosity, and thickness.

synthesizing organic molecules, but this topic has not been thoroughly explored. Studies of black rock fungi from Antarctica using ^{14}C suggested that they could directly utilize CO_2 and incorporate carbon into organic molecules (36). Earlier studies of the mold *Zygorrhynchus moelleri* provided evidence for the direct nonphotosynthetic incorporation of CO_2 into pyruvate (37). Hence, one can imagine a situation in an extreme environment such as Antarctic mountains where the combination of radiation harvesting by melanin combined with some capacity for utilizing inorganic carbon could produce a process akin to radiosynthesis.

MAJOR QUESTIONS AND FUTURE RESEARCH DIRECTIONS

At this time there is experimental evidence for the following observations: (i) melanin is an energy-transducing molecule with the capacity to absorb a broad spectrum of electromagnetic radiation; (ii) melanotic fungi exposed to high-energy radiation grow faster than exposed nonmelanotic mutants and unexposed fungi, both melanotic and amelanotic; (iii) melanin can interact with high-energy electromagnetic radiation and transduce it to chemical and electrical energy. In aggregate, these observations suggest that melanotic fungi have the capacity to utilize high-energy electromagnetic radiation to sustain some biological processes. This, combined with the possibility that fungi have some capacity to fix carbon, raises the possibility of radiosynthesis. However, we lack information about the detailed processes by which electromagnetic energy is harvested and converted into biologically useful energy. The ability of irradiated melanin to convert NAD to NADH *in vitro* suggests that it may contribute to energy utilization through simple oxidation-reduction reactions that harvest electrons for biological use. However, there is also a possibility that melanin-related energy utilization involves a sophisticated molecular apparatus such as an antennae complex to shuttle electrons from extracellular cell wall-associated melanin to the cell interior.

The biological advantages of melanin-mediated energy transduction are readily apparent. For organisms in extreme environments such as black rock fungi of Antarctica, the ability to harvest some light energy for biological processes could provide a tremendous survival advantage relative to nonmelanotic organisms. However, the exact contribution of this mechanism relative to the energy available from conventional nutritional processes available to fungi from other sources such as degradation of plant matter is unknown. Establishing the importance of this mechanism in fungi is a much more difficult undertaking than showing the importance of photosynthesis in plants, because the latter are totally dependent on sunlight for their survival, whereas fungi can access nutrients from other sources. In this regard, it is noteworthy that experiments showing that electromagnetic radiation enhances growth have relied on measuring growth increments relative to nonirradiated conditions or albino mutant controls rather than establishing an absolute requirement for growth, since the latter criterion has been experimentally difficult. Consequently, establishing the importance of melanin energy capture is an open question that will probably require innovative experimental design.

IMPLICATIONS FOR BIOLOGY AND EXOBIOLOGY

Given the widespread abundance of melanotic fungi in the biosphere, any amount of conversion of electromagnetic energy into biologically useful energy is likely to have a major impact on estimates of planetary energy flows. For example, photosynthesis is estimated to convert approximately 130 terawatts of sunlight into biologically useful energy, an amount that could increase significantly with melanin-related energy conversion. The ability of melanotic fungi to harvest energy would make them autotrophs and place them alongside plants as important contributors to the conversion of solar and physical electromagnetic energy sources into biologically useful energy. Because the energy of the ionizing radiation is several orders of magnitude higher than the energy of white light, even a very inefficient mechanism of its harvesting will still produce energy transfer. The fact that melanin pigments are easy to synthesize and are found in all biological kingdoms raises the tantalizing possibility that melanin-related energy transduction is ancient, predating photosynthesis, and served as a significant energy-harvesting mechanism for early life on Earth, which emerged in conditions of much higher radiation exposure.

Melanin-related energy transduction has immediate implications for exobiology since it implies that this pigment not only confers the capacity for survival in extreme environments but also provides a means for harvesting electromagnetic energy. The survival of melanotic fungi in simulated Mars-like conditions suggests that the resiliency conferred by melanin already provides some Earth microbes with the capacity to survive on other worlds, thus extending the limits of terrestrial life.

INTRODUCTION

The Biology of Circadian Rhythms

What are circadian rhythms?

Despite years of study and a great deal of exposure in the scientific press, there is still sometimes confusion regarding what are the defining characteristics of a rhythmic process that makes it truly circadian. The essence of this is that the rhythm must be shown not to depend in any way on continued environmental cycles, and to have a period of about a day. So, in this way, it is obvious that in petri dish cultures grown under a light-dark cycle, a rhythmic change in orange color in *Neurospora crassa*, or in melanin in *Aspergillus fumigatus*, could not be categorized as circadian, because the change in pigmentation would be seen as the result of light induction of, respectively, carotenoid or polyketide synthesis. As humans, our pupils constrict in proportion to the amount of light to which the eye is exposed, so a daily rhythm in pupil size would not be circadian but would instead reflect a diurnal cycle in ambient light. This part of the definition identifies the rhythm as truly endogenous in nature, in this way being the overt expression of an internal circadian oscillator. Beyond this, the definition is more subtle and reflects the biology of rhythms.

What does it benefit a cell to have a circadian oscillator and not simply an hourglass timer that is set at environmental transitions such as dusk or dawn? There are at least two answers. One is that an oscillator does not need to be restarted every day; it will continue even without a time cue, for instance, even if the organism (like a fungus) is growing underground. Another answer is that it provides an additional level of flexibility in responding to a changing environment. In this context, we should briefly talk about phase and phase angle (Fig. 1). Every rhythm perforce has a peak and a trough as well as other defining points (e.g., point of sharpest decline, midway to peak, etc.), and, in general, such definable points are called phase reference points. In circadian biology, phase or phase angle is defined as the difference in time between the phase reference points of the environmental cycle and the circadian cycle. For instance, in *Neurospora* growing on an agar surface or a piece of bread in a light cycle consisting of 12 h light and 12 h dark, the number of aerial hyphae and conidia peaks about 2 h before dawn, so, if the phase reference point of the environmental cycle is dawn and the phase reference point of the circadian cycle is the peak of conidiation, then the phase of conidiation is about −2 h (i.e., before dawn), which is the same as +22 h (after dawn) on a 24-h cycle. When free-running under constant conditions, two rhythms can have the same period length but have different phases, because the peaks occur at different times with respect to the last light-to-dark transition. For a rhythm to be useful to the organism, it must be able to control activities so that they happen at appropriate times of day, and appropriate means not just a given number of hours after dawn or dusk but, more often, for example, the middle of the day period or night period, a point that can be a different number of hours after dawn or dusk depending on the season. To achieve this, circadian rhythms are entrained to environmental cycles as distinct from synchronized with them. Synchronized

[1]Department of Molecular and Systems Biology, Geisel School of Medicine at Dartmouth, Hanover, NH 03755; [2]Department of Biochemistry and Cell Biology, Geisel School of Medicine at Dartmouth, Hanover, NH 03755.

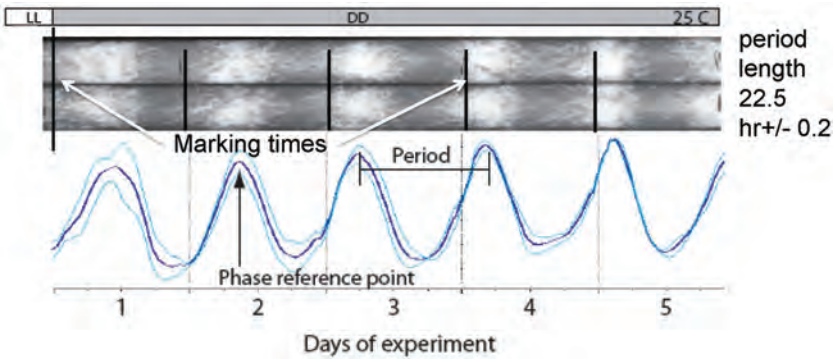

Figure 1 *Neurospora* circadian output as seen by control of growth and development in a culture growing across an agar surface. Cultures are inoculated at the left and grow to the right. After a period in constant light, the culture is transferred to constant darkness. The position of the growth front at the time of transfer is marked and is marked again every 24 h, giving a measure of time since the light-to-dark transfer. Below the images of the cultures is a densitometric scan of the mycelial/conidial optical density. The peak of conidiation happens roughly 10 h after the light-to-dark transfer and recurs after that roughly every 22.5 h (one circadian day) for cultures grown at 25°C. Typically, the peak in conidiation is used as a phase reference point, but any definable point in the cycle can be used. Adapted with permission from reference 49.

would mean that the rhythm tracks the external cycle and assumes a fixed phase and period length of the external cycle, whereas entrained means that the rhythm assumes the period, but the phase reflects interplay between the circadian oscillator and the environmental cycle. The value of this is that the circadian system can evolve (and has) to preserve phase across the spectrum of light-dark cycles seen in a year. At the temperate latitude in Vermont where we live, daylight can range from 8 to 16 h depending on the season. The circadian system can keep an important biological activity (say conidiation in *Neurospora* or sleep in people) occurring at roughly the same point in the cycle, such as late at night, despite changes in the light-dark cycle. As described in more detail later in the review, in *Neurospora*, a large variety of processes ranging from gross characteristics, such as sexual and asexual developmental potential, growth rate, and the cell cycle, to gene expression and fluxes through metabolic pathways, are all coordinately regulated by the circadian system. This coordination is adaptive because it helps the organism to organize its growth and metabolism in anticipation of dependable environmental changes such as temperature, ambient light, and UV stress.

Circadian homeostasis

Another environmental variable that has profound impact on biological systems is temperature. For a clock to be useful in the context described above, namely, being sure to keep important processes happening at the right time(s) of day, it would not do for the rate of progression of the clock to be strongly influenced by ambient temperature. Physiologists and biochemists often frame general discussions of temperature effects on rates of processes in terms of Q_{10}, the rate of a process at one temperature divided by the rate at 10°C lower temperature. A typical enzymatic reaction will have a Q_{10} of 2, and a complex set of reactions such as mitochondrial respiration may have a Q_{10} of 4. Imagine the effect on phase angle if the clock ran three times faster during a 30°C day in July as on a 15°C night. Circadian rhythms are special because they have evolved to have a Q_{10} of close to 1. A process with a Q_{10} of exactly 1 would be temperature independent; circadian period lengths are not temperature independent, and even in the same organism across some ranges, the Q_{10} can be slightly less than 1 and, across other ranges, slightly greater than 1. For this reason, circadian period lengths are said to be temperature compensated.

Another aspect of circadian homeostasis is that circadian period length is resilient to the effects of changing nutrition. This again makes sense ecologically, especially for a fungus that can encounter enormously variable nutritional conditions over the course of weeks as it moves from fresh to rotting to desiccated substrates. Temperature and nutritional compensation distinguishes circadian rhythms from other ca. 24-h rhythms such as the mammalian cell cycle.

Time cues for keeping internal time in sync with external time

While circadian period length needs to be resilient to the effects of ambient temperature, it is immediately plain that the clock needs to be sensitive to daily changes in a variety of environmental variables so that internal time can be a proxy for external time. In most organisms, daily changes in light intensity set the phase of the internal clock, with lights-on corresponding to dawn and lights-off corresponding to dusk. All circadian organisms including fungi have evolved ways to detect even low levels of light and to use changes in intensity to set their clocks. Indeed, humans and fungi use light in the same way, and the understanding of how light is used to reset the circadian clock was first elucidated in *Neurospora* as discussed later. Clocks are sensitive to temperature changes to the extent that they can also be used as time cues for day and night. Indeed, in many organisms (including *Neurospora*), temperature can be a stronger time cue than light.

The Definition of Circadian Rhythm

To paraphrase, we have defined a true circadian rhythm in this way: a circadian rhythm is an oscillation in a biochemical, physiological, or behavioral function that persists under conditions of constant light or darkness, temperature, and other environmental variables with a period length of about a day, whose phase can be reset by a brief interruption in the constant regimen, and whose period length is relatively independent of temperature and nutrition within the physiological range of normal growth (1). Thus, these rhythms are not a simple response to the environment but are phased by it. Overall, it is these few characteristics—period length of about a day, persistence under constant conditions, resettable by changes in this constant regimen, and compensated against ambient changes in temperature or nutrition—that define a rhythm as being circadian. Rhythms having these characteristics, whether in fungi or animals, are united by a common biology and, as it turns out, by a common molecular mechanism. These are also the characteristics that molecular models for the circadian oscillators have sought to explain. Specifically then, there have been three salient questions: How does the oscillator work (mechanism)? How do environmental cues impart time-of-day information on the oscillator (input)? How does the oscillator control the behavior and metabolic potential of the cell (output)? Work on *Neurospora* played *a*, or in some cases *the*, leading role in answering the first two of these questions and remains at the forefront of answering the third.

Circadian Rhythms in Fungi

Many fungi can express one (or even more than one) kind of rhythm—growth, morphology, or even in gene expression—if the medium and environmental conditions are just right (2–4). In the vast majority of cases, these are not truly circadian by the definition described above, and, in fact, true circadian rhythms in fungi have been described in only a few organisms including *Neurospora* spp. (4) and the closely related *Sordaria fimicola* (5), *Aspergillus flavus* (6), *Cercospora kikuchii* (7), *Botrytis cinerea* (8, 9), *Pyronema confluens* (10), and the basidiomycete *Neonothopanus gardneri* (11) where the circadian clock controls fungal bioluminescence and is thought to help with spore dispersal. Extensive effort has failed to reveal convincingly a rhythm in *Aspergillus nidulans* or *A. fumigatus* (although a rhythm in *gapdh* mRNA has been reported in *A. flavus* [6]), and reports of circadian rhythms in the yeasts *Schizosaccharomyces* (12) and *Saccharomyces* (13) have been questioned or not been reproducible. Given the extensive conservation of the core clock elements FRQ, WC-1, and WC-2 within the Ascomycota, in general, and the Sordariaceae, in particular, it seems likely that rhythms could be identified in many additional organisms. A wonderful example of this is the recent description of a canonical FRQ/WCC-based clock in the pathogen *B. cinerea* that influences its pathogenesis (8, 9).

The field of rhythms in fungi other than *Neurospora* has been excellently reviewed elsewhere recently, and interested readers may want additional perspectives (8, 14–20). While rhythms can include both circadian and infradian noncircadian cycles, more attention will be paid to the relatively extensive literature describing noncircadian rhythms in fungi near the end of this review. Before that, the focus will be on the true circadian rhythm in *Neurospora* and what it has shown about circadian rhythms in general.

THE *NEUROSPORA* CIRCADIAN OSCILLATOR

The historical development of this field has been quite interesting but has been adequately reviewed elsewhere (21–29) and will not be redeveloped in depth here. Instead, we will aim for a succinct and comprehensible (at the expense of comprehensive) overview of how the circadian system works.

WCC Drives *frq*

The white collar complex or WCC comprises WC-1 and WC-2. WC-1 is a GATA-type transcription factor

having a Zn finger DNA binding domain and three PAS-like domains, amino acid sequences often associated with protein-protein interaction or with ligand binding (30). One of these is a specialized PAS domain called a LOV domain, a subtype associated with light, oxygen, and voltage regulation. As discussed below under "Input," WC-1 is the founding member of the principal class of fungal blue light photoreceptors, an activity mediated by the LOV domain, although, for the circadian oscillator itself, the LOV domain is dispensable (31). The other PAS domains, however, are essential in that they mediate the interaction between WC-1 and its partner protein in the WCC, WC-2. Figure 2A shows a cartoon of the domains of WC-1 and WC-2 and describes the activities associated with these domains as well.

The WCC binds to two places in the promoter of the *frequency* (*frq*) gene (32) (Fig. 2B). One is the proximal light regulatory element (PLRE) that is very near to the transcription start site (TSS) and that is required for the acute induction of *frq* expression by light that forms the basis of light resetting of the clock (see "Input," below). Binding to another element more than a kilobase distal (5′) from the TSS, the clock box (C-box) is required for circadian activation of *frq* expression as a part of the circadian oscillator. Binding of WCC to the C-box displaces local nucleosomes (33) and requires the Zn fingers of both WC-1 and WC-2 as well as a basic region of WC-1 just N-terminal from the WC-1 Zn finger, a region called the DBD because proteins lacking it are defective in DNA binding (34). One might reasonably ask how binding of WCC to the C-box can effect transcriptional activation if the site is more than a thousand bases away from the TSS. The answer is that an N-terminal region of WC-1 serves to attract the SWI-SNF chromatin remodeling complex (31), a group of proteins known to be involved in nucleosome removal and chromatin remodeling as well as in bending of DNA (35). Thus, the model is that SWI-SNF promotes bending of the DNA in the *frq* promoter to bring the WCC bound to the C-box into proximity with the TSS where it can attract the general transcription factors and Mediator complex involved in initiation of transcription (31).

In addition to the transcription of *frq* in the sense (coding) direction, there is also a *frq* antisense transcript (36) named, appropriately, *qrf* (*frq* spelled backward) (Fig. 2B). The WCC binds downstream of the *frq* coding region where it serves to mediate light induction of this antisense transcript; the exact location of the

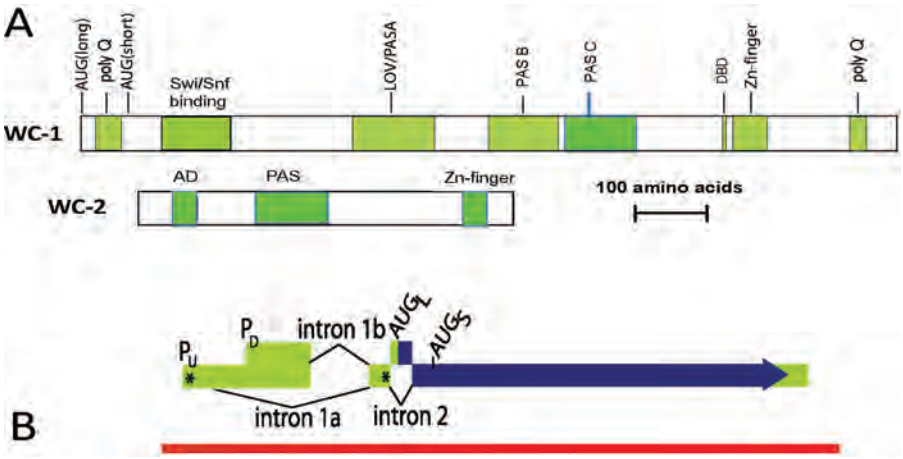

Figure 2 The WC-1 and WC-2 proteins and the *frq* locus. (**A**) Cartoon schematics of WC-1 and WC-2 are shown to scale. Landmarks include protein start sites (AUG) polyglutamine stretches (polyQ), the binding site for SWI/SNF (31), the LOV domain that mediates photoreception, the two PAS domains of WC-1 that mediate interaction with the PAS domain on WC-2, and the DBD domain that assists the Zn finger in DNA binding to the C-box. The putative transcriptional activation domain (AD) of WC-2 is marked. (**B**) Complex regulation and splicing involved in *frq* expression. The C-box and PLRE are upstream from P_U and P_D, the upstream and downstream start sites for transcription, respectively. The parts of the primary transcript left after splicing of intron are marked in green, asterisks mark upstream ORFs that influence the amount of FRQ made, and purple marks the FRQ coding region. Temperature-regulated splicing of intron 2 governs whether AUG_L or AUG_S is used to initiate FRQ. The *frq* antisense transcript, *qrf*, is marked in red. Adapted from reference 128.

promoter driving constitutive *qrf* expression has not been mapped. Xue et al. (37) have recently provided a nice rationale for the expression of the antisense *qrf* transcript: even in the absence of WCC binding to the C-box, there is a low level of sense strand *frq* expression, and the resulting low level of FRQ expression causes the oscillator to dampen. Constant low-level *qrf* expression runs counter to the sense strand expression and serves to reduce this background to near zero, thereby keeping the oscillator from damping (37). *qrf* expression also provides antisense transcripts that may elicit dicer-independent siRNA (disiRNA)-mediated facultative heterochromatin formation at *frq* and thereby aid in shutting down *frq* expression (38). WCC binding within the *qrf* promoter promotes light induction of *qrf*, and the spike of antisense transcript coincident with the spike of light-induced sense *frq* transcript aids in light resetting of the clock by making sure that FRQ appears as a pulse and not a tonic increase. Light resetting is compromised in the absence of *qrf* expression (36).

FRQ Is Made and Acts

frq mRNA moves to the cytoplasm for translation although there is a surprisingly long lag between when it first appears and when FRQ protein finally turns up several hours later (Fig. 3). The cause of this long lag is unknown, but it is likely a result of explicit regulation because, after acute light induction of *frq*, the FRQ protein appears well within an hour (39). The translation of FRQ has received some attention recently with interesting results. It has been known for a long time that the codon bias of *frq* is strongly skewed toward rarely used codons, those that require low-abundance tRNAs. Zhou et al. examined the importance of this by changing the codon bias in favor of those codons ser-

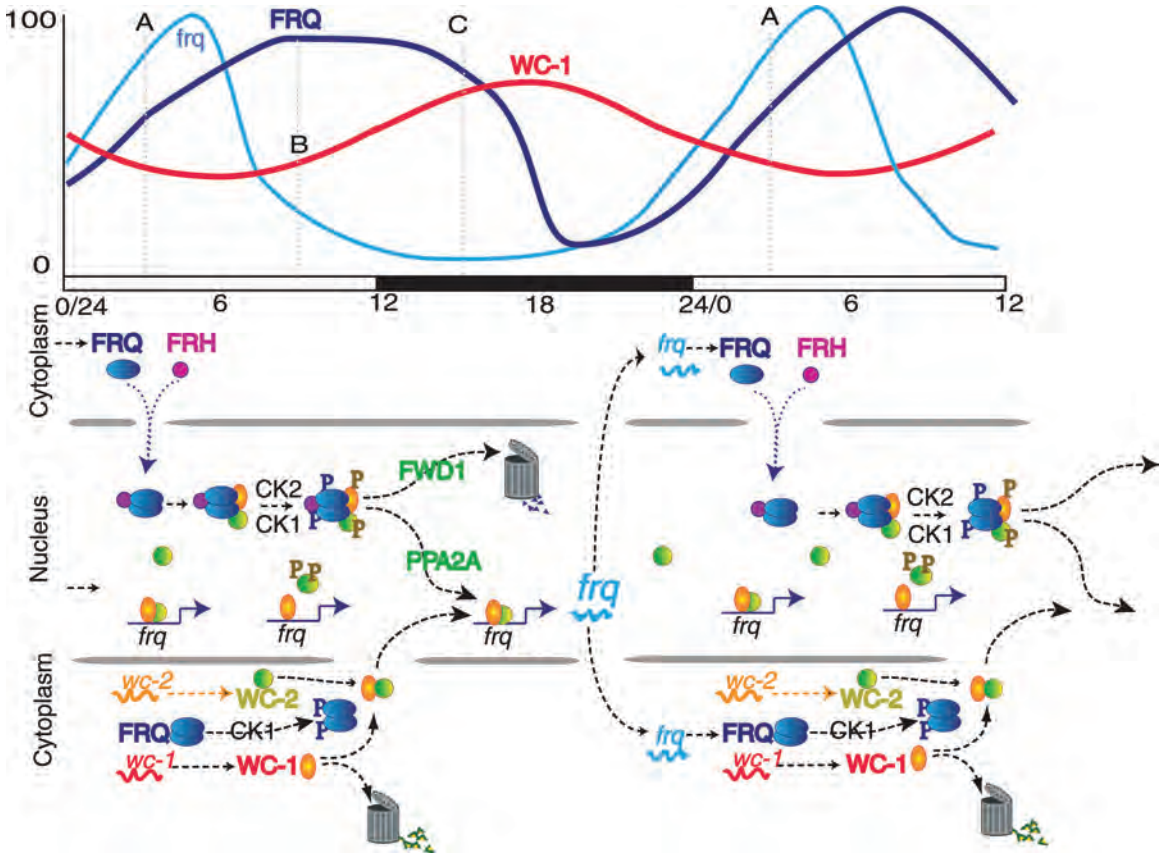

Figure 3 Temporal outline of the *Neurospora* circadian clock. (**Top**) Amounts of clock-relevant RNAs and proteins cycle. (**Bottom**) Shown as a function of time are the locations of RNAs and proteins important for the circadian oscillator. Time goes from left to right, beginning at subjective dawn (CT 0, about 11 h after a light-to-dark transfer). Trash can, proteasome; PP, phosphatases. Adapted from reference 24.

viced by abundant tRNAs and the result was more FRQ, as expected, but less functional FRQ: the FRQ produced by the codon-bias-"improved" gene was less stable, less able to enter into productive complexes, and less able to support its role in the oscillator (40). The model is that FRQ folds cotranslationally, perhaps promoted by interaction with other protein(s) as described below, and that this cotranslational folding and interaction require some pausing of translation as helped by the codon choice in the wild-type gene (41).

Upon translation, FRQ dimerizes and forms a complex with another protein, FRH. Dimerization of FRQ is essential (42) as FRQ's immediate interaction with its partner protein FRH. FRQ is an intrinsically disordered protein (IDP), meaning that, unlike more typical proteins, it has no inherent structure. Most proteins fold up into specific structures and can be thought of as oil droplets where hydrophobic residues are pushed away from water and into the center of the protein, allowing hydrophilic amino acid residues to be on the outside. For proteins such as these, the structure of the protein plays an essential role in its function and also contributes to its stability. When such proteins are heated so that the structure is disrupted and the hydrophobic residues face outside, the protein becomes denatured and falls out of solution; think of the albumin of a cooked egg. IDPs, however, have no inherent structure, so, when heated, they remain in solution, but they are also subject to rapid proteolysis in the cell unless they are protected by another protein—enter FRH.

Two Cellular Roles for FRH

FRH, the FRQ interacting RNA helicase, was identified in 2004 as an essential protein that interacts stoichiometrically with FRQ (43). As its name implies, FRH has a "normal function" in a subcellular structure called the exosome that plays a role in the turnover of RNA (44), specifically in unwinding the RNA in a process driven by the hydrolysis of ATP. FRH belongs to a well-studied family of such ATP-dependent RNA helicases, several of which have crystal structures and all of which bear conserved sequences that are essential for their enzymatic functions including binding and hydrolyzing ATP. With all this evidence pointing to an enzymatic function for FRH, it was natural to assume that the role of FRH in the clock was enzymatic; surprisingly, however, this is not so. In a startling turn of events, mutants of FRH that have lost their required catalytic residues have been shown to still function normally in the clock (45). FRH is thus understood to play a purely structural role, stabilizing the IDP FRQ and protecting it from proteolytic turnover.

Processive and Choreographed Phosphorylation of FRQ

The observant reader will be asking how FRQ can do what it does if it has no structure and is just a random coil of amino acids in a chain floating in the cytoplasm. The answer is that FRQ is one of the most heavily post-translationally modified proteins known, and it is almost certainly these modifications that lead FRQ to participate in the diverse time-of-day-specific interactions that lead to a functional clock. A cartoon structure of the functional domains of FRQ is shown in Fig. 4. FRQ is phosphorylated at over 100 serine and threonine residues across much of the protein, but this happens very gradually over the course of the circadian day and in a highly choreographed fashion (Fig. 4), such that some regions of the protein become highly phosphorylated before other regions are significantly modified (46–48). It is very likely that the addition of the highly charged phosphate groups changes the local charge of the protein, and this suggests that each wave of phosphorylations elicits changes in the local structure of FRQ and in its ability to interact with other proteins. Consistent with this finding, the mutation of phosphorylation sites within FRQ can speed up the cycle or slow it down depending on where the sites are and when in the cycle they are phosphorylated (Fig. 4). Indeed, this is seen when one looks at the spectrum of proteins with which FRQ interacts (Fig. 3). With the exception of FRH, these change in a time-of-day-specific manner. Early in the day, FRQ interacts strongly with WC-1 and WC-2 and, as the day goes on, this interaction decreases until, by the end of the day, there is no strength to the interaction above background. This seems to fit well with the net action of FRQ in inhibiting the transcriptional activity of the WCC. As soon as FRQ appears, WCC activity plummets with the result that *frq* mRNA is elevated for only a relatively short period of time, whereas FRQ protein is elevated for most of the day.

A bit later in the day, the interaction of FRQ and FRH with casein kinase I (CK1) increases, and, after this, CK1 is also a part of the complex containing FRQ, FRH, WC-1, and WC-2. These are the strongest interactions, strong enough to survive purification of FRQ through multiple steps in preparation for the mass spectrometry in which the FRQ-interacting partners were identified and the sites of phosphorylation determined (47). There are, however, very likely a number of additional kinases that interact more transiently with FRQ, because these have been identified explicitly with various functions or activities (24, 49–51). For instance, in addition to the data showing physical interactions,

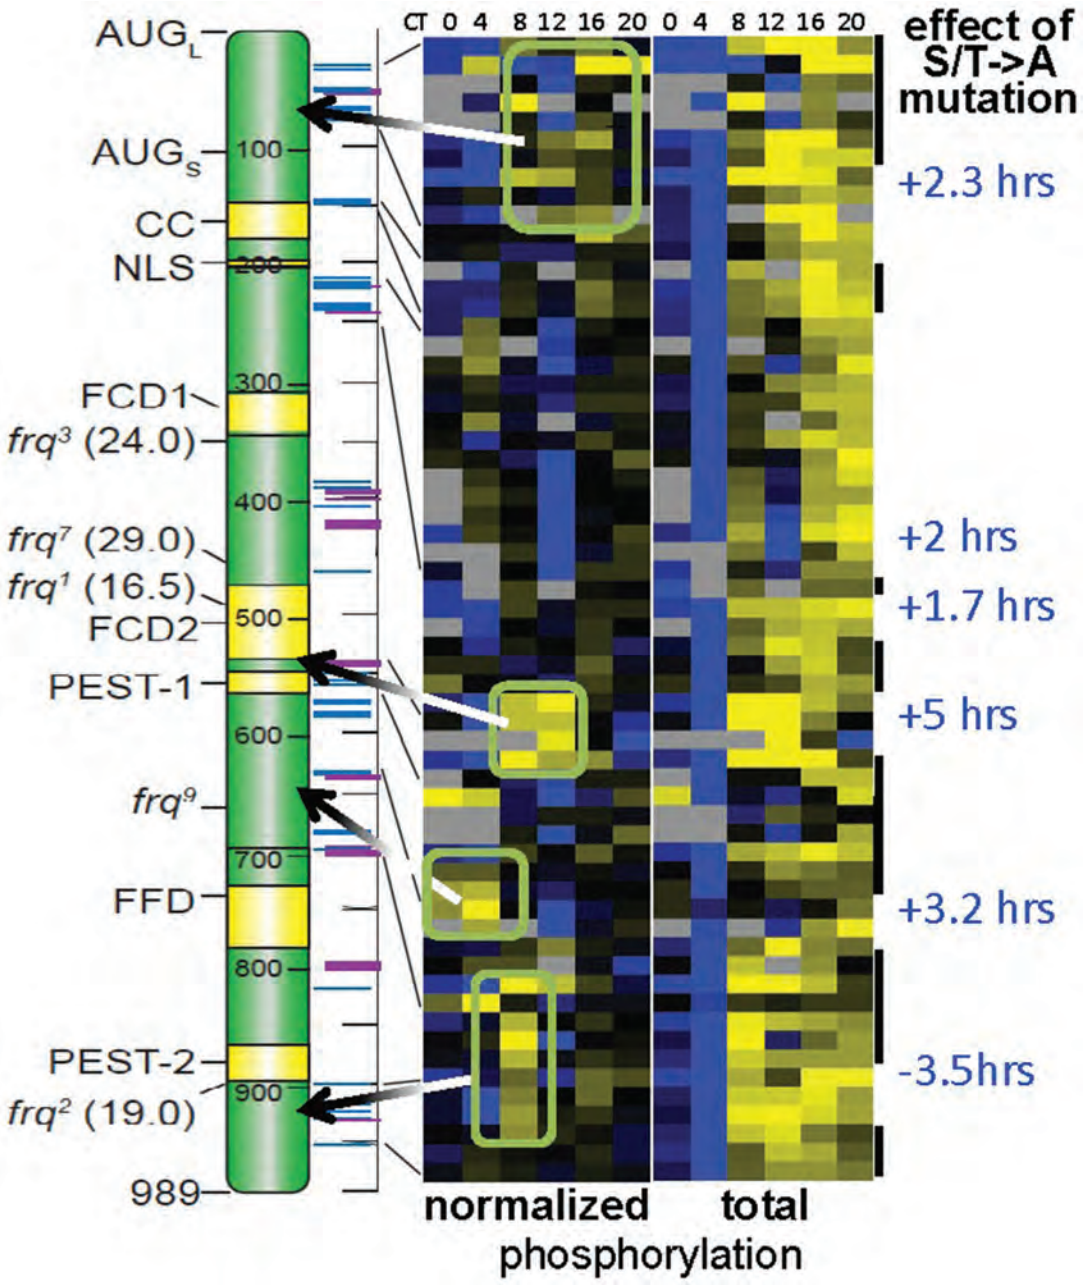

Figure 4 FRQ domains and their time-of-day-specific modifications. A cartoon of the domains of FRQ is shown to the left: CC, coiled-coiled domain; NLS, nuclear localization signal; FCD, FRQ-CKI interacting domain; FFD, FRQ-FRH interacting domain; PEST-#, PEST domains important for protein turnover; *frq*$^{\#}$, *frq* alleles followed by period length. Moving to the right in the figure, the positions of phosphorylations are marked. The two heat maps show how these change over time, with yellow marking higher phosphorylation and blue marking lower phosphorylation; each heat map consists of six columns corresponding to 4-h blocks of time in the circadian day from subjective dawn (CT0) through dusk (CT12) to the next night (CT20). The heat map to the right shows total phosphorylation, and, in the heat map to the left, the level of phosphorylation at any time is normalized to the total phosphorylation of the protein to better highlight where changes are occurring; these areas are marked with boxes and arrows showing where they lie within FRQ. Farthest to the right are noted the effects of mutating the serines or threonines that are phosphorylated at the locations noted to alanines. Modified from reference 47.

Neurospora strains bearing mutations in CK1 show abnormal period lengths (52). Likewise, casein kinase 2 (CK2) weakly interacts with FRQ and, importantly, CK2 has been shown to play a role in temperature compensation as described below (51, 53). PRD-4 in *Neurospora* is the ortholog of checkpoint kinase-2, a kinase activated by DNA damage. In *Neurospora*, the clock controls the cell cycle and DNA damage arrests the cell cycle in part through the action of CHK2, and also resets the circadian clock again through the action of CHK2 (i.e., PRD-4) (54). Protein kinase A (PKA) and calcium calmodulin kinase-1 (CAMK-1) have been implicated in FRQ phosphorylation and clock function, because mutants in them affect circadian period length and because they can phosphorylate FRQ *in vitro* (55). Relatedly, three protein phosphatases (proteins that remove phosphates from proteins) have been implicated in clock function (56). These are PP1, PP2A, and PP4; however, these may be indirect effects because *in vivo* analysis of FRQ phosphorylation revealed no strong evidence for dephosphorylation of any residues. Instead, the progression appeared to be unidirectional. Many of these protein-modifying enzymes have conserved roles in the circadian oscillators of animals as described later on.

FRQ Becomes Inactive, the Cycle Begins Again, and FRQ Is Turned Over

The function of the extensive posttranslational modifications of FRQ is plainly to regulate its activity, but a separate question concerns how the daily cycle is terminated. One of the first and most durable hallmarks of all circadian oscillators in the fungal and animal lineages is the observation of a daily cycle in the mRNA encoding the negative elements, accompanied by a daily cycle in their abundance (57–59). In addition in both *Neurospora* and *Drosophila*, there is an excellent correlation between the measured half-life of the negative elements (FRQ and PER, respectively) and circadian period such that longer half-life (more stable proteins) corresponds to longer period lengths (60, 61). This gave rise to the very reasonable assertion that the circadian cycle ends when the negative element is degraded, thereby releasing the positive element to begin the cycle of transcription anew. Despite the common restatement of this in nearly every clock review, recent work in *Neurospora* (62), while validating the correlation, has shown it to be just that, only a correlation, and that the underlying causal connection between clock protein stability and circadian period length does not exist.

This surprising turn of events began with the study of FRQ turnover that identified a ubiquitin ligase, FWD-1, as the enzyme responsible for ubiquitylating FRQ, the signal modification that targets it for protein turnover in the proteasome (63). In a very large number of proteins, FRQ included, phosphorylation of groups of amino acids in domains of the protein is the signal that targets a protein for ubiquitylation and turnover, so the extensive phosphorylation of FRQ fits this pattern well. A prediction, however, is plain, namely that mutations in FWD-1 that increase the half-life of FRQ must increase period length in a predictable manner, even yielding arrhythmicity, and, indeed, when examined on race tubes, strains lacking FWD-1 do not display a rhythm (63). However, surprisingly, when the clocks of such strains are examined using a luciferase reporter, an underlying rhythm is revealed (62). At the level of the oscillator itself, the rhythm is of normal amplitude, and, moreover, the canonical allelic series of short-period and long-period mutations in FRQ has the same effect on the oscillator, indicating that the clock in these strains is the same clock as is normally seen on race tubes. The feedback loop is being closed, determining period length, without a concomitant turnover of FRQ protein. How can this be?

The model proposed to explain these data (62) is that as FRQ (and, by extension, the other salient negative element clock proteins in animals such as PER in mammals) undergoes its unidirectional daily cycle in phosphorylation, its changes in charge allow it to participate in sequential structures and complexes that impact the activity of the WCC, and perhaps other enzymes. The cycle ends when FRQ becomes so phosphorylated that it no longer interacts with the WCC or other relevant proteins; indeed, by day's end, there is no longer any statistically significant interaction between FRQ and the WCC (47). Beyond this point, it does not matter if it is there, and, in fact, in the FWD-1 knockout strains, it is still there. Total cellular FRQ can have a very long half-life, but the clock as measured by luciferase runs along with little change, the small period differences being explained by effects of loss of FWD-1 on other substrates.

In wild-type strains, once FRQ has no further function and no further interactions with other relevant proteins, it is degraded; however, this act is viewed as only cellular housekeeping. By the time FRQ is being turned over, the WCC has already begun a new cycle of FRQ expression and a new circadian day has started.

Temperature and Metabolic Compensation

As described in "Circadian homeostasis" above, for a circadian clock to be truly useful to the organism, it needs to be compensated against changes in the ambient

environment. This is known as metabolic/nutritional and temperature compensation and is a core property of clocks as reflected by the fact that even isolated mammalian tissues and cells in culture display temperature compensation (64, 65). The mechanism for compensation is not known and, indeed, there are few clues, in part, because the experimental analysis is challenging. Rather than just determining the period length of mutant strains to see if compensation is altered, the period length must be determined by growing organisms at several different temperatures across the physiological range. Moreover, partial loss of compensation is commonly associated with period defects, suggesting that it may not be informative to the mechanism, if only because mutant proteins may have altered stability. In this case, a temperature gradient turns into a gradient in activity or effective dosage. However, in the study of compensation, *Neurospora* again led the way. Because loss of compensation mutations might not be informative, mutations yielding enhanced compensation were targeted for study. The *Neurospora* clock is normally modestly undercompensated, meaning that the period length becomes slightly shorter as the temperature increases from 20°C to 30°C. Two mutants, *prd-3* and *chr*, reverse this and instead show overcompensation or extended compensation (66). Cloning of these genes revealed them to encode separate subunits of casein kinase 2 (CK2): *chr* encodes the regulatory β subunit that also contributes to substrate recognition and *prd-3* is mutated within the catalytic core of the α subunit (50). The finding that the only two mutants known to cause overcompensation are subunits of the same enzyme is strong circumstantial evidence pointing to a role for CK2 in temperature compensation.

In many circadian systems, CK2 is known to play a circadian role. In *Arabidopsis* the β subunit CKB3 associates with CCA1 and overexpression of CKB3 leads to a shorter period (67); and, in *Drosophila*, CK2β and CK2α are defined, respectively, by *Andante* and *Timekeeper*, two long-period clock mutants. In *Neurospora*, FRQ is phosphorylated *in vitro* by CK2 and period lengthens with reduced dosage (53); although CK2α null mutants will not germinate, Δ*ckb-1* is viable but arrhythmic, the effect of CK2 dosage on compensation can be assessed in this background. When the regulatable *quinic acid-2* (*qa-2*) promoter (e.g., references 68 and 69) was used to drive *ckb-1* expression, leaky expression absent inducer causes a long 28- to 30-h period at 25°C (50). Interestingly, however, as CK2β1 levels are increased, the period drops to within the wild-type range, and strains expressing high levels of CK2β1 are slightly undercompensated like the wild-type clock; and, with less inducer as CK2β1 levels decrease, compensation passes through a range of better than normal compensation, finally changing to overcompensated mimicking the $ckb\text{-}1^{chr}$ overcompensation. Only the dose of WT proteins is being controlled in these experiments. The straightforward interpretation is that higher temperature results in more kinase activity (as confirmed in reference 50), and this acts to slow the pace of the clock at higher temperatures. These data establish a clear role for CK2 in effecting compensation.

INPUT TO THE CLOCK

Although much emphasis historically has been placed on the mechanism of the oscillator and the precision of the clock, it is the ability to be reset every day that may really be most important. Even a bad watch is still useful if it is corrected twice a day at dawn and dusk, and, in fact, this makes the clock useful in many different photoperiods spanning the seasonal differences from a winter of 6 h of light and 16 h of dark to the summer of long days and short nights. Clocks use available dependable environmental cues for clues as to time of day and these are known as zeitgebers from the German for time givers. The most dependable environmental cues are light and temperature, and these act on all known circadian clocks, although more complicated organisms such as people can also use derived cues such as feeding time or even social interactions.

Light

The mechanism through which fungal and mammalian circadian oscillators are reset by light was first elucidated in *Neurospora*. The key to understanding how this works is to understand the task in resetting. A single unidirectional environmental cue, the presence of light, must result in a bidirectional shift in the phase of the rhythm: if light is seen in the latter part of the night, it means that dawn has arrived and so the light signal should act to shift the phase of the clock forward to morning, whereas, if light is seen in the early part of the night, it means that the sun has not yet set, so the light signal should delay the clock back to the previous dusk. And of course, if light is perceived during the middle of the day it should have little effect on the clock.

This is achieved through the simple existence of a daily cycle in FRQ abundance and the fact that light induces the expression of *frq* mRNA and FRQ protein (Fig. 5) (70). Succinctly, in the daily cycle of *frq* mRNA abundance, it takes about 8 to 9 h to go from trough to peak and about 12 to 14 h to go from peak to trough.

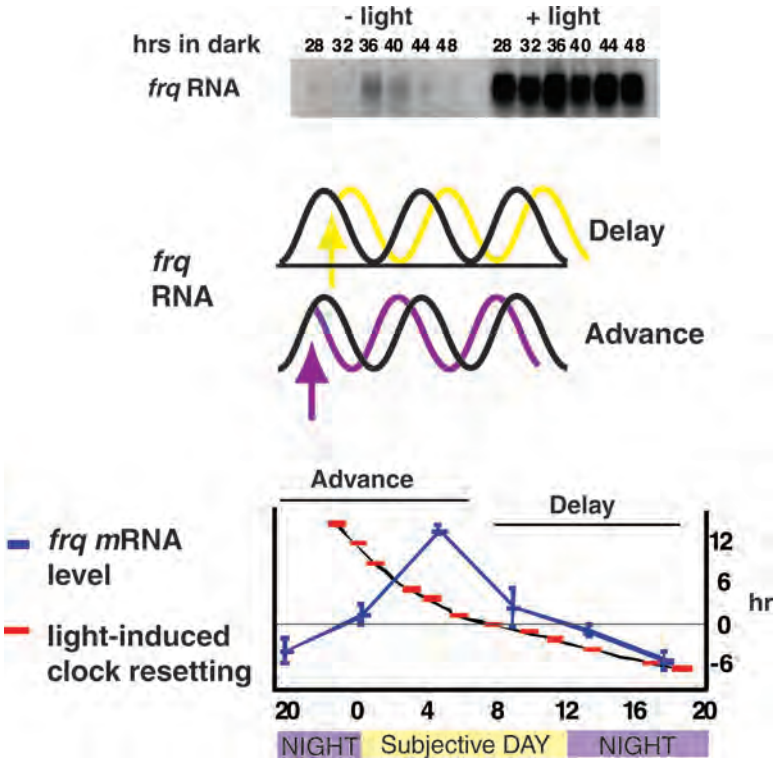

Figure 5 Light resets the clock. (**Top**) The daily cycle in the abundance of *frq* RNA is shown along with how a brief exposure to light at any time greatly increases this. (**Middle**) The cycle of *frq* transcription is shown in black, and the colored lines show the effect of light-induced *frq* expression on the steady-state rhythm. (**Bottom**) The response of the clock to light is juxtaposed with the daily cycle of *frq* expression: When light is seen while *frq* levels are rising, the phase of the cycle is advanced because *frq* rises to peak levels sooner. When light is seen while *frq* levels are falling, the cycle is set back. Adapted from reference 24.

If mRNA is rising slowly and the organism sees light, then *frq* is rapidly induced and rises; what would have taken hours now happens within minutes, essentially an immediate phase advance. Conversely, if *frq* mRNA levels are falling and the organism sees light, then *frq* is rapidly induced and the clock is set back to the time of peak. In constant conditions, peak *frq* mRNA levels happen in the subjective morning (the phase that would be morning on a light-dark cycle), so the effect of resetting is always to push the clock to subjective morning.

In *Neurospora*, the photoreceptor that brings about this acute light induction is WC-1 (32), the same transcription factor protein that heterodimerizes with WC-2 to make the positive element in the core feedback loop. There is a specific protein domain that senses light, the LOV domain, which is a specialized kind of PAS domain. The LOV domain binds a chromophore, FAD (flavin adenine dinucleotide) that strongly absorbs blue light (32, 71). When it absorbs blue light, it becomes chemically excited and makes a covalent adduct with a cysteine in the binding pocket of WC-1. By analogy to the VVD protein that also possesses a LOV domain and is a blue light photoreceptor (72), this event causes structural changes in the WC-1 protein that propagate to the surface of the protein where a helix is released, exposing an interaction surface. WC-1 interacts with itself (multimerizing [32]), exposing a transcriptional activation domain(s) that interacts with general transcription machinery to drive the acute induction of the *frq* gene, events that all happen within minutes of light exposure. These events happen at the PLRE in the *frq* promoter, a region that is close upon the transcription start site and, as described earlier, well separated from the C-box where WC-1/WC-2 (the WCC) mediate activation of *frq* as a part of the circadian cycle that happens in constant darkness.

Interestingly, clocks in mammals are reset in very much the same way, although they use a different means to detect light (73). As we all know, in mammals, photoreceptors for light are present only in the eyes, so

light perception elicits neuronal signals from each eye that travel down the optic tracks to the brain; the tracks cross at the optic chiasm. There in the hypothalamus, and directly above the optic chiasm, lie two bundles of neurons called the suprachiasmatic nuclei (SCN), about 10,000 each, that comprise the central pacemaker that controls locomotor activity and sleep-wake cycles. The light signal goes to a part of the SCN where it elicits release of the neurotransmitter glutamate, which elicits intracellular release of calcium ions, activating PKA and other kinases that phosphorylate and activate CREB (cAMP response element binding protein) and CRTC1 (CREB-regulated transcription coactivator 1), which bind to the *Per*1 and *Per*2 promoters and induce their expression, thus resetting the mammalian core clock (73, 74). Thus, although the means to achieve clock gene induction are different and reflect the biology of the cell types involved, the overall mechanism, acute light induction of negative elements in the core oscillator, is the same in *Neurospora* and in mammals.

Interestingly, the regulatory parallels between fungi and mammalian clocks do not end with the mechanism of light resetting; light also induces an acute repressor of the light response. This was also first elucidated in *Neurospora* where light acutely induces *vivid* that encodes VVD, another photoreceptor protein that acts as a negative regulator of the WCC (75). VVD physically interacts with WC-1 (76–78) and dampens its activity, and this has two effects. First, VVD turns what would be a step increase in WCC activity into a pulsatile increase followed by a return to background levels of activity. Second, VVD facilitates a graded response to successively higher light responses; this is because VVD binds to light-activated WC-1 and sequesters it, and the next higher intensity light signal then releases some of the sequestered WCC to allow reinduction of light-regulated genes (79). In mammals, light-driven CREB activity induces Sik1 (salt-inducible kinase1), which inactivates CREB through phosphorylation (80). Thus, as with acute light induction of circadian negative elements, there is conservation of the regulatory architecture of the light response in mammals to achieve the same end, turning what would be a step increase into a pulsatile increase.

Temperature

Temperature is the environmental variable, other than light, that is most dependable on planet Earth and, as a result, it influences phase of all known circadian clocks. Interestingly, and despite our well-described mechanisms for whole-body temperature homeostasis, this even extends to clocks in isolated human cells.

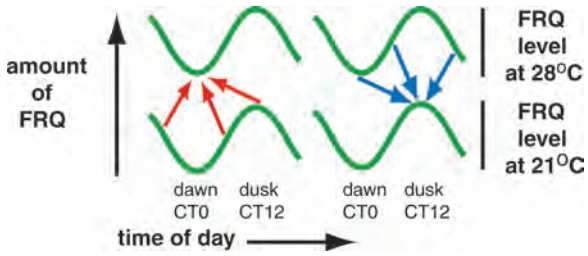

Figure 6 How temperature might reset the circadian cycle. Cycles in FRQ levels at different temperatures are shown in green. A step up in temperature at any time (red arrows) results in not enough FRQ to close the feedback loop, so the clock is reset to the time corresponding to low FRQ, subjective dawn. A step down in temperature at any time leaves the clock with sufficient FRQ to close the feedback loop; the cycle is reset to the time marked by high FRQ, around subjective evening. Adapted from reference 24.

There is a reliable daily rhythm in body temperature with an amplitude of greater than 1°C; cycles of this magnitude are sufficient to entrain the clocks of cells in culture (81) and probably contribute to keeping cells in synchrony within our bodies.

The molecular mechanisms underlying temperature entrainment were first examined in *Neurospora* and the molecular response appears distinct from that seen for light (Fig. 6). In *Neurospora*, the amount of *frq* mRNA is not regulated by temperature and remains fairly constant across the physiological range; however, posttranscriptional mechanisms govern the amount of total FRQ made such that FRQ cycles around a higher mean level at higher temperatures (82). Even the lowest amount of total cellular FRQ seen at 30°C is higher than the highest amount seen at 20°C, and this fact drives the model for resetting based on temperature steps (83). When there is a step from high to low temperature, no matter at what time of day, the shift happens; there is so much FRQ that the clock is set to the time corresponding to peak FRQ levels, around subjective dusk. Conversely, following a shift from low to high temperatures, there is so little FRQ that the clock is set to the time of day corresponding to low FRQ levels, around subjective dawn (84).

OUTPUT FROM THE CLOCK

Circadian clocks are important because they control and coordinate the activities of cells so that appropriate biochemical activities happen at appropriate times of day. There are numerous examples from the circadian literature demonstrating the advantage of circadian regulation, chiefly by showing that organisms with clocks whose period lengths correspond with environmental

cycles outcompete organisms with clocks whose period lengths are different from the environment: for instance, wild-type clocks do better than long-period clocks in a 24-h environment, but long-period clocks do better than wild-type clocks in a long-period environment (e.g., reference 85). There are a variety of reasons why this might be the case. For instance, organization and partition of metabolism by time of day would prevent futile cycles and ensure that necessary precursors are available for metabolic needs.

In *Neurospora*, as has been described earlier, there is a very obvious rhythm in growth and development. This is seen under light-dark cycles but not in constant darkness unless carbon sources are limited or efforts are made to reduce ambient CO_2 or to enhance levels of reactive oxygen species (86, 87). It follows that there should be a rhythm in gene expression that supports these visible outputs from the clock, and indeed there is, but it should be noted that this plain quest for clock-regulated genes was first formulated and pursued in *Neurospora* (88). In the late 1980s, efforts were undertaken to use subtractive hybridization to enrich for genes whose expression peaked in a time-of-day-specific manner and this resulted in the identification of *clock-controlled gene*-1 (*ccg*-1) and *ccg*-2 (later shown to be allelic to *eas* [89]). This work also introduced the term "clock-controlled gene" into the circadian lexicon where it is now commonly used: clock-controlled genes are genes whose daily expression is controlled in a circadian fashion by the clock, but whose gene products do not generally impact the operation of the clock (Fig. 7A). This distinction, although it seems obvious now, was truly novel at the time and laid the foundation for studying output as a distinct subfield with circadian research.

Circadian Control of Transcription

It is now widely recognized that the principal means of output from the clock in all organisms from bacteria through humans is through daily control of transcription and the generation of *ccg*s. Efforts to identify *ccg*s have tracked the available technologies through the years, beginning with subtractive hybridization, and then differential hybridization, expressed sequence tag (EST) sequencing, microarrays, and most recently (and successfully) RNA-seq, which is now taken as the state of the art. This technology has been applied to identify the *ccg*s in a wide variety of organisms including *Neurospora*.

Some technical issues surrounding the identification of *ccg*s should be mentioned. Overall gene expression will change in response to time-of-day in constant conditions (true circadianly regulated genes), but will also change in response to age of the culture, ambient temperature, changes in nutrition (e.g., a shift in nitrogen sources from ammonium to nitrate, or from glucose to cellulose, or a variety of other factors). Because of this, efforts must be made to avoid such changes, beginning with the use of a medium such as Bird (90) that contains only one nitrogen source. Cultures must be as close as possible to the same age (hours since germination) as is feasible, and, to address this, strict schedules have been developed to adjust the times of transfer from light to dark (the cue that sets the clock running) of sets of cultures so that when all are harvested they can be the same developmental age but represent different circadian clock times (88, 91). There have been steady developments in software to extract rhythmic signals from the nonrhythmic background; these are now highly developed, but, in passing, a few technical issues should be noted. There are more stringent (JTK [92, 93]) and less stringent (ARSER [94]) software and algorithms available for calling rhythmic genes. To be dependably able to call rhythmic genes, sampling density must be high; samples taken at least every 2 h over 2 days are needed to reliably identify even 80% of rhythmic genes, and hourly sampling is better (92). Last, time series data can be highly influenced by initial conditions, and, in *Neurospora*, the first hours are still strongly influenced by the previous light-dark cycle; in no case can data from a single day be concatenated to make an imaginary two-day time series unless the goal is imaginary data.

Early studies (e.g., references 88 and 95) identified *ccg*s, but, because of their inherent limitations, tended to identify only the most abundantly expressed genes, and these were numbered in the order they were identified from *ccg*-1 to *ccg*-16. At this point, there was the realization that there would be potentially thousands of *ccg*s (as there now are) and so this method of naming was discontinued (96, 97). The most recent data that adhere to the standards of the previous paragraph are shown in Fig. 7B. These data were collected from cultures growing in liquid medium with glucose and gentle shaking in constant darkness. Under these conditions, there will be only very limited development (no aerial hyphae, for instance) so the spectrum of *ccg*s might be greatly expanded if cultures were collected from solid medium. Nonetheless and despite the relatively restricted overt development, the data show that as much as 40% of the genome is clock controlled (false discovery rate of 0.05) and roughly 10% is strongly and dependably clock controlled (91). This is likely to be an underestimate because, when random promoters were

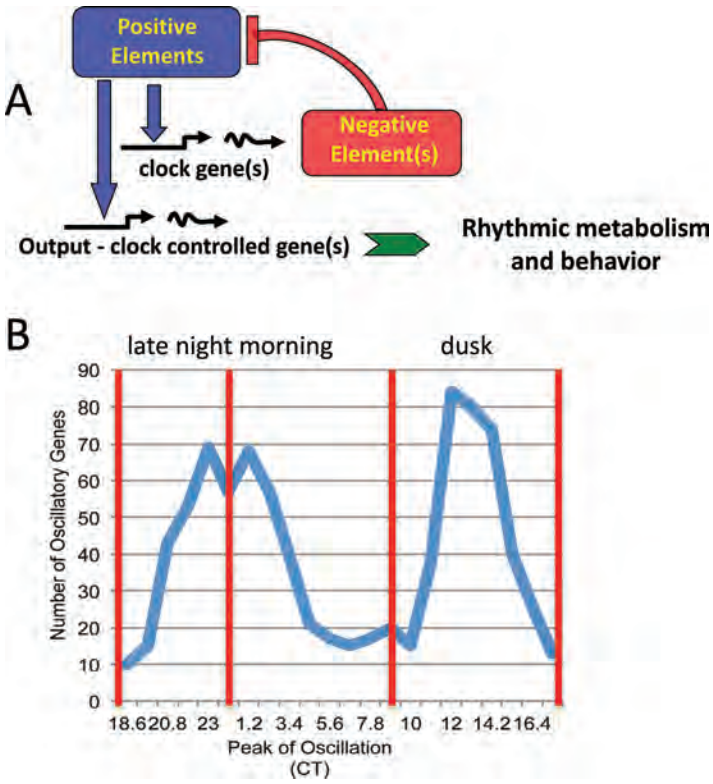

Figure 7 Output from the circadian clock. (**A**) The relationship of output to the oscillator is shown. The circadian clock is fungi and animals can be approximated as a single-step negative feedback loop in which the Positive Elements (in blue, the heterodimer of WC-1 and WC-2 or in animals BMAL1 and CLOCK) drive expression of the gene(s) encoding the Negative Elements (in red). The Negative Elements feed back, physically interact with the Positive Elements, and turn down their activity. The cycle thus generates rhythmic activity of the Positive Elements. When they, in turn, regulate genes whose products do not participate in the feedback loop, there are the means for transcriptional output from the clock. These are the *ccg*s. Adapted from reference 58. (**B**) The abundance of *ccg*s is shown as a function of the time of day at which their levels peak. The data are from 2-h bins across the day, with a bimodal peak of gene expression in the late night to morning and another peak around dusk (from reference 91).

assayed for their ability to drive circadian gene expression by fusion with a luciferase reporter, 75% were shown to be rhythmic only by luciferase; these were predominantly low-abundance genes, suggesting that the depth of sequencing was underpowered to detect rhythms at a 0.05 confidence level when there were simply too few transcripts present. Another interesting conclusion is that the spectrum of *ccg*s changes with the composition of the growth medium. It is plain that circadian regulation exerts a profound influence on the genome, and, in fact, if the criteria for choosing *ccg*s are relaxed just a bit, the majority of expressed genes will show some influence of time of day.

This finding has several important implications. First, it is plain that culture conditions matter a great deal in all experiments and not just if one is looking for *ccg*s. Prior light-dark treatment, as well as light-dark conditions during an experiment, can manifestly influence what is and is not seen. The level of expression of a gene might appear to be 10-fold higher or lower depending on when tissue is collected from an incubator that excludes light. Sometimes effects are due to circadian regulation but sometimes it is just light. An interesting example is the identification of DNA methylation at several places in the genome including the *frq* locus; methylation is plainly seen if cultures have been exposed to light but not if they have been in extended darkness or at elevated temperatures (33). There are also implications simply for choosing invariant "control genes" for normalization of reverse transcriptase-

quantitative PCR data, because many genes, including those commonly used as "invariant controls" such as *gapdh* (also known as *ccg*-7), are in fact clock controlled. In a useful spin-off from this study, mathematical tools were developed and used to identify truly invariant genes whose expression levels span the range of normal gene expression (98). The genes listed in this study provide truly valid control genes for normalization of gene expression studies.

The data of Hurley et al. (91), and to some extent Sancar et al. (although, because of the experimental design, these data are strongly influenced by the prior light-dark cycle [99]), reveal significant metabolic partitioning as a function of time of day that extends to control of major aspects of cell biology including growth, protein synthesis, stress responses, and intermediary metabolism. The greatest influence of circadian control on gene expression is seen around subjective dawn and dusk and the fewest relative number of *ccg*s peak in the middle of the day and night. While a great amount of detail is known and could be written about this, it suffices to say here that, in broad outline, morning and daytime gene expression tends to favor catabolism, energy production, and precursor assembly, whereas dusk and nighttime gene expression tends to favor genes whose products are involved in biosynthesis of cellular components and biomass accumulation (91).

The timing of transcriptional regulation itself provides abundant means for regulation. Whenever the WCC drives expression of another transcription factor (TF), regulation of that TF can provide a means for altering phase because it can feed back or forward to influence other TFs and coregulators, and, in addition, the TF itself can be posttranslationally modified. A current edge of research is the description of this network of TFs that drives their expression and other TFs that they in turn regulate.

After the first tier of transcriptional regulation, of course, a number of additional steps are involved in filtering the output from the clock. This is most clearly understood when one realizes that the circadian signal begins with the rhythmic activation of the WCC that, based on the expression of *frq*, its most salient output, peaks in the morning. It follows that, in order to obtain the spectrum of peak output phases shown in Fig. 7B, there must be many additional levels of regulation. We can begin with the act of transcription yielding a nascent transcript. Splicing of the transcript can be regulated followed by transcript stability. As a rule of thumb, as the stability of a transcript increases, its peak phase will become more and more delayed compared with the peak time of it transcription. Hurley et al. attempted to estimate regulation at the posttranscriptional level by comparing the peak times of *ccg*s from RNA-seq (i.e., total amounts) with the peaks times of expression based on promoter luciferase fusions for around 300 genes (91). The two did not match well for a large number of genes, indicating that additional levels of posttranscriptional regulation of transcripts are not uncommon.

Moving down the Central Dogma from mRNA there can be regulation at the level of translation, posttranslational modification of the protein to influence its binding partners, activity, or intracellular localization, and finally to regulate its stability. Many of these levels of regulation also have the capacity for global effects. For instance, another edge of research in *Neurospora* is regulation of kinase activity. Roles for mitogen-activated protein kinases (MAPK) in cellular responses to stress or in mating are well known (e.g., reference 100) and they activate a wide variety of proteins, but interestingly the clock has been shown to regulate basal MAPK signaling (101, 102). In *Neurospora*, OS-4 is the MAPKKK that initiates signaling through the cascade in response to stress and OS-2 is the terminal effector kinase in the MAPK cascade. In the subjective morning, OS-2 activity is high both because the WCC directly drives high OS-4 levels and because the activity of the OS-4 inhibitor RRG-1 is low, again due to circadian regulation. In the evening, the reverse is true. Circadian regulation of MAPK signaling is another aspect of regulation conserved between *Neurospora* and mammals (103).

NONCIRCADIAN OSCILLATORS IN FUNGI

Most fungi will display discernible rhythms in growth, morphology, or development under light-dark and temperature cycles, but only a few of these are actually circadian in nature. The "rhythms" appear because most fungi, with the exception of yeasts, can perceive and respond to light, as described in the review by Fischer et al. (129), and temperature is an all-pervasive metabolic controller. However, as noted earlier, under the right conditions—even conditions of constant nutrition, darkness, temperature, and humidity—a wide variety of fungi will express rhythms in growth habit, growth rate, hyphal branching, morphology, any or all of which are likely accompanied by changes in gene expression. These rhythms no doubt contribute to the vitality of the organism and they received much attention in the 1960s and 1970s; however, as the definition of circadian was refined, it became clear that they are not truly circadian (3). This was an important stage in the development of circadian biology as a field, because it was only when

such diverse systems were jettisoned that it became possible to focus on commonalities in approach and mechanism. As every geneticist knows, screens are possible only when phenotypes are robust, so it was this winnowing of noncircadian from truly circadian rhythms (e.g., 22, 104) that allowed the field to focus and deliver a molecular answer to the question of how the circadian clock works. The first screens for clock mutants were initiated by Jerry Feldman in the early 1970s (105) and yielded the *frq* gene whose cloning in the early 1980s (106) nucleated the molecular dissection of the clock in *Neurospora*.

Leaving circadian rhythms aside for the present, there is a very rich biology describing noncircadian rhythms, although much of it is now becoming dated. Noncircadian rhythms in hyphal branching or zonation are known in *Podospora anserina* (107), *Aspergillus niger* (108), *Leptosphaeria michotii* (e.g., 109), *Nectria cinnabarina* (110), along with *Penicillium* spp., *Alternaria tenuis*, and a number of additional fungi (3, 111). There is even a rhythm in the formation of nematode traps by the nematophagous fungus, *Arthrobotrys oligospora* (112). The first noncircadian rhythms in *N. crassa* date from the 1960s (113), and more than 3 decades ago, the defining FLO rhythm was described in the *frq*-null strain frq^9 (114, 115). When *frq* was cloned and the mutant alleles analyzed, the allele was shown to encode a truncated and nonfunctional FRQ, and the existence of the noncircadian oscillator was confirmed (68); it can have a period between 12 and 34 h depending on the nutrition and temperature (that is, it is completely uncompensated) and cannot be entrained by light. Since then, in *Neurospora* where cellular rhythms have been studied more deeply than in any other cell, there are at least nine noncircadian rhythms described that can be distinguished by their period lengths or the means used to induce them (e.g., 96, 116, 117–121). Generically, these are termed FLOs (for FRQ-less oscillators [122]). All share the property of cyclicity displaying in the aggregate periods ranging from 10 to over 100 h, and none show the full range of defining circadian characteristics.

Much confusion in the field, and within fungal biology, has arisen from investigators confusing the output of the circadian clock with the clock itself. In *Neurospora*, the clock controls conidiation as seen on race tubes. The logical fallacy has been to assume that anything that controls conidiation must therefore be part of the circadian clock. This statement is obviously flawed because conidiation, like any developmental process, can be controlled by many factors and will not always happen; it is merely one obvious aspect of overt circadian control along with all of the rhythms in gene expression noted above. Although there are detailed descriptions of many FLOs, to date it is still unclear whether these serve any adaptive function to the organism or whether they are simply accidental by-products of metabolic regulation by feedback. On this point, the NRO oscillator, which appears to derive from feedback loops associated with regulation of nitrate reductase, is instructive (116). In part because of the logical fallacy of equating all conidiation rhythms with circadian rhythms, some FLOs have been studied in depth in the hope that they would reveal something of use for understanding circadian rhythms, and one that has been studied most intensively is induced by choline starvation (119). This CDO (choline deficiency oscillator) exerts control of overt growth and development such that conidiation rhythmicity can assume a period well in excess of 100 h, and growth is up to 8-fold faster between conidial bands than within conidial bands. The CDO is not temperature compensated, has lost phase control, and is light-sensitive in $wc\text{-}1^+$ genetic backgrounds and (obviously) does not require *frq* (123). The question of whether this oscillator interacts with the circadian FRQ/WC oscillator was answered definitively in experiments using a luciferase reporter to track *frq* expression and WCC activity under conditions of choline limitation where the CDO had taken control of conidiation. These experiments, done in *frq*+ and *frq* [period mutant] backgrounds, clearly showed the circadian FRQ/WC oscillator running in the background with a period appropriate to the *frq* allele (22 or 29 h), while the CDO ran with a ca. 80-h period length. The two cycles crossed each other at all phases more than once with no evidence for interaction (124).

Although the CDO plainly does not interact with the circadian clock, other FLOs might take input from the clock, in particular, those with period lengths comparable to the circadian clock, i.e., circa 24 h, like the NRO but unlike the CDO. In this context, one rationale for the existence of FLOs is that they might serve as slave oscillators that could under the right conditions assume proximal control of aspects of metabolism while remaining under the overall control of the circadian system. A slave oscillator could be open to evolutionary fine-tuning without altering the more finely tuned compensated/entrainable circadian clock, and the slave need not have the full complement of circadian properties; in a normal cell it would still be a part of the circadian system as it would be entrained by the circadian clock. In a *frq* or *wc* null mutant background and absent the circadian clock, each slave reverts to its inherent periodicity (28, 29, 125, 126).

CONCLUSION

Neurospora has provided a durable system for the study of biological clocks and oscillators in the broadest sense, and more specifically in circadian rhythms. Decades of analysis have shown that the *Neurospora* circadian clocks share a common regulatory architecture as well as conserved components with circadian oscillators in animals, and many aspects of circadian biology and molecular biology in these organisms were first elucidated in *Neurospora*. These include the first systematic screens for *ccg*s and elucidation of transcriptional control as a principal means for circadian output (88), experimental proof that transcriptional negative feedback is at the core of the clock (68), elucidation of the mechanism for light-induced (70) and temperature-induced (83) clock resetting, identification of the first PAS domain-mediated heterodimer as the positive element in a circadian feedback loop (127), and closure of the loop in a single step via action of the negative element on the positive element (127). Work on *Neurospora* also led the way to understanding the cellular roles of noncircadian oscillators and documented the fact that many such oscillators can coexist within a single mycelium. Many of the components involved in both kinds of oscillators are conserved among fungi and even more broadly.

Target of Rapamycin (TOR) Regulates Growth in Response to Nutritional Signals

25

Ronit Weisman

INTRODUCTION

A universal feature of all organisms is their ability to respond to nutrient availability by regulating growth and developmental programs. The identification of the target of rapamycin (TOR) pathway was a seminal discovery in the quest to understand the molecular mechanisms that govern such processes. TOR is an evolutionarily conserved serine/threonine kinase belonging to the family of phosphatidylinositol kinase-related kinases. Other members of this family include the mammalian DNA damage checkpoint kinases ATM and ATR,which are conserved from yeast to human, and DNA-PK and SMG1, which are not found in yeasts. TOR regulates growth (accumulation of mass), proliferation (accumulation in cell number), and survival in response to nutritional changes by diverse mechanisms that include regulation of anabolic and catabolic metabolism, nutrient uptake, protein translation and turnover, gene transcription, and the epigenome (reviewed in 1–3).

The first TOR genes were isolated in the budding yeast *Saccharomyces cerevisiae* as point mutations that conferred resistance to the growth-inhibiting effect of rapamycin (4–6). Rapamycin is a small hydrophobic molecule, a product of the soil bacterium *Streptomyces hygroscopicus* that was first isolated as an antifungal antibiotic but later proved to be a potent inhibitor of cellular growth in humans via inhibition of mammalian TOR (mTOR). The antiproliferative effect of rapamycin has proved beneficial for several clinical applications, including immunosuppression for the prevention of allograft rejection, treatment of cancer, and elution of stents to prevent restenosis after angioplasty (7, 8). Rapamycin induces cell growth arrest by mimicking a starvation-like response, which is characterized, among other features, by the induction of autophagy. This feature of rapamycin and its derivatives, or second-generation ATP-competitive TOR-specific inhibitors, may prove useful for the treatment of neurodegenerative and metabolic diseases (7, 8). Rapamycin, somewhat similar to calorie restriction, extends the life span in several model systems, including yeast, *Caenorhabditis elegans*, *Drosophila melanogaster*, and mice, making it the first drug with the potential to treat aging (7, 8).

TOR proteins can be found in two distinct evolutionarily conserved complexes termed TOR complex 1 (TORC1) and TOR complex 2 (TORC2) (see Fig. 1). TOR provides the catalytic subunit in these complexes and is accompanied by TORC1-specific and TORC2-specific subunits, as well as protein subunits that are shared by the two complexes. TORC1 and TORC2 are controlled by distinct upstream and downstream regulators but share common features, such as the phosphorylation and activation of AGC kinases (a family of protein kinases named after protein kinases A, G, and C) at their C terminal hydrophobic and turn motifs. Since distinct AGC kinases are phosphorylated and activated by TORC1 and TORC2, monitoring the phosphorylation status of these kinases at specific sites is most useful for determining TORC1- or TORC2-specific activation (1).

In higher eukaryotes (nematodes, flies, mice, and humans) there is a single gene for TOR. In contrast,

Department of Natural and Life Sciences, The Open University of Israel, Raanana, 435379, Israel.

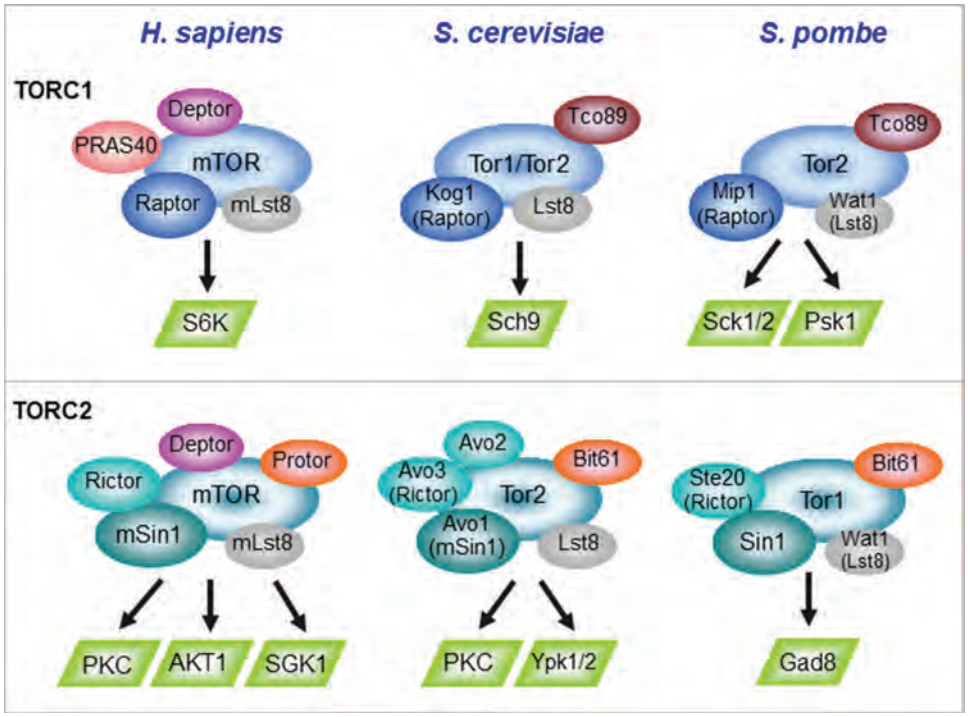

Figure 1 TORC1 and TORC2 subunits and downstream AGC kinases in mammalian, *Saccharomyces cerevisiae*, and *Schizosaccharomyces pombe* cells. TORC1 and TORC2 have shared and unique components. The human protein Raptor is TORC1-specific and is conserved in both yeast species. The human proteins Rictor and Sin1 are TORC2-specific subunits and are conserved in both yeast species. The target kinases of TORC1 and TORC2 are shown as green parallelograms.

two TOR genes are found in several fungal groups as the result of independent events of whole genome or segmental duplications (9). The two best-studied unicellular organisms for TOR signaling are the budding yeast *S. cerevisiae* and the fission yeast *Schizosaccharomyces pombe*, which contain two TOR genes. In *S. cerevisiae*, TORC1 (*Sc*TORC1) mainly contains *Sc*Tor1 as the catalytic subunit, but a minor *Sc*TORC1 variant that contains *Sc*Tor2 also exists; ScTORC2 contains *Sc*Tor2 as the catalytic subunit (10). In *S. pombe*, *Sp*Tor2 mainly acts as the catalytic subunit of *S. pombe* TORC1 (*Sp*TORC1), while *Sp*Tor1 mainly acts as the catalytic subunit of *Sp*TORC2 (11, 12). This awkward naming of the *S. pombe* TOR genes is the result of their identification prior to the isolation of the TOR complexes in *S. cerevisiae* (13) and reflects the lack of known specific sequences for the TOR catalytic subunit that can predict its association with TORC1 or TORC2 subunits. A single TOR gene is found in *Candida albicans* and filamentous fungi, and TOR inhibition plays an important role in the pathogenicity of these organisms (14–16) (see further discussion below).

TORC1: A MASTER REGULATOR OF GROWTH AND STARVATION RESPONSES

TORC1 Architecture, Rapamycin Sensitivity, and Downstream Signaling

TORC1 is defined by the essential subunit known as Raptor in metazoans, Kog1 in *S. cerevisiae*, and Mip1 in *S. pombe*. A highly conserved but nonspecific subunit is Lst8 (also known as GβL in metazoans and Wat1 or Pop3 in *S. pombe*), which is found both in TORC1 and TORC2. Other components of TORC1 are not as highly conserved; Tco89 is found in *S. cerevisiae*, *S. pombe*, and *C. albicans*, but no homologues have been identified in higher eukaryotes. In contrast, PRAS40 and Deptor are found in higher eukaryotes, but no homologues have been identified in fungi (1) (see Fig. 1).

The TOR catalytic subunit in TORC1 binds rapamycin when the drug is in complex with the prolyl isomerase FKBP12. The FKBP12-rapamycin complex (hereafter referred to simply as rapamycin) binds the FKBP12-rapamycin binding (FRB) domain in TOR, which is located in close proximity to the kinase domain. As a

result, most (but not all) TORC1-dependent activities are inhibited. Studies of *S. cerevisiae* played a central role in understanding the mode of action of rapamycin, including the identification of FKBP12 and the FKBP12-rapamycin binding (FKBP12/rapamycin-binding) domain and the characterization of the differential sensitivity to rapamycin of TORC1 and TORC2 (1, 4–6, 10). Still, the mechanism by which rapamycin inhibits TOR signaling and the determinants that establish rapamycin sensitivity are not fully understood. Several mechanisms of action have been suggested, including rapamycin-mediated disruption of TOR complexes and inhibition of the access of specific substrates to the kinase domain of TOR (reviewed in 17). TORC2 is less sensitive to inhibition by rapamycin compared with TORC1 or is not sensitive at all. Recent structural studies of *Sc*TORC2 suggest that the *Sc*TORC2-specific subunit Avo3 (Rictor in metazoans) masks the rapamycin-FKBP12 binding site of Tor2, thus preventing the inhibition of *Sc*TORC2 signaling (18).

The specificity of rapamycin for TORC1 proved most useful in deciphering cellular functions of this complex. Disruption of TORC1 in *S. cerevisiae*, either through genetic manipulations or inhibition by rapamycin, results in a phenotype that resembles starved cells, including arrest at the G1 phase of the cell cycle, G0-like cellular morphology and physiology, rapid drop in protein synthesis, repression of ribosomal gene expression, induction of stress- and nutrient-starvation genes, and stimulation of autophagy (19–22). Further studies demonstrated a conserved role of TORC1 in growth regulation through stimulating nutrient uptake, ribosome biogenesis, and the synthesis of proteins, lipids, and nucleotides (23–25; reviewed in 1, 26). To methodically screen for conditions that activate *Sc*TORC1, the phosphorylation status of Sch9, the AGC kinase downstream of *Sc*TORC1, was monitored. These studies demonstrated that Sch9 becomes dephosphorylated and inactivated in response to nitrogen, carbon, or phosphate starvation; high temperature; salt or redox conditions (27); and amino acid starvation or low quality of the nitrogen source (28). However, the signal or signals that are transduced to *Sc*TORC1 under these conditions are only partially understood.

Somewhat curiously, the growth of wild-type *S. pombe* cells is resistant to treatment with rapamycin (29). Yet rapamycin inhibits the phosphorylation of Psk1, the AGC kinase that lies downstream of *Sp*TORC1, or the phosphorylation of the Rps6 protein (S6 in human), the substrate of Psk1 (30, 31). S6 is a well-established target for mTORC1-S6K in humans and is often used to screen for hyperactivation of mTOR in cancer cells (32). Since rapamycin does not inhibit the essential function of *Sp*TORC1, conditional mutants of the catalytic subunit of *Sp*TORC1, *tor2*, or *mip1* (Raptor homologue) are used to study the cellular functions of *Sp*TORC1. Disruption of *Sp*TORC1 resulted in a phenotype that specifically resembles nitrogen-starved cells: growth arrest at the G1 phase of the cell cycle (unlike growth arrest at the G2 phase, characteristic for carbon starvation in *S. pombe*), small and rounded cell morphology, induction of nitrogen-starvation-induced genes, and activation of the sexual development pathway (11, 12, 33, 34). Complete withdrawal of the nitrogen source from the medium or a shift to a poor-quality nitrogen source (proline instead of ammonium) resulted in downregulation of *Sp*TOC1 activity as measured by decreased Rps6 phosphorylation (30, 35), leading to division at a reduced size and advancement into mitosis (36, 37). In *C. albicans*, rapamycin inhibits growth via inhibition of the single TOR gene, *Tor1*, while nitrogen and carbon starvation both result in reduced *Ca*S6 phosphorylation (15, 38), suggesting that similar to *S. cerevisiae*, *Ca*TORC1 is sensitive to rapamycin and responds to both carbon and nitrogen limitation.

At the transcriptional level, inhibition of *Sc*TORC1 or rapamycin treatment in *S. cerevisiae* (20, 21, 39, 40), disruption of *Sp*TORC1 (12, 33), or rapamycin treatment in *C. albicans* (41) led to the reduction of ribosomal gene expression and induction of starvation- or stress-responsive transcription. Of note is the regulation of the response to changes in quantity or quality of the nitrogen source by the conserved TORC1-protein phosphatase 2A (PP2A) module, which regulates the activity of GATA-transcription factors (a family of transcription factors that are characterized by their ability to bind DNA sequences that contain the GATA motif). Early studies identified the zinc-finger GATA transcription factors Gln3 and Gat1 as targets for *Sc*TORC1 (20, 21, 40). Further studies unraveled a pathway in which *Sc*TORC1 regulates the activity of PP2A and PP2A-like phosphatases such as Sit4 by regulating their association with the inhibitory regulatory subunit Tap42. Upon reduction of the quantity or quality of the nitrogen source, *Sc*TORC1 is inactivated, promoting the disassociation of Tap42 and the activation of the phosphatases. In turn, the Ure2 protein that sequesters Gln3 and Gat1 is dephosphorylated, and Gln3 and Gat1 are dephosphorylated and translocate into the nucleus (20, 21, 42–44). Gln3 and Gat1 are required for transcriptional activation of genes that are normally repressed in the presence of high quantity and quality of the nitrogen source and are critical regulators of nitrogen

catabolite repression, the processes by which high-quality nitrogen sources are imported and assimilated in preference to poor-quality nitrogen sources.

The *C. albicans GLN3* and *GAT1* homologues are also required for regulation of nitrogen metabolism, and their disruption resulted in rapamycin resistance, similar to the effect of disrupting *GLN3* and *GAT1* in *S. cerevisiae* (45). More recently, *Sp*TORC1 was demonstrated to regulate the phosphorylation and nuclear localization of the GATA transcription factor Gaf1. Gaf1 becomes dephosphorylated and inactivated in a manner dependent on the PP2A phosphatase Ppe1 in response to nitrogen (but not carbon) starvation (46, 47). The conservation of the TORC1-PP2A-GATA-transcription signaling in the distantly related *S. cerevisiae* and *S. pombe*, two yeasts that diverged in evolution more than 300 million years ago, suggests that this pathway may also be conserved in higher eukaryotes.

Early studies showed that treatment of *S. cerevisiae* with rapamycin led to a rapid drop in protein synthesis (19). Further studies revealed that *Sc*TORC1-Sch9 and *Sc*TORC1-Tap42-PP2A play prominent roles in the regulation of ribosome biogenesis, one of the most energetically demanding processes and thus a focal point for the coordination of growth with nutritional changes. *Sc*TORC1 regulates ribosome biogenesis at many levels, including transcriptional induction of rRNA, ribosomal proteins, and the ribosome biogenesis (Ribi) regulon. Several transcription factors were identified as targets of *Sc*TORC1 in the regulation of ribosome biogenesis, including Maf1, the repressor of RNA pol III (23, 48), Sfp1 (49), the forkhead transcription factor Fhl1 (50), and the transcriptional repressors Stb3, Dot6, and Tod6 (24). *Sc*TORC1 also directly binds 35S rDNA promoters to promote rRNA synthesis (51). Similar to *S. cerevisiae*, *Sp*TORC1 also regulates transcription of ribosomal proteins (33) and phosphorylates the repressor of RNA pol III Maf1 (52). At the posttranscriptional level, *Sc*TORC1 regulates protein synthesis through regulation of the translation-initiation factor eIF2α, in a manner that is at least partially conserved in *S. pombe* (53, 54). In both *S. cerevisiae* and *S. pombe* eIF2α is phosphorylated in response to amino acid starvation or rapamycin treatment. The phosphorylation of eIF2α is mediated via the *S. cerevisiae* or *S. pombe* Gcn2 kinases; however, *Sc*TORC1 regulates the phosphorylation of Gcn2 at sites that are not conserved in *S. pombe*.

Autophagy is a general name for catabolic processes mediated by membrane trafficking pathways that lead cytoplasmic material from the cytosol into the lumen of the lysosome or vacuole, where massive degradation takes place. *Sc*TORC1 inhibits autophagy under favorable growth conditions through the phosphorylation of Atg13 that inhibits the assembly of the Atg1 protein kinase complex (55). Autophagy has been linked to several human pathologies, including cancer and neurodegenerative diseases and is also implicated in the process of aging. Most interestingly, rapamycin treatment or reduced TORC1 activity in *S. cerevisiae*, in *S. pombe*, or in higher eukaryotes extended the life span (56–58). TORC1 controls aging through Sch9 in *S. cerevisiae* (56), in a process that involves the induction of autophagy and stress genes, as reviewed in more detail in reference 8. Additional downstream effects of TORC1 have been studied in detail, including amino acid uptake, regulation of cell size, and developmental responses, including entrance into quiescence or regulation of filamentous growth. These are not detailed here due to limited space but are reviewed elsewhere (1, 59).

TORC1 Upstream Signaling and the Response to Nitrogen Quantity or Quality or the Presence of Amino Acids

In yeast cells, the activity of TORC1 is sensitive to nutritional starvation and a variety of stresses, while mTORC1 is also sensitive to energy levels (ATP) and growth factors (3). The direct signals or mechanisms for activation of TORC1 are as yet unknown; however, a large body of evidence suggests that the nitrogen source and/or amino acids (which may also serve as a nitrogen source) play a key role in TORC1 activation.

Nitrogen is an essential element required for synthesis of amino acids, nucleotides, and other cellular components. Yeast cells can sense, take up, and assimilate several nitrogen sources. A high-quality nitrogen source (glutamine or ammonium) is defined by its ability to promote rapid growth and suppress the nitrogen catabolite repression genes (60). As described above, *Sc*TORC1 and *Sp*TORC1 are major regulators of the transcriptional control in response to the quality and quantity of the nitrogen source, and the activity of these complexes drops in response to low levels or poor quality of the nitrogen source (28, 30, 35). *Sc*TORC1 and *Sp*TORC1 are also activated in response to specific amino acids such as leucine, glutamine, asparagine, arginine, aspartate, methionine, and cysteine (28, 61–64), raising the intriguing possibility that the nitrogenous compounds critical for TORC1 activation are amino acids. This possibility is particularly tempting in view that in higher eukaryotes, amino acids (particularly leucine, glutamine, and arginine) are potent activators of mTOR signaling (65–67). Whether amino acid levels are directly sensed by TORC1 and, if so, by what mechanisms is

still an open question. Moreover, the mechanism of activation of TORC1 by the quantity and quality of the nitrogen source appears distinct from the mechanism of response to amino acids (28, 36). Moreover, different amino acids are thought to activate TORC1 through different mechanisms, including glutaminolysis and leucyl-tRNA synthetase (61, 68).

TORC1 and several remarkably conserved upstream regulators of TORC1 are localized to the vacuole in yeast cells and to its equivalent compartment, the lysosome, in higher eukaryotes (reviewed in 17). At the vacuolar or lysosomal surface TORC1 is activated by two distinct guanosine triphosphate GTPases: the Gtr (Rag in higher eukaryotes) and the Rhb1 (Rheb in higher eukaryotes). The Rag/Gtr-TORC1 axis is conserved in *S. cerevisiae* and *S. pombe*, while the Rhb1/Rheb-TORC1 axis is conserved in *S. pombe* but is absent in *S. cerevisiae* (see Fig. 2). The vacuole and lysosome act as major sites for protein degradation and reservoirs of amino acids; however, whether TORC1 responds to amino acids in the vacuole/lysosome or in the cytoplasm is not known yet.

In *S. cerevisiae*, the Gtr complex is composed of Gtr1 and Gtr2. Gtr1 is analogous to the mammalian RagA or RagB, while Gtr2 is analogous to RagC or RagD. Only when Gtr1 or RagA/B is bound to GTP and Gtr2 or RagC/D is bound to GDP is the heterodimer active and able to lead to activation of TORC1

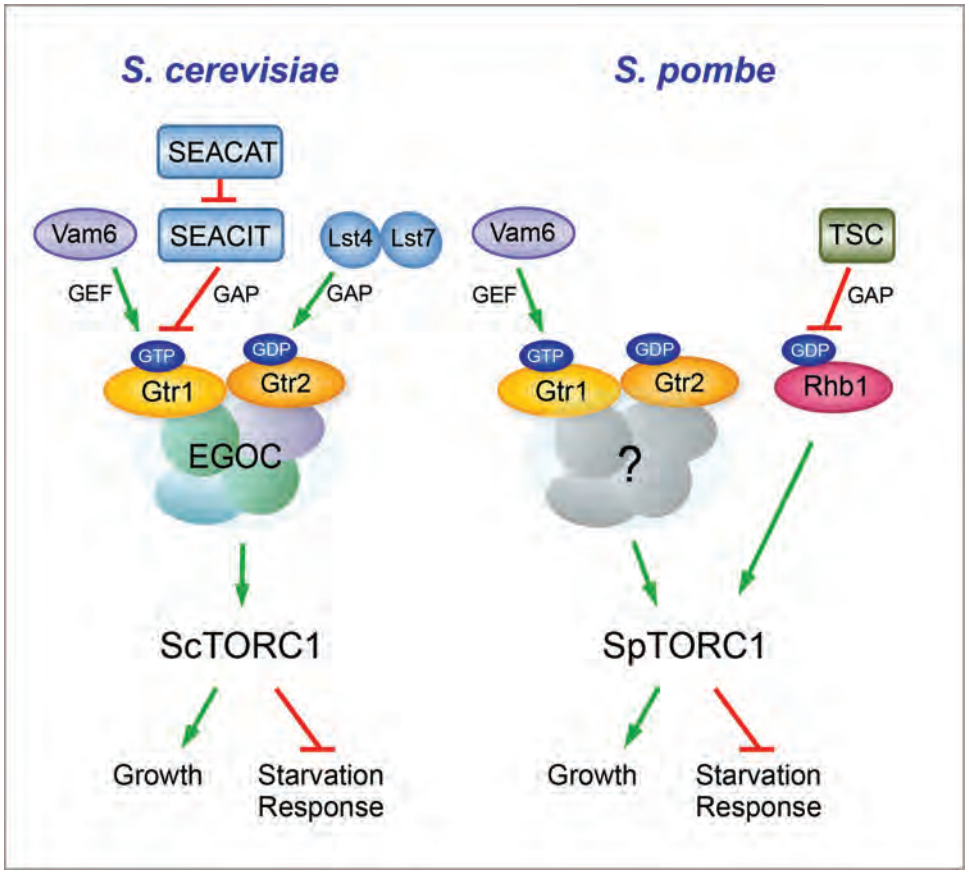

Figure 2 TORC1 is activated by GTPases to promote growth and inhibit starvation responses. *Saccharomyces cerevisiae* TORC1 (*Sc*TORC1) and *Schizosaccharomyces pombe* TORC1 (*Sp*TORC1) are activated by the GTPase complex Gtr1/Gtr2. The complex is active when Gtr1 is bound to GTP and Gtr2 is bound to GDP. Vam6 is a guanine exchange factor (GEF) for Gtr1 that is conserved between *S. cerevisiae* and *S. pombe*. In *S. cerevisiae*, the Gtr1/Gtr2 complex is associated with the EGO complex and is controlled by the SEACIT (which acts as GTPase activating protein, GAP), SEACAT, and Lst4-Lst7 complexes. These complexes have as yet unidentified equivalents in *S. pombe*. *Sp*TORC1 is also regulated by the Rhb1 GTPase (Rheb in mammals) and the TSC (tuberous sclerosis complex, a tumor suppressor complex in mammals), which acts as a GAP towards Rhb1.

(69–71). The Gtr1/2 GTPases associate with the EGO complex, which contains Ego1, Ego2, and Ego3 to form a complex that tethers Gtr1/2 and *Sc*TORC1 to the vacuolar membrane (71–73). The EGO equivalent complex in higher eukaryotes is the pentameric Ragulator complex, which is required for lysosmal localization and also acts as a guanine exchange factor toward RagA/B. In *S. cerevisiae* the guanine exchange factor activity toward Gtr1 is provided by Vam6 (vacuolar morphogenesis protein), which apparently has no mammalian equivalent (reviewed in 17). The vacuolar Vam6-Gtr1/2 module is conserved in *S. pombe* and activates *Sp*TORC1 in response to the presence of amino acids (62). The interaction and activation of either *Sc*TORC1 or *Sp*TORC1 by the Vam6-Gtr1/2 module are sensitive to the presence of amino acids, but *Sc*TORC1 and *Sp*TORC1 are localized to the vacuole irrespective of the nutritional status (62, 71). In contrast, mTORC1 dissociates from the lysosome upon amino acid starvation (69, 70). The Gtr and Rag complexes are negatively regulated by conserved GAP (GTPase activating protein) complexes that are named SEACIT and GATOR1 in *S. cerevisiae* and humans, respectively (Fig. 2). SEACIT and GATOR1 are in turn subjected to negative regulation by additional conserved complexes, SEACAT and GATOR2 (74; reviewed in 17) (Fig. 2). More recently, Lst4-Lst7 was identified as the complex that acts as a GAP toward Gtr2, promoting the binding of GDP to Gtr2 and thus activating *Sc*TORC1 (64), similar to the FNIP-folliculin complex in mammalian cells (reviewed in 17).

The *S. cerevisiae* Gtr1/2 GTPases regulate TORC1 activity but are not essential genes, suggesting that they play only a limited role in activation of *Sc*TORC1. Similarly, disruption of *gtr1/2* in *S. pombe* leads to a reduced level of *Sp*TORC1 activity and a hyper-mating phenotype, characteristic of conditional loss-of-function *Sp*TORC1 mutants; still, *S. pombe* cells lacking Gtr1/2 or Vam6 can respond to changes in the nitrogen quantity or quality. These findings argue that the Gtr-TOR axis plays only a relatively limited role in activation of TORC1 (62).

While the Gtr1/2 complex is dispensable for activation of TORC1 in yeast cells, the *S. pombe* Rhb1 GTPase (Rheb in human) is essential for *Sp*TORC1 activation (75–78). Accordingly, loss of function of Rhb1 results in a phenotype that mimics nitrogen starvation and is highly similar to disruption of *Sp*TORC1, including the G1 arrest and activation of nitrogen-starvation gene expression. Rhb1 is negatively regulated by the TSC1-TSC2 complex, which is conserved in humans and functions as a GAP toward Rhb1. The TSC complex functions as a tumor suppressor complex, and mutations in either TSC1 or TSC2 can lead to the tuberous sclerosis syndrome, which is characterized by rapid development of tumors and severe neurological defects (79). Disruption of the TSC complex in *S. pombe* results in prolonged phosphorylation of ribosomal S6 under nitrogen starvation (31), reduced transcription of nitrogen-starvation-induced amino acid permeases, and reduced amino acid uptake (80, 81). These findings suggest that deletion of TSC in *S. pombe* leads to hyperactivation of *Sp*TORC1 that shuts down transcriptional programs dedicated to scavenging for nitrogen sources. *C. albicans* homologues for Rheb and TSC2 were also identified. Disruption of *Ca*Rhb1 resulted in hypersensitivity to rapamycin, while *Ca*Rhb1 overexpression and *Ca*Tsc2 deletion are defective in filamentous growth under low or poor nitrogen, suggesting that Rhb1 activates *Ca*TORC1 and prevents normal responses to nitrogen starvation (82).

The TSC-Rheb axis acts as a hub for several signaling pathways, among them the AMPK, a serine/threonine kinase that coordinates cell growth and metabolism with available energy resources (reviewed in 83). AMPK is a heterotrimeric complex composed of a catalytic (α) subunit and two regulatory (β and γ) subunits. In humans, the tumor suppressors LKB1 and CaMKK (calcium/calmodulin-dependent protein kinase kinase) activate mammalian AMPK, which in turn directly phosphorylates TSC2 and activates its GAP activity, leading to conversion of Rheb to its inactive form and inhibition of mTORC1 (84; reviewed in reference 83). It was recently demonstrated that in *S. pombe*, the α subunit of AMPK is required to respond to changes in the quality of the nitrogen source. Under nitrogen stress conditions (shift from a high-quality to poor-quality nitrogen source), a specific homologue of CaMKK (Ppk34) stimulates *Sp*AMPK activity, which leads to downregulation of *Sp*TORC1 in a manner dependent on the TSC-Rhb1 (36). How TORC1 may integrate the complex signals from different pathways and coordinate these with the nutritional status awaits further studies.

TORC2: ROLES IN CELLULAR METABOLISM, GROWTH, AND SURVIVAL

TORC2 Architecture and Downstream Signaling

TORC2 contains the TOR catalytic subunit together with two additional highly conserved proteins that are essential for the function of the complex: Rictor

in metazoans (Avo3 in *S. cerevisiae* and Ste20 in *S. pombe*) and mSin1 in metazoans (Avo1 in *S. cerevisiae* and Sin1 in *S. pombe*) (see Fig. 1). TORC2 contains the Lst8 subunit, which is also found in TORC1. The Protor subunit in mammals has orthologues in *S. cerevisiae* and *S. pombe* (Bit61). Avo2 is specific for *S. cerevisiae* and *C. albicans*, while Deptor (which is also part of mTORC1) has been identified only in mammals (reviewed in 1).

The cellular functions of TORC2 are less well understood compared with TORC1. This is partly due to the lack of TORC2-specific inhibitors. In addition, in contrast to the starvation-like phenotypes observed upon disruption of TORC1, the loss of TORC2 results in diverse effects (reviewed in 85), making it difficult to attribute a primary cellular function to TORC2. Recent findings suggest that TORC2 plays significant roles in cellular metabolism, including cancer metabolism, growth control, and survival, encouraging further research of TORC2 and the search for TORC2-specific inhibitors (85, 86). As in TORC1 signaling, AGC kinases downstream of TORC2 play important roles in mediating downstream effects (see Fig. 1). The best-studied AGC kinases downstream of *Sc*TORC2 are Ypk1 and Ypk2 (87), while most of *Sp*TORC2 functions are mediated via Gad8 (88).

*Sc*TORC2 is essential for growth, while *Sp*TORC2 becomes essential only under starvation and a variety of other stress conditions. So far, only a limited overlap exists between the functions attributed to *Sc*TORC2 and *Sp*TORC2. It is not clear whether this reflects a true divergence in function or our incomplete understanding of the cellular roles of TORC2. *Sc*TORC2 was first implicated in the regulation of the polarization of the actin cytoskeleton, suggesting that it mainly regulates spatial aspects of cell growth (89, 90). Further studies revealed that *Sc*TORC2-Ypk1/2 also controls endocytosis (91) and sphingolipid biosynthesis (92–95), in a manner that is antagonized by the calcium- and calmodulin-dependent protein phosphatase calcineurin, which acts either directly downstream of *Sc*TORC2 or in a parallel pathway (92, 93). *Sc*TORC2 regulates actin polarization and endocytosis via flipase protein kinases (96–99), in a manner that was also suggested to be linked to the control of reactive oxygen species accumulation (97, 98). Interestingly, the level of reactive oxygen species is regulated by *Sc*TORC2 and can act as a signal to activate *Sc*TORC2 (97, 98). The Slm proteins, which were first identified downstream of *Sc*TORC2, can also function upstream of *Sc*TORC2 to promote activation of this complex in response to plasma membrane stress, resulting in a homeostatic loop in which *Sc*TORC2 regulates several aspects of membrane biogenesis and is also affected by changes in the membrane (100). Recently, it was demonstrated that *Sc*TORC2-Ypk1 positively regulates autophagy in response to amino acid starvation (101). This finding is interesting because it suggests that *Sc*TORC1 and *Sc*TORC2 oppositely regulate autophagy, albeit by different mechanisms. It may also suggest that *Sc*TORC2 is linked to nutritional changes more closely than has previously been recognized.

The most pronounced effects of loss of function of *Sp*TORC2-Gad8 become apparent under starvation and stress conditions. *Sp*TORC2 is essential to execute the two main responses to starvation: sexual development and entrance into stationary phase. Thus, cells that lack *Sp*TORC2 or Gad8 are highly sterile and quickly die once they exit the logarithmic phase (13, 102). Loss of *Sp*TORC2-Gad8 also renders cells sensitive to a variety of stress conditions, including low or high temperature, osmotic or oxidative stress, and DNA damage or replication stress conditions (13, 103, 104). Under normal growth conditions, *Sp*TORC2-Gad8 is required for the G2/M transition, and cells disrupted for *Sp*TORC2 show an elongated phenotype characteristic of a delay in entrance into mitosis (13, 103, 105, 106). *Sp*TORC2 is also required for amino acid uptake (107) and for the localization of Ght5, a high-affinity glucose transporter, to the cell surface under low-glucose conditions (108). An abnormal distribution of actin cortical dots and excess actin polymerization at the cell equator occur in cells lacking functional *Sp*TORC2 (106), as do defects in reorganizing the actin observed during new end take-off, the phase during which the new cell end starts to grow (109).

Unexpectedly, transcriptional profiles of *S. pombe* cells lacking the catalytic subunit of *Sp*TORC2 resembled those of cells lacking histone deacetylases or chromatin remodeling subunits (104). This finding led to the identification of additional defective phenotypes in *Sp*TORC2 mutant cells, including elongation of telomeres and loss of gene silencing (104). Of interest are the similarities observed upon loss of function of *Sc*TORC2 or *Sp*TORC2 with respect to DNA damage sensitivity (104, 110). In both cases, TORC2 plays a role in survival of DNA damage in a manner that is independent of DNA checkpoint activation but involves suppression of accumulation of DNA damage sites. However, in *S. cerevisiae*, elevated levels of DNA damage are thought to be the result of the defect in the actin cytoskeleton, whereas in *S. pombe* no such link is known (85). Interestingly, the inability of cells that lack *Sp*TORC2 or Gad8 to execute nitrogen starvation

responses is opposite to the "always starved for nitrogen" phenotype of cells lacking *Sp*TORC1 (35, 106). This is somewhat reminiscent of the opposite effects of *Sc*TORC1 and *Sc*TORC2 in the regulation of autophagy and may suggest regulatory links between *Sp*TORC1 and *Sp*TORC2.

TORC2 Upstream Signaling and the Response to Glucose Availability

The upstream regulation of TORC2 is poorly characterized. *Sc*TORC2 has been localized to membrane structure organelles, primarily to the plasma membrane, but has also been detected throughout the cytoplasm (111, 112). Visualization of GFP tagged *Sp*TORC2 components also indicated cytoplasmic as well as cortical localization (113), but a biochemical approach has suggested that Tor1, the catalytic subunit of *Sp*TORC2, and Gad8 are also found in the nucleus (114). *Sc*TORC2 is activated by direct association with the ribosome (115, 116), in a manner that is conserved in mammals and that may link TORC2 to growth capacity. In accord with the localization of *Sc*TORC2 to the plasma membrane, *Sc*TORC2 is activated by plasma membrane stress, which stems from cell surface expansion or stress on the plasma membrane (100). This mode of activation is thought to reflect a feedback loop mechanism in which *Sc*TORC2 regulates membrane biosynthesis but is also affected by membrane growth (17). In *S. pombe*, glucose but not nitrogen is required for activation of *Sp*TORC2 (117, 118). The activity of *Sp*TORC2-Gad8 in response to glucose requires the activation of Rhy1, a Rab family GTPase that lies upstream of *Sp*TORC2-Gad8 (118). The regulation of *Sp*TORC2-Gad8 in response to glucose availability is fast and does not require protein translation, suggesting a close link between a nutritional change and TORC2 activation, although the nature of the glucose signal that is sensed by *Sp*TORC2 is as yet unknown.

TOR IN PATHOGENIC FUNGI

Virulence in plant or human pathogenic fungi requires several cellular traits, including invasive growth, morphogenetic yeast-to-hyphal transition (e.g., in *C. albicans*), vegetative hyphal fusion, and expression of adhesion and stress response genes. As discussed above, TOR signaling regulates many aspects of the stress response as well as the switch from vegetative growth to developmental programs in response to environmental changes. Accordingly, accumulation of data indicates that TOR signaling is critical for virulence in several pathogenic fungi and may thus serve as a target for antifungal treatment. Early studies demonstrated that rapamycin and several less immunosuppressive analogues inhibited growth in *S. cerevisiae*, *C. albicans*, and *Cryptococcus neoformans*, suggesting that the use of rapamycin analogues may be beneficial as antifungal agents (15; reviewed in 16). Further support of the role of TOR in *C. albicans* pathogenicity is evident from studies that demonstrate the role of *Ca*Tor1 in regulating the expression of cell wall- and hyphal-specific genes, including adhesins (41). Moreover, genetic manipulation of *Ca*TOR signaling, including disruption of *Ca*Sch9 (119), *Ca*Rhb1 or *Ca*Tsc2 (82), or *Ca*Sit4 (120), supports a role for *Ca*Tor1 in promoting hyphal formation and virulence in response to nutritional changes, as well as in response to changes in pH (121). Interestingly, reduced *Ca*Tor1 signaling during hyphal initiation leads to the expression of the GATA transcription factor Brg1, which competes for promoter binding with Nrg1, the major transcription repressor of hyphal development (122). Thus, similar to *S. cerevisiae* or *S. pombe*, TOR is found to regulate a family member of the GATA transcription factors in *C. albicans*, but unlike *S. cerevisiae* or *S. pombe*, *Ca*Tor1 regulates the level of Brg1 indirectly via the Hog1 MAP kinase pathway (122). A study of fluconazole-sensitive mutants in *C. neoformans* also suggests that TORC2 signaling is conserved and may play an important role in recurrent infections of *C. neoformans* (123). Thus, for example, similar to equivalent mutations in *S. cerevisiae*, the deletion of *C. neoformans* Sin1 or Ypk1 resulted in hypersensitivity to inhibition of sphingolipid synthesis, and the mutant cells contained low levels of complex sphingolipids (123).

Rapamycin also induced growth inhibition in filamentous fungi, including the human pathogens *Aspergillus fumigatus* (124) and *Aspergillus nidulans* (125). The single gene encoding the TOR kinase in *A. fumigatus* (*Af*Tor1) is essential for growth. However, the use of a conditionally repressible version of *Af*Tor1 in combination with proteomic analysis identified potential protein targets of *Af*Tor1 that are involved in cell cycle regulation, nutrient sensing, and stress response (124). *Af*Tor1 also regulates siderophore biosynthesis and the adaptation to iron starvation, a response that is critical for the virulence of *A. fumigatus* (124). TOR signaling may play an essential role in *Aspergillus* growth via its function as part of TORC2. Thus, for example, the Sin1 homologue in *Aspergillus niger*, RmsA, is required for hyphal elongation and branching (126) and for viability and stress responses (127), reminiscent of the roles identified for TORC2 in cell polarity and stress response in yeasts.

Conservation in the architecture of TOR signaling and the response to rapamycin also exists in phytopathogenic fungi. Rapamycin inhibits the growth and virulence of phytopathogenic fungi, including several species of *Fusarium* (128, 129). Moreover, it was demonstrated that TOR participates in nitrogen metabolite repression (e.g., in *Fusarium fujikuroi* [128]). In addition, the Tap42-type 2A phosphatase module (129) and Sch9 homologues (130) were identified as downstream targets of TOR signaling in *Fusarium graminearum*. Still, better understanding of the response of pathogenic and filamentous fungi to rapamycin or other TOR inhibitors awaits further identification of TOR components, especially the characterization of the distinct cellular roles of TORC1 and TORC2 and the identification of additional components of these pathways.

CONCLUDING REMARKS AND FUTURE PROSPECTS

Since its early discovery as the target for action of rapamycin, TOR has emerged as a central signaling pathway that regulates many different aspects of growth in response to environmental changes, in particular nutritional changes. Regulation of TORC1 in response to nitrogen availability and/or amino acids is the most well-established nutritional response for the TOR pathway. TORC2 may also respond to nutritional changes, but the mechanisms involved are far less well understood. How TOR signaling mediates response to stress conditions, other than nutritional stress, also remains to be determined. The finding that TOR complexes often act as part of feedback loops has suggested that TOR may function primarily as a mediator of cellular homeostasis (17).

The identification of the two TOR complexes marked a breakthrough in our understanding of TOR signaling pathways and rapamycin response. TORC1 and TORC2 are structurally and functionally distinct, and the search for specific TORC1 and TORC2 downstream and upstream effectors is still the focus of many studies. More recent studies suggest that understanding the regulatory links between TORC1 and TORC2 is also critical for understanding the role of TOR in growth control. *Sp*TORC1 and *Sp*TORC2 oppositely regulate several responses to nitrogen starvation including sexual development and transcriptional reprogramming (131). mTORC1 negatively regulates mTORC2 through phosphorylation of several mTORC2-specific components, while mTORC1 and mTORC2 also converge to control certain aspects of metabolism (86). Future studies are expected to unravel the links between TORC1 and TORC2 in more detail.

Finally, *S. cerevisiae* has played a key role in deciphering the mode of action of rapamycin, a drug that has already proved most valuable for the treatment of several human pathologies. The powerful tools of yeast genetics are expected to contribute to further understanding of the mode of action of rapamycin and second-generation ATP-competitive TOR inhibitors. TORC2-specific inhibitors have been much sought after. Whether yeast will also contribute to finding such valuable research tools and possible drugs is an exciting option that at present remains an open question.

Fungal Cell Cycle: A Unicellular versus Multicellular Comparison

26

Ilkay Dörter and Michelle Momany

DNA is the master instruction set, encoding everything that makes cells work. So it is no surprise that faithful duplication of DNA and proper distribution of new copies to daughter cells is highly choreographed and tightly controlled. The appearance of nuclei changes in predictable patterns during the cell cycle, passing through the morphologically uneventful interphase into the dramatic rearrangement of mitosis. The core cell cycle machinery is highly conserved among eukaryotes. Many of the mechanisms that control the cell cycle were worked out in fungal cells, taking advantage of their powerful genetics and rapid duplication times.

The critical insight made by researchers working with fungi in the late 1970s and early 1980s was that distinct cell morphologies could serve as landmarks indicating cell cycle stage. This insight combined with the elegant use of conditional mutants allowed dissection of the control of cell cycle progression, the dependency relationships, and checkpoints that ensure fidelity (1). Hartwell and coworkers used temperature-sensitive mutants arrested in the emergence and enlargement of the bud, the cell division cycle (*cdc*) mutants, to follow the state of the single nucleus of *Saccharomyces cerevisiae* (2). Similarly, Nurse and coworkers used conditional mutants arrested at specific cell sizes, also called cell division cycle (*cdc*) mutants, to follow the nucleus of the fission yeast *Schizosaccharomyces pombe* (3, 4). Morris and coworkers used conditional mutants with abnormal nuclear number and morphology, the blocked in mitosis (*bim*) and never in mitosis (*nim*) mutants, to follow the multiple nuclei of the filamentous fungus *Aspergillus nidulans* (5, 6). In this review we will focus on an overview of the cell cycle in the unicellular budding yeast *S. cerevisiae* and compare and contrast it with the cell cycle of the multicellular filamentous fungus *A. nidulans*, pointing out orthologous gene products where they are known (Table 1). For both fungi, we will consider the cell cycle only during vegetative growth because this is where most studies have been done. It should be noted, however, that in reproductive growth (sporulation) basic cell cycle modules are undoubtedly regulated in different ways.

Though much of the basic cell cycle machinery is evolutionarily conserved, the fact that *S. cerevisiae* is uninucleate and unicellular while *A. nidulans* is multinucleate and multicellular leads to significant differences in cell cycle regulation. In *S. cerevisiae* the single nucleus moves to the neck for division, and septum formation and cytokinesis occur as mitosis ends (7). This tight coupling of mitosis, septation, and cytokinesis means that budding yeast cells always have a single nucleus. In contrast, septation does not follow every mitosis in the filamentous fungus *A. nidulans*, and cytokinesis results in partitioning of cells rather than separation (Fig. 1). Typically, cell cycle studies in *S. cerevisiae* begin with vegetatively budding cells. In contrast, cell cycle studies in *A. nidulans* begin with dormant, asexual spores (conidia). The first two or three rounds of mitosis take place in the initial cellular compartment formed when the conidium breaks dormancy and establishes polarity. After the cell passes a critical size threshold, the next mitosis (typically the third or fourth division, depending on conditions) triggers formation of the first septum dividing the hypha asymmetrically into two compartments (8). Subsequent mitotic divisions are also followed by septation, with the tip cell remaining mitotically active and subapical cells arresting in interphase until branch formation (9).

Many of the cellular events underlying these morphological shifts in *S. cerevisiae* and *A. nidulans* have been described and are themselves landmarks; that is,

Fungal Biology Group and Plant Biology Department, University of Georgia, Athens, GA 30602.

Table 1 Cell cycle proteins discussed in text[a]

Protein function	*S. cerevisiae*	*A. nidulans*	Function
Cell cycle machinery	Cdc28	NimX	Mitotic cyclin-dependent kinase (CDK)
	Clb1		B-type cyclin required for transition from G2 to M phase
	Clb2	NimE	B-type cyclin required for transition from G2 to M phase
	Clb3-4		B-type cyclins needed for formation and elongation of mitotic spindle
	Clb5-6		B-type cyclins that induce replication in S phase
	Cln1-3		G1 cyclins needed to pass START and enter S phase
	Far1		Sc: inhibitor of Cdc28-Cln complex
	Kin3	NimA	Kinase Sc: possible role in DNA damage response An: essential for entry into M phase
	Mih1	NimT	Phosphatase that modifies CDK
	Sic1		Sc: Repressor of B-type cyclins, prevents premature entry into S phase
	Swe1	AnkA	Kinase that phosphorylates CDK and inhibits entry into M phase
FEAR and MEN/SIN networks	Cdc5	PlkA	Polo-like kinase Sc: role in FEAR and MEN pathways An: needed for initiation and progression through M phase
	Cdc14		Phosphatase Sc: needed in MEN
	Cdc15	SepH	Kinase Sc: needed in MEN, promotes mitotic exit An: involved in septation
	Dbf2	SidB	Kinase Sc: MEN component and SPOC component An: SIN component, required for septation and conidiation
	Esp1	BimB	Peptidase Sc: promotes sister chromatid separation An: required for progression through M phase
	Fob1		Negative regulator of FEAR network
	Hct1		Needed for MEN; activator of APC/C complex
	Mob1	MobA	Sc: component of MEN, required for Cdc15-dependent phosphorylation of Dbf2 An: SIN component required for septation and conidiation
	Net1		Inhibitor of Cdc14, keeps Cdc14 in nucleolus
	Slk 19		Promotes Cdc14 release from nucleolus
	Spo12		Promotes Cdc14 release from nucleolus by antagonizing Fob1 function
	Swi5		Transcription factor that triggers the transcription of the CDK inhibitor Sic1
DNA damage and replication checkpoint	Chk1	ChkA	DNA damage response kinase
	Ddc2	UvsD	DNA damage checkpoint protein Sc: binds RPA and ATRIP
	Mec1	UvsB	ATR ortholog Sc: DNA damage sensor for processed DSBs An: DNA damage sensor and inhibits septation in hyphae with DNA damage
	Mre11	MreA	DNA repair protein Sc: MRX subunit, part of the intra-S phase checkpoint
	Pds1		Phosphorylated Pds1 blocks sister chromatid separation
	Rad50	SldI	DNA damage response protein Sc: MRX subunit
	Rad51	UvsC	DNA damage response protein Sc: replaces RPA in DSB repair An: mutants sensitive to DSB
	Rad53	ChkC	DNA damage response protein
	Tel1	AtmA	

(Continued)

Table 1 *(Continued)*

Protein function	*S. cerevisiae*	*A. nidulans*	Function
			ATM ortholog
			Sc: DNA damage sensor for unprocessed DSBs
			An: regulates DNA damage checkpoint, required for polarized growth
	Xrs2	ScaA	DNA repair protein
			Sc: MRX subunit
Spindle assembly and spindle position checkpoints	Bfa1		SPOC, negative regulator of Tem1, also component of MEN
	Bub1	SldA	SAC protein kinase prevents progression into anaphase in presence of spindle damage
	Bub2	BubA	Sc: SPOC, forms complex with Bfa1, also component of MEN
			An: putative SIN component
	Bub3	SldB	SAC protein kinase prevents progression into anaphase in presence of unattached kinetochores
	Cdc20	Cdc20	SAC; activator of APC/C complex
	Ipl1	Aurora	SAC Aurora kinase
	Kin4	KfsA	SPOC kinase
			An: present at septa but not SPBs
	Knl1		SAC KMN complex member
	Lte1		SPOC, positive regulator of Tem1, also component of MEN
	Mad1	Mad1	SAC
			Sc: forms complex with Mad2 and inhibits APC/C
			An: localizes to NPC
	Mad2	Mad2	SAC
			Sc: forms complex with Mad2 and inhibits APC/C
			An: localizes to NPC
	Mps1	Mps1	SAC kinase
			Sc: required for SPB duplication
			An: essential protein kinase
	Ndc80	Ndc80	SAC KMN complex member
			Sc: acts as a scaffold for Mad1/Mad2 complex
	Tem1	SpgA	SPOC, GTPase
			Sc: termination of M phase, also component of MEN
			An: roles in mitotic exit and SIN
Morphogenesis checkpoint	Cdc3	AspB	Septin
			Sc: found in septal ring at mother-bud neck
			An: found at forming septa and conidia, but not shown to be involved in checkpoint
	Cdc10	AspD	Septin
			Sc: found in septal ring at mother-bud neck
			An: found at forming septa and conidia, but not shown to be involved in checkpoint
	Cdc11	AspA	Septin
			Sc: found in septal ring at mother-bud neck
			An: found at forming septa and conidia, but not shown to be involved in checkpoint
	Cdc12	AspC	Septin
			Sc: found in septal ring at mother-bud neck
			An: found at forming septa and conidia, but not shown to be involved in checkpoint
	Elm1		Kinase, recruits Hsl1 to septin ring at mother-bud neck
	Hsl1		Kinase, recruits Hsl7 to septin ring at mother-bud neck
	Hsl7		*N*-Methyltransferase, required for Swe1 recruitment to mother-bud neck

[a]Though orthologs have been predicted based on amino acid conservation, only orthologs with experimental data are included here. Functions are based on annotations in SGD (http://www.yeastgenome.org/) and AspGD (http://www.aspgd.org/) and on references cited in the text. Sc: ortholog in *S. cerevisiae*; An: ortholog in *A. nidulans*. Other abbreviations: DSB, double-strand break; MEN, mitotic exit network; SIN, septation initiation network; SPOC, spindle position checkpoint.

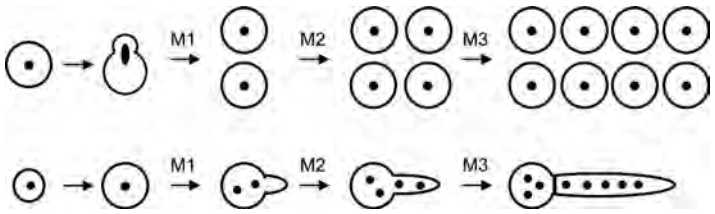

Figure 1 Mitosis, septation, and cytokinesis in *Saccharomyces cerevisiae* and *Aspergillus nidulans*. Three rounds of mitosis in *S. cerevisiae* beginning from vegetatively growing yeast cell (top) compared to *A. nidulans* beginning from dormant conidium (bottom). Black dots are nuclei. M1, M2, and M3 denote the indicated mitotic divisions.

they always occur with the same stage of the cell cycle and thus can be used to anchor and order observations.

S. CEREVISIAE LANDMARKS

The unicellular yeast *S. cerevisiae* propagates by budding, and the cell must grow to a critical size before it initiates a new cycle. Attaining this critical size in the G1-phase (gap 1) of the cycle allows the cell to pass START, which is defined as the point at which the cell irreversibly commits to the mitotic cell cycle (10). The size threshold at START prevents cell size decrease through premature cell cycle progression (11). Though the mechanisms are not clear, START appears to involve some of the same cyclin-dependent kinases (CDKs) and cyclins that drive the cell cycle (see below) (12).

After passing START, the cell enters the S phase (synthesis phase), where DNA and the spindle pole body (SPB) are duplicated (Fig. 2). The SPBs are microtubule organizing centers, functionally equivalent to centrosomes of higher organisms (7). However, unlike in higher eukaryotes, the nuclear envelope does not break down in *S. cerevisiae*, so the SPBs are embedded in the nuclear envelope. During S phase the SPBs separate, forming short microtubule spindles between them. The SPBs continue to separate, eventually reaching the opposite poles of the nucleus, where they anchor the medial spindles thought to function in metaphase (13).

The presence of short spindles during S phase is unusual. In most organisms, spindle formation is one of the defining features of M phase (14). The presence of short spindles during S phase has led to disagreement about whether *S. cerevisiae* has a true G2 phase; consequently, many *S. cerevisiae* researchers use the designation "G2/M." However, the evolutionary conservation of cell cycle processes and careful measurements suggesting that DNA replication finishes before medial spindle assembly has led others to designate a separate G2 phase (7). To make comparisons between *S. cerevisiae* and *A. nidulans* easier, we will use the convention of separate G2 and M phases in this review.

Late in S phase, the actin cytoskeleton polarizes toward a region on the cell surface and directs secretory vesicles to the site of future polarity establishment (15). This leads to the formation of a bud, certainly the easiest S phase landmark to spot in *S. cerevisiae* (Fig. 2).

The G2-phase (gap 2) follows the successful completion of S phase and is characterized by rapid cell growth and protein synthesis, which prepare the cell for mitosis. The M phase (mitotic phase) is subdivided into prophase, metaphase, anaphase, and telophase (Fig. 2). During the closed mitosis of *S. cerevisiae*, regulated active transport through the nuclear pore complexes still occurs (14). During prophase the chromatin condenses and the microtubules of the mitotic spindle attach to the kinetochores. In contrast to higher eukaryotes, yeast chromosomes do not line up at the midzone of the spindle to form a metaphase plate (16). The absence of a metaphase plate can make metaphase difficult to detect, but it is generally defined as the point when all chromosomes show bipolar attachment to the spindle microtubules (13). During anaphase sister chromatids separate and travel to opposite poles and are equally distributed between the mother and daughter cells (17). In telophase chromosomes decondense and cytokinesis rapidly follows, separating mother and daughter cells by contraction of the actomyosin ring and synthesis of a new cell wall between the cell bodies (18).

A. NIDULANS LANDMARKS

While a START commitment point has not been characterized in *A. nidulans*, it seems likely that an analogous size threshold is present, because G1-arrested dormant conidia (19) all expand to a similar size before germ tube emergence (M. Momany, personal observations). Any such size threshold in conidia would be

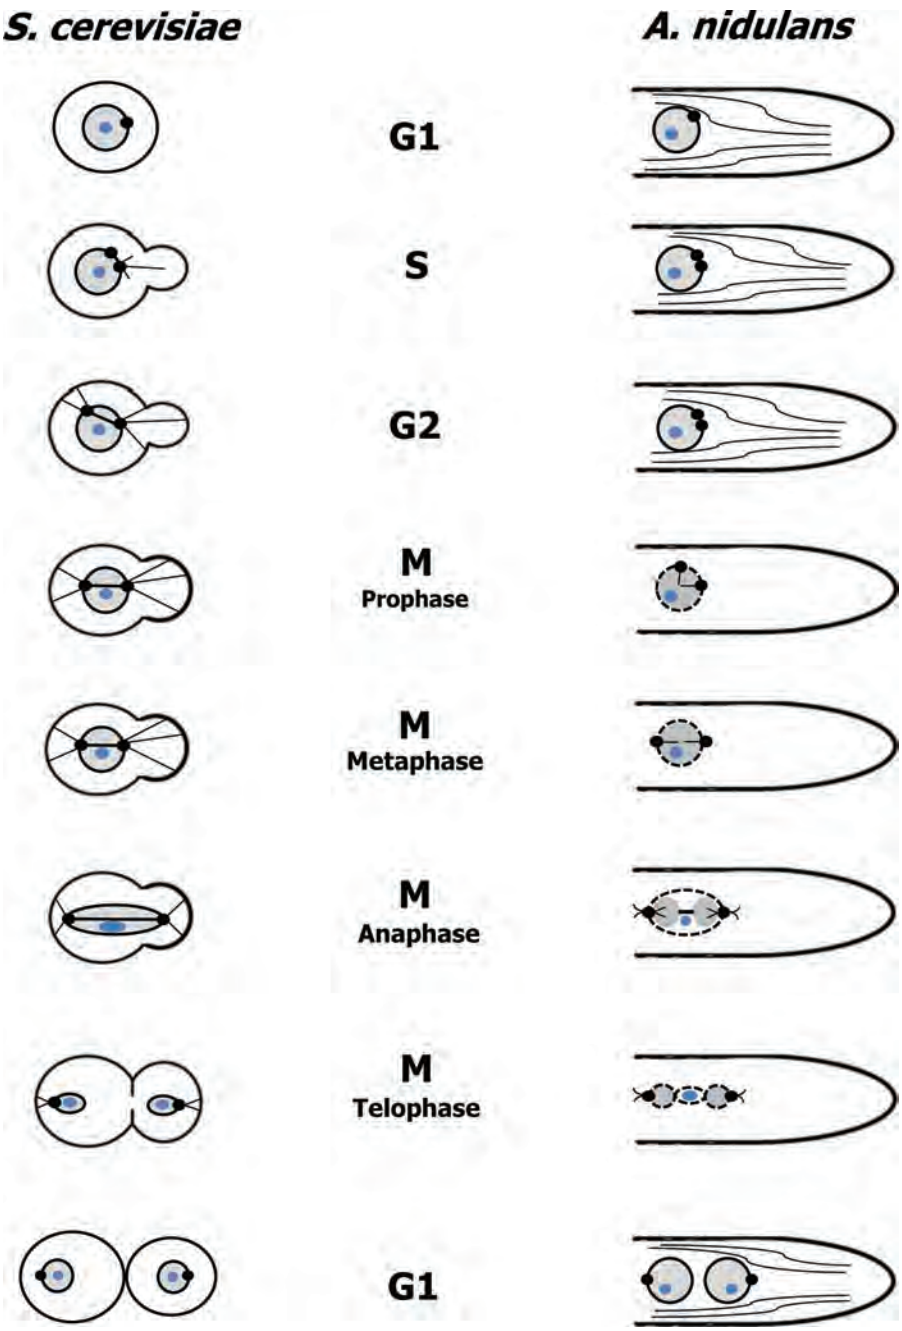

Figure 2 Cell cycle landmarks in *Saccharomyces cerevisiae* and *Aspergillus nidulans*. Major morphological landmarks for each cell cycle stage are shown for *S. cerevisiae* (left) and *A. nidulans* (right). Gray circle, nucleus; solid border, intact nuclear envelope; broken-line border, partial nuclear pore complex disassembly; small black dots, spindle pole bodies; blue dots, nucleolus; lines, microtubules. (Data from references 117 and 120.)

used only once before emergence of the first germ tube, as opposed to START in yeast, which occurs in every cell cycle. It is possible that other commitment points gate entry into subsequent cell cycles in *A. nidulans*. Certainly, a critical size threshold must be crossed in hyphae before septum formation (cytokinesis) can be triggered (20). In S phase (Fig. 2), the nucleus undergoes replication and the spindle pole body is duplicated

(14, 21). The two SPBs do not separate until the cell passes the G2/M boundary (22). As the cell enters mitosis the cytoplasmic microtubules depolymerize (23) and the nuclear pore complexes (NPCs) partially disassemble (14). The partial disassembly of the NPCs allows tubulin molecules to enter and form spindle microtubules originating from the nuclear face of the SPBs (22, 24). In prophase the SPBs move apart (25). Similar to *S. cerevisiae*, the bipolar attachment of chromosomes to the spindle does not trigger the formation of a distinct metaphase plate. During anaphase as the sister chromatids begin to move toward the poles, microtubules between the two SPBs elongate, astral microtubules form on the cytoplasmic face of the SPBs (26), and the segregating DNA is separated from the nucleolus. The nucleolus is excluded to the cytoplasm within telophase, and nucleolar proteins are reimported into the daughter nuclei during G1 (27).

CDKs AND CYCLINS DRIVE CELL CYCLE PROGRESSION

The cell cycle is driven by the interaction of the CDKs with cyclins (7). Cyclins, so named because of their periodic, cyclical expression (28), bind CDKs and regulate their phosphorylation of target proteins. The CDKs and cyclins are themselves regulated via phosphorylation. One of the best-studied CDK/cyclin pairs is CDK1 and cyclin B, which controls entry into mitosis. Many of the details of CDK/cyclin interaction were worked out in *S. pombe*, so the S. *pombe* naming conventions are used. CDK1/cyclin B is phosphorylated by the Wee1 kinase, inhibiting entry into mitosis, and is dephosphorylated by the Cdc25 phosphatase, allowing mitosis to proceed (Fig. 3). As might be expected for such critical control pathways, CDK-cyclin complexes are also regulated by other mechanisms including binding by inhibitors, transcription, and proteolytic degradation. Targeted proteolysis of cell cycle regulators by the ubiquitin proteasome system, including cyclins, helps make the cell cycle irreversible and unidirectional, which imposes a further control mechanism. The degradation takes place at three different time points: during the transition between G1 and S phase, before anaphase, and at mitotic exit (29).

S. cerevisiae Cell Cycle

In *S. cerevisiae* the CDK regulating cell cycle event is Cdc28 (7). Yeast cyclins are divided into two classes: the G1 cyclins Cln1 to Cln3, which predominantly regulate events at the end of G1 and are essential to pass START (30), and the B-type cyclins Clb1 to Clb6, which are expressed between START and mitotic exit (31). CDK-cyclin complexes are themselves regulated by phosphorylation and dephosphorylation (Fig. 3).

G1 phase

Cln3 is expressed early in G1 together with the Cdc28-Cln inhibitor Far1 (32). As G1 progresses levels of Far1 fall below the threshold needed to inhibit the Cdc28-Cln3 complex (33). This allows Cdc28-Cln3 to stimulate the transcription of G1 cyclins including Cln1 and Cln2, pass START, and trigger entry into S-phase (34).

S phase

The Cdc28-Cln1 and Cdc28-Cln2 complexes initiate DNA replication and the events that lead to bud emergence and SPB duplication, two main S phase landmarks (35). In addition, the Cdc28-Cln2 complex stimulates the degradation of Sic1, a repressor of B-type cyclins (36, 37). This enables the activation of the Cdc28-Clb5 and -Clb6 complexes, which induce DNA replication and ensure entry into S phase (38, 39). Cdc28-Clns trigger their own degradation via autophosphorylation (40). S phase ends when DNA synthesis is correctly completed (see "DNA Damage and Replication Checkpoints", below).

G2 phase

As described in the discussion of *S. cerevisiae* landmarks above, the presence of short spindles during S phase in *S. cerevisiae* has led to disagreement about precisely when M phase starts and the existence of G2 phase.

M phase

To enter into M phase the Cdc28-Clb2 (CDK-cyclin B) complex must be activated (Fig. 3). In G2 the Cdc28-Clb2 complex is inhibited by phosphorylation by the Swe1 kinase (41). The inhibitory phosphate is removed by the phosphatase Mih1. The degradation of Swe1, mediated by the morphogenesis checkpoint (see below), generates a positive feedback loop that is responsible for a rapid increase of active Cdc28-Clb complexes. This ensures the entry into M phase and subsequent bud growth (42, 43). In conjunction with Cdc28, the mitotic cyclins Clb1 to Clb4 control the initiation and the progression through the cell cycle. Cdc28-Clb3 and Cdc28-Clb4 trigger the formation and elongation of the mitotic spindle, whereas Cdc28-Clb1 and Cdc28-Clb2 activate the anaphase promoting complex APC/C.

The APC/C degrades G1 cyclins, B-type cyclins, and securin, whose loss initiates the separation of sister chromatids (44). The expression of the Cdc28-Clb

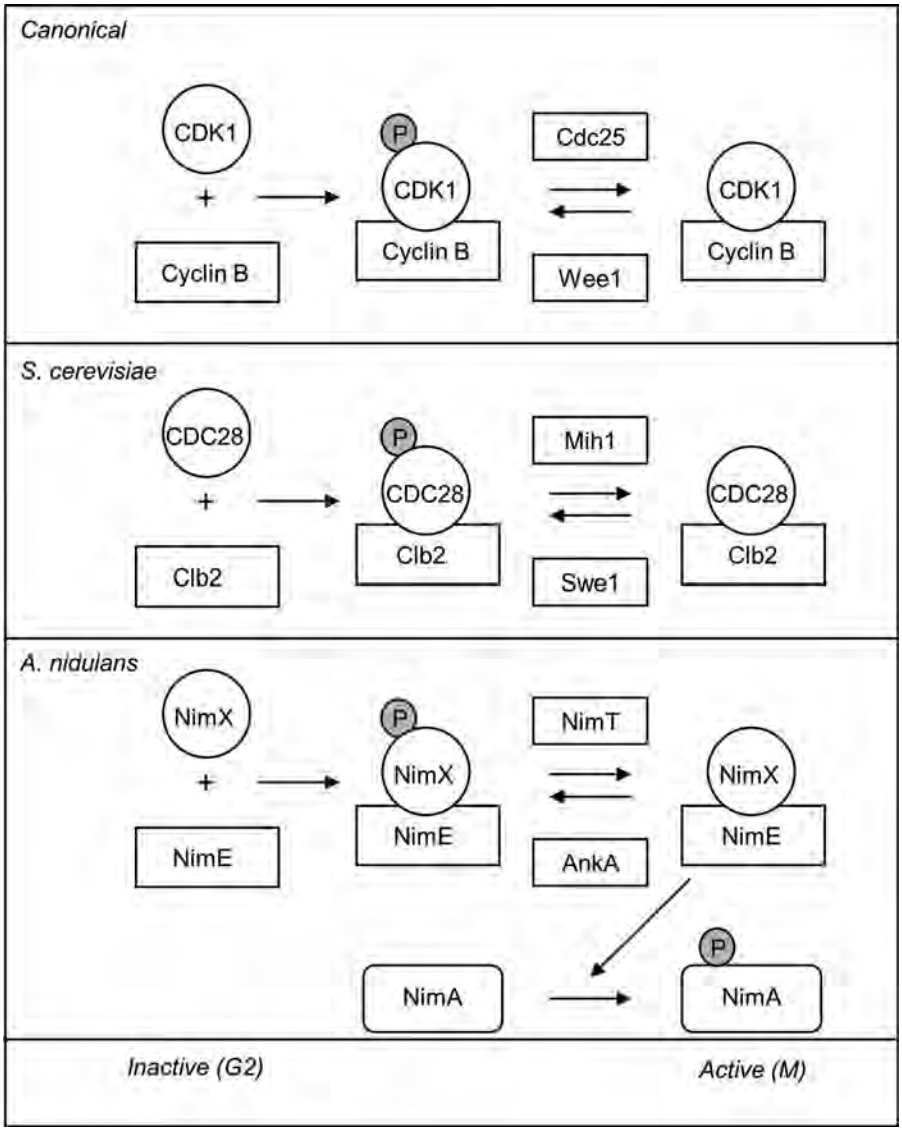

Figure 3 Cyclin-dependent kinase (CDK)/cyclin B regulation. Comparison of CDK and cyclin activity at G2/M phases in *Schizosaccharomyces pombe* (canonical), *Saccharomyces cerevisiae*, and *Aspergillus nidulans*. (Data from reference 52.)

inhibitor Sic1 and activation of the phosphatase Cdc14 is also required for mitotic exit. Sic1 represses B-type cyclins, and Cdc14 dephosphorylates substrates of Cdc28, which reinitiates the G1-phase (45, 46).

The activity of Cdc14 is controlled by the inhibitor Net1, which keeps Cdc14 anchored in the nucleolus and inactive throughout the G1, S, G2, and early M phases (47). Two pathways control the release of Cdc14: the FEAR (Cdc fourteen early anaphase release) network and MEN (mitotic exit network) (Fig. 4). The FEAR network releases Cdc14 from the nucleolus during early anaphase, and the MEN maintains Cdc14 in the released state during late anaphase and telophase. The MEN includes several components that are also part of the spindle assembly and position checkpoints. These are discussed in more detail in the checkpoint section of this review.

The FEAR network includes the separase Esp1, the kinetochore protein Slk19, the nucleolar proteins Spo12 and Fob1, and the polo kinase Cdc5 (48). The protease Esp1 is responsible for the cleavage of cohesins at the onset of anaphase. Slk19 is also a target of this protease, but its role in the FEAR network is still unclear. Cdc5 promotes the activity of the spindle position

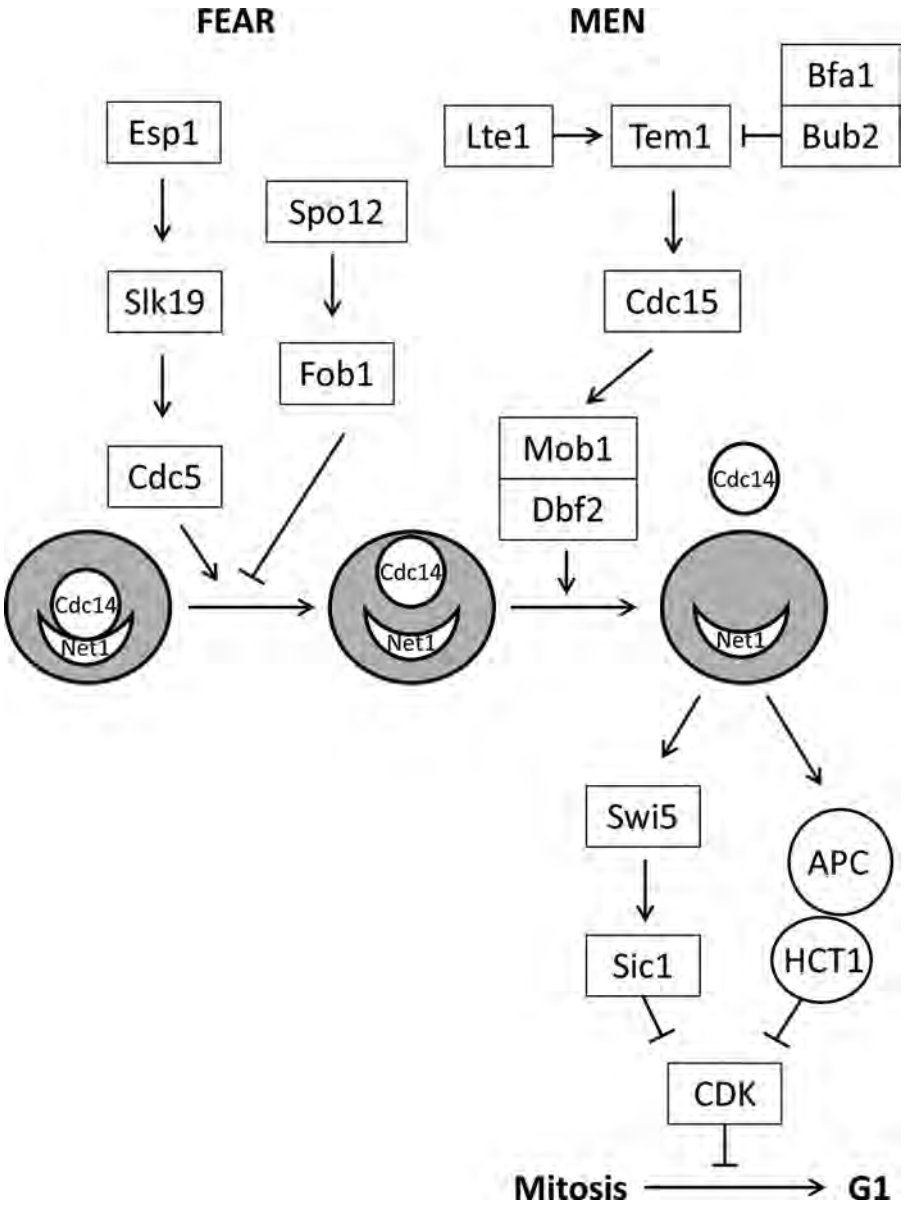

Figure 4 Model of the Cdc fourteen early anaphase release (FEAR) network and mitotic exit network (MEN) at the end of mitosis. In early anaphase in *Saccharomyces cerevisiae* the FEAR network promotes the release of Cdc14 from the nucleolus. In late anaphase the MEN releases Cdc14 from the nucleus into the cytoplasm, where it activates both Swi5 and Hct1. Swi5 triggers the transcription of the cyclin-dependent kinase (CDK) inhibitor Sic1. Hct1 binds the anaphase-promoting complex (APC), and this complex marks Cdk1 for degradation. These events cause the cell to exit mitosis and enter into a new cell division cycle. Gray circles represent the nucleus. (Modified from reference 121 with permission.)

checkpoint protein Dbf2 and probably activates Bub2 and Bfa1 (47). Cdc5 is essential for the release of Cdc14 from the nucleolus and for its maintenance in the released state (49).

The MEN (Fig. 4) consists of several proteins that are part of the spindle assembly checkpoint (SAC) including the GTPase Tem1, its negative regulators Bub2 and Bfa1, and its positive regulator the GDP-GTP exchange factor Lte1. After interacting with Lte1, Tem1 activates Cdc15. The protein kinase Cdc15 then activates the kinase Dbf2 through phosphorylation. Phosphorylated Dbf2 activates proteins involved in septum

formation and cytokinesis (50). Tem1 localizes to the SPB and migrates into the daughter cell during anaphase, whereas Tem1's exchange factor Lte1 localizes to the bud. Tem1 and Lte1 are in the same cellular compartment when the nucleus enters the daughter cell. This ensures that mitotic exit occurs only when the genetic material is distributed between mother and daughter cells (51).

A. nidulans Cell Cycle

In *A. nidulans* NimX is the CDK equivalent of the *S. cerevisiae* Cdc28 (52) (Fig. 3). The only characterized mitotic cyclin is NimE, a homolog of cyclin B, though cyclins involved in development have been investigated (53), and putative cyclin orthologs have been identified based on sequence conservation (54). In addition to the CDK NimX, *A. nidulans* requires a second kinase, NimA, for entry into mitosis. The NimX and the NimA kinases are responsible for the initiation of mitosis in *A. nidulans*, and their inactivation is required for progression through mitosis (55, 56). Interestingly, the *S. cerevisiae* homolog of NimA, Kin3, is not essential and appears to play a role in DNA damage response.

G1 phase

A. nidulans orthologs of the G1 cyclins have been computationally predicted, but they have not been characterized (54). The Ca^{2+}/calmodulin-regulated kinases CMBK and CMKC have both been reported to have roles in progression through G1/S, though how they interact with the other cell cycle machinery is not yet clear (57).

S phase

The CDK cyclin machinery that drives *A. nidulans* entry into and exit from S phase is not well understood, though more is known about the DNA replication checkpoints that allow exit from S phase when DNA synthesis is correctly completed (see checkpoints below).

G2 phase

During interphase NimX is associated with NimE (cyclin B) and phosphorylated by AnkA, the *A. nidulans* homolog of the *S. cerevisiae* phosphatase Swe1 (52, 58, 59). NimX is inhibited (G2 arrest) by AnkA phosphorylation and activated by NimT dephosphorylation (60). However, activation of NimX alone is not sufficient to trigger mitotic entry. A temperature-sensitive mutant version of the NimA kinase (*nimA5*) causes a late G2 arrest at restrictive temperature (61), while the NimX/NimE complex is fully active at the *nimA5* arrest point (62). This demonstrates that NimA is required for the G2/M transition by a mechanism independent from that of NimX. NimX and NimE are excluded from nuclei in G2-arrested *nimA* mutants (59), suggesting that NimA regulates mitotic entry by affecting the localization of NimX/NimE. NimA is located in the cytoplasm throughout G2 (24).

M phase

To exit from G2 and enter into M phase, the NimX-NimE (CDK-cyclinB) complex must be activated (Fig. 3). In G2 NimX is inhibited by phosphorylation by the AnkA kinase. To move into M phase the NimX CDK must be activated by the NimT phosphatase (60). Once activated, the NimX-NimE (CDK-cyclin B) complex phosphorylates and activates the NimA kinase. Subsequently, NimA moves into the nucleus, locates at the spindle poles during mitosis, and is degraded at mitotic exit (63, 64).

Mitotic exit in *S. cerevisiae* is mediated by the MEN. The equivalent network in the fission yeast *S. pombe*, known as the septation initiation network, has been extensively studied. As noted above, in *S. cerevisiae* mitotic exit and cytokinesis are tightly coupled, but they are temporally separated in *A. nidulans*. Mitotic exit in *A. nidulans* is more similar to the *S. pombe* septation initiation network than to the *S. cerevisiae* MEN (65). Both the polo kinase Plo1 and the cyclin-dependent kinase Cdc2/Cdc13 activate the septation initiation network in *S. pombe* and coordinate it with mitotic events (66). Once activated, the upstream GTPase Spg1 activates the downstream protein kinase cascade Cdc7 to Sid1 to Sid2 (67). Ultimately, the Sid2/Mob1 complex is relocated from the spindle poles to the contractile actin ring, where it is required for ring contraction and septum deposition (i.e., cytokinesis) (68).

In *A. nidulans* repeated mitotic divisions without cell separation lead to the formation of a mycelium of multinucleate cells that are separated by multiple septa. Strains carrying a temperature-sensitive mutation in the Ser/Thr protein kinase SepH resulted in a viable strain that failed to septate at restrictive temperature (69). Further studies suggested that SepH is required for the construction of the actin ring (70). It is likely that SepH, which catalyzes the initial event of septum formation, collaborates with other proteins such as SidB and MobA (70, 71). In *S. pombe* Mob1, the ortholog of MobA, is associated with Sid2, the ortholog of SidB. Mutant versions of SepH, SidB, or MobA do not impair hyphal growth or colony formation in *A. nidulans*, whereas their respective orthologs Cdc7, Sid2, or Mob1 are essential for cytokinesis in *S. pombe*. This shows that cytokinesis is essential in the uninucleate

fission yeast but not in the vegetative growth of the multinucleate, filamentous fungus *A. nidulans* (71).

CHECKPOINTS GUARD CELL CYCLE TRANSITIONS

As described above, there are several CDK-cyclin-dependent mechanisms that establish the correct order of cell cycle events including size control at START, phase-specific gene expression, posttranslational modification (especially phosphorylation and dephosphorylation), and targeted proteolysis. In addition, critical cell cycle events are monitored by a series of checkpoints that halt progression to the next phase until key events are complete and error free (72). A checkpoint generally consists of sensors that monitor the completion of a cell cycle event, transducers which forward information from the sensor, and effectors that halt cell cycle progression (73) (Fig. 5). Checkpoints are usually identified through the use of toxic agents that cause major damage and thus impose an exaggerated cell cycle delay while damage is repaired, but surveillance of major cell cycle events by checkpoints occurs under normal (nonstressed) growth conditions too (74, 75). For example, the cell uses many of the same proteins to perform routine DNA repair and to trigger the DNA damage checkpoint (76).

DNA Damage and Replication Checkpoints

The evolutionarily conserved DNA damage checkpoint ensures that DNA is correctly and completely replicated before mitosis is triggered. This checkpoint is one branch of the DNA damage response pathway (or network) that also includes branches that trigger DNA repair, damage-induced transcription, and in multicellular organisms, apoptosis (76). The DNA damage checkpoint is triggered by double-strand breaks (DSBs) or replication fork stalls. Depending on when the checkpoint is triggered, cell cycle progression can be delayed or halted at the G1/S or G2/M boundaries by downregulating the appropriate CDK, or the checkpoint can slow down replication by preventing more origins from firing (sometimes called the "intra-S" or "slowed-S" checkpoint) (77–79). The G2/M block in the DNA damage checkpoint is covered below with an emphasis on checkpoint-specific components rather than replication and repair machinery that also play roles in the checkpoint.

S. cerevisiae

In *S. cerevisiae* the sensors for DNA damage can include repair and replication complex proteins (which can also be effectors) along with phosphatidylinositol-3-OH-like kinases (79). The sensor for processed DSBs and replication fork stalls is the phosphatidylinositol-3-OH-like kinase Mec1 (ATR in mammals), and for unprocessed DSBs the sensor is Tel1 (ATM in mammals) (80, 81). Both of these DNA damage sensors and their interacting proteins are physically associated with the DNA repair machinery and replication forks (Fig. 6).

Before DNA is replicated in S phase, the double helix is opened up by a multiprotein complex. DNA binding proteins, helicases, polymerases, and other specialized proteins are recruited to form the replisome which makes new DNA strands bidirectionally at the fork. Replisomes can stall when they hit obstacles or when nucleotide pools are low. When replisomes stall, helicase and polymerase activities are uncoupled, which produces excess single-stranded DNA (ssDNA). It is this excess ssDNA along with the RPA (replication protein A) that coats it which appears to be the physical trigger for the DNA damage checkpoint. Ddc2, the *S. cerevisiae* ATR interacting protein ortholog, binds to RPA and associates with Mec1, thus targeting it to sites of DNA damage.

To repair DSBs, multiple proteins are recruited to the lesion, including the MRX complex (Mre11, Rad50, Xrs2; called MRN in mammals). The MRX complex in turn recruits the *S. cerevisiae* ATM ortholog Tel1. In the process of repairing DSBs, the DNA repair machinery makes 3′ssDNA tails. The RPA complex coats these ssDNA tails, which leads to recruitment of Mec1 and DNA damage checkpoint activation. RPA is later displaced by Rad51 and Rad52.

Several activators of Mec1 (the ATR kinase) are needed for its full activity, including Rad17-Mec3-Ddc1 (the "9-1-1 complex" in mammals) (81). Activated Mec1 phosphorylates DNA damage response kinases Rad53, Chk1, and Dun1. In *S. cerevisiae* the DNA damage checkpoint ultimately blocks sister chromatid separation by phosphorylation of Pds1. In most other organisms, including mammals and *S. pombe*, the DNA damage checkpoint acts by phosphorylation of the CDK1 and a block at the G2/M boundary, often through inhibition of the Cdc25 phosphatase.

A. nidulans

The *A. nidulans* DNA damage checkpoint appears to have the same basic structure as that of *S. cerevisiae*. *A. nidulans* has an ATR kinase ortholog, UvsB, and an ATM kinase ortholog, AtmA. Based on sensitivity of deletion mutants to genotoxic agents, the *A. nidulans* ATM appears to be mainly involved in repair of DSBs,

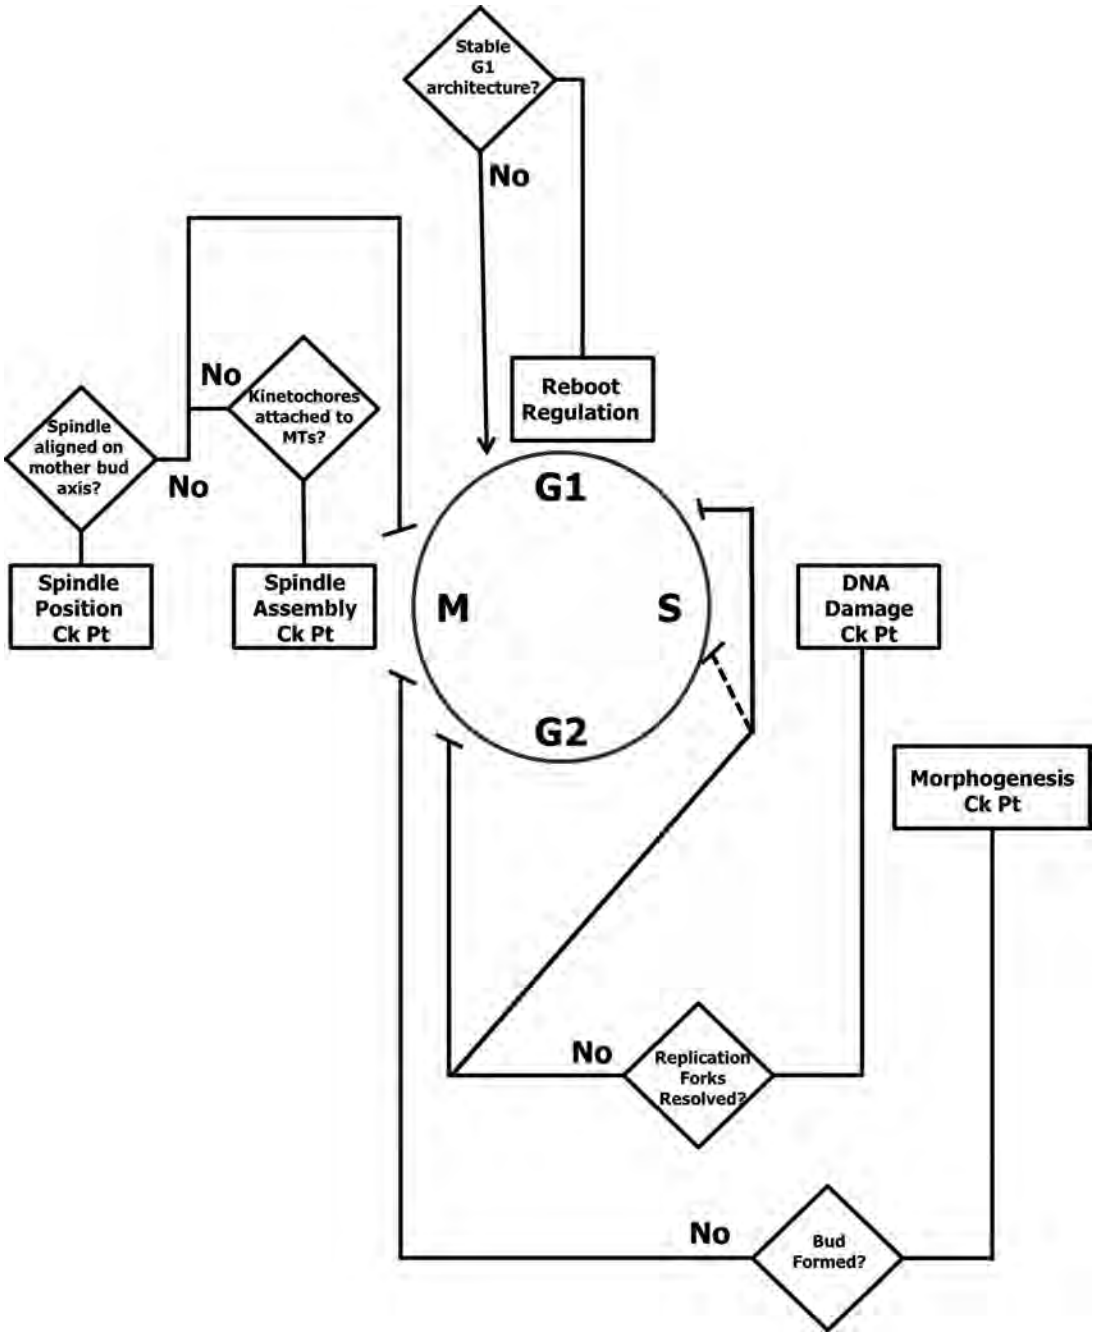

Figure 5 Cell cycle checkpoints in *Saccharomyces cerevisiae* and *Aspergillus nidulans*. Sensors (depicted as rectangles) monitor the completion of specific cell cycle events (depicted as diamonds) and forward the information to effectors that halt or reboot the cell cycle. G1: Reboot regulation (not reported in *S. cerevisiae*). S phase: DNA damage network includes branches that are responsible for DNA repair and damage-induced transcription. Depending on when the checkpoint is triggered, cell cycle progression can be delayed or halted at G1/S or G2/M boundaries or DNA replication can be slowed (shown as dotted line). S/G2: Morphogenesis checkpoint (not reported in *A. nidulans*). M phase: Spindle assembly checkpoint (SAC) and spindle position checkpoint (SPOC) SAC arrests at metaphase, preventing anaphase. SPOC not reported in *A. nidulans*. (Data from reference 122.)

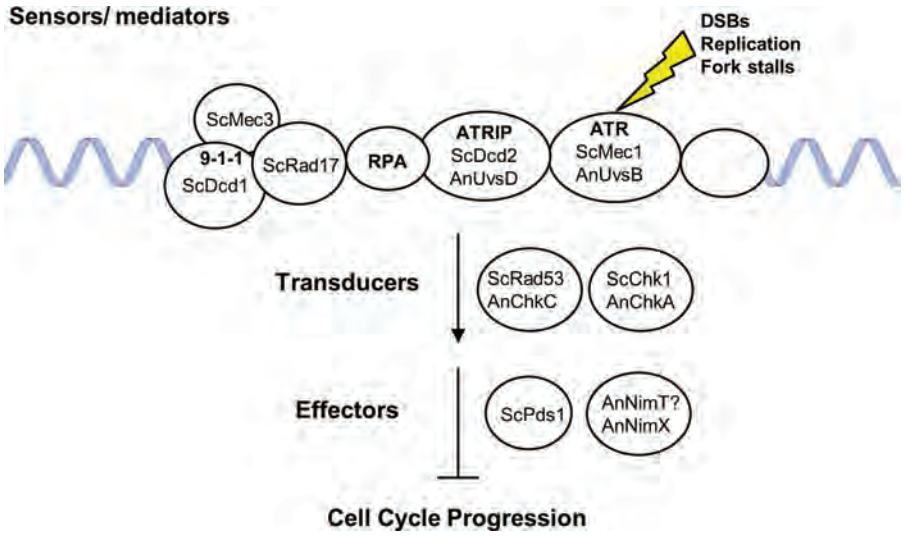

Figure 6 DNA damage checkpoint in *Saccharomyces cerevisiae* and *Aspergillus nidulans*. Sensor proteins monitor DNA damage and transmit the information to transducers and effectors that ultimately modulate the cell cycle. Only proteins discussed in text are shown. DSB, double-strand break; RPA, replication protein A; ATRIP, ATR interacting protein. (Data from reference 80.)

while ATR recognizes both DSB and replication fork stalls (52, 82–86).

Unlike *S. cerevisiae*, but like most other organisms, the DNA damage checkpoint in *A. nidulans* triggers an arrest at the G2/M boundary by inhibitory phosphorylation on NimX, the CDK1/Cdc28 ortholog. It is not yet clear how the Cdc25 phosphatase (NimT) and Wee1 kinase (AnkA) are involved in this process. Also different from *S. cerevisiae*, the *A. nidulans* ATM (AtmA) and ATR (UvsB) appear to be partially redundant because the double ATM/ATR mutant is nonviable (86). In addition to its role in regulating the DNA damage checkpoint, UvsB/ATR inhibits septation in predivisional hyphae that have sustained DNA damage (85, 87, 88). Similarly, in addition to its role in the damage response, AtmA is required for polarized growth (89, 90).

Another possible DNA damage checkpoint in *A. nidulans* includes the nuclear pore protein SonB. The *nimA* G2 arrest can be suppressed by mutations in *sonB*, first identified as a suppressor of *nimA* (91). Certain *sonB* mutants are hypersensitive to DNA damage but have a functional G2 DNA damage checkpoint. These same mutants also show synthetic lethality with mutants in the MRX complex member *scaA*, leading to the suggestion that SonB might play a novel role in the DNA damage response pathway in *A. nidulans* (52, 82).

SACs and Spindle Position Checkpoints

For proper chromosome segregation at anaphase, sister chromatids must be stably attached to opposing spindle microtubules so that they will be pulled in opposite directions. The SAC monitors the attachment of chromosomes to microtubules at kinetochores and prevents the transition from metaphase to anaphase until all sister chromatids are properly attached (92, 93). The transition from metaphase to anaphase is driven by the anaphase-promoting complex/cyclosome (APC/C), a multisubunit E3 ubiquitin ligase, which targets securin, along with other cell cycle proteins, for degradation. The APC/C is activated by binding to Cdc20. The presence of even a single unattached kinetochore triggers the assembly of the mitotic checkpoint complex (MCC), which binds to Cdc20 and prevents it from activating the APC, thereby halting anaphase and cell cycle progression.

S. cerevisiae

The main components of the SAC were discovered in the early 1990s through *S. cerevisiae* mutants that did not arrest in metaphase in the presence of spindle toxins. These include the products of the mitotic arrest deficient (MAD) genes *MAD1*, *MAD2*, and *MAD3* and the budding uninhibited by benzimidazole (BUB) genes *BUB1* and *BUB3*, which are highly conserved in all eukaryotes (94).

Kinetochores are decorated with multiple KMN complexes (Knl1, Mis12, and the Ncd80 complex) that work together like "molecular Velcro" to bind microtubules (93) (Fig. 7). The SAC kinase Mps1 associates with kinetochores in early mitosis, an association that requires the Ncd80 complex and is regulated by the Ilp1 Aurora kinase. Ilp1 detects improper tension between sister chromatids and phosphorylates microtubule binding sites, thereby destabilizing the connection between kinetochores and spindle microtubules. As a consequence, the SAC is activated and SAC components are recruited to the kinetochore to form the MCC (Mad2, Mad3, Bub3, and Cdc20) (92). Mad2 can exist in two conformations: the inactive open form (Mad2-O) and the active closed form (Mad2-C). Through binding to Mad1, Mad2 undergoes a conformational change from inactive (Mad2-O) to active (Mad2-C), forming a stable Mad1-Mad2-C complex (95). This complex is recruited to the unattached kinetochore and serves as a receptor for the recruitment of more inactive Mad2-O protein from the cytoplasm. After binding to the Mad1-Mad2-C receptor, the inactive Mad2-O is converted into an active Mad2-C, which facilitates the binding of Cdc20 (96). The resulting MCC binds the APC/C and inhibits its activity (97, 98). The MCC itself is unstable and must continually be renewed to maintain the SAC block on cell cycle progression in the presence of unattached kinetochores.

APC/C inhibition is released once all sister chromatid kinetochores are properly associated with microtubules. Properly attached kinetochores no longer trigger high levels of Mps1 kinase activity and the resulting Mad1 and Mad2 recruitment. Quick inactivation of the SAC signal also requires dynein, which transports previously activated SAC proteins toward the microtubule poles, and the protein phosphatase 1,

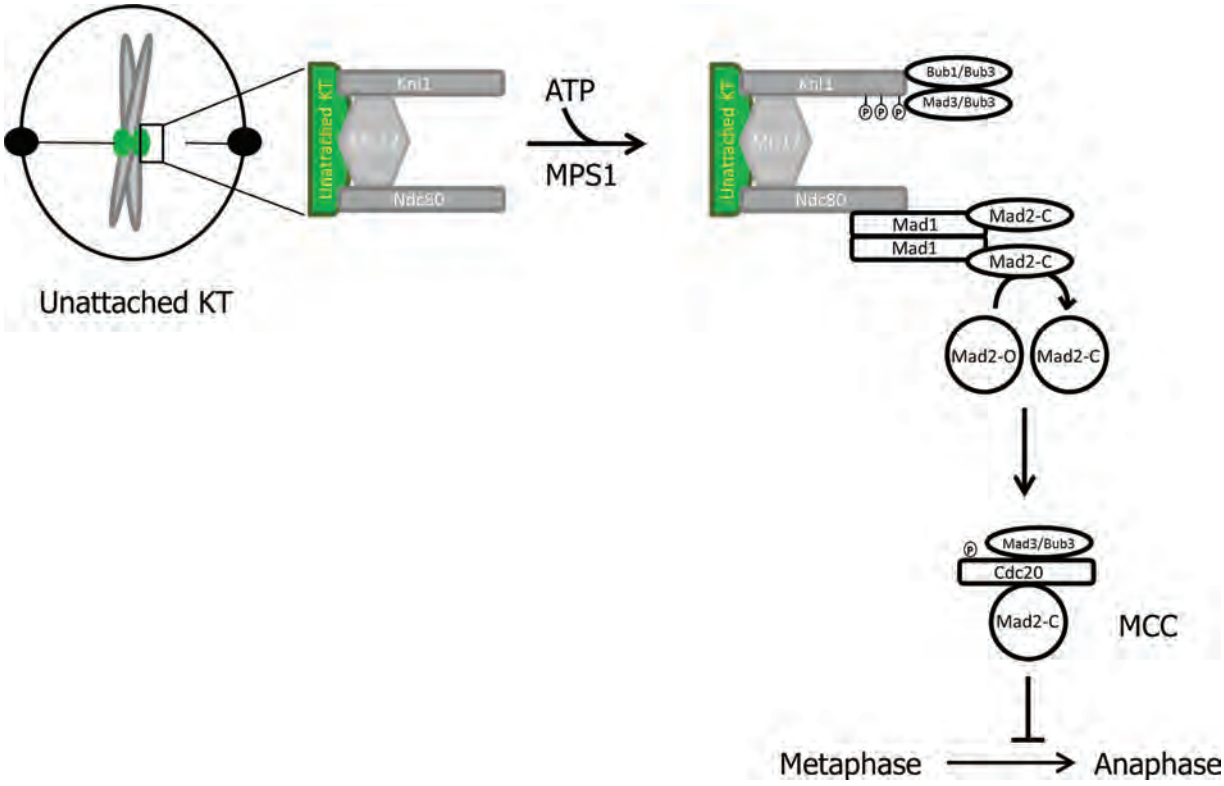

Figure 7 Spindle assembly checkpoint (SAC) in *Saccharomyces cerevisiae*. Unattached kinetochores activate the SAC response by recruiting MPS1, which phosphorylates Knl1. The KMN (Knl1-Mis12-Ndc80) network serves as a scaffold for the recruitment of checkpoint proteins. Binding of Bub1/3 promotes the recruitment of the Mad1/Mad2 core complex. Kinetochore-bound Mad1/Mad2 catalyzes the conformational change of the open Mad2-O to the closed Mad2-C form. Mad2-C interacts with Cdc20 and forms the mitotic checkpoint complex (MCC) consisting of Cdc20, Mad2-C, BubR1, and Bub3. This inhibits the anaphase-promoting complex activator Cdc20 and blocks the metaphase to anaphase transition. KT, kinetochore. (Data from reference 92.)

which dephosphorylates kinetochore substrates necessary for the formation of the MCC (93, 99, 100).

After anaphase is triggered, another checkpoint must be satisfied before *S. cerevisiae* cells are permitted to exit mitosis. The spindle position checkpoint prevents cells with misaligned spindles from exiting mitosis (101) (Fig. 8). Tem1, a RAS-like GTPase that controls the MEN, is the key protein in this process. In response to spindle alignment defects, the GTPase-activating dimer complex Bub2/Bfa1 accelerates GTP-hydrolysis of Tem1, maintaining it in its GDP-bound inactive form. Support is provided by the Ser/Thr kinase Kin4, which protects Bub2/Bfa1 from an inhibitory modification by the polo-like kinase Cdc5 (102). The subcellular localization of these proteins changes during the cell cycle. From G1 to metaphase the inactive Tem1 and Bub2/Bfa1 complex are located at both SPBs. The amount of Tem1 increases at the SPB of the daughter

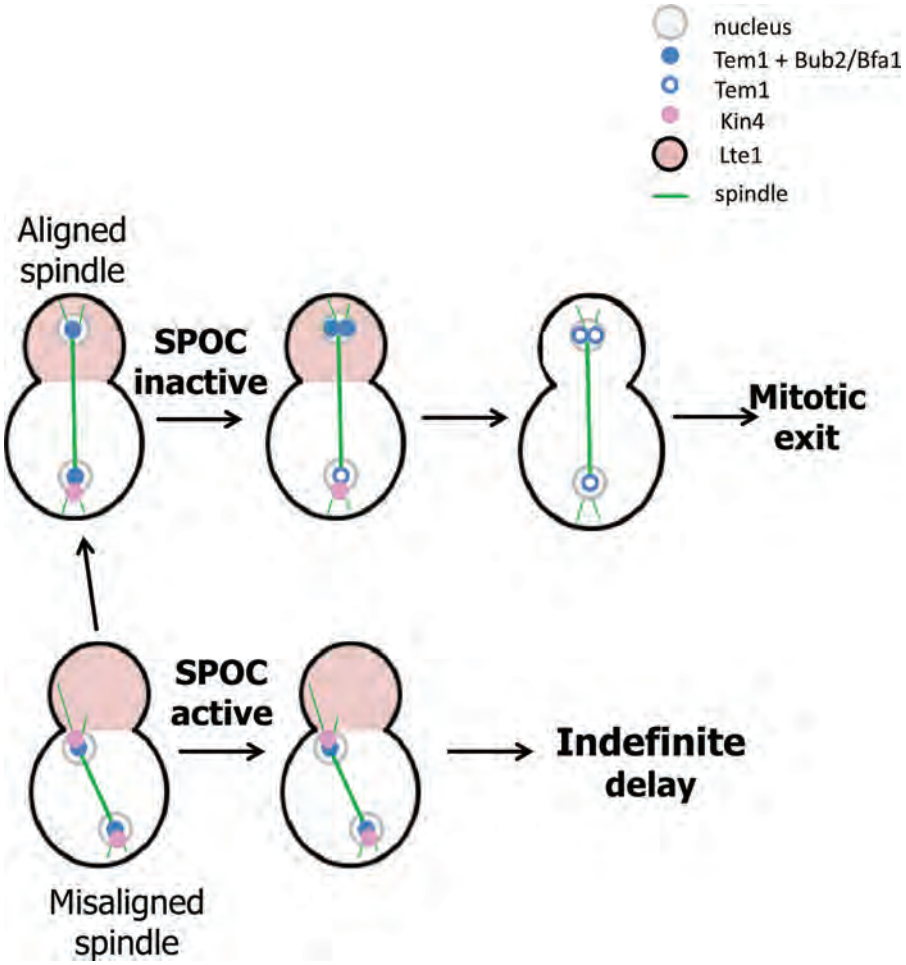

Figure 8 Spindle position checkpoint (SPOC) controls mitotic exit in *Saccharomyces cerevisiae*. When the spindle is misaligned, Bub2/Bfa1 keeps Tem1 in its inactive form. Kin4 protects Bub2/Bfa1 itself from an inhibitory modification. Bub2/Bfa1 disappears from the mother cell once one spindle pole body (SPB) is correctly positioned in the daughter cell. At the same time the amount of Tem1 and Bub2/Bfa1 increases at the SPB of the daughter cell. Lte1, which is located at the cortex of the daughter cell, activates Tem1, and Bub2/Bfa1 is phosphorylated by the polo kinase Cdc5. Bub2/Bfa1 disappears from the daughter cell, whereas Kin4 is removed from the SPB of the mother cell. Simultaneously, Lte1 diffuses into the cytoplasm of the mother and daughter cells. It is possible that all these events contribute equally to the activation of the mitotic exit network. The nucleus is depicted as a gray circle, and the pink highlighted part of the cell shows Lte1 in the cytoplasm. The blue empty circle represents the GTPase Tem1, and the blue filled circle is Tem1 associated with the dimer complex Bub2/Bfa1. (Data from reference 123.)

cell once the correctly positioned spindle passes the bud neck. Here Bub2/Bfa1 is inhibited by the polo kinase Cdc5. Lte1, which is exclusively localized at the cortex of the daughter cell, activates Tem1, which phosphorylates the protein kinase Dbf2 and initiates the MEN (102).

A. nidulans

Much of the SAC machinery is conserved between *A. nidulans* and *S. cerevisiae* (22). Consistent with *A. nidulans* undergoing a semiopen mitosis, in which NPCs partially disassemble, rather than a closed mitosis as in *S. cerevisiae*, *A. nidulans* possesses a layer of additional spatial regulation. In interphase, An-Cdc20 and SldA (the *A. nidulans* homolog of Bub1) are in the cytoplasm, An-Mps1 is at SPBs, An-Mad1 and An-Mad2 are localized to the nuclear periphery, and SldB (the *A. nidulans* homolog of Bub3) is in the nucleoplasm (22, 103). After the partial disassembly of the NPCs at mitosis, An-Mad1 and An-Mad2 enter the nucleus and concentrate at unattached kinetochores. Subsequently, SldA (Bub3) and An-Cdc20 enter the nucleus and accumulate at the SPB/kinetochore complex. An-Cdc20 spreads through the nucleus while SldB leaves it (22). The SAC mitotic arrest in *A. nidulans* has a finite life span and is actively turned off, even when cells cannot make a mitotic spindle (104, 105).

No spindle position checkpoint has been identified in *A. nidulans*. This is not surprising, because in *S. cerevisiae* determination of the cytokinetic division plane precedes mitosis, and the spindle must later be aligned to deposit one set of chromosomes each in mother and daughter (101). Because conidiophore formation in *A. nidulans* requires multiple coordinated budding steps, it is possible that a spindle position checkpoint might be involved in asexual reproduction.

Morphogenesis Checkpoint

In *S. cerevisiae* the morphogenesis checkpoint delays mitosis until the bud is of a suitable size to receive the daughter nucleus. The morphogenesis checkpoint has not been found in other organisms, but it would be surprising if the principle of ensuring proper morphology before mitosis is not eventually found elsewhere.

S. cerevisiae

Yeast cells contain a highly polarized actin cytoskeleton that is responsible for polarized growth and therefore bud formation (106). Perturbation of actin polymerization was shown to delay bud formation but not to uncouple the budding cycle from the cell cycle (107). This suggested the presence of a checkpoint mechanism that monitored bud formation. Mutant strains lacking the protein kinase Swe1 display a functional cell cycle under normal conditions (41) but do not arrest when actin polarization is impaired (108). Under normal conditions, septins, filament-forming cytoskeletal proteins encoded by *CDC3*, *CDC10*, *CDC11*, and *CDC12*, produce an hourglass-shaped collar at the bud neck between the mother and daughter cell (109) (Fig. 9). After bud emergence the "bud sensor" Elm1 and the protein kinase Hsl1 are recruited to the bud side of the septin collar and recruit the methyltransferase Hsl7 (110, 111). As a consequence, a subpopulation of Swe1 is transported from the nucleus to the neck region (112), where Swe1 is degraded. This leads to a depletion of nuclear Swe1, which promotes cycle progression because Swe1 normally inhibits Cdc28 via phosphorylation. Actin depolymerization and delayed budding activate the morphogenesis checkpoint, which stabilizes

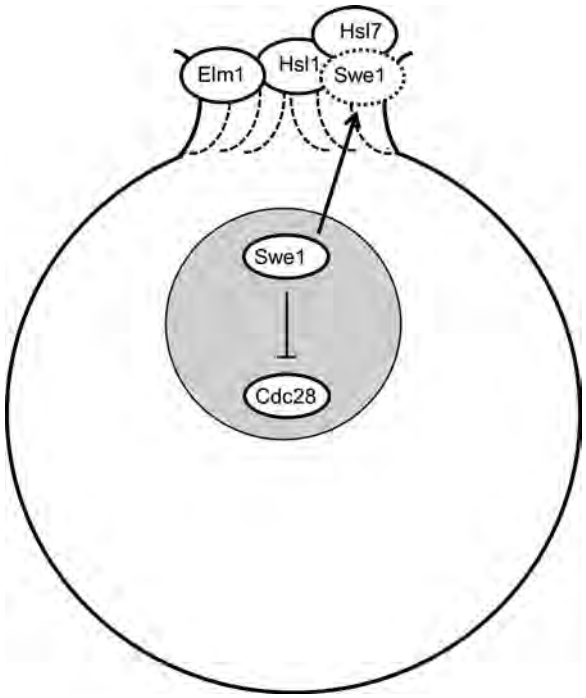

Figure 9 Summary of the morphogenesis checkpoint in *Saccharomyces cerevisiae*. In the nucleus the kinase Swe1 inhibits Cdc28 via phosphorylation. When the bud emerges, Elm1, Hsl1, and Hsl7 are recruited to the bud side of the septin collar and in turn recruit a subpopulation of Swe1 from the nucleus to the bud side of the septin collar, where it is degraded. This depletes nuclear Swe1 and allows progression into mitosis. Actin depolymerization and delayed budding activate the morphogenesis checkpoint, which stabilizes Swe1. Dotted lines represent the septin collar between mother and bud. The gray circle represents the nucleus. Swe1 with a solid border is stable and active. Swe1 with a broken line border is destabilized. The arrow shows recruitment of Swe1 from the nucleus.

Swe1 by blocking its degradation (113). Swe1 inhibits the Cdc28 CDK1 (114).

A. nidulans

Though no morphogenesis checkpoint has been identified yet in *A. nidulans*, it is possible that an analogous mechanism exists, especially in the budlike process of conidiophore formation. Conidiophore development is severely disorganized in septin deletion mutants, consistent with the possibility of a septin-dependent morphogenesis checkpoint operating at this developmental stage (115, 116).

Reboot Regulation

Classic checkpoints halt cell cycle progression when requisite events are not correctly completed to provide sufficient time for repair. But what happens when errors in cell cycle key events cannot be repaired, regardless of time? In recent work Osmani and colleagues uncovered a situation where cells appear to back up and retry cell cycle transitions multiple times, a mechanism they dubbed "reboot regulation" (117). Though reboot regulation has not yet been reported in any organism other than *A. nidulans*, it would be surprising if it was not more widespread.

S. cerevisiae

Reboot regulation has not yet been reported in *S. cerevisiae*.

A. nidulans

The eukaryotic nucleus is enclosed by a nuclear envelope (NE), which consists of an outer and an inner nuclear membrane separated by a perinuclear space (118). NPCs are large assemblies that span pores in the NE and control the nuclear transport of macromolecules across the double-membraned NE (119). *A. nidulans* undergoes a semiopen mitosis in which the NE remains largely intact, the NPCs partially disassemble, and the nucleolus is expelled from the nucleus (24, 27). After mitotic exit, functional G1 nuclei once more contain intact NPCs that gate transport and contain nucleoli.

By following NPC gating of RFP (red fluorescent protein) fused with a nuclear organization signal (NLS-RFP) and nucleolar markers, a recent study uncovered an unexpected cell cycle regulatory mechanism (117). In the absence of the inner nuclear membrane protein Src1, nuclei exit mitosis, move into G1, but then cycle back into mitosis based on NPC modifications and disassembly of nucleoli. Nuclear transport appears to be properly controlled, leading to the suggestion that there is a defect in G1 architecture. This cycle of M to G1 can repeat multiple times, indicating that the G1 nucleus is not stable. Osmani et al. coined the term "reboot regulation" to describe this cycling between M and G1 (117). They suggest that there are errors in nuclear architecture that cannot be repaired by simply allowing more time and, in these cases, the cell must dismantle and rebuild the nucleus. As the authors point out, a precedent for the cell dismantling and rebuilding incorrectly formed nuclear structures is seen in Aurora kinase action on improper spindle/kinetochore attachments. Reboot regulation promotes repetition of defective cell cycle transitions until the architectural defect is corrected (117).

CLOSING THOUGHTS

The successful cell cycle must accomplish two critical tasks: duplicating DNA and partitioning it to daughter nuclei. CDK-cyclin complexes and their regulators reliably drive the cycle forward between phases, but the timing of several critical events within the cycle are at least somewhat stochastic. The length of time it takes polymerases to synthesize new copies of DNA can be influenced by the state of DNA condensation, the supply of nucleotides, and the temperature. Similarly, kinetochore capture depends on collisions of spindle microtubules with the appropriate kinetochore region of chromosomes. It is not surprising then that surveillance (checkpoint) mechanisms have evolved to ensure that prerequisite events occur before the cycle proceeds.

We certainly have not yet found all of the surveillance mechanisms that ensure the integrity of the cell cycle. Undiscovered checkpoints seem especially likely in the case of filamentous fungi and higher organisms where nuclei must be coordinated across multiple compartments. How cell cycle signals are integrated across multiple compartments in differing developmental states is a particularly exciting question and one that studies on filamentous fungi are poised to answer.

Acknowledgments. *We thank Stephen A. Osmani (Ohio State University) and Lukasz Kozubowski (Clemson University) for critical reading of the manuscript.*

A Matter of Scale and Dimensions: Chromatin of Chromosome Landmarks in the Fungi

27

Allyson A. Erlendson, Steven Friedman, and Michael Freitag

CHROMATIN: AN ASSEMBLY OF DNA, PROTEINS, AND RNA

Chromosomes of fungi are linear segments of DNA, covered by a diverse assembly of RNA and proteins. They contain three landmarks required for function, namely, origins for DNA replication, centromeric DNA as attachment points for kinetochores, and telomere repeats to circumvent the end replication problem for linear DNA. Because fungi have been excellent model organisms for trail-blazing basic research since the adoption of *Neurospora crassa* as one of the workhorses for genetics in the 1940s (1), much of the foundation for general knowledge of eukaryotes was first uncovered with fungi, specifically the four species uniquely suited for genetics, biochemistry, and genomics: *Schizosaccharomyces pombe*, *Saccharomyces cerevisiae*, *Aspergillus nidulans*, and *N. crassa*. This has also been true for studies on chromatin and chromosomes.

Chromatin, the building material for chromosomes, is an assembly of DNA, proteins, and RNA, organized into nucleosome units, most of which contain octamers of canonical core histone proteins (2). The three landmarks on chromosomes mentioned above—origins of replication, telomeres, and centromeres—are characterized by different specialized chromatin modifications, for example, DNA base modifications such as cytosine or adenine methylation, and posttranslational modifications of histones; it is the set of gene silencing modifications at those chromosome landmarks that will be examined here in more detail. The occupancy of proteins binding specialized nucleosomes, and the presence of regulatory RNA species, also affects regional chromatin composition. Because this chromatin composition is generally heritable through mitosis or meiosis yet the underlying DNA base sequence is not changed, these variable chromatin compositions are considered by some as "epigenetic," acting above the DNA level to effect gene regulation, including large-scale changes in chromosome structure (2).

Since the isolation of the first histone acetyltransferase enzyme from the ciliate *Tetrahymena thermophila* (3), chromatin biology has undergone a revolution, reflecting the importance of studying transactions carried out on DNA within the normal cellular context rather than with purified DNA. In the model organisms, studies of transcriptional and posttranscriptional gene silencing, DNA methylation, cell cycle control, and the production of secondary metabolites have driven the work on chromatin structure and modification. Much of what we know about histone modification enzymes, RNA interference, and cell cycle control was first addressed in *S. cerevisiae* and *S. pombe* (4, 5). Thus, fungi have been at the cutting edge of this emerging discipline, and many recent reviews are available for exploring the details of yeast chromatin and epigenetics (4–13) or chromatin of other, mostly filamentous, fungi (14–26). One important purpose of this contribution is to suggest where additional data are necessary to better define the structure and function of chromatin and chromosomes in the fungi.

The scale of observation is important to develop a complete picture of chromatin and chromosome dynamics: are we observing a single gene, a region of coregulated genes, specific landmarks such as telomeres

Department of Biochemistry and Biophysics, Oregon State University, Corvallis, OR 97331.

or centromeres, whole chromosomes, or the entire set of chromosomes? Scale will affect the representation of and our thinking about the segments observed, because genes or even whole chromosomes are often drawn as simple scalar plots or histograms, even though in the nucleus, chromosomes fold and interact in a nonlinear way and in three-dimensional space. High-resolution cytology (27) and sequencing-based techniques such as chromosome conformation capture (3C) followed by high-throughput sequencing (Hi-C) (28) allow unprecedented studies on fungal chromosome dynamics. Lastly, one important goal for chromatin and chromosome research in the near future will be to capture dynamic processes across time, and also at different scales, for example, milliseconds for changes in transcription upon induction by small molecules, to minutes or hours during mitosis and cytokinesis, or across a whole day when studying circadian rhythms. Under these various conditions metastable or stable rearrangements of chromatin complexes occur, some of which alter the structure of whole chromosomes in the nucleus. This is where traditional model species excel and are exceedingly useful, because of their large arsenal of methods and strains.

Of course, the kingdom Mycota is much more diverse than the current representation by a handful of models suggests. Luckily, technological advances, especially in high-throughput DNA sequencing, proteomics, and nanoscopy, make almost any organism a facile "model." Chromatin scaffold proteins, like core histones, are ancient and conserved in the fungi (29). Genes for the enzymes that modify DNA or histones are also largely conserved (14, 18, 26). One recent major discovery is the rather widespread distribution of 6-methyladenine observed in the basal lineages that is apparently absent from the Dikarya (30). Similarly, the Saccharomycetaceae can no longer methylate cytosines or adenines in DNA or methylate lysines of histone H3 at positions 9 and 27 (Fig. 1). Based on the overall phylogeny, these losses occurred more than once in different lineages, so the ancient state is predicted to be a full complement of DNA and histone modification capabilities, similar to that observed in many plants and animals. The purpose of this article is to make some of the deep knowledge garnered from a small group of organisms from restricted phylogenetic backgrounds accessible, in combination with findings from emerging model fungi, always remembering that it may be premature to derive hard and fast rules for larger groups. Ultimately, comparative biology—especially of the poorly understood chytrids and zygomycetes—will yield a much broader understanding of nature to allow us to separate the general from the specific in answering the question of how fungi assemble and maintain dynamic chromosomes.

It is far beyond the scope of this review to go into great detail on all pathways of DNA or protein modifications that can affect chromatin states. In the section on subtelomeric gene silencing we will, however, discuss two examples in more depth, namely, the histone deacetylase Sir2 and fungal homologues of the *Drosophila* histone H3K27 methyltransferase enhancer of zeste [E(z)], because they inform work in all eukaryotes.

CHROMOSOME LANDMARKS: ORIGINS, TELOMERES, AND CENTROMERES

Origins of Replication

DNA replication in eukaryotes is initiated at several loci along the chromosome, short segments called "replication origins," which are selected by binding of the origin recognition complex (ORC) (31, 32). During the late M and early G1 phase, ORC, Cdc6, and Cdt1 direct the loading of "mini-chromosome maintenance" complexes, assembling prereplication complexes that, at entry into S phase, trigger DNA unwinding and allow DNA replication. While replication origins differ in timing and frequency of activation, the maximum is only once per each nuclear cycle. While much progress has been made in a few organisms, a complete understanding of initiation efficiency and timing is still elusive, even in *S. cerevisiae*, which has been thoroughly studied (33–35). Nucleosome positioning, posttranslational histone modifications, and absence of active transcription all have some influence on the selection of ORC binding sites and replication initiation (10, 32, 36).

In some eukaryotes, including *S. pombe*, sequence requirements for replication origins are not strict, and almost any highly AT-rich sequence of ~1 kilobase (kb) is sufficient (37, 38). Specific sites are selected by interaction with the AT-hooks of the Orc4 subunit in *S. pombe* (39). This is different in *S. cerevisiae*, where specific loci function as replication origins, initially called autonomously replicating sequences (ARS), which contain consensus sequences called ARS consensus sequences that are required to allow ORC binding (40–42) (Fig. 2). Functional replication origins in *S. cerevisiae* have now been mapped by several techniques, including chromatin immunoprecipitation (ChIP) followed by genome-wide mapping via microarrays, revealing between 430 and 530 sites (33–35).

Evidence for true replication origins from most other fungi is still lacking, except for *Candida albicans* and

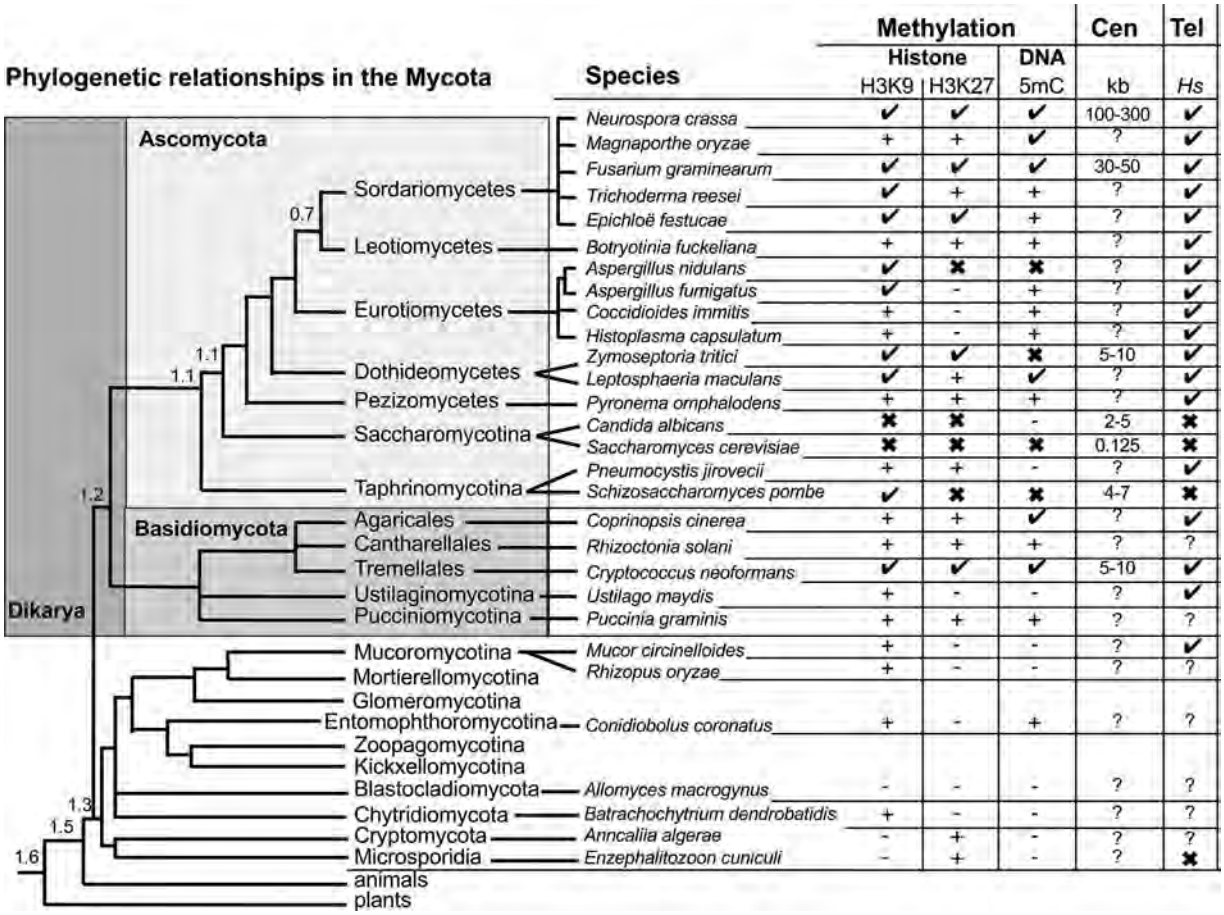

Figure 1 Presence and absence of selected histone H3 and cytosine DNA methylation marks, structure of centromeres, and sequence of telomere repeats in selected fungi. Representative fungi from various clades were selected to show the phylogenetic distribution of chromatin characteristics. Species in which the presence (check) or absence (cross) were experimentally validated are largely found within the Ascomycota, while species for which only genome sequencing-based evidence for the presence (plus) or absence (minus) of genes is available are in the Basidiomycota and the large group of early-diverging lineages. No experimental data on chromatin modifications in chytrids and microsporidia are available; some chytrids have predicted DNA methyltransferases (DNMTs) that are similar to those in animals, while some zygomycetes (e.g., *Phycomyces*) have DNMTs similar to those in ascomycetes (257). *Zymoseptoria tritici* has no cytosine methylation, but sister species have intact genes for DNMTs. No obvious DNMTs are found in the *Candida* genome, yet there have been reports on cytosine DNA methylation. *Pneumocystis*, unlike *S. pombe*, appears to have genes to carry out all modifications listed here, suggesting large diversity in the Taphrinomycotina. More recently, an entirely new class of cytosine DNA methyltransferases has been identified in fungi, demonstrating DNA methylation in species that were long thought to be devoid of methylation such as *C. neoformans* (258). The overall distribution pattern suggests that genes necessary to catalyze the two major gene silencing histone modifications, H3K9me and H3K27me, are ancient and have been lost in several branches over evolutionary time. The presence of conserved genes does not necessarily mean the presence of the expected chromatin modification. Centromeric DNA segments (Cen) are defined as regions with CENP-A or CENP-C enrichment, are highly variable in size, and even for some of the best-studied fungi such as *Aspergillus*, we still do not have experimental data. Pericentric regions, flanking the Cen regions, are larger and also of variable size. Most fungi use the mammalian and human (*Hs*) consensus telomeric repeat sequence, 5′-TTAGGG-3′, sometimes with a variable number of Gs like in *Cryptococcus*. Data on telomere repeats were compiled from the literature (54, 61, 65, 70, 72, 73, 75, 119, 124, 151, 194, 259–263).

	origins	centromere	telomere repeats
Saccharomyces cerevisiae	consensus ARS	consensus CDE	5'-$TG_{2-3}(TG)_{1-6}$-3'
Schizosaccharomyces pombe	AT-rich segments	4-7 kb core	5'-G_{0-4}GGTTACAC_{0-1}-3'
Neurospora crassa	?	100-300 kb core	5'-TTAGGG-3'
Cryptococcus neoformans	?	5-10 kb core	5'-TTAGGG-3'

Figure 2 Chromosome landmarks in four model organisms. Characteristics of DNA sequences for replication origins and centromere and telomere repeats are compared between budding yeast (*S. cerevisiae*), fission yeast (*S. pombe*), *N. crassa*, and the basidiomycete yeast *C. neoformans*. Few origins have been mapped in *C. neoformans*, so it seems premature to say whether they share specific characteristics (45). ARS, autonomously replicating sequence.

Cryptococcus. The short centromeric and pericentric regions in *C. albicans* replicate early in S phase (43) and were found to contain *bona fide* replication origins characterized by short sequence motifs (44). In *Cryptococcus deneoformans*, replication origins were mapped by enriching DNA containing replication bubbles (45). One origin was localized in the nontranscribed spacers of ribosomal DNA (rDNA) repeats. Seven additional regions on five chromosomes were identified, which—based on two-dimensional gel analyses—resemble those of *S. pombe* and humans in their relatively inefficient usage, suggesting the existence of replication zones rather than well-defined sequence elements for ORC binding (45). Note that the taxonomy and nomenclature of *Cryoptococcus* have been updated (46) and that *Cryptococcus neoformans* var. *grubii* is now referred to as *Cryptococcus neoformans*, while *Cryptococcus neoformans* var. *neoformans* is now *Cryptococcus deneoformans*.

In the other popular model species such as *N. crassa*, *A. nidulans*, and *Fusarium* species, true functional chromosomal replication origins remain to be discovered and mapped. Early attempts to find ARS in fungi outside budding and fission yeasts utilized functional approaches to isolate DNA segments—often derived from mitochondrial plasmids—to stabilize introduced DNA and to increase transformation efficiency (47–51) or used DNA segments that were preselected because of their DNA structure (52). Domestication of a transposable element, the *Aspergillus* MATE (mobile *Aspergillus* transformation enhancer), allowed the construction of a "fungal artificial chromosome" for the expression of secondary metabolite gene clusters (53), although strictly speaking, these large elements are still metastable plasmids rather than true chromosomes because no telomere sequences were captured, unlike on the *Fusarium*, *Histoplasma*, and *Cryptococcus* plasmids that have been in use but that also do not act like true artificial chromosomes (48, 54–56). ChIP-seq with a combination of ORC and mini-chromosome maintenance subunits seems to be the most obvious approach to map true chromosomal replication origins and their dynamic chromatin context, and this would close a wide knowledge gap in fungal biology.

Telomeres

Telomere repeat sequences and the shelterin complex

Telomeres were first discovered in the ciliate *T. thermophila* (57), but budding yeast soon became a facile model to uncover the structure and function of telomeres. Most organisms that have been examined use simple sequence repeats of various composition and length as a telomeric DNA sequence. In fungi, the vast majority have 5′-TTAGGG-3′ repeats, similar to the ends of mammalian chromosomes (58), but important exceptions are found within the ascomycetous yeasts in both the Saccharomycetaceae and the Taphrinomycotina (Fig. 1). One major difference between mammals and fungi is the overall length of the telomere repeat tracts, only 100 to 200 bp compared to several kilobases in most mammalian species that have been examined (59–62).

The 16 chromosomes of *S. cerevisiae* end in 75 to 300 $TG_{2-3}(TG)_{1-6}$ repeats (63), with a 12- to 15-nucleotide G-tail (64). *C. albicans* has longer, 23-nucleotide tandem repeats that are overall GC-rich and contain a *5′*-TGGTGT-*3′*; this arrangement is also found in other *Candida* species (65, 66) (Fig. 2). The canonical tandem repeat in *S. pombe* is G_{0-4} $GGTTACAC_{0-1}$ (67, 68), while the animal and human pathogens in the Taphrinomycotina, *Pneumocystis carinii* and *Pneumocystis jirovecii*, have telomere repeats composed of the more common *5′*-TTAGGG-*3′* sequence (69, 70). Telomeres from Dikarya in classes outside of the Taphrinomycotina and Saccharomycotina were found to be *5′*-TTAGGG-*3′* repeats, like in *N. crassa* (71, 72) and *A. nidulans* (73, 74); many additional species have been examined as part of genome sequencing projects (Fig. 1), though many projects did not capture any telomere repeats, e.g., in *Rhizoctonia* or *Puccinia*. There may be exceptions even in these lineages, because *Aspergillus oryzae* uses a 12-mer repeat, *5′*-TTAGGGTCAACA-*3′* (59). Direct sequence or biochemical evidence of telomere repeats is even more sparse in the early diverging lineages, e.g., among the chytrids or zygomycetes, where the standard *5′*-TTAGGG-*3′* repeat has been documented in *Mucor circinelloides* (75). Based on the genome sequences available in various databases, the microsporidia, among them *Enzephalitozoon cuniculi* and numerous *Nosema* species, appear not to have consensus telomere repeat sequences.

The telomeric DNA repeats serve as platforms for single-stranded or double-stranded DNA-binding proteins, forming protective caps or, more often, loops at chromosome ends (Fig. 3). In animals, this complex is called "shelterin" and is important for the maintenance of genome integrity, acting as a tumor suppressor involved in DNA repair (76). In fungi, analogous complexes are involved in regulated maintenance of telomere length by promoting replication at telomeres. In both *S. cerevisiae* and *S. pombe*, the telomeric repeats are free of nucleosomes and instead are organized into specialized chromatin by action of the telomere-binding protein Rap1 and two Rap-interacting proteins, Rif1 and Rif2; in *S. pombe*, the DNA-binding function of Rap1 is taken over by Taz1, and Rif2 is replaced by Rap1 (Fig. 3). As for the telomere repeat sequence, there is great diversity among telomere-binding proteins that are ill-conserved at the primary sequence level. Aside from *S. cerevisiae*, *C. albicans*, and *S. pombe*, there is still not much known about shelterin in the fungi, and mechanistic studies are sorely needed. Budding yeast and its close relatives seem to have derived protein complexes rather than representing the ancient state, whereas *S. pombe* shelterin shares functional similarities with shelterin identified in mammals (76–78). While homologues for shelterin components have been found by sequence similarity searches in many fungi (Fig. 3), it is unclear if they are also functionally conserved, illustrated by their different roles in *S. cerevisiae*, *S. pombe*, and *N. crassa* (76, 79–83).

Subtelomeric heterochromatin controls expression of disease-related genes

Segments of DNA immediately neighboring the telomeres are called "subtelomeric" and contain nucleosomes that are organized into transcriptionally silent heterochromatin in many species. Pioneering work on heterochromatin-mediated gene silencing was carried out in *S. cerevisiae* and has been reviewed recently (4, 10). Silent genes in the subtelomeric regions are intermingled with active genes; not all of the telomere-near segments are silent at all times, and silent chromatin blocks are relatively short (84). "Telomeric silencing" was first discovered by means of the *URA3* reporter gene and selection on 5-FOA medium (85). The strength of silencing is generally correlated with the length of the *5′*-TGGG-*3′* repeats, and internal telomere repeats, dispersed along chromosome arms, can aid in silencing neighboring genes in budding yeast (86). Silencing complexes restrict access to the DNA for the transcriptional machinery; i.e., switching from active to silent chromatin or *vice versa* results from a local balance between silencing and activating factors, generating so-called facultative heterochromatin.

In *S. cerevisiae*, three heterochromatic regions have been studied in great detail, namely, the silent mating type loci, subtelomeric regions, and rDNA. All three regions require the presence of the silent information regulator protein, Sir2, a conserved NAD^+-dependent histone deacetylase (4, 10, 11, 87). Sir2 is recruited to silencers or proto silencers by the action of Sir1, ORC, Rap1, and Abf1. At the silent mating type loci and subtelomeric regions, the specialized yeast Sir3 and Sir4 proteins are recruited, and spreading of this Sir complex is dependent on Sir2 deacetylase activity on H4K16 (88, 89). How exactly spreading occurs is still not resolved. The conventional idea has been that spreading of heterochromatin occurs in a linear fashion along chromosomes, though interactions *in trans* are possible, similar to some enhancer-promoter interactions. Hi-C experiments may resolve this question in the near future. Lastly, generating patches of Sir2/3/4-enriched chromatin may not be sufficient on its own to silence transcription. Several studies suggest that a

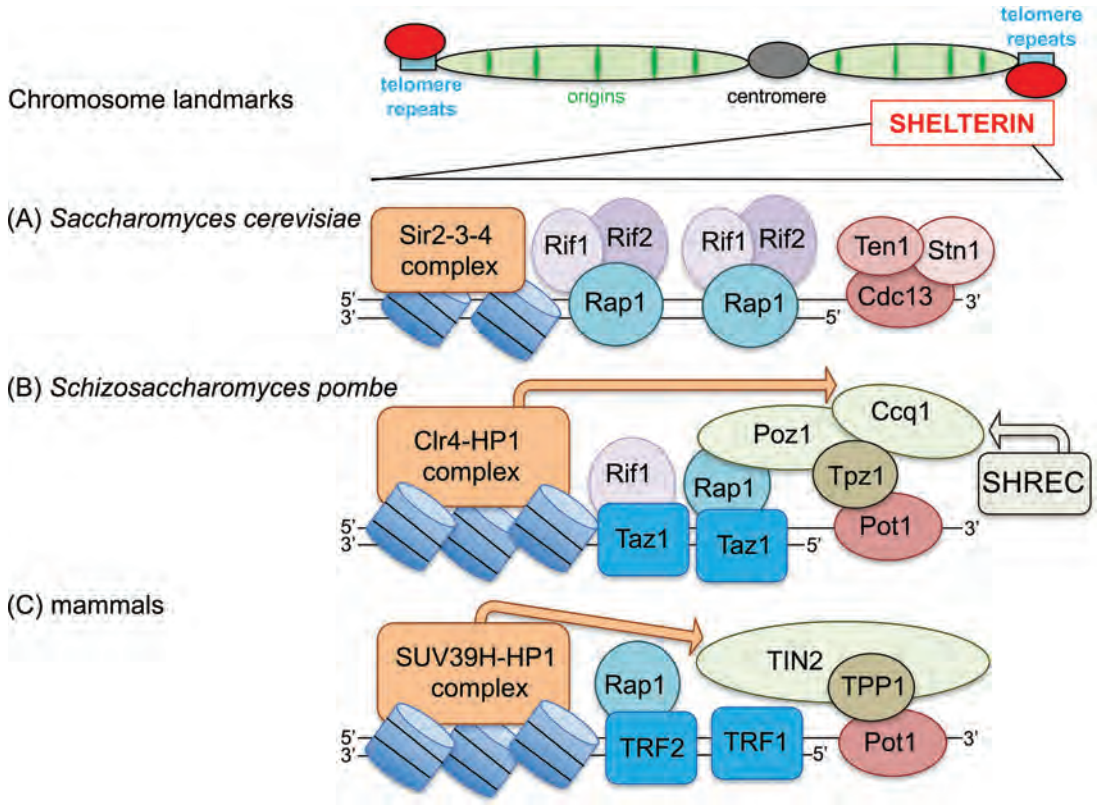

Figure 3 Telomere-repeat binding complexes homologous to mammalian shelterin. (**A**) The budding yeast *S. cerevisiae* has a CST (Cdc13, Stn1, Ten1) complex that binds to single-stranded 3′-G-rich-tail overhangs. The nucleosome-free double-stranded DNA is bound by Rap1, which in turn forms complexes with Rif1 and Rif2. Subtelomeric regions are transcriptionally silent because of hypoacetylation initiated by Sir2 and propagated by the Sir complex. (**B**) The fission yeast *S. pombe* has poorly conserved proteins serving similar functions as the CST complex, namely Pot1, Tpz1, and Ccq1. Poz1 creates a bridge to the Rap1/Taz1 complex, but Rap1 has different functions than in *S. cerevisiae*, even though there is slight sequence conservation. There is no Sir2-3-4 complex; instead, fission yeast uses H3K9me2-mediated silencing catalyzed by the Clr4 complex and recognized by HP1 (called Swi6 in *S. pombe*). (**C**) The shelterin complex first identified in mammals by purification of the first telomere-repeat factors is very similar to the *S. pombe* complex, though Ccq1 is apparently missing. In both *S. pombe* and mammals, HP1 acts on the CST complex homologues, and in *S. pombe* a histone deacetylase complex (SHREC) is involved.

"maturation" step is necessary, which may be demethylation of H3K79me3, because deletion of the sole H3K79 methyltransferase Dot1 resulted in accelerated establishment of silencing (90, 91).

In fungi closely related to *S. cerevisiae* such as *Candida glabrata*, the subtelomeric regions are enriched for genes that encode glycoprotein pathogenicity and virulence factors, similar to what has been found for parasite genomes, e.g., *Plasmodium* (92). The study of Epa adhesins, which allow binding to human cells, revealed a staggering variety in the expression of these loci near chromosome ends, and differential expression was controlled by Sir-protein-mediated transcriptional silencing (93–95). While the Sir proteins were essential, Rif1 and the Ku70/Ku80 proteins involved in nonhomologous end joining showed differential effects at only some subtelomeres (96).

During the annotation of the *C. albicans* genome, a novel family of "telomere-associated" (TLO) genes was discovered (97), which encode subunits of the Mediator coactivator complex (98–100). TLOs are involved in pathogenicity functions such as filamentous growth and biofilm formation and were considered to be adaptive by binding to specific target genes. More recent data suggest that increased protein levels of TLOs in *C. albicans* may affect regulation of virulence factors at

the transcriptional level by competition with basal transcription factors that bind to targets affecting key pathways such as filamentous growth (101). Lab evolution studies on TLO genes showed how quickly the repertoire of these genes can change; subtelomeric recombination generated diversity in copy number and sequence for TLO genes (102). Earlier work had revealed that deletion of Sir2 resulted in the rapid appearance of novel phenotypes (103), resembling (but mechanistically not related to) phenotype switching. Indeed, Sir2 is required for recombination at specific sites, called TLO recombination elements. TLO recombination elements enhance recombination, but Sir2 generally inhibits recombination, and Sir2 action can be bypassed by environmental stressors such as azole drugs and hydrogen peroxide (104).

The *S. pombe* Sir2 homologue is important for heterochromatin formation at silent mating type loci, centromeres, and subtelomeres, and it recruits Swi6 to telomeres (105). Swi6 is a homologue of the animal heterochromatin protein 1 (HP1) and binds to H3K9 that is di- or trimethylated (106). Another Sir2 homologue, Hst4, also was found to be important for subtelomeric silencing (107). In contrast to the Saccharomycetaceae, *S. pombe* uses H3K9 methylation and HP1 to induce formation of heterochromatic regions (108), and the interplay between H3K9me3 and H4K16, H3K9 and H3K14 acetylation and deacetylation has received much attention in the past decade (5). While an in-depth discussion of this topic is beyond the scope of this review, a few hallmark findings will illustrate the differences in telomeric silencing when compared to *S. cerevisiae*. Deposition of H3K9me3 and HP1 binding is dependent on the machinery that generates small interfering RNA (109), and this pathway acts at subtelomeric regions as well (110). However, Taz1 can also recruit $HP1^{Swi6}$ independently from the RNA-induced transcriptional silencing pathway (111). A Clr3 histone deacetylase complex containing the Mit1 chromatin remodeling factor ATPase, called SHREC, regulates nucleosome positioning at heterochromatic regions (112). Deletion of another telomere-associated protein, Sde2, results in decreased recruitment of SHREC and increased minichromosome formation, suggesting a role in telomere maintenance (113). SHREC directly interacts with the shelterin component Ccq1, linking Taz1, RNA-induced transcriptional silencing, and HP1-containing silencing complexes. These analyses have now come full circle, because there is accumulating evidence for the role of shelterin components Taz1 and Ccq1 in heterochromatin formation at late replicating origins that are sites for double-strand break formation during meiosis and genome organization in general (114, 115). Data obtained from high-resolution three-dimensional structured illumination fluorescence microscopy suggested that the "condensed" heterochromatin at subtelomeres in *S. pombe* is less condensed than nearby "knobs" that were eliminated by ablation of H3K36me3 (116), a histone mark correlated with gene expression and enriched in the 3′ regions of genes but actually repressing transcription from cryptic promoters and controlling transcript elongation (117, 118). Genes inserted into the condensed knobs were not silenced, whereas silent genes in the subtelomeric regions outside of the knob were less condensed, challenging our current notion of "heterochromatin" as a condensed or less accessible silent region.

In *Neurospora* there are no obvious signatures of specific gene families near the telomeres. This is different in several other filamentous fungi. Before the *Candida* virulence gene families (*epa* and *tlo*) were studied in detail, work with *Magnaporthe oryzae* had identified a family of telomere-linked RecQ-like helicases, and ectopic recombination, aided by the presence of transposons or transposon relicts, had been invoked to explain the proposed terminal truncations and reshuffling of these loci observed in this species (119, 120). In many other taxa, secondary metabolite gene clusters and genes involved in pathogenicity as "effectors," i.e., short, cysteine-rich secreted peptides or proteins, are enriched toward the telomeres, but this can encompass many hundreds of kilobases and thus is not strictly "subtelomeric silencing" (121–128).

Subtelomeric silencing has been studied in *N. crassa*, especially as it relates to H3K9me3-dependent DNA methylation and H3K27me3-mediated silencing (83, 129–137). While *S. cerevisiae* lacks H3K9, H3K27, and cytosine DNA methylation, and *S. pombe* lacks H3K27 methylation, *Neurospora* serves as an excellent model organism to decipher the roles of H3K27 and cytosine DNA methylation (23, 24), two chromatin modifications that are essential for proper development and differentiation in animals (138, 139). The *N. crassa* Sir2 homologue, NST-1, is involved in subtelomeric silencing, which was at least partially relieved when *nst-1* or three different sirtuins, *nst-2*, *nst-3*, and *nst-5*, were mutated. Even double or triple *nst* mutants, however, were not as effective in derepression of reporter genes as single deletions of HP1 or the gene for the H3K9 methyltransferase, *dim-5* (137). Because DNA methylation was only partially affected, these results suggested a DNA-methylation-independent role for H3K9 methylation in *Neurospora*. Recent studies showed that wild-type importin alpha (called DIM-3 in *N. crassa*) is

required for normal DIM-5 function (132) and for normal genome organization (131), but the mechanism for this is still unresolved.

H3K27 methylation is a hallmark of "facultative heterochromatin" in many fungi

Over the past 5 years H3K27 methylation has attracted the attention of several research groups working with *Neurospora*, *Fusarium*, *Zymoseptoria tritici*, *Epichloë festucae*, and *C. neoformans*. H3K27 methylation is catalyzed by the polycomb repressive complex 2 (PRC2), which has three core subunits: KMT6, EED, and SUZ12 (Fig. 4). The genes, E(z), Esc, and Su(z)12, respectively, were first discovered in *Drosophila* in enhancer and suppressor screens for loci affecting position effect variegation (138, 140). Specifics of the situation in *Neurospora* and *Cryptococcus* have been recently reviewed (23, 24), so the discussion here will be limited to contrasting these results with what has been found in the other three taxa.

Like the original PRC2 from *Drosophila*, NcPRC2 contains three core subunits: SET-7 (KMT6), EED, and SUZ12 (Fig. 4A); in subtelomeric regions, an additional component, NcNPF (identical to *S. cerevisiae* Msi1, *Drosophila* p55, and mammalian RbAp46/48), is required for H3K27me3 (134). The same core subunits are essential for H3K27me3 in *Fusarium graminearum*, but the Msi1 homologue, FgMSL1, is not required for H3K27me3 (L. R. Connolly and M. Freitag, unpublished results). The *Cryptococcus* $Ezh2^{EZH2}$ complex contains three conserved proteins (Ezh2, Eed, and Msl1) and two proteins unique to *Cryptococcus* (Bnd1 and Ccc1), but it lacks a recognizable SUZ12 homologue that is usually associated with E(z) (141). While there are no clear homologues of Bnd1 in ascomycetes, the best Ccc1 homologues in *Neurospora* and *Fusarium* are not involved in H3K27 methylation (130) (Connolly and Freitag, unpublished results). A partial crystal structure of the core PRC2 from *Chaetomium thermophilum*, a species of Sordariales relatively closely related to *Neurospora* and *Fusarium*, for the first time defined important functional motifs in any E(z) and EED homologue (142, 143). Allosteric interactions between KMT6 and EED had been reported previously (144), but the crystal structure and *in vitro* enzyme assays further defined interaction motifs in the H3K27me3 and H3K27 forms (143). In KMT6, 10 motifs were described (143), which are well conserved between fungal versions of the protein but are not easily discerned by sequence comparisons with proteins from animals (Fig. 4B). One clear difference in the organization of KMT6 homologues from ascomycetes is the extended sequence at the C-terminus, which is lacking from the *Cryptococcus* Ezh; the structure and function of this domain remain unknown because this segment was not included in the crystal structure. While the EED homologues all have seven WD40 motifs that form a seven-bladed β-propeller, fungal EED proteins are characterized by a long "insertion domain" (143); this is a highly variable region that is not directly involved in KMT6-EED interactions, and the function of this domain is unknown (Fig. 4C). SUZ12 homologues are overall fairly conserved when they are present in fungal genomes (Fig. 4C), though functional and structural motifs remain to be uncovered because the partial crystal structure contained only a short fragment, the VEFS motif (143).

The most obvious function of H3K27 methylation in *Neurospora* and *Cryptococcus* was proposed to be gene silencing, though loss of silencing does not result in drastic overt defects in either species (134, 141). In both species, H3K27me3 is found mostly in subtelomeric regions and a few dispersed regions on the chromosome arms, covering less than 10% of the genome (Fig. 5A). This situation is different in *F. graminearum*, where ~20% of all genes were newly turned on or upregulated when KMT6 was deleted, and where H3K27me3 covers almost a third of the whole genome (145). In *Fusarium fujikuroi*, deletion of *kmt6* is lethal, and effects of derepression of secondary metabolite gene clusters were studied by RNAi-mediated downregulation of *kmt6* (146). Again, H3K27me3 covers almost a third of the whole genome, including almost all of the smaller chromosomes (Fig. 5C), the so-called accessory chromosomes (22). In *E. festucae*, H3K9me3 and H3K27me3 in combination were reduced in secondary metabolite gene clusters that produce lolitrems and ergot alkaloids when the fungus was growing *in planta* (147). Whether the situation found in *Fusarium* and *E. festucae* is common to other pathogens needs to be resolved in the near future. There are indications that in some species such as *Leptosphaeria maculans* (148), H3K9me3 may control the activity of virulence-related genes, although the idea that long clusters of secondary metabolite genes are controlled by H3K9me3 in *Aspergillus* species may need to be readressed (149).

Studies on the interplay between H3K9 and H3K27 methylation showed that in *Neurospora*, HP1 is key for the proper distribution of H3K27me2/3 (130, 133, 150). In mutants lacking H3K9me3 or HP1, almost all H3K27me3 is mislocalized to regions previously enriched with H3K9me3, most strikingly the centromeres, and deleting components of the PRC2 at least

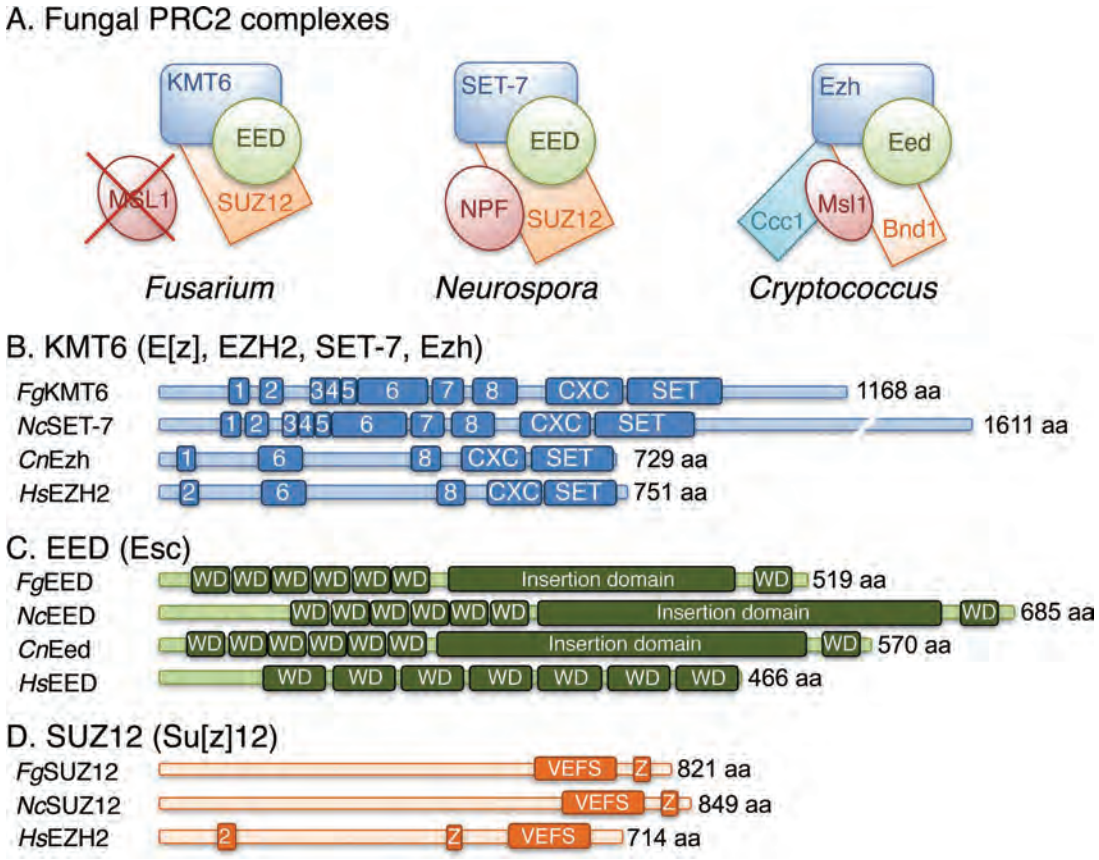

Figure 4 Polycomb repressive complex 2 (PRC2) from three fungi has different components. (**A**) Facultative heterochromatin, enriched with H3K27me2/3, is generated by PRC2 complexes. Approximate arrangement of complex subunits is based on published structures of human (264) and *Chaetomium* PRC2 (143). *Fusarium* has a core PRC2 complex that lacks a homologue of the *S. cerevisiae* Msi1 homologue (crossed out MSL1) that is found in PRC2 of *Neurospora* (NPF) and *Cryptococcus* (Msl1). While genes for KMT6, EED, and SUZ12 homologues are found in many taxa, the CnCcc1 and CnBnd1 proteins are restricted in distribution, suggesting diversification of PRC2 across the fungi. (**B**) *Chaetomium thermophilum* Ezh (*Fusarium* KMT6, *Drosophila* E(z), human EZH2, *Neurospora* SET-7, *Cryptococcus* Ezh) contains 10 structurally distinct motifs (adapted from reference 143): (i) SBD (SANT1L-binding domain), (ii) EBD (Eed-binding domain), (iii) BAM (b-addition motif), (iv) SAL (SET activation loop), (v) SRM (stimulation-responsive motif), (vi) SANT1L (SANT1-like), (vii) MCSS (motif connecting SANT1L and SANT2L), (viii) SANT2L (SANT2-like), (ix) CXC (cysteine-rich pre-SET domain), and (x) the catalytic SET domain. The SANT motifs are the least conserved surfaces in the *Chaetomium* crystal structure. (**C**) Fungal EED proteins (*Drosophila* Esc) contain WD40 (WD) domains that generate a seven-bladed propeller structure, for which the C-terminus folds back toward the N-terminus to generate propeller 1. The function of the extended C-terminal insertion domain is unknown. The accessory Msl1/NPF subunit of *Cryptococcus* and *Neurospora* is conserved in humans (RBAp46/48); all Msi1-like proteins share the WD40 propeller structure with EED. (**D**) SUZ12 [*Drosophila* Su(z)12] contains an Eed-binding domain (2), a Zn-finger region (Z), and a conserved VEFS domain that in the crystal structure is wedged between KMT6 and EED.

partially suppresses defects observed in *dim-5* mutants. In HP1 mutants, H3K9me3 and H3K27me2/3 are found in largely overlapping regions, a situation that is common in wild-type strains only in subtelomeric regions (130, 133, 150). In *Cryptococcus*, Ccc1 is involved in H3K27me3 recognition and binding, and disruption of *ccc1* results in redistribution of H3K27me3 into H3K9me2 domains, again especially the centromeric regions. If H3K9me2 deposition is abolished by deletion of the Clr4^{SUV39} homologue, H3K27me3 is

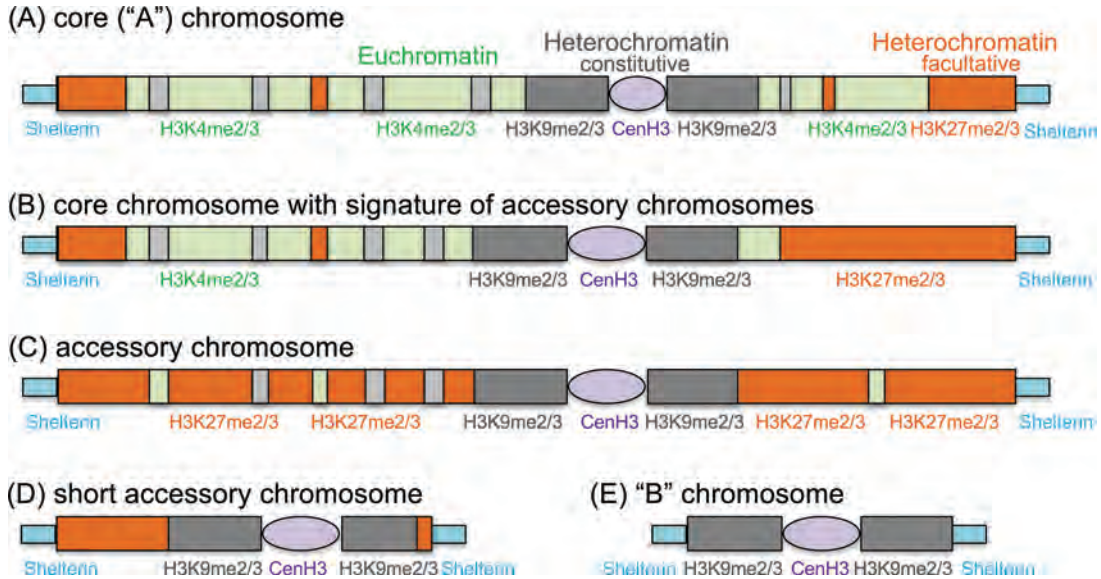

Figure 5 Histone modifications associated with transcriptionally active euchromatin and transcriptionally silent heterochromatin on four types of chromosomes found in many fungi. (**A**) Core or "A" chromosomes have a mixture of transcriptionally active euchromatin (green), constitutively silent heterochromatin (gray) that remains densely packaged even in interphase, and facultative heterochromatin (orange) that becomes transcriptionally active upon external or internal cues. Modifications on core chromosomes most often correlated with euchromatin are H3K4 di- and trimethylation (H3K4me2/3), which are usually found in sharp peaks around the nucleosome-free transcriptional start sites or in the 5′ regions of genes. In constitutive heterochromatin, which is often found in repetitive DNA sequences such as centromeric regions that also contain CenH3 nucleosomes (purple), in pericentric (dark gray) regions, or in transposable elements (light gray), H3K9 is di- or trimethylated (H3K9me2/3) and DNA is often methylated at cytosines. In facultative heterochromatin, H3K27 is di- or trimethylated (H3K27me2/3) and controls the expression of genes in a time- and space-dependent manner. Telomeric repeats (blue) have specialized chromatin structures in many fungi; some are free of nucleosomes and bound by shelterin-like complexes. In addition to the histone modifications shown here, lysines in the H3 and H4 tails of euchromatic regions are hyperacetylated (H3ac, H4ac), H3K79 and H3K36 are trimethylated (H3K79me3, H3K36me3), and H2BK120 is mono-ubiquitylated (H2BK120ub1); canonical H2A is replaced by the variant H2AZ. In heterochromatin, H3 and H4 lysines are hypoacetylated and H2AK119 is mono-ubiquitylated (H2A119ub1). (**B**) In several *Fusarium* species and in *Z. tritici*, complete chromosomes or segments of chromosome arms from accessory chromosomes that are enriched for H3K27 methylation have translocated onto core chromosomes, generating bipartite chromosomes with different histone modification environments. (**C**) Most accessory chromosomes from *Fusarium* and *Zymoseptoria* species that have been studied show almost complete coverage with H3K27me3. A very minor fraction of genes is active and enriched with H3K4me2/3, while pericentric regions and centromeric regions in *Fusarium* species are enriched with H3K9me3. In *Z. tritici*, H3K9me3 and H3K27me3 are partially overlapping in repeat-rich regions, but H3K27me3 is mostly found at silent genes. In this species no clear correlation with centromeric chromatin and any tested histone modification has been found. (**D**) The shortest accessory chromosomes have no active genes and show equal fractions of H3K27me3 and H3K9me3. (**E**) Predicted structure of true "B" chromosomes similar to those that have been found in plants and animals. These simplest chromosomes are completely gene-free and have only constitutive H3K9me3-enriched heterochromatin, centromeres, and telomeres. No such true B chromosomes have been documented in fungi.

also lost from these regions in the *ccc1* background (141). These results suggest that normal binding of the Ezh2 complex to its product, H3K27me3, via Ccc1 suppresses an inherent activity toward H3K9me2-modified centromeric chromatin regions (141). Redistribution of either H3K9me3 into H3K27me3 regions or *vice versa* has not been observed in *Fusarium* mutants (Connolly and Freitag, unpublished results). In *Z. tritici*, H3K9me3 and H3K27me3 distributions were found to overlap not only in subtelomeric regions but in most segments that are not transposons or transposon relicts (62).

In several *Neurospora*, *Fusarium*, and *Zymoseptoria* species, a correlation between subtelomeric blocks of nonsyntenic DNA and H3K27me3 has been found (62, 123, 134, 145, 146). H3K27me3 seems to act like an immune system for the fungus, perhaps silencing novel incoming DNA sequences (134), though this idea has been difficult to test, and a sequence-based "signal" for H3K27me3 targeting has yet to emerge from studies with *Neurospora* or *Fusarium*. The four chromosomes of *F. graminearum* likely resulted from chromosome fusions of the ancestral 11 or 12 chromosomes that are present in extant sister species (151). Recombination profiles (151–153) and chromatin structure analyses (145, 146) suggest that the epigenetically defined and usually silent or "cryptic" regions within chromosome arms maintain sequence diversity but also have been maintained as "subtelomeric-like regions" over millennia. What emerges from the combination of the studies discussed in the previous sections is a large variety of regulatory circuits in different taxa, suggesting that we are just beginning to uncover how and why H3K27 methylation is necessary in fungi.

Centromeres

Centromeric DNA attracts the kinetochore interaction network

Centromeres are essential chromosomal loci, dictating nucleation points for kinetochore and spindle assembly during chromosome segregation. While a handful of organisms, all related to *S. cerevisiae*, have sequence-dependent "point" centromeres that often involve as few as one or two nucleosomes, most other fungi, animals, and plants have epigenetically defined "regional" centromeres that stretch across several kilobases or even hundreds of kilobases (Fig. 1). These regional centromeres are functionally defined by the presence of a specialized histone H3 variant, CENP-A, or the presence of kinetochore complex components (154, 155). CENP-A and another essential centromere foundation protein, CENP-C, recruit the rest of the constitutive centromere-associated network, which forms the inner kinetochore, and the KNL1-MIS12-NDC80 complexes, which form the outer kinetochore and serve as the attachment point of chromatin to microtubule spindles. In combination, the constitutive centromere-associated network and KNL1-MIS12-NDC80 complexes form the kinetochore interaction network (156), where "centromere" denotes DNA and DNA-binding chromatin proteins, and "kinetochore" refers to proteins that do not directly contact DNA (157).

Compared to replication origins and telomere biology, much more is known about fungal centromeres. Among the earlier diverging ascomycetes in the Taphrinomycota, *S. pombe* is one of the best studied models. Well-defined pericentric flanking regions including the outer repeat (*otr*) and innermost repeat (*imr*) surround the central core (*cc* or *cnt*; 4 to 7 kb) (158), which contains the majority of nucleosomes with CENP-A^{Cnp1} (159). The discovery of *S. pombe* centromeres showed early on that fungi can have regional centromeres that do not depend on conserved recognition sequences for kinetochore complexes and that they can be excellent genetic models for animal centromeres (160), and by now several sister species have been studied as well (161). The poorly conserved *cc* sequences are not sufficient to allow CENP-A^{Cnp1} recruitment (162). To assemble a functional kinetochore, the *otr* and *imr* repeats or similar regions producing siRNA are required to assemble *de novo* heterochromatin marked by histone H3 lysine 9 dimethylation (H3K9me2), which is also involved in recruitment of cohesins for the binding of sister chromatids (5, 109, 163, 164). A role for centromeric repeat sequences to generate *cis*-acting short or long noncoding RNA seems to be shared by animal and plant taxa as well (165, 166).

Searches for centromere consensus sequences showed that *S. cerevisiae* has a genetically defined centromere with three conserved centromere-determining elements (CDEI, CDEII, and CDEIII) (167, 168). CDEI, an 8-bp palindromic sequence, is bound by Cbf1, and CDEIII, a conserved 26-bp motif, is bound by the CBF3 complex, interrupted by 75 to 86 bp of AT-rich CDEII sequence; Cbf1 and CBF3 are conserved only in the Saccharomycotina. This topic has recently been reviewed in great detail, and discoveries with budding yeast facilitated trail-blazing research into the requirements for kinetochore formation and "portable" centromere signals (169). Emergence of point centromeres seems to have occurred before the whole-genome duplication event that occurred in the ancestors of *Saccharomyces*, *C. glabrata*, *Naumovozyma castellii*, and *Vanderwaltozyma* (*Kluyveromyces*) *polyspora*

but after divergence of the "true" *Candida* species and *Komagataella phaffii* (*Pichia pastoris*), which have short regional centromeres (170). Thus, although sequence-specific point centromeres were discovered first, largely because of the genetic tractability of budding yeast, the combination of molecular and phylogenetic evidence suggests that point centromeres of many Saccharomycotina represent a more recently evolved state (171). One possibility is that specific sequence elements invaded chromosomes resulting in preferred binding of centromere-associated proteins and replaced ancestral regional centromeres present in the last common ancestor.

The genus *Candida* includes some of the best-studied human pathogens within the fungi, and recent work has thoroughly examined the centromeres of *C. albicans*, *Candida dubliniensis*, *Candida lusitaniae*, and *Candida tropicalis*. *C. albicans* centromeres were identified by immunoprecipitation of DNA with antibodies against CENP-A^{Cse4}, followed by cloning and sequencing (172). This direct identification of centromeric DNA showed that *C. albicans* has small (~3 to 5 kb) centromeres composed of nonrepetitive sequence elements that are not conserved, even on chromosomes of the same strain or species. Syntenic centromeric regions have different sequences in *C. dubliniensis* and *C. tropicalis* (173, 174), and centromere cores of *C. tropicalis* are flanked by inverted repeats, similar to the organization found in *S. pombe* and *K. phaffii* (173). The seven centromeres of *C. tropicalis* are more similar than those of the other species, suggesting ongoing homogenization by gene conversion. The core regions have the highest CENP-A^{Cse4} occupancy, but when (inverted) repeats are present, they are often enriched with CENP-A^{Cse4}. At the same time, *Candida* centromeres have—like *S. cerevisiae*—a single kinetochore-microtubule spindle attachment per chromosome (175, 176), thus blurring the line between point and regional centromeres.

The filamentous fungi comprise most taxa in the early diverging lineages and the Dikarya (Fig. 1). In *N. crassa*, a 16-kb region that mapped to the centromeric region of LG VII was identified in a yeast artificial chromosome library and sequenced (177, 178). The approximate sizes of all centromeres were determined after the genome had been nearly completely assembled by traditional shotgun Sanger sequencing (14, 179). Assembly of the AT-rich regions in *Neurospora* is aided by the presence of repeat-induced point mutation, a premeiotic mutator system that affects duplicated sequences as short as 150 bp (180, 181) and whose effect is heterogenization and inactivation of populations of identical retrotransposons. *Neurospora* has large (170 to 300 kb) regional centromeres, enriched with inactivated retroelements. This is similar to plants and animals, but satellite repeats are absent (182). Based on ChIP-seq with CENP-A^{CenH3}, the centromeric core regions are surrounded by short (2 to 45 kb) regions of pericentric heterochromatin. Limited examination of the *N. crassa* Mauriceville wild-type strain showed large differences in the architecture of centromeric DNA segments, initially by analysis of AT-rich segments that also had cytosine DNA methylation (183), and later by comparison of near-complete centromeric DNA sequence (184). The patterns of changes suggested that mitotic or meiotic recombination events, perhaps anchored in the near-identical repeats of nonfunctional transposons, result in large-scale insertions or deletions.

Taxa most closely related to *Neurospora* all have shorter regional centromeres, with active or incapacitated retrotransposons, similar to those found in the putative centromeric regions of *M. oryzae* (185) and *Verticillium* (127, 186). For many of these species, CENP-A^{CenH3} has not yet been mapped by ChIP-seq, though several species in the genus *Fusarium* (*F. graminearum*, *Fusarium asiaticum*, *Fusarium oxysporum*, *Fusarium solani*, *F. fujikuroi*) have been examined more closely and revealed centromeric DNA of 30 to 50 kb. All have centromeres that are enriched with retrotransposons, some of which appear to be active. Centromeres of the Eurotiomycetes, a medically and industrially important class of ascomcyetes, have still not been studied in detail, so centromeric sequences from *Penicillium*, *Aspergillus*, *Histoplasma*, and *Coccidioides* remain unknown or unassembled. In *A. nidulans*, repeat elements, e.g., the *Dane1* and *Dane2* long terminal repeat elements, have been found (187), and based on comparative genomics, centromeric regions are thought to be between 8 and 80 kb long (188). Like in *Candida*, centromeres of the sister species are embedded in regions with high synteny, even though centromeric sequence has diverged. In the Dothideomycetes, the location of centromeres had been predicted based on the longest AT-rich regions on each chromosome. Surprisingly, such predictions turned out to be wrong for the genus *Zymoseptoria*, in which most centromeres are not associated with AT-rich DNA (62). Instead, ChIP-seq with *Z. tritici* CENP-A^{CenH3} revealed short (5 to 10 kb) CENP-A-enriched regions without distinct sequence patterns; some centromeres contain expressed genes, while others harbor active or silent retroelements.

Among the Basidiomycota, only *C. neoformans* has been examined in any detail for centromere sequences,

both by sequence comparisons and ChIP-seq with CENP-C (45, 189). Together, the pericentric and centromeric regions are between 20 and 65 kb long and enriched for active or disabled Tcn1-Tcn6 retrotransposons. Mapping of CENP-C showed that this centromere foundation protein binds to a core region within the centromeric and pericentric region, covering ~5 kb on *CEN14*. The flanking regions found in *C. neoformans* and *C. deneoformans* are mostly syntenic, but the chromosome numbering is different for the two subspecies; a similar arrangement was observed with the more distantly related *C. gattii* (45). The well-studied *Ustilago maydis* seems to have short centromeres that are associated with ARS (190, 191), but again, no detailed studies have been undertaken.

The last common ancestor of fungi split from the animal lineage ~1.5 billion years ago, and the most basal fungal lineages, the Microsporidia and Cryptomycota, separated from the precursors of the zygomycetes, Ascomycota and Basidiomycota, ~1.3 billion years ago (Fig. 1) (192, 193). No molecular studies have investigated the position of centromeres in the basal taxa, and standard genome sequencing alone will likely prove insufficient because it is unclear that all centromeres are in long AT-rich regions. The genome of the industrially important *Trichoderma reesei* has been assembled by 3C followed by Hi-C (194). This method makes no *a priori* assumptions about centromere clustering (131), so application of Hi-C-aided assembly allows the precise mapping and assembly of centromeres of many fungi. While this method will provide important information, the extent of centromeres should always be confirmed by localization of the defining epigenetic marker, CENP-A.

What emerges from investigations on short point or extended regional centromeres in the fungi is the realization that genes surrounding the centromeric core or repeat regions of related species are syntenic, while the core regions are highly divergent. This suggests that centromeric sequences undergo mutation without repair at a higher frequency than surrounding sequences. It remains to be determined whether this implies positive selection toward highly adapted sequence signals aiding deposition of CENP-A (195, 196) or, rather, genetic drift because CENP-A deposition is determined entirely epigenetically by pre-existing CENP-A nucleosomes, thus making DNA sequences immaterial.

Centrochromatin

That centromeric chromatin is different from bulk chromatin became clear when CENP-A was identified as a histone H3 variant (197–199). The sparsity of genes, enrichment with repeat elements and active or disabled retrotransposons, transcriptional repression, and compaction during interphase pegged centromeric chromatin as constitutive heterochromatin, but this idea was challenged by results that showed the presence of histone modifications commonly associated with active transcription in fission yeast, *Drosophila*, and human cells (110, 200, 201). Thus, along with transcriptionally active euchromatin and silent heterochromatin, "centrochromatin" may constitute a distinct, third form of chromatin.

CENP-A is rapidly evolving, especially the N-terminal tail, loop 1 of the histone fold domain, and the CENP-A targeting domain, which are all involved in CENP-A localization and kinetochore interactions. In fungi, this has been studied in the Taphrinomycotina (202), Saccharomycetaceae (203), and Sordariomycetes (P. Phatale, S. Friedman, and M. Freitag, unpublished results). The C-terminal tail is important for recruitment of two essential constitutive centromere-associated network components: CENP-C and CENP-N (204–207). The controversy about the shape and size of centromeric nucleosomes across the cell cycle has been reviewed (169), and the balance of CENP-A nucleosomes and posttranslationally modified H3 nucleosomes is a topic of ongoing investigations; earlier studies uncovered roles for histone modifications in *de novo* establishment of stable fission yeast centromeres (162). How histone modifications may aid in centromere maintenance, however, remains to be uncovered in most organisms. Because the complement of histone genes is very simple in fungi—there are single genes for H2A, H2B, and H3 and only two genes encoding identical H4 proteins (208)—and because most fungi are genetically and molecularly tractable organisms, this may be the area where they can contribute the most to advances on centrochromatin in the near future.

Centromere inactivation or deletion experiments in *C. albicans* demonstrated the utility of this system for the study of "neocentromere" formation and inheritance (209). Neocentromeres are previously naive chromatin regions that give rise to functional kinetochores competent for chromosome segregation. Upon inactivation or deletion of the original centromeres, *Candida* neocentromeres form almost anywhere on the chromosome, though there is some preference for transcriptionally silent pericentric and subtelomeric regions (43, 210–212). Like in *S. cerevisiae*, centromeres and neocentromeres in *Candida* interfere with transcription of nearby genes (210), also suggesting heterochromatin characteristics. The role of histone modifications for centrochromatin in *Candida* is unresolved;

like *S. cerevisiae*, *Candida* lacks the conserved heterochromatin pathways that rely on methylation of H3K9 and H3K27.

Constitutive heterochromatin, defined in many eukaryotes by the presence of H3K9 di- or trimethylation (H3K9me2/3) and cytosine DNA methylation, is also a characteristic of most regional pericentric or centromeric regions. In *S. pombe*, the RNAi machinery is essential to recruit H3K9me2 to the pericentric repeat and help to incorporate CENP-A^{Cnp1} on naive plasmid sequences (162). Once assembled, however, the heterochromatin machinery, including the histone methyltransferase Clr4^{SUV39} and the H3K9me2 adapter protein Swi6^{HP1}, is no longer required for CENP-A^{Cnp1} inheritance. Nevertheless, heterochromatin is essential for proper chromosome segregation and chromosome structure, likely by the recruitment of cohesins (163, 213–215). Early genome-wide ChIP studies showed that the *imr* and *cc* (*cnt*) regions were enriched for a euchromatic mark, H3K4me2 (110), but recent experiments suggest that H3 nucleosomes are depleted from the centromeric core and that CENP-A^{Cnp1} nucleosomes and the CENP-T complex dominate (159).

There have been far fewer studies on centrochromatin of other clades in the fungi. Centromeric regions of *N. crassa* contain blocks of canonical nucleosomes that are enriched with H3K9me3 interspersed with blocks of CENP-A^{CenH3} nucleosomes (182, 216). In mutants lacking the H3K9me3 methyltransferase DIM-5^{SUV39} and the H3K9me3-binding protein HP1, the regions enriched for CENP-A^{CenH3} were smaller. H3K4me2/3 did not associate with the formerly H3K9me3-enriched nucleosomes, though overall nucleosome occupancy seemed unaltered (182). Further studies revealed relocalization of H3K27me2/3 to regions usually occupied by H3K9me3 in DIM-5^{SUV39} and HP1 mutants, suggesting that HP1 prohibits H3K27 di- and trimethylation in H3K9me3 regions (130, 133). Single mutants lacking DIM-5^{SUV39} and HP1 show growth and chromosome segregation phenotypes and are homozygously sterile or result in aberrant progeny (217, 218), while SET-7^{EZH2} mutants show no overt defects (134). In DIM-5^{SUV39} SET-7^{EZH2} or HP1 SET-7^{EZH2} double mutants, these phenotypes are largely suppressed (130, 133), suggesting that it is the presence of H3K27me2/3 at centromeres or its absence from normal facultative heterochromatin that results in the chromosome segregation defects.

A link between the RNAi and meiotic silencing pathways and heterochromatin establishment in *N. crassa* has not been found (219), unlike in fission yeast. In *F. graminearum*, centrochromatin is similar to *Neurospora*, although the relocalization of H3K27me2/3, which has been observed in *Neurospora* DIM-5^{SUV39} and HP1 mutants (130, 133) as well as *C. neoformans ccc1* mutants (141), does not occur in *F. graminearum* (Connolly and Freitag, unpublished results). Overt phenotypes are also drastically different from those observed in *Neurospora* (134), because H3K9me3-defective strains have no discernible phenotypes under standard growth conditions, while single mutants lacking H3K27me3 or double mutants lacking H3K9me3 and H3K27me3 show numerous developmental and other defects (145). In *Z. tritici*, centrochromatin cannot easily be defined because CENP-A-enriched regions do not show any obvious DNA sequence or chromatin pattern (62). So far, only H3K4, H3K9, and H3K27 methylation have been tested, but none of these marks overlap reliably with CENP-A localization. The only basidiomycete whose centrochromatin has been studied is *C. neoformans* (45, 189). H3K9me2 is found almost exclusively in the centromeric, pericentric, and subtelomeric regions. Overall, fungi represent diverse opportunities to test centrochromatin plasticity that is still difficult to carry out in many other organisms. All known variants of centrochromatin in fungi are more similar to heterochromatin than euchromatin, whether due to the presence of silencing marks (e.g., H3K9me2/3) or the involvement of the RNAi machinery in *S. pombe*.

NOT ALL CHROMOSOMES ARE EQUAL

How To Tell Core from Accessory Chromosomes

Many eukaryotes carry extra "B" chromosomes in addition to the set of core ("A") chromosomes (220). By definition, B chromosomes are not essential; most are harmful to the host, and at best they are neutral elements. In fungi, however, an overwhelming majority of B chromosomes seems to confer benefits by carrying genes involved in plant or animal colonization or to be involved in detoxifying host defense compounds, explaining the term "pathogenicity" chromosomes (221, 222). Selective advantages through pathogenicity determinants do not hold for all of these extra chromosomes, however (122, 223). In some fungi, B chromosomes are found only in specific accessions of one species, hence the name "lineage-specific" chromosomes (221); other monikers are "conditionally dispensable," "supernumerary," or "accessory" chromosomes (224–226).

Animal and plant B chromosomes use various forms of meiotic drive and self-accumulation mechanisms to

propagate, and many of the inheritance patterns are non-Mendelian. While there is much variation, some rules seem to apply (220, 227, 228). The more B chromosomes there are in a single nucleus, and the harsher the environment, the more pronounced are the negative effects of B chromosomes. B chromosomes can affect recombination frequency on A chromosomes, and in plants, inbreeding promotes the accumulation and spread of rare beneficial B chromosomes. Overall, the presence of B chromosomes is positively correlated with low ploidy, low chromosome numbers, and large genomes (and therefore much larger domains of repetitive DNA). B chromosomes are also more prevalent in genomes with acrocentric chromosomes, and smaller B chromosomes are mitotically less stable than large ones (220, 227, 228). In fungi, the rule seems to be that accessory chromosomes are rarely larger than the smallest A chromosome, and this is true in most eukaryotes. B chromosomes are small, containing sometimes only the elements required for propagation, i.e., telomeres, centromeric DNA for kinetochore and spindle attachment, and origins of replication, but there is a large diversity in B chromosomes in plants and animals.

So what separates accessory and B chromosomes? The chromosome structure of *Fusarium* and *Zymoseptoria* species has been studied extensively, because they have a large number of accessory chromosomes (62, 224–226). Overall, accessory chromosomes are depleted for genes and enriched for repeated elements, mostly active and mutated transposons that are shared or rarely of different types than on the core chromosomes (221, 225, 229). Very few—if any—genes have been found on B chromosomes in plants or animals; it appears that an increase of gene density on accessory chromosomes is thus positively correlated with benefit to the host organism. Matching the finding of few active genes, cytological data from plants and animals suggest that B chromosomes are heterochromatic, and most studies suggest that they are enriched for H3K9me2/3 (230, 231). In fungi, the hallmark chromatin feature of accessory chromosomes is H3K27me3 (22, 62, 145, 146), though transposable elements are still covered by H3K9me3 in *Fusarium* and *Z. tritici* (Fig. 5). Thus, the separating characteristic—at least for now—seems to be the presence of H3K27me3 and facultative heterochromatin on accessory chromosomes.

How Do B Chromosomes or Accessory Chromosomes Arise?

Plant and animal B chromosomes are likely predominantly generated within the host by aberrant chromosome segregation during division; "horizontal chromosome transfer" (HCT), similar to horizontal gene transfer in bacteria but involving entire chromosomes, is considered a less likely pathway (220). The finding that species with acrocentric chromosomes are more likely to generate B chromosomes supports this idea, providing a mechanism that suggests breakage within centromeric DNA regions and addition of telomere repeats to generate a minichromosome that can be segregated in mitosis. This may be inefficient, however, especially when centromeric regions are insufficient for optimal kinetochore and spindle attachment, resulting in stochastic inheritance of B chromosomes, which may result in extinction at accelerated rates (220).

For fungi, HCT has been long considered as one model for the acquisition of accessory chromosomes, but HCT may mean different things to scientists from various disciplines. Most authors have made no distinction about species boundaries when discussing HCT (221, 222, 232–235), using "horizontal" or "lateral" transfer merely to describe a process distinct from the "vertical" transfer through the germline. Others may argue that transfer of new chromosomal material has to occur between different species before it is truly horizontal. This very specific condition is only rarely fulfilled; even horizontal gene transfer between species is difficult to detect, although there are some cases in which genes encoding host-specific toxins have been transferred (236). The hurdles for HCT even within species are high; no satisfying mechanistic explanation for how this may occur in *Fusarium* or *Alternaria* has been conclusively validated.

Chromosomes with drastically altered gene sequences, transposon or repeat content, and codon bias that may no longer resemble those commonly found in the same species have been observed in some species (221, 225, 237). Interspecific hybridization may occur between fungal genera, yet endogenous sources for the generation of accessory chromosomes seem more likely, especially in light of recent results obtained with *Fusarium* and *Zymoseptoria*. While HCT has been shown to occur within the "species" *F. oxysporum* between different *formae specialis* under strong selection (221, 238, 239), this is more difficult to show for different species or across different genera. The emerging consensus is that accessory chromosomes in *F. oxysporum* are not only "lineage-specific" but appear to be *bona fide* pathogenicity factors because of the reliable conversion of nonpathogenic strains into pathogenic strains (240–244). How many traits or specificity factors can be assembled into one such chromosome?

One wonders whether one pathogenicity gene or set of pathogenicity genes on each accessory chromosome is specific to only one host. In other words, are pathogenicity chromosomes inherited as a single trait?

Studies with *Fusarium* and *Zymoseptoria* also showed that core chromosomes with large segments of facultative chromatin typical of accessory chromosomes exist (62, 221). These cases suggest that either subtelomeric H3K27me3-enriched regions increase and spread to encompass longer segments, or—perhaps the more likely scenario—translocations between accessory and core chromosomes occur on a regular basis (Fig. 5B). Some evidence for the second idea is provided by mapping of *Z. tritici* chromosome 7, where the boundary between core and accessory chromosome characteristics falls almost precisely in the regions where the rDNA cluster was mapped (62, 245). This suggests that there may be preferred regions for reciprocal or nonreciprocal translocations, which predominantly seem to be linked to H3K9me3-enriched transposable elements (62, 126).

While intraspecies HCT and translocations from preexisting accessory chromosomes can explain some of the variation within a species, these mechanisms still do not explain how relatively gene-rich fungal accessory chromosomes arise in the first place. Endogenous generation of a novel chromosome from two existing accessory chromosomes by chromosome fusion followed by degenerative breakage, as proposed by the "breakage-fusion-bridge" model (246, 247), may serve as a general explanation for how accessory chromosomes in *Z. tritici* arise (226). Repetitive DNA may result in nonallelic homologous recombination between repeats to generate a dicentric and an acentric chromosome. The dicentric chromosome (in the case of *Z. tritici* chromosome 17) may have undergone breakage-fusion-bridge cycles (226), while the acentric chromosome was simply lost in subsequent divisions. There are indications that chromosome loss in this species is quite common (223), especially in meiosis where short chromosomes may not support the necessary cross-over events for successful segregation (248).

Successive cycles of translocations or breakage-fusion-bridge may result in chromosomes that are successively more enriched in H3K27me3 facultative heterochromatin and depleted in H3K4me2/3 euchromatin (switch from panel B to C in Fig. 5), and further degeneration of chromosomes may result in extremely short accessory chromosomes that have a mixture of H3K27me3 and H3K9me2/3 marks but no longer carry any essential genes that would be enriched with H3K4me2/3. If driven to the extreme, this may result in true B chromosomes that carry only H3K9me2/3 (Fig. 5E), like in some plant and animal species, though this type of chromosome has not yet been observed in fungi.

CHROMATIN INTERACTIONS WITHIN THE WHOLE NUCLEUS

On the previous pages we examined landmark regions required for chromosome function in a reductionist fashion, but the pieces must work together. There are various ways to examine chromosome dynamics, one being cytology (4, 12), which has now entered into the age of high-resolution "nanoscopy" (249). Another way to resolve contacts between chromosomal regions at high resolution is 3C followed by Hi-C (28, 250) and its many variants (251). Several studies of budding and fission yeast, as well as *N. crassa*, resolved the importance of chromosome landmarks for normal growth in fungi. Hi-C and cytological studies with wild types and mutants defective in constitutive (H3K9me2/3-enriched) or facultative (H3K27me2/3-enriched) heterochromatin showed that, like in budding (252) and fission yeast (214, 253), all centromeres of *N. crassa* are colocalized within the nucleus, revealing Rabl orientation (129, 131). Surprisingly, all mutants that disturb features of transcriptional silencing, or "heterochromatin," namely those that are lacking HP1, the H3K9 methyltransferase DIM-5 (i.e., KMT1, SUVAR39), or the H3K27 methyltransferase SET-7 [i.e., KMT6, E(z)] revealed only minor changes in overall chromosome organization (Fig. 6). Cytology showed altered position and increased numbers of centromere foci in the SET-7 but not the DIM-5 and HP1 single or *set-7*, *dim-5* double mutants (129). These data suggest a role for H3K27me2/3 in the control of centromere maintenance. In fission yeast, cohesins and condensins seem to play a major role in maintaining overall chromosome structure (13, 214, 254). Recent studies revealed surprising roles of condensins in organizing centromeric regions in fission yeast (255, 256). Thus, Hi-C studies suggest that there is higher-order organization to chromatin, though the precise role of heterochromatin, cohesins, condensins, or other scaffolding proteins is still uncertain.

In summary, while it is clear that chromatin modification enzymes are important for the establishment of large chromatin segments, more work must be done to determine what, if any, negative effects on chromosome segregation occur in a large number of chromatin mutants. Cytology has been carried out for a long time, but 3C-based studies carried out across the cell cycle in synchronized cells will be necessary to provide a much

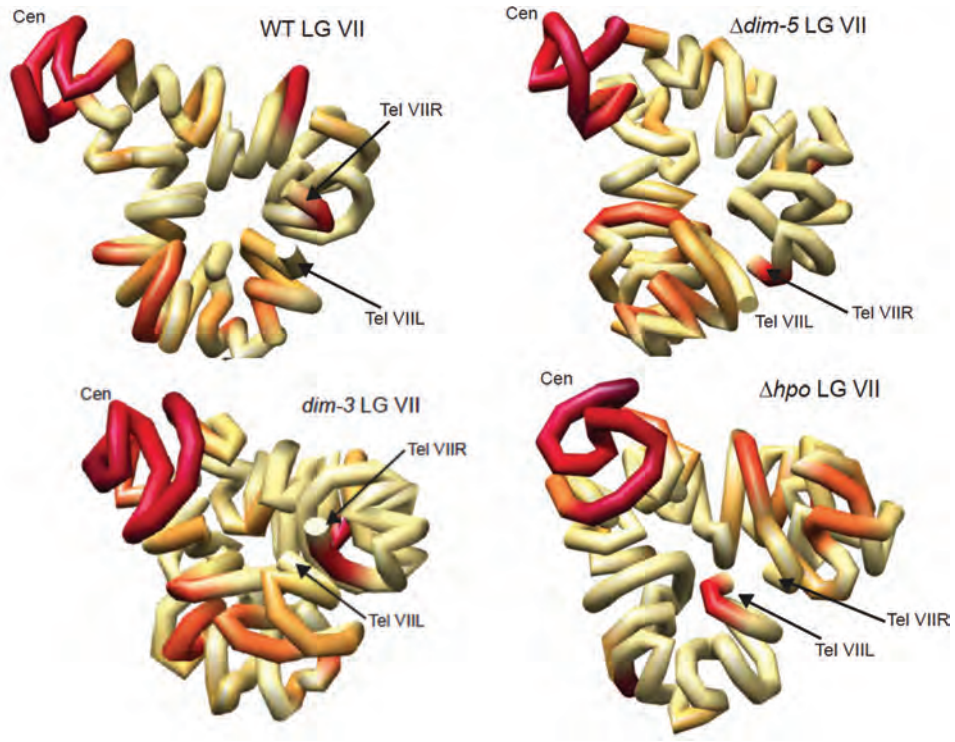

Figure 6 Three-dimensional models of *N. crassa* linkage group (LG) VII based on Hi-C data. Chromosomes are represented as wire diagrams, where the wire path runs through the center of a series of 50-kb "spheres" determined by the contact frequencies calculated from Hi-C datasets for the wild type and three chromatin mutants (*dim-5*, *hpo*, *dim-3*). The chromosome path is calculated by attractive or repulsive forces between each sphere so that the system relaxes to a low energy state. Regions that are enriched with one heterochromatic mark, H3K9me3, in the wild type are shaded in red. Centromeres and subtelomeres are separated, but telomeres are closer to each other than to the centromere (adapted from reference 131).

deeper understanding of the relationships between chromatin state and chromosome landmark functions.

INTRODUCTION

Cellular ploidy is the number of complete sets of chromosomes in a cell. Many eukaryotic species have two (diploid) or more than two (polyploid) sets of chromosomes (1). These diploid and polyploid states are often the result of ancient whole-genome duplication (WGD) or hybridization events that occurred throughout the evolution of plants, animals, and fungi (2–4). Ploidy changes also occur during the development of many organisms and can vary within different tissues of the same organism and between individuals of the same species. For example, ploidy changes occur during the sexual cycle of eukaryotes, from haploid gametes to diploid somatic cells. Additionally, some cells continue to increase in ploidy during development, resulting in somatic tissues that have a mixture of diploid and polyploid cells, including human hepatocytes and megakaryocytes (5–7). These ongoing, developmentally programmed changes in ploidy are important for viability and are beneficial to many organisms (8), but the mechanisms controlling ploidy and the physiological significance of each ploidy level are not well characterized.

Many clinically relevant fungi undergo ploidy changes during adaptation, especially to adverse or novel environments. Some fungi exist as stable haploid, diploid, or polyploid (e.g., triploid, tetraploid) cells, while others change ploidy under certain conditions and revert back to the original ploidy level in other conditions. Aneuploidy, an abnormal chromosome number, is observed in novel environments, during periods of cellular stress, and during ploidy level changes. An increase in ploidy can occur through mating, endoreduplication, or failure to undergo cytokinesis after replication (described in detail below). Here we refer to events that increase cellular ploidy as WGD, diploidization (e.g., haploid to diploid), or polyploidization (e.g., diploid to tetraploid). A decrease in fungal ploidy can occur through meiosis, reductional division, and random chromosome loss events (9). We will discuss only nonmeiotic ploidy decreases and refer to these events as whole-genome reduction events or haploidization events (e.g., diploid to haploid). The examples we provide here challenge the textbook definition of somatic ploidy as a consistent or defining trait of a fungal species. Instead, fungal ploidy is often context-dependent and can rapidly change from one environment to the next.

Ploidy values currently assigned to fungal species may be influenced by laboratory growth conditions and selection for traits that prove to be beneficial for conducting genetic manipulations. However, as whole-genome sequencing (WGS) and molecular assays for ploidy detection become standard in fungal research labs, the identification of ploidy variants is increasing. For example, polyploid strains of the typically haploid and/or diploid species *Saccharomyces cerevisiae*, *Candida albicans*, and *Cryptococcus neoformans* exist in diverse environments including desert canyons, fermentation and industrial cultures, and from human patients before and after therapeutic treatment with antifungal drugs (10–16). This suggests that many different ploidy-environment interactions may select cells with increased or decreased ploidy that provide these cells with an adaptive advantage (1, 17, 18). A mechanistic understanding of what drives environment-dependent ploidy changes remains to be discovered. Genome sequencing and phenotypic characterization of mutations in these comparatively small eukaryotic genomes (e.g., compared to human genomes) will likely place fungi at the forefront of ploidy research (19–21).

Molecular Detection of Ploidy and Aneuploidy

Ploidy is most commonly measured by flow cytometry of fluorescently labeled cells (e.g., propidium iodide), where the relative fluorescence of an unknown isolate is compared to strains of known ploidy (22). More than 30,000 single cells can be analyzed within seconds, and linear increases in ploidy are detected with great accuracy (Fig. 1A). Aneuploid isolates are detectable by flow cytometry with the caveat that isolates with a single aneuploid chromosome may not be significantly different in the fluorescent signal compared to the known ploidy control. In addition, the fluorescent signal of isolates with multiple aneuploidies (e.g., gain of one and loss of another chromosome) may not show different DNA fluorescence by flow cytometry because these specific aneuploidies cancel each other out. Instead, more quantitative methods must be used to identify the specific aneuploid chromosomes. Flow cytometry coupled with additional molecular methods such as comparative genome hybridization (aCGH), quantitative PCR, and double-digest restriction site-associated DNA sequencing (ddRADSeq) is the most comprehensive approach to detect ploidy changes and identify specific aneuploidies (23–25).

The ploidy level and chromosome copy number of isolates can also be determined using WGS. The copy number of each chromosome is determined relative to the entire genome based on the number (depth) of aligned sequence reads. Aneuploidy is detected as an increase or decrease in read depth relative to the entire genome (Fig. 1B). Segmental chromosome aneuploidies and small gene amplifications/deletions are also detected. Additionally, WGS bioinformatics tools use allele frequencies to determine the baseline ploidy of the sequenced genome (16, 26). For example, a haploid (1N) genome has allele frequencies at 1, a diploid (2N) genome has allele frequencies at 0.5 and 1, a triploid (3N) genome has allele frequencies at 0.33, 0.67, and 1, and a tetraploid (4N) genome has allele frequencies at 0.25, 0.5, 0.75, and 1 (Fig. 1C and D). While limited to strains with significant heterozygosity, WGS simultaneously detects cellular ploidy level, chromosome copy number, and sequence polymorphisms. Further studies are needed to truly understand the extent of ploidy variation in natural populations within and between species.

Ploidy Variation in Natural Isolates

We first highlight three examples of ploidy variation found in isolates of *S. cerevisiae*, *C. neoformans*, and *C. albicans*. These three species have different genome sizes, haploid chromosome numbers, sexual cycles, and preferred base ploidy levels. Despite these differences,

Figure 1 Methods for detection of ploidy and aneuploidy. (**A**) Ploidy is determined with flow cytometry. Total genome fluorescence, measured using a fluorescent nucleotide label (e.g., propidium iodide or Sytox Green). Cells are first fixed (in ethanol) and RNA is removed with RNase, then genomic DNA is fluorescently labeled and analyzed on a flow cytometer. Cells are passed through a laser, and the number of cells are plotted as a function of fluorescence intensity. Cells in a population typically have two fluorescent peaks, representing cells in either G1 or G2 phases of the cell cycle. Flow cytometry plots for yeast with the following ploidy levels are shown: haploid (1N), diploid (2N), triploid (3N), tetraploid (4N), and a near-tetraploid aneuploid. (**B**) Chromosome copy number is determined with WGS and microarray aCGH. The *y* axis represents a $\log_2$ fold change of sequence reads relative to the reference sequence and chromosome number increases from left to right starting with chromosome I and ending with chromosome XVI (*x* axis). Chromosome copy number plots for *S. cerevisiae* with the following ploidy levels indicate euploid genome for haploid (1N), diploid (2N), triploid (3N), and tetraploid (4N). However, the near-tetraploid isolate (bottom panel) is aneuploid for ChrXII (pentasomic) and ChrXIV (trisomic) and contains a segmental aneuploidy of ChrIV. Figures generated from data obtained in reference 20. (**C**) Allele frequencies obtained from WGS data also can be used to determine the ploidy of a strain. The *y* axis shows the heterozygous allele frequencies ranging from zero to one, plotted as a function of chromosome number starting with chromosome I and ending with chromosome XVI (*x* axis). Allele frequency plot of the example haploid strain with single nucleotide polymorphisms (SNPs) at allele frequencies at 1.0; a diploid strain with SNPs at allele frequencies of 0.5 and 1.0; a triploid strain with SNPs at allele frequencies of 0.33 and 0.66; and a tetraploid strain with SNPs at allele frequencies at 0.25, 0.5, 0.75, and 1.0. Images obtained from reference 16. (**D**) A diploid strain that is trisomic (three copies of a chromosome) for chromosome XII (left panel). Interestingly, the allele frequency plot has SNPs at allele frequencies of 0.5 and 1.0 for all chromosomes except ChrXII, which is at allele frequencies of 0.33 and 0.66, supporting that this chromosome is aneuploid (right panel).

all three have been isolated from natural ecosystems and/or human and animal hosts with ploidies that range from haploid to polyploid. Furthermore, all three species can undergo somatic ploidy changes under laboratory conditions.

S. cerevisiae

The budding yeast *S. cerevisiae* contains 16 haploid chromosomes and reproduces by mating and meiosis or asexually via budding. Environmental isolates of *S. cerevisiae* include haploids, diploids, and polyploids (12, 27–30). Clinical and industrial isolates also show a wide range of ploidies and aneuploidy (16, 29). For example, WGS of 145 *S. cerevisiae* clinical isolates found that 34% were triploid or tetraploid and 36% were aneuploid (16). Many of these ploidy changes are thought to be adaptive, but the correlation between environmental selection and ploidy changes is not well characterized (17).

C. neoformans

Naturally found in diverse environmental niches, *C. neoformans* is responsible for pulmonary infections as well as cryptococcal meningoencephalitis in immunocompromised individuals (31, 32). Basidiospores are thought to be the infectious propagules, which are inhaled into the lungs followed by dissemination into other organs (33). *C. neoformans* is normally found in the haploid state with 14 chromosomes and reproduces both sexually and asexually, and these haploid cells can vary in chromosome copy number due to nondisjunction events (34) or due to unisexual or bisexual reproduction (35). Dramatic ploidy changes have been observed during infection. Polyploid "titan" cells that range from 4N to >64N make up ~20% of the infectious population within the host tissue (36, 37). In conjunction with the ploidy increase, cell size, capsule structure, and cell wall structure are also modified. A haploid *C. neoformans* cell is generally 5 to 10 μm in diameter; titan cells can be much bigger, with some reaching upward of 50 to 100 μm in diameter (38, 39). Very little is known about the mechanism of titan cell formation; it may involve endoreplication due to alteration of cyclin proteins as is observed in *Drosophila melanogaster* and human hepatocytes (40, 41). Aneuploidy, in particular the amplification of chromosome 1, has also been observed in response to antifungal drug stress (42, 43).

C. albicans

The most common human fungal pathogen, *C. albicans*, contains eight homologous chromosome pairs. Though it was previously considered an obligate diploid organism (44, 45), alternative ploidy states have been described including haploid, triploid, and tetraploid cells (10, 15, 46–48). No meiosis has been observed in *C. albicans*. Rather, it undergoes a parasexual cycle in which cells of opposite mating type fuse to form tetraploids (49–53). Under nutrient starvation, tetraploid cells show an increase in genome instability that leads to the loss of individual chromosomes over time, returning progeny cells to either diploidy or (more often) near-diploidy (9, 50, 52, 54). Ploidy changes also occur in response to specific environmental conditions. For example, growth on alternative carbon sources (e.g., L-sorbose), exposure to antifungals (e.g., fluconazole), high temperature, and interactions with the host all result in ploidy changes and aneuploidy within a few cell divisions (15, 55–62). The molecular mechanisms driving these ploidy changes are currently unknown.

Other Fungi with Altered Ploidy Levels and Evidence of Aneuploidy

Aneuploidy has been found in many other fungi. *Ashbya gossypii*, a filamentous fungus, has a single syncytia with multiple nuclei, and each nucleus can have a different ploidy (63). In *A. gossypii*, ploidy increases with age, while stress exposure can shift a population with high ploidy variation toward a more homogenous, haploid population (63). Ploidy level variation and aneuploidy are also common in isolates of the amphibian chytrid pathogen, *Batrachochytrium dendrobatidis* (64), and in plant pathogens such as *Fusarium oxysporum* (65, 66). In fact, karyotype variability in *B. dendrobatidis* seems to be the norm rather than the exception; out of 22 isolates analyzed by WGS, 18 were aneuploid, with base ploidies ranging from diploid to tetraploid (64). While these are only a few examples of ploidy changes that are known to occur in the fungal kingdom, they highlight that ploidy changes play a central role in adaptive evolution and genomic diversity.

PLOIDY CHANGES IN THE CONTEXT OF LABORATORY MUTANTS: TOWARD A MECHANISM OF ASEXUAL PLOIDY CHANGE

The underlying mechanisms that drive ploidy changes are not completely understood (12). Some genes encoding ploidy regulators have been identified in yeast deletion mutant screens and gene overexpression studies (67). However, in many mutants the ploidy-altering phenotype is not 100% penetrant (see below), indicating

that there are redundant mechanisms that regulate genome copy number. Alternatively, the mutant genotype may stochastically acquire fitness-associated ploidy changes, in which case the ploidy change would be secondary to the initial gene mutation.

Here we will discuss mutations that affect cell cycle, spindle pole body (SPB), kinetochore attachment, cohesion, chromatin formation, and cytokinesis, focusing on their impact on ploidy changes. Many mutations that affect chromosomal instability can also cause ploidy increases or decreases. Importantly, because chromosome aneuploidy is frequently observed in mutants that undergo ploidy change, it is difficult to determine if aneuploidy itself is driving whole-genome ploidy changes. For example, a mutation may cause aneuploidy, which then gives rise to a whole-genome ploidy change. Alternatively, this mutation may first induce a whole-genome ploidy change, and subsequent aneuploidy results from increased genome instability. The examples provided below support that the mechanisms driving changes in whole-genome ploidy and chromosome copy number are extremely complex and often involve the essential machinery of the cell.

Mutations Underlying Ploidy Amplification

Alterations in cell cycle control can cause ploidy amplification. Endoreplication, the process in which DNA replication is followed not by cytokinesis, but instead by another round of DNA replication, has been described for multiple organisms (68–70). In the fission yeast *Schizosaccharomyces pombe*, cyclin B ($p53^{cdc\text{-}13}$) regulates the temporal order of DNA replication and mitosis. Control of cyclin B levels and the timing of this cell cycle regulator are important; formation of the $p34^{cdc\text{-}2}$-$p53^{cdc\text{-}13}$ complex specifies that the cell is in the G2 phase of the cell cycle. Loss of this complex redefines a cell in the G2 phase to a G1 phase cell, and the cells can then re-enter S-phase and rereplicate their genomes, causing unscheduled WGD. Re-entry into S-phase can occur multiple times and can lead to ploidy shifts from 1N to 32N (71). Interestingly, 42 uncharacterized genes were recently identified in human cells for their role in preventing endoreplication (72), supporting that DNA replication controls are still being discovered.

Under certain circumstances endoreplication is an environment-induced or programmed cell event. For example, environment-induced endoreplication likely leads to titan cell formation in *C. neoformans* (36, 38, 39). The exact mechanism of cell cycle alteration is not known for titan cell production, but like in *S. pombe*, the control of cyclin B level is a potential candidate. In the human liver, hepatocytes undergo genome replication followed by programmed cytokinesis failure to produce a binucleate daughter cell that is 4N (73). These binucleate tetraploids can then undergo another round of DNA replication followed by cytokinesis to generate mononucleate tetraploid cells. This cycle can continue to produce octaploid cells and so on. In addition, these polyploid hepatocytes can undergo mitosis with multipolar spindles, resulting in ploidy reduction and aneuploidy (8). It has been hypothesized that these aneuploid daughter cells may provide adaptive benefits during periods of cellular stress and allow for repopulation and restoration of the liver (73–75).

Accurate SPB function and attachment of the spindle microtubules to the chromosomes are required for proper chromosome segregation, and ploidy changes can occur when different components of the SPB complex are altered. During normal cell division, sister chromatids are attached to opposite SPBs and are pulled apart, thereby segregating the sister chromatids. *NDC1* (nuclear division cycle 1) encodes a subunit of the nuclear pore complex in *S. cerevisiae* and is required for SPB duplication and insertion into the nuclear membrane (76). Mutant *ndc1* cells have only a single functioning SPB to which all chromosomes attach and are then segregated into a single daughter cell, resulting in WGD.

Proper attachment of the SPB microtubules to the kinetochore is a major point of regulation during cell cycle progression. In *S. cerevisiae*, mutations in the essential gene *IPL1* (increased ploidy level 1) can result in aneuploidy and/or elevated ploidy level. *IPL1* encodes Aurora kinase, which is involved in the attachment of the spindle microtubules to the kinetochores, chromosome segregation, and checkpoints including mitotic spindle dis/assembly and DNA damage (77–79). Ipl1 is also responsible for sensing mitotic spindle attachment at the kinetochore and preventing segregation in cases where the chromosome is attached to only one SPB. Using a temperature-sensitive mutant of *IPL1*, Chan and Botstein (67) observed that haploid cells rapidly acquired multiple aneuploid chromosomes when grown at the restrictive temperature, and some of these mutants gained enough chromosomes to result in a ploidy increase.

In addition to SPB subunits, ploidy is affected by defects in chromosome cohesion. After replication, sister chromatids are packaged together by cohesion, a protein complex that holds the sister chromatids together until they are separated during anaphase (80). Improper loading or disassembly of the cohesion complex during the cell cycle leads to aberrant chromosome seg-

regation that results in ploidy shifts and aneuploidy (81). Defects in the cohesion complex, as well as regulators of the complex, lead to release of sister chromatids before proper attachment to the SPB. This increases the chance that sister chromatids will be inherited together because the sensing of microtubule attachment does not occur and segregation of sister chromatids is no longer interdependent (81).

Chromatin structure and regulation are important regulators of ploidy. The dynamics of chromatin structure are determined by histone conformation and modifications. Mutations within the globular domain of histone 4 (H4) result in heterogeneous colony sizes and an increased frequency of WGD and aneuploidy in *S. cerevisiae* (82). Further analysis of these colonies shows that small colonies consist of a mixed population of haploid and diploid cells, while large colonies are completely diploid, suggesting extensive autodiploidization. Alterations of the amino acids in the globular domain of H4 (L97, Y98, or G99 to alanine) do not alter the ability of H4 to interact with other histones. Instead, these mutations alter the H4 interaction with the histone chaperones Rtt106 and Caf-I. Disruption of these interactions prevents the nucleosome from being loaded onto the DNA. This decrease in histone occupancy could disrupt kinetochore architecture and assembly, leading to the increase in aberrant chromosome segregation and autodiploidization (82).

Just as histone modification can affect genome stability, nucleosome stability at centromeres is necessary for kinetochore assembly and proper chromosome segregation. Nucleosome stability is achieved through proper distribution of histone variants. The histone variant H2A.Z is conserved across all fungi and higher eukaryotes and is enriched at pericentric DNA but excluded from CENP-A (Cse4) nucleosome binding sites (83). Ies6 is an essential subunit of the INO80 chromatin-remodeling complex. Loss of Ies6 causes polyploidization and increased localization of pericentric H2A.Z (84), resulting in changes to chromatin structure that inhibit centromere/kinetochore function. Furthermore, overexpressing H2A.Z in an *ies6* mutant strain further increases chromosome instability, leading to more rapid polyploidization (84).

After genome replication and chromosome segregation, the cell undergoes a cleavage event controlled by the contraction of an actin ring found between the mother and daughter cell. Myo1, the sole myosin II motor in *S. cerevisiae*, associates with the actin ring and promotes cleavage between the mother and daughter cell (85). Haploid strains with a *myo1* deletion often undergo WGD events to survive, causing ploidy level increases from 1N to 4N (86). Many of the polyploid *myo1* evolved clones are mononucleate and contain multiple aneuploid chromosomes. These polyploid *myo1* evolved clones are not only viable but have restored cytokinesis through a variety of mechanisms, unlike most of the *myo1* cells that remain haploid. Therefore, the mutations that disrupt cell division and alter ploidy level can provide increased adaptability (86).

Mutations Underlying Ploidy Reduction

Several *S. cerevisiae* mutations have been identified that lead to genome reduction from diploid to haploid. For example, diploid cells with a null mutation in *RAD52* (involved in strand exchange during recombination and DNA damage repair) undergo chromosome loss via sequential aneuploid transitions (87). Loss of Rad52 leads to a failure of the repair mechanism that keeps the chromosome homologs together after a double strand break (DSB). Loss of this pathway gradually leads to genome reduction toward haploidy over ~500 generations. Interestingly, cells with higher ploidy showed increased Rad52 dependency because *RAD52* is essential for growth of tetraploid cells but not isogenic diploid cells (88). This supports that increasing ploidy results in an increased frequency of DSBs that must be repaired by Rad52, and diploids, but not tetraploids, can resolve some of this damage by sequential chromosome loss and eventual ploidy reduction.

In addition to mutations in *RAD52*, null mutations in *CTF18* (involved in sister chromatid cohesion) also lead to rapid genome reduction from diploidy to haploidy (89). This reduction in ploidy occurs over a relatively short amount of time (~50 generations) and suggests that the haploid cells have a fitness advantage over the diploid progenitor. Surprisingly, genome duplications are also observed within the diploid *ctf18* population, resulting in a heterogeneous population (haploid, diploid, aneuploid, and polyploid cells). This suggests that specific mechanisms of genome instability may simultaneously induce aneuploidy, ploidy loss, and ploidy gain.

IMPACT OF PLOIDY LEVEL ON DNA DAMAGE REPAIR

At all ploidy levels, DSBs are repaired by two main pathways: nonhomologous end-joining and homologous recombination. Nonhomologous end-joining repairs DSBs via ligation of the broken DNA ends with little or no processing of the DNA ends. Nonhomologous end-joining is considered error-prone because this process can introduce novel mutations. Alternatively,

homologous recombination uses a homologous DNA sequence to serve as a donor for recombination and DSB repair (90, 91). The availability of homologous DNA sequences (sister chromatid, homologous chromosome, or an ectopic sequence) is influenced by the ploidy of the cell and phase of the cell cycle: haploid cells have homologous DNA sequences available during S/G2 only, while diploid and polyploid cells have homologous DNA sequences available throughout the cell cycle. Therefore, diploid and polyploid cells have an increased preference for homologous recombination to repair DSBs, resulting in increased frequencies of recombination, gene conversion, crossover events, and gross chromosomal rearrangements (GCR) (92–94).

Isogenic yeast strains with different ploidies exhibit different mutation rates and sensitivity to DSBs. The forward mutation rate at either the *CAN1* or *URA3* locus is two orders of magnitude higher in diploids than in haploids, and diploids are less sensitive to DSBs than haploids (88, 89, 95). Interestingly, the forward mutation rate at *CAN1* is lower in tetraploids compared to diploids (88). Ploidy also affects sensitivity to DSBs: both haploids and tetraploids are more sensitive to DSBs than diploids. One reason for these observations may be the different requirements for DSB repair at different ploidy levels (94).

Ploidy-specific genome maintenance mechanisms may exist, but many questions still remain (94). For example, in *S. cerevisiae* there are ploidy-specific stress responses to GCR (96), and tetraploid yeasts have a greater requirement for genes involved in recombination and mitosis than haploids or diploids (88). This phenomenon, called "ploidy-specific lethality," is used to identify the physiological alterations that accompany tetraploidy. Out of 3,740 yeast deletion mutants, only 39 genes exhibit ploidy-specific lethality. Almost all of these mutations affect genomic stability by impairing homologous recombination, sister chromatid cohesion, or mitotic spindle function (88). Why tetraploid cells have an increased requirement for these genes remains unknown (97). The rate and spectrum of mutations available to each ploidy level is remarkably different, so genome maintenance mechanisms could play an important role during adaptation.

GENOME INSTABILITY IN POLYPLOID CELLS

One of the most striking features of polyploid cells is their increased genome instability relative to diploid cells. This phenomenon is seen across many eukaryotic species, including many plant species (98–101). In fungi, polyploid cells frequently give rise to aneuploid progeny (both whole chromosome and segmental), chromosome rearrangements, and translocations. For example, tetraploid *S. cerevisiae* cells have a 200- to 1,000-fold increase in the rate of chromosome loss compared to isogenic diploid cells (88, 102, 103). Similarly, tetraploid *C. albicans* cells have a 50-fold higher rate of loss of heterozygosity (LOH) compared to isogenic diploid cells (54). Increased genome instability often results in rapid ploidy reduction during *in vitro* growth of most polyploid populations (9, 19, 20, 43, 54, 104), yielding progeny with high karyotypic diversity. Here we highlight examples for *C. neoformans*, *C. albicans*, and *S. cerevisiae*.

The dramatic ploidy reduction of *C. neoformans* titan cells was recently analyzed by microdissection of sequential daughter cells from a polyploid titan cell followed by colony formation assays and WGS (43). In a replete environment, polyploid titan cells produced true haploid daughter cells. In contrast, when exposed to fluconazole, titan cells frequently generated aneuploid haploid and aneuploid diploid daughter cells (43). Furthermore, daughter cells from the same titan cell parent had diverse aneuploid karyotypes, while point mutations were rarely observed. It remains to be tested whether this aneuploidy is due to an effect of fluconazole on mitotic fidelity (as was seen in *C. albicans* [62]) or is the result of a general stress response.

A foundational study of *C. albicans* tetraploid cells found that they undergo a rapid, nonmeiotic genome reduction in response to nutrient starvation, termed "concerted chromosome loss" (9). Genetic analysis of many progeny by microarray (single nucleotide polymorphism [SNP]) and aCGH arrays) found that only a very small fraction returned to a true euploid diploid state, and the majority of the progeny were aneuploid for one or more chromosomes. In addition, recombination, albeit limited to a few progeny, occurred between heterozygous loci on homologous chromosomes during tetraploid genome reduction (52). The appearance of multiple gene conversion tracts within several strains, and the general absence of gene conversion tracts in other strains, suggests that some cells become generally competent for recombination at more than one locus, while other strains do not undergo such recombination events at all. Importantly, these recombination events were dependent on Spo11, a conserved protein required for the introduction of DSBs (52). These findings suggest that at least one meiosis-specific gene has been reprogrammed to mediate genetic recombination during the alternative parasexual life cycle of *C. albicans*.

Recent studies have characterized the rate of concerted chromosome loss in different growth environments. For example, populations of tetraploid, triploid, and diploid *C. albicans* strains were grown for 28 days in yeast extract-peptone-dextrose (YPD), and chromosome loss dynamics were analyzed at different time points using flow cytometry and ddRADSeq. Initially, the tetraploid-evolved clones were highly aneuploid, and once the cells became aneuploid, further ploidy reduction accelerated, with aneuploid strains changing ploidy faster than tetraploid strains (54). Eventually, the tetraploid and highly aneuploid evolved cells converged to stable euploid levels: diploid, triploid, and (rarely) tetraploid. In addition, this study showed that chromosome loss was random; ploidy reduction in biological replicates of the same polyploid strain rarely followed the same chromosome loss trajectory.

Similar nonmeiotic ploidy reductions have been observed in tetraploid populations of *S. cerevisiae* during *in vitro* evolution (19). In this study, tetraploid *S. cerevisiae* strains were passaged for ~1,800 generations in rich or high-salt medium, and genome reduction at the population level was detected with flow cytometry after ~186 generations. Results from this study support that ploidy loss occurs as if selection is acting on multiple chromosome loss events simultaneously rather than on individual, sequential chromosome loss events (105). In addition, these *in vitro* evolution experiments found that ploidy loss in a tetraploid population often paused at near-euploid levels, from tetraploid to near-triploid to near-diploid (105). Furthermore, aneuploidies (detected by aCGH) present in the tetraploid progenitor were often found to be the only aneuploidy that remained in the near-diploid evolved population (19). Thus, while the mechanism of tetraploid genome reduction is unknown, the rapid ploidy loss observed in these environments supports that multiple chromosomes can be lost simultaneously.

The ploidy reduction process of *S. cerevisiae* tetraploid cells was further analyzed with WGS of strains from many parallel *in vitro* evolution experiments (20). The ploidy of tetraploid-evolved clones was determined by flow cytometry, and the copy number of every chromosome was determined by WGS. It was found that aneuploidy is more extensive during the tetraploid to diploid transition than previously appreciated. In raffinose medium, ploidy reduction did not occur by loss of a full set of chromosomes; rather, many of the tetraploid evolved cells were highly aneuploid, including individual chromosome copy numbers that ranged from 4C to 2C in the same cell (Fig. 2). This indicates that while some chromosomes are lost multiple times, others are maintained at the original tetrasomic level (e.g., 4C, 3C, and 2C). Interestingly, specific chromosome pairs were more frequently lost together and underwent multiple loss events independent of other chromosome pairs (20). These copy number differences were likely a result of the environmental selection for particular karyotypes with increased fitness; indeed, the most common aneuploid chromosome in this study, amplification of chromosome XIII, was found to provide a significant fitness benefit to tetraploid cells in raffinose medium (20).

These studies of *C. albicans* and *S. cerevisiae* show that tetraploid-evolved clones can be highly aneuploid, with many evolved isolates reaching a near-euploid state (near-triploid or near-diploid). The rate of chromosome loss is largely dependent on the growth environment and generation time, as well as the frequency of sampling throughout the experiment. In general, the random chromosome loss that occurs during *in vitro* culturing of tetraploid *C. albicans* and *S. cerevisiae* populations appears mechanistically distinct from the haploid bud produced from *C. neoformans* titan cells. Future studies in these and other fungi may identify unique mechanisms of chromosome and genome stability and aneuploid tolerance in polyploid cells.

Given that ploidy reductions can occur over short evolutionary timescales, it is puzzling that polyploid cells are observed at all. One hypothesis is that polyploidy is simply an intermediate state to which a cell shifts for survival, for example, after cytokinesis failure due to cell wall stress (86, 106). However, another hypothesis is that the polyploid state is beneficial in specific environments and is selected upon due to increased fitness. Indeed, tetraploid *S. cerevisiae* strains passaged *in vitro* for ~1,000 generations at 23°C stably maintain euploid tetraploid genomes (107). These evolved tetraploid cells are resistant to benomyl, a microtubule depolymerizing drug that tetraploid cells are more sensitive to than diploids (88). The stable tetraploids have increased levels of Sch9, a kinase involved in protein homeostasis, G1 cell cycle progression, nutrient signaling, and stress response, suggesting that newly formed tetraploid cells can acquire genome stability through improved cell growth processes (107).

IMPACT OF PLOIDY ON FUNGAL PHYSIOLOGY

Alterations in genome architecture have wide-reaching effects on many cellular processes. How ploidy shifts change cellular physiology is a long-standing question. A ploidy increase is associated with enlarged cell size in

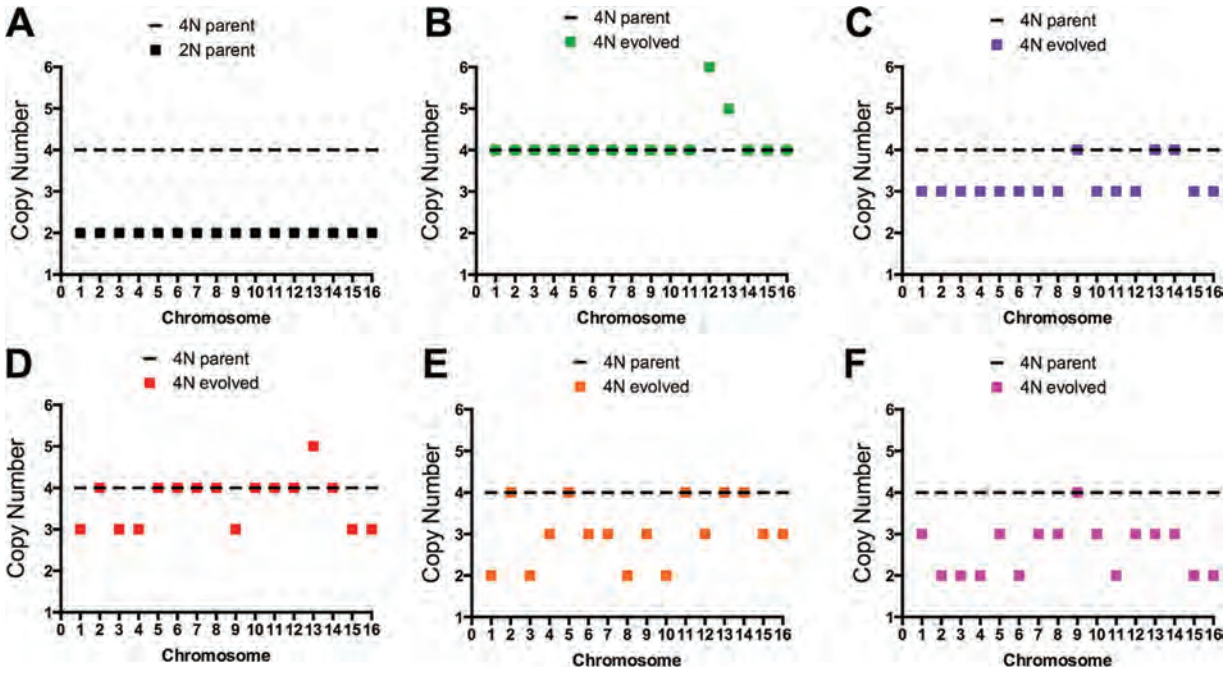

Figure 2 Many polyploid-evolved clones are highly aneuploid. Chromosome copy number was determined by WGS and plotted for the (**A**) parental diploid (2N) and tetraploid (4N) strains and different tetraploid evolved clones after 250 generations in raffinose medium. Adaptation resulted in clones with (**B**) increased chromosome copies, (**C**) approximately trisomic copies of every chromosome (~3N), or (**D-F**) highly aneuploid genomes. all eukaryotes (38, 39, 108–111). However, we lack a mechanistic understanding of how genome size controls cell size (112). Research that has compared growth rate, gene expression patterns, and cell surface area to volume ratios between haploid and diploid, or diploid and polyploid cells has provided insight into the complex, sometimes subtle, differences between isogenic fungal strains of different ploidy. Here we highlight how ploidy affects the physiological properties of cell size and gene expression.

The reduction in cell surface area to volume ratio of polyploid cells likely impacts nutrient transport, signaling pathway components, and ultimately growth rate in some environments. Upon genome duplication, polyploid cells underwent a 2-fold increase in cell volume, but only a 1.57-fold increase in cell surface area relative to their diploid progenitors (88, 113, 114). This reduced surface area in polyploid cells was expected to cause growth disadvantages in environments where nutrients are absorbed across the membrane. However, there was little evidence to support this cell surface area-to-volume ratio theory in polyploid cells (115). A robust analysis of this theory, performed with 51 haploid and diploid *S. cerevisiae* and *S. paradoxus* strains in 33 growth conditions, found that ploidy accounts for a majority (70%) of the differences in growth rate between strains (17). However, the results were inconsistent with the surface area-to-volume model. Rather, it appeared that the preference for the haploid versus diploid state was due to condition-specific effects in the strains tested, not due to differences in surface area (17). Thus, more research is needed to understand the physiological changes that occur after polyploidization and what effect the environment has on fitness and genome stability. Furthermore, identifying transcriptional changes that occur in other environments, including nutrient limitation, will provide important clues to the growth differences polyploids experience in these environments.

Gene expression studies have been used to identify molecular signatures that are unique to polyploid cells. The first gene expression microarray study on polyploid *S. cerevisiae* cells identified only a few genes with significantly different levels of expression in isogenic haploid and tetraploid cells when grown in rich medium (114). For example, tetraploid cells had reduced expression of genes encoding G_1 cyclins (*CLN1* and *PCL1*) and proteins involved in cytoskeletal orga-

nization (e.g., *GIC2*). In another study, a different *S. cerevisiae* strain (S288C instead of Σ1278b) was analyzed under the same growth conditions, and no genes had significantly different levels of expression in isogenic diploid and tetraploid cells (88). This suggests that either there are more transcriptional differences between haploids and tetraploids compared to diploids and tetraploids, or there are strain-specific ploidy differences (116).

Using RNA sequencing analysis, Wu et al. identified 65 transcripts with differential expression in isogenic haploid and tetraploid *S. cerevisiae* cells, again in rich medium (109). A majority of these genes encoded cell surface proteins, which suggests that the enlarged cell size of tetraploids caused the differential regulation of these genes, and not ploidy *per se*. Indeed, it was found that haploid mutants with increased cell size showed differential expression for many of the same genes as tetraploids, and the degree of changes in expression correlated with the degree of size increase (109). Importantly, gene expression of most of these cell surface proteins was repressed in tetraploid cells (and enlarged haploids), likely due to the reduced surface area relative to cell volume (88, 113, 114). These observations are consistent with proteomic studies that found reduced amounts of cell surface proteins in diploids compared to haploids (117).

PLOIDY CHANGES AND ANEUPLOIDY IN THE CONTEXT OF EXPERIMENTAL EVOLUTION

Ploidy Changes and Aneuploidy Occur During *In Vitro* Evolution and Provide a Fitness Benefit

In vitro evolution experiments provide the strongest evidence that fungi can undergo asexual ploidy changes during adaptive evolution. The environmental cues driving these genome changes are not known, and a comprehensive study of environments that induce ploidy changes (WGD and ploidy reduction) is lacking (Table 1). In this section, we will examine the different environments in which ploidy changes and acquisition of aneuploidy are documented in fungi and how these genome size changes affect organismal fitness and adaptation.

We describe the *in vitro* studies in which whole-genome ploidy changes and chromosome copy number changes are observed. Many of these examples describe changes in ploidy that occur at the population level. If beneficial (e.g., increasing fitness), ploidy or chromosome copy number changes are selected for within the population. The exact order of events and mechanisms that drive the initial ploidy change is unknown.

Results from multiple studies showed that in *S. cerevisiae*, whole ploidy level changes causing diploidization are advantageous in multiple environments. For example, isogenic haploid, diploid, and tetraploid *S. cerevisiae* populations passaged in rich medium, medium containing high salt, or increased concentrations of ethanol all converged toward diploidy (19, 105, 118). The diploidized cells had significantly higher fitness than the isogenic progenitor strains in competition experiments (118). Furthermore, the rate of ploidy change is dependent on the specific growth conditions. For example, in high-salt medium, the rate of diploidization of haploids was faster than the rate of diploidization of isogenic tetraploids (19). Therefore, becoming diploid under these growth conditions was one of the most common and accessible routes to increased fitness.

Frequent diploidization of haploid cells also occurred during *in vitro* evolution experiments under glucose depletion (21, 119). In this unique study, the evolving populations consisted of ~500,000 uniquely barcoded haploid *S. cerevisiae* lineages. The autodiploidized clones had a strong fitness benefit relative to their haploid progenitor, and WGS revealed that in most cases diploidy was the only adaptive mutation (21). The autodiploid lineages were traced back to their respective founding populations, suggesting that the transformation conditions (lithium acetate and heat shock) used for barcoding led to the formation of autodiploids (21). Interestingly, transformation conditions also induced ploidy loss, aneuploidy, and LOH in *C. albicans* (55, 120).

Convergence toward diploidy is also observed in *C. albicans*. Tetraploid mating products and rare haploid isolates returned to the diploid state after *in vitro* passage (9, 47, 54). The convergence toward diploidy occurred under different growth conditions but ultimately depended on the environment and initial genotype, not necessarily the fitness benefit of the acquired ploidy change (121). For example, during phosphorus depletion, the autodiploidization rate of haploids was reduced, while the diploidization rate of tetraploids was increased. Further studies are needed to uncover the factors that drive organisms to a "baseline" ploidy.

In contrast to the convergence toward diploidy observed in many environments, a wide array of genome changes can occur under a single growth condition. For example, growth in the fungistatic drug fluconazole often resulted in a wide variety of ploidies and aneu-

Table 1 Summary of experimental evolution studies in fungi and the ploidy and aneuploidy associated with different environmental stresses. Ploidy levels of haploid (1N), diploid (2N), triploid (3N), and tetraploid (4N) are euploid states, while aneuploidy is indicated if known.

Fungi	Stress	Timeframe	Ploidy change/aneuploidy	Reference(s)
S. cerevisiae	YPD, high salt	1,800 generations	1N → 2N and 4N → 2N	19
S. cerevisiae	YPD	186 generations	4N → 2N and 3N → 2N	105
S. cerevisiae	Raffinose	250 generations	4N → 4N–2N aneuploidies common 2N → 2N and 1N → 1N (no ploidy change)	20
S. cerevisiae	Ethanol	200 generations	1N → 2N and 4N → 2N	118
S. cerevisiae	Low glucose (LiAc transformation)	88–132 generations	1N → 2N	21, 119
C. albicans	L-Sorbose, presporulation at 37°C	5–7 days	4N → 2N and aneuploid 2N	9, 52
C. albicans	L-Sorbose	2 days	2N → 2N monosomic for Chr5	56
C. albicans	YPD	28 days	4N → 4N, 3N, or 2N 2N → 2N	54
C. albicans	Rich media and nitrogen depletion	140 generations	1N → 2N and 4N → 2N	121
C. albicans	Minimal media and phosphate depletion	140 generations	1N → 1N and 4N → 2N	121
C. albicans	Fluconazole (2–10 μg/ml)	8–12 h	2N → 4N, 8N, 16N trimeras (20% of cells in the population)	62
C. albicans	Fluconazole (100 mg disk)	12–16 h	2N → 1N	123
C. albicans	Fluconazole (increasing MIC)	330 generations	2N → 2N–3N aneuploidies common: whole chromosome, isochromosomes, and telomere-telomere fusions	46, 59, 61
C. albicans	Murine host	1–5 days	2N → 1N and aneuploid 1N	47
C. albicans	Murine host	Single passage	2N → 2N aneuploid	60
C. albicans	Heat shock (51°C)	90 seconds	4N → 2N	55
C. tropicalis	L-Sorbose	8–10 days	4N → 2N	104
C. tropicalis	Rich media	>120 generations	4N → 2N	104
C. neoformans	Fluconazole (32 μg/ml)	3–5 days	1N → 1N aneuploidies common	42, 124
C. neoformans	Fluconazole (8 μg/ml)	48–96 h	Polyploid titan cells → 1N and 2N aneuploidies common	43
C. neoformans	YPD, oxidative and nitrosative stress	48 h	Polyploid titan cells → 1N	43
C. neoformans	Murine	3 days	1N → polyploid titan cells (20% of population)	38
C. neoformans	Unisexual reproduction	~2 weeks	1N → 2N and aneuploidies common	35
A. gossypii	NaCl, $ZnSO_4$, fluconazole (325 nM), heat (37°C)	6 h	Polyploid and aneuploid → euploid 1N (distribution of ploidies shifted toward haploid)	63
A. gossypii	Caffeine	6 h	Polyploid and aneuploid → polyploid and aneuploid	63

ploid changes in *C. albicans* and *C. neoformans* (35, 43, 46, 59, 61, 62, 122–124), and just 8 to 12 hours of drug exposure resulted in both ploidy reduction and ploidy amplification in *C. albicans* (62, 123). Fluconazole is known to alter membrane fluidity, which causes abnormal cytokinesis and cell cycle defects leading to polyploid and aneuploid formation (62). The immediate fitness effect of these ploidy level mutations is not known, but it can be inferred by measuring how rapidly mutant cells accumulate within a population. For example, during *in vitro* evolution of *C. albicans* in the presence of fluconazole, acquisition of multiple aneuploid chromosomes was detected after just ~3.3 generations in the majority of cells in the population (61). One of these aneuploidies, isochromosome 5L [i(5L)], conferred fluconazole resistance due to the amplification of two genes, *ERG11* and *TAC1* (13, 59). Due to the high fitness benefit, i(5L) accumulated rapidly in the population, and in many cases was maintained over ~330 generations in the presence of fluconazole (61).

Many additional examples support that acquisition of aneuploid chromosomes can lead to rapid adaptation to specific environments, and like ploidy changes, these aneuploid chromosomes are reversible. For example, growth on alternative carbon sources led to loss

of specific chromosomes in multiple fungal species, and the addition of glucose led to reduplication of the remaining chromosome (56, 104). Additionally, during adaptation to heat stress, *S. cerevisiae* rapidly duplicated chromosome III, but after continued heat stress the chromosome aneuploidy was lost while elevated expression of genes on this chromosome was maintained, suggesting that aneuploidy provided time for cells to search for optimal adaptive solutions (125).

While acquisition of aneuploidy is not always beneficial (126), aneuploidy can lead to a wide variety of fitness effects in different growth environments. Studies of the heat shock protein Hsp90 in *S. cerevisiae* showed that during periods of heat stress Hsp90 was titrated away from its regular clients such as kinetochore proteins (127, 128). Importantly, exposure to heat stress or inhibition of Hsp90 led to a marked increase in chromosome instability and tolerance to other stressors including hydrogen peroxide, cyclohexamide, tunicamycin, benomyl, and radicicol (128). More recently, Dunham and colleagues performed a comprehensive analysis of aneuploid genotypes in *S. cerevisiae* and found that each karyotype had large, but condition-dependent, changes in fitness, supporting that aneuploidy can be an important driver of adaptation (129, 130). Many more *in vitro* evolution experiments showed that aneuploidy and ploidy change can be beneficial during adaptation, especially during adaptation to nutrient limitation and heat stress (55, 120, 131).

While we have discussed how changes in ploidy and chromosome copy number can be adaptive in certain environments, some species of pathogenic fungi carry multiple, nonessential chromosomes called accessory, supernumerary, B, or dispensable chromosomes (132). Accessory chromosomes are characterized by highly variable regions, high mutation rates, and genes acquired via horizontal gene transfer (133–136). Many of these harbor virulence genes that allow the fungus to infect its host. The plant pathogen *Nectria haematococca* carries an array of genes on accessory chromosome 14 that allow the fungus to detoxify phytoalexin used by the pea plants as a defense mechanism (136, 137). In *F. oxysporum*, a striking 40% of the genome was found exclusively in strains that infect tomato plants. Moreover, most of the genetic material in these accessory chromosomes lacks sequence homology to any close relatives of *F. oxysporum* (138). Further research is needed to investigate how these accessory chromosomes evolved, are maintained, and what roles they play in virulence.

Many filamentous fungi, including the cotton pathogen *A. gossypii*, have evolved alternative strategies to generate genotypic diversity. This fungus has syncytia that undergo asynchronous nuclear division (139). It was originally thought to be a predominantly haploid fungus, but Gladfelter and colleagues recently demonstrated frequent ploidy variations for different nuclei within the same syncytium, including aneuploidy (63). To identify ploidy changes, they used lac operator arrays to track the copy number of individual chromosomes within the nuclei of the same syncytium and found nuclear ploidies ranging from 1N to >4N (63). Interestingly, in response to cellular stress (cell wall stress, osmotic stress, excess zinc, the antifungal fluconazole, and increased temperature), polyploid nuclei diminished and haploid nuclei predominated. These results suggest that nuclei with different ploidies are tolerated within single syncytia, and that there may be costs associated with ploidy level variation, because stress homogenizes the genome content of nuclei (63). Remarkably, ploidy reduction and homogenization of ploidy under stress is the opposite of what has been observed for the human fungal pathogens *C. albicans* and *C. neoformans*, where stress led to genomic diversification within populations and increased aneuploidy (43, 59, 61).

The above examples establish that fungal organisms can adapt rapidly to their environment by undergoing ploidy and chromosome copy number changes. It also highlights the challenge of determining the causative interactions between environment and ploidy levels (Table 1). While it is unclear what types of ploidy changes will arise in any given environment, it is a common strategy of pathogenic fungi to generate genomic variation in response to environmental perturbations.

It is important to note that in any given fungal population, one or more subpopulations may exist that have acquired viable aneuploidies or undergone ploidy shifts. This is due to background rates of chromosome mis-segregation and failed mitosis. It is of great interest to understand how entire populations of cells, when subjected to stress, can become polyploid or aneuploid. Are the vast majority of cells dying and selection acts upon the survivors, resulting in cells with ploidy changes beneficial for survival? Or could there be a mechanism permissive or instructive in the generation of aneuploid or polyploid organisms? Both of these questions remain open to further investigation.

Ploidy and Aneuploidy Changes Arise During *In Vivo* Evolution

Ploidy level heterogeneity and aneuploidy are frequently observed in clinical isolates of fungal species including *C. albicans*, *C. neoformans*, and *Candida glabrata*

(10, 11, 15, 140, 141). However, very little is known about the dynamics of ploidy changes during *in vivo* evolution and the effects on host-fungus interactions.

To assess the types of genome alterations that *C. albicans* undergoes upon host encounter, single-passage *in vivo* experiments were conducted in a murine model of systemic infection. Ploidy changes compared to the diploid progenitor were detected in ~3% of recovered strains and included segmental and whole chromosome aneuploidy. While this frequency is relatively low, no aneuploids were detected in strains from an *in vitro* control population. Results from this study suggest that conditions within the animal host affect chromosome disjunction more strongly and that this may reflect the very different population growth responses *in vivo* (60). More recent studies on the adaptive potential of *C. albicans* in response to the oral and systemic host niche show that the acquisition of aneuploidy is much more frequent than previously reported. Excitingly, the first haploids ever reported for *C. albicans* were found among strains recovered from an oral model of infection (47). Haploid isolates arose as early as 3 days postinfection with a frequency of $\sim 2 \times 10^{-5}$ and not only differed in their genotypes (e.g., *MTL* status) but also showed phenotypic differences compared to their diploid progenitor. These phenotypes include decreased fitness in YPD at 30 and 37°C and defects in filamentation (47; A. Forche, unpublished). Importantly, haploids arose independently in six mouse hosts, and multiple haploids with different genotypes were found in the same host (A. Forche, unpublished). Overall, the frequency of phenotypic changes such as fitness at different temperatures, filamentation, or the production of hydrolytic enzymes that accompanied aneuploidy in general was much higher compared to cells that remained diploid. This suggests that some of these aneuploid states may be adaptive. Interestingly, the dramatic changes in ploidy may be specific to pathogenic host niches: passage of *C. albicans* using a murine commensal model found no ploidy or chromosome copy number changes by flow cytometry and WGS (142), supporting that host microenvironment impacts genome architecture.

Upon infection with *C. neoformans*, the host's immune system responds by trying to combat the fungus via oxidative or nitrosative attacks by macrophages and neutrophils. The formation of polyploid titan cells inside the host (as discussed above) is accompanied by a ploidy shift from a 1N euploid state to one up to >64N (143). Current evidence points to the importance of titan cells and their ability to withstand various stresses that may be encountered within a host (38, 43). For example, among cells harvested from infected lungs, titan cells exhibited resistance to both sodium nitrate and *tert*-butyl hydroperoxide and survived under conditions lethal to non-titan cells (38, 43).

In summary, single passage of diploid *C. albicans* cells in an oropharyngeal model of infection leads to ploidy reduction to a haploid or near-haploid state (47). In addition, aneuploidy arises frequently upon encounter with the host in different models of infection (60). In contrast, haploid *C. neoformans* undergoes polyploidization upon host encounter (144). It is currently unknown what specific factors influence ploidy shifts in these fungi, but it is likely a combination of many variables including temperature, pH, host immune cells, and interaction/competition with other microbes (145, 146).

THE BENEFICIAL EFFECTS OF PLOIDY CHANGES

Adaptation of an organism to a novel environment is a function of the rate in which beneficial, growth-promoting mutations are acquired and spread throughout the population. The rate of adaptation is affected by multiple, interrelated properties that determine the appearance, persistence, and fixation of beneficial mutations in a population. These properties include the rate of beneficial mutations, the fitness effect of these mutations, the dominance of mutant alleles, and effective population size (147–153). While aspects of this process are still poorly understood, theoretical studies indicate that ploidy affects the rate of adaptation (2, 154, 155).

Ploidy change can impact the evolutionary trajectory of a cell by altering the rate and spectrum of beneficial mutations. For example, a ploidy increase (WGD) increases the mutational target size. A ploidy increase also provides the cell with the ability to buffer deleterious mutations due to redundant gene copy numbers (1, 156). Furthermore, some mutations and/or genome changes are only accessible to cells with specific ploidies, and this can have a profound impact on adaptation. For example, diploid and polyploid cells can undergo LOH, while haploid cells can acquire recessive mutations upon which selection can act (1, 157, 158). Similarly, polyploid cells have high rates of whole-chromosome aneuploidy, which can provide fitness benefits during adaptation (20, 86, 88), yet haploid cells rarely acquire aneuploidy during adaptation, likely due to the increased fitness cost of these mutations in most environments (126). Lastly, the fitness effect of a given mutation is assumed to be equal across all ploidy levels, but recent

experimental evidence suggests that this is not the case for all mutations (20, 159–161).

IMPACT OF PLOIDY AND ANEUPLOIDY ON CANCER BIOLOGY

Ploidy changes and acquisition of aneuploid chromosome copy numbers are hallmarks of cancer cells. Tetraploid cells are frequently observed in precancerous lesions of Barrett's esophagus (162, 163) and in preneoplastic cervical cells (164). Recently, a systematic comparison of over 5,000 human tumors found that 37% had undergone genome duplication during tumorigenesis (165). Evidence for ploidy changes in these tumors came from gene copy number and allelic ratio data obtained from SNP microarrays. Compared to diploid tumors, tumors that underwent WGD had higher rates of gene copy number alterations, including chromosome loss, resulting in ploidy levels ranging from triploid to tetraploid. WGD often preceded other gene copy number alterations in these tumors, supporting that WGD can be a driver of tumorigenesis. The idea that WGD can promote tumor development was previously shown in a mouse breast cancer model (p53–/– mammary epithelial cells [166]). Isogenic diploid and tetraploid cells were generated *in vitro*, mimicking a recent WGD event. When transplanted into mouse mammary epithelia, only the tetraploid cells generated tumors (166). Additional studies support that WGD resulting in tetraploidy is an intermediate step toward aneuploidy and tumorigenesis (106, 164), while other studies support that in some cancer types aneuploidy may precede the tetraploidization event (167).

Whole-genome reduction is also observed during development of rare leukemia subtypes, including acute lymphoblastic leukemia (168). These haploid leukemias are considered near-haploid because the lymphoblastic cells are often aneuploid for one or more chromosomes (1N+1), frequently involving chromosome 21 (168). Haploidization and LOH nearly across the entire genome may underlie the aggressiveness of these cancers, resulting in very poor prognosis (168). However, this haploid population appears to be unstable and undergoes WGD (autodiploidization) with some frequency. Evidence for autodiploidization was found in patients with mixed lymphoblast populations of both a near-haploid karyotype (1N+1) and a near-diploid population that was exactly twice that of the aneuploid karyotype (2N+2) (168). These data support that ploidy variation is directly linked to cancer evolution, yet the effects of ploidy change versus the effects of aneuploidy *per se* are difficult to distinguish.

CONCLUDING REMARKS AND OUTLOOK

There is a common theme in the examples discussed in this review: somatic ploidy changes increase the genetic heterogeneity of a population of cells (169–171). This genetic heterogeneity includes increased frequency of aneuploidy, but importantly, both ploidy and aneuploidy are reversible genomic changes. For example, a diploid cell that has undergone chromosome loss can later duplicate the remaining homologue (albeit losing heterozygous information on the lost chromosome). Similarly, WGD from a diploid to a tetraploid cell frequently results in chromosome loss and eventually ploidy is returned to the diploid state.

The initial ploidy-changing event may arise very rarely in some environments, but if there is a fitness benefit that accompanies the ploidy change, then it will spread throughout the population over time. What is surprising then is how often these ploidy-changing events occur within short-term *in vitro* evolution experiments and over eons of evolution. Perhaps the adaptable genome is the most successful genome, and cells with the ability to undergo rapid genome expansion and/or contraction are able to survive the most environmental insults. Additionally, it is possible that there is a subpopulation of persister cells that are primed and/or programmed to undergo ploidy changes during the response to stress. More population-level and single-cell approaches are needed to define the mechanisms and environmental conditions that cause ploidy changes in all eukaryotes (especially during fungal infections and tumorigenesis). The impressive examples of genomic heterogeneity observed in fungal pathogens support using these simple model systems to determine the mechanisms of ploidy change that occur during the somatic evolution of human cancers.

Fungal Genomes and Insights into the Evolution of the Kingdom

29

Jason E. Stajich

EVOLUTIONARY RELATIONSHIPS OF FUNGI

Studies of fungal evolution require an understanding of the phylogenetic relationships and relative evolutionary divergence of organisms. The first approaches to organizing fungi into related groups relied on morphological characteristics (1). These approaches provided a broad framework to organize fungal organisms for taxonomic classification based on recognizable morphological characteristics such as spore shape, asexual and sexual structures, and in mushroom-forming fungi, the shape and presence/absence of gills, veil attachments, and spore color. In zoosporic chytrid fungi the characteristics seen by scanning electron microscopy of zoospores reveal that the ultrastructure of the kinetosomes and flagellum are all diagnostic for the classification of many lineages (2). However, the microscopic nature of many fungi and especially of yeast-forming fungi with limited visible differences, and the prevalence of convergent evolution to homoplasies or similar characteristics across a tree, has made taxonomic classification of groups of fungi difficult or easily misled. The invention and application of DNA sequencing (3) and PCR (4) and the development of primers to amplify fungal rRNA enabled a new era of molecular phylogenetic studies in fungi (5). These approaches provided invaluable information that was used to resolve the major fungal lineages (2, 6–20) and the delineation of species (21–24). Using DNA approaches to study the entire fungal tree of life provided new insight into the order of branching of major groups and the timing of morphological changes such as the loss of the flagellum found in zoosporic fungi (14, 17, 18, 25).

With improved resolution of the phylogeny of fungal species, the timing of the emergence and changes in species traits and lifestyles can be compared, such as the evolution of host-associated symbioses and pathogenic interactions with plants or animals. Analysis of the evolution of morphological complexity along a phylogeny can establish the approximate time when complex growth emerged, such as fruiting bodies and multicellular structures, or simplified to establish transitions when unicellular yeast morphology emerged (26). Changes in subcellular characteristics such as septate hyphae, polarized hyphal growth, and the presence or absence of a flagellated life stage can be mapped on the tree to study the order and timing of their emergence relative to other structures or host-associated lifestyles (27, 28). With the availability of genome sequence data, the history of these phenotypic changes can be mapped onto the phylogeny and compared to the evolution of individual genes or the presence or absence of a gene family or be correlated with changes in evolutionary rates of gene sequences (29). These changes may reflect gains, but losses can also drive morphological changes such as simplification (26). The data and approaches are only recently becoming available to support robust analyses to link genes to phenotypes. Some examples of successful applications of the approaches include the acquisition of enzymes needed for anaerobic growth by Saccharomyces (30–32), gains of subtilase genes related to animal-associated lifestyles (33–35), genome reduction correlated to a yeast growth form (36, 37), and changes in structure of centrioles for microtubule attachments (38).

As technology advanced to support inexpensive high-throughput genome sequencing, improved phylogenetic software and high-performance computing have further improved the resolution of the phylogenetic relationships of fungi (Fig. 1). Fungi were some of the

Department of Plant Pathology and Microbiology and Institute of Integrative Genome Biology, University of California, Riverside, CA 92521.

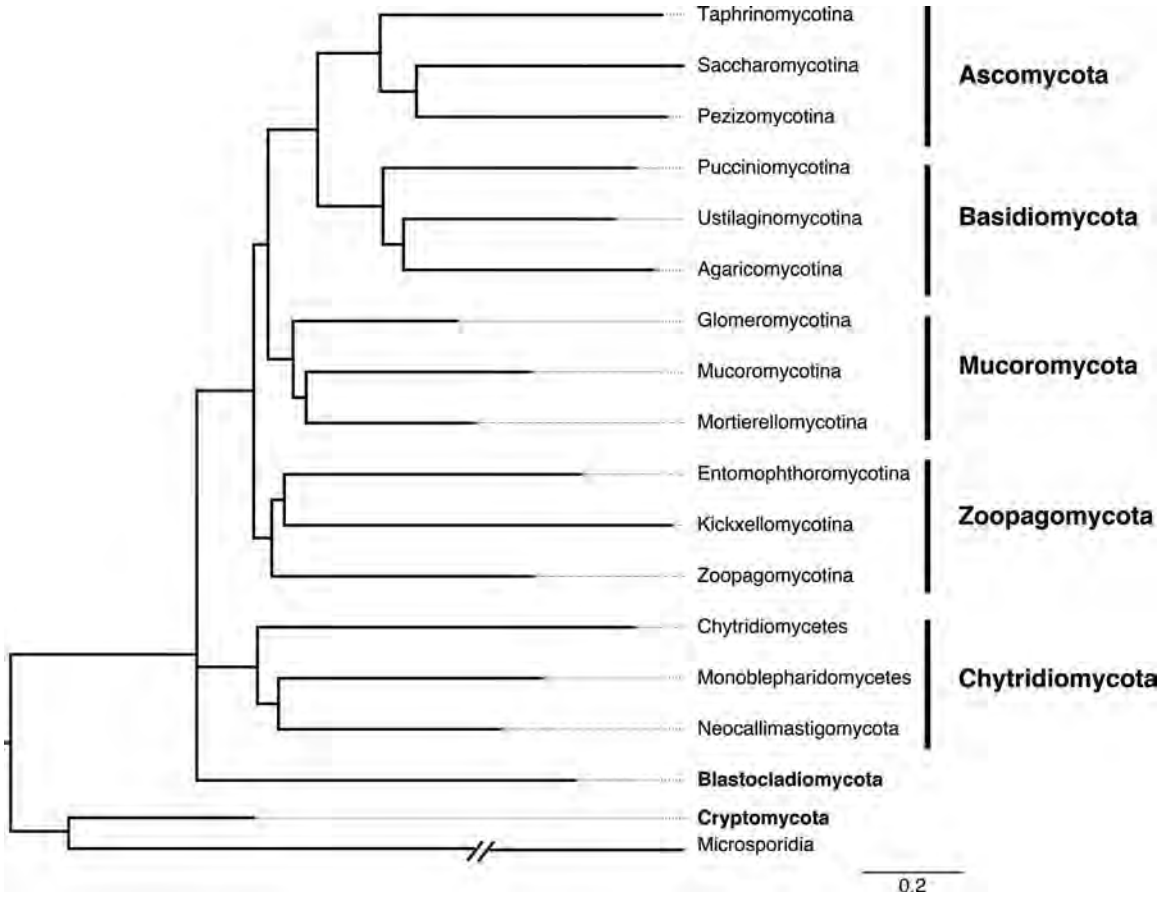

Figure 1 Phylogenetic relationships of the fungal phyla and subphyla. A phylogenetic tree from 434 conserved protein-coding genes resolves the relationships of most of the known lineages of fungi. This tree is a simplified version of that presented by Spatafora et al. (43). Phyla are presented in bold and subphyla in regular type. The Chytridiomycetes and Monoblepharidomycetes represent lineages for which a subphylum is not yet named.

first eukaryotes to benefit from these technological advancements to support the application of phylogenomic methods. Phylogenomics uses multiple orthologous genes, each sampled from a species genome to construct a composite phylogenetic tree from a concatenated dataset or individual gene trees (36, 39–43). A large collection of orthologous loci mined from genome or transcriptome sequences enables phylogenomic studies and tests for conflicting phylogenetic signals. These conflicts may be caused by genomic loci with different evolutionary histories due to, for example, incomplete lineage sorting, horizontal gene transfer, or different selective pressures (40, 44–48). Identification of gene tree and species tree conflicts can help to generate the best representation of the species tree and reveal current or historical selective pressures on genetic loci.

IMPACTS OF ECOLOGICAL NICHE ADAPTATION ON FUNGAL GENOME EVOLUTION

Genome sequencing has enabled comparisons of gene content and sequence changes to begin to predict the likely molecular basis for traits and adaptations. As heterotrophic organisms, fungi obtain carbon and nitrogen from external sources. A variety of cooperative and parasitic associations of fungi with other organisms are found throughout the fungal kingdom. Saprotrophic fungi liberate nutrients by degrading organic matter in habitats ranging from soils, dead insects and plants, compost piles, animal dung, and water-damaged homes. Ectomycorrhizal and arbuscular mycorrhizal fungi form mutualistic partnerships with plants and trade plant-produced carbon in the form of sugars in exchange for

inorganic nitrogen, phosphorus, iron, and other minerals. Fungi can live as commensal associates of plants and animals, for example, as plant endophytes or asymptomatic skin fungi, but also can cause devastating diseases in animals and plants via multiple invasive strategies. Some pathogenic fungi produce toxin molecules or effector proteins to kill host cells or disable host defenses, while others are opportunistic pathogens that only cause disease when the host becomes sick or immunocompromised.

Ectomycorrhizal fungi have mutualistic lifestyles with plants that involve trading resources. Plant pathogens secrete enzymes to break down cell walls. These enzymes can induce a plant defense response (49, 50). Fungi engaged in mutualistic fungal-plant symbioses typically have a reduction in genes encoding enzymes for plant cell wall degradation to avoid eliciting a plant defense response (51). Instead, effectors including small secreted proteins are typically expressed in the ectomycorrhizal fungal-plant interface to establish and promote the two-way partnership (51–53). Arbuscular mycorrhizal fungi also are important plant symbionts contributing to plant health. The molecular components of the interaction and roles of arbuscular mycorrhizal fungi-produced effectors are still emerging areas of research (54, 55).

Historical biotic and abiotic interactions have shaped the evolution of genes and the genome organization of fungi. Through the comparison of fungal genomes, the impact of natural selection and neutral processes has been assessed to indicate genes and genomic regions of importance in the evolution of species. For example, wood-degrading fungi are classified as brown or white rot fungi depending on their ability to degrade recalcitrant lignin polymers. The woody material in trees and bushes is made up of cellulose and lignin, the latter providing strength to plants. Lignin is highly recalcitrant to degradation, and when linked to hemicellulose and cellulose it can be inaccessible to ligninolytic enzymes. To access the lignin, white rot fungi secrete a combination of enzymes and organic acids to break down and later absorb carbohydrate degradation products of cellulose, hemicellulose, and lignin (56). Comparative analysis of the genomes of brown and white rotters found that metabolic and enzymatic gene families varied. The presence of specific families in the brown or white rot species was consistent with their classification and the chemical reactions these fungi can induce to break down woody material (42, 57–60). However, additional analyses have identified that some species of white rot fungi have unexpectedly missing genes that would typically predict that they were unable to degrade lignin (61). Exploration of the genomes of two white rot fungi indicated that despite similar lignin degradation capabilities, the species contained different enzyme classes, and this suggests that additional pathways of delignification exist and remain to be discovered (62).

Fungi can exist in extreme environments such as the anaerobic rumen stomachs of ruminants (63, 64), the dry Atacama Desert in Chile (65, 66), and hypersaline salterns with NaCl concentrations up to 30% (67) and as endolithic inhabitants of rocks in Antarctica (68, 69). Thermophilic fungi that grow in the desert can survive at temperatures above 60°C (70, 71). Studies of these thermophiles and their genome sequences have led to the development of new enzymes for biotechnology and cell biology studies due to their thermostability (72–74). Molecular adaptations that have allowed these fungi to colonize these extreme niches are still being uncovered, and genomic sequencing and comparisons among relatives of extremophiles should provide candidate genes that impact these abilities.

EVOLUTION OF GENOME SIZE

Genome sizes of fungi can vary by almost 3 orders of magnitude. A sampling of 325 phylogenetically diverse fungi has shown that genome sizes vary from 2 Mb in Microsporidia to 2 gigabases (Gb) in Pucciniales fungi, with a median of 35 Mb (https://github.com/1KFG/genome_stats/; Fig. 2). This vast range is the result of multiple genome reduction and expansion events. The total number of predicted protein-coding genes in these fungi varies by an order of magnitude, ranging from 1,800 genes in *Encephalitozoon* (Microsporidia) to 35,000 genes in *Sphaerobolus* (Agaricomyoctina), with a median gene count of 11,000. Some of the smallest and most compact genomes can be found in the obligate parasites Microsporidia, with sizes in the 2 to 6 Mb range (75–78). The free-living yeasts in the Ascomycota and the Cryptomycota parasite *Rozella* typically have genomes in the 7 to 12 Mb range (79–83), and the Basidiomycota *Cryptococcus* yeasts are around 20 Mb (83–85). Lineages containing yeast-forming species tend to have smaller genomes (such as *Schizosaccharomyces* and *Ashyba*), but this apparent reduction has occurred independently and multiple times in fungal history (36, 37, 86).

At the upper end of the range of currently sequenced species are the 150- to 175-Mb genomes of *Cenococcum geophilum* (Dothidiomycetes; Ascomycota), *Sphaerobolus stellatus* (Agaricomyoctina; Basidiomycota), *Tuber melanosporum* (Pezizales; Ascomycota),

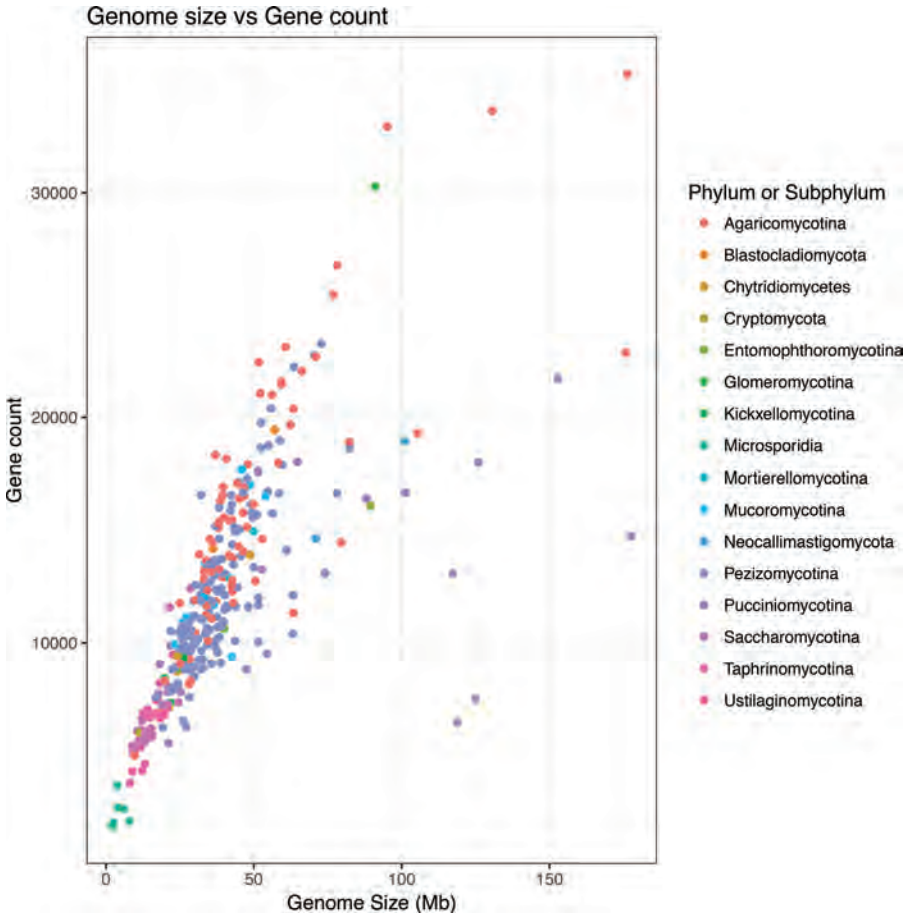

Figure 2 Scatter plot showing the relationship between genome size and gene count. Genome size varies among subphyla of fungi, with some of the smallest genomes in the Microsporidia and the largest currently sequenced genomes in the Agaricomycotina and Pezizomycotina. Primary data are gathered from genome information available at the National Center for Biotechnology Information (https://www.ncbi.nlm.nih.gov/) and Joint Genome Institute Mycocosm (https://jgi.doe.gov/fungi) and archived in the 1KFG genome_stats github project (https://github.com/1KFG/genome_stats).

and *Blumeria graminis* (Leotiomycetes; Ascomycota) (51, 87–89), which are primarily plant-associated fungi with both biotrophic and mutualistic lifestyles. Genome expansions in these species appear to have been driven mostly by transposon element content expansion. The total gene count is also higher in these genomes, which may belie an increase in gene duplication or insertion events that accompany the evolutionary processes that enabled increased transposon copy number.

Genomes of Entomophthoromycotina (Zoopagomycota) also are extremely large. The genome of *Entomophaga aulicae* is estimated to be as large as 8 Gb based on estimates using nuclear staining approaches (90), though sequencing has not yet been attempted. The genomes of the insect-killing zygomycete fungi *Entomophthora muscae* and *Zoophthora radicans* (Entomophthoromycotina; Zoopagomycota) appear to be in the ~700 Mb to 1.5 Gb range based on sequencing done through the Joint Genome Institute for the 1000 Genomes Project and others (M.B. Eisen and H. de Fine Licht, personal communication). The large genome size appears to be driven by increases in transposable elements, while gene count is not substantially expanded based on RNA-seq of these and related species (91, 92). Genome size estimation using flow cytometry has indicated that many of the rust fungi (Pucciniales; Pucciniomycotina) also have large genomes with estimated sizes of 300 to 900 Mb (93).

Genome reduction has also occurred in several fungal lineages, with the highly reduced genomes of the obligate parasitic microsporidian fungi being some of the most prominent examples, with tiny genomes (by

fungal standards) in the 2 to 6 Mb range (75–78). However, not all Microsporidia have tiny genomes; some are in the 16 to 20 Mb range, which seems to be due to transposon insertions in the few cases that have been examined (94). A smaller genome lends itself to fewer genes; as such, Microsporidia have a highly reduced gene set, dispensing with most small-molecule production and energy production pathways in favor of uptake transporters to obtain these resources from hosts (78, 95–97). In addition to fewer genes, the lengths of gene sequences themselves are reduced because the selective pressures that resulted in reduced genome size also contributed to reduced gene length (76, 95, 98). Coding space is at such a premium, with genes found nearly every 1,000 bp in some species (75), that some transcribed genes overlap (98, 99). Other obligate parasites in the fungal kingdom such as *Pneumocystis* demonstrate reduced genomes in the 8 Mb range, with approximately 3,700 genes (100–102), suggesting the presence of common selective pressures to reduce genome size as part of a tight host association in some parasitic fungal-host interactions.

Reduced genomes are a hallmark of yeast-forming lineages. Prominent examples include the Saccharomycotina yeast *Ashbya gossypii*, with a 9-Mb genome and 5,300 genes, and the Taphrinomycotina fungus *Schizosaccharomyces pombe*, also known as fission yeast, with a 12-Mb genome and 5,100 genes (80, 86, 103). The fern pathogen *Mixia osmundae* (Pucciniomycotina; Basidiomycota) has a 14-Mb genome (82) and 7,000 genes, and the human pathogenic *Cryptococcus* yeasts (Tremellomycetes; Basidiomycota) (83–85) have 19-Mb genomes with around 7,000 protein-coding genes. In each of these clades of yeast-forming fungi the genome sizes tend to be smaller than their filamentous sister clades. The filamentous Pezizomycotina fungi, sister to the Saccharomycetales yeasts, have genomes in the 35 to 45 Mb range, and the Agaricomycotina fungi sisters to the Pucciniomycotina are typically in the 45 to 60 Mb range. Analyses of gene gain and loss in yeast lineages have revealed that major gene losses occurred in the evolutionary history of these lineages, indicating genome reduction in the transition to single-celled growth (36, 37, 86).

Efforts to study how changes in gene content and evolution affect different lineages have identified classes of genes and genomic regions that change at different rates (104, 105). Within a genome, gene family copy number dynamics, transposable element transposition frequency, and individual gene evolution vary across a genome, which could be a consequence of different selective pressures but which also influenced random genetic drift. An important driver in the importance of random genetic drift versus selection in shaping a genome is the effective population size of a species. An organism's mode of dispersal, outcrossing frequency, and rapidity of cell division can all influence the effective population size, though the driving factors that determine effective population size are not well explored in fungi. Some of these regions, such as effectors and defense genes, can be important pathogenic or symbiosis-associated genes. The processes that establish and maintain different rates of change are likely not universal, but genome regions with extremely high rates of molecular evolution are particularly common in plants, fungi, and oomycete species (106–111) and may be important sources for novelty within species.

Many of the studies of genome size change are limited to lineages that diverged many millions of years ago. This divergence does not allow for the study of the mechanisms of genome size changes occurring at the population level. While aneuploidy and polyploidy manipulation and large-scale acquisition of DNA have been explored in *Saccharomyces* (112–115), studies of recent changes in genome size by massive gene duplications or transposon proliferation could reveal fitness consequences and the relative role of neutral versus directional selection in the success of lineages with genome size expansions (116, 117). Increased genome size may also result from changes in effective population sizes leading to relaxed selection and genome size increase (116). What might drive changes in population sizes? A newly acquired plant-associated lifestyle may impose constraints on reproductive modes (e.g., timing and availability of partners) or dispersal (e.g., how spores are produced). A better understanding of the pressures that drive genome size change could help us to understand how demography and transposable element proliferation influence fungal evolution, and in some cases how they have enabled the emergence of many disease-causing plant pathogens.

Gene and Gene Family Size Dynamics

Sampling entire genomes has allowed for increased resolution regarding the relationships between fungal lineages as well as the history of individual genes. Reconstruction of individual trees for each gene in the genome can provide a means to establish the age and coalescent history of a gene; e.g., a gene could originate with the Eukaryotes, in the Animal-Fungi ancestor, or be fungal-specific. Tools such as PhylomeDB and Ensembl Genomes Compara provide interfaces to explore these reconstructions to understand the history of a single gene (118, 119). Other events that generate

copy number expansions of a gene or gene family through duplication can be identified, and the timing of these duplication events can be established when comparing the copy number of the same gene family across a phylogeny of species with sequenced genomes. Likewise, a comparison of gene family contractions and gene losses can be studied to identify when potential function or diversity was lost. These changes in genome content provide important insights into adaptations that organisms may experience due to shifts in ecological niches or associations with a plant or animal host.

Gene family expansions

Comparisons of gene families between species have revealed several instances of gene copy number expansions possibly driven by evolutionary adaptations; such expansions have been instrumental in the evolution of pathogenicity traits. Copy number expansions of fungal genes containing the carbohydrate-binding LysM motif have been documented in both animal and plant pathogens (120–123). LysM protein motifs bind chitin or chitin-like carbohydrates and peptidoglycans (120, 124), and their role in fungi may be to bind the chitin in fungal cell walls to avoid triggering recognition by the plant or animal host defenses (125). The expanded copy number of these genes and the domain may be a signature of species that have biotrophic interactions with a host, and recent expansions could indicate a recent shift to this association from a saprotrophic lifestyle. The genomes of the human pathogenic fungi and basidiomycete yeasts *Cryptococcus neoformans* and *Cryptococcus gattii* show expansions of sugar and major facilitator superfamily genes (83, 84) hypothesized to play a role in increased uptake of these molecules from the environment (126) and could be important in synthesis and transport of the prominent capsule that is composed of the polysaccharides glucuronoxylomannan and glucuronoxylo-mannogalactan (127–129).

Expansion of the subtilase and metalloprotease gene families has also been noted as important in the transition to an animal pathogenic lifestyle in the filamentous ascomycetes Onygenales (33, 35, 130). The M36 metalloprotease family has expanded in *Coccidioides* fungi and their close relatives and is hypothesized to be linked to the switch from plant- to animal-associated ecologies and the switch from obtaining nutrients from plant-based carbohydrates to animal keratin and proteins (33, 34, 131). Research in animal-associated dermatophyte fungi has revealed similar, but typically independent, expansions of proteases in *Blastomyces* (132), *Trichophytoni*, and *Microsporum* (123). Interestingly, the human pathogen *Sporothrix*, not an Onygenales fungi but a member of a different clade (Ophiostomataceae; Sordariomycete), does not show signatures of recent protease family expansion, suggesting a different transition to mammalian association.

Comparison of the genes in the amphibian disease-causing chytrid fungus *Batrachochytrium dendrobatidis* to a nonpathogenic relative also identified expansions within protease families (133). The copy number of aspartyl and multiple metalloprotease gene families and the chitin-binding domain CBM18 are dramatically expanded in the pathogen as compared to nonpathogenic sister species (133). The importance of these expansions in pathogenesis is suggested by several investigations. One study found that a subtilisin-like serine protease was upregulated in response to amphibian host expression of thyroid hormone necessary for amphibian development (134). The CBM18 gene has the highest copy number of any fungus, ranging from 65 to 90 copies among sequenced strains, and has been under recent positive selection, indicating that it may be an important contributor to its pathogenicity (135, 136). Cloning and expression of the domain demonstrated that it also is capable of binding chitin (137). Comparison with the closest relative, *Batrachochytrium salamandrivorans*, also a successful and recently emerging pathogen, supports a hypothesis that the timing of these protease and CBM18 gene family expansions coincides with the emergence of the two *Batrachochytrium* lineages (136).

Plant pathogenic fungi have also undergone gene copy number expansion, effectively enabling host colonization and the ability to overcome plant defenses. One example is secreted effector proteins, which are expanded and diversifying in rust genomes (Pucciniomycotina; Basidiomycota) (138). Recent transposable element expansion, which is associated with gene duplications and accelerated rates of effector gene evolution, is noted in *Leptosphaeria maculans* (Pleosporales; Dothideomycetes) (106, 110). Other members of the *L. maculans* species complex have small genomes and lack this genome expansion. The powdery mildew *B. graminis* has a large genome with an expansion of atypical avirulence genes and signal peptide-containing genes (89). Metalloproteases and alpha amylases are expanded in the important plant disease-causing fungus *Zymoseptoria tritici* (formerly *Mycosphaerella graminicola*) (Capnodiales; Dothideomycetes). In contrast, contraction of CAZy family genes in *Z. tritici* suggests a specialization on the types of carbon sources utilized for nutrition (139).

Recent gene gains and losses have occurred during the evolution of insect-associated fungi, and these

changes appear to impact host specificity. The transition between generalist and specialist in *Metarhizium* species may have been driven by gene family contractions (140, 141). The "domesticated" fungus cultivated by leaf cutter ants, *Leucoagaricus gongylophorus*, has an expansion of CAZymes related to polysaccharide degradation. These enzymes are differentially expressed depending on the plant substrates "fed" to the fungus garden by leaf cutter farming ants (142–148). The specialized gongylidia that are swellings of the hyphal tip have evolved to provide a sugar nutrient source for the ants in exchange for the input of leaf and plant material into the fungal garden. The expansion and specialization of the fungal enzyme families necessary for rapid extraction of carbohydrates from plant material have likely been driven by this highly mutualistic symbiosis (146–148).

Expansions are not always linked to pathogenicity. The extensive light-responsive nature of the zygomycete *Phycomyces blakesleaanus* (Mucoromyoctina; Mucoromycota) is likely the result of the expansion of signaling pathways (149). These signaling protein expansions are also seen in the relatively closely related species *Rhizopus delemar* (previously identified as *Rhizopus oryzae*) (150), which may have enabled these coprophilic fungi to optimize the timing of fruiting and spore maturation in sync with the ephemeral ecology of a dung. Producing and orienting spore-forming structures at the right time of day can maximize the probability that offspring will be dispersed and establish the next generation. Genes encoding hydrophobin proteins, which are important for fruiting body development in mushrooms, are also expanded in copy number in Agaricomycotina species (151–154). The p450 monoxygenase family is also highly expanded in mushroom-forming fungi, especially in white rot fungi such as *Phanerochaete*, which likely allow it to degrade a rich collection of substrates including lignin (62, 151, 155). These expansions may have been important in niche adaptations and the evolution of specific traits such as lignin modifications and degradation, decomposition of complex hydrocarbons, and the ability to grow as a biotrophic plant pathogen (156–162).

Gene family contractions

Gene family contraction and gene loss have contributed to the evolution of fungal genomes. Some of these changes can be correlated to recent shifts in ecology, while other analyses have revealed ancient changes that appear to underlie a simplification in growth morphology. Researchers undertook a comparative analysis of 59 fungal genomes and examined changes in gene families corresponding to five independent lineages that grow primarily as single-cell yeast forms. The analysis used a newly developed method called COMPARE (comparative phylogenomic analysis of trait evolution) to infer that evolution of yeast growth forms occurred by convergent evolutionary processes leading to parallel, independent gene family losses (36). The predominant pattern of observed losses was in plant cell wall-degrading enzymes, fungal lysozymes, p450 families, and cyclophilins that serve as molecular chaperones.

Gene family contractions are evident in the plant pathogen *Colletotrichum* (Glomerellales; Sordariomycetes) and are associated with host range contractions (163), suggesting that host specificity may be a result of gene losses. Extensive gene losses were noted in the genome of *Escovopsis weberi*, an ascomycete pathogen of the *Leucoagaricus* ant-farmed basidiomycete fungi. These extensive gene losses in this species could result from specialization to mycoparasitism (164). Gene family contractions are not seen in the related mycoparasitic *Trichoderma* sp., suggesting a different route of host specialization in *Escovopsis*. Losses of gene families such as of dehydrogenases have been documented in the insect pathogens *Metarhizium* and interpreted to reflect adaptation to host specificity (141).

A lack of duplicate genes is not always a direct result of gene loss. In species in which repeat-induced point mutation (RIP) occurs, gene duplications cannot persist because RIP, a genome defense mechanism, targets duplicated sequences so that they accumulate point mutations during the meiotic cycle (165, 166). RIP is hypothesized to be a potent defense against transposable element proliferation because both the source and transposed copy of an element will become mutated. The genome of the ascomycete *Neurospora crassa* has been shaped by RIP. *N. crassa* does not have a reduced genome (40 Mb, ~10,000 genes), lacks nearly any active transposable elements, and also does not have any large gene families (167, 168).

GENOME STABILITY AND PAN-GENOMES

Gene content and genome copy number can vary, sometimes dramatically, in a population and across a species. Sequenced genomes represent a snapshot of the genomic information of a species or strain. The inventory of genes revealed by sequencing can be useful when comparing between isolates or sampling a population of individuals at different times. Changes in genomic content can occur among individuals in a population or even within a strain over time. Considering the complete set of genes across all strains or individuals of a

species is deemed the pan-genome (169), which can be a useful way to think about not just gene presence/absence compared to a "reference" but also about the complete set of genes that exists in a species or a collection of individuals (170). Genetic variation includes single nucleotide substitutions, insertion/deletions, or larger genetic content changes such as transposable elements and transposition events. The presence (1), absence (0), or amplification of copy numbers (>1 copy) in a gene can also be evaluated among individuals in a population. Together, these approaches can rank and identify quickly or slowly evolving genes and evaluate the evolutionary lability of genes and pathways which could underlie changes in function among populations and species.

Investigations have revealed that gene content and genome copy number can vary, sometimes dramatically, in a population and across a species. In *Saccharomyces cerevisiae*, completed genomes of 100 individual strains have been used to generate a pan-genome of fungal genes, some of which are present in some but not all strains (171). Changes are more common, but not exclusive to subtelomeric regions of chromosomes. Variation in the tempo and mode of chromosomal rearrangements and gene shuffling can be seen in wild and domesticated species when comparing *S. cerevisiae* and *S. paradoxus* (172) and wild or domesticated *Aspergillus* strains (173, 174). The human pathogen *C. gattii* has genomic segments that vary in copy number, segregate in the population, and could be a contributing mechanism to virulence differences among strains (85, 175).

The importance of genome variation at the population level is also appreciated in plant pathogenic fungi where variation in virulence and prevalence from year to year can sometimes be linked to a single gene or to changes in chromosome content. Genes encoded on dispensable chromosomes are sources of rapid changes in gene content because these chromosomes can be transferred between individual strains and often lost without disruption of primary metabolic or cellular functions (176–178). Also known as accessory chromosomes, these may accumulate transposable elements and evolve more quickly than other chromosomes because they typically do not encode essential genes (108, 179). These chromosomes further support a mechanism of gaining or losing sets of genes that may be important in adaptation to new host plants (178). The relative importance and molecular mechanism impacted by these genetic elements in modulating adaptability of species remains to be explored but can be important contributors to genome evolution.

CONCLUSIONS

Complete sequencing of fungal genomes has enabled comparisons of the dynamic genome size and gene content across a range of time in fungal evolution. Genome differences that are also identified through comparative genomics can help to form hypotheses about molecular mechanisms for adaptation to new ecological niches or fungal-host specialization. These identified changes establish guides for further genetic and molecular biology experimentation. Genome content comparisons also highlight the relative lability of fungal processes: core metabolism changes little, but copy numbers of transcription factors, secondary metabolites, and transporter families ebb and wane across the kingdom. Sequencing and analysis tools have permitted the detailed cataloging of where and how much change occurs across genomes, providing rationale for molecular experiments to study the functions of the genes implicated.

SOURCES OF FUNGAL GENETIC VARIATION

Genetic variation is the stuff of evolution: if there is no variation, there can be no evolution. This review of fungal genetic variation begins with a survey of its sources and then discusses means of associating natural genetic variation with phenotypic variation, including phenotypes that are important to fungal adaptation or those that interest cell and developmental biologists engaged in basic or translational research. The tale of the study of fungal genetic variation is also a tale of advances in genomic science, and it is appropriate to note that the first Eukaryote to have its genome sequenced was a fungus, the model yeast *Saccharomyces cerevisiae* (1). Shortly thereafter, yeast was joined by filamentous Ascomycota, e.g., *Neurospora* (2), and Basidiomycota, e.g., *Phanerochaetae* (3). Not long after, three *Aspergillus* species were sequenced—*Aspergillus oryzae* (4), *Aspergillus fumigatus* (5), and *Aspergillus nidulans*—and the comparisons of their genomes (6), along with those of yeasts closely related to *S. cerevisiae* (7), represent landmarks in the field of comparative fungal genomics. A survey taken in April 2017 of fungal genomicists associated with the Joint Genome Institute and FungiDB estimated the number of fungal species with sequenced and assembled genomes at 2,000 and estimated that another 1,000 to 1,500 genomes represent multiple individuals from species that are studied by population genomics. No other group of eukaryotes enjoys as deep a genomic database as is seen for the fungi.

Gene Gain and Loss

The sources of genetic variation covered in this review are listed in Table 1. One of the first types of genetic variation discoverable by comparing genomes was gene gain and loss by duplication or excision. Again, the model fungus *S. cerevisiae* was involved because it showed abundant gene duplication. The debate that ensued over the source of gene duplication, whether by whole-genome duplication (8) or by the accrual of smaller duplications (9), was settled in favor of whole-genome duplication when genomes of outgroup yeasts were analyzed (10, 11). This episode made two seminal contributions that will be revisited in this article: that interspecific hybridization is an important source of genetic variation in the Fungi (12, 13) and that duplications as large as chromosomes are routinely gained and lost throughout the Fungi (14, 15).

Most duplications are rapidly lost, and where duplicated regions are retained, natural selection is likely responsible, as will be seen below. As more representatives of Ascomycota were sequenced, broader comparisons became possible (16). These comparisons revealed abundant examples of gene gain and loss and made two additional discoveries. First, duplications are more common in proteins that respond to stress than in those involved in core metabolism and, second, where duplications are retained, they result in the evolution of differential expression of the paralogs more often than the evolution of new functions. Where the duplicated protein formerly participated in more than one pathway,

Table 1 Genetic variation and its use in associating genotype and phenotype

Sources of genetic variation in fungi
Single nucleotide mutations and recombination (76–82, 98)[a]
Gene gain and loss (7–17)
Gene family expansion and contraction (20–26)
Horizontal gene transfer (33–38, 45–53)
Selfish DNA (39–43)
Aneuploidy (54–60, 148)
Conditionally dispensable chromosomes (59)
Loss of heterozygosity (61–64)
Genome rearrangements (18, 19, 65–75)
Epigenetic modifications (83, 84)
Endofungal bacteria (85–90)
Fungal viruses (91–94)
Mitochondria (95–97)
Hybridization and introgression (111–141)
Using natural variation to associate genotype and phenotype
QTL, GWAS, and reverse ecology (98–110)
Hypothesis testing in wild fungi (142–147)

[a]References germane to topic.

duplication allowed the copies to evolve to focus on just one pathway or the other (16). This disentangling of pathways may explain why more duplicated genes are retained, and in a recognizable form, than would be predicted by evolutionary theory that assumed retention would require neofunctionalization (17). Although gene gain clearly gets more attention than gene loss, when it comes to plant-pathogenic fungi, gene loss can be an important contributor to infection of novel hosts through the loss of genes whose products engage host defenses (18, 19).

Gene Family Expansion and Contraction

As regions of the fungal tree of life became more densely populated with whole genomes, comparative phylogenomics uncovered gene family expansions and contractions that could be correlated with adaptation (Fig. 1). Using an approach developed for all eukaryotes (20), plant pathologists compared the rice blast fungus, *Magnaporthe*, with *Neurospora* and *Aspergillus* and found expansion in nearly 10 gene families, including those associated with pathogenesis, e.g., cytochrome p450 genes and G-protein-coupled receptors (21). Subsequent addition of genomes expanded the search to more pathogens and the discovery of more expanded gene families including those whose products populate the secretome (22). The approach was refined (23) and expanded to animal-pathogenic fungi, where the shift from eating plant cell walls to eating animal protein was documented by expansions in genes coding for proteinases and contractions in those coding for cellulases and other enzymes that deconstruct plant cell walls (Fig. 1) (24). Gene family expansion and contraction have even been applied to major shifts in the geologic record, such as the end of the coal age (25). Here, while studying genes coding for enzymes that saprotrophic fungi used to decay lignin, mycologists found an expansion that they could correlate with the end of the Carboniferous age, thereby supporting speculation that these fungi helped spell the end of widespread coal formation. Of course, expansions and contractions are relative events, and a caveat in the search for gene family expansion and contraction was recently sounded, where what was thought to be an expansion of genes coding for proteins with LysM domains in a group of dermatophytic fungi proved rather to be a contraction in a related fungal clade that harbors the systemic pathogens *Coccidioides immitis* and *Coccidioides posadasii* and their nonpathogenic relatives (26).

Interkingdom Horizontal Gene Transfer

The same genomes that permitted the discovery of gene duplication within a genome also permitted the discovery of genes gained from outside the species by the process of horizontal gene transfer (HGT). An early and prescient review discussed the possibilities in fungi (27) at a time when HGT was being studied in whole genomes of prokaryotes (28), and there have been a number of subsequent reviews (e.g., 29). To demonstrate HGT, it is necessary to show that the phylogeny of the transferred genes is truly in conflict with the organismal phylogeny as inferred from other genes. Before genomes, it was not easy to demonstrate HGT, but whole genomes provide more than enough data to achieve a statistically significant result. Plant-fungal HGT has been shown to work in both directions and, although infrequent and apparently ancient, exchanges of transport proteins and siderophores are thought to have aided the invasion of the terrestrial environment by both fungi and plants (30). Far more common are HGT events between the kingdom Fungi and Oomycota; here it can be fairly said that HGT from Fungi, mostly Ascomycota, enabled Oomycota to become plant parasites (31). Among the genes transferred from Ascomycota to Oomycota are those that code for proteins responsible for deconstruction of plant cell walls, uptake of nutrients, resistance to plant defenses, and the aggressiveness of the parasitism. Traffic from Oomycota to Fungi is far less frequent, with the best example being a monooxygenase-like protein involved in antibiotic synthesis (31).

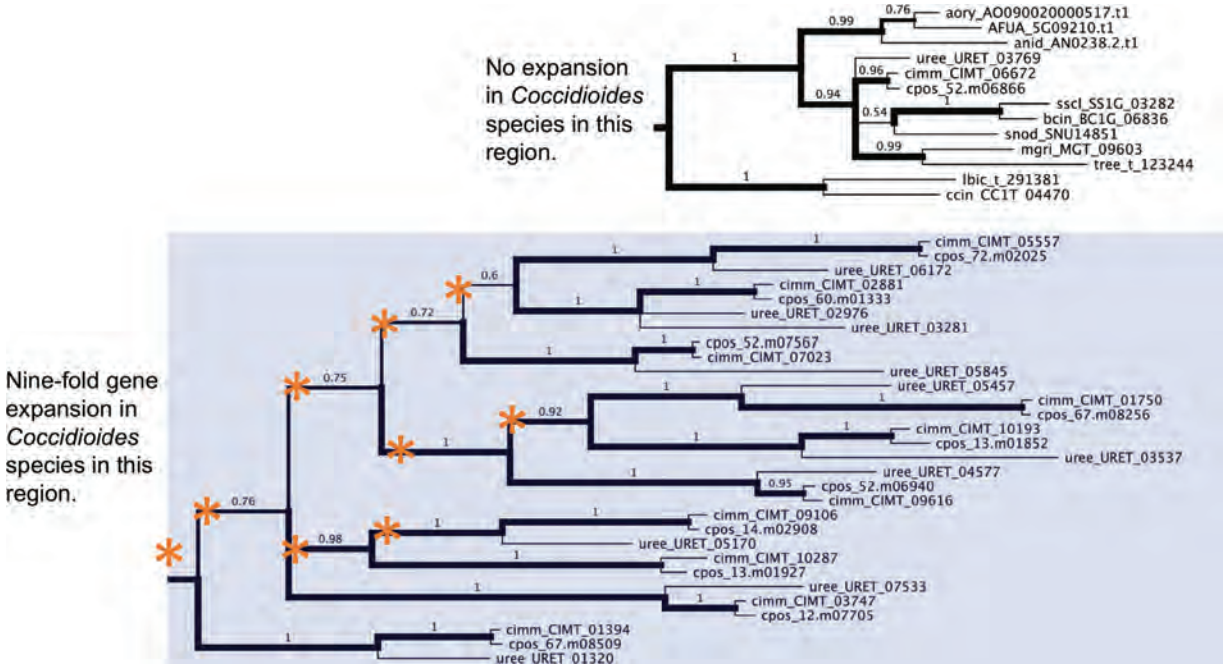

Figure 1 Gene family Bayesian phylogeny for proteinase genes with S8 domains showing (top) some phylogenetic lineages with no expansion and (below) others with a large expansion due to nine gene duplications (asterisks). Key to taxon abbreviations preceding gene identifiers: *Aspergillus oryzae* (aory), *Aspergillus fumigatus* (afum), *Aspergillus nidulans* (anid), *Uncinocarpus reesii* (uree), *Coccidioides immitis* (cimm), *C. posadasii* (cpos), *Sclerotinia sclerotiorum* (sscl), *Botrytis cinerea* (bcin), *Stagonospora nodorom* (snod), *Magnaporthe grisea* (mgri), *Trichoderma reesii* (tree), *Laccaria bicolor* (lbic), and *Coprinopsis cinerea* (ccin). Adapted from reference 24.

Fungi living in the guts of animals also experience HGT, and one of the most remarkable examples of interdomain HGT concerns the Chytridiomycota that live in the stomachs of ruminants. These fungal symbionts clearly received glycosyl hydrolase genes from bacteria, a transfer that helped them adapt to feeding on plant cell walls in the stomachs of ruminants (28). Gut fungi in the Zoopagomycota also have experienced HGT in the form of a ubiquitin gene received from their mosquito hosts (32). Could these genes, known to mark proteins for degradation or to alter their function or location, be involved in manipulating the host? As related above, interkingdom and interdomain HGT is well documented, but the mechanisms of gene transfer among distantly related organisms are not understood.

Transposable Elements

Not all HGT involves genes that confer an advantage to the recipient, at least initially. Some involves selfish nucleic acids, and the most prevalent types are transposons and retrotransposons, which are capable of moving and copying themselves in one genome or among genomes (33–35). Transposable elements (TEs) provide genetic variation by disruption of existing genes and gene order, by stimulating rearrangements and duplications, as well as by simply adding genetic material that can then evolve to new functions. Many fungi have an active defense against TEs, e.g., repeat induced point mutations (RIP) (36). RIP targets regions of repeated DNA sequence and in both copies mutates C-G pairs to A-T, sometimes spilling over into an adjacent, unduplicated sequence. Thus, it can reduce genetic variation by restricting gene duplication and also enhance it by generating mutations (37). However, the strength of RIP varies widely among fungi, as does the presence of TEs, and many symbionts, whether mutualists, i.e., ectomycorrhizal fungi, or pathogens, have large genomes due to an abundance of these mobile elements (38). A recent study of a Basidiomycota plant parasite, *Microbotryum*, showed that, despite RIP, TEs show bursts of activity that periodically increase the size of fungal genomes (39). Another recent study, focused on the Ascomycota plant pathogen *Fusarium*, investigated the role of TEs in a type of aneuploidy that will be discussed below (40). A different type of TE is a homing endonuclease, which enters recipient genomes at

extremely conserved sites, e.g., ribosomal RNA genes, and which spreads faster than Mendel imagined by being transmitted to all progeny. Homing endonucleases have a "life cycle" of transmission to a new species followed by the spread among the individuals of the new species until all available invasion sites are filled. At that point, there can be no additional transmission and no selection for active endonuclease, so the elements degenerate and disappear from the species, making it ripe for new introduction (41, 42). Work on these elements in yeast led to a proposal that homing endonucleases could be used to extirpate insect vectors of disease, such as the mosquitoes that vector malaria (43), an idea that has gained popularity with the application of the CRISPR-associated protein-9 nuclease system to genetic manipulation (44).

HGT Among Fungi

Fungus-to-fungus HGT of coding genes is also a source of genetic variability involved in adaptation, and none is more spectacular than the transfer among Ascomycota of a toxin gene, *ToxA*, that instantly confers on the recipient the ability to attack wheat cultivars that possess the toxin-sensitive allele of the plant gene *Tsn1* (45). In this case, the direction of HGT could be determined by assessing, in the two fungi, the amount of genetic variation in the transferred toxin gene, *ToxA*. Using the logic that the more variable species was the donor and the species with little to no variation was the recipient, the flow could be shown to be from *Parastagonospora nodorum* to *Pyrenophora tritici-repentis* (45). Remarkably, the plant gene targeted by the toxin is a member of a wall-associated class of kinase receptors that help plants resist rusts and biotrophic fungal pathogens by killing affected cells and starving the fungus. When the fungus is a necrotroph, as is *P. tritici-repentis*, the programmed plant cell death initiated by the toxin instead opens the plant to attack by the necrotroph—a heavy cost to maintaining resistance genes (46–48).

Among cases of fungal HGT, equally amazing as the ToxA story is the horizontal transfer of the multigene complexes that produce secondary products, or extrolites, e.g., polyketides such as aflatoxin or nonribosomal peptides such as penicillin. Although most polyketides may be transmitted vertically (49), it is clear that these complexes experience HGT, and it is equally clear that the dense clusters of genes in the complexes and their position near telomeres facilitate their transfer (50). It even has been hypothesized that the genes are aggregated to foster their later spread by HGT (51). Although it is clear that production of a specific extrolite is less likely to be transferred if the genes responsible for its synthesis are distributed throughout a genome, it is difficult to understand how selection could act on a potential future event. The more prosaic explanation for the clusters, i.e., that natural selection favors gene clusters because their regulation is better coordinated, likely provides the selective advantage needed to keep clusters intact, as in the case of the massive clusters found in species of the Ascomycota, *Penicillium*, involved in cheese making (52, 53).

Aneuploidy

The advent of massively parallel methods of DNA sequencing, and the high throughput sequencing they support, gave mycologists the ability to obtain genomes from populations of individuals. The strains of fungi that are resequenced to enable population genomics can come from members of a natural, interbreeding population, from strains collected from a clonal outbreak of a pathogen spread by asexually produced spores, or from a series of strains that have evolved inside a single patient. It is the last of these collections, made from a single patient infected with the pathogenic yeast *Candida albicans*, that let genomics demonstrate the importance of aneuploidy, the possession of more or fewer chromosomes than normal, as a source of fungal genetic diversity (Fig. 2) (54). In this study, *C. albicans* strains that had been isolated from candidiasis patients undergoing treatment with azole antifungal drugs had an extra, aneuploid chromosome made of two copies of the left arm of chromosome 5. In this diploid yeast, this aneuploidy doubled the copies of efflux pumps that can export the drug, a transcription factor positively regulating the pumps, and the target of the azole drug, an enzyme in the ergosterol synthesis pathway. Studies of another human pathogenic fungus, the Basidiomycota *Cryptococcus neoformans*, showed that a different type of clonal reproduction, unisexual mating, whereby meiotic basidiospores arise from the fusion of two mitotically produced nuclei, can also generate aneuploid progeny (55). In this latter research, the authors documented shortening of chromosomes among strains, as well as chromosome duplications, and found that unisexual progeny displayed significant phenotypic variation for traits involved in virulence. These traits included temperature sensitivity (but without loss of virulence in mice), increased resistance to antifungal azole drugs, and increased production of the virulence factor melanin. The authors also showed that unisexual mating was not essential for the generation of aneuploidy because the phenomenon was also seen in biparental, sexual progeny of two different *Cryptococcus* species (55).

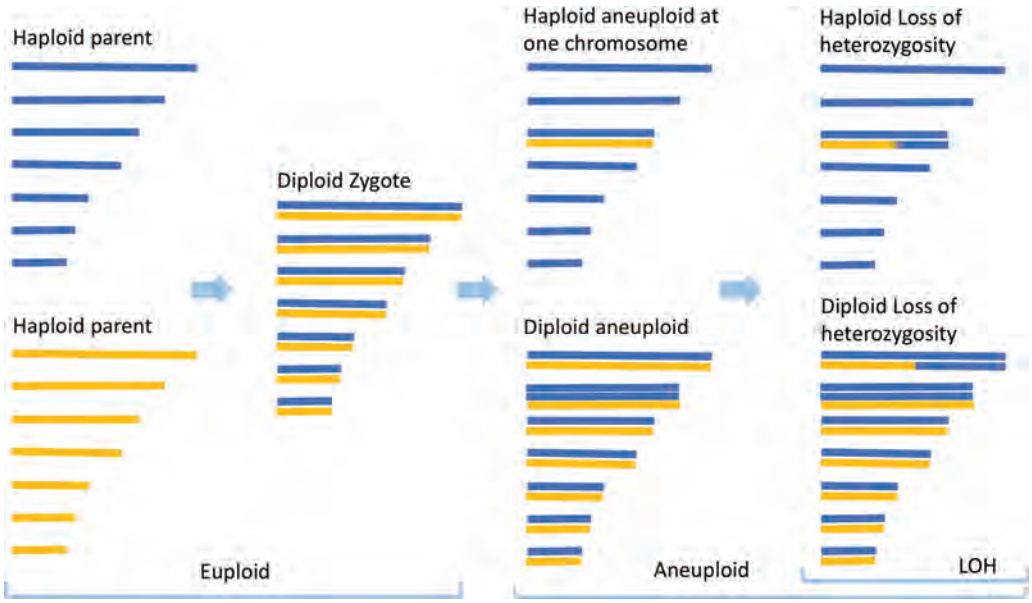

Figure 2 Diagrams showing aneuploidy and loss of heterozygosity (LOH) in haploid and diploid genomes. Each individual has seven distinct chromosomes colored to show heterozygosity.

Aneuploidy has also been shown to be involved in virulence in another animal pathogen, the Chytridiomycota that is responsible for amphibian decline, *Batrachochytrium dendrobatidis*. Amphibian decline has been correlated with the global pathogenic lineage (GPL) of strains obtained from infected animals. Aneuploidy is seen in both the GPL and, to a lesser extent, among individuals in the population from which the GPL emerged (56, 57). Data presented in both of these referenced studies show that passage of the fungus in the laboratory can result in loss and gain of aneuploid chromosomes and that genes known to code for virulence factors are hot spots for genomic change. More recently, comparison of the genomes of isolates from the same lineage, one original and the other having endured 6 years of laboratory transfers, also showed a correlation between reduced virulence and aneuploid loss of chromosomes (58).

Conditionally Dispensable Chromosomes

A different type of aneuploidy is seen in symbiotic Ascomycota, whether parasitic or mutualistic, that may have more chromosomes than do their nonsymbiont relatives. Unlike canonical aneuploidy, here the extra, conditionally dispensable chromosomes (CDCs) are different from, and in addition to, the chromosomes in the core genome (Fig. 3). Their presence varies among individuals in the species, and CDCs contain a disproportionate number of TEs. They may contain virulence factors not seen in the core genome, and they can be transmitted among species by hybridization, thereby conveying the ability to become parasites (59). A recent study with a well-assembled genome of *Fusarium poae* reported that the dispensable chromosomes lack an effective RIP, which explains their being riddled with TEs (40). This study also showed that CDCs act as a reservoir for duplicated genes and that the genes can then be transferred back to the core genome. Most of the fungi possessing dispensable chromosomes are plant symbionts, and one wonders if access to the abundant resources of a photosynthetic organism allows them to support an enlarged genome. Could this source of variation be a benefit of association with a domesticated plant, albeit an evolutionarily Faustian bargain given the danger of narrow host specialization? Alternatively, do fungi that have their pathogenicity factors in volatile regions of the genome respond more quickly to changes in host plant defenses and thereby avoid narrow host specialization?

Another type of unusual ploidy is demonstrated by hybridization among haploid, Ascomycota grass parasites in the genus *Epichloë*. These events, apparently not involving sexual processes, have produced diploid and triploid, asexual, mutualistic endophytes that are dispersed as hyphae in the seeds of their hosts. This unusual combination of aneuploidy and HGT, albeit among close relatives, has produced fungi that have a life history that is extremely different from their parental

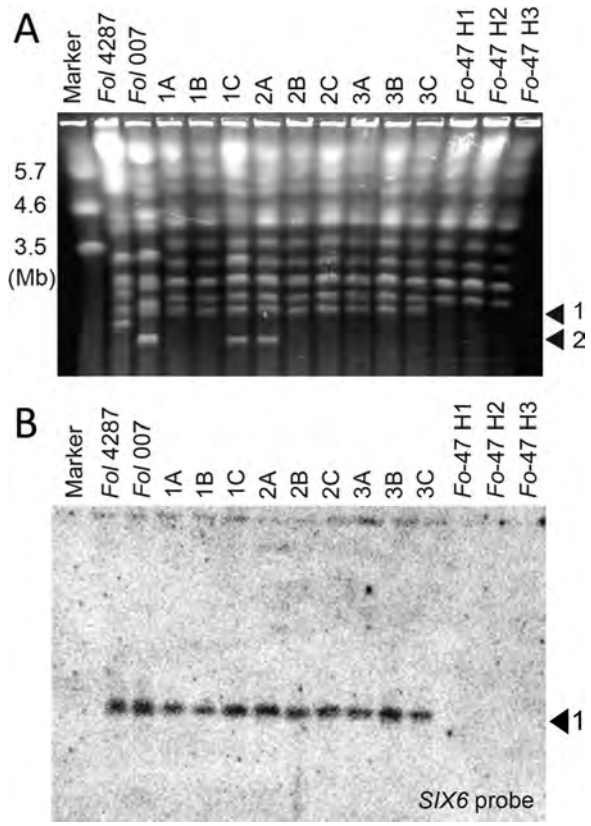

Figure 3 Contour-clamped homogeneous electric field gel karyotype of *Fusarium oxysporum* chromosomes showing conditionally dispensable chromosomes (CDCs) and their transmission between strains. (**A**) Donor strain *Fol*007 (left) harbors CDCs 1 and 2 (arrows), and recipient strain *Fo*-47 (right) lacks them. Strains 1A-3C (middle lanes) are derived from simple coincubation of *Fol*007 and *Fo*-47. These strains have the *Fo*-47 karyotype and have gained CDCs 1 or 2 (arrows), or both, from *Fol*007. (**B**) Southern hybridization of the contour-clamped homogeneous electric field gel to a probe with DNA from CDC 1 (*SIX6*), confirming the presence of CDC 1 in donor strain *Fol*007 and progeny strains 1A-3C, which possess the karyotype of the recipient strain *Fo*-47. Adapted from reference 148.

species, which are sexual, *Epichloë* species that transmit themselves horizontally via their ascospores and then aggressively parasitize and sterilize their grass hosts (60).

Loss of Heterozygosity

Where organisms are more than haploid, i.e., diploid, aneuploid, or polyploid, they are almost certainly heterozygous at many genes, itself an obvious source of genetic variation. These heterozygous organisms can lose heterozygosity through gene conversion or crossing over or other events that leave portions of homologous chromosomes genetically identical (61) (Fig. 2). At first it might seem that loss of heterozygosity would necessarily reduce phenotypic variation, but phenotypic diversity can be increased if dominant alleles are lost and release the activity of the recessive allele. Such a case could also occur through aneuploidy, where loss of one copy of a chromosome would expose recessive alleles on the remaining, now haploid, copy. An insightful example of this type of loss of heterozygosity was reported in *C. albicans* strains that are resistant to azole antifungal drugs due to the activity of multidrug efflux pumps. Here, it was mutations in the gene coding for a transcription factor on chromosome 3 (which regulates the aforementioned pumps on chromosome 5) that were responsible for the constitutive expression of the pump genes. *C. albicans* being diploid, and the mutant transcription factor genes being recessive, the phenotype was seen only when the dominant wild-type allele was lost. Selection by the azole drug favored strains of *C. albicans* that both had the mutation in one of the copies of the transcription factor and had lost the wild-type allele through aneuploidy (62).

One of the tenets of population biology, Haldane's sieve, states that adaptive alleles are more likely to be dominant because newly mutated alleles are rare and cannot experience positive selection unless they are dominant and support a heterozygous phenotype. However, adaptation due to recessive alleles being released from dominance by loss of heterozygosity was recently demonstrated in an experimental study employing *S. cerevisiae* strains under selection for resistance to the antifungal drug nystatin (63). Diploid strains were created that were either homozygous for a recessive allele that conferred resistance to nystatin or heterozygous with a wild-type, susceptible allele. When grown without the drug, fitness was not strictly correlated with hetero- or homozygosity. When, however, the strains experienced nystatin stress, the strains homozygous for the resistant allele outperformed heterozygotes unless loss of heterozygosity removed the dominant, susceptible allele from heterozygotes, showing how recessive alleles can be adaptive. Loss of heterozygosity has also played an important role in the evolution of the GPL of *B. dendrobatidis* by generating variation among individuals of the GPL through recombination associated with mitosis, alone or in combination with meiosis (64). Here, is it possible that the loss of heterozygosity has released recessive alleles that promote virulence in this amphibian pathogen?

Genome Rearrangement

Rearrangement of the genome is also a source of fungal genetic variation, and one that provides a mechanism for gene family expansion and contraction through

gene duplication, deletion, or disruption (65). In the Ascomycota class Dothideomycetes, comparison of rearrangements among the genomes of 18 representative taxa showed that most rearrangements were within chromosomes (66), an example of mesosynteny (67). The most intensive study of fungal genome rearrangements has focused on those associated with an absence of recombination, specifically in mating loci and mating chromosomes. In these regions, recombination in the mating locus would produce progeny unable to mate, a phenotype readily eliminated by natural selection. Studies of barriers to recombination associated with rearrangements have been enabled by well-assembled genomes in the Ascomycota *Neurospora tetrasperma* (68, 69) or in the Basidiomycota *Cryptococcus* (70, 71) and *Microbotryum* (72–74). An interesting but unanswered question is whether the rearrangements seen in these mating regions suppress recombination or whether recombination is suppressed by some other means, thereby allowing rearrangements to accumulate. Expect much more research on the impact of genetic rearrangements in the near future (75) as it becomes economically feasible to practice population genomics with the superbly assembled genomes provided by the new generation of long-read, single-molecule DNA sequencers.

Mutation and Recombination

Until this point, we have avoided mention of the obvious contribution of sexual recombination to fungal genetic variation, although mutation, mating, and recombination, which provide the ability to generate progeny with genotypes different from parents and siblings, are at the heart of genetic variation. So important is this contribution that large natural populations, as must be the norm for many fungi, are thought to have all possible mutations in their genomes as a result of a combination of recent, ongoing mutation and standing variation (76). A recent study of polymorphism in North American and Russian populations of the Basidiomycota *Schizophylum commune* showed that this fungus is the most genetically diverse Eukaryote yet discovered, due to a rapid mutation rate and likely a large population size (77). As diverse as *S. commune* is, it is not alone and is in the close company of roundworms and choanoflagellates (78). Despite all of the costs associated with mating and recombination compared to clonal reproduction, i.e., from finding a mate, to loss of well-adapted genotypes, to having to share half of the genomes of progeny with a partner, sex and recombination are omnipresent in fungi (79) because they accelerate adaptation to changing environments, as shown by careful experimentation employing *S. cerevisiae* (80). Variation, however, cannot be limitless because some genetic combinations must be deleterious and selected against under conditions encountered in nature. Evidence for these natural limits is seen when phenotypes of parents and their progeny from laboratory crosses are compared; the variation in the progeny typically exceeds that of the parents or the natural population from which they were sampled. This transgressive variation exhibited by the progeny is often seen in the progeny of artificial crosses for complex traits, for example, the fungal phenotypes of aggressiveness in a plant pathogenic fungus (81) or growth rate in a wood decay fungus (82). Sexual reproduction deserves more mention, and it will be taken up again, below, in the section on associating genetic and phenotypic variation.

Epigenetics

Epigenetics is another important source of variation in fungi, not only among individuals but also among hyphal segments in a single individual (83), and its true importance is likely not yet appreciated because no population study of epigenetic variation has been published. As with studies of rearrangements, studies of epigenetic variation are to be expected in the near future because the aforementioned new generation of long-read, single-molecule DNA sequencers also have the ability to assess methylation of nucleotides (84).

Endosymbiotic Bacteria

Endofungal, bacterial symbionts, although not part of the fungal genome *per se*, are also a source of genetic variation for fungi, and one whose importance is emerging. These endosymbionts had been discovered in arbuscular mycorrhizal fungi by microscopy (85), but the extent of their presence was not appreciated until genomic studies of fungi revealed bacterial DNA among the expected fungal sequences (86). Recent studies show a fitness advantage to fungi possessing the endobacteria (87) and a lack of genome degeneration in the endobacteria themselves (88, 89). Nor are endosymbiotic bacteria restricted to arbuscular mycorrhizal fungi; one well-studied endobacterium is in the Mucoromycota *Rhizopus microsporus*, where it produces a toxin essential for the ability of this fungus to parasitize rice (90).

Fungal Viruses

Less explored is the role of fungal viruses as sources of genetic variation in fungi. The best-studied case is a virus that reduces virulence and reproductive capacity in the tree pathogen *Cryphonectria parasitica* (91). An equally compelling example is a virus that, along with

its host Ascomycota, *Curvularia protuberata*, confers improved thermotolerance in this endophytic fungus and its host plant, *Dichanthelium lanuginosum*, allowing them to live in geothermal areas of Yellowstone National Park (92). Although it is clear that fungi have strong defenses against virus (93), a recent search of RNA and virus particles isolated from five well-known plant-pathogenic fungi using a metatranscriptomic approach found 66 previously undescribed mycoviruses (94). Surely, many additional virus sequences are lurking unrecognized in the unsequenced pool of fungal genetic material. The nucleic acid diversity found in viruses and endofungal bacteria, plus that found in another cytoplasmic feature, the mitochondrion, can contribute to phenotype directly and by interacting with nuclear diversity. The role of cytoplasmic elements in heritability of a fitness phenotype, growth rate, was recently explored in yeast (95) and might also prove valuable in studies of fungi where mating can create progeny with identical nuclei but different mitochondria, for example, Basidiomycota (96) or dikaryotic Ascomycota (97).

USING NATURAL GENETIC AND PHENOTYPIC VARIATION TO ASSOCIATE GENES WITH PHENOTYPES

Having discussed different sources of genetic variation for fungi, it is time to ask, Is there any practical value to this knowledge—that is, value beyond satisfying the insatiable curiosity of mycologists and, of course, providing the genetic variation that enables fungi to adapt to the ever-changing environment? A simple answer to this question is that the same genetic variation that facilitates the adaptation of fungi can be used to solve a problem faced by many modern biologists, i.e., finding the genetic features responsible for a phenotype of interest or, more generally, associating phenotypic variation with genetic variation.

The Standard Laboratory Strain

It is still the case that molecular, cell, and developmental mycologists use a few strains of their study organism to facilitate comparison of research conducted in different laboratories and at different times. For example, neurosporologists favor *Neurospora crassa* OR74A (also known as FGSC 2489), saccharomycetologists favor S288C, cryptococcologists favor H99, candidologists favor SC5314, aspergillologists favor A4, and so on. Alas, in doing so, they miss out on the alleles and traits found in natural strains and they work with an individual that has become adapted to the laboratory environment and is no longer representative of the wild population from which it was cultivated. The key question for cell and developmental mycologists is, Would moving to multiple wild strains to better associate genetic and phenotypic variation be worth the loss of comparability found in a standard strain?

First, it must be acknowledged that mycologists who work with standard strains go to a lot of effort to develop genetic variation in the standard strain by inducing mutations. With the forward-genetic approach, which begins with a phenotype of interest and artificially induces mutations in thousands of strains, the mycologist then has to screen thousands of mutants and, having found the desired mutant phenotype, associate the mutant gene with the mutant phenotype. If, instead of a phenotype, the researcher begins with an interest in a particular gene, then the process is reversed and the gene is first mutated or deleted, and the search begins for a phenotype, a process that can seem neverending given that a particular phenotype may be encountered only under very specific and unknown conditions. For both forward and reverse genetics, the sequencing of the standard strain is a boon that facilitates either identifying the gene or confirming that it, alone, has been mutated, but it is also a boon that reinforces the community focus on standard strains.

Quantitative Trait Loci

A traditional way of increasing genetic and phenotypic variation in a study without resorting to mutagenesis is to mate the standard strain with a partner that shows genetic and phenotypic differences and then use the progeny to associate phenotypic and genetic variation. As mentioned above, the progeny will display variation in the form of combinations of alleles and resulting phenotypes that exceed those seen in nature. The genes or loci responsible for complex, quantitative traits can then be mapped in this quantitative trait locus (QTL) approach using markers developed to cover the genome. This approach was used with the filamentous fungus *Neurospora crassa* to find QTL associated with female mate choice and to show that the reinforced barriers to sexual reproduction behind mate choice had evolved by natural selection (98). However, as is often the case with QTL studies, the authors were not able to find specific genes responsible for the trait. This problem arises because each QTL can comprise tens to hundreds of genes, owing to the relatively few recombination events in a meiosis, even when hundreds of independent meioses are involved in generating a progeny population. With QTL analysis, full genomes are not a panacea, because it is not a paucity of markers that is the problem but, rather, the large regions in linkage.

Two means of decreasing the size of the linked regions are typically employed. One, an advanced intercross, simply increases the number of matings and meioses used to make the progeny for the mapping population. Although it is labor-intensive to make the cross, this method has been used successfully with *S. cerevisiae* to associate genes with the phenotype of stress resistance (99). The other approach, bulked (or bulk) segregant analysis, increases the number of progeny and, when phenotyping the progeny, sorts those with the most extreme phenotypes into two groups, e.g., those that are the most tolerant and least tolerant to a stressful environment. Bulked segregant analysis is even more efficient when the phenotypic screen recovers only survivors, for example, growth in the presence of an antifungal drug. Individuals with the extreme phenotypes, or the survivors, are sequenced en masse, and the reads are aligned. In these alignments, nearly all genes show the variation present in both parents, except for genes strongly associated with the phenotype; here, the allele of one or the other parent will predominate. Bulked segregant analysis has been used successfully with fungi to find genes involved in sugar metabolism in *Saccharomyces* (100), salt tolerance in the Ascomycota *Lachancia* (101), and, in *Neurospora*, temperature-responsive cell cycle regulation (102) and germling communication and fusion (103).

Recognizing Populations of Fungi

The genetic and phenotypic variation in a study can be further increased by studying many individuals in a wild population and then using an approach developed for studies of human genetics, genome-wide association studies (GWAS), or reverse ecology, an approach developed to mine populations of genomes, among them *S. cerevisiae*, to find genes with a history of strong natural selection (104). As noted above, with QTL analysis, even the hundreds of independent meioses resulting from a cross of fungi cannot break long, linked regions of the genome. In contrast, the old history of mating and recombination in a wild fungal population makes for very short linked regions and remarkable precision in associating genes and phenotype. For example, a recent GWAS in *Neurospora* found that single nucleotide polymorphisms (SNPs) in the 3′ untranslated region of a gene, but not SNPs in the coding region, were associated with the phenotype, a hypothesis validated by subsequent gene deletion experiments (105). GWA requires that populations first be accurately recognized (Fig. 4). If GWA is mistakenly practiced on a mixture of even two populations, the strongest phenotypic differences, which are most likely to be studied, will be between the populations and will associate with every fixed, genetic difference between populations. At the outset, one cannot know the extent of a fungal population, so the genomes of a representative sample of individuals, selected to maximize geographic and phenotypic diversity, must be sequenced, and the variation in the DNA sequence, i.e., the SNPs, compared to identify the populations. Well-diverged populations can be recognized by using the SNPs to construct a phylogenetic tree or network. Population structure can also be discovered using clustering approaches. Phylogenetic trees have the advantage that statistical support for branches can be assessed; clustering methods have the advantage that admixture can be detected. The process of recognizing populations is iterative and may require additional collection if what was thought to be a single, interbreeding population proves to be a complex of several populations.

Genome-Wide Association Studies (GWAS)

GWAS in humans require thousands to tens of thousands of individuals to accurately associate genes with complex traits, e.g., heart disease. However, with fungi, studies employing as few as 23 individuals have found genes associated with traits as complex as pathogenesis or signaling between individuals in a species of fungi, although these genes enjoyed a balance of alleles in the population and a strong effect on the phenotype. A pioneering GWAS of virulence in the Basidiomycota pathogen of coniferous trees, *Heterobasidion*, used just 23 individuals to find a dozen SNPs associated with virulence, and 4 of them were in genes already known to affect virulence in other fungi (106). Cell-to-cell communication and fusion between germinating conidia provided another complex trait where GWAS successfully associated a gene coding for a calcium sensor with the communication trait using just 24 *Neurospora* individuals, albeit 24 individuals preselected from a larger, preliminary screening (105). In this *Neurospora* study, the one significant association, to a calcium sensor, led to another two genes whose proteins were known to associate with the sensor and, when a higher likelihood of false positives was accepted, another six genes associated with the trait. In this study, the nine hypothesized associations were validated (i.e., could not be disproved) by gene deletion experiments (105). Among recent studies with plant-pathogenic Ascomycota (reviewed recently [107]), GWAS found a new virulence factor in *P. nodorum* (108), the gene coding for a small secreted protein virulence factor in *Zymoseptoria tritici* (109), and genes for virulence, toxin production, and sensitivity to azole antifungal drugs in *Fusarium graminearum* (110).

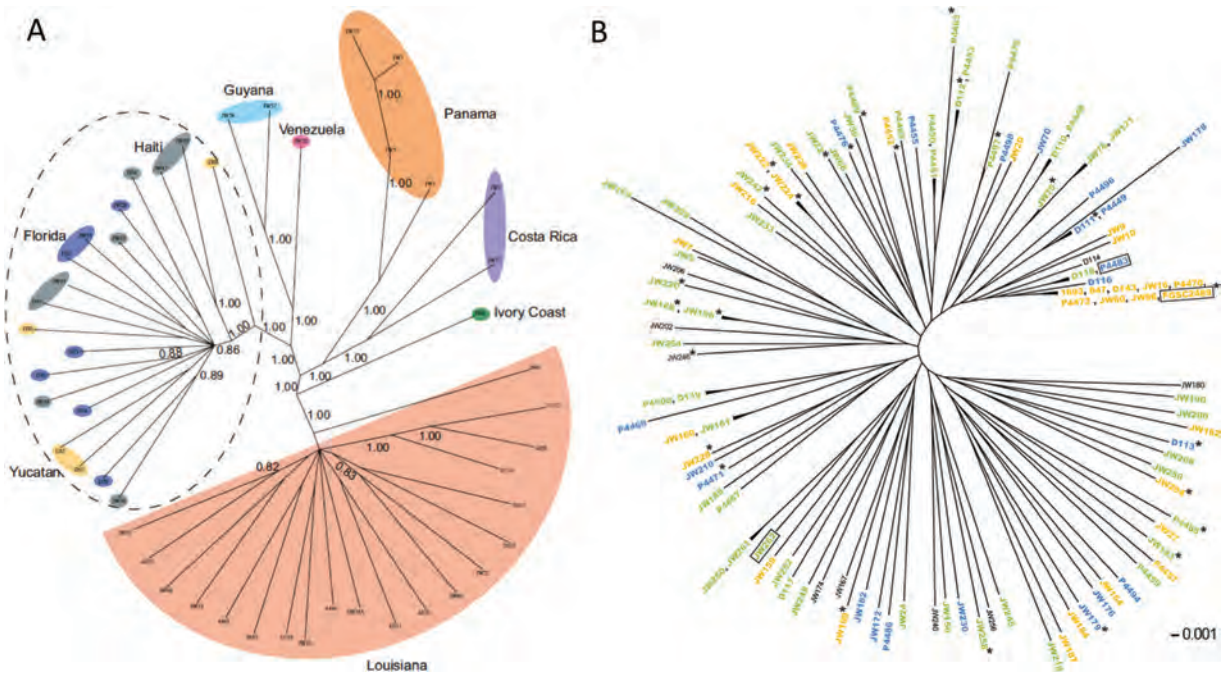

Figure 4 Population structure. (**A**) Bayesian phylogenetic analysis of SNPs from transcriptomes of 50 *Neurospora crassa* individuals from around the Gulf of Mexico showing that individuals thought to form one population actually are found in seven populations. Adapted from reference 112. (**B**) Bayesian phylogenetic analysis of SNPs from transcriptomes of 112 *N. crassa* individuals from the same geographic area as the Louisiana population in A showing no population subdivision. Note the many individuals with the same genotype as the laboratory strain, FGSC 2489, indicative of mistakes made in transferring isolates. Adapted from reference 103.

Hybridization

The ideal natural population for GWAs would be an old, natural hybrid population with twice the variation of the species contributing to the hybrids and the short genomic regions in physical linkage found in freely interbreeding groups. There is evidence that these populations do occur in fungi, as shown by a study of a parasite of wild grass in Iran, *Zymoseptoria pseudotritici*, a relative of the well-known wheat pathogen, *Z. tritici* (111). Comparison of genomes from five *Z. pseudotritici* individuals showed, in half of the genome, twice the genetic variation seen in *Z. tritici* and, in another half, no variation. In the genome half where variation was found, it was of just two types, and within each type there was no variation. The authors inferred that *Z. pseudotritici* originated from a population of F1 hybrids between two, as yet undiscovered, *Zymoseptoria* species, that the hybrids were not able to mate with either parent population, and that severe bottlenecks caused the loss of parental variation in the young F1 population. The example of *Z. pseudotritici* adds homoploid hybrid speciation (speciation originating by hybridization with no increase in chromosome number) to the ways that fungal species can originate and, in this case, it was estimated to have occurred as recently as 200 years or 380 to 550 sexual generations ago. *Z. pseudotritici* sports dispensable chromosomes, like *Z. tritici*, which may indicate that such chromosomes are not restricted to fungi that parasitize agricultural crops. The *Z. pseudotritici* results found hybridization without introgression, but hybridization with introgression has also been discovered in fungi and provides a way for mycologists to discover genes important to adaptation, as will be discussed in the next section.

Gene Flow between Populations

Where population genomic studies of fungi have discovered more than one population or species, they have often also found evidence of gene flow into the populations or among the species. The explanation for this gene flow is that mating between members of the different populations or species leads to hybrids, and these hybrids can then mate with individuals in either of the parental populations, promoting introgression of genes

from one population into the other. The regions that persist in the recipient population are those whose genes confer a selective advantage to the recipient and, if the advantage is strong enough, sweep through the recipient population. These regions can be detected in populations of fungi with sequenced genomes because they show either exceptional divergence or exceptional similarity compared to the surrounding genome, as described below.

When the population divergence is recent and the genomes of both populations are aligned, regions of exceptional divergence are easily recognized against the background of very similar regions (Fig. 5). Where the population divergence is older, regions of exceptional similarity stand out, but regions of exceptional divergence also may be detected (Fig. 6). The genomes resequenced from the populations need not be complete; they can even be transcriptomes, as long as one well-sequenced genome is available to align the others. To search for regions of exceptional divergence or similarity, measures of genetic diversity are calculated for short windows of aligned sequence and the process is repeated as this virtual window is moved along the entire genome. Measures of divergence that have been used for these sliding windows include measures of relative divergence (relative between populations), e.g., Fst, and those of absolute divergence (within regions of aligned genomes), e.g., Dxy (112). Dxy is simply the number of nucleotide substitutions per site between populations and Fst is the proportion of genetic variance found in one population compared to that found in all populations. Use of several measures is recommended because each can be confounded by different patterns of nucleotide variation (113, 114).

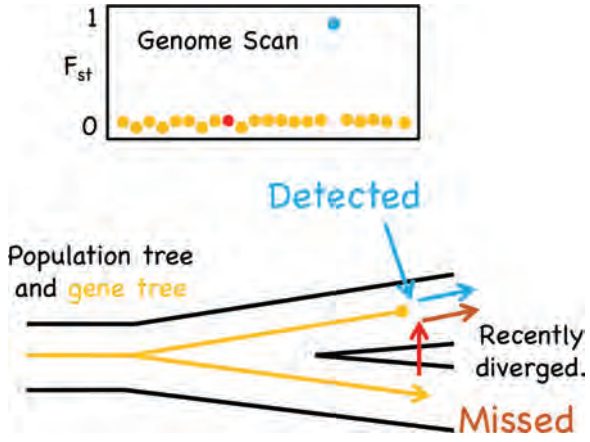

Figure 5 Hybridization and introgression in weakly diverged populations. Hybridization and introgression can be detected in genome scans of closely related populations when the genes are introduced from a more diverged population. (**Top**) Genome scan by Fst (a measure of relative genetic divergence) showing that nearly all genes have low divergence (yellow dots and one red dot), but one gene shows exceptionally large divergence (blue dot). (**Bottom**) Population tree with one gene tree highlighted in yellow showing that well-diverged genes entering from older, more diverged populations (blue dots and arrows) will be detected by comparison with the low divergence in the rest of the genome. However, genes exchanged between the populations will be missed (red dots and arrows) due to their low divergence being indistinguishable from the rest of the genome.

There are limits to this approach. In the case of recently diverged populations, the scant variation between the populations is not sufficient to permit discovery of any regions that have moved between the population, although such exchange must be frequent (Fig. 5). Instead, it is regions that have invaded the populations from more diverged populations, likely unknown, that can be found (Fig. 5). Conversely, when comparing well-diverged populations, regions that move into one or the other population from evolutionarily more distant populations may not appear to be more diverged than the rest of the well-diverged genomes (Fig. 6). In this case, it is the regions that move between the populations that are easily detected, because they show little or no divergence (Fig. 6).

Yeast Population Genomics

As might be expected, the first fungal report of population genomics was with *S. cerevisiae* (115), finding populations in the species that correlated with geography and evidence of hybridization, likely associated with domestication of this socially important fungus. When 99 Asian individuals were added to the analysis, the amount of genetic variation doubled and new populations were discovered, some of them in areas undisturbed by human activity (116). Surprisingly, neither GWAS nor reverse ecology has been practiced with *S. cerevisiae*, although the potential for such studies seems immense (117). One reason that such studies in yeast would be rewarding is that hypothesis testing is possible on a remarkably large scale, as shown in a recent study of sugar use in *S. cerevisiae* and its close relative, *Saccharomyces bayanus* (118). *S. cerevisiae* is a picky eater, preferring glucose when fed mixtures of glucose and galactose, whereas *S. bayanus* consumes both indiscriminately. To test the hypothesis that the phenotype of sugar use was under control of the seven-gene galactose pathway, the researchers swapped promoters of all seven genes, en masse, from *S. cerevisiae* into *S. bayanus*, largely recapitulating in *S. bayanus* the *S. cerevisiae* phenotype. As the authors note, "genetic mapping of complex phenotypes is within reach" (118).

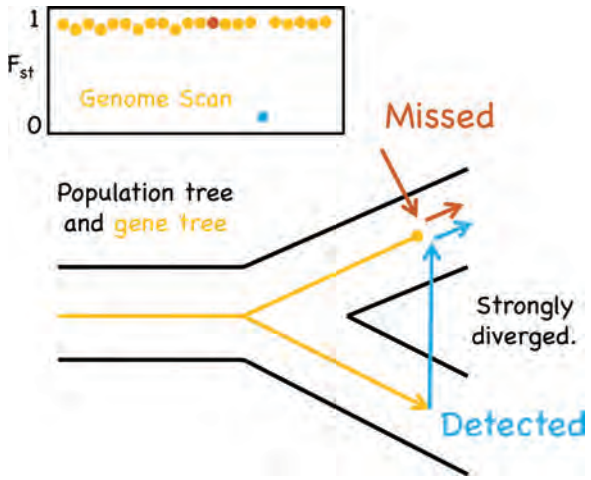

Figure 6 Hybridization and introgression in strongly diverged populations or species. Hybridization and introgression can be detected in genome scans of distantly related populations or species when the gene flow is between the two well-diverged groups. (**Top**) Genome scan by Fst (a measure of relative genetic divergence) showing that nearly all genes have high divergence (yellow dots and one red dot), but one gene shows exceptionally low divergence (blue dot). (**Bottom**) Population tree with one gene tree highlighted in yellow showing that genes exchanged between the populations will be detected (blue dots and arrows) due to their lack of divergence compared to the high divergence of the rest of the genome. However, genes entering from populations from other well-diverged lineages (red dots and arrows) will show divergence similar to the rest of the genome and be missed.

It is *Saccharomyces paradoxus*, the sister species to *S. cerevisiae*, in which population genomics has been researched, enabled by studies of its populations (119) and more than 100 individuals (120). In two North American *S. paradoxus* populations, study of adaptation to the environmental parameters of temperature and frequency of freeze-thaw cycles found that the more northerly population was better adapted than the more southerly one to growth at extreme low and high temperatures and to growth during freeze-thaw cycles (121). The authors attributed the adaptation to a higher mean temperature in the south that resulted in fewer days with temperatures both above and below freezing. Subsequent genome sequencing discovered a third population sympatric with the southerly end of the southern population that originated from hybridization between the northern and southern populations (122). Polyploidy was not involved, as it was with the genome duplication associated with the origin of the *S. cerevisiae* clade; rather, homoploidy was involved, and members of this population have the tolerance for extreme temperatures found in the northern population and the sensitivity to freeze-thaw cycles found in the southern one. Based on genetic similarity, the third population arose by introgression of northern genes into individuals from the original southern population such that the third population has between 2 and 6% northern genes. Interestingly, the third population shows the same reduced fertility in crosses to either parent, perhaps due to reinforced barriers to mating that can arise in sympatry, as was noted above for *Neurospo*ra (98).

Reverse Ecology: Ascomycota Populations

Among filamentous Ascomycota, *N. crassa* has been a model for population studies due to a remarkable collection of wild isolates (123) and a well-studied laboratory strain that has been the subject of both a genome sequencing project (2) and a comprehensive gene deletion project (124). An *N. crassa* population bordering the Gulf of Mexico that included the laboratory strain was chosen for GWA (125). When 50 of the individuals had been sequenced, phylogenetic analysis revealed not one but seven populations (112) (Fig. 4). No population had enough individuals for a GWAS, but fortunately, two of them had at least 20 members, one in Louisiana and one further south in the Caribbean. These two populations differ by 2° to 10° of latitude and a difference in average winter temperature of 9°C. When the aligned genomes were scanned to detect regions of exceptional divergence, using measures of both relative and absolute divergence, more than 30 such regions qualified, but only 2 were identified by all three approaches. Among the genes in these two regions were two known to protect against cold temperatures: a cold shock RNA helicase and a prefoldin chaperone that, in yeast, protects actin from cold temperatures (Fig. 7). The resulting hypothesis, that the Louisiana population had adapted to life at low temperature, was not disproved by measuring the growth of 10 isolates from each population at low (10°C) and normal (25°C) temperature.

A second test was devised using a similar growth approach and the aforementioned gene deletion collection (124). For all eight genes found in the two regions, a gene deletion strain was obtained from the gene deletion collection, and these strains were screened at 10°C. Most gene deletion strains showed no loss of cold tolerance (an important control for the possibility that simply deleting genes would affect cold tolerance), but this was not so for strains deleted for the RNA helicase or the prefoldin. The same result was again found in progeny of crosses between these two deletion strains and wild type; i.e., inheritance of the wild-type allele conferred adaptation to low temperature that was lost if it was deleted. The authors called this approach to dis-

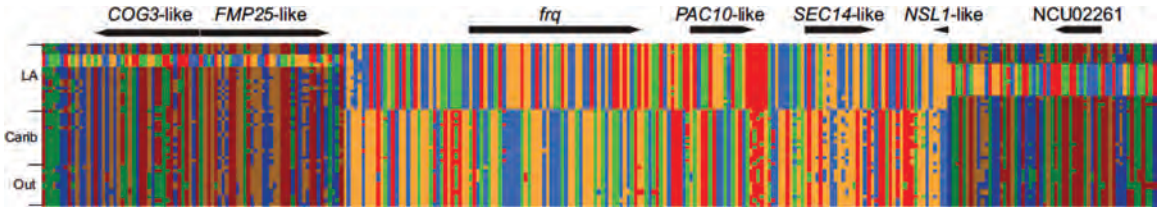

Figure 7 Regions of extreme divergence between populations of *N. crassa*. Rows are aligned genomes of Louisiana (LA), Caribbean (Carib), and other populations (out) seen in Fig. 4. Columns are nucleotide positions in four colors for the four bases. Highlighted is the region of high divergence between the Louisiana population and the Caribbean and other populations. The genome variation in this region is consistent with a history in the Louisiana population of hybridization and introgression. Low variation among Louisiana individuals in this region is consistent with a recent selective sweep. Variation in the length of introgressed regions in the Louisiana population may indicate that the sweep is still in progress. Among the six genes in the region of divergence is *PAC10*-like, which codes for a prefoldin that chaperones cold-sensitive proteins. Adapted from reference 112.

covering adaptation reverse ecology (104), because it is the reverse of most studies of adaptation. Normally, adaptation studies begin with knowledge of a phenotype adapted to an environmental pressure, e.g., the darkening of coat color in mice that have adapted from life on light-colored desert soils to life on dark-colored lava flows (126). In reverse ecology, one begins with genomes, identifies genes subject to natural selection (in the case of *N. crassa*, selection associated with hybridization, introgression, and selective sweeps), and with the knowledge of the genes and their function combined with knowledge of variation in the physical environment, infers the environmental factor (with *N. crassa*, growth at low temperature).

Reverse Ecology: Basidiomycota Populations

Basidiomycota have also been the subject of reverse ecology, e.g., the dikaryotic, ectomycorrhizal mushroom *Suillus brevipes* (127). This basidiomycete is symbiotic with pines, and 11 individuals were cultivated from fruiting bodies found in coastal California and another 17 from fruiting bodies in the Sierra Nevada of California. Using a guide sequence from the montane population, the 28 genomes were aligned, and half of the 1.2 million SNPs were used to make a phylogeny that found two populations, one coastal and one montane. These two populations are extremely similar, with only 0.01% of the SNPs being reciprocally fixed in the two populations. The same populations were recognized by a population structure approach (128), which showed no admixture. Despite the extremely similar genomes, Bayesian population analysis (129) estimated that the two populations had been diverged for 25,000 generations, with undetectable gene flow. Scans of the aligned sequences using metrics of relative and absolute divergence found two regions of the genome that, together, contained half of all reciprocally fixed SNPs. Of the four genes found in these two regions, one (*Nha1-like*) is invariable and homozygous in the coastal population, suggestive of a hard, selective sweep. It encodes a protein homologous to a Na+/H+ exchange protein found in yeast membranes that is involved with salt tolerance. It is tempting to speculate that the coastal population must contend with more salt than the montane population, but this speculation has not yet been tested. More recently, the *Suillus* study was expanded to include individuals from throughout western North America. With more geographic coverage, the study found evidence of admixture in Canadian populations situated between two, less diverse populations, one in Colorado and the other in Minnesota (130). The authors used evidence for selective sweeps and analyses associating genetic variation with environmental parameters (temperature and moisture) to identify proteins that may be involved in adaptation, e.g., membrane transporters, nucleic acid helicases, and the aforementioned Na+/H+ exchange protein. As often is the case with nonmodel fungi, hypotheses about the involvement of these genes in adaptation await testing.

Reverse Ecology: Ascomycota Species

Our discussion of fungal reverse ecology began with closely related, fungal populations, but the first such study was with well-diverged species in the Ascomycota human pathogens *C. immitis* and *C. posadasii*, agents of the human disease coccidioidomycosis (131). These fungi were studied just as high throughput sequencing was becoming possible, and most of the genomes were sequenced by the traditional Sanger method. The substantial investment was made possible

by prior studies of species and populations of these fungi, which identified at least five populations spread over two species (132, 133), a concrete example showing that evolutionary studies can have an impact in medicine. With the aim of comparing at least two individuals from each population, 20 genome sequences were obtained and aligned. Between the two species, 43% of all SNPs were reciprocally fixed, a much higher proportion than the 9% fixed differences between the Louisiana and Caribbean *N. crassa* populations or the 0.01% between the coastal and montane *Suillus* populations. As with *Neurospora* and *Suillus*, regions of the *Coccidioides* genomes were found with exceptional measures of relative divergence, in this case, exceptionally low Fst, which indicated that as much as 7% of the genome of each species had a history of hybridization and introgression between the two species (131). One region of introgression from *C. posadasii* into the Southern California population of *C. immitis* was amplified and sequenced from an additional six individuals. When aligned, the introgressed regions in all individuals shared a common edge marked by a metalloproteinase gene, Mep4, which is related to a known virulence factor, Mep1 (134). The assumption that selection for Mep4 drove the introgression was challenged when a subsequent study failed to find a difference in Mep4 transcription in the saprobic and parasitic *Coccidioides* growth phases, especially when the study found a 20-fold difference in a small (99 amino acid) previously undiscovered gene lying between Mep4 and the edge of the introgressed region (135). Again, the hypothesis that this small gene drove introgression awaits testing.

Reverse Ecology: Basidiomycota Species

A more recent example of reverse ecology with well-diverged populations or species comes from the Basidiomycota *Cryptococcus gattii*, a haploid capable of causing disease in otherwise healthy humans (136). This example is interesting because it shows that it is possible to find regions of exceptionally large divergence even between well-diverged populations or species if one uses a comparator with a broad scale, e.g., Dxy, rather than one with a restricted scale such as Fst. *C. gattii* has four distinct, species-level (137) groups, VGI-VGIV, with VGII containing the strains responsible for outbreaks of cryptococcosis in otherwise healthy hosts in Vancouver, Canada, and the U.S. Pacific Northwest. Genomes were sequenced from 53 individuals representing all four VGs, with a focus on the outbreak population. From a Dxy sliding-window scan of the aligned VGII sequences, two adjacent regions were found within a 15-kb region of one scaffold that showed exceptionally high percentages of polymorphic sites (136). Phylogenetic analyses of the first of these regions suggested that it originated by hybridization and introgression from a different VG, VGI. In one of the VGII individuals, an introgressed region is also aneuploid and homozygous, suggesting duplication after introgression. This introgressed region contains three genes that, by homology with *S. cerevisiae*, appear to be involved in actin polymerization, dissociation of Rad51 D-loops, and metal ion transport plus vacuole protein targeting. It will be very interesting to see if deletions or allele swaps of any of these three genes have an effect on virulence, although the adaptation implied by the introgression could be related to any biological or physical environmental parameter. It seems likely that the hybridization occurred by sexual reproduction, consistent with the discovery of a diverse, outbreeding population of VGII in South America that also embraces the genetic variation displayed by strains found in northwestern North America, Australasia, and Southeast Asia (136, 138, 139).

Reverse Ecology with Uncultivatable Fungi

Earlier, it was noted that population genomic studies are facilitated when the fungal individuals can be cultivated. A recent study of an obligate plant parasite, one that has never been cultivated, shows that cultivation is not essential. Comparison of genomes of 46 individuals of the obligate plant pathogen that causes powdery mildew, *Blumeria graminis*, that had been collected from three crops—wheat (*B. graminis* f. sp. *tritici*), rye (*B. graminis* f. sp. *secalis*), and the hybrid plant triticale (*B. graminis* f. sp. *triticale*)—revealed a fascinating evolutionary history (140) that recalls the aforementioned study of Zymoseptoria (111). Based on genome comparisons, *B. graminis* f. sp. *triticale* is a recent hybrid of the other two powdery mildews, and one that arose in the past 50 years, coincident with the introduction of the hybrid plant, triticale, to agriculture. *B. graminis* f. sp. *triticale* has regions of DNA from both parents, but most came from *B. graminis* f. sp. *tritici*, indicating that the initial hybridization was followed by introgression of the F1 into the *B. graminis* f. sp. *tritici* population. Based on the amount of genetic variation seen in *B. graminis* f. sp. *triticale*, hybridization involving several parents as well as their F1 progeny likely contributed to its origin. Given that one parent, *B. graminis* f. sp. *secalis*, can cause some disease symptoms on triticale, whereas the other parent, *B. graminis* f. sp. *tritici*, cannot, it is assumed that *B. graminis* f. sp. *secalis* effectors are important to the

ability of *B. graminis* f. sp. *triticale* to infect triticale. Unexpectedly, transcription studies have not implicated any of the known *B. graminis* f. sp. *secalis* effectors found in *B. graminis* f. sp. *triticale*. Again, this is a system with great potential for gene disruption studies to identify the genetic basis of *B. graminis* f. sp. *triticale* infection of triticale.

Hybridization: Caught in the Act

The population genomic studies presented so far show evidence of hybridization and introgression, but none have caught populations in the act of hybridization. The most recent hybrid found so far comes from a recent study of *Neurospora discreta* (141), a close relative of *N. crassa*. One phylogenetic species in the *N. discreta* complex, PS4, has an exceptionally large latitudinal range in North America, from New Mexico to Alaska, and also is found in Europe and Asia. When genomes were sequenced and analyzed for more than 50 individuals from this species, they showed three, well-diverged lineages (with 35 to 45% of SNPs reciprocally fixed between populations): Alaska and Europe (AK-EU), California and Washington state (CA-WA), and New Mexico and Washington state (NM-WA). Among the Alaskan individuals was one possessing, evenly distributed through its chromosomes, 12% of the genome of the apparently allopatric, NM-WA lineage (Fig. 8). Mysteriously, at one collecting site in Washington, where the CA-WA and NM-WA lineages are clearly sympatric, there was no evidence of hybridization. Clearly, this is a case where more individuals should be sampled and studied.

LAST WORD

Every technical advance in examining fungal genomes has added to our knowledge of the type and extent of genetic variation available to fungi. There is every reason to think that this trend will continue as fully assembled genomes of more and more individuals become available to mycologists, for example, the aforementioned population genomic studies of genome rearrangement and epigenetics that are expected to emerge from genomes obtained from single molecule, real-time sequencing.

Among the many outputs of genomic research, none outstrips hypothesis generation. An outcome of this abundance is a bottleneck for the completion of any

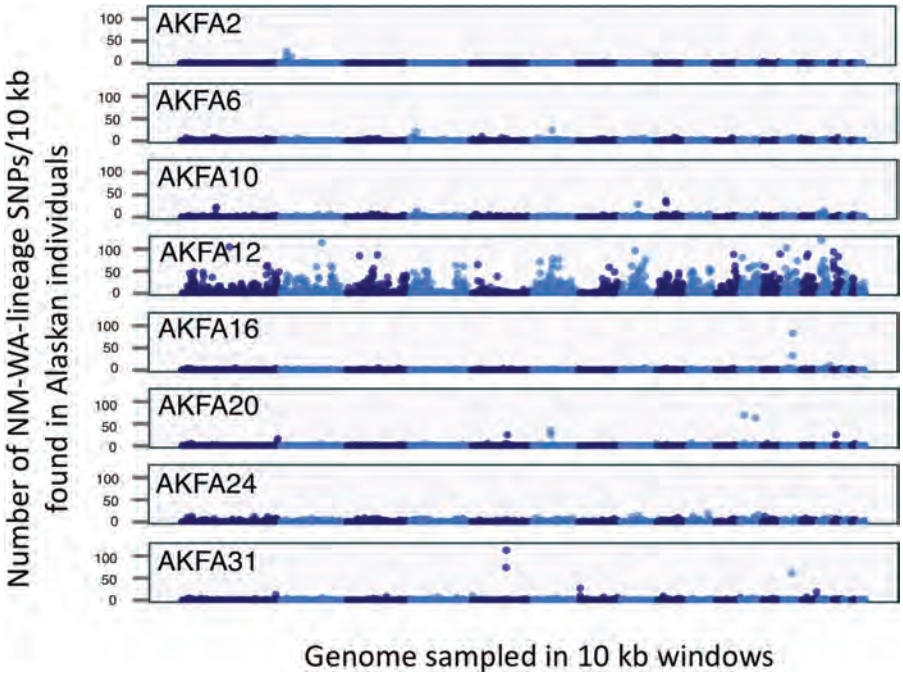

Figure 8 Evidence of recent hybridization. Genome scans for introgressed DNA in the 20 largest contigs of eight *Neurospora discreta* individuals from the Alaska-European lineage. Numbers of SNPs introgressed from the New Mexico-Washington (NM-WA) lineage are shown on the *y* axis. Alaskan strain AKFA12 stands out as having 12% of its genome introgressed from the NM-WA lineage, as expected from a few matings between a hybrid individual and members of the Alaskan population. Adapted from reference 141.

scientific endeavor: hypothesis testing. Here, again, technological advances may prove important. For example, the successful use of CRISPR-associated protein-9 nuclease to transform *S. cerevisiae* (142), filamentous fungi in the Ascomycota genera, *Aspergillus* (143), *Trichoderma* (144), and *Pyricularia* (= *Magnaporthe*) (145), as well as the Basidiomycota genera *Ustilago* (146) and *Cryptococcus* (147), indicates that hypothesis testing in all types of fungi may become, if not routine, then at least possible.

A unifying feature of genetic diversity in fungal genomes, with the exception of HGT between phylogenetically distant lineages, is that every means of generating diversity is operating all the time, such that fungal genomes are remarkably fluid and variable. That there is any constancy at all to fungal genomes is a strong testament to the power of purifying natural selection. Is there something special about fungi in terms of their life cycles or population sizes that makes them unusual in terms of generating genetic variation and enduring particularly strong natural selection? Or is it simply that the data exist for fungi because they threaten our health and food supply? Other Eukaryotic microbes have life cycle features and population sizes similar to those of fungi, as do some animals, e.g., corals. It may be that fungi are not unique in terms of genetic diversity and strength of natural selection and that the same observation will be made for plants and animals when population genomics becomes affordable for these kingdoms.

RNA Interference in Fungi: Retention and Loss

31

Francisco E. Nicolás and Victoriano Garre

INTRODUCTION

RNA interference (RNAi) is a mechanism conserved in eukaryotes that represses gene expression by means of small noncoding RNAs (sRNAs) of about 20 to 30 nucleotides (nt). Before the identification of the RNAi mechanism, its effects were observed in different organisms and described as independent processes. These effects were first observed in plants, in which the introduction of sequences intended to increase the production of floral pigments had the opposite effects, resulting in albino transformants. Hence, this phenomenon was called cosuppression (1, 2). The same phenomenon was also observed in the fungus *Neurospora crassa*, in which an albino phenotype was obtained after transformation with extra copies of the gene *al-1*, which is involved in the production of carotenoids (3). The characterization of this phenomenon revealed reversibility of the albino phenotype, since some descendants of the original albino transformants reverted to the wild type phenotype. At that time, this phenomenon was not linked to the process of cosuppression observed in plants and was named "quelling." The discovery of quelling in *N. crassa* represented a milestone in the field of RNAi, because this fungal model allowed the use of classic genetic tools to unravel the machinery of RNAi. The molecular mechanism of RNAi was finally uncovered by Fire et al., who discovered the central role of double-stranded RNA (dsRNA) in the RNAi of *Caenorhabditis elegans* (4). This central role of dsRNA was soon established in all the organisms harboring a functional RNAi mechanism, including plants, fungi, and animals. Cosuppression, quelling, and other posttranscriptional gene-silencing-related phenomena were integrated into the same conserved mechanism of RNA interference (5).

The initial function assigned to RNAi was its role as a defensive mechanism against invasive nucleic acids such as viruses, transposons, and other exogenous sequences such as transgenes and plasmids (6). The protective mechanism of RNAi is based on targeting and repression of the transcription (transcriptional gene silencing) or translation (posttranscriptional gene silencing [PTGS]) of invasive nucleic acids. However, the endogenous regulatory function of this mechanism is the aspect of RNAi that has attracted most of the research in this field. In plants and animals, the discovery of microRNAs (miRNAs), small endogenous RNAs that control the expression of target genes, unveiled the role of RNAi as a whole new regulatory layer at the RNA level, controlling most of the known cellular processes such as growth, development, differentiation, cell death, and disease (7, 8). In fungi, the regulatory role of RNAi has been extensively studied in the fungus *Mucor circinelloides*, as RNAi mutants in this fungus are affected in growth, hyphal morphology, sexual and asexual sporulation, stress response, and cell death (9–11). No miRNAs have been found in *M. circinelloides*, although particular regulatory small RNAs called exonic-siRNAs (ex-siRNAs) were identified and characterized in this fungus (12).

The RNAi mechanism is highly conserved in the fungal kingdom (13), which together with its defensive and regulatory roles, suggests that it is an essential mechanism that has been positively selected during evolution. However, the discovery of several fungi lacking an active RNAi pathway raises the question of how they can survive without the protective and regulatory role of RNAi. This article will discuss this question and will also review the machinery, mechanism, and functions of RNAi.

Department of Genetics and Microbiology, Faculty of Biology, University of Murcia, 30100 Murcia, Spain.

COMPONENTS OF THE RNAi MACHINERY

The machinery of RNAi is well conserved in the eukaryotic domain, although different functional pathways can be found in different groups of organisms or even in the same organism. In the fungal kingdom, these pathways involve three specialized components that comprise the central core of the fungal RNAi machinery: an RNA-dependent RNA polymerase (RdRP), the enzyme Dicer, and the Argonaute (AGO) protein (Fig. 1). The activation of the mechanism by sense transgenes depends on the RdRP component, which produces dsRNA molecules from single-stranded RNA precursors. Then the second component, an RNase III ribonuclease known as Dicer, cleaves the dsRNA and generates short interfering RNAs (siRNAs). These small RNAs are loaded into the third component, an AGO protein that usually forms a complex known as RISC (RNA-induced silencing complex), which uses the siRNA as a guide to target complementary specific RNA sequences. The interaction of AGO-containing complexes with an RNA target may block either transcription or translation or induce the degradation of the target RNA. Fungi often have more than one gene for each of the three basic RNAi components (13), and it is also common to find different functions for each member. Besides these three basic components, there are other pathway-specific components that are also reviewed in the corresponding sections.

The RdRP

RdRP enzymes can be found in plants, nematodes, and most fungi, except basal fungi such as the chytrid *Batrachochytrium dendrobatidis* and the microsporidia *Nosema ceranae* (13). Recent studies place RdRPs right at the onset of RNAi activation, because they have been proposed to directly produce aberrant RNA (aRNA) from a DNA template. The crystal structure of QDE-1, the RdRP of *N. crassa* involved in quelling, revealed a strong similarity to eukaryotic DNA-dependent RNA polymerases, instead of viral RdRPs, suggesting that QDE-1 might act as both an RdRP and a DNA-dependent RNA polymerase (14,

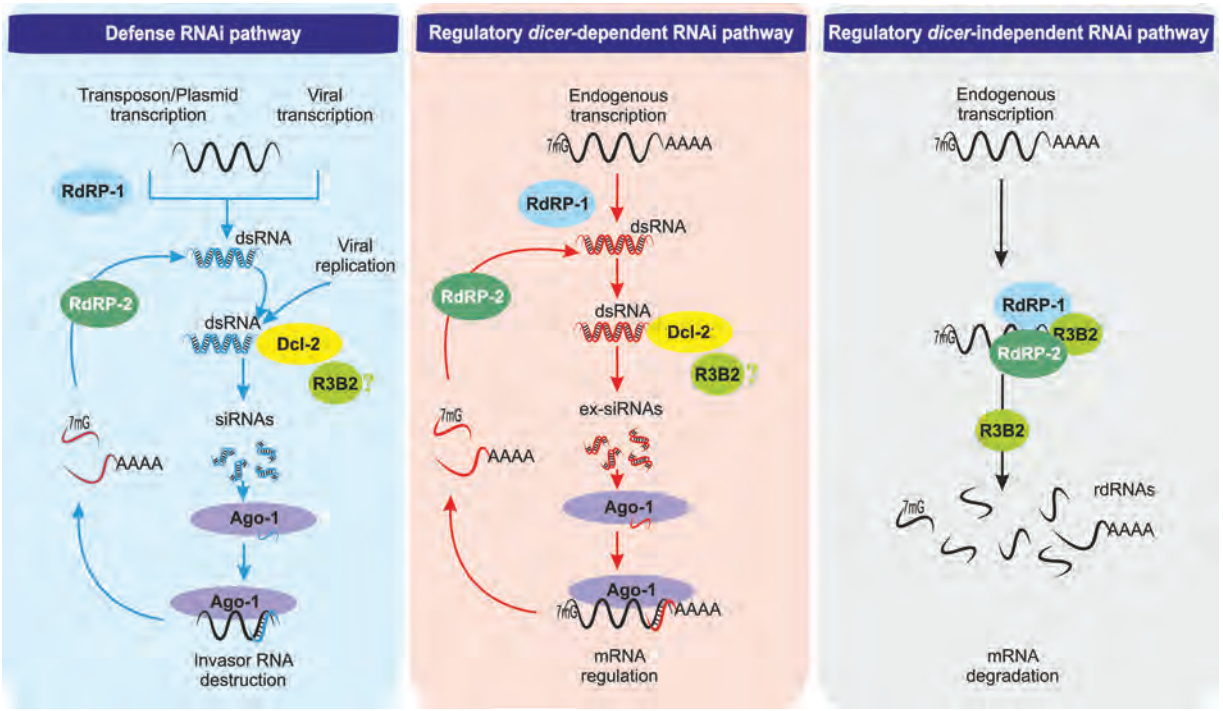

Figure 1 Main RNA interference (RNAi) pathways identified in *Mucor circinelloides*. Fungal RNAi-mediated defense mechanisms against exogenous nucleic acids in fungi is exemplified by the *M. circinelloides* defense mechanism (left box). This fungus shows an amplification step mediated by RdRP-2, which has not been found in other fungi. In addition to this defense pathway, this fungus shows two distinct RNAi pathways to regulate the expression of endogenous genes (central and right boxes). Question marks indicate that the R3B2 protein participates in these pathways, although its precise function is unknown.

15). These two activities of QDE-1 were experimentally demonstrated, confirming that RdRPs could be required both for the production of the aRNA and the subsequent dsRNA generation (14). The most intriguing question about the mechanism of RNAi activation is how production of aRNA occurs in specific DNA sequences, e.g., transposon sequences. This question has been recently answered in a study that links double-strand breaks in DNA and homologous recombination with the production of aRNA and further RNAi activation (16). Repetitive DNA, one condition known to be necessary for RNAi activation in *N. crassa*, is susceptible to DNA damage, which in turn is the signal for QDE-1 to synthesize aRNA from the affected region. The second step in the activation of RNAi is the synthesis of dsRNA, which occurs via RdRP enzymes that transform the aRNAs into the triggering dsRNA molecules (17, 18).

In organisms that show amplification of the silencing signal, RdRPs have a third function devoted to stabilizing silencing through the production of secondary siRNAs (19, 20). Secondary siRNAs are produced by RdRPs from the targeted RNAs rather than from the initial triggering molecules like primary siRNAs. Secondary siRNAs can be produced upstream and downstream of the initial inducer sequence, whereas primary siRNAs are only generated from sequences of the initial triggering dsRNA molecules. This is a process known as "transitivity," and it can be different depending on the organism in which it has been studied. In fungi, this phenomenon has been described only in *M. circinelloides* (Fig. 1), which has three RdRPs. Two of these RdRPs, RdRP-1 and RdRP-2, are involved in RNAi with differentiated roles for the initiation and amplification steps. RdRP-1 is involved in the activation of RNAi by the synthesis of dsRNA from the sense transgene, showing no activity related to the accumulation of secondary siRNAs or silencing stability (21). Therefore, the function of RdRP-1 in *M. circinelloides* seems to be similar to the QDE-1 of *N. crassa* in RNAi induced by sense transgenes (17, 22). Conversely, RdRP-2 of *M. circinelloides* only participates in the amplification step of silencing. Thus, an *rdrp-2* mutant shows a low silencing frequency and very unstable silenced phenotype both in RNAi induced by sense transgenes and in dsRNA producing transgenes (21).

The Dicer Enzyme

The main characteristic of Dicer enzymes is their ability to cleave dsRNA molecules (Fig. 1), an enzymatic activity that defines the RNase III family of ribonucleases. The way of cleaving dsRNA is also specific to this family, which consists of leaving the 5′ end with a monophosphate group and 2-nt overhang at the 3′ end (23). Dicer enzymes are only found in eukaryotes, displaying a unique structure based on two tandemly arranged RNase III domains, a single dsRNA-binding domain, an amino-terminal helicase DEXD/H-box domain, a small domain for protein-protein interaction (the DUF283 domain), and a PAZ (PIWI-Ago-Zwille) domain. The two catalytic domains are arranged to adopt an intramolecular homodimerization in charge of cleaving the two strands of dsRNA, resulting in the production of short dsRNAs of 21 to 25 nt (24). The length of the product is determined by the distance between the PAZ domain and the RNase III domains, which can change in different organisms (25). This distance is determined by a long nonconserved helix that functions as a molecular ruler and explains the different sizes of siRNAs found across species (26).

The fungi that have, or likely have, RNAi pathways often possess more than one gene coding for the Dicer enzyme (13). *N. crassa* has two *dicer* genes, *dcl-1* and *dcl-2*, which have redundant functions (27), whereas the two Dicer enzymes found in *M. circinelloides*, Dcl-1 and Dcl-2, present distinct functions, because only Dcl-2 is required for a functional RNAi mechanism (28). *M. circinelloides* mutants in the *dcl-1* gene show a fully functional RNAi mechanism, indicating that this gene is not essential for RNAi induced by invasive nucleic acids. Interestingly, these mutants presented an abnormal phenotype with reduced growth and altered hyphal morphology. These observations were the first evidence involving the fungal RNAi mechanism in the endogenous regulation of cellular processes (10).

The AGO Protein

The AGO protein is the third essential component of the RNAi machinery. Its role is to load the guide strand of the siRNAs generated by Dicer in the AGO-containing complexes, named RISC (Fig. 1). AGO proteins harbor a specific binding pocket in which the sRNA guide strand is anchored. The AGO-containing complexes use this guide strand to target the corresponding complementary sequence, which is either transcriptional or translationally repressed. In the case of PTGS, the degree of complementarity between the guide sRNA and the target determines either a slicing event and further release of the target, in case of perfect complementary (29, 30), or translation blockage of the target mRNAs and prevention of RISC complex release, in the case of partial complementary. Eventually, inhibition of translation leads to degradation of the target mRNA (31).

The architecture of the AGO protein family is based on three well-conserved domains: PAZ, MID (middle), and PIWI (32, 33). The guide siRNA binding pocket is harbored in the PAZ domain, which anchors the two overhang nucleotides of the 3′ end, whereas the MID domain binds the 5′ phosphate at the other end (34, 35). The PIWI domains contain the catalytic activity of the AGO proteins, which relies on a catalytic center similar to RNase H. This catalytic domain possesses a triad DDH, with the two aspartate residues being highly conserved (32, 33). All fungal AGO proteins share a well-conserved domain architecture, although functional diversification is observed in different fungi. For example, the AGO protein of *N. crassa*, named QDE-2, and Ago-1 of *M. circinelloides* have an essential role in RNAi induced by exogenous invasive nucleic acids, both with sense RNA- and dsRNA-expressing transgenes (9, 36). Besides an essential role in the induction of RNAi by exogenous sequences, the *qde-2* mutants have no other physiological process affected. However, a second AGO protein of *N. crassa*, named SMS-2, is involved exclusively in meiotic silencing by unpaired DNA (MSUD) (37).

FUNCTIONAL DIVERSITY OF RNAi

RNAi is widely conserved in eukaryotes, including fungi, indicating that this regulatory mechanism evolved before fungi diverged from animals. Thus, the common fungal ancestor possessed a functional RNAi pathway that has evolved along fungal evolution to generate diverse RNAi pathways, which can carry out different functions in extant fungal species. This section summarizes the main functions of RNAi in fungi.

Maintenance of Genome Integrity

In nature, organisms are confronted with a variety of threats, such as viral infections or genome damage, which put their existence at risk. Genome integrity can be affected by the movement of mobile genetic elements or accidental breaks produced spontaneously or induced by chemical or physical mutagens. The persistence of organisms on our planet is possible because they have developed mechanisms to maintain genomic integrity. The RNAi pathways play a predominant role in protecting cells from exogenous genetic material such as viruses or transposons or any other genetic material introduced by any means, as was demonstrated by the experimental introduction of transgenes or plasmids. Some of these protective RNAi mechanisms work specifically during vegetative growth, whereas others operate in processes related to sexual reproduction.

Recent results derived from the characterization of several RNAi pathways have also shown that RNAi is implicated in double-strand break repair in fungi, as occurs in plants and animals (33, 38). Moreover, RNAi also protects genomic integrity by maintaining a repressive heterochromatic state in repetitive regions of the genome, most notably those regions which harbor mobile genetic elements (39).

The next sections focus on the role of RNAi in the maintenance of fungal genome integrity, although several of the conclusions derived from these studies could be applied to other eukaryotes.

Defense responses during vegetative growth

RNAi-mediated defense mechanisms against exogenous nucleic acids that act during vegetative growth can be found in many fungi, and some of them have been characterized in detail. Although the best-characterized mechanism is quelling, in the ascomycete *N. crassa*, other mechanisms have been analyzed in other fungal groups, such as mitotic-induced silencing in the basidiomycete *Cryptococcus neoformans* and gene silencing in the *Mucoromycotina M. circinelloides* (Fig. 1). Mitotic-induced silencing is very similar to quelling in *N. crassa*, because both processes are associated with multiple copies of the integrated transgene, the strength of silencing correlating with transgene copy number (16, 40, 41). In *M. circinelloides*, transgenes do not integrate into the genome because they are carried by self-replicative plasmids, but there is also a correlation between silencing efficiency and transgene copy number (42). All of these silencing mechanisms act posttranscriptionally and require core RNAi components and accessory proteins. In organisms in which more than one protein for each core component is present, a functional specialization is usually observed. However, this is not the case for Dicer enzymes in quelling, because both proteins are redundant. In addition to the two Dicer enzymes, quelling in *N. crassa* requires one particular AGO protein (QDE-2), one particular RdRP (QDE-1), and the exonuclease QIP (QDE-2-interacting protein), which cleaves and removes the nicked passenger strand from the siRNA duplex in a QDE-2-dependent manner (17, 43). Mitotic-induced silencing in *C. neoformans* only requires one of two Dicer proteins (Dcr2) in addition to the single AGO and RdRP proteins (41, 44), while transgene-induced PTGS in *M. circinelloides* requires one of the two Dicer proteins (Dcl-2), one particular AGO protein (Ago-1), QIP (our unpublished data), and two RdRPs, which carry distinct functions (45).

The initial molecular events that trigger siRNA production and subsequent PTGS have been elegantly

deciphered in *N. crassa* and connected with maintenance of genome stability (16). In this fungus, quelling is tightly associated with the presence of multiple transgene copies, particularly tandem repeats, rather than integration at multiple sites. However, the tandem repeats alone are not sufficient for gene silencing and siRNA production; double-strand breaks at the tandem repeat locus and homologous recombination (HR) are also required (16, 46, 47). Quelling is initiated when a double-strand break occurs in the tandem repeat locus that results in HR of repetitive sequences. The model proposes that recombination intermediates produced during HR can be specifically recognized by components of the quelling pathway, likely QDE-3, a putative RecQ DNA helicase (48). QDE-3 may resolve the recombination intermediates into ssDNA using its DNA helicase activity. It also recruits the replication protein A (RPA), a single-stranded DNA-binding complex, and the dual-functional enzyme QDE-1, which may use its DNA-dependent RNA polymerase and RdRP activities to first produce aberrant single-stranded RNA and then dsRNA to activate the downstream RNAi pathway (14). This mechanism ensures that siRNAs are specifically produced from repetitive DNA loci, such as those corresponding to transposons, but not from nonrepetitive regions of the genome.

In addition to PTGS, the RNAi pathway is involved in maintaining genome integrity because mutants that lack a functional RNAi pathway cannot maintain transgene tandem repeats after double-strand breaks, showing a rapid loss of the repeats (16) and reduced copy number of the highly repetitive sequences of rDNA loci (49). Moreover, DNA damage in *N. crassa* results in the production of rDNA loci-derived QDE-2-associated sRNAs, named qiRNAs, that require the same components as quelling (QDE-1, QDE-3, Dicer, and RPA) (14, 50) and HR (46, 47). Repetitive sequences are known to be a major source of genome instability due to hyperrecombination events as a result of replication stress (51, 52). Moreover, the Dicer enzyme (Dcr1) of *Schizosaccharomyces pombe*, but not other components of the RNAi pathway, promotes the release of RNA polymerase II (Pol II) from sites of replication stress and DNA damage, such as rDNA loci, where Pol II release facilitates DNA replication and prevents homologous recombination, which would otherwise lead to a loss of rDNA repeats, especially during meiosis (53). DNA damage-induced small RNAs have been reported in other eukaryotes such as *Arabidopsis*, *Drosophila*, and mammals (9, 33), suggesting that DNA damage is a common trigger for sRNA production in eukaryotes. In summary, small RNA and RNAi components might have a broad role in maintaining genome stability in eukaryotes, including defense against transposons.

Fungal RNAi pathways are supposed to protect against fungal virus (mycovirus), because most known mycoviruses have dsRNA or single-stranded RNA genomes (54). Although mycoviruses are widespread in all major taxa of fungi (55), their control by RNAi has been demonstrated only in the ascomycete *Cryphonectria parasitica* (56). In this fungus, specialization of the RNAi core components also is remarkable because only one of two Dicer enzymes (DCL2) and one of four AGO proteins (AGL2), but none of four RdRPs, are involved in defense against several mycoviruses (56–58). Interestingly, some mycoviruses have developed strategies for interfering with this antiviral RNAi-mediated silencing for their survival (59). Importantly, the characterization of these strategies can contribute to understanding the RNAi machinery itself.

Sex-induced silencing

The RNAi-mediated defense mechanisms that work in vegetative mitotic growth have in common that they are triggered for multiple copies of a DNA sequence, which are integrated either in tandem in ascomycetes and basidiomycetes or in self-replicative plasmids in the *Mucoromycotina M. circinelloides*. Interestingly, in the basidiomycete *C. neoformans*, a transgene-induced posttranscriptional silencing mechanism silences tandem transgene arrays at a high frequency during the sexual cycle but at a frequency ~250-fold lower during asexual mitotic vegetative growth. Hence, this phenomenon was named sex-induced silencing (60), and it operates at similar efficiency during both unisexual reproduction and opposite-sex mating (61). Sex-induced silencing is mediated by RNAi via sequence-specific sRNAs and requires central components of the RNAi pathway, including the single AGO protein, the two Dicer enzymes, although Dcr2 plays the major role, and the single RdRP (60). The small RNAs map to repetitive transposable elements, suggesting that the main function of sex-induced silencing is to protect genome integrity from the activity of selfish DNA elements during mating, reducing the generation of a high mutational burden. This may be crucial for *C. neoformans* because transposons and retrotransposons are more active during sexual reproduction. According to this hypothesis, RNA machinery components are more abundant during mating or under mating growth conditions (60).

Meiotic silencing by unpaired DNA

Studies of *N. crassa* have revealed the existence of an RNAi-related mechanism that protects genome integrity

during meiosis. This mechanism transiently silences any sequence that is unpaired during meiosis, so it was called meiotic silencing by unpaired DNA (MSUD) or simply meiotic silencing (62). This process is initiated by the identification of the unpaired sequences in the prophase I of meiosis I and lasts until ascospores are formed (63). MSUD is mediated by small RNAs, referred to as MSUD-associated small interfering RNAs (masiRNAs), which are thought to direct silencing of mRNAs by complementary base pairing. masiRNAs are similar to siRNAs generated in quelling, but not identical, since they are mostly 25 nt in length and have a strong bias for 5′ uracil (64).

MSUD can be divided into two main distinct processes: detection of unpaired DNA and silencing of the corresponding sequences. The mechanism for detection of unpaired regions is poorly characterized, although two essential proteins for MUSD, SAD-5, and SAD-6 may be involved in this process because of their nuclear localization. Interestingly, SAD-6 possesses a well-characterized domain that places it within a protein family that includes *Saccharomyces cerevisiae* Rad54. Enzymes from this family participate in searching for DNA homology during double-strand break repair by homologous recombination, suggesting that identification of unpaired DNA in MUSD may use a similar mechanism (65). Unpaired DNA detection is thought to trigger the production of an aRNA that could be delivered to a silencing complex stationed in the perinuclear region, where silencing occurs (66). In this region seven proteins are located that are essential for MUSD, and at least six of them form a complex, which includes several RNAi proteins, some of them shared with quelling (66). There, the aRNA is converted to dsRNA by the RdRP SAD-1, with the participation of the helicase SAD-3. Then, Dicer DCL-1 processes the dsRNA into masiRNAs, which are bound to the AGO SMS-2, and the passenger strand is removed by the exonuclease QIP. MasiRNAs bound to SMS-2 are utilized to target homologous mRNAs to posttranscriptional silence of unpaired DNA and any other homologous sequence (37). The complex is maintained by SAD-2, a presumptive scaffold protein that tethers these silencing factors in the perinuclear region. In addition, a seventh protein located in the nuclear periphery, SAD-4, is required for MSUD-specific small RNA generation (64), although its participation in the complex has not been proven.

That quelling and MSUD both employ specific and common RNAi components, such as DCL-1 and QIP, suggests that quelling and MSUD may have evolved from an ancestral RNAi mechanism that has specialized throughout evolution (67). However, MSUD occurs only in ascomycetes because proteins homologous to some members of the MSUD pathway are absent in *Basidiomycota* and *Mucoromycotina* fungi (68, 69). On the other hand, additional RNAi components in both fungal groups are without a recognized function, suggesting that some other pathways, currently unknown, could function as genome defense during the sexual cycle. In fact, silencing by unpaired DNA during meiosis has been observed in numerous species of animals, including *C. elegans*, *Drosophila melanogaster*, and mice, indicating that it is a highly conserved phenomenon (70, 71).

For a long time, it was suggested that MSUD protects the genome by controlling the spread of mobile elements present in only one parent, because they will be unpaired during sexual crosses and thus become natural substrates for meiotic silencing (72). This hypothesis received strong support when the active DNA-type transposon Sly1-1 was identified in the genome of the most widely used laboratory *N. crassa* wild type strain. Deep sequencing of small RNAs accumulated during meiotic development detected masiRNAs that originated from Sly1-1. Furthermore, the meiotic silencing machinery is required for the production of masiRNAs emanating from Sly1-1 (73), suggesting that its transposition during meiosis is prevented by MSUD.

Heterochromatin formation

Heterochromatin is a condensed form of chromatin that is of fundamental importance to the regulation and stability of eukaryotic genomes. Constitutive heterochromatin covers regions of the genome containing highly repetitive sequences, mainly derived from mobile elements, that prevent transcription as well as recombination. In this context, the fission yeast *S. pombe* offers unique advantages for investigating the basic mechanisms that underlie heterochromatin formation because there are conserved pathways of heterochromatinization between fission yeast and multicellular eukaryotes (74). *S. pombe* chromosomes contain extensive heterochromatic regions that are associated with underlying repetitive DNA elements at the centromeres, subtelomeric regions, and silent mating-type loci (75). Formation of heterochromatin in these regions requires RNAi components, because mutations in the corresponding genes result in a loss of centromeric heterochromatin (76). The nucleation process is triggered by transcription during S-phase by Pol II of the repeats named dg and dh, which are characteristic of the heterochromatin domains (76). The noncoding transcripts produced at

these genomic regions are then reverse-transcribed into dsRNAs by the RNA-directed RNA polymerase complex, which includes the single RdRP of *S. pombe* (77). The dsRNAs are processed by the single Dicer enzyme into siRNAs that are loaded onto the RNA-induced transcriptional silencing complex (RITS), which includes the single AGO protein of *S. pombe*. RITS is targeted to the repeat regions through base pairing between siRNAs and the nascent transcripts, reinforcing silencing by facilitating the localization of the RNA-directed RNA polymerase complex (78). Moreover, RITS recruits the Clr4 methyltransferase complex that provokes the H3K9 methylation of this region, which is required to recruit the HP1 family proteins Swi6 and Chp2 and subsequently histone deacetylases such as SHREC to further compact chromatin (79).

One of the unknown parts of this process is how the noncoding transcripts produced by the heterochromatin domains are recognized by the RNAi components to trigger the whole process. One hypothesis suggests that dsRNAs are initially produced by bidirectional transcription of the centromeric repeats (76). Alternatively, the components of the spliceosome could provide a platform for RNAi because several proteins involved in splicing are required for centromeric heterochromatin formation (80, 81). Some of these proteins were found to associate with pericentromeric chromatin and with the RNAi element Cid12, one of the components of the RNA-directed RNA polymerase complex (80). The connection between RNAi and mRNA processing has been also reported in *C. neoformans*. In this fungus, transcripts with suboptimal introns show abnormally high occupancy of spliceosomes that, in this case, trigger RNAi-dependent degradation of the transcripts via a complex named SCANR (spliceosome-coupled and nuclear RNAi), which contains the single RNAi components of *C. neoformans* (RdRP, AGO, and QIP) and the splicing component Srr1 (82). Interestingly, noncoding RNAs produced from centromeric repeats undergo inefficient splicing that could result in either accumulation of the splicing machinery itself or possibly splicing intermediates, which may serve as a signal to recruit the RNAi machinery to target transcripts. A phenomenon reminiscent of this is present in the RNAi-less yeast *S. cerevisiae*, in which inefficient splicing seems to act as a regulatory signal tagging transcript for degradation by the RNA surveillance machinery (83). Connections between RNAi and splicing factors have been found in plants (84), worms (85), and flies (86), suggesting that recruitment of RNAi components by splicing machinery could be widespread in eukaryotes.

Regulatory Functions of RNAi

Although RNAi is best known for its protection of the genome against foreign nucleic acids, particularly transposons, it is also involved in the regulation of fungal physiology and development. This latter function of RNAi in fungi is less well characterized due to the absence of obvious physiological phenotypes in the RNAi-defective mutants in most fungal species. In this context, the *Mucoromycotina M. circinelloides* has recently become a valuable model because mutants in RNAi components show clear phenotypes that affect its physiology and development. Moreover, it uses several regulatory pathways (Fig. 1), which will be described in the next sections, to regulate the expression of a large number of genes (11).

Endogenous small RNAs involved in gene regulation

RNAi-mediated regulation is associated with noncoding endogenous small RNAs (esRNAs) of about 20 to 30 nt. The most relevant example of regulatory esRNAs is the animal and plant miRNAs, a class of esRNAs that are produced from hairpin-structured RNAs and block the translation or provoke degradation of target mRNAs (87). For a long time, miRNAs have been considered to be absent in fungi, but the application of deep sequencing technologies has revealed the existence of esRNAs similar to miRNA, named miRNA-like small RNAs (milRNAs) (88), in several ascomycetes and basidiomycetes (45). However, so far, none have been clearly linked to a particular physiological or developmental process. In addition to milRNA, several additional types of esRNAs have been identified, some of them with clear regulatory functions such as the *M. circinelloides* ex-siRNAs (see below).

milRNAs

The milRNAs were initially found and exquisitely characterized in *N. crassa*, which has at least four classes of milRNAs according to their mechanisms of biogenesis that use different combinations of RNAi components, including the two Dicer enzymes, QDE-2, QIP, and the putative RNase III domain-containing protein MRPL3 (88). Despite how they are produced, these milRNAs are similar to animal and plant miRNAs because they are predominantly derived from one strand of hairpin-like single-stranded RNA precursors, with a strong preference for U at their *5′* termini. Most interestingly, *N. crassa* milRNAs can repress the expression of endogenous genes, and levels of the predicted miRNA target genes are upregulated in RNAi mutants, suggesting that

milRNAs regulate gene expression. Thereafter, milRNAs have been identified in an increasing number of dikaryotic species, i.e., *Ascomycetes* and *Basidiomycetes*, but not in basal fungi, including *Mucoromycotina* species (45). Despite the presence of milRNAs in many fungi, their physiological importance remains to be determined.

Nat-siRNAs and disiRNAs

Natural antisense transcripts (NATs) are noncoding RNAs complementary to sense RNAs. The presence of NATs in eukaryotic genomes is widespread, and studies of several eukaryotes have demonstrated that they participate in the regulation of their complementary sense transcripts via a range of mechanisms, including RNAi (89). They are also present in fungi, but the connection with RNAi is not clear, except for yeasts, in which overlapping sense and antisense transcripts form dsRNAs that are recognized by the RNAi machinery and processed into siRNAs (90, 91). These siRNAs are named nat-siRNAs, from NAT-derived siRNAs, to distinguish them from the siRNAs produced from RdRP-derived dsRNAs. However, *N. crassa* accumulates Dicer-independent small interfering RNAs (disiRNAs) that are also derived from overlapping transcripts. Despite having canonical siRNA characteristics (22 nt long and a 5′ uridine bias) and being bound by AGO protein QDE-2, their biogenesis is independent of all canonical RNAi components (Dicers, AGO, and RdRP), suggesting that they are produced by an unknown RNAi-independent mechanism (88). Interestingly, disiRNAs arise from several gene-rich regions, where they mediate a new type of transcription-dependent DNA methylation event (disiRNA loci DNA methylation), which is triggered by convergent transcription and enriched in the promoter region (92). Moreover, disiRNAs also mediate the recruitment of enzymes that modify heterochromatin to establish facultative heterochromatin regions at promoters to regulate the expression of sense target transcripts. This type of regulation has been observed in the circadian gene *frq* of *N. crassa*, and it is needed to establish the appropriate circadian phase. However, the molecular mechanism of disiRNA-mediated heterochromatin formation is still unknown (93).

esRNAs of *M. circinelloides*

The *Mucoromycotina* fungus *M. circinelloides* represents an outstanding fungal model because of its evolutionary distance from classical dikaryotic models, providing a different perspective on fungal biology. This fungus accumulates esRNAs enriched in exonic sequences compared with intergenic and repetitive regions, which is in contrast to other fungi, in which most esRNAs are produced from repeats and transposons (12). A large number of these exon-derived esRNAs, named ex-siRNAs, are generated by Dicer-dependent RNAi pathways (Fig. 1). These ex-siRNAs are heterogeneous in structural characteristics and biogenesis pathways. Thus, four classes of ex-siRNAs (classes 1 to 4) have been defined according to the combination of the silencing machinery components required for their biogenesis (9, 12), which define four RNAi pathways (94). Classes 1 and 2 are produced by canonical RNAi pathways and show characteristics of functional siRNAs such as a defined size of 23 to 24 nt with no strong strand bias, binding to the Ago-1 protein, and a very strong bias for uracil at the 5′ position of the ex-siRNAs. Unlike classes 1 and 2, class 3 and 4 ex-siRNAs are not bound by Ago-1 and show different structural features that suggest they are produced by a noncanonical RNAi pathway (12). The crucial breakthrough in the *M. circinelloides* RNAi field was the discovery that ex-siRNAs regulate the expression of the protein-coding genes from which they are derived by guiding degradation of the corresponding mRNAs (74). The existence of both a large number of genes regulated by ex-siRNAs (11) and clear-cut phenotypes of mutants for strains lacking RNAi components indicate that ex-siRNAs are regulatory esRNAs generated by Dicer-dependent RNAi pathways. Exon-derived esRNAs with putative regulatory functions have also been described in the ascomycete *Trichoderma atroviride*. Similar to *M. circinelloides*, differential accumulation of some exon-derived esRNAs correlates with differential accumulation of the corresponding transcripts (95).

In addition to Dicer-dependent ex-siRNAs, *M. circinelloides* accumulates a significant amount of esRNA generated by a noncanonical *dicer*-independent but *rdrp-1*- and/or *rdrp-2*-dependent RNAi pathway, in which an RNase III-like protein called R3B2 plays a crucial role (Fig. 1). Most of the esRNAs produced by the *dicer*-independent *rdrp*-dependent RNAi pathway correspond to exons and show characteristics that suggest that they are nonrandom degradation products of specific mRNAs. Therefore, they were named *rdrp*-dependent degraded RNA (rdRNA). Interestingly, this new noncanonical RNAi pathway regulates mRNA levels, because a reduction in rdRNA levels correlates with an increase in mRNA accumulation of the corresponding genes (96). Moreover, R3B2 is an interesting protein because it sports an unusual domain, formed by one RNase III and two dsRNA-binding domains, which

defines an RNase family specific to the *Mucorales*. In addition to being required for the production of esRNAs by the noncanonical RNAi pathway, it is also essential for the biogenesis of several classes of *dicer*-dependent ex-siRNAs (96), suggesting that it might also interact with Dcl-2 to positively affect Dicer activity in ex-siRNA generation (Fig. 1) (94).

Physiological and developmental responses governed by *dicer*-dependent RNAi pathways

Mutants in each of the core components of the *M. circinelloides* RNAi pathway exhibit defects in physiology or development, which are probably a consequence of altered expression of genes regulated by esRNAs (11). Several phenotypes are shared for more than one mutant, suggesting that the esRNAs generated by particular combinations of RNAi proteins orchestrate particular physiological and developmental responses. This section deals with the processes controlled by different groups of *M. circinelloides dicer*-dependent ex-siRNAs that include vegetative growth and hyphal morphology (10), asexual sporulation (9, 11, 28), and hyphal autolysis in response to nutrient starvation (9). In a similar way, *T. atroviride dcr2* and *rdr3* genes drive reproductive conidiation, while *dcr1* together with *dcr2* promotes vegetative growth, suggesting that these processes are also regulated by *dicer*-dependent exonic esRNAs in this fungus (95). In both fungi, these cellular processes are impacted by environmental signals such as nutrient availability, suggesting that RNAi pathways may mediate responses to environmental signals in other fungi (45, 97).

Analyses based on deep sequencing technology have identified several hundred genes in *M. circinelloides* that are probable targets of the *dicer*-dependent ex-siRNAs. Interestingly, the patterns of mRNA accumulation in different RNAi mutants fit quite well with the patterns of ex-siRNAs, suggesting that each class of ex-siRNA regulates the expression of a particular group of genes that control a specific physiological or developmental process. This is clearly observed in asexual sporulation and hyphal autolysis. Both processes are affected in *dcl-2*, *ago-1*, and *rdrp-2* mutants, which present altered expression of a common group of genes coding for proteins that are involved in signal transduction or regulation and in specific metabolic pathways associated with asexual sporulation and/or autolysis in other fungi (11, 94). The *dcl-2*, *ago-1*, and *rdrp-2* genes are required for the biogenesis of class 1 ex-siRNAs (12), suggesting that this ex-siRNA class controls asexual sporulation and autolysis in response to nutrient starvation (11).

As expected for direct regulation, the mRNA levels of several target genes of *M. circinelloides* ex-siRNAs increased in RNAi mutants unable to produce the ex-siRNAs, although a higher number of genes showed a decrease in transcript levels, suggesting they are secondary targets (11, 45). The existence of secondary targets, which has also been detected in *T. atroviride* (95), implies an amplification of the regulation by ex-siRNAs.

A dicer-dependent RNAi pathway is also involved in the virulence of *Botrytis cinerea*, although only part of the RNAi pathway implicated in pathogenesis operates in this fungus. In this process, this fungal pathogen transfers virulent sRNA into host plant cells to silence host genes in order to debilitate plant immunity and promote infection. These mobile sRNAs are processed by the two partially redundant Dicer proteins of *B. cinerea* from long RNA precursors derived from clusters within long-terminal repeat retrotransposons in the fungal genome. The *B. cinerea* sRNAs transferred to plant cells structurally mimic plant sRNAs and hijack the plant RNAi machinery by binding to AGO proteins. After that, *B. cinerea* sRNAs target genes with complementary sequences that are involved in plant immunity against *B. cinerea* (98). In recent years an increasing number of examples of RNA-signal exchange have been described to occur between organisms of different kingdoms (99), suggesting that *B. cinerea* may represent only the tip of the iceberg and that other fungi could transfer or receive sRNAs from other organisms, including other fungi. Almost all aspects of this trans-kingdom silencing phenomenon, from the selection of specific sRNAs to be transported to the hijacking of the host RNAi machinery to silence target genes, remain poorly understood. However, transport of sRNAs by extracellular vesicles has been proposed as a candidate mechanism by comparison with the transport of sRNAs within the cells of an organism and given the accumulation of vesicular material in the interphase between the plant and pathogen (99).

Physiological and developmental responses operated by *dicer*-independent RNAi pathways

Two cellular processes, response to oxidative stress and sexual interaction, are regulated by the *rdrp*-dependent *dicer*-independent RNA degradation pathway in *M. circinelloides*. Mutants in genes of this pathway, i.e., *rdrp-1*, *rdrp-2*, and *r3b2*, show increased resistance to oxidative stress and reduced production of zygospores, the sexual structures formed when mycelia of opposite mating types interact (96). The existence of complex physiological and developmental processes

altered in mutants of this degradation pathway, reinforced by the nonrandom generation of *rdrp*-dependent degraded RNAs, suggests that the *rdrp*-dependent *dicer*-independent RNAi pathway actively governs the expression of a specific set of genes, rather than just being an accessory RNA degradation mechanism. Many of the genes controlled by this pathway code for metabolic enzymes or proteins involved in regular cellular functions such as mRNA processing, translation, or signaling, including proteins associated with responses to different environmental stresses (28). Nevertheless, the high number of genes targeted by this noncanonical pathway predicts other cellular processes regulated by this RNAi mechanism that likely are not directly visible under standard growth conditions (94).

Phenotypic plasticity mediated by epigenetic mechanisms

The reversibility of the RNAi mechanism may provide remarkable phenotypic plasticity for rapid adaptation to changing environments, and RNAi-mediated silencing of specific gene expression under adverse environmental conditions can offer an important selective advantage, because descendants of silenced strains can inherit and maintain this specific epigenetic gene repression as long as the adverse environmental conditions continue to be present. If the environmental conditions change, the RNAi mechanism can interrupt repression of target genes, and the silenced strains can reverse to the original phenotype. This adaptive mechanism has been observed in *M. circinelloides*, in which the canonical RNAi pathway silences one specific gene to generate epimutants that are drug resistant (100). *M. circinelloides* develops spontaneous resistance to the antifungal drug FK506 via two distinct mechanisms. One involves Mendelian mutations that confer stable drug resistance, whereas the other is activated via an epigenetic RNAi-mediated pathway that results in unstable drug resistance. FK506 blocks the transition to hyphae and enforces yeast growth by interaction with the peptidyl-prolyl isomerase FKBP12 to form a complex that inhibits the protein phosphatase calcineurin (101, 102). Mutations in either the *M. circinelloides fkbA* gene encoding FKBP12 or the calcineurin *cnbR* or *cnaA* genes confer FK506 resistance, restoring hyphal growth in the presence of this drug. In parallel, RNAi is spontaneously triggered to silence the *fkbA* gene, producing drug-resistant epimutants. FK506-resistant epimutants are readily reverted to the drug-sensitive phenotype when selection is released by growth without this antifungal drug (100). Retention of the RNAi machinery in most fungi leads to the possibility that this epigenetic mechanism of rapid adaptation may operate in other fungi.

LOSS OF RNAi

The functional diversity of RNAi pathways supports the idea of positive selection and evolutionary advantages for the organisms that have retained this mechanism. Surprisingly, several organisms, including some fungi, lack an active RNAi mechanism due to the loss of *dicer*, *argonaute*, or both genes. The loss of RNAi in fungi affects the subphyla *Saccharomycotina* and *Ustilaginomycotina*, class *Wallemiomycetes*, and some fungi of the phylum *Microsporidia* (13), in addition to some species such as the highly virulent *Cryptococcus deuterogattii* (44, 60). The absence of a functional RNAi pathway raises the question about the advantages of its loss. The answer to this question might rely on the context in which these organisms had to evolve. For instance, there are yeasts such as *S. cerevisiae* and other filamentous fungi that are susceptible to be infected with "killer virus," a dsRNA virus that can be cytoplasmically inherited. This virus produces a toxin that kills other noninfected cells, whereas it confers immunity to the cells making the toxin. However, the dsRNA genome of this virus is not compatible with an active RNAi mechanism, which turns out to be a disadvantage under these circumstances. This could explain the existence of several RNAi-defective species in which loss of this virus defense mechanism confers a selective advantage over its RNAi-competent neighbors (103). Also related to viral infections, some microbial pathogens retain the genome of infective viruses because they confer new virulence mechanisms, improving their pathogenicity. This is the case for some trypanosomatid protozoans such as *Leishmania* species, which present increased virulence when they are bearing dsRNA viruses named LRV (*Leishmania* RNA virus) (104, 105), but this phenomenon has not been observed in fungi.

A third situation in which loss of RNAi becomes a selective advantage might be the case of parasitic organisms that are continuously evolving to escape from host defenses. These organisms need a high genome plasticity that ensures a high genetic diversity in the population. One way of ensuring this genome plasticity is allowing the movement of retrotransposable elements by loss of an active RNAi mechanism. This mechanism of rapid evolution based on loss of RNAi has been proposed in some strains of *C. deuterogattii* with increased virulence (60). Comparison of RNAi-deficient strains of *C. deuterogattii* with RNAi-proficient genomes of

the *Cryptococcus* pathogenic species complex revealed that a set of conserved genes, several of them playing roles in RNAi pathways, were lost in all *C. deuterogattii* isolates examined, suggesting that RNAi loss could have contributed to its pathogenic trajectory (44). In addition to the movement of retrotransposon elements, loss of RNAi also can benefit genome plasticity by extrachromosomal gene amplifications, which has been described in RNAi-deficient *Leishmania* (104). In summary, RNAi loss might seem an ingenious adaptation solution for the species described here. However, the deleterious effects of active transposons and the lack of an antiviral defense mechanism might imply a risk of extinction in the future of these species.

A HYPOTHESIS ON THE ORIGIN OF RNAi

RNAi has been a hot topic in biology since its discovery, becoming a milestone in the progress of understanding the complex biological mechanisms underlying gene regulation. Despite all of the accumulated knowledge, an explanation of the origin of this complex mechanism still remains elusive. The answer to this question might rely on the possible link between RNAi and the mechanism of standard mRNA decay, a more ancestral mechanism that shows evolutionary conservation across all domains of life. The first link between these two mechanisms showed how they compete for aRNA. Mutants with an impaired mRNA decay mechanism show boosted efficiency of transgene-induced gene silencing, indicating that degradation of aRNAs limits their entry into the RNAi pathway (106–108). Another link forged between these otherwise distinct RNA decay mechanisms is the discovery of a noncanonical *rdrp*-dependent *dicer*-independent RNAi pathway that is involved in degradation of specific mRNAs in *M. circinelloides* (Fig. 1) (96). This pathway could represent an intermediate evolutionary state between mRNA decay and RNAi, because a typical RNAi component, the RdRPs, participate in RNA degradation. The way RdRPs discriminate between canonical RNAi and RNA degradation pathways could be related to the transcriptional level of the target RNA. Thus, a high transcriptional level results in overproduction of aRNA, and an excess of aRNA could drive RdRP to activate the noncanonical degradation pathway (109–111). Accordingly, most genes regulated by the *rdrp*-dependent *dicer*-independent degradation pathway are highly expressed (96). In addition, when the noncanonical degradation pathway is blocked in *rdrp-1* mutants, the excess of aRNAs enhances the efficiency of the canonical RNAi pathway, and similarly it was enhanced by mutations in the canonical mRNA decay pathway (100). In summary, the dual role of RdRPs in the mechanisms of RNA degradation and canonical RNAi of *M. circinelloides* could be the initial step in the evolution of the RNAi system, followed by the appearance of Dicer enzymes with the role of processing the dsRNA generated by RdRPs. Finally, AGO proteins would have evolved to convert the siRNAs generated by Dicer into the effector molecules of the RNAi mechanism. Functional diversification would come later in multicellular eukaryotes, generating the complexity of the modern RNAi world (96).

Amyloid Prions in Fungi

32

Sven J. Saupe,[1] Daniel F. Jarosz,[2] and Heather L. True[3]

INTRODUCTION

In 1994, a paper signed by a single author based on genetic approaches opened a decisive breach leading to a dramatic expansion of our perception of the biological significance of the prion phenomenon (1). In the following years, biochemical reconstitution and transformation established that these biological entities, originally identified and defined in the context of mammalian diseases such as Kuru or Creutzfeldt-Jacob disease, also exist in yeast as "protein-based genes" and correspond to previously described non-Mendelian genetic elements (2, 3). It is now clear that in most known cases the physical basis for prion propagation is the formation, growth, and fragmentation of an amyloid aggregate. Amyloids are ordered protein polymers with a so-called cross-β structure (4). The original definition of prions as "infectious proteinaceous particles" is imprecise enough to still be operational today but as a consequence embraces a variety of biological phenomena and structural features (5). Defining prions thus remains a nontrivial task. While a more restrictive definition is perhaps neither possible nor desirable, this general term induces some confusion and controversy. In an attempt to clarify discourse, at some point investigators in the mammalian disease-related field denied the fungal "infectious proteinaceous particles" the name of prions and proposed instead to term them "prionoids" (6). These semantic battles should not be disregarded as sterile, but rather should be taken as an indication of the variety of the biological realities that the term covers.

Prions are not necessarily harmful entities, nor do they necessarily correspond to amyloid structures (7). By some definitions they do not need to correspond to propagation of a specific conformational state (8). The situation is further complicated by the description of so-called prion domains; prion-forming domains (PFDs) are protein domains that confer the ability to other proteins to behave as prions in an *ad hoc* experimental setting. However, this observation does not necessarily imply that the native protein from which the domain is isolated also behaves as a prion (9, 10). That said, this chapter provides a description of prions and prion domains in the fungal kingdom. Our minimal operational definition of a prion here will be a protein able to adopt a transmissible conformation, this conformation being transmitted vertically to mitotic (and often meiotic) progeny and horizontally between strains through cytoduction (in yeast) or somatic anastomosis (in filamentous fungi) (Fig. 1). We will more specifically focus on models for which the amyloid nature of the prion particle is known or can be suspected.

The study of prions in fungi is largely that of prions in the yeast *Saccharomyces cerevisiae*, but a prion and several PFDs have also been identified in filamentous fungi. Three historical prion models, [URE3], [*PSI*$^+$] in yeast, and [Het-s] in *Podospora anserina*, were identified and studied as non-Mendelian genetic elements before they were found to correspond to prions (11–13). [*PIN*$^+$], in turn, was identified in relation to prion curing experiments carried out on [*PSI*$^+$] strains (14). The list of fungal prions now amounts to about a dozen (15). The work on yeast prions dominates the literature in terms of sheer amount, diversity of models, and level of detail. In many aspects, yeast models and the [*PSI*$^+$] system have established the general paradigms and methods that are used in the field. Prions from filamentous fungi (that is, essentially the [Het-s] model), are considered by comparison to this paradigm, and in some aspects, but not all, they conform to it. Yeast prion systems are also intensively used to study the aggregation and toxicity and prion behavior of proteins

[1]Institut de Biochimie et de Génétique Cellulaire, UMR 5095, CNRS, Université de Bordeaux, Bordeaux, France; [2]Department of Chemical and Systems Biology and Department of Developmental Biology, Stanford University School of Medicine, Stanford, CA; [3]Department of Cell Biology and Physiology, Washington University School of Medicine, St. Louis, MO.

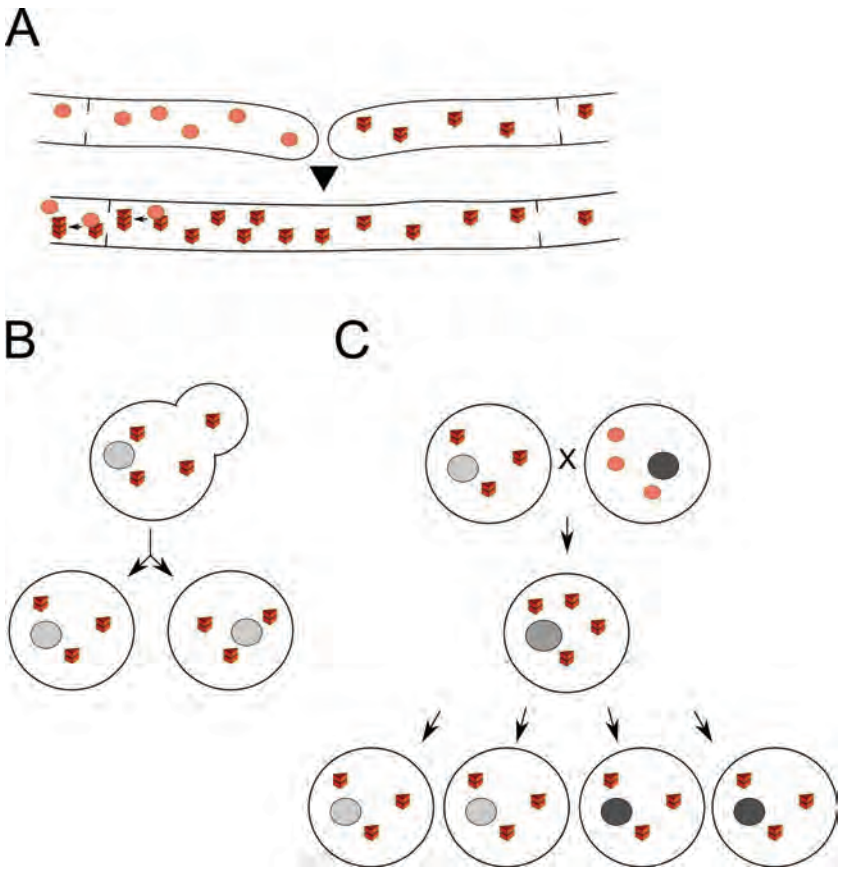

Figure 1 Natural situations of prion propagation in fungi. (**A**) Prion propagation after hyphal anastomosis in a filamentous fungus (for instance, [Het-s] in *Podospora anserina*). The prion form is transmitted from a donor-infected strain (right) to a recipient strain (left). The prion form then converts the entire mycelium to the prion state due to cytoplasmic continuity throughout the thallus. Prion transmission also occurs in meiotic crosses with maternal inheritance (not depicted here). (**B**) Prion propagation during mitotic cell divisions in yeast. Prion seeds are transmitted from mother to daughter cells during budding. (**C**) Prion transmission during sexual crosses. In a cross between a [PRION$^+$] (left) and a [*prion*$^-$] strain (right), the resulting diploid is [PRION$^+$] and there is non-Mendelian segregation of the [PRION$^+$] character (often, but not always, with 4:0 segregation as in the example depicted here).

or protein domains derived from other species. This approach has been used commonly, but not exclusively, for proteins relevant to human protein-deposition diseases (see references 16 and 17 for recent examples of this approach). This line of research will not be specifically discussed here.

PHYSIOLOGY OF PRION FORMATION AND PROPAGATION IN FUNGI

The initial discovery of prions in fungi, and immediate follow-up work, focused on cells being in one of two states: [*PRION*$^+$] and [*prion*$^-$]. Because their inheritance involves self-templating changes in protein conformation, [*PRION*$^+$]-based traits have very different patterns of inheritance in genetic crosses than DNA-based traits: their phenotypes are dominant (denoted by capital letters) and segregate to meiotic progeny in a non-Mendelian fashion (denoted by brackets). The characterization of [*PRION*$^+$] and [*prion*$^-$] states quickly moved beyond phenotypic assessment and epigenetic inheritance of the phenotype to focus on the aggregation of the prion protein itself. The aggregated state of the prion protein was followed by microscopy with fusion proteins and by sedimentation analyses that could discern soluble and insoluble, or higher molecular weight

species (2, 18–20). Below we highlight specific examples that laid the foundation for this burgeoning field.

[*PSI*$^+$]: The Most Studied Fungal Prion

The prion form of the translation termination factor Sup35 (eRF3) results in inefficient termination and detectable nonsense suppression (21). Strains harboring a premature termination codon in either the *ADE1* or *ADE2* genes (the *ade1-14* or *ade2-1* alleles) are unable to synthesize adenine. The loss of either Ade1 or Ade2 proteins in an otherwise functional pathway results in the buildup of a metabolic intermediate that gives the colonies a red color. Read-through of the premature termination codon (nonsense suppression) and completion of the pathway restores the colony color to white when nonsense suppression is high or to pink when it is not as high. Thus, *ade1-14* or *ade2-1* colonies are red when cells are [*psi*$^-$] and Sup35 is soluble and translation termination is efficient. They are white when cells are [*PSI*$^+$] and Sup35 is in the prion state.

Prion Variants and Prion-Forming Domains

The sensitive phenotype associated with the [*PSI*$^+$] prion enabled the discovery of distinct [*PSI*$^+$] prion variants (22). Different heritable states of [*PSI*$^+$] were observed without any genetic change. That is, they arose from the same Sup35 protein sequence. These states were termed prion "variants" and are analogous to mammalian prion strains. These are thought to be different self-propagating structures of the mammalian prion protein PrP that are largely responsible for variation in pathologies in mammalian prion diseases (23). [*PSI*$^+$] variants are discernable phenotypically by stable and distinct colony colors that range between red and white. How white or pink the colony is correlates to how much Sup35 is in the nonfunctional prion state. This can also be assessed biochemically by the relative amount of insoluble Sup35 protein in [*PSI*$^+$] variant lysates (21, 24–26).

Prion variants are distinct self-propagating structures of a prion protein. They are derived from the same polypeptide sequence. Thus, the stable phenotypic differences are a consequence of these structural changes. Proof of that concept was provided by the generation of biophysically distinct amyloid structures *in vitro* with purified recombinant Sup35 protein, which was then used to infect [*psi*$^-$] yeast and generate phenotypically discernable [*PSI*$^+$] variants (27). Such prion variants are not unique to [*PSI*$^+$] and have been observed with [URE3] (28, 29) and [*PIN*$^+$/*RNQ*$^+$] (30–32) as well. In addition, PrP has been suggested to replicate as over 30 prion strains. Many (perhaps all) amyloidogenic proteins associated with human disease can form multiple self-replicating β-sheet-rich structures (33). In contrast to what has been described for several yeast prion models, no prion variants have been reported for the [Het-s] system. One may argue that the lack of a sensitive detection assay has prevented identification of such hypothetical variants. Yet the fact that HET-s prion fibrils are characterized by the absence of structural polymorphism further supports the notion that there are no [Het-s] variants (34).

Distinct amyloid structures formed by the same protein involve different primary structure elements. Thus, changes in protein sequence can have differential effects on the propagation of distinct prion variants. For example, mutation of an amino acid residue that is buried in the core (packed in the templating β-sheet structure) of one amyloid structure but on the outside of the core in another amyloid structure can prevent propagation of one structure but have no effect on another (21, 35–39).

Although some mutants can prevent propagation of a particular amyloid structure, the ability to establish a prion state appears to be more dependent on the overall amino acid composition of the PFD (40, 41). For most of the prion proteins identified (particularly those in *Saccharomyces*), the PFD is a long stretch of amino acids rich in glutamine and asparagine residues. These domains are typically devoid of predictable secondary structure and are thought to be intrinsically disordered. Proteins with intrinsically disordered domains are not uncommon and are generally thought to acquire a stable structure upon interaction with a cofactor or complex (42). Such domains may render the protein susceptible to aggregation, however. Indeed, a wide spectrum of human protein conformational disorders may be caused by the aggregation of proteins with intrinsically disordered domains. Many of these harbor glutamine- and asparagine-rich sequences. Initial structure/function work to investigate regions of Sup35 required for prion formation determined that the amino terminal PFD was not only necessary, but also sufficient for prion propagation (43). The prion-conferring activity was transferable to a different protein by simply fusing the PFD to it (43). This appeared to be true for other PFDs as well, such as the Ure2 (44) and Rnq1 PFDs (45).

Chaperones Modulate Prion Formation and Propagation

Yeast allowed the identification of Hsp104 as the first chaperone to alter prion propagation (46). In fact, the activity of Hsp104 is required for most prions to

faithfully propagate and transmit from mother to daughter cells. Hsp104 works in conjunction with Hsp70 and Hsp40 cochaperones, primarily Ssa1/2 and Sis1. Hsp70 and Hsp40 work together to recognize misfolded or aggregated polypeptides and deliver them to Hsp104, which then unfolds substrates by ATP-dependent threading through a central pore in its hexameric structure (47–50). This system is required for the propagation of amyloid-based prions and is thought to generate smaller oligomeric amyloid seeds that not only increase the free ends for efficient propagation, but also more readily transit the mother-bud neck to maintain stable inheritance. The prion variant-specific chaperone activity requirements may stem from the ability of chaperones to recognize specific accessible sequence elements as well as the amount of energy needed to break up the amyloid structure to generate oligomeric seeds. While many of these effects are challenges that alter cellular chaperone balance in a specific, and possibly nonphysiologic, manner, one variant of the [*PSI*$^+$] prion can be cured by transient heat shock (51). In this case, prion propagation is altered by a global cellular reaction to stress that would mimic a naturally occurring chaperone response.

Prion-specific effects of chaperones have been reported as well. While Hsp104 has perhaps the most general effect on different yeast prions (though it does not affect all prions), its relationship to [*PSI*$^+$] is unique in that the overexpression of Hsp104 can cure cells of [*PSI*$^+$]. Most prions affected by Hsp104 are cured by its inhibition or deletion and are not affected by its overexpression. One plausible explanation for this relates to the necessity for activity of Sup35 for viability. *SUP35* cannot be deleted because some Sup35 activity is required for translation termination. This likely limits the array of [*PSI*$^+$] prion variants that can propagate and maintain cell growth. If Sup35 were to form a very efficiently propagating prion structure, cell viability would be compromised. Indeed, some data support this (52, 53). It is possible that the structural array of [*PSI*$^+$] variants and the requirement for a pool of soluble, functional Sup35 results in less flexibility in the amount of Hsp104 activity that can support [*PSI*$^+$] maintenance. There is some specificity in the Hsp70 involvement with Hsp104 in prion maintenance as well. Ssa1 is the Hsp70 required for the propagation of [*PSI*$^+$], while the nearly identical Ssa2 is required for the propagation of [*URE3*]. In addition, the Hsp70 nucleotide exchange factor Sse1 is required for the propagation of [*URE3*] but for only some variants of [*PSI*$^+$] (54, 55). Furthermore, some chaperones selectively impact the propagation of the [*URE3*] prion. The Hsp90/Cpr7 chaperone system is required for the propagation of [*URE3*] (56). Finally, Hsp42 overexpression also cures [*URE3*] in a manner that is dependent on a putative protein transport system that also shows some variant-specific effects on [*URE3*] propagation (57).

Prion-variant-specific effects of the chaperone machinery have also been reported. For instance, it was reported that the PFD of the prion protein Rnq1 is sufficient to propagate some [*RNQ*$^+$] variant structures, but not all. This may be primarily because there is a chaperone binding site in the non-PFD domain of Rnq1, and the binding of that chaperone, the Hsp40 Sis1, is required for the propagation of the [*RNQ*$^+$] prion (39). The reduction in Sis1 binding or activity cures the cells of the [*RNQ*$^+$] prion (58). Sis1 appears to interact tightly with Rnq1, only in the [*RNQ*$^+$] prion state (59), but interacts with every [*RNQ*$^+$] variant tested (31, 60). Moreover, Sis1 interacts with at least two regions of Rnq1 (39, 61). The function of Sis1 in [*RNQ*$^+$] propagation is tied to the activity of the Hsp104 disaggregase. Sis1 is also essential for the propagation of other prions tested, including [*PSI*$^+$] (62), and different variants of [*PSI*$^+$] show different requirements for Sis1 activity to propagate (62). The Hsp104 chaperone was also found to be involved in the propagation of the [Het-s] prion, where the propagation rate and the number of prion particles per cell is reduced in a mutant background for Hsp104 (63). The [Het-s] prion can also be propagated in yeast (64), indicating that the chaperone machinery is able to replicate a totally alien prion. In this setting also, Hsp104 was required for prion propagation.

There is also evidence for the involvement of other cellular machineries distinct from the chaperone network in the maintenance of prions. For instance, overexpression of the Btn2 protein involved in endosomal protein sorting cures [*URE3*] (57), and autophagy protects against [*PSI*$^+$] formation (65). In addition, the actin cytoskeleton and the ubiquitination systems have also been found to modulate prion propagation (reviewed in reference 66).

FUNCTIONS AND TOXICITY

Because the prion concept was initially conceived to explain a baffling pattern of disease transmission, the term has long been associated with pathology. However, in the intervening decades many examples of functional amyloids have been reported in a wide variety of organisms. Although their evolutionary value has been controversial (67, 68), multiple lines of evidence suggest that many fungal prions can exert both positive

and negative phenotypic effects, depending on strain and circumstance.

Functional versus Pathogenic Prions

Proteins with prion-like properties have been discovered in organisms ranging from yeast to mammals (15, 69). Their effects range from being necessary in non-self recognition ([Het-s] in *P. anserina*; see reference 70) to deadly (neurodegenerative diseases caused by PrP in humans, deer, and elk; see references 5 and 71). Computational analyses suggest that PFDs are ubiquitous in fungal proteomes (10, 72). Molecular characterization in *S. cerevisiae* indicates that some of these putative prions do indeed have the capacity to adopt multiple self-templating conformations under normal physiological conditions (10, 73). Their ubiquity, and the observation that fungal prions result in diverse phenotypes, some of which are adaptive (74–76), leads to a fundamental question about the biology of these epigenetic elements: Are prions purely selfish replicating elements, or can they provide some benefit to the organism? This question has been the subject of vigorous debate. Some argue that prions are often adaptive "bet-hedging" elements that can facilitate survival in fluctuating environments. Others have maintained that most fungal prions are simply diseases.

The bet-hedging hypothesis (68, 75, 77–79) is based on observations of phenotypic diversity imparted by prion switching and on the fact that rates of [*PRION*$^+$] acquisition and loss are much higher than the rate of spontaneous mutation. For example, within a [*prion*$^-$] yeast colony, a few [*PSI*$^+$] cells will appear sporadically, expressing heritable new phenotypes. If the [*PSI*$^+$] phenotype is detrimental, only a few individuals will be lost from a genetically identical population. If it is advantageous in a stressful environment, however, those few individuals might ensure survival of that genome when it would otherwise have been lost. [*PSI*$^+$] is also lost sporadically, providing a complementary survival advantage should the environment again change to favor the [*prion*$^-$] state. Thus, switching between the [*prion*$^-$] and the [*PRION*$^+$] states could enhance phenotypic diversity and promote survival of genetic lineages in fluctuating environments where they might otherwise have perished. Indeed, some have argued that repeated cycles of prion gain and loss (and indeed even spontaneous translation errors) may create a situation in which variation in the 3′-untranscribed regions (3′-UTR) of genes subject to [*PSI*$^+$]-mediated read-through have already experienced some selection (80).

Evidence supporting this hypothesis includes (i) the abundance of PFDs in fungal genomes (10, 72) and their common occurrence in regulatory proteins; (ii) prion induction and loss in stressful conditions when phenotypic variation would be most beneficial (81, 82); (iii) the existence of prion variants—akin to genic alleles (26, 30, 83–86); (iv) modular domain architecture (for example, Sup35's PFD does not appreciably affect translation termination but has been retained in fungi for ~500 million years [87]); (v) the recent appreciation that prion-based traits are common in wild yeast populations and that some of these are strongly beneficial (74); (vi) genetic assimilation of traits that are initially dependent on [*PSI*$^+$], which can be rendered independent of the prion via meiotic recombination of the cryptic genetic variation that initially drives them (74, 77)—this provides a means to separate the beneficial phenotype from the costs of the mechanism generating it; and finally (vii) because of their capacity to regulate translational fidelity throughout the transcriptome, the traits produced by [*PSI*$^+$] are genetically complex (75, 77) and would require far longer to achieve by mutation alone (see below).

Others have argued that most fungal prions are selfish elements, diseases, or even artifacts of laboratory cultivation (53, 67, 88) and that the rare beneficial phenotypes they induce are a side effect of infection. This line of thinking posits that the evolutionary retention of prion proteins can be explained because selection has been too weak to remove them (89). Evidence supporting this hypothesis includes (i) the fact that most individual prions are present at low frequencies in natural populations (74, 88); (ii) the occasional generation of lethal [*PSI*$^+$] variants *in vivo* when the prion and translation domains are separated (53); (iii) the observation that population allele frequencies of some prions are similar to those that would be expected for deleterious elements in outcrossing populations (89); (iv) the existence of structural variants for most prions, which could reflect an absence of positive selection because at least one prion, [Het-s], shows no such variation; (v) some PFDs having additional functions that could explain their evolutionary conservation (67); and (vi) prion acquisition leading to a stress response in some genetic backgrounds (90).

These hypotheses are not mutually exclusive, and most fungal prions show some degree of antagonistic pleiotropy. That is, they are beneficial in some environments and detrimental in others. Indeed, prions are clearly not universally beneficial, or they would have been fixed in natural populations of fungi. Standing frequencies of [*PSI*$^+$] and [*MOT3*$^+$] in natural populations of yeast (74) are consistent with a modest (~1%) fitness detriment on average for these elements (89).

These models necessarily make many assumptions about rates of [*PRION*$^+$] gain and loss and the frequency of outcross mating. Alternative values for these parameters, which have been observed in other studies (91), suggest a fitness benefit (69). Further investigation of these questions in the appropriate physiological context will be critical to resolve these questions. Computational modeling has also placed these arguments within a theoretical framework grounded in population genetics (79, 92, 93). These analyses suggest that [*PSI*$^+$]'s potential benefit as a bet-hedging element would not likely be sufficient to explain its evolutionary retention under nonstressed conditions. In contrast, bet-hedging would be sufficient to motivate retention of [*PSI*$^+$] in stressful environments, even with realistic rates of sex. The selective advantage calculated with these models is even stronger for another prion, [*GAR*$^+$] (see below).

Yeast Prions in (Epi)Genetic Diversity and Prions in Biotic Interactions

[*PSI*$^+$] is formed by the translation-termination factor Sup35, which ensures faithful termination by the ribosome at stop codons. The regions downstream of such stop codons (i.e., in the 3′-UTR of genes) are comparatively free to accumulate mutations because they are not under selective pressure to produce a protein (although they often are subject to selection as regulatory sequences). Acquisition of [*PSI*$^+$] causes translational read-through of many stop codons throughout the transcriptome (94) and consequently drives the emergence of new heritable phenotypes. This process is conceptually analogous to duplicated genes that are inactivated by a premature stop codon and are retained as pseudogenes, providing a source for the generation of new functional gene products via mutation and eventual reactivation (95).

This prion-dependent phenotypic diversification is strongly dependent on genetic background. That is, a phenotype elicited by [*PSI*$^+$] in one strain background might not be elicited in another. For example, in *S. cerevisiae* strain 33G the acquisition of [*PSI*$^+$] led to increased resistance to bleomycin and sensitivity to benomyl. In contrast, acquisition of [*PSI*$^+$] led to sensitivity to bleomycin and resistance to benomyl in *S. cerevisiae* strain 5G (75). Genetic dissection established that [*PSI*$^+$]-induced changes in translational fidelity produce new phenotypes based on genetic variation that was previously silent or "cryptic" (75, 77). Most phenotypes produced by [*PSI*$^+$] are driven by multiple polymorphisms. [*PSI*$^+$] thus provides immediate access to traits that otherwise require the serial acquisition of multiple rare mutations. The degree to which this mechanism has contributed to the evolution of biological novelty remains to be established. However, the presence of [*PSI*$^+$] in wild strains of *S. cerevisiae* (74) and its capacity to fuel strong phenotypes in those backgrounds suggest that this prion has exerted an important influence on the phenotypic landscape of natural fungal isolates.

In the 2 decades since [*PSI*$^+$] was recognized as a prion, approximately 10 other fungal prions have been discovered (15). Some, such as [*OCT*$^+$], formed by the Cyc8 transcriptional repressor (96), were found serendipitously. Others, such as [*MOT3*$^+$], formed by the Mot3 transcription factor, were found in a systematic screen to identify proteins with N/Q-rich sequences that resembled three other prion proteins known at the time: Sup35, Rnq1, and Ure2 (10). Investigation of [*MOT3*$^+$] revealed that it governs the acquisition of facultative multicellularity in *S. cerevisiae*, likely through both gains and losses of function (73). This phenotype is driven by [*MOT3*$^+$]-dependent transcription of *FLO11*, a major determinant of cell-cell adhesion, in response to nutrient deprivation. [*MOT3*$^+$] can be regulated by the environment. It is induced in response to ethanol and lost in response to hypoxia, providing some suggestion that it may be engaged in a subpopulation of cells during natural respiro-fermentative cycles (73). These phenotypes (in addition to others produced by the prion [see reference 74]) are highly strain-dependent. Thus, in addition to [*PSI*$^+$], [*MOT3*$^+$] can exert a strong influence on the phenotypic manifestation of natural genetic variation.

For decades, prions that create new traits (e.g., [*PSI*$^+$] and [*MOT*$^+$]) had not been found in wild strains of *S. cerevisiae* (88). Although these studies were limited in scope, they led to the perception that prions could be rare diseases or artifacts of laboratory cultivation. However, an examination of hundreds of wild *S. cerevisiae* isolates revealed that ~1 to 2% harbored [*PSI*$^+$] and ~6% harbored [*MOT3*$^+$] (74). These elements conferred many beneficial phenotypes under diverse selective conditions. Approximately one third of the wild strains examined in this study had heritable phenotypes that required the activity of Hsp104 to be propagated from one generation to the next. Those that were tested could also be transmitted from one strain to another through cytoplasmic mixing without transferring nuclear material. That is, these traits had prion-like patterns of propagation. Although the molecular origin of these traits remains to be identified, these experiments established that a potentially broad array of prion-like elements can influence the phenotypes of wild strains.

Switching between [*prion*$^-$] and [*PRION*$^+$] states is generally thought to be a rare event. For example, although the rates of [*MOT3*$^+$] acquisition are increased in response to ethanol, most cells still do not switch under these conditions (73). The [*GAR*$^+$] prion provides a striking exception to this paradigm. Discovered by chance decades ago in a screen for mutants that reverse glucose repression (97, 98), [*GAR*$^+$] is a protein-based element of inheritance that allows fungi (*S. cerevisiae* and other related yeast species including *Nauvozyma castellii* and *Dekkera bruxellensis*) to circumvent a normal hallmark of their biology: extreme metabolic specialization for glucose fermentation (7, 99, 100).When glucose is present, even in trace quantities, yeast will not metabolize other carbon sources. [*GAR*$^+$] allows cells to circumvent this "glucose repression," and arises at different frequencies in wild fungal isolates. These parameters strongly correlate with the ecological niche from which the strain was derived (100).

Through serendipitous contamination of a selective plate it was discovered that switching to [*GAR*$^+$] can be induced in virtually all *S. cerevisiae* cells when they are cocultured with certain species of bacteria (99). This cross-kingdom communication proceeds through an as yet unidentified small molecule secreted by the inducing bacteria. The results of this communication benefit yeast and bacteria alike. Providing an advantage for the bacteria, [*GAR*$^+$] yeast cells produce less ethanol than [*gar*$^-$] yeast cells. Providing an advantage for the yeast, [*GAR*$^+$] cells can readily metabolize complex carbohydrates and survive better in late-stage fermentations. As expected for a mechanism whose adaptive value originates from the selective pressures of life in biological communities, the ability of bacteria to induce [*GAR*$^+$] and the ability of yeast to respond to bacterial signals have been lost repeatedly during the monoculture inherent to laboratory domestication. These data suggest that [*GAR*$^+$] is a broadly conserved and often adaptive strategy to link environmental and social cues to heritable changes in metabolism.

Prion Domains in Signal Transduction in Filamentous Fungi

In the filamentous fungus *P. anserina*, the prion protein HET-s is involved in a cell death process known as heterokaryon incompatibility (70). Such incompatibility arises when a strain bearing the [Het-s] prion (in its amyloid form) and a strain expressing a different allelic variant of this protein (termed HET-S) come into contact. The [Het-s] prion is common in natural isolates of *P. anserina*, leading to the prevailing view that the prion is adaptive (66, 101). HET-s and HET-S are two-domain proteins with an N-terminal globular domain and a C-terminal prion-forming domain. Interaction with [Het-s] causes HET-S to relocalize from the cytoplasm to the cell periphery (102). Biochemical and structural studies suggest that this interaction drives conformational conversion of a HET-S PFD region into a β-solenoid fold which in turn induces a refolding of the globular HeLo domain (Het-s/LOP-B; see more on structure in the next section) to expose an ~34-residue transmembrane segment at the N-terminus of the protein. This converts HET-S into an integral membrane protein. Once it is at the membrane, HET-S oligomerizes and fuels the loss of membrane integrity in a manner resembling pore-forming toxins (103). The role of this type of conformational conversion in signaling intrinsic programmed cell death is only beginning to be appreciated. The *P. anserina* genome contains a gene encoding a Nod-like receptor protein (NWD2) adjacent to the gene encoding HET-S (104). Strikingly, NWD2 contains an N-terminal region that is homologous to the amyloid motif of HET-s. When NWD2 binds its cognate ligand, this interaction also drives conversion of HET-S into the amyloid conformation (105).

The paradigms established by the study of HET-s appear to be echoed in programmed cell death in other fungi. The short prion motif and globular HeLo domain characteristic of HET-S are also associated with other proteins such as lipases and regulatory Nod-like receptors in other fungi. The functional and evolutionary significance of this relationship has recently been examined in the saprophytic fungus *Chaetomium globosum* (106). A cluster of genes harboring short prion motifs was examined that included a protein known as HELLP (because it contains a HeLo-like domain). HELLP also has an N-terminal transmembrane helix that is homologous to that of HET-S. Despite the evolutionary distance between this organism and *P. anserina*, HELLP behaves as a HET-S analog, relocating to the membrane upon interaction with the prion form of the short prion motif. Moreover, the HeLo-like domain of HELLP bears homology to mammalian pore-forming domains involved in necroptosis, suggesting the possibility of an ancient evolutionary relationship between these processes.

Amyloid/Prion Toxicity in Yeast

The toxicity of prion amyloids in yeast has been the subject of intense debate. Most commonly studied variants of [*PSI*$^+$] have a slight fitness defect. However, overexpression of the NM domain of Sup35 induces [*PSI*$^+$] variants with a wide spectrum of effects. Those that are lethal are normally purged from the population

but can be maintained when the C-terminus of Sup35 (Sup35C, which cannot be converted into [*PSI*$^+$] but is competent for translation termination) is expressed on a plasmid (53). In these experiments ~8% of the induced [*PSI*$^+$] variants were lethal. The remaining variants were either slow-growing or nontoxic. The slow-growing variants were unstable upon loss of the Sup35C plasmid. In contrast, the nontoxic [*PSI*$^+$] variants were stable. Analogous results were seen with [URE3] in these experiments, highlighting the fact that selection has already operated on the ensemble of prion conformers typically studied in the laboratory. The molecular interactions governing prion loss remain to be fully elucidated but involve multiple chaperone activities including Hsp104, Hsp42 Btn2, and Cur1 (57).

In other cases, prion proteins are toxic only when overexpressed, and only in [*PRION*$^+$] cells. For example, Rnq1 is profoundly toxic in [*RNQ*$^+$] but not [*rnq*$^-$] cells (61). This toxicity is not caused by a general proteotoxic stress. Rather, in these cells Rnq1 sequesters the core spindle pole body component Spc42 in an insoluble protein deposit, engaging the Mad2 cell cycle checkpoint. The Hsp40 chaperone Sis1 suppresses this toxicity, but rather than inhibiting aggregation of Rnq1 it drives assembly of the protein. Interfering with this Sis1-triggered aggregation exacerbates Rnq1 toxicity. These data underscore the fact that amyloids are not always the toxic species in prion-like aggregation pathways. Molecular understanding of these distinctions, as well as the structural differences between toxic and nontoxic amyloid species stand as goalposts for future work.

FUNGAL PRION STRUCTURES

Structural characterization of amyloids, which constitute the physical basis of many fungal prions, is a considerable challenge, and one faced by the amyloid field in general. The most adapted technique to gain access to high-resolution structures of amyloid assemblies is currently solid-state nuclear magnetic resonance (NMR) (107). Other approaches include X-ray diffraction techniques that so far can only inform on the overall fold or fold modification. The Eisenberg group has also reported high-resolution X-ray crystallography structures of seven amino acid peptides derived from the Sup35 PFD assembled into nanocrystals (108), but this approach cannot be applied to the full-length PFD so far. One of the central limitations hindering progress in the structural determination of amyloids is structural heterogeneity. It appears that many amyloids, in particular disease-related amyloids but also yeast prion models, exist as mixtures of structural polymorphs displaying subtle or large differences in their amyloid architecture (109).

The [Het-s] prion is currently the only model for which a high-resolution structure is available. Solid-state NMR could be successfully applied here, because HET-s PFD fibrils are not polymorphic and lead to well-resolved solid-state NMR spectra. The HET-s PFD adopts a so-called β-solenoid structure with two rungs of β-strands per monomer. This structure resembles other β-helical structures found in soluble proteins (110). The HET-s PFD comprises two conserved 21-amino acid residue imperfect repeats connected by a poorly conserved 15-amino-acid-long loop (111). Each of these repeats forms one 4.7-Å layer of a stacked β-sheet structure (111, 112). Each repeat comprises four β-strands; the first three β-strands delimit a triangular hydrophobic core, and the fourth protrudes from the core (34, 113) (Fig. 2). At the C-terminal end of the PFD, an aromatic loop folds back into a groove delimited by the third and fourth β-strands to form a semihydrophobic pocket (113). Two asparagine ladders, a frequent motif in amyloids, occur at the beginning of the first and fourth β-strands (N226/N262 and N243/279), and three salt bridges (K229/E265, E234/K270, and R236/E272) stabilize the stacking of the two rungs of β-strands. The inner core is composed exclusively of hydrophobic residues, with the exception of two hydroxyl residues occupying different layers, that can form a hydrogen bond inside the core (T233/S273). Glycine residues occupy the β-arches between the third and the fourth β-strand in both layers. A short C-terminal loop containing two aromatic residues (F286 and W287) folds back onto the fourth β-strand to form a semihydrophobic pocket.

The structure-function relationship in the HET-s PFD was analyzed in detail with site-directed mutagenesis approaches (111, 114, 115). The β-solenoid fold was found to be robust. The majority of the sequence alterations did not affect the global fold or the prion-forming ability. Exceptions are the glycine residues of the β-arches between the third and fourth strand of each rung, whose mutation affects the overall fold and abolishes prion function (114). The different structural elements mentioned above (N-ladders, salt bridges, hydrophobic core, buried polar residues) contribute to various extents to the prion function, β-solenoid fold, and fibril stability and fibril formation rate. Importantly, the C-terminal aromatic loop modulates the prion-forming ability, although this region is not part of the rigid cross-β core of the fold (114). In addition to the solid-state NMR structure, a cryo-electron

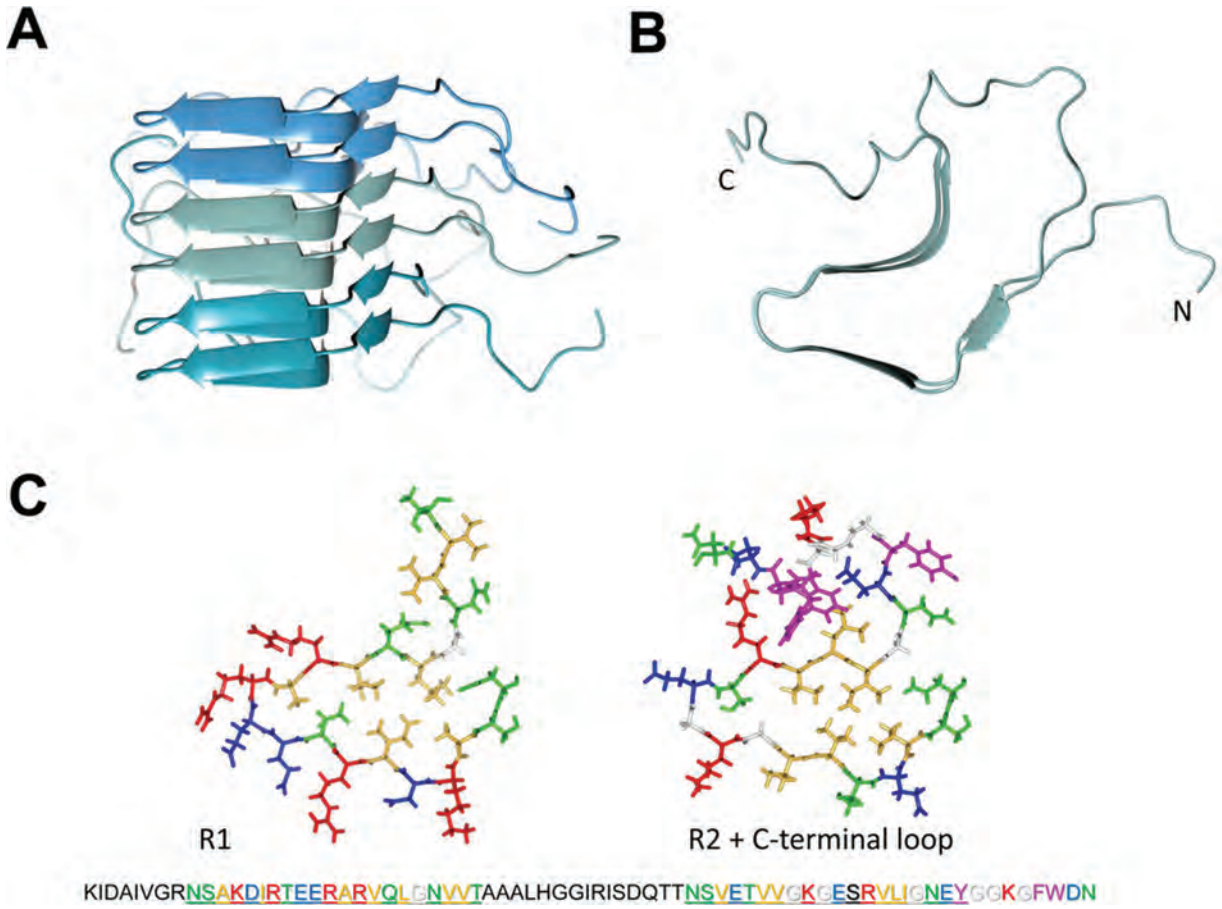

Figure 2 Structure of HET-s prion-forming domain. (**A**) Lateral view of a trimer of HET-s (218–289) in the prion amyloid conformation. Each monomer bears a different color, after pdb 2KJ3. (**B**) View from the fibril axis of one HET-s(218–289) monomer; the N- and C-terminal ends are marked, after pdb 2KJ3. (**C**) Structure of the two individual repeats of HET-s(218–289) marked R1 (position 226 to 246) and R2 (position 262 to 282) as well as the C-terminal semihydrophobic loop (position 283 to 289), after pdb 2KJ3. Amino acids are coded by chemical property (G in light gray, polar in green, hydrophobic in yellow, positively charged in red, negatively charged in blue, and aromatic in magenta). The sequence of HET-s(218–289) is given below with the same color coding in R1, R2 (underlined), and the C-terminal loop.

microscopy structure of the HET-s PFD has also been reported and largely agrees with the solid-state NMR structure (116).

Although no high-resolution structure of a yeast prion is yet available, valuable information on the overall fold of the prion amyloid state of Sup35, Ure2, and Rnq1 was obtained. Several lines of evidence converge to suggest that these yeast prions may adopt an in-register parallel β-sheet structure. Prior to its experimental validation, this organization was already hypothesized based on the experiments mentioned above, showing that shuffled Ure2 and Sup35 PFD sequences (retaining the same amino acid composition) are still able to form prions (41). It was argued that only a parallel in-register β-sheet architecture (and not alternate β-helical or antiparallel or parallel out-of-register models) could explain retention of prion formation with scrambled sequences. Using selectively labeled samples and solid-state NMR, the parallel in-register architecture was supported by dipole-dipole relaxation rates for all three models (101, 117–119). Mass-per-length measurements of prion filaments are also compatible with models in which a single protein molecule occupies one layer of the β-sheet structure (that is, 4.7 Å) (85, 120, 121). Collectively, these results are compatible with the structural model proposed by Kajava and coworkers (122) and can account for strain

variation. They stand in contrast to an alternative β-helical model for Sup35 based on chemical cross-linking approaches (123). The highly degenerate nature of Sup35 fibers complicates interpretation of these data, and a full atomic-level understanding of yeast prion structure will likely require the application of new technologies to the problem.

CONCLUSION

Our understanding of prion biology is built on the rich curiosity of researchers investigating undefined epigenetic phenotypes in fungi beginning over 50 years ago. Their persistence has led to a wealth of knowledge that now impacts our understanding of biological complexity and human health in a multitude of ways. While many incredible discoveries have been made thus far, these systems lend themselves to additional advances relating to epigenetics, the biology of complex phenotypes, prion structure and replication, prion diversity, the effects of intracellular and extracellular modulators, and the impact of protein-based elements on organismal fitness and survival.

Repeat-Induced Point Mutation and Other Genome Defense Mechanisms in Fungi

33

Eugene Gladyshev

DEFENDING THE GENOME AGAINST MOBILE DNA

Mobile DNA, comprising both active and decaying copies of transposable elements (TEs), is present in nearly all living organisms. Although fungal genomes tend to be significantly smaller than the genomes of plants and animals, they still can vary dramatically with respect to their TE loads (1). While TEs have been proposed to provide some beneficial functions to their hosts, e.g., by promoting genetic diversity and accelerating adaptive evolution (2–5), their overall impact is considered deleterious (6). Insertional mutagenesis, gene misexpression, and genome instability represent some well-known examples of the deleterious effects associated with TEs. Importantly, by being able to move between vertical genetic lineages, TEs can still proliferate in a population of sexually reproducing individuals despite causing substantial fitness defects (6).

The ability of TEs to multiply exponentially in the host genome is opposed by the host genome defense systems. Known defense mechanisms differ significantly with respect to their specific modes of TE recognition and suppression, yet all of them face the same basic challenge of being able to recognize TEs among many other potential genomic targets. Specific recognizable features of TEs include (i) frequently aberrant modes of replication and transcription of TEs, (ii) the presence of multiple TE copies in the host genome, and (iii) the occurrence of polymorphic TE insertion sites in the host population. Once detected, TEs can be silenced by a number of molecular approaches. The canonical examples of transcriptional and cotranscriptional silencing include RNA-directed methylation of DNA (cytosines) in plants (7) and of H3K9 in the *Drosophila* germ line (8), as well as various cotranscriptional modalities involving RNA processing and quality control (9–14). TE-encoded RNA can also be restricted posttranscriptionally by RNA interference (RNAi) and RNA editing. In addition to these transcription-related processes, TEs can also be inactivated by the physical elimination of their DNA, as it occurs during chromatin diminution in selected eukaryotic groups including ciliates, foraminifera, and some animals (15, 16).

GENOME DEFENSE MECHANISMS IN FUNGI

In fungi, TEs are opposed by several genome defense mechanisms including repeat-induced point mutation (RIP) and methylation induced premeiotically (MIP), meiotic silencing by unpaired DNA (MSUD), sex-induced silencing (SIS), somatic quelling (cosuppression), and several cotranscriptional RNA surveillance processes (exemplified by spliceosome-coupled and nuclear RNAi [SCANR]).

Cotranscriptional RNA Surveillance Processes: SCANR

TEs are often associated with aberrant transcription, which is recognized by cotranscriptional RNA surveillance and which triggers silencing either by a localized assembly of heterochromatin or by an RNAi response (9–14). Because cotranscriptional RNA surveillance can act on individual TE copies in vegetative cells, it provides the first line of defense and allows the host to

silence TEs that do not normally produce double-stranded RNA (dsRNA) and do not exist as tandem repeat arrays. One such mechanism was recently described in the basidiomycete *Cryptococcus neoformans* by Phillip Dumesic, Hiten Madhani, and colleagues (13), who discovered and characterized the SCANR complex. Their results led to a kinetic model of post-transcriptional silencing, by which the presence of sub-optimal introns in TE-encoded pre-mRNAs promotes inefficient splicing and induces spliceosome stalling, thus providing SCANR with sufficient time to initiate the RNAi (13).

Somatic Quelling (Cosuppression)

The phenomenon of somatic quelling was first described by Nicoletta Romano and Giuseppe Macino in *Neurospora crassa* (17). Generally known as cosuppression in plants and animals, somatic quelling represents a paradigmatic example of an RNAi-mediated posttranscriptional defense mechanism. In somatic quelling, small interfering RNAs are produced specifically from chromosomal loci that contain repetitive DNA (18). In addition to the canonical RNAi factors (the RNA-dependent RNA polymerase QDE-1, the Argonaute protein QDE-2, and Dicer-like proteins DCL-1 and DCL-2), somatic quelling also requires RPA (replication protein A), QDE-3 (RecQ/SGS1 DNA helicase), and the key recombination factors Rad51, Rad52, and Rad54 (19). In light of these and other results, a model was proposed by which single-stranded DNA intermediates formed during aberrant recombinational DNA repair can serve as templates for the production of primary single-stranded "aberrant" RNAs using the DNA-dependent RNA polymerase activity of QDE-1. Single-stranded aberrant RNAs would be converted to dsRNAs by the second, RNA-dependent RNA polymerase activity of QDE-1. In their turn, dsRNAs would then be processed into mature small RNAs (qiRNAs) associated with the Argonaute protein QDE-2 (19).

Interestingly, in *N. crassa*, repetitive transgenes that can potentially produce qiRNAs may also become associated with heterochromatic H3K9me3 and DNA methylation by a poorly understood process that does not involve RNAi (20–23). It is tempting to speculate that both RNAi-dependent and RNAi-independent mechanisms cooperate to silence expression of deleterious repetitive elements in vegetatively growing cells.

Meiotic Silencing

The phenomenon by which "unpairable" chromosomal segments become reversibly silenced in meiosis was first discovered by Robert Metzenberg and colleagues in *N. crassa* (24, 25). Together, their pioneering studies demonstrated that the presence of a gene-sized DNA segment on only one of the two homologous (parental) chromosomes could trigger potent yet transient silencing of all its copies (both pairable and unpairable) in the meiotic cell. This phenomenon was named meiotic silencing by unpaired DNA (MSUD) (25). In *N. crassa*, MSUD acts as a *bona fide* defense mechanism against TEs (26) and meiotic-driven elements called spore killers (27). This silencing process can be triggered by a chromosomal segment of unpairable DNA as short as 1 to 2 kbp, and increasing the segment length to 4 to 5 kbp leads to a much stronger effect (27). In its scope of detected targets, MSUD appears to be complementary to RIP (below). Both processes operate during the sexual cycle, yet while RIP specifically inactivates TEs that exist in a given parental genome as multiple copies, MSUD can detect only one TE copy as long as this copy is present in only one parental genome.

Processes analogous to MSUD were also described in animals (28). The earliest observations of meiotic silencing in mammalian males pertained to the phenomenon of meiotic sex chromosome inactivation, in which the XY bivalent becomes progressively condensed and associated with repressive chromatin modifications during the first meiotic prophase (28). Subsequent studies by several groups showed that meiotic silencing in animals was not restricted to the sex chromosomes (29–32). Because much larger chromosomal regions were required to trigger silencing (as compared with MSUD in *N. crassa*), the animal process was named "meiotic silencing of unsynapsed chromatin." In both animals and fungi, meiotic silencing is activated in prophase I, when pairs of homologous chromosomes become progressively condensed and synapsed (28). Whereas meiotic silencing in animals operates primarily at the transcriptional level and involves changes in the pattern of histone modifications over large chromosomal domains, meiotic silencing in fungi is mediated at the posttranscriptional level by RNAi (27, 33).

How MSUD can recognize unpairable DNA remains a great mystery. Intriguingly, MSUD fails to detect two identical chromosomal segments as unpairable if these segments are present on homologous chromosomes at nonallelic positions separated by a few thousand base pairs (34). This result suggests that as long as two DNA segments with the same or nearly the same nucleotide sequences have an opportunity to interact with one another in the context of the juxtaposed homologous chromosomes, they are likely to be recognized as homologous and thus suppress the MSUD response. Once the distance between such nonallelic segments is

increased, the probability of their interaction decreases, triggering MSUD (34). These important results hint at a possibility that relatively short chromosomal segments behave as spatially constrained yet quasi-autonomous entities (27). In this case, each segment may be evaluated for the presence of a pairable partner independently from its neighboring genomic sequences. The nature of the constraint that limits interactions between homologous segments present at widely separated nonallelic positions is unknown. Yet it has been speculated that it might be imposed by the basic organization of meiotic chromosomes that involves chromatin loops tethered to the chromosomal axis (27). In light of these considerations, MSUD may emerge as a powerful new tool for probing the structure of condensed meiotic chromosomes.

The majority of factors required for MSUD in *N. crassa* (including an RNA-dependent RNA polymerase SAD-1, the Dicer-like protein DCL-1, an Argonaute protein SMS-2, and an RNA helicase SAD-3) are concentrated in the perinuclear space and therefore are physically removed from the presumptive site of homology recognition involving meiotic chromosomes (35, 36). The mechanism by which the presence of a locally unpairable DNA segment in the nucleus triggers the RNAi response in the perinuclear space remains deeply mysterious (27, 33). Recent work by Tom Hammond, Patrick Shiu, and colleagues in *N. crassa* identified SAD-6 as the first conserved nuclear factor involved in MSUD (34). SAD-6 belongs to a SWI/SNF subfamily of chromatin-remodeling proteins that also includes ATRX (34), yet because MSUD still occurs in the absence of SAD-6, this factor could play a redundant or secondary role in meiotic silencing.

Sex-Induced Silencing (SIS)

Joseph Heitman and colleagues discovered SIS in *C. neoformans* (37). In SIS, tandem repeat arrays are detected and silenced by RNAi during the premeiotic stage of the sexual cycle. While the same tandem repeat array can trigger an RNAi response in *C. neoformans* prior to entering the sexual phase, the efficiency of this somatic process appears to be much lower than in SIS (37, 38). Interestingly but not unexpectedly, all the canonical RNAi components required for SIS (RNA-dependent RNA polymerase as well as Dicer and Argonaute proteins) become transcriptionally upregulated specifically during the sexual phase when SIS occurs (37). Once initiated, SIS can be propagated during vegetative growth for many generations in the absence of any apparent repressive epigenetic modifications that are normally associated with heritable silencing in fungi (37), suggesting that RNAi alone can permit stable inheritance of the silenced state.

Intriguingly, SIS in the basidiomycete *C. neoformans* appears to share some basic features with both RIP (below) and somatic quelling (above) in ascomycete fungi. For example, similar to somatic quelling, SIS involves RNAi and is triggered by the presence of tandem repeat arrays. On the other hand, similar to RIP, SIS is strongly activated during the premeiotic phase. In general, the premeiotic phase appears to play a special role in both basidiomycetes and ascomycetes, perhaps by allowing the parental genomes to be thoroughly searched for TEs before these genomes become mixed, recombined, and inherited by the next generation.

RIP Mutation

Soon after transformation techniques were developed in *N. crassa* (39), it was noticed that transgenic repetitive DNA became unstable specifically during the sexual phase in this organism (40). At about the same time, Eric Selker and Judith Stevens reported strong cytosine-to-thymine (C-to-T) mutation and concomitant methylation of nearly all remaining cytosines in a naturally occurring tandem duplication of a 5S RNA gene (41). A peculiar association of strong C5-cytosine methylation with repeated DNA encouraged the idea of a causal relationship, whereby the presence of repeats provided a signal for cytosine methylation and mutation (41). Pioneering work by Selker and colleagues demonstrated that the repetitive nature of DNA indeed provided such a signal in a process named repeat-induced point (RIP) mutation. Subsequent work by Selker and colleagues defined some key properties of RIP in *N. crassa* (42–44). Specifically, it was shown that RIP

- Occurs specifically in haploid parental nuclei that continue to divide by mitosis in preparation for karyogamy and ensuing meiosis
- Detects duplications of chromosomal DNA above a certain length threshold (~0.4 kbp), irrespective of their transcriptional status, origin, and relative as well as absolute positions in the genome (although closely positioned repeats are detected much more readily than widely separated repeats)
- Mutates cytosines on both strands of each DNA duplex in a pairwise fashion (e.g., preferentially affecting none or both repeated sequences)
- Occasionally spreads from duplicated sequences into neighboring nonrepetitive regions
- Remains unaffected in *mei-2* crosses that exhibit a strong defect in meiotic pairing of homologous chromosomes

Since its discovery in *N. crassa* nearly 30 years ago, the existence of RIP has been experimentally confirmed in several ascomycete species including *Magnaporthe oryzae*, *Podospora anserina*, *Leptosphaeria maculans*, and *Fusarium graminearum* (45). Further bioinformatic analysis of the sequenced genomes of filamentous fungi revealed widespread signatures of RIP-like mutation (46–48). Intriguingly, elevated C-to-T mutation of repetitive sequences was also reported in several basidiomycete fungi, suggesting that the evolutionary appearance of RIP had preceded the separation of Ascomycota and Basidiomycota (49). Yet, while being a potentially ancient phenomenon, RIP does not seem to be strongly conserved even between related species. For example, while RIP is particularly strong in *N. crassa*, it cannot be detected at all in its relative *Sordaria macrospora* (50).

Methylation Induced Premeiotically (MIP)

Soon after the discovery of RIP, Christophe Goyon and Godeleine Faugeron (51) provided the first account of a related premeiotic silencing phenomenon that occurred in a distant relative of *N. crassa*, the ascomycete *Ascobolus immersus*. Unlike RIP mutations, the silenced phenotype could be spontaneously reversed during subsequent vegetative growth by the loss of cytosine methylation (51). These and other pioneering observations suggested that in *A. immersus* premeiotic silencing was mediated by cytosine methylation alone and did not involve permanent changes in the DNA sequence. By analogy with RIP, this process was named methylation-induced premeiotically (MIP) (52).

Further work by Jean-Luc Rossignol, Godeleine Faugeron, and colleagues provided strong evidence that both MIP and RIP represent two manifestations of the same basic process (43, 52, 53). Just like RIP, MIP detects gene-sized duplications of chromosomal DNA involving either native or foreign sequences (54). For a duplication of a given length, closely positioned repeats were always detected more efficiently than widely separated repeats. Similarly to RIP (55), MIP also appears to sense repeats in a pairwise fashion: if three repeat copies were present in the same nucleus, normally two or, less frequently, three copies would become inactivated, whereas silencing of only one copy was rarely observed (54). Further analysis of the homology length requirements for MIP showed that MIP could detect closely positioned repeats as short as 317 bp (56) and widely separated repeats as short as 1.2 kbp (57). Very similar length requirements had been reported for RIP (42–44), and in both processes cytosine modifications occurred primarily over the extent of the repeated region.

CYTOSINE METHYLTRANSFERASES Masc1 AND RID AS THE CANONICAL MEDIATORS OF MIP AND RIP

The discovery of Masc1 (methyltransferase from ascobolus 1) by Fabienne Malagnac and colleagues offered the first mechanistic insight into the nature of MIP and, consequently, RIP (58). Masc1 was identified by cloning a short fragment of the *masc1* gene using a degenerate PCR approach. Because Masc1 appeared to play an essential role during the sexual stage in *A. immersus*, its role in MIP could only be examined in heterozygous conditions. In those situations, MIP could still be reduced by more than 2 orders of magnitude, thus showing a strong dependence on Masc1. Interestingly, cytosine methylation was still maintained in postmeiotic cells carrying the silenced copy of *masc1* (58). This finding suggested that another, Masc1-independent mechanism was responsible for propagating cytosine methylation induced by Masc1 in the premeiotic cells. Because Masc1 played an essential role during the sexual cycle and because it specifically affected DNA repeats, it was proposed to regulate timely expression of developmental genes associated with naturally occurring instances of repetitive DNA (58). By this proposal, MIP could fulfill both the genome-defense and regulatory functions.

N. crassa has only one Masc1 homolog, and studies by Michael Freitag, Eric Selker, and colleagues showed that it also played a critical role in RIP (59). Because of its essential role in RIP in *N. crassa*, the protein was named "RIP defective" (RID). Unlike Masc1, the absence of RID does not result in any apparent defect during the sexual cycle because homozygous *rid/* crosses develop normally and still produce large numbers of viable progeny spores (59). This finding suggests that, unlike Masc1 in *A. immersus*, RID may play a more specialized role in *N. crassa*, perhaps restricted only to its genome defense function during RIP. One RID homolog is also present in *S. macrospora*, which does not appear to have active RIP but which still contains a surprisingly low number of TEs, hinting at a possibility that a related RID-dependent genome defense mechanism could be involved (50).

Subsequently, Masc1/RID homologs were identified in nearly all ascomycetes, where they appear to play a conserved role during the sexual stage (60). For example, another RID homolog, DmtA, was recently implicated in regulation of asexual development and secondary metabolism in the ascomycete *Aspergillus flavus* (61). Among all known representatives of this ancient clade of putative cytosine methyltransferases, its founding member

Masc1 still appears to have the most prototypical structure. The predicted amino acid sequence of Masc1 includes a compact catalytic domain of about 300 amino acids and an N-terminal region of about 200 amino acids. *Neurospora* RID, in addition to the catalytic and the N-terminal regions, also includes a long C-terminal extension of 260 amino acids that is also present in the homolog of RID in *S. macrospora* (50). The N-terminal regions of both Masc1/RID can be fully aligned with the corresponding region of the mammalian DNMT1 and contain a weak signature of a bromo-adjacent homology domain (62). Interestingly, Masc1/RID proteins comprise a very ancient group of proteins that emerged long before the separation of animals, plants, and fungi (58, 63), yet these proteins can only be found currently in the subphylum of Pezizomycotina.

Intriguingly, all Masc1/RID proteins appear to have the structure of motif VI that deviates from the structure of motif VI in all other prokaryotic and eukaryotic C5-cytosine methyltransferases (63). The canonical amino acid sequence of motif VI contains the ENV (glutamate-asparagine-valine) triad. The glutamate residue is absolutely essential for catalysis (64) and it is also conserved in the Masc1/RID proteins (Fig. 1). The adjacent asparagine residue (ENV) interacts with the proline residue of the catalytic triad PCQ (in motif IV) and thus plays an important architectural role by controlling the positions of the ENV and PCQ triads with respect to one another (65, 66). The valine residue of ENV also appears to be functionally important, because changing it to alanine in the model prokaryotic methyltransferase M.HhaI inactivates the enzyme (67).

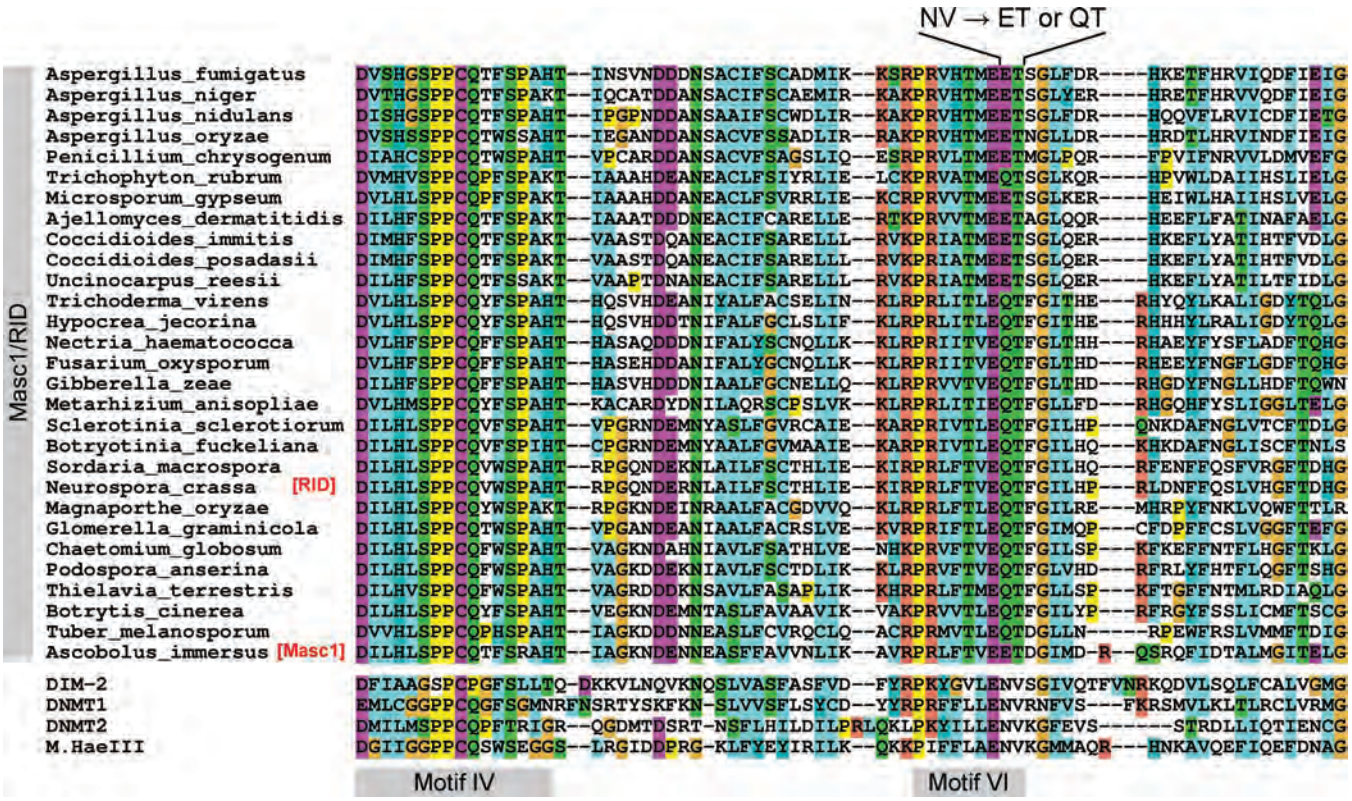

Figure 1 The structure of motif VI in Masc1/RID proteins is not canonical. The canonical motif VI contains the absolutely conserved NV diad (asparagine-valine). This diad is present in all C5-cytosine methyltransferases except Masc1/RID. The asparagine residue of NV physically interacts with the proline residue of the catalytic triad PCQ (in motif IV) and thus plays a critical role by controlling the positions of these segments with respect to one another in the native structure of the protein. The valine residue of NV is also functionally important, because its substitution for alanine is known to inactivate the catalytic activity of M.HhaI. Yet in all Masc1/RID proteins the NV diad is replaced with either QT (e.g., in *Neurospora* RID) or ET (e.g., in *Ascobolus* Masc1), hinting at the possibility that Masc1/RID proteins might have unique catalytic and/or substrate requirements.

Yet in all Masc1/RID proteins, the NV diad is replaced with either QT (e.g., in *Neurospora* RID) or ET (e.g., in *Ascobolus* Masc1), hinting at the possibility that these enzymes might have evolved unique catalytic and/or substrate requirements. Interestingly, the catalytic activity of the purified Masc1 protein could not be detected *in vitro* (58), thus further supporting that idea that Masc1/RID proteins may be different from the other C5-cytosine methyltransferases and/or may require auxiliary factors for catalysis.

UNDERSTANDING THE HOMOLOGY REQUIREMENTS FOR RIP

The apparently pairwise nature of repeat mutation during RIP (55, 68) suggested that the process of repeat recognition might also involve a pairwise comparison of DNA sequences. The discovery that RIP proceeded normally in the absence of SPO11 and MEI-3 (the only RecA homolog in *Neurospora*) excluded the most obvious recombination-mediated pairing mechanism (69, 70), yet it did not provide any new leads toward understanding the nature of the homology search process during RIP.

A Quantitative Measure of RIP Mutation

Additional insights into the mechanism of repeat recognition for RIP were obtained by systematically investigating the homology requirements of this process. As a starting point, a sensitive assay for RIP was developed in *N. crassa*, by which the propensity of engineered repeats to induce RIP mutation could be accurately quantified (69, 70). By this approach, each tested repeat construct was first integrated into a standard chromosomal locus of a standard *Neurospora* strain. It was then exposed to RIP during the sexual phase, while the occurrence of C-to-T (and G-to-A) mutations was revealed by sequencing the entire construct in a sample of randomly selected progeny spore clones (62). This quantitative approach was made possible by some specific features of *Neurospora* reproductive biology, by which individual DNA molecules were subjected to RIP over the course of several days, while the final molecular product of RIP was released from the perithecium as a spore clone that could be recovered by PCR and sequenced. A bioinformatic pipeline was developed to detect and analyze the occurrence of C-to-T and G-to-A mutations along each individual RIP product. By this approach, new aspects of RIP could be revealed by evaluating the dependence of RIP mutation on the configuration and homology relationships of strategically designed repeat units.

The assay also incorporated a number of features that permitted reliable quantitative readout of RIP (62). First, RIP activity was expressed and analyzed as the total number of mutations. Second, RIP activity was maximized by assaying pairs of closely positioned repeats. Third, the analysis was focused on meiotic spores produced relatively late in the cross, because such spores were associated with intrinsically higher levels of RIP. Fourth, noting that RIP mutation could vary substantially between different strains and between spore clones in the same cross, the extraneous variation in RIP activity was minimized by (i) integrating all repeat constructs into the same locus (*csr-1*) of the same strain (FGSC#9720) and (ii) crossing each transformant (as a male parent) to the same female strain (FGSC#4200). This particular pair of strains (FGSC#4200 × FGSC#9720) was chosen because they consistently produced a large number of viable progeny spores, thus providing an adequate statistical population from which individual RIP products could be sampled. In this case, per-spore variability in RIP levels could be addressed by sampling a substantial number of spores from these large populations (62). Finally, the variation in RIP levels between experiments involving different repeat constructs was further reduced by analyzing constructs in which one (and always the same) repeat copy was held constant, while the other repeat copy could be manipulated as desired (with respect both to its length and orientation as well as to its base pair sequence).

Quantifying RIP Response to Perfect Homologies of Varying Length

During RIP, the presence of homologous DNA sequences results in characteristic mutations over these same sequences. To understand the basic relationship between the length of homology and the number of ensuing mutations, the response of RIP to repeats of graded length (ranging from 155 to 802 bp) was measured (69). It was discovered that 155 bp of perfect homology could trigger very low but still detectable levels of RIP. The fact that this homology length was significantly shorter than the previously published threshold (71) suggested that the assay indeed provided a very sensitive readout of RIP activity. Intriguingly, further analysis showed that the mean number of RIP mutations over a region of interest shared between all the constructs was strongly proportional to the fourth power of homology length, specifically for repeats ranging between 220 and 520 bp (69). This finding suggested that the number of mutations could be used as a sensitive and accurate measure of DNA homology in the length range amenable to experimentation.

Recognition of Weak Interspersed Homologies by RIP

Recognition of partially homologous repeats by RIP in *N. crassa* was previously examined by Selker and colleagues (72). In this pioneering work, instances of partial homology were generated by the process RIP mutation itself. It was discovered that new cycles of RIP could be triggered by previously mutated repeats that retained more than 80% of sequence identity (72). This result suggested that the mechanism of repeat recognition for RIP required substantial DNA homology. It was consistent with the idea that DNA homology was sensed in the context of an uninterrupted alignment of single strands, because that is the case for the canonical, recombination-mediated homology recognition.

Intriguingly, recent studies revealed that, despite being very sensitive to the overall amount of homology, RIP could easily "overlook" substantial interruptions in homology if such interruptions occurred in the middle of the repeated sequence (69). This result hinted at a possibility that the mechanism of homology recognition for RIP did not necessarily require a continuous sequence alignment. The next question raised by these results was the following: if RIP could readily detect trivial cases of interrupted homology, what would be the weakest (or the atomic) instance of interrupted homology that could still be recognized by RIP?

The advent of efficient DNA synthesis technologies permitted systematic analysis of the homology requirements for RIP (69). Because RIP was particularly sensitive to the overall amount of homology in the range of 220 to 520 bp (69), synthetic DNA segments of the relevant size could be made rapidly and inexpensively, and thus many such segments could be tested and analyzed for their ability to promote RIP (62, 69). By this approach, it became clear that homology patterns with overall sequence identity much less than 80% could still be detected by RIP. Systematic examination of many such patterns suggested that only specific homology configurations could be recognized. All "active" homology patterns consisted of short homologous units (3 bp or more) that had to be spaced at regular intervals of 11 or 12 bp along the overall extent of homology (69, 70). Figure 2 provides an example of one such pattern, in which homologous units of 4 bp are interspersed with the periodicity of 11 bp along the total length of 500 bp. Importantly, for this process to work, DNA segments had to be coaligned along their length. This result suggested that homology was detected between coaligned and rigid objects. When considered together with the periodicity requirement, these results suggested that these rigid objects could be the double helices of DNA. Thus, a model was proposed by which homologous DNA molecules could become engaged in multiple, interspersed, triplet-mediated, cooperative interactions taking place over the length of several hundred base pairs. Additional results suggested that RIP mutation could be decoupled from the process of homology recognition, suggesting a possibility in which the DNA-modifying activities were recruited to DNA segments after they have been defined as homologous.

THE HETEROCHROMATIN-RELATED PATHWAY OF RIP

The Universal Phenomenon of Heterochromatic Silencing of Repetitive DNA

In the genomes of nearly all eukaryotic organisms, highly repetitive DNA sequences are organized in the form of constitutive heterochromatin, a specialized state of chromatin that remains condensed during interphase and associated with conserved repressive epigenetic modifications, such as di- and trimethylated lysine-9 residues of histone H3 (H3K9me2/3). The apparent mechanistic connection between the repetitive nature of the genetic material and its heterochromatic nature was noted by Guido Pontecorvo in 1944 when he wrote, "a heterochromatic segment should arise every time that a minute euchromatic region undergoes repeated reduplications in the genotype and the replicas remain adjacent to each other on the chromosome" (73).

The idea that the heterochromatic state can be induced by homologous interactions between repeat elements was further advanced by Douglas Dorer and Steven Henikoff in 1944 (74). Working with *Drosophila melanogaster*, the authors generated a series of tandemly repeated *mini-white* transgenes and discovered that the level silencing of these repetitive transgenes was dependent on the number of repeat copies. Based on these and other results, it was suggested that heterochromatin proteins could specifically recognize the higher-order chromatin structures produced by the stable, homology-dependent association of nearby repeat copies (74). By this proposal, and in accord with the original idea of Pontecorvo, heterochromatin could form on repetitive DNA of any particular sequence, simply because of its ability to pair with itself and produce higher-order structures. The authors also noted that such homology-directed pairing could underlie silencing of long tracts of simple trinucleotide repeats (74). Notably, this same idea, by which the expanded trinucleotide

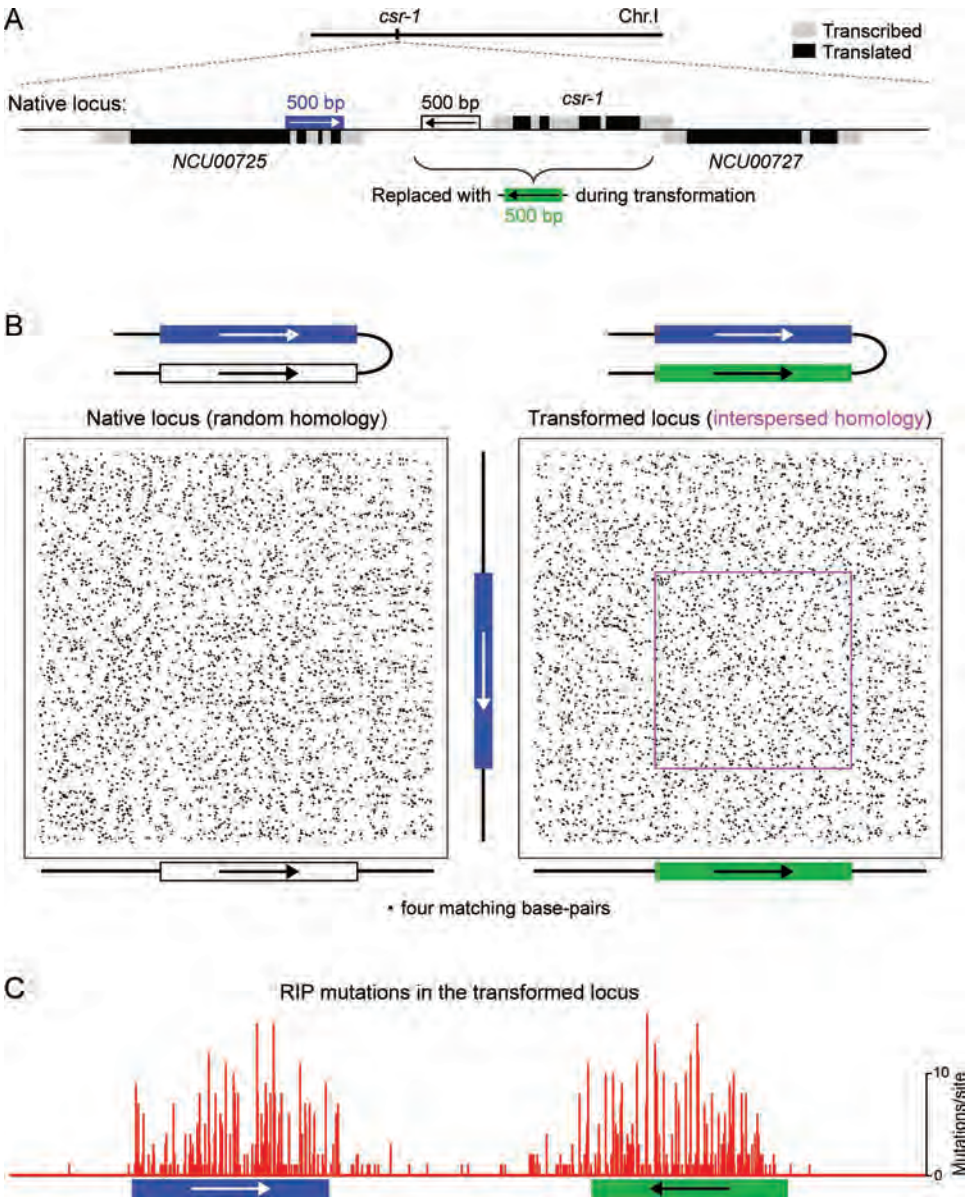

Figure 2 Recognition of interspersed homology during RIP in *N. crassa*. This assay detects and quantifies the occurrence of RIP mutations in response to engineered DNA repeats. Instances of DNA homology are created between two short segments of chromosomal DNA, one of which is normally represented by an endogenous sequence, while the sequence and orientation of the other segment can be manipulated as desired. In this situation, the number of RIP mutations provides a very sensitive readout of DNA homology perceived by the recombination-independent mechanism of repeat recognition for RIP. (**A**) Weak interspersed homology is formed between the endogenous 500-bp segment (blue) and a synthetic DNA segment (green) integrated at a nearby position as the replacement of the *cyclosporin-resistant-1* (*csr-1*) gene. This particular pattern involves 4-bp units of homology spaced with the periodicity of 11 bp and exists between "repeat units" in the inverted orientation. (**B**) Pairwise sequence comparisons showing all matches of 4 bp long. Two situations are presented: random homology (left panel) and interspersed homology (right panel). No cryptic homology can be seen except the intended pattern of weak interspersed homology (magenta box). (**C**) The occurrence of mutations induced by weak interspersed homology. Seventy progeny spores from the "XKO" cross (70), which had been previously found to contain at least one RIP mutation, were reanalyzed by sequencing of an additional 255 bp in the "left" flank of the construct (corresponding to the single-copy coding/translated sequence of *NCU00725*).

arrays could act as two closely positioned repeat copies, was also proposed by Goyon, Rossignol, and colleagues in the context of their studies on MIP (56).

Subsequent studies of *D. melanogaster* by Sarah Elgin and colleagues, using some of the original *mini-white* arrays of Dorer and Henikoff, showed that the heterochromatic state of these repeats was dependent on the presence of functional RNAi (75). Furthermore, around the same time, the key role of RNAi in heterochromatic silencing was also demonstrated in fission yeast (76, 77) and in plants (78), suggesting that the presence of tandem repeats *per se* was not sufficient, at least in some situations, to program the formation of functional heterochromatin.

The Canonical Heterochromatin Pathway in *Neurospora*

In *N. crassa*, the bulk of H3K9me3 and C5-cytosine methylation can be found in the context of AT-rich DNA that was previously mutated by RIP (33). All mechanistic aspects of this pathway were elucidated largely by the work of Selker and colleagues (33). In brief, the canonical pathway starts with RIP generating AT-rich DNA in premeiotic cells, which then provides a signal for the recruitment of heterochromatin factors in vegetative cells (33). The key heterochromatin mark, H3K9me3, is catalyzed by the conserved SUV39 methyltransferase DIM-5 (33). H3K9me3 is recognized by the *Neurospora* HP1, which directly recruits the cytosine methyltransferase DIM-2 to DNA (33). This pathway involves some additional factors (33), and in some situations, it can deviate from its canonical form (79).

Both RIP and repeat-induced heterochromatic silencing may be considered as serving the same purpose of suppressing repetitive DNA. Yet in *Neurospora*, the relationship between RIP (which occurs in premeiotic cells) and heterochromatic silencing (which occurs in vegetative cells) presented a puzzle (43). It was known for a long time that in *N. crassa*, newly introduced highly repetitive transgenes could become associated with H3K9me3 and cytosine methylation in vegetative cells, prior to RIP and in the absence of RNAi (20–23, 80, 81). These results, which were obtained by several independent research groups, supported the idea that the presence of repetitive DNA could induce heterochromatin directly, in accord with the original proposal by Pontecorvo (73) and Dorer and Henikoff (74).

Neurospora RIP Can Be Mediated by the Heterochromatin Pathway

Recently, it was discovered that *Neurospora* RIP could occur in the absence of RID, suggesting that (i) RID was not essential for the process of repeat recognition *per se*, and (ii) RID was not the only mediator of RIP mutation (82). Surprisingly, it was further discovered that all RID-independent RIP required DIM-2 and the catalytic activity of DIM-5 (82). Further investigation revealed that the DIM-5/DIM-2 pathway of RIP (i) was triggered specifically by the presence of repetitive sequences, (ii) could respond to repeats present at closely positioned as well as widely separated genomic positions, and (iii) mutated repeats that had never been previously subjected to RIP. Importantly, the DIM-5/DIM-2-mediated RIP could also be activated by weak interspersed homologies, in which 3-bp or 4-bp units of homology were arrayed with the 11-bp periodicity, supporting the idea that both the RID- and DIM-5/DIM-2-dependent pathways of RIP are triggered by the same homology signal. In every case examined, DIM-5/DIM-2-mediated mutations typically spread from the repetitive elements into the neighboring single-copy regions, whereas RID-mediated mutations are largely restricted to the repeats *per se* (82).

A Putative Two-Step Mechanism of RIP Mutation

The original discovery of RID as a principal mediator of RIP (59) presented a puzzle: while RIP involves C-to-T mutation, RID resembles a canonical C5-cytosine methyltransferase. Although the predicted catalytic site of RID differs from all other C5-cytosine methyltransferases (above), so does the active site of Masc1, which mediates cytosine methylation, without any sign of mutation (58). Thus, it was originally proposed that the modification of cytosines during RIP might occur as a two-step process, in which C5-methylation by RID would be followed by N4-deamination of the C5-methylated cytosine by an unrelated enzymatic activity (59). An alternative proposal was also put forward by which RID alone could mediate C-to-T mutation, via modulation of its catalytic activity (59). This hypothesis was supported by earlier studies (83, 84), which implicated canonical cytosine methyltransferases (such as the prokaryotic site-specific methyltransferase M. HpaII) in catalyzed deamination of cytosines under conditions of extremely low levels of the methyl group donor *S*-adenosylmethionine.

The finding that DIM-2 can mediate RIP provides additional support for the two-step mechanism. In vegetative cells, DIM-2 normally catalyzes cytosine methylation in all dinucleotide contexts (85). Yet DIM-2-dependent RIP exhibits a very strong bias for CpA dinucleotides (82). While it is formally possible that the intrinsic substrate preference of DIM-2 in premeiotic

versus vegetative cells is different, the strong CpA bias of DIM-2-mediated RIP mutation argues in favor of the presence of two separate enzymatic activities for catalyzing cytosine methylation and deamination. By this model, repeat-induced cytosine methylation (by either DIM-2 or RID) would be converted to mutation (5meC → T) by a deaminase activity that is specifically present during the premeiotic (germ line) phase. Interestingly, novel deaminase activities (involved in A → I editing of RNA) were recently identified in *Neurospora* and some other filamentous fungi (86, 87). These activities are only present during the sexual stage, as would be expected from the hypothesized deaminases involved in RIP. Nevertheless, it is important to note that in *Neurospora* vegetative cells, DIM-2 can also methylate coding, nonrepetitive parts of the genome (88). If cytosine methylation of genic regions also takes place in premeiotic cells, then the proposed two-step mechanism would further require the deamination step to be homology-dependent.

Hypothesis: Nucleation of Heterochromatin by Homologous dsDNA/dsDNA Interactions

The newly discovered role of the DIM-5/DIM-2 pathway in RIP suggests that homologous interactions between coaligned double-stranded segments of chromosomal DNA, which were previously proposed to mediate repeat recognition for RIP (69), can provide a specific signal for the recruitment of these heterochromatin factors. It has been known for a long time that in *N. crassa* the same pathway can mediate RNAi-independent heterochromatic silencing of repetitive transgenes in vegetative cells. Taken together, these results suggest that the heterochromatic silencing of transgenes in vegetative cells can also be programmed by interactions between homologous dsDNA molecules. By this general model, the occurrence of homologous dsDNA/dsDNA interactions provides a physical signature of DNA homology.

In *Neurospora* vegetative cells, homology-directed heterochromatic silencing could play a backup role and/or could come into play in situations where repetitive DNA is newly introduced prior to RIP. Intriguingly, the structure and function of DIM-5 are conserved in other fungi, as well as in plants and animals, hinting at the possibility that homology-directed heterochromatic silencing may be a general phenomenon. This homology-directed process can function in combination with other, more canonical silencing mechanisms. In this case, transient H3K9me3 marks, induced by dsDNA/dsDNA interactions, can be amplified and propagated by additional mechanisms involving site-specific DNA binding proteins, such as Zeste (74, 89), or RNA (74). Because the proposed pairwise dsDNA/dsDNA interactions involving nearby repeats can occur in several successive rounds, and because multiple independent interactions may take place over a long repeat array at the same time, this process could be particularly efficient over large repetitive regions, such as those found in (peri)centromeric and (sub)telomeric regions of chromosomes.

CONCLUDING REMARKS

Because of their ability to move between genetic lineages and proliferate exponentially, TEs pose an existential threat to genome stability. The evolutionary race between TEs and the host genome defense systems produced a large repertoire of solutions to the basic problem of keeping the mobile repetitive DNA in check. Most of these solutions are not absolute, and none of them (with the exception of RIP in *N. crassa*) can neutralize all TEs at once. Yet the emergence of especially strong RIP in *N. crassa* has come with a cost, because this organism appears to lack gene duplications, a major source of evolutionary novelty (90).

The genomes of most eukaryotes contain large amounts of TEs and other forms of repetitive DNA that are normally silenced in the form of constitutive heterochromatin. The newly discovered role of the heterochromatic pathway in *Neurospora* RIP suggests that these two phenomena may be evolutionarily related. In this case, RIP may simply represent a specialized heterochromatin-related process that terminates in C-to-T mutation instead of cytosine methylation. Previous studies have indicated that the mechanism of repeat recognition for RIP may involve interactions between coaligned dsDNA molecules. A possibility now emerges that such direct dsDNA/dsDNA interactions may underlie a much more general phenomenon of heterochromatic silencing of repetitive DNA, possibly representing a primordial genome defense mechanism. Further analysis of homology-directed silencing phenomena will likely illuminate the fundamental properties of this mechanism in fungi and, potentially, in other eukaryotic organisms.

Fungal Interactions with Plants: Impact on Agriculture and the Biosphere

VI

The Fungal Kingdom

Plant Pathogenic Fungi

34

Gunther Doehlemann,[1] Bilal Ökmen,[1] Wenjun Zhu,[2] and Amir Sharon[2]

INTRODUCTION

Fungi have developed a plethora of strategies to colonize plants, and these interactions result in a broad spectrum of outcomes ranging from beneficial interactions to death of the host. With respect to plant pathogens, fungi represent probably the most diverse group of ecologically and economically relevant threats. Fungal plant pathogen species are primarily in the phyla Ascomycota and Basidiomycota. Among ascomycetes, plant pathogens are in various classes such as the Dothideomycetes (e.g., *Cladosporium* spp.), Sordariomycetes (e.g., *Magnaporthe* spp.), or the Leotiomycetes (e.g., *Botrytis* spp.). Basidiomycetes are represented by the two largest plant pathogen groups: the rusts (Pucciniomycetes) and the smuts (spread among the subphylum of Ustilaginomycotina).

Fungal infections cause an enormous spectrum of disease symptoms. Traditionally, fungal plant pathogens are divided into two main groups: biotrophic pathogens, which form intimate interactions with plants and can persist in and utilize living tissues (biotrophs), and necrotrophic pathogens, which kill the tissue to extract nutrients (necrotrophs). In addition to these two groups, members of another group, hemibiotrophic pathogens, start as biotrophs and then switch to become necrotrophs. Necrotrophs cause necrosis and eventually even death of infected plants. Symptoms caused by biotrophs in many cases may appear mild. Nevertheless, some of the economically most devastating pathogens belong to this group. Fascinating interactions can be found in highly specified biotrophic interactions, where organ development of the host is massively modulated by the microbe, e.g., leading to formation of pseudo-flowers (rust) or plant tumors (smuts), to promote fungal propagation. In this article, we give an overview of the biology of plant pathogenic fungi with a focus on differentiation of pathogenic structures and the function of virulence factors. The impact of plant pathogenic fungi on agriculture is discussed, and important model organisms are profiled.

IMPACT OF FUNGAL PATHOGENS ON AGRICULTURE

Phytopathogenic fungi have been devastating threats throughout the history of agriculture. In ancient times, plant diseases were blamed on gods, which was a major driving force for the development of religious beliefs. In Greece, Demeter was deified as the god of grain and fertility from about 1300 BC. In the ancient Roman empire from the 5th century BC, Ceres (*crescere* = growing) appeared as Demeter's female pendant. Ancient Roman religion held a spring festival (Robigalia) for the god Robigus, who was the personal manifestation of agricultural disease. Namely, this disease (Robigo) is a form of wheat rust causing red color, which was mythologically linked to the god Mars, a god of both agriculture and bloodshed. To please Robigus and prevent crops from being destroyed by rust disease, the Romans sacrificed red dogs, foxes, and cows—with probably uncertain success.

The first relevant scientific contribution to the knowledge of fungal plant disease can be attributed to Theophrastus (370–288 BC), a student of Aristotle. In his botanical studies, he described the appearance of rust diseases on different host species and in the context of landscape. In retrospect, it appears staggering that for almost 2,000 years there was hardly any scientific progress on the understanding of plant infections, which were continually interpreted as the wrath of God. Besides smut fungi infecting monocot crops such as barley (e.g., *Ustilago hordei*), wheat (e.g., *Ustilago tritici*), or maize (e.g., *Ustilago maydis*), rusts are traditionally serious threats in agriculture. In the 17th cen-

[1]Botanical Institute and Center of Excellence on Plant Sciences (CEPLAS), University of Cologne, BioCenter, D-50674 Cologne, Germany;

tury, wheat stem rust (*Puccinia graminis* f. sp. *tritici*) was found to correlate with the presence of barberry (*Berberis vulgaris*) plants growing near wheat fields. Consequently, these plants were eliminated to control rust infection of wheat. This rather simple cure was successful, since the *P. graminis* sexual life cycle requires barberry as an intermediate host that is infected by monokaryotic basidiospores to form spermatia (1). A fungal plant pathogen with enormous agricultural and cultural influence throughout human history is *Claviceps purpurea*, the causal agent of ergot of rye, barley, oats, and wheat. Ergot sclerotia, which contain a broad spectrum of toxic alkaloids including LSD, replace kernels in the heads of crops and thereby cause contamination of harvested grains and, finally, flour. Numerous epidemics of the resulting human diseases, such as "devil's curse" or "holy fire," have been reported, with many thousands of victims and social and political consequences (1).

Fungal epidemics also have had significant social and economical impact. One historical example is the coffee rust, *Hemileia vastatrix*. Until the 1870s, Ceylon (Sri Lanka) was one of the world's greatest coffee producers. This dramatically changed after *H. vastatrix* reached Ceylon in 1875. From 1870 to 1885, its coffee production dropped about 95%, and the fungus completely destroyed coffee plantations in this region, which today is of course mainly known for its tea. Today, coffee rust is still a significant threat to coffee production, with recent outbreaks in Central and South American growth regions (2).

While in modern agriculture, most fungal pathogens can principally be controlled by modern crop management, massive epidemics with devastating yield losses still occur. Recent examples of this are epidemics caused by the Asian soybean rust (*Phakopsora pachyrhizi*) and wheat blast outbreaks in several Asian countries caused by Brazilian *Magnaporthe oryzae* isolates (3). In the following section, we give an overview of a (noncomprehensive) selection of plant pathogenic fungi that play important roles in agriculture and plant pathology research.

FUNGAL MODEL SYSTEMS IN AGRICULTURE AND RESEARCH

Botrytis and *Sclerotinia* spp.

Botrytis cinerea and *Sclerotinia sclerotiorum* are the best examples of broad-host-range, necrotrophic plant pathogens. They were originally treated as types of *Sclerotinia*, and largely on the authority of De Bary, *B. cinerea* had been considered the conidial form of *Sclerotinia fuckeliana* (4). According to current phylogeny, *B. cinerea* belongs to the genus *Botrytis,* and its sexual form is *Botryotinia whetzel*, family Sclerotiniaceae (5). The genus *Botrytis* consists of 22 species and includes pathogens of monocotyledons and dicotyledonous plant species (6). Except for *B. cinerea*, all other species are considered specialists with a narrow host range, with the exception of *Botrytis fabae*, which can infect species of the genera *Vicia*, *Lens*, *Pisum*, and *Phaseolus* (6). Whereas most *Botrytis* spp. have a narrow host range and the majority of them infect monocotyledonous plants, *B. cinerea* belongs to a distinct phylogenetic clade of broad-host-range species which infect predominantly dicotyledonous plants. Other members of this clade are *Botrytis pelargonii*, *Botrytis fabae*, *Botrytis pseudocinerea*, and *Botrytis calthae* (5, 7). Based on a multiloci analysis, *B. cinerea* morphological species were further divided into two genetic groups, group I (referred to as *Botrytis pseudocinerea*) and group II (*B. cinerea sensu stricto*) (8). Strains in these two groups exhibit differences in their ecology and their resistance pattern to fungicides and are unable to cross with each other, suggesting that they represent phylogenetic species. Recently, a novel group, called *Botrytis* group S, was described (9). This group, which is closely related to but distinct from *B. cinerea* and the more host-specific species *B. fabae*, is widespread in strawberry fields in Germany but mostly absent in other regions. Among the various species of *Botrytis, B. cinerea* strains B05.10 and T-4 have been used in most studies. Both strains belong to group II and can be considered model strains in studies to elucidate *B. cinerea* pathogenicity.

The most familiar disease caused by *B. cinerea* is gray mold. This disease is widespread and results in serious economic damage worldwide. It is most destructive on mature or senescent tissues of dicotyledonous hosts. Usually the fungus gains entry to such tissues at an early stage of crop development and remains quiescent until the environment is conducive and the host physiology changes. Therefore, serious damage is caused in storage following harvest of apparently healthy crops. *B. cinerea* also causes massive losses in field- and greenhouse-grown horticultural crops prior to harvest, primarily in fruits, vegetables, and ornamental flowers.

The most common route of *B. cinerea* infection is by conidia, which penetrate the cuticle with the aid of nonmelanized appressoria. When plants are inoculated with mycelium, a different form of penetration takes place, whereby hyphae growing on the plant surface heavily ramify into short bulbous cell aggregates that

resemble the "infection cushions" or "complex appressoria" of the closely related fungus *S. sclerotiorum*. At the end of the infection cycle, the fungus develops sclerotia within dying host tissues, which represent an important survival mechanism. Mycelium can also survive within infected dead host tissues and inside some seeds to serve as primary inoculum. *B. cinerea* also forms microconidia from phialides abundantly in aging cultures, which function primarily as spermatia. The sexual cycle involves the spermatization of sclerotia, leading to the production of apothecia and asci with eight binucleate ascospores.

Cladosporium fulvum (*Passalora fulva*)

C. fulvum (*P. fulva*) is a nonobligate biotrophic fungal pathogen that is a causal agent of tomato leaf mold (10, 11). Until now the teleomorph stage of *C. fulvum* has never been observed in nature or in laboratory conditions. The infectious cycle starts with germination of conidia on the lower side of the tomato leaf. Subsequently, the runner hypha enters the host leaf only through the open stomata without differentiation of an appressorium and exclusively colonizes in the extracellular space of tomato leaves. At 12 days postinfection *C. fulvum* produces many conidiophores that block the stomata and result in some chlorosis or necrosis on the leaf (11). *C. fulvum* was a serious disease of tomato that caused big losses until the 1960s; however, since the introduction of different *Cf* resistance genes into commercial tomato cultivars, this mold disease has been kept under control very efficiently. Although *C. fulvum* is no longer a threat for tomato production, it is a valuable model for the study of plant-fungus interactions.

C. fulvum belongs to the Dothidiomycete class, which contains more than 6,000 species that can infect all types of crop plants. Therefore, the information obtained from the *C. fulvum*-tomato pathosystem can be used to enlighten our understanding of other plant-microbe interactions. For example, homology-based BLAST search revealed the presence of two functional homologs of chitin-binding proteins of *C. fulvum*, Avr4 and Ecp6, in various phytopathogenic fungal species, including *Mycosphaerella fijiensis* (banana pathogen), *Dothistroma septosporum* (pine tree pathogen), *Zymoseptoria tritici* (wheat pathogen), and *M. oryzae* (rice pathogen) (12–16). Like Avr4 from *C. fulvum*, Avr4 from *M. fijiensis* can also bind chitin and protect the fungus from plant chitinases (14). Furthermore, Avr4 from both *M. fijiensis* and *D. septosporum* is recognized by tomato Cf-4 resistance protein (13, 14), indicating that this *R*-mediated resistance can be used against these two devastating pathogens of banana and pine, respectively. Functional characterization of LysM-containing proteins from *Z. tritici* (Mg3LysM) and *M. oryzae* (Slp1) showed that, like Ecp6 protein from *C. fulvum*, these proteins also have the ability to scavenge chitin fragments and prevent chitin-triggered immunity (12, 15, 16). The wide distribution of LysM proteins in the fungal kingdom indicates that scavenging of chitin fragments is a general strategy that is used by many pathogenic fungi to prevent induction of pathogen-associated molecular pattern (PAMP)-triggered immunity (PTI) or microbe-associated molecular pattern-triggered immunity.

M. oryzae

The hemibiotrophic ascomycete *M. oryzae* is the causal agent of rice blast disease. This disease is one of the most devastating diseases of cultivated rice throughout the world, and the annual yield loss due to rice blast disease can be up to 30% of total rice production (17–19). *M. oryzae* can also infect wheat and other small grains; this seriously threatens global wheat production and food security (20). Because of its economic significance and easy genetic and molecular manipulation, *M. oryzae* has become a model system and is widely used for analyzing plant-microbe interactions (21, 22).

M. oryzae is a typical hemibiotrophic pathogen that derives nutrition from living cells at the early infection stage, transits into the necrotrophic stage to kill host cells for nutrition, and then produces asexual spores at later stages. To colonize and infect the rice leaves successfully, the *M. oryzae* conidia develop melanized appressorium, a special infection structure by which they penetrate through the rice cell wall via enormous turgor pressure (23, 24). Once it has successfully penetrated to the plant cell via the penetration peg, the primary hyphae spread through plant cells and develop into bulbous invasive hyphae that are sealed inside the plant membrane structure (25). Associated with the invasive hyphae, *M. oryzae* also develops a biotrophic interfacial complex structure, which is significant for the accumulation and secretion of effectors to avoid or suppress plant defense responses during the biotrophic phase (26). Subsequently, the primary hyphae of *M. oryzae* invade adjacent cells via plasmodesmata and switch to the necrotrophic stage, forming typical necrotic lesions on the surface of the rice leaves (22, 23). A number of studies have demonstrated that the cAMP signaling pathway is involved in surface recognition and appressorium initiation at the early infection stage and that the Pmk1 MAP kinase (MAPK) pathway regulates appressorium formation, appressorium penetration, and invasive growth after penetration, which

are two other critical infection processes in the infection cycle of *M. oryzae* (27).

For successful infection, *M. oryzae* suppresses the host immune response manifested as an oxidative burst or plant cell death during the biotrophic stage. This suppression is achieved by effectors, which are pathogen molecules that have an impact on the outcome of the interaction with the host; they are discussed extensively in the section "Virulence Tools of Plant Pathogenic Fungi." Other effectors are associated with the necrotrophic stage. A secreted effector protein, Slp1, of *M. oryzae* specifically accumulates at the interface of fungus-rice cells at the early stages of infection and competes with CEBiP (a chitin-binding protein of rice) for chitin oligosaccharides binding through LysM domains, thus interfering with chitin-triggered immunity in the host (16). *M. oryzae* can also secrete various effectors to suppress BAX (Bcl-2-associated X protein)- and/or Nep-1 (Necrosis- and ethylene-inducing peptide-1)-mediated programmed cell death (PCD) (28, 29). The cytoplasmic effector AvrPiz-t of *M. oryzae* can inhibit the activity of rice RING E3 ubiquitin ligase APIP6, thus suppressing the oxidative burst and PTI in rice and contributing to virulence (30). The secretory protein MSP1 can induce autophagy cell death, H_2O_2 production, and defense responses in rice leaves and contributes to pathogenicity of *M. oryzae* on barley leaves (31).

U. maydis

U. maydis belongs to the group of smut fungi, which comprises more than 1,500 species parasitizing a wide range of mono- and dicotyledonous plants. Although of rather moderate economic relevance, *U. maydis* has been developed as the prime model organism for smut fungi and also is one of the best-characterized biotrophic plant pathogens in general (32). Accessibility to reverse genetics, simple axenic growth, and a compact haploid genome with little redundancy make *U. maydis* an excellent tool for molecular fungal genetics (33). Its biphasic life cycle consists of a nonpathogenic, saprophytic phase and an infectious stage, which is initiated upon mating of compatible cells on the plant surface. *U. maydis* infects primordia of all aerial parts of the maize plant and establishes a biotrophic interaction, where the fungus spreads both inter- and intracellularly. Massive proliferation of fungal hyphae coincides with the formation of plant tumors, which represent the most prominent symptoms of the corn smut disease caused by *U. maydis* (34). In recent years, intensive efforts have been invested in the identification and functional characterization of *U. maydis* virulence factors, mainly secreted effector proteins that act in the host tissue to support fungal virulence and reprogram host tissue, promoting tumor formation (35). Details on the functional characterization of *U. maydis* pathogenic development and its virulence factors are presented later in this article.

Z. tritici (*Mycosphaerella graminicola*)

The ascomycete *Z. tritici* (syn. *M. graminicola*; the teleomorph of *Septoria tritici*) is a hemibiotrophic (or necrotrophic) fungal pathogen that is a causal agent of *S. tritici* blotch (STB) of wheat (*Triticum aestivum*) (36–38). Like *C. fulvum*, *Z. tritici* is a dothidiomycete. Both asexual and sexual stages of *Z. tritici* have been reported in all STB-occurring areas (39). *Z. tritici* causes one of the most economically important foliar diseases of wheat and is responsible for up to 30 to 50% of annual yield losses (40). STB disease control is mainly based on fungicide treatment; however, the fungus has developed resistance to multiple fungicides (41, 42) and it is now difficult to control this disease worldwide. Currently, only a few wheat cultivars that have resistance trait(s) to STB are used worldwide to control this disease. Despite its agricultural importance, very few genes are known to be involved in the virulence and pathogenicity of *Z. tritici*. Moreover, most of these known virulence factors belong to global regulators and cell signaling gene families such as MAPK pathways and cyclic nucleotide signaling (43–45).

KEY STEPS OF FUNGAL PATHOGENESIS

Fungal Host Attachment and Penetration

To find their hosts, fungal spores are dispersed by wind, water, or insect vectors. These spores are able to attach to various surfaces including host or nonhost plants. Such attachment prevents spores from being washed away from the host surface before penetration. Secretion of adhesive extracellular matrix from spores is essential for firm adhesion to the host surface. Hamer et al. showed that the attachment of *M. oryzae* spores to various surfaces requires spore-tip mucilage, which is stored in a periplasmic compartment at the conidial apex and is released upon hydration of conidia that results in rupturing of the spore wall (46).

In favorable conditions, the infection cycle of plant pathogenic fungi starts with spore germination and filamentous germ tube formation, which require complete cell reprogramming and specific regulatory networks. Upon spore germination, runner hyphae show polarized cell growth and grow along the host plant surface, which depends on recognition of distinct physical (sur-

face hardness, hydrophobicity) and chemical (cutin monomers, leaf waxes) stimuli (22). How fungi perceive these signals is not clear. A G-protein-coupled receptor, Pth11, and cognate G-α- and G-βγ-subunit proteins are essential for appressorium development on hydrophobic surfaces (19, 47).

Mechanisms of Host Penetration

Many phytopathogenic fungi, such as *M. oryzae*, *Colletotrichum* spp., and *Alternaria* spp., differentiate a dome-shaped appressorium cell to penetrate their hosts by directly breaching the cuticle layer (48, 49). The dome-shaped appressorium cell has a specialized cell wall enriched with chitin and an inner layer lined with melanin. The formation of a melanin layer is essential to *M. oryzae* appressoria, since it allows the generation of high osmotic pressure by the accumulation of glycerol (19, 23, 50). The appressorium tightly attaches to the host surface and applies a turgor-driven mechanical force onto a thin penetration peg that ruptures the cuticle at the base of the appressorium and grows into the underlying plant epidermal cell. Appressorial turgor pressure can be up to 8.0 MPa (50). This physical pressure and some degree of enzymatic degradation of the host cuticle and cell wall enable the peg to penetrate host tissues.

Recent studies, mainly on *M. oryzae*, have provided impressive insights into the regulation of signaling cascades and cellular reorganization during the formation of appressoria and their function to redirect fungal growth and initiate host infection (51). Saunders et al. (248) have reported that initiation of appressorium development in *M. oryzae* is regulated by a DNA replication-dependent checkpoint (Never-in-Mitosis 1). After a fungal spore attaches to the host leaf surface, the germ tube enters into a single round of mitosis, which is required for the cellular differentiation of appressoria (51). In addition, it has been recently shown that actin remodeling is required for appressorium development. *M. oryzae* appressoria invade plants via a septin-dependent mechanism (24). Septins form a hetero-oligomeric ring at the appressorium pore to organize a toroidal F-actin network and link this network to the appressorium membrane. Formation of the septin ring also serves as a diffusion barrier to prevent the diffusion of proteins that are involved in membrane curvature and F-actin polymerization. In this way, septins provide the cortical rigidity and membrane curvature for the extension of the penetration peg during host cuticle breach (24). Moreover, septins mediate assembly of the exocyst complex at the appressorium pore, which is necessary for appressorium repolarization (52).

Other pathogens differentiate a hyphal tip swelling of the infection hypha, which reflects the point of host penetration, but this structure is not separated by a cell wall, and its cell wall is not fortified by melanization. Although these structures are often termed appressoria, it is likely that the activity of lytic enzymes rather than a mechanical force facilitates epidermal penetration from this type of infection structure. Pathogens that form nonmelanized, nonseparated appressorial swellings include *B. cinerea* and *U. maydis* (53–55). A third group of species, including *C. fulvum* and most rust fungi, penetrate their hosts through a natural opening (stomata) of the host plants (11, 56).

Fungi that use stomata for penetration of the host have evolved directional growth patterns on the host leaf surface to locate and recognize stomatal guard cells. Physical contact of runner hyphae with topographical signals of the host leaf surface controls both oriented growth and appressorium formation. This movement of the fungal germ tubes in response to topography of the leaf surface toward the host stomata is called thigmotropism (57). Hoch and colleagues showed that the differentiation signal for *Uromyces appendiculatus* is simply the height of the ridge present on host leaf surface. Upon contact with the stomatal ridge (optimum ridge height is 0.5 m) of the leaf, the germ tube of the rust fungus *U. appendiculatus* undergoes thigmo-differentiation and forms an appressorium directly over the stomata, and the penetration peg enters the host (57). Subsequently, the pegs differentiate into invasive hyphae that rapidly colonize to epidermal and mesophyll tissues.

LIFESTYLES OF PLANT PATHOGENIC FUNGI

Plant pathogenic fungi are collectively those species that derive nutrients from plants and have a negative effect on plants' health. Similar to the situation in the entire kingdom of Fungi, they vary in nutritional requirements; certain types of pathogens completely depend on their host (these are called obligate parasites); others form a close association with the host but may also complete the life cycle of the plant. Such facultative pathogens can prosper in a variety of environments other than the organism(s) in which they cause disease.

The traditional categorization of plant pathogens (necrotrophs, biotrophs, hemibiotrophs) differentiates fungi according to their pathogenic lifestyle and the way they feed on the host. Recent findings suggest that the division is less strict than previously assumed; however, this categorization defines basic denominators

that are common to all organisms in each class and simplifies the discussion of pathogenic lifestyles.

Biotrophs

Pathogens with a biotrophic lifestyle are either obligate or nonobligate. Obligate biotrophs are the causative agents of powdery mildew (Ascomycota) and rust (Basidiomycota) diseases. Downy mildews and white rusts are also obligate parasites; however, these species are Oomycota (protozoa) and will not be discussed here. We will also restrict the discussion to parasites and therefore will not include nonpathogenic biotrophic fungi such as mycorrhizae (58).

The obligate biotrophic pathogens, rusts and powdery mildews, have evolved to match the life cycle of their host plants and depend on their host for completion of their life cycle. Rusts in particular have developed different spore types and developmental patterns, including infection of an alternative host upon senescence of the primary host (59). Rust diseases are caused by filamentous, basidiomycete fungi in the order Pucciniales (60). Eurediniospores (dikaryotic conidia) germinate on a leaf of the primary host plant and develop invading hyphae that grow into the mesophyll space through stomata. The invading hypha differentiates into substomatal vesicles, which produce primary hyphae. Powdery mildew diseases are caused by haploid filamentous ascomycetes in the order Erysiphales. Conidia of these fungi germinate on the leaf surface and penetrate the epidermal cells with the aid of appressoria (61, 62). Following transition from the surface to an internal space, these fungi cross the wall of mesophyll (rusts) or epidermis (powdery mildew) cells and differentiate haustoria, which are unique infection structures that serve as mediators of nutrient acquisition. The haustoria form behind the plant cell wall, but they do not disrupt the cell membrane. Instead, they push and invaginate the cell membrane, establishing a sustainable "cell within cell" complex. This fungus-plant hybrid structure consists of the plant cell cytoplasm and tonoplast, a polysaccharide-rich extra-haustorial matrix, and the haustorial wall and membrane (63). Following establishment within the host cells, the haustoria deploy a range of transporters to drive nutrients from the infected host cells into the haustorium (64–66). At the same time they also secrete effectors that suppress the host defense and keep the invaded cells alive (67–70) (see the section "Virulence Tools of Plant Pathogenic Fungi").

It is assumed that obligate biotrophic species are limited in their ability to utilize common substrates as energy sources, and therefore they fully depend on their host as an energy source, which makes them obligatory parasites (58, 71). Genomic analyses indicate a loss of genes in key metabolic pathways, such as genes in the nitrogen and sulfur assimilation pathways (60, 61, 72, 73). It was also found that the genomes of the powdery mildew *Blumeria graminis* (61), the rusts *P. graminis* and *Melampsora larici-populina* (60), and the nonobligate biotroph *U. maydis* (33) all have reduced numbers of genes encoding hydrolytic carbohydrate active enzymes (74). All these findings support the loss of some biosynthetic activities in obligate biotrophs. It is important to note, however, that there is no clear evidence that the loss of biosynthetic and metabolic capacity is the limiting factor in the ability of obligate biotrophic fungal plant pathogens to grow out of their host (75, 76). Furthermore, although obligate biotrophic species rely on their host plants for completion of their life cycle, all of them can be grown, although for a limited time, in axenic cultures (77, 78), suggesting that they have at least some capacity to extract nutrients and energy from a nonliving environment. An alternative hypothesis is that in obligate biotrophs the regulation of metabolic gene expression is dependent on signals and signal gradients that are only found in host plants. According to this hypothesis, obligatory biotrophs utilize cues from the host to control their metabolic capacity. Evidence that supports this hypothesis is the coordinated regulation of expression of metabolic genes in barley powdery mildew, during both development and pathogenic attack (75), and the expression of important metabolic and uptake functions in rust haustoria (66, 79, 80).

Nonobligate biotrophic plant pathogens are taxonomically more variable than obligate biotrophs and can be found in a wider range of genera. Among them are the smuts (Basidiomycota, *Ustilaginales*) and certain species of *Claviceps* (Ascomycota, *Claviceptacea*). Unlike the obligate species, nonobligate species can survive and live without the host. For example, the ergot disease fungus *C. purpurea* behaves as a true biotroph *in planta*, but it can be easily grown in axenic culture (81). Infection is initiated by wind-borne ascospores that germinate on the pistil surfaces of grass florets at anthesis. Following penetration through stigmatic hairs, the fungus reaches and colonizes the ovarian tissue, grows down toward the base of the ovary, and establishes a specific and persisting host-pathogen interface. A mycelial stroma develops in the ovary and produces masses of conidiospores that are exuded into a sugar-rich fluid derived from phloem sap. About 2 weeks postinfection, sclerotia are formed, which serve as overwintering structures. *C. purpurea* shows no

necrotrophic growth pattern in any phase of infection, and it does not kill host cells in advance of colonization. Although it does not produce classical haustoria, intracellular hyphae, which are completely covered by the host plasma membrane, could have haustorial functions (82). Among smut fungi, the maize pathogen *U. maydis* stands out because of its amenability to molecular genetic manipulation and its small genome size. *U. maydis* enters primordia of all aerial organs of the maize plant, where it locally induces formation of tumors, in which fungal spores develop (32).

Necrotrophs

As opposed to biotrophic pathogens, which feed on living plant tissues, necrotrophic plant pathogens feed on dead tissue. It is important to make a distinction between true necrotrophic pathogens, which attack and kill healthy plants, and secondary necrotrophic-like pathogens, which are saprophytic in nature but may occasionally infect plants that have been previously weakened, e.g., by other pathogens, injury, or abiotic effects. Here we only discuss true necrotrophs.

The basic concept of necrotrophy is defined as the mode of infection in which the pathogen kills the tissue before colonization (83). This definition is somewhat oxymoronic since at least the initial contact of the pathogen is with a living tissue. Indeed, the early stages following the first encounter with the host are most critical; to survive, the pathogen must subvert the plant defense and generate a zone of dead (necrotic) tissue in which it will be protected from the host and on which it can feed. The following stages of necrotrophic diseases are characterized by spreading of necrosis around the initial infection zone, which precedes pathogen progression. This two-phase strategy entails a "survive or die" scenario at the initial stage, in which the pathogens are in direct confrontation with the host defense, and a more quantitative scenario during disease spread. As described, biotrophic interactions also have initial and late stages; however, in this case the early stage does not involve direct conflict with the host defense, but rather a silent "sneaking in" strategy, while all later stages necessitate close contact with the living host and hence a continuous conflict with the host defense. Accordingly, biotrophic pathogens also have a "survive or die" stage at the first encounter with the plant defense, but only after penetration into the tissue, prior or during establishment of the biotrophic interface. Because biotrophic pathogens thrive to keep the tissue alive, the plant defense strategy at this critical stage is a suicidal one in the form of a hypersensitive response (HR), while the pathogen strategy is prevention of this response.

The realization that necrotrophic pathogens must cope with the plant defense during the first encounter and overcome it in order to initiate infection highlights the true nature of this type of pathogen. It is now clear that necrotrophic pathogens use an array of specific molecules (effectors) and mechanisms to cope with and manipulate the host defense during infection, in a manner that is not less sophisticated than biotrophic pathogens. This is in contrast to an earlier paradigm that assumed a more simplistic strategy of massive killing of tissue using a battery of hydrolytic enzymes and toxins (8). Compared to true biotrophic pathogens, true necrotrophic pathogens include a much wider range of species that belong to diverse genera. Although the two-phase paradigm holds true for all of the necrotrophic pathogens, not all necrotrophs are made equal. It is convenient to divide all necrotrophic pathogens to narrow-host-range and broad-host-range species (84). Host specificity of necrotrophic species is conferred through the production of host-specific toxins (HST), which are essential pathogenicity factors on a compatible host. Examples include the HSTs from *Cochliobolus* spp.: HC-toxin from *Cochliobolus carbonum*, T-toxin from *Cochliobolus heterostrophus*, and victorin from *Cochliobolus victoriae* (85). Other examples of HSTs are ToxA toxins, which determine the host range of the wheat tan spot, and blotch diseases caused by *Pyrenophora tritici-repentis* and *Parastagonospora nodorum*, respectively (86). In all cases in which HSTs are involved, they interact with a specific host gene, much in the same way that Avr or effector proteins interact with resistance proteins (R proteins). In fact, HSTs share many characteristics with avirulence gene products: they have a primary virulence function, they are specifically recognized by host resistance counterparts, and they can be recognized by the plant immune system as virulence factors. It therefore seems appropriate to define HSTs as effectors. This is discussed in more detail in reference 249.

Broad-host-range necrotrophs lack HSTs and may attack a wide range of plant species. This group is best represented by *B. cinerea* and the taxonomically closely related *S. sclerotiorum*. Both fungi have considerably broader host ranges than most plant pathogens (200 to 400 plant species), and each causes multimillions of dollars in pre- and postharvest annual crop losses worldwide (87–89). Melanized sclerotia play a central role in the life cycle of both fungi by germinating either vegetatively for local colonization or carpogenically to initiate the sexual cycle, including production of apothecia from which ascospores are released. There are a plethora of additional broad-host-range necrotrophs,

including many species in the genus *Alternaria* and others in different taxa. While simply inherited resistance traits are sufficient for conferring protection against host-specific necrotrophs, the genetic basis of resistance against broad-host-range necrotrophic pathogens is much more complex and typically quantitative (83, 84). This is in contrast to R-gene-mediated resistance or HST-blocking genes, which provide complete resistance. For this reason, it is much harder to control broad-host-range necrotrophic pathogens, which might partially explain their growing economical importance.

Regardless of host range, the basic strategy of all necrotrophic plant pathogens is to convert living tissue into dead material. To achieve this goal, necrotrophs target the host cell death pathways. Studies in recent years show that induced host cell death accompanies all stages of necrotrophic infection, and different types of cell death pathways are targeted. At early stages of infection, necrotrophs produce and secrete necrosis-inducing effectors such as Neps, cerato-platanin, and certain glycosyl hydrolases to induce local necrotic cell death (83, 84, 90–92). At later stages, they probably require different types of effectors, which induce PCD. For example, *S. sclerotiorum* produces oxalic acid, which induces PCD in the host while suppressing autophagy (93, 94). It is important to note that the role of autophagy in pathogenicity is still vague: in some cases it is probably a salvation mechanism that alleviates damage and rescues host cells following PCD, but in other situations it serves as a prodeath mechanism (95). Production of reactive oxygen species (ROS) is another central element that mediates the necrotrophic lifestyle (96). Similar to autophagy, ROS probably have multiple effects, and therefore, although they are considered a defense response, they might also serve as a virulence factor, at least in necrotrophic interactions. For example, active modulation of the host redox status appears to be crucial for *B. cinerea* and *S. sclerotiorum* diseases (8, 91, 94, 97). In fact, *B. cinerea* seems to exploit the plant's oxidative burst and might even contribute to ROS production. Similar results have been obtained for other necrotrophic fungi, e.g., in *Leptosphaeria maculans*, a pathogen of *Brassica napus* (98).

Originally, necrotrophy was interpreted as rather brutal toxin-assisted maceration of the host tissue. Indeed, studies showing the use of hydrolytic enzymes by necrotrophic pathogens go back as far as the beginning of the previous century (4, 99). While current studies show that these enzymes do not work alone, and they might have additional roles other than sheer hydrolysis of plant polymers, it is important to remember that successful necrotrophs rely on massive secretion of such hydrolytic enzymes for maceration and utilization of the plant tissues as a nutritional source. The relatively large number of genes coding for cell-wall-degrading and other hydrolytic enzymes that are present in genomes of necrotrophic fungi support this notion (88, 100). The high redundancy of many of these enzymes, which is unusual in fungi, also supports their essentiality in these species. Finally, transcriptome and secretome analyses show that a large number of these enzymes are produced and secreted at various stages of the infection process (92, 101, 102).

Hemibiotrophs

Intuitively, hemibiotrophic pathogens are those species that combine biotrophic and necrotrophic lifestyles. Most scientists define hemibiotrophs as species that have a variable length of a biotrophic phase before switching to necrotrophy (103–105). This definition entails an initial true biotrophic phase that is mediated by special biotrophic organs. During this phase fungal pathogens also secrete effectors to suppress the plant defense. At the end of the transient biotrophic stage, the fungus undergoes a massive developmental change that mediates the transition from a biotrophic mode to a necrotrophic mode. Two cases best fit this scenario: the rice blast fungus *M. oryzae* and species within the genus *Colletotrichum* (103). Pathogens belonging to these groups answer the classical definition of hemibiotrophy: following penetration into the subepidermal or epidermal cells, they develop specialized hyphae that form close contacts with the host and invaginate the host cell membrane, thereby forming a true (although transient) biotrophic interphase. After a certain period of time that may last from 1 to several days (depending on the species), the fungus switches to a classical necrotrophic mode. This transition includes differentiation of the new type of hyphae, secretion of enzymes and toxins, and delivery of specialized effectors.

Magnaporthe and *Colletotrichum* species are important plant pathogens; they can be cultured and are amenable to genetic manipulations, and they exhibit classical hemibiotrophic behavior. For these reasons, *M. oryzae* and *Colletotrichum* spp. have been used as models for the hemibiotrophic lifestyle. Many other species that belong to a wide range of genera are also considered hemibiotrophic. Among them are important plant pathogens such as *Fusarium* (106, 107), *Verticillium* (108), *Mycosphaerella* (109, 110), and many others. According to a loose definition, all of the species that are not defined as necrotrophs or biotrophs are potentially hemibiotrophs. We believe that this grouping might cause confusion, since most of these

other species do not exhibit a true hemobiotrophic lifestyle. In fact, the common denominator of all of these species is a symptomless stage that varies in length, but in most cases they do not differentiate the typical biotrophic specialized organs and do not form close contact with the host cell, but rather remain in the apoplastic or intracellular sphere. As such, the pathogenic lifestyle of these species includes symptomless, quiescent, latent, or endophytic stages, but they do not meet the criteria of hemibiotrophy as defined above and therefore should not be treated in the same way. For this reason, we limit the discussion of the hemibiotrophic lifestyle to *M. oryzae* and *Colletotrichum* spp. Further, although certain species, including *M. oryzae* and *Colletotricum graminicola*, can cause systemic infections, the main and prevalent mode of *M. oryzae* and *Colletotricum* spp. is foliar and stem infection, and only this mode will be reviewed here.

Hemibiotrophic species seem to have evolved highly successful infection strategies, and they are among the most aggressive plant pathogens. Concerning host range, *M. oryzae* can cause disease in a limited number of grasses; however, it is most well known for the rice blast disease, the most destructive disease of rice (17, 19, 103). *Colletotrichum* spp. cause anthracnose diseases in more than 600 dicot and monocot plant species and include severe pathogens of important crops (48). Examples are *C. graminicola*, which causes anthracnose in maize (111), *Colletotrichum orbiculare*, a pathogen of cucurbits (112), *Colletotrichum acutatum*, a pathogen of strawberries and tomatoes (113), *Colletotrichum lindemuthianum*, which attacks bean plants (105), and *Colletotrichum gloeosporioides*, which can attack a wide range of plant species (114). While some species have a relatively wide host range, others are highly specific and specialize on a single host, and therefore they are defined as *forma speciales* (f. sp.). An example is *C. gloeosporioides* f. sp. *aeschynomene*, which specifically attacks the legume weed *Aeschynomene virginica*. Its high aggressiveness and restricted host range were exploited to develop a bioherbicide product (Collego) from conidia of this fungus (115).

Infection of *M. oryzae* and *Colletotrichum* spp. is typically initiated by conidia. Following sensing of the leaf surface, conidia germinate and form a short germ tube. Interestingly, germination of conidia on a leaf or on surfaces with similar chemophysical properties differs significantly from germination in carbohydrate-rich media. When *C. gloeosporioides* is pregerminated in a rich medium, conidia are unable to infect plants. Hence, pathogenic and nonpathogenic germination styles were identified (116, 117). Studies with *M. oryzae* and *C. gloeosporioides* also have revealed that cellular processes during pathogenic germination are well orchestrated, involving cell cycle and cell architecture as well as PCD (118). Pathogenic germination ends with the formation of a well-developed, dome-shaped appressorium, which has become the hallmark of hemibiotrophic species, in particular *M. oryzae*. A series of groundbreaking studies on appressorium formation in *M. oryzae* has elucidated the structural, mechanistic, and molecular mode of action of appressoria (22, 49, 119, 120). Clearly, the main function of appressorium in these species is bringing the fungus underneath the cuticle without alarming the plant defense. This is achieved by poking an extremely thin hole in the cuticle by physical force, thereby avoiding release of plant-derived elicitors. Once the fungus has successfully moved from the surface of the leaf to the subcuticular space, a transient biotrophic phase begins. Similar to the situation in the other lifestyles, these late infection stages are less uniform and vary in details from one species to another.

In *M. oryzae*, the penetrating peg breaches the wall of the cell underneath the appressorium and immediately differentiates into a thin filamentous primary hypha that grows in the cell lumen and invaginates the host plasma membrane. In this respect, the first biotrophic stages of *M. oryzae* resemble the biotrophic development that is typical of powdery mildews. The primary invasive hyphae differentiate into bulbous invasive hyphae that become sealed in an extra-invasive hyphal membrane compartment and exhibit pseudohyphal growth as they fill the invaded cell (25, 26, 121). At a specific time, the invasive hyphae move to adjacent cells, probably though plasmodesmata, and repeat the same invagination and proliferation steps, while the hyphae in the original cell switch to a necrotrophic behavior and instantly kill the host cell. Clearly, this sequence of events must be closely coordinated with the host defense. Indeed, *M. oryzae* utilizes a range of stage-specific effectors to affect the host, starting at the stage of appressorium formation and continuing for the entire course of the interaction (103, 122, 123). Furthermore, *M. oryzae* uses distinct pathways for secreting cytoplasmic and apoplastic effectors (124). Secretion of apoplastic effectors occurs through the conventional Golgi-mediated secretion pathway. However, cytoplasmic effectors accumulate in the biotrophic interfacial complex.

In *Colletotrichum* spp. there are two main types of biotrophic stages. The first resembles the biotrophic phases of rice blast and powdery mildews, in which the penetration peg breaches the wall of a subcuticular cell

under the appressorium and differentiates a primary hypha, which invaginates the cell membrane, forming a transient biotrophic stage. This type of interaction is best studied in *Colletotrichum higginsianum*, a pathogen of crucifers including *Arabidopsis thaliana* (104). In *C. higginsianum*, biotrophic infection is confined to the initially infected epidermal cell, and development then switches to necrotrophic infection hyphae, which ramify throughout the host cells. The second type of *Colletotrichum* biotrophy resembles the biotrophic phase of rusts, in which primary hyphae first invade the mesophyll and then form intimate contact with mesophyll cells. This mode of development is best exemplified by the maize pathogen *C. graminicola*. Biotrophic invasion of new cells by *C. graminicola* persists at the advancing colony margin. Necrotrophic hyphae develop later in the center of the colony and advance outward, resulting in the overlapping of biotrophic and necrotrophic phases (125, 125). Similar to *M. oryzae*, the genomes of *Colletotrichum* spp. encode a large number of putative effectors. Expression of many of these putative effectors in *C. higginsianum* is highly orchestrated, and they fall into four distinct expression clusters (48). Gene expression studies also show orchestrated expression of many genes of secondary metabolism, at least several of which are suspected to play a role in infection (104, 127). As might be expected, the genomes of these species are also enriched for genes encoding plant cell wall-degrading enzymes (CWDEs), which are expected to be necessary at the necrotrophic phase (104).

Plant Cell Death in Fungal Interactions

In a broad sense, all fungal pathogens might be divided into killers and nonkillers, regardless of the specific lifestyle (128). According to this point of view, the ultimate goal of killer pathogens is conversion of living tissue into dead organic matter, and therefore they are programmed to efficiently kill host cells. Nonkiller pathogens aim to keep their host alive, and therefore they are programmed to prevent host cells from dying. While the details differ from one pathogen to another, this categorization ultimately relies on the general infection strategy: immediate killing or prevention of death of host cells. As a consequence, cell-death-regulating pathways are expected to play a central role in mediating all types of pathogenic fungal-host interactions. For example, it is intuitive to expect that nonkiller pathogens are armed with effectors that suppress PCD, while killer pathogens have molecules that trigger and maintain PCD. This hypothesis is supported by the opposite effects of antiapoptotic genes on infection by killer and nonkiller pathogens. For example, expression of heterologous (e.g., Bcl2, Bcl-xL) or endogenous (BI-1) antiapoptotic genes protects plants against killer pathogens such as *B. cinerea* and *S. sclerotiorum* (129, 130) while increasing susceptibility to powdery mildew (131, 132).

Host Specificity

Another aspect to consider is a possible connection between lifestyle and host specificity. As described above, host range varies considerably, from single-host-specific species to broad-host-range pathogens that are capable of causing different types of diseases either in the same host or on numerous hosts. Obligate biotrophic species seem to have more restricted host specificity than species with hemibiotrophic or necrotrophic lifestyles. Even nonobligate biotrophic species seem to have the capacity to infect a broad range of hosts, as demonstrated by *C. purpurea*, which is capable of infecting more than 400 plant species (81). Moreover, at the genus level even obligate biotrophic pathogens may have a broad host range. For example, powdery mildews cause diseases in over 10,000 plant species, including monocots and dicots, shrubs and trees (133). Hence, species with a broad host range seem to exist in all types of lifestyles. Additionally, as mentioned earlier, some necrotrophic species are highly specialized, as demonstrated by species in the genus *Cochliobolus* (85). Thus, pathogens with a restricted or broad host range exist in the entire array of lifestyles. It is, however, possible that the host range in each class is limited by different types of elements of the plant defense. For example, the take-all fungus *Gaeumannomyces graminis* f. sp. *tritici* is unable to infect oat because it is blocked by avenacine B, a saponin that accumulates in the oat roots (134, 135). However, a closely related species, *G. graminis* f. sp. *avena* can degrade avenacine B and therefore can infect both oat and wheat. In this case, host range is limited by a single defense molecule that confers resistance to the pathogen, while a single fungal enzyme is sufficient to extend the host range to additional plants. In the case of obligate parasites, it is enough for the plant to initiate the HR response for elimination of the pathogen. It is possible that for this reason host range is restricted by recognition factors (resistance/avirulence proteins) that instantly trigger HR, rather than by enzyme- or metabolite-mediated activities.

VIRULENCE TOOLS OF PLANT PATHOGENIC FUNGI

Disease establishment of fungal pathogens on their host plants relies on diverse virulence factors, including effector proteins, secondary metabolites, and even small

RNA molecules. These virulence factors could be involved in host penetration, prevention, or suppression of host defenses and nutrient acquisition. In addition to these factors, virulence of plant pathogenic fungi also requires morphological transitions to establish host colonization and complete their life cycles. On the other side, plants have evolved diverse innate immune systems to defend against pathogen infection. The pattern recognition receptors localized on the plant cell membrane are designed to recognize PAMPs. These microbial signatures (such as flagellin, chitin, and glucan fragments) trigger the basal resistance response called PTI, including oxidative burst, ion fluxes, activation of MAPK signal pathways, synthesis of plant hormone, and callose deposition (35, 136, 137). Many fungal virulence factors aim to inhibit or avoid PTI and dampen basal defenses, but they can also be perceived by plant leucine-rich repeat proteins, which are known as R proteins, triggering an effector-triggered immunity (138–140). The effector-triggered immunity defense is often accompanied by localized plant cell death or HR (138, 141). To infect plant hosts effectively, these pathogens with different lifestyles adopt diverse strategies and/or virulence factors to manipulate the physiology of host plants and thus to interfere with plant immunity systems and promote virulence or compatibility effectively.

Mycotoxins

Under favorable environmental conditions, fungal pathogens can secrete a variety of secondary metabolites, including mycotoxins and secretory proteinaceous toxins, which induce cell death and contribute to the pathogenicity on plant hosts (142). These toxins can be divided into general toxins and HSTs.

General toxins

The best-known non-host-specific sesquiterpene phytotoxin is botrydial, which is produced by the necrotroph *B. cinerea* during plant infection (143). Botrydial induces chlorosis and collapse of French bean tissues (144) and causes necrosis in *A. thaliana* leaves (145). Further studies demonstrated that botrydial can also induce the accumulation of ROS and phenolic compounds, callose deposition, expression of the defense-associated genes *PR1* and *PDF1.2*, which are involved in salicylic acid (SA) and jasmonic acid signal pathways, respectively, and the expression of HR marker *HSR3* in host plants (145). Additionally, deletion of one of the botrydial biosynthetic pathway genes, *bcbot1*, led to reduced virulence only in the T4 strain, indicating that botrydial is a strain-dependent virulence factor (146).

Oxalic acid (OA), another well-known non-host-specific toxin, is considered an important pathogenicity factor in *S. sclerotiorum*. This pathogen secretes copious amounts of OA to rapidly kill host plants, chelate Ca^{2+}, and reduce pH for activation of CWDEs during infection to facilitate pathogenicity (147). Consequently, OA-deficient mutants were found to be nonpathogenic (148). However, several studies indicated that OA has more significant roles than only functioning as a direct killer, because it can suppress host oxidative burst (149) and trigger ROS-mediated apoptotic-like PCD (94). Recent studies also indicate that OA can reduce the plant's redox environment conditions ahead of advancing hyphae (93, 97), suppressing autophagy and callose deposition during an early infection stage, but once infection is established, promoting host PCD at a later infection stage (93).

Sphinganine mycotoxin fumonisin B1 produced by several *Fusarium* spp. can induce plant cell death, accumulation of camalexin and ROS, callose deposition, and expression of defense genes in *A. thaliana* (150, 151). Fumonisin B1 also contributes to fungal pathogenicity and is necessary for development of disease symptoms on susceptible maize seedlings (152, 153). Some *Fusarium* spp., such as *Fusarium graminearum*, can produce multiple trichothecene mycotoxins, including deoxynivalenol (DON), acetyldeoxynivalenol (3-ADON or 15-ADON), nivalenol (NIV) and acetylnivalenol (4-ANIV), and polyketide zearalenone, in infected plant tissues (154, 155). DON can inhibit protein synthesis in eukaryotic organisms and also acts as a significant virulence factor during infection (156–159). Other toxins, such as fusicoccin from *Fusicoccum amygdali* and AAL toxin from *Alternaria alternata*, can induce both expression of pathogenesis-related genes and cell death in host plants (160).

HSTs

HST proteins are produced by a small number of host-specific necrotrophs. These proteins can function as effectors by interacting with their host targets and utilizing plant resistance signaling pathways to trigger HR and/or PCD for facilitating infection (86, 161). To date, multiple interactions between HST effectors of necrotrophic fungal pathogens and their host target proteins have been reported. Victorin produced by *C. victoriae* can interact with its targets TRX-h5 as well as LOV1 of *A. thaliana*, mimicking the roles of conventional effectors of biotrophic and hemibiotrophic pathogens to activate an HR-like response for promoting disease (162, 163). The *Sorghum bicolor Pc* locus determines the sensitivity to PC toxin protein of the

pathogen *Periconia circinata* (164). This inverse gene-for-gene method also exists in the wheat pathosystem *P. nodorum*. To date, nine pairs of secreted necrotrophic effector-host sensitivity gene interactions have been identified in this system: SnToxA-Tsn1 (165), SnTox1-Snn1 (166), SnTox2-Snn2 (167), SnTox3-Snn3-B1 (168, 169), SnTox3-Snn3-D1 (170), SnTox4-Snn4 (171), SnTox5-Snn5 (172), SnTox6-Snn6 (173), and SnTox7-Snn7 (174). These are discussed in some detail in reference 249.

CWDEs

A diverse range of CWDEs, including xyloglucanases, polygalacturonases, glucanases, cellulases, and pectinases, are secreted by fungal pathogens. These enzymes are necessary for degradation of the main structural polysaccharide of plant cell walls, primarily cellulose, hemicellulose, and pectin (175–178). To study the direct contributions of CWDEs to the virulence of fungal pathogens during infection, genes encoding CWDEs have been disrupted and the effect on virulence has been evaluated in the mutants. Mutation in *B. cinerea* xylanase gene *Xyn11A* resulted in reduced ability of the mutants to infect grape berries and tomato leaves (179). In *C. gloeosporioides*, deletion of the pectate lyase gene *PelB* resulted in weak virulence on avocado fruit (180), while deletion of another pectate lyase gene, *CcpelA*, in *Colletotrichum coccodes* led to a substantial loss of virulence on green tomato fruit (181). Two cellulases from *M. oryzae*, belonging to glycosyl hydrolase families 6 and 7, were proved by RNA interference to contribute to penetration of the fungus into wheat leaf epidermis and for further invasion (182). Deletion of either endopolygalacturonase gene *Bcpg1* or *Bcpg2* in *B. cinerea* resulted in obvious reduction in virulence on bean and tomato leaves (183, 184).

Previously, it was generally accepted that the effect of CWDEs on pathogens' virulence was dependent on its enzymatic activity, and the lack of a clear pathogenicity phenotype in many CWDE mutants was attributed to redundancy. However, several recent studies have shown that at least some CWDEs may also act as virulence factors, either dependent or independent of their enzyme degradation activity. Several studies demonstrated that multiple CWDEs are detected as PAMPs by plant innate immune systems to induce responses (185, 186). For example, several endopolygalacturonases from *B. cinerea* can be recognized as PAMPs by the *A. thaliana* receptor-like protein RLP42 to promote immune responses (187), and one of these endopolygalacturonases, BcPG1, can induce defense responses independently of its enzymatic activity (188). The *B. cinerea* glucan 1,4-alpha-glucosidase BcGs1 can elicit systemic resistance against *B. cinerea*, *Pseudomonas syringae* pv. tomato DC3000, and tobacco mosaic virus (189). After Xyn11A was found to be necessary for virulence of *B. cinerea* (179), further studies showed that the enzymatic activity did not contribute to virulence, which was only affected by the necrosis-inducing activity of the peptide (190). The cutinase ScCut from *S. sclerotiorum* causes HR-like PCD in host plants and functions as an elicitor to trigger multiple defense responses in plants (191).

Effectors

Biotrophic effectors

Biotrophs depend on secreted effectors at several levels. Primarily, effectors are required during penetration to inhibit plant defense responses and/or to keep the host alive because of the lifestyle of biotrophic pathogens. Functional studies of several effectors have been conducted in the maize smut *U. maydis*. The effector Pep1 was first identified to be required for epidermal penetration (192). Later it was found that Pep1 can suppress the activity of the maize peroxidase POX12, which is involved in ROS generation (193, 194). The secreted effector Pit2 from *U. maydis* can inhibit the activity of maize cysteine proteases which can induce plant defenses of SA signal pathways (195), and mutation of *Pit2* in *U. maydis* causes severely attenuated tumors and virulence (196). The plant hormone SA is involved in a defense response against pathogens, especially biotrophic pathogens (197, 198). The chorismate mutase Cmu1, which is secreted into plant cells' cytoplasm by *U. maydis*, can reduce the levels of SA precursor chorismate, thus interfering with the synthesis of SA and promoting infection (199). The *U. maydis* effector See1 can interfere with the MAPK-triggered phosphorylation of maize SGT1, thus inhibiting its activity and resulting in modulation of reactivation of DNA synthesis in leaf cells, which is crucial for tumor progression (200). The *U. maydis* effector Tin2 interacts with and stabilizes maize kinase ZmTTK1, thus targeting the pathway of the maize secondary metabolite anthocyanin and promoting infection (201, 202).

In the *C. fulvum*-tomato pathosystem, for almost all identified effectors there is a corresponding tomato *Cf-R* trait (203). The presence of many cloned and functionally characterized avirulence genes and their corresponding *Cf* genes of tomato, and the emergence of many races overcoming newly introduced *Cf* genes, has made the *C. fulvum*-tomato interaction a good model system. Eleven effectors have been identified in *C. fulvum*, including Avr2, Avr4, Avr5, Avr9, Ecp1,

Ecp2, Ecp4, Ecp5, and Ecp6 (203, 204). However, only three of them have been functionally characterized. Avr4 is a chitin-binding protein that shields the fungal cell wall and protects the fungus against the deleterious effect of plant chitinases (14). The LysM domain containing effector Ecp6 is another chitin binding protein that sequesters chitin fragments released from fungal cell walls to prevent the elicitation of chitin-induced plant defenses (12). Avr2 is a cysteine protease inhibitor that binds to and inhibits the function of tomato Rcr3 cysteine protease activity (205). During coevolution, different pathogens that share the same host can independently develop different types of effectors that interact with the same host target important for plant immunity. For example, Avr2 of *C. fulvum* (fungi) (205, 206), EPIC1, and EPIC2B of *Phytophthora infestans* (an oomycete that causes late blight in potato and tomato) (207) and Gr-VAP1 of *Globodera rostochiensis* (yellow potato cyst nematode that can infect tomato) (208) can interact and inhibit tomato cysteine protease, $Rcr3^{pim}$.

The effector candidate CSEP0055 from the biotrophic pathogen *B. graminis* f. sp. *hordei* can interact with plant pathogenesis-related proteins PR1 and PR17, leading to inhibition of plant immunity (209). Silencing of *CSEP0055* by host-induced gene silence technology resulted in decreased frequency of fungal penetration sites (209). Silencing of RNase-like effectors BEC1011 and BEC1054 in *B. graminis* f. sp. *hordei* indicated their involvement in virulence, and complementation experiments showed that both of them may function inside the plant cell and that BEC1011 may be involved in interfering with pathogen-induced host cell death (210). The putative effector BEC4 from *B. graminis* f. sp. *hordei* can interact with ADP ribosylation factor-GTPase-activating protein and may interfere with defense-associated host vesicle trafficking (211). The yeast two-hybrid assay indicated that candidate secreted effector proteins CSEP0105 and CSEP0162 from *B. graminis* f. sp. *hordei* can interact with small heat shock proteins Hsp16.9 and Hsp17.5 of barley. Silencing of either of them resulted in decreased rates of haustorial formation. CSEP0105 contributes to fungal virulence by compromising the chaperone activity of barley Hsp16.9, which is involved in defense and stress responses against pathogen infection (212).

Hemibiotrophic effectors

Hemibiotrophic fungi require effectors to suppress the plant's immune system during their biotrophic stage, while a different set of effectors is needed to kill plant cells at the necrotrophic stage.

Prominent examples of effector interactions during the biotrophic phase in hemibiotrophs (but also in true biotrophs) include recognition of cell wall fragments. The LysM domain-containing pattern recognition receptor protein CEBiP in rice can recognize and bind the chitin oligosaccharides released from the cell walls of fungal pathogens directly, thus promoting chitin-triggered immune responses in rice cells (213, 214). The secretory effector protein Slp1 of *M. oryzae* also contains LysM domains, and it specifically accumulates at the interface of fungus and rice cells at the early stages of infection. Slp1 can compete with CEBiP for chitin oligosaccharides binding through the LysM domains, thus interfering with chitin-triggered immunity in the host. Consequently, virulence of *M. oryzae slp1* gene deletion strain Δ*slp1* was decreased compared to wild type (16). The cytoplasmic effector AvrPiz-t of *M. oryzae* contributes to virulence in rice plants that carry the R protein Piz-t. AvrPiz-t interacts with the rice RING E3 ubiquitin ligase APIP6 and inhibits its activity, thus suppressing oxidative burst and PTI in rice, which promotes virulence of *M. oryzae* (30).

The *M. oryzae* avirulence protein ACE1 contains a polyketide synthase and a nonribosomal peptide synthetase domain. ACE1 is exclusively upregulated in appressoria during the penetration stage (215–217). The unknown secondary metabolite synthesized by Ace1 is recognized by the R protein Pi33 in rice, which causes resistance. Mutations in the polyketide synthase domain of Ace1 led to the abolishment of Pi33-mediated avirulence activation (217). The predicted metalloprotease protein Avr-Pita from *M. oryzae* could elicit R protein Pi-ta-dependent resistance response in rice cells, but it did not contribute to virulence (218). The virulence-associated effector MC69 is involved in development of invasive hyphae after appressorium formation in rice leaf sheath, indicating its important roles in interaction with host plants. In addition, deletion of the MC69 orthologous gene in *C. orbiculare* also reduced the pathogenicity on both cucumber and tobacco leaves (219).The Pwl effectors Pwl1 and Pwl4 in *M. oryzae* can also act as Avr proteins that confer species-specific avirulence on weeping lovegrass (220, 221). An effector from *M. oryzae* that contributes to the necrotrophic phase is the snodprot1 homolog, MSP1, a member of the cerato-platanin family. MSP1 is secreted and contributes to the pathogenicity of *M. oryzae* on barley leaves. Application of recombinant MSP1 produced in *Escherichia coli* induces autophagy cell death, H_2O_2 production, and defense responses in rice leaves (31). Recently, a number of novel effectors were uncovered by genomic and transcriptomic analysis in the most

aggressive *M. oryzae* strain, 98-06. Five of the tested proteins can inhibit BAX-mediated apoptosis-like PCD in *Nicotiana benthamiana* leaves. The isolate-specific effector candidates Iug6 and Iug9 play significant roles in fungal propagation and pathogenicity, and overexpression of them suppresses the expression of defense-related genes in rice, suggesting their roles in the inhibition of host SA and ethylene signal pathways (28).

The tomato pathogen *Fusarium oxysporum* f. sp. *lycopersici*, which primarily grows in xylem vessels, secretes SIX (secreted-in-xylem proteins) effector proteins into the xylem to promote infection. To date, 14 SIX effector proteins (Six1-14) have been identified using mass spectrometry in *F. oxysporum* f. sp. *lycopersici*-infected tomato (222, 223). Several studies demonstrated that SIX1 (Avr3), SIX3 (Avr2), and SIX6 are required for pathogenicity on susceptible tomato lines (224–226). All three proteins also function as Avr proteins that trigger activation of resistance in the presence of the resistance genes; SIX4 (Avr1), Avr2, and Avr3 can trigger HR in plants harboring the R proteins I-1, I-2, and I-3, respectively (226). Additionally, Avr1 inhibits I-2- and I-3-mediated resistance (227), and recently, SIX6 was suggested to be involved in suppression of Avr2/I-2-mediated cell death when coexpressed in *N. benthamiana* (226, 228). Recently, a study showed that Avr2 interacts with SIX5, and the AVR2-SIX5 pair is required to activate I-2-mediated resistance in tomato (229).

Hemibiotrophic pathogens from *Colletotrichum* spp. can devastate many crop plants worldwide. To date, a number of genomic and transcriptomic studies in *Colletotrichum* spp. fungi have been conducted, and many candidate effectors were revealed during the interaction with host plants (48, 104, 127, 230, 231). The expression of the *CgDN3* gene encodes a secreted protein from *C. gloeosporioides* that was induced at the early infection stage, and the *CgDN3* deletion transformant failed to infect and reproduce on intact host leaves. Furthermore, CgDN3 was also involved in averting the hypersensitive-like response in host *Stylosanthes guianensis* (232). A necrosis-inducing secreted protein 1 (NIS1), which induces cell death in *N. benthamiana* leaves, was identified by functional screening of *C. orbiculare* cDNA, and the NIS1-induced cell death was suppressed by CgDN3 (233). The gene *CtNUDIX*, which encodes a nudix hydrolase domain containing effector from *C. truncatum*, is exclusively expressed during the late biotrophic stage, and CtNUDIX can elicit HR-like cell death in tobacco leaves. However, overexpression of *CtNUDIX* in *C. truncatum* and *M. oryzae* resulted in an HR-like response in infected plants and caused incompatibility with the host plants, indicating that *C. truncatum* utilizes CtNUDIX to elicit cell death to signal the transition from biotrophy to the necrotrophy phase (234). The host's nuclear targeted effector CgEP1 from the maize anthracnose pathogen *C. graminicola* is synthesized at the early stages of infection and contributes to disease development in maize. CgEP1 can bind to the promoter regions of several genes, thus transcriptionally regulating their expression to affect host immunity (235). Another effector of *C. graminicola* Cgfl (fungalysin metalloprotease), which specifically expressed at the biotrophic stage of infection, was identified with a role in virulence on maize leaves and roots. The maize leaves exhibited increased chitinase activity in the absence of Cgfl in the *in vitro* chitinase activity assays (236).

Necrotrophic effectors

Since necrotrophs extract nutrition from dead plant tissue, their virulence factors mainly aim to induce host necrosis to facilitate infection. The cerato-platanin BcSpl1 secreted by *B. cinerea* elicits the hypersensitive response in several host plants, and deletion of this gene results in reduced virulence in a variety of host plants, indicating that BcSpl1 is required for virulence (237, 238). Furthermore, BcSpl1 also induces systemic acquired resistance in tobacco to *P. syringae* and *B. cinerea* (239). *B. cinerea* could also manipulate the antagonistic effects between different immune pathways by utilizing exopolysaccharide β-(1,3)(1,6)-D-glucan to activate the SA signal pathway in tomato, thus inhibiting the jasmonic acid signaling pathway through NPR-1 and resulting in enhanced host susceptibility to *B. cinerea* (230). *B. cinerea* can also deliver virulent small RNA effectors into host plant cells to bind to *Arabidopsis* Argonaute 1 (AGO1), hijack the plant's RNA interference machinery, and selectively silence host immunity genes, thus suppressing host immunity and facilitating infection (241).

S. sclerotiorum secretes an integrin-like protein, SSITL, which functions as an effector to directly or indirectly suppress jasmonic/ethylene signal pathway-mediated immune responses in host plants at the early stages of infection. Silencing of *SSITL* caused a significant reduction in virulence and other phenotypic defects (242). Ss-Caf1 is another *S. sclerotiorum* small secretory protein with a putative Ca^{2+}-binding motif. Ss-Caf1 functions as a pathogenicity factor to trigger host cell death during the early stages of *S. sclerotiorum* infection and plays a significant role in the formation of infection cushion and sclerotial development (243). Another *S. scletoriorum* protein, SsCm1,

has high structural and functional similarity to the *U. maydis* effector Cmu1. One could speculate that this putative effector might serve a similar function as Cmu1 in *U. maydis* (199). A small secreted virulence-related protein, SsSSVP1 from *S. sclerotiorum*, induces plant cell death, and targeted silencing of SsSSVP1 causes decreased virulence. In addition, SsSSVP1 can interact with and hijack the activity of QCR8 (cytochrome b-c_1 complex subunit 8) by changing its subcellular localization from mitochondria to cytoplasm, hence disabling its biological functions. This causes abnormal plant phenotype and cell death (244). A new proteinaceous elicitor, sclerotinia culture filtrate elicitor 1 (SCFE1) from *S. sclerotiorum*, has been partially purified and induces typical PAMP-triggered immune responses through the RLP30/SOBIR1/BAK1-dependent signaling pathway in *A. thaliana* (245). A cysteine-rich secretory protein, SsCVNH from *S. sclerotiorum*, is essential for the virulence and sclerotial development, suggesting its diverse roles in host-nonspecific necrotrophic fungi (246). Two genes encoding necrosis and ethylene-inducing peptides, SsNep1 and SsNep2, have been cloned from *S. sclerotiorum*. Transient expression of them in tobacco leaves induces necrosis, and SsNep2 is involved in virulence (247).

CONCLUSIONS

As outlined in this article, fungi are a highly diverse group of plant pathogens with an enormous impact on agriculture. Fungi have a broad spectrum of lifestyles and high genetic flexibility, which allows pathogens to quickly invade new hosts, as well as to develop resistance to fungicide treatments or to break R-gene-mediated plant resistance. Therefore, fighting fungal diseases will remain a major challenge in plant pathology for the future. To develop new strategies to control plant pathogenic fungi, we need to increase our knowledge of fungal virulence mechanisms, of how pathogenic traits evolve, of the molecular basis of host adaptation, and in particular, of how crop resistance can be engineered in a more sustainable way.

Besides these applied aspects, plant pathogenic fungi are fascinating organisms that have developed a plethora of strategies to colonize a living plant. Studying the molecular mechanisms underlying these complex interactions will not only teach us about microbial virulence, but is also an excellent strategy to study cellular processes in plants. In particular, effector proteins are great molecular tools to study plant pathways, because they represent perfectly adapted probes to target specific cellular processes in the host. Beyond effector proteins, there is still little known about the functions of micro RNAs in fungal-plant interactions. Similarly, secondary metabolites are clearly an understudied field when it comes to biotrophic interactions. Finally, in past years, fungal-plant interactions were mostly studied in one-to-one situations, but this is very artificial because plants are always colonized by a complex microbiome in which multiple microbes influence each other and affect the plants in multiple ways. It is getting more and more evident that multitrophic interactions shape the outcome of pathogen infections. Therefore, future research on fungal plant pathogens will need to consider the effect of microbial communities on pathogen development and plant health.

The Mutualistic Interaction between Plants and Arbuscular Mycorrhizal Fungi

35

Luisa Lanfranco, Paola Bonfante, and Andrea Genre

AN OVERVIEW OF MYCORRHIZAL INTERACTIONS

Mycorrhizal fungi are a heterogeneous group of diverse taxa associated with the roots of over 90% of all plant species, from liverworts to angiosperms. Although they can spend part of their life cycle in the rhizosphere, mycorrhizal fungi always associate with the roots of plants, including forest trees, wild grasses, and many crops, and colonize environments such as alpine and boreal zones, tropical forests, grasslands, and croplands. Both partners benefit from the relationship: mycorrhizal fungi improve the fitness of their host plants by influencing mineral nutrition and water absorption and by increasing tolerance to biotic and abiotic stresses. The host plant rewards the fungal symbiont with carbon compounds derived from the photosynthetic process (1).

Irrespective of their taxonomic position, mycorrhizal fungi develop an extensive hyphal network in the soil, the aptly named wood-wide web, which can connect whole plant communities and potentially grant the horizontal transfer of nutrients. Such an underground web has caused a paradigm shift in our knowledge of plant ecology by introducing the key role of below-ground microbes and opening the discussion on how they influence the composition and fitness of plant communities (2).

The term "mycorrhiza" is derived from the Greek words for "fungus" and "root": a beautiful linguistic rendering of such biological synergies. This does not in any way imply that mycorrhizal fungi only colonize roots; in fact, so-called basal plants lacking true roots also rely on mycorrhizal fungi for their nutrition and host the symbionts in other organs, such as the liverwort thallus. This feature is an evolutionary reminder of the first known mycorrhizal interactions: 450-million-year-old fossils of some of the first land plants display characteristic symbiotic fungal structures in their simple, prostrate shoots. In short, the evolution of mycorrhizal symbioses predates the appearance of roots, even if mycorrhizal fungi are currently restricted to roots in the vast majority of extant plants.

Mycorrhizal fungi can be divided into two major groups: aseptate endophytes such as Glomeromycota and septate Asco- and Basidiomycota. Usually, the classification of mycorrhizal interactions is based on plant anatomical traits and identifies two broad categories (Fig. 1): ectomycorrhizae, in which the fungus is restricted to the intercellular spaces of outer root tissues, and endomycorrhizae, in which fungi penetrate the living host cells (3). In ectomycorrhizae, which colonize trees and shrubs, hyphae remain extracellular, inducing important changes to root morphogenesis, while their presence leads to subtle modifications in epidermal or cortical cells. In endomycorrhizae, i.e., ericoid, orchid, and arbuscular mycorrhizae (AM), hyphae penetrate the root cells to establish an intracellular symbiosis. While AM are common to diverse plant taxa, ericoid and orchid mycorrhizae are restricted to the order *Ericales* and the family *Orchidaceae*, respectively. Such taxonomic and morphological diversity has stimulated the study of the colonization process in numerous host plants since the start of the 19th century. Indeed, new information generated by genomic sequencing, the use of mutants affected in their symbiotic capabilities, and live cell imaging has significantly changed our view of the colonization process (4).

Department of Life Sciences and Systems Biology, University of Torino, Torino, 10125, Italy.

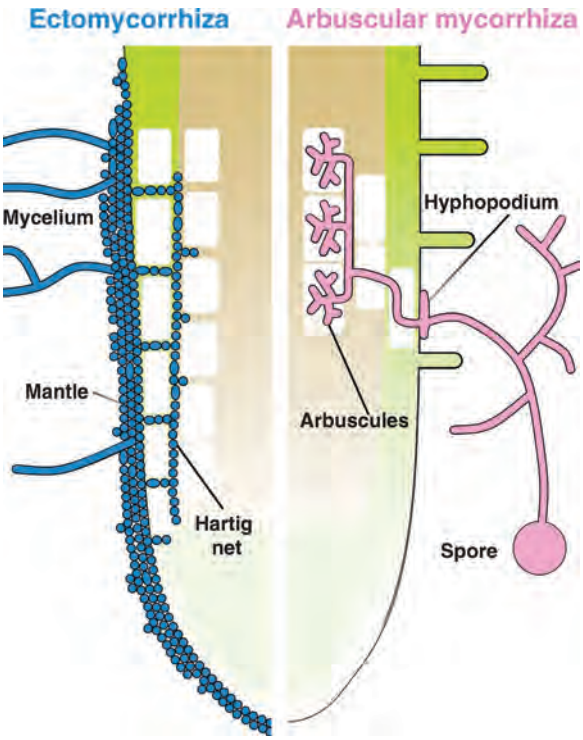

Figure 1 Root colonization in ectomycorrhizal (blue) and arbuscular mycorrhizal (pink) interactions. Ectomycorrhizal fungi envelop root tips with a thick mycelial mantle. From this mantle, intercellular hyphae generate the so-called Hartig net around epidermal cells. In the case of arbuscular mycorrhizae, the root tip is usually not colonized; hyphae developed from a germinated spore produce a hyphopodium on the root epidermis. Intraradical colonization proceeds both inter- and intracellularly, culminating with the development of highly branched arbuscules inside inner cortical cells. Reprinted from *Nature Communications* (3) with permission of the publisher.

The AM symbiosis is the most widespread plant-fungus mutualistic association. AM fungi are found in association with all plant phyla, including agriculturally relevant species, and play a crucial ecological role in the functioning of low-input environments. All AM fungi belong to the Glomeromycota phylum and are very specialized symbionts, as revealed by their obligate biotrophy. Currently there is broad interest in AM fungi because of their potential to support a reduction in the use of chemical fertilizers and pesticides and to positively impact sustainable crop production systems to feed a globally growing human population (5, 6). For these reasons this article will focus on the AM symbiosis, providing an overview of the current knowledge of the molecular mechanisms controlling this ancient and deeply intimate plant-fungus association.

ARBUSCULAR MYCORRHIZAE

AM fungi form a mutualistic symbiosis with the roots of ~80% of plant species in natural and agricultural systems and are considered a central component of the plant microbiota.

AM fungi have the unusual ability to grow in two extremely different niches: the soil and the lumen of plant cells. In soil, the extensive hyphal network has been estimated to reach a density of 100 m/cm^3 (7). This hyphal network can acquire water and nutrients with great efficiency and reach a volume of soil that is inaccessible to roots alone (8). The presence and activity of AM fungal mycelia also directly influence the physico-chemical properties of soil (9). Inside their host plant, AM fungi penetrate single cells of the root cortex, where they develop a structure that is the distinctive feature of this association: the arbuscule (Fig. 2). Named from the Latin word for bush or small tree, each arbuscule results from repeated branching of a single hypha in the lumen of a parenchymatic cell from the inner root cortex (10). With their impressive surface-volume ratio, arbuscules are considered the major site of nutrient exchange (11).

As obligate biotrophs, AM fungi strictly depend on their plant hosts for both growth and reproduction (3, 12). Up to 20% of the photosynthesis products of terrestrial plants is consumed by AM fungi (13). Interestingly, the carbon flow from the plant to the fungus seems to be proportional to the amount of phosphate that the fungus returns to its host (14). Consequently, while the beneficial effects of AM fungi become evident when the nutrient and water supplies are limited, root colonization decreases in soils with abundant nutrients.

The AM interaction also supports important ecological services such as an increase of soil quality (15) and of biodiversity of the associated plant communities (16). Additionally, many studies have highlighted the positive influence of the AM symbiosis on plant responses to biotic (17, 18) and abiotic stresses such as drought, salinity, and heavy metal contaminants (6, 19, 20).

Classification and Phylogeny of AM Fungi

AM fungi have existed and coevolved with plants for at least 450 million years (21) as shown by fossils (22). Due to their importance in nutrient transfer, they are supposed to have played a crucial role during land colonization by plants. The widespread occurrence of AM fungi in plants from most parts of the world, particularly in the tropics, was acknowledged in the 19th century (23, 24). In 1844 the Tulasne brothers described the first AM fungal species, *Glomus microcarpum* and *Glomus macrocarpum* (25). In 2001 Schüßler and col-

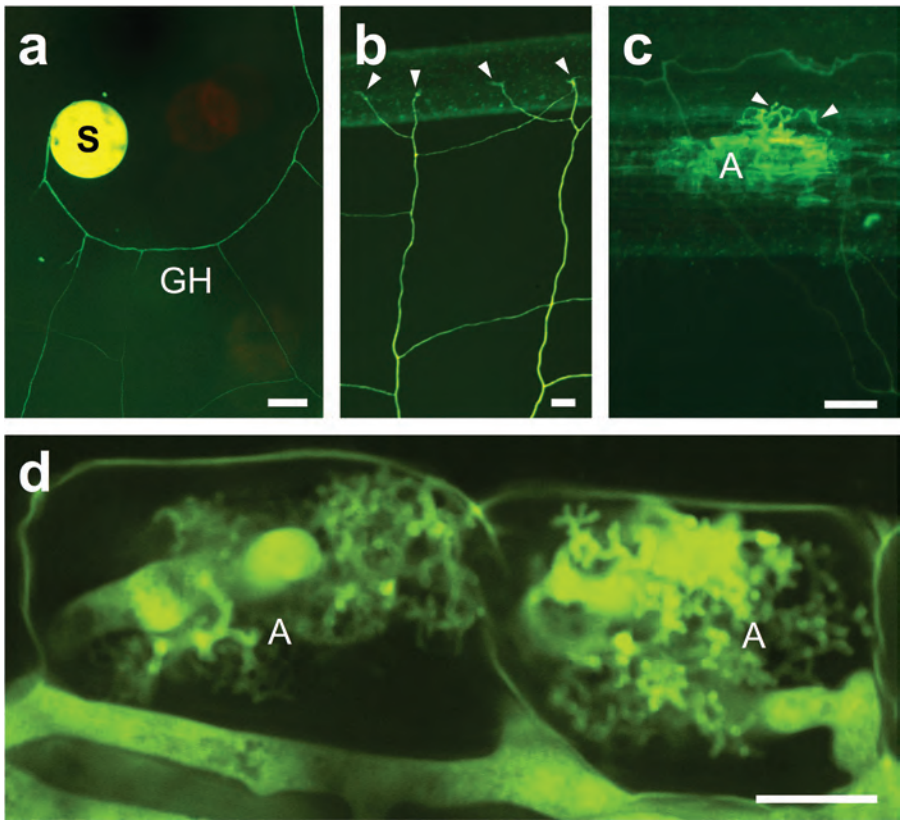

Figure 2 Fluorescence micrographs of different stages in the life cycle of the AM fungus *Gigaspora gigantea*. (**a**) A spore (S) and the germination hyphae (GH) show strong cytoplasmic autofluorescence. (**b**) Hyphopodia (arrows) on the surface of a host root give rise to single infection units (**c**) with several arbuscules (A) in the inner root cortex. (**d**) A high magnification from a root longitudinal section showing two arbuscules in adjacent cortical cells. Bars = 100 μm (a–c), 25 μm (d); fungal fluorescence was excited with 380–405 nm UV light.

leagues grouped AM fungi within a new monophyletic phylum, the Glomeromycota, distinct from the Zygomycota, where they had previously been placed (26).

The phylum Glomeromycota is currently represented by about 250 described species (4), although molecular analyses suggest a broader diversity (27). A recent survey of the global distribution of these plant symbionts showed that AM fungal communities reflected local environmental conditions and the spatial distance between sites. However, despite AM fungi apparently possessing limited dispersal ability, 93% of taxa were found on multiple continents and 34% on all of the six surveyed continents (28).

Before the advent of molecular techniques, the identification of AM fungi was based on the microscopic examination of spores. These are roundish, from about 30 to 400 μm in diameter and with features with taxonomic value such as color, dimension, cell wall structure, presence of septa, and connection to sustaining hypha. However, morphological similarities do not always reflect phylogenetic relationships. The development of PCR-based approaches and advances in molecular analyses led to novel identification rules (26, 29). Since then, the taxonomy of Glomeromycota has been subjected to several changes, and it is still largely open to discussion. On the basis of rRNA gene phylogeny Glomeromycota were described as a sister group of Ascomycota and Basidiomycota (26, 29). However, phylogenetic reconstructions based on mitochondrial (30–32) or protein-coding nuclear (33) sequences suggest a closer relationship with Mortierellales or Mucorales (Mucoromycotina). Recently, on the basis of the complete genome sequence of *Rhizophagus irregularis* (34, 35), Glomeromycota were again phylogenetically placed closer to Mucoromycotina (see later in this article). Indeed, Mucoromycotina, a basal group of fungi characterized by a coenocytic mycelium, is now considered a sister group of Glomeromycota (36). Interestingly,

Mucoromycotina form functional mycorrhiza-like associations with basal plant lineages (37), suggesting that the symbiotic options available to the first plants emerging onto dry land were more varied than previously thought (38). It now appears likely that the last common ancestor of both fungal groups thrived in primeval soils long before plants colonized the land (36).

Biological Features, Genome Organization, and Genetics of AM Fungi

AM fungi are also intriguing from a cellular and genetic point of view. They display many unusual biological features in addition to their obligate biotrophism: spores and coenocytic hyphae contain thousands of nuclei in a common cytoplasm, and no uninucleate life stage is known to occur. This makes classical genetic approaches challenging (12, 36). Depending on the species, a single spore contains from 800 to about 35,000 nuclei (39). Single spores are populated by flows of unrelated nuclei streaming from the mycelium, rather than by the replication of one or a few nuclei within the developing spore (40).

The concept of species is poorly defined in this group of organisms, since they show a high degree of genetic variability. For example, the intrasporal variability of the internal transcribed spacer ribosomal region can range between 6% for *Gigaspora margarita* (41), 18% for *Glomus intraradices* (42), and over 20% in other *Glomus* "*intraradices*-like" strains (43).

In spite of being among the oldest living terrestrial organisms, AM fungi surprisingly appear to have lost sexual reproduction, because no sexual cycle has ever been described.

The genetic organization of coexisting nuclei in the Glomeromycota (i.e., coenocytic organisms) has been a major source of debate for the past 15 years, with two opposite hypotheses being supported within the research community: heterokaryosis (44) and homokaryosis (45), which support, respectively, the presence or the absence of internuclear genetic divergence (46). Furthermore, the possibility that AM fungi contain a uniform population of nuclei characterized by intranuclear polymorphism has also been proposed (47). Heterokaryosis may originate by hyphal anastomosis between genetically different mycelia or by the accumulation of mutations. Hyphal anastomosis and the exchange of nuclei have indeed been observed in a few fungal taxa (48, 49); nevertheless, such events have only been observed between distinct isolates of the same species from one sampling area (50), but not between isolates from different geographical areas (51). These opposing hypotheses have been reconciled by recent analyses of complete genome sequences of AM fungi (see next paragraph).

A further increase in the genetic complexity of AM fungi is evidenced by the presence of endobacteria and viruses. Many AM fungi harbor endobacteria in their hyphae and spores; two types of endobacteria are known in Glomeromycota: rod-shaped Gram-negative endobacteria, limited in distribution to members of the *Gigasporaceae* family, and coccoid Mollicutes-related endobacteria, distributed across different lineages of AM fungi (52). The genomes of a few endobacteria have been sequenced: all are characterized by a limited size (0.5 to 1.8 Mb), which is consistent with complete dependence on their fungal host and their inability to grow in pure culture (53–55). So far, the biological role has only been investigated for "*Candidatus* Glomeribacter gigasporarum," the rod-shaped bacterium hosted by *G. margarita*. The endobacterium enhances fungal sporulation, bioenergetic capacity, ATP production, and ability to detoxify reactive oxygen species. Endobacteria also appear to enhance fungal responsiveness to strigolactones (SLs), root-exudated signals that act as hyphal branching factors for AM fungi. Overall, this endosymbiosis improves the fungal ecological fitness by priming mitochondrial metabolic pathways and giving the AM fungi more tools to face environmental stresses (56, 57).

Our knowledge of mycoviruses of AM fungi is still very limited (58, 59). In one case a biological function has been reported: the presence of the virus led to the production of more spores and increased stimulation of plant growth (58). Altogether, these studies underline the importance of these additional genetic components of AM fungi, because such components can contribute to the symbiosis.

The First Genome Project Dedicated to an AM Fungus

Extensive efforts were made to sequence the first genome of an AM fungus. Two independent research groups (34, 35) published the genome sequences of the same *R. irregularis* isolate DAOM197198 (60). By sampling the extraradical hyphae of mycorrhizal hairy root cultures, Tisserant and colleagues obtained an assembly of 101 Mb out of an estimated genome size of 153 Mb (34). This assembly, although highly fragmented, is believed to include almost all the protein-coding genes (23,561 high-confidence gene models) and places the genome of *R. irregularis* among the largest fungal genomes sequenced to date, along with those of obligate biotrophic powdery mildews (61) and the ectomycorrhizal symbiont *Tuber melanosporum* (62).

To specifically address the issue of the heterokaryotic nature and to determine the extent to which nuclei differ from each other, Lin and colleagues performed a *de novo* genome sequencing of individual nuclei collected from crushed spores (35). Their comparative analysis revealed a surprisingly low level of polymorphism: >99.97% of the aligned genome sequences were identical in different nuclei. The genome organization of this strain is therefore considered basically homokaryotic. By contrast, within a single nucleus, the 45S rDNA repeat unit—in particular, the internal transcribed spacer region—turned out to be highly diverged, and the relative abundance of alleles appeared to differ between nuclei. Genome annotation resulted in 27,392 protein-coding gene models representing 30,003 putative transcripts with a high level of putative/predicted (retro-)transposable elements (35), findings consistent with those of Tisserant et al. (34).

The gene repertoire of *R. irregularis* mostly overlaps with the repertoire of sequenced Mucoromycotina species (34, 35), and phylogenomic analyses demonstrated that Glomeromycota are more closely related to Mucoromycotina than to their postulated sister Dikarya (35).

The obligate biotrophy of AM fungi is not mirrored by any drastic loss of metabolic complexity in central metabolism. One striking genomic feature is the lack of genes encoding plant cell wall-degrading enzymes; the same situation has been observed in obligate biotrophic pathogens (61) and ectomycorrhizal symbionts (62).

More recently, the *in silico* genome analysis of five *R. irregularis* isolates (63) has highlighted substantial genetic diversity among isolates. Two isolates contained a stable population of two dominant divergent haploid nuclei (a unique dikaryon-like condition), while the other three isolates only displayed one dominant genotype (63). *R. irregularis* therefore appears to develop both homokaryotic and heretokaryotic mycelia, even if the modes by which this differential genomic pattern arises remain unclear. In addition, the identification of a putative mating type locus suggests the existence of cryptic sex-related processes (34, 63). Besides reconciling the previous contrasting results, such novel data indicate that conventional modes of reproduction—including mating—may exist in this lineage, which can suggest approaches to deliver genetic improvement of AM strains.

The Colonization Process

The establishment of the AM symbiosis requires a succession of well-characterized developmental steps (Fig. 3) (3). In advance of direct plant-fungus contact—the so-called presymbiotic stage—diffusible molecules mediate reciprocal recognition between the two symbionts. Then the fungal hyphae contact the root epidermis, where they form adhesion structures called hyphopodia; these precede root entry and mark the initiation of the symbiotic phase. In response to these chemical and physical stimuli, the contacted epidermal cell develops an intracellular accommodation structure, called the prepenetration apparatus (64), which drives fungal penetration and guides hyphal passage across the epidermal cell and toward the inner root tissues. Within the root, hyphae grow inter- and intracellularly to reach the deepest cortical cells, where arbuscules develop (65). As root colonization proceeds, the AM fungus explores the soil, developing an extensive hyphal network, the extraradical mycelium, which also can produce a new generation of asexual spores.

Host plants control each step of symbiosis development, leading to a precise synchronization of fungal and plant developmental processes (65, 66). Over the past decade, the molecular components controlling AM colonization have been intensively studied in angiosperms (11, 65) and more recently in basal land plants (67, 68).

Presymbiotic signaling

AM fungi perceive the vicinity of a host via root-exuded molecules that induce spore germination and hyphal branching (69, 70). The most-studied plant symbiotic signals are carotenoid-derived phytohormones called strigolactones (SLs) (71), which have a primary role in plant development (72). AM fungi sense SLs in root exudates at concentrations as low as 10 nM. Fungal responses to GR24, a synthetic molecule commonly used to study SL actions, include the enlargement of mitochondria, a rapid increase in ATP, and NADH and nuclear proliferation (73–76). GR24 exposure also causes a sharp increase in Ca^{2+} concentration in the fungal cytoplasm (77). Although fungal SL receptors remain unknown, such observations suggest that SLs are perceived via a Ca^{2+}-mediated signaling pathway and trigger a cellular and molecular prelude to root colonization (74, 75, 78).

AM fungi also release signal molecules that trigger plant symbiotic responses (79), including transcriptional regulation, nucleus-associated Ca^{2+} signals, starch accumulation in roots, and lateral root formation (80–86). Repeated oscillations in nuclear Ca^{2+} concentration (spiking) have been observed in the root epidermal cells contacted by AM fungal hyphopodia, but also when the same cells were treated with exudates from germinated AM fungal spores (83). Similarly, the expression of the early symbiotic gene *ENOD11* in *Medicago truncatula*

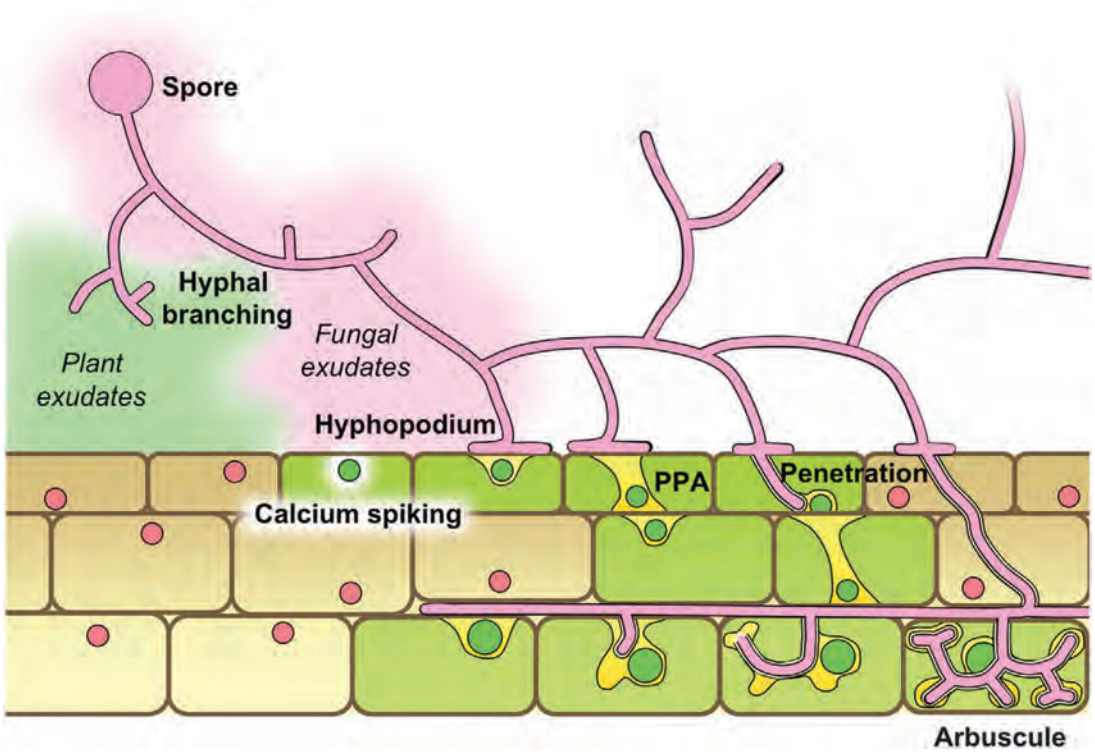

Figure 3 Root colonization by AM fungi. Spore germination generates a short explorative mycelium. The perception of root exudates induces repeated hyphal branching, increasing the probability of direct contact between the symbionts. Concurrently, fungal exudates are also released and activate the common symbiotic signaling pathway in root cells. Signal transduction includes nuclear-associated calcium signals (spiking) and leads to the activation of cellular and transcriptional responses (green cells and nuclei). Plant-fungus contact is followed by the formation of an adhering hyphopodium on the root surface. The contacted epidermal cell then assembles a prepenetration apparatus (PPA), a broad cytoplasmic aggregation (yellow) responsible for the exocytotic biogenesis of the symbiotic interface compartment, where the intracellular hypha is hosted. Root colonization proceeds through the epidermis into the inner cortical cells with a PPA-like process. Intercellular hyphae can also develop along the root axis. Eventually, highly branched arbuscules develop in the lumen of inner cortical cells, deploying an extensive surface for nutrient exchange. Reprinted from *Nature Communications* (3) with permission of the publisher.

is upregulated upon both fungal contact (87) and the perception of fungal exudates (80).

Different *N*-acetylglucosamine oligosaccharides have been characterized in AM fungal exudates as bioactive molecules responsible for such plant responses. They include tetra- and penta-chito-oligosaccharides (CO4 and CO5) (86) as well as lipo-chito-oligosaccharides, which are very similar to nodulation (Nod) factors released by nitrogen-fixing rhizobia (85). When applied as purified molecules, such chitin derivatives mimic the perception of fungal exudates in the host roots, including nuclear Ca^{2+} spiking (85, 86) and the regulation of symbiosis-related genes (80, 85, 88). Interestingly, the release of CO4 and CO5 in *R. irregularis* exudate is boosted upon GR24 treatment (86), suggesting the existence of a positive loop between plant and fungal signal perception and production of these oligosaccharides.

The study of plant signaling mechanisms involved in the perception of AM fungal signals has been developed in legumes such as *M. truncatula*, largely following the research on rhizobial Nod factor signaling. Such comparative investigations have revealed the existence of a so-called common symbiotic signaling pathway (CSSP), which includes several genes that are essential for both symbioses (89, 90). Evidence that the same genes are also involved in diverse symbiotic, pathogenic, and parasitic plant interactions is accumulating (91).

The CSSP starts on the plant cell membrane, with a malectin-like domain leucine-rich repeat receptor-like

kinase (known as SYMRK, in *Lotus japonicus*). SYMRK forms a complex with Nod factor receptors NFR1 and NFR5 and is believed to interact also with the so far unidentified receptor(s) for AM fungal signals (90). In its cytoplasmic domain, SYMRK also interacts with a MAP kinase kinase (92) and HMGR1, a 3-hydroxy-3-methylglutaryl-CoA reductase involved in mevalonate synthesis. Indeed, mevalonate has recently been demonstrated to trigger downstream symbiotic responses such as nuclear Ca^{2+} spiking and ENOD11 expression (93).

All the remaining CSSP proteins that have currently been identified are localized to the nucleus. They include three nucleoporins (NUP85, NUP133, and NENA [94–96]) possibly involved in nuclear targeting of CSSP actors, as well as the ion channel CASTOR/POLLUX and the SERCA-type Ca^{2+}-ATPase MCA8. Both these latter proteins localize to the nuclear envelope (97, 98) and are essential for nuclear Ca^{2+} spiking (98–101). The nuclear envelope lumen is considered to be the site where Ca^{2+} is stored and released during symbiotic Ca^{2+} signaling. The Ca^{2+}- and calmodulin-dependent protein kinase CCaMK localizes to the nucleoplasm and is composed of a serine/threonine kinase domain, a calmodulin-binding domain, and three Ca^{2+}-binding EF-hand domains (102, 103). Upon an increase in Ca^{2+} concentration, CCaMK is subject to a complex conformational change (102, 104, 105). When active, CCaMK regulates gene expression through its interacting partner, CYCLOPS (106–108), and the action of transcription factors such as NSP1 and NSP2 (109–112), NIN (113, 114), and reduced arbuscular mycorrhiza 1 (RAM1) (89, 115).

The exchange of chemical signals that mediate reciprocal recognition probably becomes more intense as soon as a hyphopodium adheres to the surface of the root epidermis. Hyphopodium differentiation depends on plant cell wall-bound signals as shown by the seminal studies of Giovannetti et al. (116) and Nagahashi and Douds (117). Only recently, though, monomeric cutin has been proposed to be responsible for hyphopodium differentiation. This deduction comes from the observation that RAM1 activation increases the expression of RAM2, a glycerol-3-phosphate acyl transferase involved in the biosynthesis of cutin precursors (115, 118).

Interestingly, in a recent paper Gutjahr et al. (119) identified loss of responsiveness to AM fungi in a rice mutant, which was also mirrored by the absence of physical contact and of characteristic transcriptional responses to AM fungal diffusible signals. The gene responsible for the loss of symbiosis, *DWARF 14 LIKE* (*D14L*), encodes an alpha/beta-fold hydrolase that is a component of an intracellular receptor complex involved in the detection of the smoke compound, karrikin. Thus, D14L seems to be required to support initial colonization events by AM fungi. Overall, these results reveal a novel plant recognition strategy for AM fungi and envisage the existence of an additional signaling molecule, the D14L ligand.

Host cell colonization

As soon as a hyphopodium develops on the root surface, the nucleus of the underlying epidermal cell moves toward the fungal contact site, then migrates to the opposite side of the cell traversing the lumen and partially displacing the vacuole. Concurrently, a broad, columnar cytoplasmic aggregation assembles between the nucleus and the fungal contact site. This aggregate is rich in endoplasmic reticulum, cytoskeleton, Golgi stacks, and secretory membranes and constitutes the so-called prepenetration apparatus, or PPA (Fig. 3) (64, 66, 120). Such features characterize the PPA as a broad exocytotic process finalized at the construction of the novel membrane domain—an extension of the host plasmalemma—where the fungus will be hosted: the perifungal membrane which envelops all intracellular fungal structures (120). Only after the PPA is fully deployed, a penetrating hypha develops from the hyphopodium, crosses the epidermal cell wall, and enters the cell lumen, strictly following the PPA route (64). PPAs are not observed in plants that lack CSSP genes such as *dmi2* or *dmi3* (64). Furthermore, constitutive expression of an active CCaMK variant induces cytoplasmic aggregates that resemble a PPA (121). Consequently, one key function of the CSSP is the activation of the cellular program responsible for fungal hosting (11).

PPA formation is not limited to epidermal cells, where the fungus starts its intracellular development, but is also observed in outer and inner cortical cells in preparation for arbuscule formation (66). Cortical cells that are preparing to harbor an arbuscule display the most extensive PPAs: here, the cell membrane invagination does not envelop a single hypha but progressively expands to line each of the fine branches that can fill up most of the cell lumen (10). The perifungal membrane around intracellular hyphae or the periarbuscular membrane (PAM) around arbuscules (65) outlines the so-called symbiotic interface, the novel cell compartment where the fungus is hosted and where most of the signal and nutrient exchanges are believed to occur (122, 123). In line with this, the PAM comprises a specific subset of membrane-associated proteins (124). Though the signal that induces branching and differentiation of arbuscules is currently unknown, several

plant genes required for arbuscule development and/or function have been identified, including Vapyrin (125), two vesicle-associated membrane proteins (126), EXO70I (127), proteases (128, 129), a proton ATPase (130, 131), ATP-binding cassette transporters, stunted arbuscule and stunted arbuscule 2 (132), and phosphate transporters (133, 134).

Interestingly, trafficking of the symbiotic phosphate transporters and ATP-binding cassette transporters to the PAM requires gene expression coincident with arbuscule branching (135), leading to the hypothesis that PAM construction is achieved by synchronizing two cellular and molecular processes: the massive reorientation of exocytosis toward the developing PAM and the transcription of specific genes encoding for PAM-resident proteins (11, 135). Because transcriptional control seems crucial to ensure the correct protein composition of the PAM, plant transcription factors active in the AM symbiosis have also been characterized. So far, transcription factors required for AM symbiosis include CYCLOPS (108, 136), the gibberellin repressor protein DELLAs (137, 138), RAM1 (115), required for arbuscule development 1 (RAD1) (139), MtERF1 (140), and DELLA-interacting protein 1 (141). Recent results suggest a model where DELLA proteins regulate arbuscule development through modulation of RAM1 and RAD1 that in turn regulate genes required to support arbuscule branching (142).

Arbuscules are ephemeral structures that collapse and degenerate approximately 2 to 3 days after maturity (11, 143), while the host cell regains its previous organization and can undergo a new round of colonization.

The correct formation and functioning of an arbuscule are also expected to be under fungal control; however, the functional studies of the fungal partner are very few. Kloppholz et al. (144) discovered the first AM fungal effector, named secreted protein 7. Effector proteins are secreted by plant-colonizing microbes and are generally thought to promote compatibility or to suppress plant defense responses by interfering with metabolism or signaling pathways (145, 197). In particular, secreted protein 7, which is secreted into the host cell and localizes to the plant nucleus, counteracts the plant immune response by interacting with the pathogenesis-related transcription factor ethylene response factor 19 (144). Although their mechanisms of action have not been elucidated yet, two additional fungal genes have been recently identified with a putative role in the accommodation of fungal structures in the root (146, 147).

While such targeted investigations have started shedding light on the cellular and molecular mechanisms that act inside each host cell, transcriptomic and genomic studies suggest that these are just the first steps of the characterization of fungal effectors and their function in AM (148, 149).

The Transfer of Nutrients

Nutrient uptake and transfer to the host plant are the most documented roles of AM fungi. The extraradical mycelium acts as an extension of the root system, taking up phosphate (P), nitrogen (N), sulfur (S), and trace elements from the soil and delivering them to the host plant via the intraradical mycelium (8). The PAM is considered to be the site where this symbiotic transfer occurs: mineral nutrients released in the interface compartment are captured by PAM-bound plant transporters that translocate them to the host cell cytoplasm (150).

Phosphorus

Two pathways contribute to inorganic phosphate (Pi) uptake in mycorrhizal plants: a direct pathway by the root epidermal cells and a mycorrhizal pathway via AM fungi (151, 152). AM fungi are capable of significantly improving the uptake of Pi ions, which are characterized by low mobility and availability in soil. By using radioactive P, Smith and Smith (8) found that in mycorrhizal plants most of the P delivered to the plant came from the fungus and that the direct pathway was almost inactive. Indeed, depending on the plant and fungal species, AM fungi can contribute from 20 to 100% of the plant P uptake (153).

The mycorrhizal pathway involves initially the fungal uptake of soluble Pi from the soil. This is mediated by $Pi:H^+$ transporters, which have been described in *Diversispora epigaea* (154), *R. irregularis* (155), and *Funneliformis mosseae* (156). However, a role remains to be clarified for the putative $Pi:Na^+$ transporters RiPT1 and RiPT2, recently identified in the *R. irregularis* genome (152).

Within the extraradical mycelium, Pi can supply the metabolically active Pi pool (used for the biosynthesis of phospholipids, DNA, RNA, and proteins) or rapidly accumulate in vacuoles in the form of long-chain or short-chain polyphosphates (polyP) (157, 158), presumably through the action of the polyP polymerase/vacuolar transporter chaperone complex (148). PolyP is considered the major Pi store in hyphae as well as the main form of Pi translocation over long distances within hyphae (159). Indeed, polyP accumulation in the extraradical mycelium mirrors equivalent Pi uptake from the soil (160). Interestingly, polyP translocation toward the host is mediated by the activity of a fungal

aquaglyceroporin, which is highly expressed in the intraradical mycelium and is responsible for water transport across the plasma membrane (161). These findings provide novel insights on the mechanisms involved in the directional P transport toward the roots, and they highlight a key role of host transpiration and fungal aquaporins. PolyP degradation in the intraradical mycelium, possibly by vacuolar endopolyphosphatase and exopolyphosphatase activities, sustains Pi flux from the fungus to the apoplastic interface compartment (148, 162).

On the plant side, the activation of the mycorrhizal pathway is mirrored by the downregulation of plant Pht1 (H^+-dependent) transporters located in root epidermal cells, such as *M. truncatula* phosphate transporters MtPT1 and MtPT2 (163), and the upregulation of mycorrhiza-inducible Pth1 transporters (152 and references therein). Some of the latter are mostly or exclusively expressed in arbusculated cells. Among them, MtPT4 localizes to the PAM surrounding the arbuscule branches (124, 164). Interestingly, the two mycorrhiza-inducible Pi transporters, *MtPT4* and *LjPT4*, are expressed in the root tips of noncolonized plants, suggesting that they play a role in the Pi-sensing machinery of root tips (165).

Nitrogen

Although the impact of AM symbiosis on plant N uptake is not as clearly defined as that of Pi, there is increasing evidence for the existence of an N pathway through the fungal hyphae to the host plant, in spite of the contribution of AM fungi to the plant total N nutrition varying considerably depending on the context (8, 158, 166). Nitrogen is found in soil in both organic and inorganic compounds, and plants use all of them. The former include simple molecules such as urea, amino acids, amines, and peptides and complex molecules such as proteins, while inorganic N compounds are mainly represented by nitrate (NO_3^-) and ammonium (NH_4^+). In soils where N is limited or poorly mobile, due to drought or acidity, the contribution of the AM fungus to plant N nutrition can be considerable (152, 167), ranging between 24 and 42% of a plant total N content (168).

A few mechanisms of N uptake and transfer in the AM symbiosis have been recently described (166). Extraradical hyphae preferentially take up NH_4^+, which is energetically less costly than alternative N sources such as NO_3^- and amino acids. López-Pedrosa et al. (169) demonstrated that *GintAMT1*, a gene encoding for a high-affinity NH_4^+ transporter (AMT) in the AM fungus *R. irregularis*, is expressed in the extraradical mycelium. A second *R. irregularis* AMT has been characterized (170). *GintAMT1* and *GintAMT2* are differentially expressed during the fungal life cycle and in response to N. In contrast to *GintAMT1*, *GintAMT2* transcript levels are higher in the intraradical than extraradical hyphae.

Inside the extraradical mycelium, N compounds are converted into amino acids, mainly arginine (171, 172). Arginine is then translocated to the intraradical hyphae within tubular vacuoles and then reconverted into inorganic N compounds by the sequential enzymatic activity of arginase and urease: NH_4^+ is the most likely form of N transferred from fungus to plant (173, 174). It has been proposed that arginine binds to the negatively charged polyP and that both could move together within the hyphae (171, 175). The eventual transfer of NH_4^+ from the apoplast to the plant cells probably relies on NH_4^+ transporters sitting on the PAM (176–178). Remarkably, mutations in AM-specific Pi and NH_4^+ transporters have an impact on intraradical fungal development and arbuscule lifespan (179, 180). It has been speculated that these transporters not only deliver nutrients to the plant cells, but also trigger signaling processes that control arbuscule maintenance (180).

Even though the flux of mineral nutrients within the periarbuscular space is assumed to be directed toward the plant cell, fungal Pi (181, 182) and NH_4^+ transporters (170) are expressed in arbuscules. This finding suggests that the fungus may recover nutrients from the periarbuscular interface as a mechanism to control the amount of nutrients delivered to the host.

As well as taking up inorganic N, AM fungi also appear to obtain N from complex organic material (183–186). Such a process probably involves, among other transporters, an amino acid permease (AAP). A fungal AAP (GmosAAP1) has been characterized in *F. mosseae*. Since *GmosAAP1* is expressed in the extraradical mycelium and upregulated upon exposure to organic nitrogen (187), this gene may play a role in the first steps of amino acid acquisition from the soil. Since short peptides can represent a greater proportion of N in soils than free amino acids, it is notable that AM fungi also possess functional dipeptide transporters such as RiPTR2 (188). In yeast complementation assays, RiPTR2 allowed the uptake of several dipeptides such as Ala-Leu, Ala-Tyr, and Tyr-Ala. *RiPTR2* is expressed in the extraradical hyphae, suggesting a role in the uptake of organic N from soil; however, a stronger expression is consistently observed in the intraradical phase (188). This finding points to a function for this transporter in the mobilization of organic N in mycorrhizal roots.

Despite all the interesting findings, many critical questions about N transport through the fungal hyphae and across the mycorrhizal interface are still unanswered and should be addressed in future studies (166).

Other mineral nutrients

In addition to the improvement of plant N and P nutrition, physiological studies also have highlighted a role for AM fungi in enhancing the absorption of other ions such as sulfur, potassium, or different secondary macro- and microelements (1, 152).

Sulfur (S) is a key macronutrient for plant growth, development, and response to several stresses. Casieri et al. (189) observed an increased S content in mycorrhizal compared to nonmycorrhizal plants and the upregulation of two S transporters (*MtSULTR1.1* and *MtSULTR1.2*) in *M. truncatula*. More recently, an *L. japonicus* transporter (LjSultr1;2), specifically involved in sulfate uptake from arbuscules, has been identified (190).

Despite the importance of potassium (K^+) for plant growth, the contribution of AM symbiosis to plant K^+ nutrition has only occasionally been studied. It appears that plant K^+ nutrition is improved by mycorrhization, especially under K^+ limiting conditions. Moreover, this improvement could affect abiotic stress tolerance, P homeostasis maintenance, or exclusion of soil contaminants such as radiocaesium (191 and references therein). The characterization of genes involved in the transport and metabolism of K^+ and other mineral nutrients is required before a comprehensive map of the transportome of arbuscular mycorrhizae can be developed.

Carbon

In exchange for plants' improved access to nutrients, AM fungi take advantage of carbon compounds of plant origin, consuming between 10 and 30% of the plant photosynthates (192). The transcriptional regulation of genes involved in sucrose transport has been reported in several plant-fungus combinations (152 and references therein), although more efforts are required to clarify which plant sucrose transporters and regulatory mechanisms are active in sucrose partitioning during mycorrhization. On the fungal side, only one high-affinity monosaccharide transporter (MST), probably responsible for C uptake from the interface compartment, has been described (193). The gene *MST2* is highly expressed in arbuscules and intercellular hyphae. The high affinity and transport capability for xylose residues suggest that the use of derivatives from plant cell wall polymers could be an additional source of C. Interestingly, *MST2* is also expressed in extraradical hyphae, which can take up glucose and xylose, suggesting a partial metabolic independence of AM fungi from host plants.

For full mutualism to occur, a functional linkage between C and P exchange, under fine control by both partners, is likely to be in place. Recent studies have demonstrated that a strategy of reciprocal rewards rules AM interactions: in the presence of multiple partners, the most beneficial partner is rewarded with the majority of resources (14, 194). A similar mechanism also appears to regulate C and N exchange (175). These striking results support the idea that biological market dynamics ensure the stable regulation of resource exchange in the evolution of AM symbiosis. However, other evidence suggests that reciprocal regulation represents only a fraction of the forces determining resource exchange in the AM symbiosis, and such reciprocity is only found in a subset of symbionts under specific conditions (195).

The Impact of AM Symbiosis on Aboveground Organs of the Host Plant

The impact of the AM symbiosis goes beyond the root apparatus and involves distal parts of the plant through a fine shaping of the whole plant physiology. The first molecular evidence of a systemic effect was observed at the level of gene expression profiles: changes in transcript pattern, which were not a mere consequence of an improvement in P nutrition, were observed in shoots of *M. truncatula* upon root colonization by AM fungi (196). A transcriptional reprogramming was also reported for other plants such as tomato and maize (198–200). Gerlach and colleagues (200) also performed parallel ionomic and metabolomic analyses showing drastic changes in leaf elemental composition, a general increase in C versus N metabolism, and an accumulation of secondary metabolites. The AM symbiosis therefore influences the physiological status of plant leaves.

The systemic effect of the AM symbiosis was recently shown also to extend to fruits with the potential to increase their nutritional values. Lycopene, carotenoid, and volatile compound contents were significantly increased in fruits of mycorrhizal tomato plants compared to those of nonmycorrhizal plants (201, 202). An overall increase in fruit yield of mycorrhizal tomato plants, as well as qualitative and quantitative changes in amino acid profile, accompanied phenological modifications as an accelerated flowering and fruiting time (203, 204). Not only vegetative but also reproductive traits are therefore under the influence of the AM

symbiotic interaction. This situation has major ecological and agronomical implications.

Such systemic effects have been proposed to depend, at least to some extent, on the action of phytohormones, which are also involved in AM establishment and functioning (205–207). The levels of several hormones such as salicylic acid, jasmonic acid, abscisic acid, auxin, and ethylene are altered during AM colonization (208–211). In addition, salicylic acid, ethylene, and cytokinins are considered negative regulators of fungal penetration and root colonization (205). At later stages, arbuscule development is suppressed by biologically active gibberellins and promoted by DELLA gibberellin repressors (137, 205, 212). By contrast, abscisic acid and auxins positively regulate arbuscule development and functionality (213, 214), while contrasting effects have been described for jasmonates (215).

The alteration of transcriptional profiles and hormonal balance in mycorrhizal plants may also have an impact on the plant response to abiotic and biotic stresses (6, 18, 216–218). AM symbiosis often reduces the damage caused by soil-borne pathogens, while the effect on pests and pathogens attacking from aboveground are more variable and are highly dependent on the combination of AM fungus, plant, and attacker (18). The effect of AM at both the local and systemic scale strongly suggests that the bioprotective role of mycorrhization is not simply related to improved mineral nutrition, changes in the root apparatus, and/or changes in the microbial rhizosphere communities, but rather to the activation of systemic defense responses (218–223). In support of this hypothesis, stress- and defense-related genes are upregulated in mycorrhizal plants, which in turn show increased tolerance to foliar bacterial pathogens (196, 199).

In this context, the combined action of plant hormones and gene regulation may contribute to the generation of a primed status in the plant, allowing a more efficient activation of defense mechanisms in case of a subsequent attack (200). The identification of the full set of defense regulatory elements deployed by mycorrhizal plants and indirectly driven by AM fungi will have important practical implications regarding the effectiveness of the AM symbiosis in biological control and integrated management of pests and diseases.

The Common Mycorrhizal Network

AM fungi can also influence plant community dynamics and plant-plant interactions; this has major implications for natural and agricultural systems. A fascinating feature of AM fungi is the ability of their extraradical mycelium to interconnect individual plants of the same or different species in "common mycorrhizal networks" (CMNs) (224). CMNs are very common in terrestrial ecosystems, where they are thought to play key roles. Plants invest between 10 and 30% of their photosynthetic products in their fungal symbionts and receive in exchange up to 90% of their mineral requirements (4, 192). CMNs represent possible pathways for the movement of soil-derived nutrients and plant-derived carbon within the network and between CMN-interconnected plants. However, the knowledge of how C, N, and P (as well as other nutrients) are exchanged and redistributed via the CMNs is still limited. The transfer of C via CMNs has been demonstrated from autotrophic to achlorophyllous (nonphotosynthetic) plants, yet its transfer between autotrophic plants remains more controversial (225–227). Similarly, the role of CMNs on mineral (e.g., N) transport between plants is not so clear (228).

Moreover, the terms of trade, that is, the relationship between the investment of a given plant into a CMN (amount of assimilated C) and the return of investment in terms of mineral nutrients provided by the CMN, are unresolved. Different cocultivated plants benefit differently from their CMN, depending on the AM fungal species involved (229–231). To address such questions, Walder et al. (232) set up an elegant microcosm experiment with a pair of plants (flax and sorghum) interlinked by a CMN of either *R. intraradices* or *F. mosseae*. Fluxes of C, P, and N were then monitored through C-stable isotope tracing and ^{15}N and ^{33}P labeling. Depending on the fungal species, a strong asymmetry was observed in resource exchange: flax invested little C but obtained up to 94% of the N and P provided by the CMN. Furthermore, the overall biomass was larger when the plants were grown together than in monoculture. Overall, CMNs appear to contribute to the productivity increase that is often observed in intercropping compared with conventional monocropping systems (233). These findings clearly challenge the "biological market" model where the most beneficial partners are favored (14) and suggest that resource exchange in the AM symbiosis is determined by more complex factors (195).

Recently, a new role for CMNs was discovered. Plants can exploit CMNs to transfer defense signals to neighboring individuals. The first demonstration of interplant signaling via CMNs was in tomato plants attacked by the foliar necrotrophic fungus *Alternaria solani*: six defense-related genes were upregulated in uninfected plants that were only connected to the infected individuals by CMN (234). The CMN-mediated transfer of defense signals was also observed between

insect-attacked plants and healthy neighboring plants (235, 236). Altogether, CMN seems to act as a belowground interplant defense communication system. Nevertheless, the nature and the mechanism of signal transfer through the fungal mycelium as well as the ubiquity and ecological impact of interplant signaling in nature remain to be fully understood (237).

CONCLUDING REMARKS

Our understanding of the AM interaction at multiple levels, from cells to ecosystems, is increasingly benefiting from the developments and advances of investigation tools such as "omics" technologies, live cell imaging, stable isotope tracking, and genetic manipulation. Already, genome sequencing and analyses have accelerated our understanding of enigmatic aspects of the genetics and biology of AM fungi. It is likely that mycorrhizal research will rely more and more on multidisciplinary approaches and combinations of analytical techniques—in both controlled and natural conditions—to answer numerous questions concerning the evolution, ecology, and functioning of this fascinating interaction. The holistic knowledge generated by such approaches will be crucial to boost the fruitful application of the AM symbiosis in sustainable agronomical practices to face current challenges in global food production and security.

Lichenized Fungi and the Evolution of Symbiotic Organization

36

Martin Grube[1] and Mats Wedin[2]

INTRODUCTION AND HISTORICAL BACKGROUND

Lichens were generally accepted as an independent group of organisms when Schwendener (1) discovered that they are the result of the association of fungi and algae. This insight was not widely accepted by contemporaries but initiated a scientific revolution as lichens later became the prime example of a mutualistic symbiosis and, indeed, the phenomenon for which the term symbiosis was originally introduced in biology as "symbiotismus" (2, 3). The lichen symbiosis has proved to be one of the most important lifestyles in the *Ascomycota* and is also known from a few *Basidiomycota*. Approximately 20,000 currently known fungal species live as lichens, mostly in species-rich lineages of *Ascomycota* (4). The traditional view of lichens as a mutualistic symbiosis of a fungus and one or several green algae or cyanobacteria has always been debated (5), but it has recently been challenged more than ever by the discovery of numerous additional microorganisms that potentially occur as obligatory participants in the symbiosis.

The self-supporting associations of fungi and their partners usually form a compact and macroscopically recognizable structure, known as the lichen thallus. Different from many other fungi, which reside beneath the surface of their substrates, the lichen thallus is typically developed at the surface of the substrate or completely exposed to the atmospheric conditions, apparently without exploiting the substrates' nutrients (Fig. 1).

THE LICHEN THALLUS

The lichen thallus arose early in evolutionary history with the conquest of land, and the earliest records of internally stratified cyanobacterial and green-algal lichens were from the Lower Devonian (6). These lichens have an unclear relationship to current lichen-forming lineages in the *Ascomycota*, which originated at least as early as the Carboniferous and radiated in the Jurassic and Cretaceous to generate the diversity of the main modern groups (7). The ability to revitalize from dry stages helps the lichen thallus in many species to survive environmental fluctuations with extremes of desiccation and temperatures (8, 9). Lichens are thus prominent at high altitudes and latitudes where conditions become adverse for most other multicellular organisms. Especially in cool habitats, lichen biomass can be substantial, and lichens can then form a dominant part of the vegetation (Fig. 2). By the balance of respiration and photosynthetic energy production in the symbiotic system, many lichen thalli grow slowly but are long-lived. Usually, the fungi dominate the biomass and dictate the shape of lichen thalli. The scientific name of lichens also, by definition, refers to the fungal partner only.

Lichen fungi shelter the algal/cyanobacterial partners beneath a protective peripheral cortex layer (Fig. 3). These layers are developed by the conglutination of fungal hyphae, which seems to be correlated with increased branching and anastomoses formation. The outer walls of the fungi are thickened to form sticky contacts with neighboring hyphae. This appears to be similar to the process generally found with the formation of fungal fruit bodies, but in the case of lichens conglutination and compaction occur in the vegetative mycelium, and this could be one of the key evolutionary innovations to make lichen thallus evolution possible. The conglutination of vegetative hyphae forms a more or less coherent layer by which algal cells can

be covered and under which algal populations can form more or less coherent layers within fungal plectenchyma (i.e., tissue-like structure made of fungal hyphae). This developmental process seems to be correlated with massive branching and anastomosing of the hyphae. While genes regulating branching, anastomosing, and conglutination are known from model fungal systems, their presence and regulation in lichenized fungi have so far not been studied. The morphogenetic processes seem to be initiated as soon as the fungi contact appropriate algal cells. Once the thallus morphogenesis is initiated, the algal symbionts can proliferate massively under the fungal protectorate. The mycobionts are triggered by the interaction with the algae to produce diverse, more or less complex thallus morphologies, a wide diversity of lichen-derived secondary metabolites, and fruit bodies for sexual fungal reproduction and/or asexual structures for combined propagation of symbionts. Notably, strikingly convergent thallus morphologies have evolved in several unrelated lineages of lichenized fungi (10). The convergent shapes include complicated morphologies, for example, umbilicate thalli (leafy structures with a central, exclusively fungal holdfast), as well as reductions of complexity

and reversal to simple crustose lichens or even parasitic lifestyles, or the formation of thalli composed of grain-like fungal-algal propagules.

In certain lineages, there is a strong selectional trend toward vegetative reproduction solutions that disperse the fungal and algal partners. These include soredia, which are granules of varying size that contain algal cells and fungal hyphae, produced in structures of varying size and morphology termed soralia (Fig. 4A). Other types of vegetative propagules are corticate, which form easily detached outgrowths from the lichen thallus, called isidia (Fig. 4B). In several lineages of lichens that reproduce by vegetative means, the production of sexual spore-producing structures is rare or unknown.

While most species of lichenized fungi produce highly organized thalli with internal stratification, several "borderline" lichens produce poorly differentiated

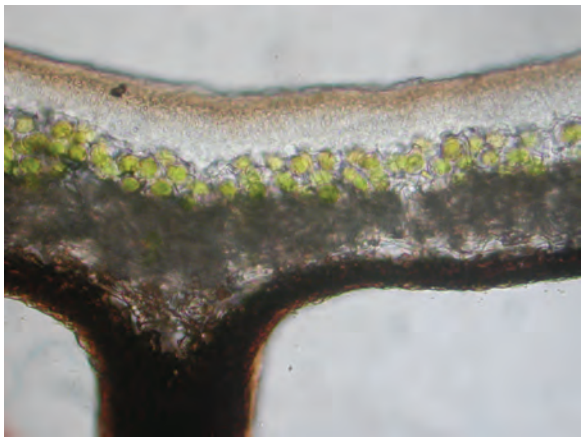

Figure 3 Vertical section through a thallus of *Parmelia saxatilis*, a foliose lichen. A distinct layer of green algal cells is clearly visible under the uppermost cortex; all other structures are made up by fungal hyphae. Photo: Einar Timdal.

Figure 4 Vegetative dispersal in lichens. (**A**) Soralia formed along the thallus margins in *Vulpicida pinastri*. thalli (11–13). A small number of fungal species also seem to be facultatively lichenized, in the sense that they sometimes are found loosely associated with algae and sometimes are not (14–16). In the *Stictidaceae*, this facultative lichenization is apparently determined by the substrate they grow on, because several species can grow as saprotrophs on dead wood (Fig. 5A) and as loosely lichenized on bark (Fig. 5B). This has been termed "optional lichenization" by Wedin et al. (17). These borderline and optional lichens may be seen as present-day analogs of early thallus evolution, before more advanced forms of thallus organization arose.

THE LICHEN FUNGI AND THEIR PHYLOGENETIC RELATIONSHIPS

The integration of lichenized fungi into the classification of *Fungi* was slow at first because very few lichenologists accepted the consequences of Schwendener's discovery. Vainio (18) was the first to classify at least some higher ranks of the lichen fungi together with other fungi, but the very influential Zahlbruckner (19, 20) treated lichens as a separate group, *Lichenes*, on a level equal to the *Ascomycetes* and the *Basidiomycetes*, which prevented further progress for many years. Nannfeldt (21) argued strongly for integrating lichenized fungi into a natural fungal system, something that was acted upon by Santesson (22–24). Only in the second half of the 20th century was this integrated classification widely accepted by most mycologists, even if the study of lichen fungi nevertheless often is still considered a matter for lichenologists and quite distinct from the study of nonlichenized fungi.

Lichenized lineages are interesting from a phylogenetic-evolutionary perspective, because they primarily have evolved and diverged in the lichenized condition with similar partners. The self-supporting, self-sufficient lichen thallus is likely to be the target of selective pressures very different from the selective forces working on nonlichenized fungi, which creates a substantial difference from what saprobic or parasitic fungi may undergo.

Within the lichens belonging to the *Ascomycota*, microscopic characteristics of the sexual reproductive structures, in particular, fruit body development and organization (25–27), and ascus structures (28–30) helped to refine the taxonomic relationships and were largely the basis of classifications in the late premolecular era. Already at that time, there was a vigorous debate about the number of times that the lichen lifestyle arose in the evolution of fungi. Since it was not feasible to grow axenic fungal cultures, it was only possible to amplify mycobiont genes directly from lichen samples after the development of fungal-specific PCR primers, which excluded the algal partners. With this technical advancement, Gargas et al. (31) were able to provide a first phylogenetic analysis of 18S rRNA genes in lichenized fungi. Their results suggested that the lichen lifestyle arose at least twice in the evolution of ascomycetes. Data from more sequences of lichenized lineages were analyzed by Lutzoni et al. (32) to revisit the fundamental question of lichen origins. The idea of two origins was not rejected, but neither was the possibility of a single origin of lichens in *Ascomycota*. Both studies convincingly showed that the lichen lifestyle was a rare innovation in the evolution of *Ascomycota*, while the latter study pointed out that the symbiotic lifestyle

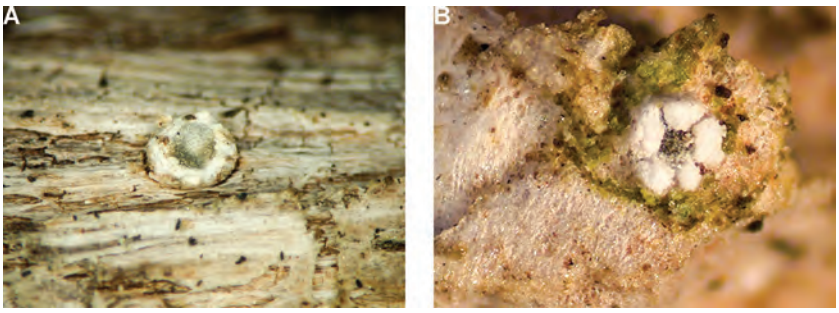

Figure 5 Optional lichenization: *Schizoxylon albescens*. (**A**) Apothecium of a saprotrophic colony on dead aspen (*Populus tremula*) wood. Photo: Lucia Muggia. (**B**) Lichenized morph on aspen bark. Note the green algal colonies around the young apothecium. Photo: Lucia Muggia.

was more frequently lost in major ascomycete groups. Later studies (33) again suggested that lichenization originated multiple times, which seems currently to be the generally agreed upon view.

During the past years our understanding of the phylogeny within the major lineages of lichenized *Ascomycota* increased significantly through a number of investigations involving large numbers of species. An updated classification of *Ascomycota* including the lichenized lineages can be found in Jaklitsch et al. (34), reflecting these discoveries. Extant lichenized fungi occur in at least six of the major lineages within the *Ascomycetes*: the *Arthoniomycetes*, *Coniocybomycetes*, *Dothideomycetes*, *Eurotiomycetes*, *Lecanoromycetes*, and *Lichinomycetes* (35–38). One additional lichenized lineage may belong to the *Leotiomycetes*. Different "relaxed clock" scenarios suggested that the origin and diversification of the *Pezizomycotina* occurred in the Cambrian (7). Prieto and Wedin (7) provided information about the timing of the main diversification events in *Ascomycota*, including estimates for classes, orders, and several families of both lichenized and nonlichenized *Ascomycota*, many of which had not been previously dated. The main lineages of lichen-forming *Ascomycota* were shown to have all originated at least as early as the Carboniferous, with successive radiations in the Jurassic and Cretaceous generating the diversity of the main modern groups.

Comparatively few representatives of *Basidiomycota* are lichenized, but recently, the *Cora-Dictyonema* complex was shown to contain a massive number of earlier undistinguished species (39). An investigation focusing on the morphological characteristic evolution in this group showed that the lichenized thallus had evolved progressively from loosely organized filamentous crusts to stereoid and corticioid basidiomata more or less incorporated into the lichenized thallus (40). This indicates that lichenized thalli may have evolved from reproductive structures in their nonlichenized ancestors.

In the overview of lichenized *Ascomycota* below, we select some examples of phylogenetic studies that contributed major advances in our understanding of morphological and chemical characteristic evolution, lichen biology and interactions, and the general understanding of major lineages of each group.

Arthoniomycetes

The *Arthoniomycetes* contain a single order, *Arthoniales*, the second-largest group of lichen-forming fungi, which is a morphologically diverse group of predominantly lichenized representatives, most of which form lichen symbioses together with green algae of the *Trentepohliaceae*. Grube (41) presented a premolecular era overview of taxonomic and phylogenetic concepts for the *Arthoniales*. This account provided discussions of selected morphological characteristics and a key to the genera now placed in the order. This work served as a baseline for subsequent molecular work. Ertz and Tehler (42) presented the first comprehensive phylogeny of *Arthoniales* focusing on lineages previously assigned to *Opegraphaceae* and *Roccellaceae*. Their two-locus phylogenetic study showed that traditional morphological characteristics such as growth form, fruit body type, exciple (a fungal layer of hyphae directly surrounding and derived from the ascoma), hypothecium and ascospore color, ascospore septation pattern, and secondary metabolism are of limited use in delimiting families and genera. They concluded that the high level of phenotypic plasticity might indicate that *Arthoniales* is an old group and that phenotypically characterized genera are paraphyletic. Frisch et al.'s recent analysis (43) focused on the heteromorphic family *Arthoniaceae* and demonstrated that previous classifications of this family did not reflect evolutionary

patterns. According to the phylogenetic hypothesis, lichen secondary metabolites such as pulvinic acid derivates and red pigments do not characterize monophyletic groups above the genus level. The study also revealed that the lichen-parasitic lifestyle in *Arthoniaceae* has evolved more than once and is found in four independent lineages of the *Arthoniaceae* clade and in the *Bryostigma* clade. *Arthoniomycetes* strains with chlorococcoid photobionts are restricted to the *Bryostigma* clade and *Chrysotrichaceae*, while the only saprophytic *Arthonia* species in the phylogeny is related to *Arthonia radiata* and grouped with lichenized taxa. The phylogenetic data provide a coherent framework for delineating further monophyletic groups in *Arthoniaceae* in the future.

Coniocybomycetes

Coniocybomycetes is a small group (one order and family, currently two genera with ca. 30 species) of crustose lichens with prototunicate (thin-walled and evanescent) asci and mazaedia-producing (mazaedium: an accumulation of loose, maturing spores covering the ascoma surface), stalked ascomata. This is the most recently described class of *Ascomycota* and is apparently related to the *Lichinomycetes* (38), but this relationship is not supported by any obvious morphological characteristics. *Coniocybomycetes* is one of the few lichen groups from which a fossil is known, which Prieto and Wedin (7) utilized in their dating of the major groups of *Ascomycota*.

Dothideomycetes

The *Dothideomycetes* is a very large fungal group characterized by ascolocular ascoma development, and only some representatives are lichenized. Schoch et al. (44) presented a comprehensive phylogenetic study of representatives of 41 families using sequences from five genes. Notably, the ancestral reconstruction of basic nutritional modes suggests numerous transitions from saprobic life histories to either plant-associated or lichenized modes. Nelsen et al. (37) integrated the primarily lichen-forming families *Trypetheliaceae*, *Monoblastiaceae*, and *Arthopyreniaceae* in a phylogeny of *Dothideomycetes*. Pérez-Ortega et al. (13) introduced the new order *Collemopsidiales*, which contains *Xanthopyreniaceae*, an interesting family including borderline lichens, many of which occur in rocky intertidal habitats, as well as lichenicolous (lichen-inhabiting) fungi.

Eurotiomycetes

Eurotiomycetes is a very large and morphologically heterogenous group in which only some representatives are lichenized, all within the subclass *Chaetothyriomycetidae*, which is an assemblage of ecologically diverse species ranging from mutualistic lichenized fungi to human opportunistic pathogens. A multigene phylogenetic study of rock-dwelling fungi concentrating on the *Verrucariales* suggested that this lichenized order is one of the ascomycete groups in which lichenization has independently evolved on a hostile rock surface (45). The delimitation of orders and families in *Chaetothyriomycetidae* was reassessed by Gueidan et al. (35) in a broad phylogenetic study which classified four orders and 10 families in *Chaetothyriomycetidae*.

Lecanoromycetes

This class comprises the largest group of lichenized fungi and one of the most species-rich classes in the kingdom of *Fungi*. Traditional concepts of classification included reproductive structures, in particular, of ascomata and ascus apex structure (which often contain characteristic amyloid features). These traditional concepts were challenged when comprehensive sequence sampling of taxa was available (46–48). Miadlikowska et al. (49) demonstrated that the *Acarosporomycetidae* and *Ostropomycetidae* are monophyletic subclasses, whereas the delimitation of the largest subclass, the *Lecanoromycetidae*, remained uncertain. This and the previous phylogenies confirmed that ascus apex morphology cannot be consistently used as a cardinal characteristic for family-level classification of lichen-forming fungi (50).

One important approach in understanding the evolution of phenetic features of lichens is to study large genera, which are pragmatically circumscribed by key characteristics. In many studies these key characteristics proved to be misleading and, rather, were symptoms of massively parallel evolution and thus produced by unrelated fungi. Examples of such misleading key characteristics are prototunicate asci and mazaedia, which used to characterize the old order *Caliciales* (including pin- and stubble-lichens), a group that in its old circumscription now has been shown to be extremely polyphyletic (38, 51) and where the families *Caliciaceae* and *Sphaerophoraceae* are now classified in the *Lecanoromycetes* (31, 38). Another example of this phenomenon was provided by Schmull et al.'s (52) analysis of the heterogenous *Lecidea* (containing 1,200 species), which are usually characterized by black fruit bodies on a crust-like thalli and single-celled, hyaline ascospores. As expected, the analyzed species of *Lecidea sensu lato* and putatively related taxa were scattered within *Lecanoromycetidae*, and some were even placed outside currently recognized orders in *Lecanoromycetidae*.

Most of the lichen fungi that form symbioses with filamentous *Nostoc* cyanobacteria belong to the *Lecanoromycetes*. *Nostoc* has a sheath around the filamentous thread-like colonies that swells and becomes extremely gelatinous when wet, and this gives many cyanolichens a gelatinous appearance when moist. Within the *Lecanoromycetes*, most gelatinous lichens are classified in the *Collemataceae*. This is yet another example of how classifications have been based on misleading key characteristics, because a number of gelatinous, *Nostoc*-containing groups formerly placed in *Collemataceae* are nested within another *Peltigerales* family, the *Pannariaceae* (53, 54). Symbioses with *Nostoc* have clearly arisen several times. Depending on the reconstruction method, most or all transformations in thallus structure within *Peltigerales* took place from a nongelatinous to a gelatinous, *Nostoc*-containing thallus (53).

Within *Lecanorales*, the phylogeny of the largest lichen family, *Parmeliaceae*, was studied in a number of papers; for example, Crespo et al. (55) showed that morphological characteristics discriminated the main clades well but that the interpretation of the morphological diversity had been quite superficial. The morphological diversity was indeed found to be substantial in this family when Divakar et al. (56) showed that the lichenicolous lifestyle originated independently three times within *Parmeliaceae* ca. 24 million years ago.

Gaya et al. (57) studied the *Teloschistales* using a supermatrix approach and showed that a progressive, cumulative addition of taxa to the matrix analyzed with a resulting increasing amount of missing data did not affect the support and resolution much but that the monophyly of the order was inconsistent depending on the combination of loci and taxa. In the *Teloschistaceae*, Arup et al. (58) proposed a completely reorganized generic classification and investigated how the apparently large morphological plasticity affected the characterization of genera and species. Secondary metabolites were frequently found to better serve as characterizing traits than morphology, at least in parts of the family.

Within *Ostropomycetidae* Baloch et al. (59) suggested that the evolution of lifestyles and ascomatal morphologies in this group was very plastic, as shown by the multiple evolution of perithecioid ascomata in the *Gyalectaceae*. Early evolutionary splits in the *Ostropomycetidae*, the second-most species-rich subclass of lichenized *Ascomycota*, were considered by Resl et al. (60) in their analysis of trapelioid fungi. The uncertain phylogenetic resolution of the c. 170 species prevented a clear backbone concept for the subclass. A monophyletic group of nine core trapelioid genera was found, which do not form the sister group of *Ostropales*, but the hypothesis of a sister group relationship of trapelioid genera and *Baeomycetaceae* or *Hymeneliaceae* could not be rejected. Recently, Miadlikowska et al. (61) provided the most comprehensive phylogenetic survey of the entire *Lecanoromycetes* class using a multigene maximum likelihood analysis with a cumulative supermatrix approach. However, the analysis of this massive data set (1,139 taxa) revealed that the cumulative addition of taxa with an increasing amount of missing data leads to relatively stable representation of relationships for many families and orders, but also in substantial loss of phylogenetic resolving power and support for deep phylogenetic relationships.

In the *Graphidaceae*, a very large family of >2,000 species, Lumbsch et al. (62) studied character evolution and found that certain characteristics (secondary metabolites, in particular) had a high frequency of reversible phenotypic state changes, whereas others, such as photobiont, hymenial persistence or ascoma aggregation, exhibited low frequency of transformations. But even in the characteristic with the highest number of state changes (changes in secondary metabolite composition), the shifts were highly structured phylogenetically, suggesting that the evolution of the characteristic, rather than the character state itself, can be used to predict phylogenetic relationships with certain accuracy.

Leotiomycetes

Trizodia acrobia is a borderline lichen and the sister group of *Leotiomycetes*. The lineage was discovered by Stenroos et al. (63) in a phylogenetic analysis of bryophilous ascomycetes. *Trizodia* is ecologically unique in its association with cyanobacterial colonies (mostly *Nostoc*) growing on the tips of peat mosses (*Sphagnum* spp.). *Trizodia* was consistently present in all *Sphagnum-Nostoc* associations studied. It envelops the cyanobacterial colonies both on the moss surface as well as inside the leaf but does not form organized thallus structures.

THE ADVANCING GENOMICS PERSPECTIVE FOR UNDERSTANDING LICHEN SYMBIOSES

Increasing the number of loci used to determine phylogenetic relationships is now possible through characterization of entire genomes of lichens. Genome-scale datasets may lead to the development of consistent, well-supported hypotheses about the evolution of lichenized fungi. A first step toward a phylogenomic analysis of lichen-forming fungi was undertaken in an exem-

plary phylogenomic study of the genus *Rhizoplaca* (*Lecanoromycetes*) by Leavitt et al. (64).

Current high-throughput sequencing technology has opened new opportunities for studying organisms that grow slowly and are difficult to establish and grow in axenic cultures. These difficulties explain why comparative genomics of lichen fungi lags behind the advances made so far in other fungal groups. Meanwhile, genetic manipulation, such as transformation, of lichens has been attempted (65). Numerous lichen genome projects have been started in the past years, and some preliminary data are already available. Basically, two strategies are followed in lichen genomics. The more traditional approach is the acquisition of genetic information from the individually cultured symbiotic partners. With the alternative metagenomics approach the total symbiotic association is first sequenced and the genetic information is then assigned to symbiotic partners by bioinformatics analysis. Such progress is possible by exploiting technologies that have significantly improved the quality of sequence assemblies (e.g., by "mate-pair" sequencing) and by powerful bioinformatics pipelines. Apart from gaining information on basic genomic features such as genome size and predicted numbers of genes (Table 1), several studies provided more detailed analyses of interesting functions.

Some of these analyses focused on the biosynthetic pathways of secondary metabolites of lichenized fungi (including depsides and depsidones, as classes of coupled phenol carboxylic acids). Sequencing the 34-Mb genome of the *Cladonia grayi* mycobiont revealed new insights in the production of the lichen depsidone grayanic acid (66) and suggested that a single polyketide synthase synthesizes two aromatic rings on tandem acyl carrier proteins and links them into a depside and that the transition from depside to depsidone requires only a cytochrome P-450 mono-oxygenase. Sequencing of the *Cladonia uncialis* mycobiont revealed a putative biosynthetic gene cluster leading to usnic acid, a dibenzofuran derivative (67). Although no typically crystallized lichen substances have been recorded for *Peltigera membranacea*, a large number of mycobiont and photobiont genes and gene clusters associated with secondary metabolite biosynthetic pathways have been identified in its metagenome, and an unusual trans-AT polyketide biosynthetic pathway of a type known only from other bacterial-eukaryote symbioses has been identified in the *Nostoc* photobiont (68).

In addition, the genome sequencing provided evidence that the tight association of fungi and prokaryotes might have favored horizontal gene transfer events. One such event was detected in the methylammonium permease family between prokaryotes and the *C. grayi* mycobiont (69). Subsequently, McDonald et al. (70) suggested that lichen-forming fungi are losing this gene family at a slower rate than other fungal lineages.

The integration of further available (meta)omics approaches, such as (meta)transcriptomics or (meta) proteomics, provides new and complementary insights into lichen symbiosis. In this context, transcriptomics reveals which of the total set of genes are activated under certain conditions, whereas proteomics suggests

Table 1 Lichenized fungal species for which genome information is available (as of March 2016)

Species	Class	Genome size (Mb)	Gene no.	Reference

which functions are actually translated into protein functions. Wang et al. (71) provided an initial full-length cDNA library as a reflection of the transcriptome, using the cultured mycobiont of the desert lichen *Endocarpon pusillum*. However, because a symbiotic context is missing, the significance of the detected gene expression for symbiosis remained unclear. In a subsequent study of the same lichen, Wang et al. (72) also analyzed dehydrated thalli and confirmed expression of 23 candidate stress responsive genes, selected from a larger set found with mycobiont cultures exposed to PEG-induced drought stress. There is also ongoing RNA-Seq work aiming to compare gene expression in the mycobiont alone in pure culture with the mycobiont in the symbiotic state to identify genes that are differentially expressed and might therefore be correlated with symbiotic interactions. Gene expression studies elucidate relative levels of active genes (73). Also, epigenetic modifications such as the presence of 5-methylcytosine in lichen genomes can be determined in conjunction with next-generation sequencing platforms.

Moving a step further, Junttila and Rudd (74) used high-throughput next-generation sequencing and expressed sequence tag sequence data to present a first transcriptome of the eukaryotic partners in the thalli of the reindeer lichen *Cladonia rangiferina* (with 62.8% reads of fungal and 37.2% of algal origin). Even though a higher percentage of algal reads was found in the wetted thalli, gene ontology terms (http://geneontology.org/) and identified Kyoto Encyclopedia of Genes and Genomes pathways (www.genome.jp/kegg/) largely agreed with eukaryotic metaproteome patterns found by Schneider et al. (75). Junttila et al. (76) tracked the expression profiles during desiccation and rehydration using microarray analyses, but the data do not provide detailed insights into the regulatory processes. Most of the differentially expressed genes do not show sequence similarity to known genes. It is, however, remarkable that the largest changes of gene expression are observed only minutes after rehydration.

Given the complexity of lichens, it is not surprising that the functional contributions of genes are organ-specific and modified by pertinent ecological and developmental conditions. The partially annotated *P. membranacea* metagenome revealed the presence of mycobiont genes encoding galectin-like proteins, which are a family of proteins defined by their binding specificity for β-galactoside sugars (77). RNA-Seq data further showed that one of these genes, *lec-1*, was differentially expressed in rhizines, a purely fungal tissue, when compared to the remainder thallus, composed of both mycobiont and photobiont (73).

While forthcoming comparative genomics studies will inform us about the evolutionary dynamics of lineages diverging in lichen-symbiotic stages, transcriptomics, proteomics, and metabolomics will improve our understanding of the symbiotic regulation and processing. *Lobaria pulmonaria*, a tripartite lichen (including both a green algae and a cyanobacterium) widely distributed in the Northern hemisphere, has been featured in publications that have explored metaproteomic issues (75, 78). Most algal proteins were assigned to energy production and conversion. Carbohydrate transport and metabolism were significant in both eukaryotic partners, but fungal functions were more diverse, with substantial read numbers suggesting biogenesis and posttranslational modification. The bacterial fraction (see also below) in the metaproteome was dominated by proteins from *Alphaproteobacteria*. The identified proteins are primarily involved in energy conversion and carbohydrate metabolism, as well as responses to stress. Also, some of the bacterial proteome spectra suggested a role of bacteria in secondary metabolite synthesis, but this has not been resolved in full detail so far.

FUNGAL-ALGAL CONNECTIONS AND INTERACTIONS IN THE THALLUS

The main role of the algal partners is the provision of photosynthetically fixed carbohydrates as the energetic basis for the self-sustained lifestyle. The lichen-forming fungi take up osmotically active monomeric sugars from the algae, which are then further metabolized. Typically, green algae supply polyols (ribitol in chlorococcal algae and erythritol in filamentous *Trentepohliales*), whereas glucose is provided by cyanobacterial algae. Apparently the process of lichenization also stimulates upregulation of photo-protective mechanisms in the photobiont (79). In turn, the photobiont stimulates the antioxidant system of the mycobiont (8, 9). Currently, it is not well known which chemical signals are transferred during the initiation and onset of lichenized stages or what effects they have in the symbiosis. By comparing algal strains, Meessen and Ott (80) detected characteristic metabolites in lichen-forming algae, such as the cyclic dipeptides cyclo-L-leucyl-L-tyrosine and cyclo-(L-tryptophyl-L-tryptophyl), rhamnose, and indole-3-carbaldehyde, a precursor or a degradation product of the phytohormone indole-3-acetic-acid. Because hyphal branching is not stimulated with these substances alone, but when unicellular algae grow in proximity (81), further metabolites seem to be involved in the signaling of lichenization. Such molecules probably include the

phytohormones abscisic acid and ethylene, as well as others (82, 83, 84).

The fungal partner frequently produces attachment or penetration structures (appressoria or haustoria, respectively) of different kinds at the mycobiont-photobiont interface. Water and dissolved nutrients can move readily between the bionts at the contact zone, within a hydrophobic coat that the fungus produces over the algal cell surface (85, 86).

Lichen fungi associate with only about 120 known species of algae, most of them green algae, and a few cyanobacterial algae (86), although the species taxonomy is so poorly understood in lichenized cyanobacteria that these currently cannot be identified to the species level (87). The photosynthetic partners are green algae in about 90% of lichen species. Hence, 10% of the lichens take advantage of bacterial nitrogen fixation and associate with cyanobacterial algae, usually with filamentous *Nostoc* strains. Another strategy is the additional association with *Nostoc* strains in specialized organs (cephalodia; Fig. 6A) in or on a green-algal thallus (88), resulting in tripartite lichens, which apparently evolved as a segregation of functions. The higher proportion of heterocysts suggests a main role of cephalodia in nitrogen fixation (89). On the other hand, several cyanobacterial lichens may also have green algae in addition to the cyanobacteria in their photosynthethic layer (90), which might widen their ecological amplitude in cool habitats. Few fungal species are even able to use either eukaryotic green or prokaryotic blue-green algae to develop independent symbiotic thalli (91). These phycosymbiodemes, primarily found in the order *Peltigerales* of the class *Lecanoromycetes*, either have similar morphologies or are shaped profoundly differently (Fig. 6B). When growing separately, they were described in independent genera, which has blurred the understanding of their phylogenetic relationships (92).

With very few exceptions, the green algae propagate clonally and do not form sexual structures in the lichenized stage. The apparent suppression of the sexual capacity of the algal partner by the lichen-forming fungi could be interpreted as a selfish strategy to avoid genetic diversification of the partner and to maintain efficient control over the algal physiology.

Refined molecular analyses meanwhile have helped to improve our knowledge about lichen photobiont diversity—their phylogenetic relationship as well as their patterns of association with their fungal hosts. Major mycobiont lineages seem to vary by their overall spectra of preferences for algal groups. While the majority of *Arthoniomycetes* have a preference for *Trentepohliaceae* (except for some species assigned to *Arthonia*), *Lecanoromycetes*, particularly members of the class *Chaetothyriomycetes* (above all, *Verrucariales*), associate with a broader range of green algae (43, 61, 93).

Recent work suggests that species of lichenized fungi frequently vary in their algal specificity and selectivity. This correlates with the range of the species and climatic differences; i.e., the same lichens occurring in different habitats often associate with related algal species with different ecological preferences (94, 95). This flexibility supports the hypothesis of habitat-adapted symbioses proposed by Rodriguez et al. (96), which suggests that the environment determines the optimal partnership of symbionts. Wedin et al. (97) showed that *Diploschistes muscorum* has an even more flexible photobiont strategy than earlier believed. *Diploschistes* starts as a parasitic fungus infecting the unrelated lichen *Cladonia* (Fig. 7), eventually taking over and forming an independent thallus. Although the *Cladonia*

used the same photobiont at all investigated sites, *Diploschistes* associated with different photobionts at all three sites, keeping the original *Cladonia* alga at one site but replacing it with others in the two other sites (97). This suggests a very generalistic photobiont strategy in this lichenicolous lichen.

Rikkinen et al. (98) suggested that lichen fungi in the *Peltigerales* form ecological photobiont guilds, within which the fungi share related photobiont cyanobacteria. Such associations can be seen both among an ecological assemblage of epiphytic macrolichens, the *Nephroma* guild, and among a group of predominantly terricolous cyanolichens, the *Peltigera* guild, where the photobionts with each guild are closely related *Nostoc* strains. Several authors have likewise observed similar photobiont-mediated guilds in green-algal lichens (5, 99).

ADDITIONAL FUNGI IN THE LICHEN SYMBIOSIS

Because lichen thalli are persistent and vary morphologically, they provide a rich diversity of small-scale niches for various microorganisms, in particular fungi and bacteria (discussed below). Lichenicolous fungi comprise all fungal species living in or on lichens, apart from the thallus-forming fungus itself (the mycobiont). This biological group has been studied extensively and was recognized even before the symbiotic nature of their lichen hosts was established. More than 1,800 species of lichenicolous fungi have been described (100), but as numerous new species are still being discovered, their precise number is unknown and is clearly currently much underestimated. The evolutionary origin of the lichenicolous lifestyle is diverse, but a substantial number of lichenicolous fungi apparently evolved after delichenization of originally lichenized lineages. Because most lichenicolous fungi seem to exploit their hosts without rapid destruction, they are highly specific for their hosts and for particular symbionts of the hosts.

Typically, lichenicolous fungi are recognizable by conspicuous reproductive structures or by their symptoms such as discolorations or gall-like hypertrophications. Some other species associate with lichens but remain cryptic. Isolation techniques and axenic cultivation revealed that these species either reside on the surfaces of the thalli (101–103) or occur internally in lichen host thalli (also known as “endolichenic fungi”) (104). Given the abundance and the potential of culturable endolichenic fungi to produce secondary metabolites, it might be debated whether these fungi have a biological effect on their host or influence the pheno-

type in various ways. However, even though microscopic evidence already demonstrates the endolichenic growth of fungi besides the mycobiont in lichens (86), it is not clear which of these fungi grow in lichens or reside as spores or otherwise in dormant stages.

Culture techniques have retrieved a surprisingly large number of fungal species from lichens (105), but these numbers represent only a subset of the total fungal diversity present in environmental samples. Therefore, culture-independent methods are now also employed to characterize the mycobiome of lichen thalli. Using DNA-fingerprinting techniques, Fleischhacker et al. (106) found a high diversity of lichen-associated fungi without correlation with the presence of externally visible lichenicolous fungi. Zhang et al. (107) provided an overview of diversity and distribution of fungi in lichens from an Arctic habitat using next-generation sequencing. Their study of the lichen mycobiome indicated that lichens harbor fungi related to those with diverse ecological contexts. Lichens thus represent a reservoir or an evolutionary hotbed for fungi that may have a role in other habitats, but the specific conditions in fungi with recurrent and prolonged cryptobiotic stages hardly favor the rise of, for example, a biotrophic plant pathogen. Studies in *Lobaria* revealed the high specificity of *Tremella lobariacearum* (108), but it is not known whether the same is true for nonsymptomatic occurrences of *Tremellomycetes*. Refined microscopic techniques can reveal to what extent the scattered occurrence of tremellalean fungi might influence the morphology of the host. Millanes et al. (109) described *Cystobasidiomycetes* as a new lineage of *Pucciniomycotina*. The lichenicolous members of this lineage, which primarily comprises yeasts, cause conspicuous fertile hypertrophications of their hosts. Recently, this lineage was found frequently in *Parmeliaceae*, and on the basis of their occurrence in the upper cortex it has been suggested that these yeasts play a role in the formation of the upper cortex (128). This exciting hypothesis needs further testing and confirmation.

BACTERIAL PARTICIPATION IN LICHEN THALLI

Fungi associated with lichens have been studied extensively for a long time, but the ubiquitous presence of bacteria in lichen thalli received more attention only comparatively recently. Sequencing of lichen-associated bacterial communities revealed information about their diversity on lichen thalli (110–118). *Alphaproteobacteria* usually dominate the bacterial communities in lichens, while other bacterial groups (frequently *Acidobacteria*, *Actinobacteria*, and *Betaproteobacteria*) are also found in significant numbers. One group of *Alphaproteobacteria*, the lichen-associated *Rhizobiales*, is a clade of bacteria so far known only from lichens (113, 115). Sequence-based data are complemented with microscopic information, in particular, employing fluorescence *in situ* hybridization (119). The distribution of bacteria belonging to certain groups can be visualized under the microscope using specific probes (confocal laser scanning microscopy). Bacteria often form biofilm-like communities on the lichen thalli and are usually tightly connected with the fungal structures, in particular, with hydrophilic surfaces of the lichens. The bacteria can also intrude to various depths in the intercellular matrix of the upper cortex and are occasionally also found inside the hyphae of the fungal hosts (120). The lichen-associated bacterial communities so far investigated are host-specific in their composition (112, 115). A clear shift in microbiome profile is observed when the parasitic lichen *D. muscorum* infects, and eventually overcomes, *Cladonia symphycarpa* to form a thallus of its own (97) (Fig. 7). Here, the *Alphaproteobacteria* population dominating the *Cladonia* microbial community decreases during the transition, and the numbers of *Betaproteobacteria* or *Chloroflexi* increase substantially when *Diploschistes* takes over, supporting the view that the microbial community is highly species-specific in lichen thalli. Multiomics approaches to the bacterial communities of lichens finally suggest potential contribution to a number of symbiotic functions in lichens (78).

CONCLUSIONS

Phylogenetic studies significantly improved our understanding of the evolution and phenotypic diversification of lichenized fungi and their partners. Lichen thalli are dominated by the primary fungal symbiont, which controls the characteristic photosynthetic partners. In addition to these commonly known symbionts, unknown numbers of additional organisms can participate in the symbiont system (121). The analysis of massive amounts of molecular data from lichens, which has just started to be collected, will help us to further understand the role of these complex and fascinating partnerships.

Fungal Plant Pathogenesis Mediated by Effectors

37

Pierre J.G.M. de Wit,[1] Alison C. Testa,[2] and Richard P. Oliver[2]

INTRODUCTION

The interactions between fungi and plants encompass a spectrum of ecologies ranging from saprotrophy (growth on dead plant material) through pathogenesis (growth of the fungus accompanied by disease on the plant) to symbiosis (growth of the fungus with growth enhancement of the plant). We consider pathogenesis in this article and the key roles played by a range of pathogen-encoded molecules that have collectively become known as effectors.

Pathogenesis can be defined in terms of either the pathogen or the host. In the former the key factor is reproduction and propagation of the fungus while having a negative impact on the growth rate or product quality of the susceptible host plant. In the latter we focus on the expression of symptoms induced by the pathogen, which range from visible sporulation of the pathogen on an otherwise apparently healthy plant, as in the case of biotrophic pathogens such as powdery mildews and rusts, to the spots, blotches, and rots caused by necrotrophic pathogens. In all cases there is diminution of the reproductive potential of the host, and from an agricultural perspective, reduced quantity and or quality of the desired plant product.

Phytopathogenesis is also caused by oomycetes, bacteria, and viruses and even by animals such as nematodes. Theories of pathogenesis have been developed collectively between these pathogen types, but in this article we consider only the fungi and focus on a small number of key diseases that have formed the bulk of the experimental models.

Much progress has been made in the past decade in our understanding of the mechanisms of infection of plants by these pathogens with different lifestyles, and the key unifying concept is the fungal effector. Effectors are defined as pathogen molecules that have an impact on the outcome of the interaction with the host. This usage was adopted from the medical literature (1), initially in studies of plant pathogenic bacteria (2). The concept has also been adopted by the plant-fungal research community and encompasses effectors that have both positive and negative impacts on pathogen proliferation (3, 4). Here, we mainly focus on effectors whose intrinsic functions and host targets are known.

All plants are resistant to the majority of fungal species. Plants possess PRRs that recognize MAMPs (also known as pathogen-associated molecular patterns) and mediate MTI (or pathogen-associated molecular pattern-triggered immunity), an array of basal defense responses effective against potential pathogens (5). Successful pathogens secrete effectors that suppress MTI and alter host plant physiology to their own advantage (6). In turn, plants have evolved immune receptors, also known as resistance proteins, which recognize effectors, resulting in ETI (7). ETI usually involves the HR that induces localized cell death and is normally sufficient to combat biotrophic plant pathogens that feed only on living cells. Hemibiotrophic pathogens start infection biotrophically, but at the end of the infection cycle when host tissues collapse, they start to feed as a necrotroph on dead host tissue. Yet other pathogens, known as the necrotrophs, were considered to be primitive pathogens that simply kill host tissue before they start to feed on it. However, more detailed analysis of the infection process and comparison of genome sequences has shown that these pathogens use effectors to subvert the resistance process to create appropriate conditions for colonization, a process called NETS (8–10).

Abbreviations

CC, coiled coil; EDS, enhanced disease susceptibility pathway; ETI, effector-triggered immunity; HGT, hori-

zontal gene transfer; HR, hypersensitive response; HST, host-selective toxins; LRR, leucine-rich repeat; MAMP, microbe-associated molecular pattern; MTI, MAMP-triggered immunity; NBS, nucleotide binding site; NE, necrotrophic effector; NEP1, necrosis- and ethylene-inducing protein 1; NETS, necrotrophic effector-triggered susceptibility; NIP1, necrosis-inducing protein 1; NLP, necrosis- and ethylene-inducing protein 1-like protein; PCD, programmed cell death; PR, pathogenesis related; PRR, pattern recognition receptor; RIP, repeat-induced point; RLK, receptor-like kinase; RLP, receptor-like protein; ROS, reactive oxygen species; sRNA, small RNA; SSCP, small secreted cysteine-rich protein; TIR, toll-interleukin receptor.

ENTRY AND FEEDING OF FUNGAL PATHOGENS

Pathogenic fungi enter plants via natural openings (e.g., stomata) or wounds or penetrate directly using a penetration peg produced by an appressorium (Fig. 1). The key attribute of biotrophic pathogens is the haustorium, a specialized feeding organ for the retrieval of nutrients. Haustoria develop by local penetration of the cell wall and invagination of the plasma membrane, which is surrounded by an extrahaustorial matrix through which nutrient uptake and communication with the host take place (11). In powdery mildews, haustoria are formed directly from the appressoria in epidermal cells. The rusts and smuts invade through stomata and then produce an intercellular mycelium that surrounds mesophyll cells from which a haustorium mother cell and subsequently a haustorium is produced. Hemibiotrophic pathogens encompass a range of pathogenic strategies. Some, such as *Colletotrichum* spp. and *Magnaporthe oryzae*, produce intracellular feeding structures known as biotrophic interfacial complexes (12), while others, such as *Cladosporium fulvum* and *Zymoseptoria tritici*, remain extracellular within the apoplast throughout their lifecycle (13). Vascular wilt pathogens colonize xylem vessels and are in close contact with parenchyma cells.

(**g**) Conidiophores bearing abundant conidia on the underside of an otherwise healthy tomato leaflet.

FUNGAL INFECTION STRATEGIES

The infection strategies employed by fungal plant pathogens depend on where they thrive in their host plants. The cell wall is a major physical and chemical barrier obstacle because it contains the plant waxy cuticle, (lignified) cell walls, antimicrobial metabolites, and PR proteins (14). The sequencing of many fungal genomes has shown that pathogenic fungi contain many genes encoding different classes of cell-wall-degrading enzymes. The expression of these genes is highly upregulated during infection by necrotrophic plant pathogens (15). Biotrophic pathogens generally contain fewer genes encoding cell-wall-degrading enzymes than hemibiotrophs and necrotrophs (6). Necrotrophic fungi often also produce secondary metabolites that are toxic to plant cells, thereby facilitating their necrotrophic lifestyle, while these metabolites often have low expression or are absent in biotrophic pathogens. For example, the powdery mildew *Blumeria graminis* contains hardly any genes encoding biosynthetic enzymes for secondary metabolites (16), while in the biotrophic tomato leaf pathogen *C. fulvum* these genes are downregulated during infection (17).

Fungi protect themselves against antifungal proteins and metabolites that are present in plant cell walls and the apoplast by producing detoxifying enzymes such as proteases produced by *Fusarium oxysporum* f.sp. *lycopersici* (Fol) to degrade plant chitinases (18) or tomatinase produced by *C. fulvum* to detoxify the saponin α-tomatine to tomatidine (19).

PLANT DEFENSE

Plants have developed sophisticated defense strategies to recognize pathogens and to defend themselves against fungal pathogens. Recognition of chitin as a MAMP by PRRs induces MTI, an array of structural and chemical defense responses including callose deposition, accumulation of ROS, cell wall enforcements, and accumulation of PR proteins including chitinases, proteases, and glucanases that protect plants against potential microbial pathogens (20–22). PRRs are extracellular LRR-containing transmembrane proteins with a cytoplasmic kinase signaling domain known as RLK (23), S-RLKs, or extracellular membrane-localized LRRs that require association with RLKs to become activated by MAMPs. Successful pathogens have found ways to overcome these responses. They can suppress MTI by secreting different types of effectors that target various components of MTI (24–26). By suppressing MTI they achieve effector-triggered susceptibility. Alternatively, necrotrophic fungi produce effectors that induce necrosis and thereby create the dead tissue that supplies the nutrients the pathogens need. This is called NETS (9).

Effectors have mainly been described for various biotrophic but more recently also for hemi-biotrophic and necrotrophic fungi (6, 27, 28). All effectors manipulate host defense responses and host physiology to facilitate host colonization in various ways and are considered genuine virulence factors (6).

EFFECTORS PRODUCED BY OBLIGATE BIOTROPHIC, BIOTROPHIC, HEMIBIOTROPHIC, AND NECROTROPHIC FUNGAL PATHOGENS

Soon after Flor (29) postulated the gene-for-gene hypothesis, the search for the postulated gene products started. The hypothesis proposed that products of fungal avirulence genes interact with products of matching plant resistance genes, triggering defense responses often associated with an HR. The capacity to induce an HR facilitated the identification and characterization of Avr factors and cloning of their encoding genes. The *Avr9* gene of *C. fulvum* was the first fungal *Avr* gene to be cloned (30). Not much later the *Avr9* gene facilitated cloning of the matching *Cf-9* resistance gene, by a transposon tagging approach (31). Subsequently, multiple *Avr* genes complying with the gene-for-gene system have been cloned from different biotrophic and hemibiotrophic pathogens (6). Table 1 gives an overview of fungal effectors for which the function is known or for which a host target of a matching resistance gene has been cloned. Only those effectors for which a biological function has been found will be discussed in any detail.

Table 1 shows clearly that effector genes are very diverse and species specific. All effectors are secreted into the apoplast between host cells or into the extrahaustorial matrix (Fig. 2). Proteinaceous effectors of fungal pathogens are all secreted into the apoplast, where most of them function as inhibitors of basal plant defense. Many of them are SSCPs with even numbers of cysteine residues. In mature proteins they form disulfide bridges, making them resistant against multiple antimicrobial plant enzymes such as proteases, chitinases, or glucanases. Most effectors are also recognized by host immune receptors causing ETI. Thus, knocking out or silencing effector genes in different plant pathogenic fungi compromises not only avirulence on resistant cultivars with matching *R* genes, but also virulence on plants lacking these *R* genes (25). The expression of nearly all effector genes is strongly upregulated *in planta*, stressing their importance in virulence, likely due

Table 1 Effectors from obligate biotrophic, hemibiotrophic, and necrotrophic fungal pathogens whose intrinsic function, host target, or matching resistance gene is known[a]

Pathogen species and host	Lifestyle classification	Effector	Molecule	Molecular function/ structure	Localization in plant	Role in virulence	Resistance gene and protein (type)	Target	Reference(s)
Melampsora lini/flax	Obligate biotroph	AvrL567 (A, B and C)	Protein		Cytoplasm		*L5*, *L6*, and *L7* (TIR-NBS-LRR)		118
		AvrM	Protein		Cytoplasm		*M* (TIR-NBS-LRR)		117
		AvrP123	Protein	Kazal Ser protease inhibitor	Cytoplasm		*P*, *P1*, *P2*, and/or *P3* (TIR-NBS-LRR)		117
		AvrP4	Protein	Cystine knotted peptide	Cytoplasm		*P4* (TIR-NBS-LRR)		117
Blumeria graminis f.sp. *hordei*/ *barley*	Obligate biotroph	BEC4	Protein	Interaction with ADP ribosylation factor-GTPase-activating protein ARF-GAP proteins	Haustorium	Interference with host vesicle trafficking		ERF19	118
		Avra10	Protein		Probably in cytoplasm		*Mla10* (CC-NBS-LRR)		119
		Avrk1	Protein		Probably in cytoplasm		*Mlk1* (CC-NBS-LRR)		119
		CSEP0055	Protein	Binding to PR1 and PR17c	Apoplast	Required for penetration by secondary hyphae		PR1 and PR17	120
Cladosporium fulvum/tomato	Biotroph	Avr2	Protein	Cysteine protease inhibitor	Apoplast	Cysteine protease inhibition	*Cf-2* (RLP)	Rcr3 and Pip1	38, 121, 122
		Avr4	Protein	Chitin binding	Apoplast	Protects against chitinases	*Cf-4* (RLP)	Chitin	44, 45, 123
		Avr9	Protein	Cystine knotted protein	Apoplast	Unknown	*Cf-9* (RLP)		32, 124, 125
		Ecp6	Protein	Chitin binding (3 LysM domains)	Apoplast	Knock-down leads to reduced virulence		Chitin sequestering and perturbation of chitin receptor	126, 127
		Cftom1	Protein	Glycosidase	Apoplast	Deglycosylates α-tomatine into tomatidine; required for virulence		α-Tomatine	19

Ustilago maydis/maize	Biotroph	Cmu1	Protein	Inhibition of chorismate mutase required for SA biosynthesis	Cytoplasm	Inhibition of biosynthesis and plant defense responses		Chorismate mutase Cmu1	128
		Pep1	Protein	Inhibition of peroxidase-mediated ROS production by POX12	Apoplast	Required for pathogenic spread between host cells		Peroxidase POX12	129, 130
		Pit2	Protein	Cysteine protease inhibition	Apoplast	Reduced tumorigenesis		CP2, CP1A/B, XCP2 proteases	131
		Tin2	Protein	Enhances anthocyanin biosynthesis	Cytoplasm	Reduced supply of coumaric acid affects lignin biosynthesis		Protein kinase ZmTTK1	
Magnaporthe oryzae/rice	Hemibiotroph	Avr-Pita	Protein	Homology to metalloprotease, (not active enzyme)	Cytoplasm	Not required for virulence on rice	*Pi-ta* (CC-NBS-LRR)		49
		Avr-Pita2	Protein	Homology to metalloprotease, not active enzyme)	Probably in apoplast	Probably not required for virulence on rice	*Pi-ta* (CC-NBS-LRR)		132
		Avr-Pita3	Protein	Homology to metalloprotease, (not active enzyme)	Probably in cytoplasm	Probably not required for virulence on rice			132
		Pwl1	Protein	Glycine-rich hydrophilic protein	Probably in apoplast				133
		Pwl2	Protein	Glycine-rich hydrophilic protein	Probably in apoplast				134
		Ace1	Polyketide-nonribosomal peptide	Hybrid polyketide synthase/ nonribosomal peptide synthetase	Not secreted		*Pi33*		135
		Slp1	Protein	Chitin binding	Apoplast	Suppression of MAMP responses	*CEBiP* (RLK)	Chitin	136
		AvrPiz-t	Protein	Inhibition of RING E3 ubiquitin ligase	Cytoplasm	Suppression of PTI	*Piz-t* (NBS-LRR)	APIP6	53
Rhynchosporium secalis/barley	Hemibiotroph	NIP1	Protein	Stimulation of plasma-membrane H+ ATPase	Apoplast	Nonspecific toxin/ induces necrosis	*Rrs1*	Plasma-membrane H+ ATPase	93, 94
Fusarium oxysporum f. sp. *lycopersici*/tomato	Vascular wilt	Avr1 (Six4)	Protein		Xylem	Suppression of I-2 and I-3-mediated resistance	*I-1* (Not cloned)		137

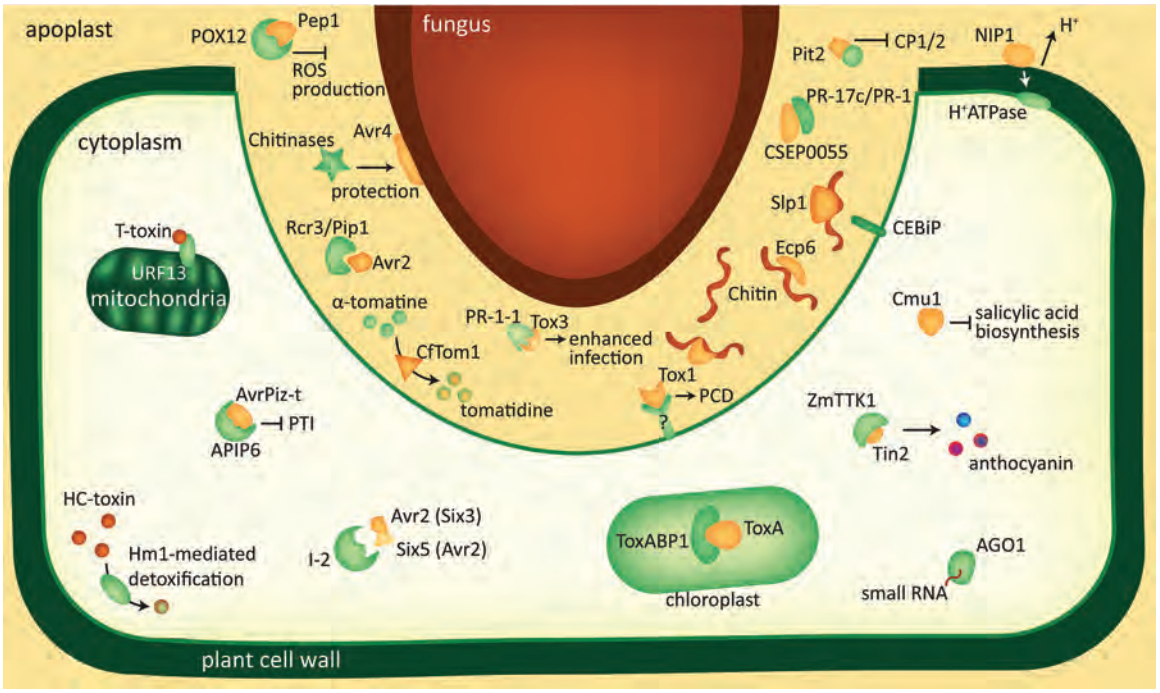

Figure 2 Interactions of fungal effectors with targets in plant host cells in biotrophic, hemibiotrophic, and necrotrophic diseases. The fungal cell interacts with the host cell via the yellow space, which represents either the extrahaustorial, matrix surrounding the haustorium, or the apoplast. Effectors from a range of fungi are presented in yellow, and their plant targets in green. Additional information is provided in Table 1. Adapted from reference 6.

to specific plant factors, but these have not been identified yet. For a few effector genes, nitrogen-limiting growth conditions induced their expression (32–34), but whether this reflects the *in planta* situation is uncertain.

EFFECTORS PRODUCED BY OBLIGATE BIOTROPHIC FUNGAL PATHOGENS

The gene-for-gene hypothesis was postulated by Flor (35) to explain the rust disease caused by the obligate biotrophic fungal pathogen *Melampsora lini* on flax. Several effectors from *M. lini* have been cloned, but their role in virulence is not known yet because transformation and targeted gene replacement have not been achieved for rust fungi. AvrP123 has structural homology with the Kazal Ser protease inhibitor, but whether this protein exhibits this function is not known. The same is true for AvrP4, which is a structural knotted peptide that is structurally related to the Avr9 protein of *C. fulvum*. Interestingly, the effector proteins from *M. lini* are translocated into the host cytoplasm, where they directly interact with TIR-NBS-LRR resistance proteins that are independent of the EDS1 defense pathway (36). Direct interaction between effectors and cytoplasmic immune receptors is the exception rather than the rule (37). Several effector genes have been cloned from the powdery mildew pathogen *B. graminis* f.sp. *hordei* including *Avra10* and *Avrk1*. These are recognized by cytoplasmic CC-NB-LRRs that trigger an EDS1-dependent defense pathway, but their intrinsic functions or host targets are not known. Two other *B. graminis* f.sp. *hordei* effectors have been described. BEC4 is secreted and reported to interact with ADP ribosylation factor-GTPase-activating proteins (ARF-GAP), while CSEP0055 binds to pathogenesis-related proteins PR1 and PR17c, whose functions are unknown. No plant immune receptors for BEC4 and CSEP0055 have been identified.

EFFECTORS SECRETED BY BIOTROPHIC AND HEMIBIOTROPHIC FUNGAL PATHOGENS

Effectors with Protease or Protease-Inhibiting Activities

The biotrophic extracellular tomato pathogen *C. fulvum* secretes several SSCPs in the apoplast of tomato leaves.

CfAvr2 inhibits the apoplastic tomato cysteine proteases Rcr3 and Pip1 (38, 39). Interaction of CfAvr2 with Rcr3 activates Cf-2-mediated defense in tomato (39). Interaction with the RLP Cf-2 is indirect and is a good example of the guard hypothesis, in which a resistance protein guards the host target of a fungal effector. Rcr3 is an important basal defense enzyme of tomato because it is also a target for secreted Oomycete (40) and nematode (41) effectors. Several effectors of other biotrophic fungi target plant cysteine proteases (42). Pit2 of *Ustilago maydis* inhibits the apoplastic maize cysteine proteases CP1 and CP2.

CfAvr9 has been suggested to be a carboxypeptidase-inhibiting protein because its structure is very similar, but carboxypeptidase activity has never been detected. CfAvr9 is recognized by the RLP Cf-9. Most of the SSCPs of *C. fulvum* have been reported to be recognized by RLPs (43). Interestingly, the biotrophic pathogen *U. maydis* secretes many effectors into the apoplast, where they exert their function or are translocated into the host cell, with or without a leader sequence, but none of them is recognized by resistance proteins in cultivated or wild corn species (6). During coevolution, they likely have become important core effectors after adapting or losing structural domains required for recognition by immune receptors.

Effectors with Chitin-Binding or Chitinase-Degrading Activities

Plant chitinases are crucial in basal plant defense as has become clear from the activity of several fungal apoplastic effectors. CfAvr4 contains a chitin-binding domain that protects fungal cell walls against hydrolysis by these enzymes (44, 45). Functional homologues of CfAvr4 occur in several related Dothideomycete fungi. *C. fulvum* Ecp6 binds chitin and does not protect against plant chitinases, but scavenges chitin fragments released by plant chitinases in the apoplast during infection and interferes with chitin-receptor heterodimerization, thereby suppressing chitin-induced basal defense responses. The wheat pathogen *Z. tritici* carries three Ecp6 homologues: Mg1LysM and Mg3LysM, which protect the fungus against plant chitinases, and Mg3LysM, which scavenges chitin fragments and suppresses chitin-induced basal defense responses (46). In addition, intercellular hyphae of *M. oryzae* secrete a chitin-binding protein, Slp1 (secreted LysM protein 1), which suppresses chitin-induced basal defense responses. The only cloned immune receptor that likely directly interacts with a chitin-binding protein is the tomato RLP Cf4, which matches CfAvr4 as well as other CfAvr4 homologues from other Dothideomycete pathogens (47). Interestingly, the necrotrophic fungal wheat pathogen *Parastagonospora nodorum* effector SnTox1 can also bind to chitin to protect the fungus against plant chitinases, indicating a dual function (48). *F. oxysporum* f.sp. *lycopersici* (Fol) secretes the metalloprotease FoMep1 and the serine protease FoSep1, which synergistically cleave tomato chitinases, reducing their antifungal activity and enhancing fungal virulence on tomato (18).

Apoplastic Effectors Inhibiting Other Apoplastic and Cytoplasmic Defense Enzymes

M. oryzae secretes the effectors Avr-Pita, Avr-Pita2, and Avr-Pita3, which all show homology to metalloproteases, but enzymatic activity has never been reported, nor has a role in virulence (49). They are recognized by the CC-NB-LRR immune receptor Pita (50). *U. maydis* secretes Pep1, which inhibits peroxidase POX12-mediated production of ROS. Fol secretes tomatinases that deglycosylate the saponin α-tomatine into the less antifungal β2-tomatidine (51), while *C. fulvum* secretes the α-tomatinase CfTom1, which deglycosylates and detoxifies α-tomatine into tomatidine (19). *U. maydis* secretes Cmu1, a chorismate mutase, to inhibit the production of the defense hormone salicylic acid (52). *M. oryzae* secretes AvrPiz-t, which is translocated into the plant cell and inhibits the RING E3 ubiquitin ligase APIP6 (53). Many more enzyme effectors are encoded by fungal genomes, but their role in virulence still needs to be determined (54).

The Effectors of the Vascular Wilt Pathogen *F. oxysporum* f.sp. *lycopersici*

A distinct group of pathogens colonize the xylem and induce wilt symptoms. The effector repertoire of Fol is well studied. Many Six (secreted into the xylem) proteins have been isolated from xylem fluids of Fol-infected tomato plants. Several of these Six proteins are Avr factors. Avr1 (Six4) is not required for virulence (in tomato) and is recognized by *I-1*, but it also suppresses *I-2*- and *I-3*-dependent resistance (55). Avr2 (Six3) is required for virulence and is translocated into the cytoplasm of host cells, where it is recognized by I-2 (56). Avr3 (Six1) is required for virulence and is recognized by I-3 (57). Also, Six5 is a virulence factor and is, like Avr2, recognized by I-2, but it requires interaction with Avr2 and vice versa for recognition by I-2 (58). In addition, Six6 contributes to virulence and suppresses I-2-mediated cell death but does not overcome I-2-mediated resistance (59).

Interestingly, Fol effectors are recognized by three types of immune receptors. Avr2 is recognized by I-2, a

cytoplasmic CC-NBS-LRR protein (60). Avr3 is secreted into the apoplast, where it is recognized by I-3, a cell surface-localized S-RLK (61), whereas the as yet unidentified Avr7 effector is recognized by I-7, a cell surface-localized RLP (62). I-7 provides resistance to races carrying Avr7, and its activity is not suppressed by Avr1. Avr1 is recognized by I-1 and encoded by a gene that has not been cloned yet, but it is also likely to be a cell surface-localized RLP. Interestingly, Avr1 inhibits ETI triggered by the Avr2/I-2 and Avr3/I-3 gene pairs, whose defense pathways are EDS1-independent, whereas Avr7-triggers an I-7-mediated defense pathway that is EDS1-dependent and cannot be inhibited by Avr1. It is also interesting that triggering of I-3-mediated resistance requires two effectors, Avr2 (Six3) and Six5 (Avr2), which interact with each other. The tomato vascular wilt pathogen *Verticillium dahliae* secretes Ave1 into xylem vessels, where it is recognized by Ve1, a cell surface RLP, (63). Ave1 shows homology with plant expansins and occurs in several other fungal pathogens and many plants (63, 64).

Effectors Secreted by Necrotrophic Fungal Plant Pathogens

Necrotrophic fungi are defined by their growth on dead or dying host tissues. Necrotrophs include species with broad host ranges, such as *Botrytis cinerea*, and these are predicted to produce effectors that are broad-spectrum phytotoxins. A second group of necrotrophs have narrow host ranges and produce a subset of effectors, now known as NEs, that contribute to virulence by inducing necrosis or chlorosis in specific genotypes of the single host species. Previously known as host-selective or host-specific toxins, these HSTs reproduce all or some of the disease symptoms induced by the pathogen itself (65). They are very diverse (Table 1) and include proteins and structurally diverse secondary metabolites. Most of these species are found in the Pleosporales family within the Dothideomycetes.

These NEs are involved in an inverse gene-for-gene interaction with host susceptibility genes, where the effector gene product interacts with the product of a matching host susceptibility gene, resulting in host susceptibility. Multiple studies now support that certain necrotrophic pathogens use the host's defenses to their advantage (66, 67) by tricking the plant into killing its own cells rather than the pathogen directly killing the plant cells. This can occur in a similar manner to *Avr* and *R* gene product interactions reported for several biotrophs, in that the NE and its recognizing host gene product interact, inducing an HR and local cell death. This prevents colonization of host tissue by biotrophic pathogens but provides a food source for necrotrophic pathogens. As such, the presence of both the NE and the matching host target leads to susceptibility, and absence of either the NE or the host target confers resistance. This strategy has been termed NETS (9).

Secondary Metabolite HSTs as NEs

The first HST to be discovered was AK-toxin in 1933, a necrosis-inducing epoxy-decatrienoic acid ester produced by the Japanese pear-infecting pathotype of *Alternaria alternata* (68). Deletion of one or more of the genes involved in the biosynthesis of AK-toxin resulted in loss of virulence (69). Since the discovery of AK-toxin, other pathotypes of *A. alternata* have also been found to produce secondary metabolite NEs. In each case the NE is the single determinant of pathogenicity and host range (70). The chemical structures of six of the seven *Alternaria* spp. HSTs have been determined, the exception being AT-toxin from the tobacco-infecting pathotype. AK-toxin and the toxins of the strawberry- and pear-infecting pathotypes, AT-toxin and ACT-toxin, are structurally analogous esters of a 9,10-epoxy-8-hydroxy-9-methyl-decatrienoic acid (70). The genes for the *A. alternata* HSTs are located on small chromosomes that are dispensable for growth, called conditionally dispensable chromosomes. Strong evidence has been obtained that these conditionally dispensable chromosomes can transfer horizontally between different *A. alternata* subspecies (71).

Victorin is the product of a nonribosomal peptide-synthetase produced by *Cochliobolus victoriae*, the fungal pathogen responsible for Victoria blight on oats (*Avena sativa*). Victorin induces cell death in certain varieties of oat, leading to susceptibility. The susceptibility gene, named *Vb*, has not been cloned, but strong evidence supports it being the same gene that confers resistance to crown rust, caused by the obligate biotroph *Puccinia coronata*. *Arabidopsis thaliana* also is sensitive to victorin (72), and the sensitivity gene *LOV1*, which encodes a NB-LRR repeat protein has been cloned (73). The inherent function of victorin is to inhibit a thioredoxin TRX-h5 that would normally provide a level of defense. Inhibition of TRX-h5 is not sufficient to promote disease. However, in the presence of LOV1, victorin induces defense responses that cause host cell death and lead to disease expression (74).

A related *Cochliobolus* species, *Cochliobolus carbonum*, causes northern corn leaf spot and ear rot on corn. *C. carbonum* produces a cyclic tetrapeptide called HC-toxin, which is responsible for increased virulence on susceptible corn plants (75). HC-toxin inhibits maize

histone deacetylases and thereby weakens the plant's defense. Susceptibility is conferred by lack of the *Hm1* gene, which encodes a reductase that detoxifies HC-toxin. *Hm1* was the first plant resistance gene to be cloned. While HC-toxin is produced by a necrotrophic pathogen and is considered an HST, it is different from the other effectors described here in that it suppresses rather than evokes host defense responses and in that susceptibility is conferred by the lack rather than the presence of a host gene.

Cochliobolus heterostrophus race T produces a polyketide toxin called T-toxin. Race T isolates are highly virulent on corn varieties carrying the Texas type male sterile cytoplasm (*T-cms*), due to an interaction between T-toxin and a mitochondrial membrane protein named URF13 present in these cultivars (76, 77). This interaction compromises the functioning of the mitochondria, resulting in cell death and increased virulence.

Proteinaceous Effectors Secreted by Necrotrophic Fungal Plant Pathogens

The NE ToxA, encoded by the gene *PtrToxA*, was identified in the wheat pathogen *Pyrenophora tritici-repentis* in the late 1990s and has since been arguably one of the most studied proteinaceous NEs (78). *SnToxA*, in the related pathogen *P. nodorum*, was identified due to its near perfect homology (99.7% amino acid identity) to the characterized *P. tritici-repentis* effector ToxA. Strong evidence supports this being an intriguing instance of recent (within the last century) horizontal gene transfer in which *P. tritici-repentis* was the recipient species (79). Different versions of SnToxA are found in different isolates of *P. nodorum*. The genes show signs of positive selection and possess varying levels of necrosis-inducing ability (80), indicating that modulation of the interaction with the host is crucial for isolate survival. All versions of SnToxA as well as PtrToxA interact with the same wheat recognizer gene *Tsn1*, a gene with a composite NBS-LRR structure (81). The direct or indirect interaction between of ToxA and Tsn1 plays a major role in susceptibility to both *P. nodorum* and *P. tritici-repentis*.

Sensitivity to ToxA results in necrosis and pathogen proliferation. In a susceptible plant, ToxA localizes to the mesophyll cells and binds to a chloroplast-localized protein named ToxABP1 and to plastocyanin (82). ROS then accumulate, followed by cell death. Determination of the ToxA crystal structure revealed a solvent-exposed loop harboring an arginine-glycine-aspartate motif (83), which is required for translocation into the host cell (84). Further details of the role of ToxA have come from metabolomics and proteomics studies which show that it induces a massive reprogramming of cellular metabolism and the induction of serotonin, an antifungal molecule that qualifies as a phytoalexin, a small molecule synthesized in response to a pathogen that has relevant antifungal activity (85, 86). The interaction between ToxA and Tsn1 is more recently reported to be mediated by an interaction with PR-1-5 (87).

The *P. nodorum* wheat disease has developed into a model system for understanding NE-based interactions. Three *P. nodorum* effector genes have, to date, been cloned. Following the identification of *SnToxA* in *P. nodorum*, a mapping and proteomics approach led to the identification of SnTox3—a 25.8-kDa protein with six cysteine residues that interacts with the recognizer protein *Snn3* (88). Subsequent studies showed that SnTox3 induces major biochemical defense responses including PR protein accumulation and the production of phenylpropanoid phytoalexins, but not serotonin (89). Like ToxA, Tox3 binds wheat PR-1 proteins. Tox3 specifically binds PR-1-1, leading to the formation of a peptide known as C-terminus of TaPR1-1 that enhances infection.

The identification of SnTox1 utilized the published genome sequence (90), using a bioinformatics scoring system based on the protein properties, genomic context, and interisolate comparisons to arrive at a list of putative effectors (91). SnTox1 is exceptionally cysteine-rich, because it contains 16 cysteine residues (13.7% cysteine). SnTox1 has a dual function in that it protects the fungus against host chitinases (48) while at the same time inducing defense-like responses in wheat carrying the *Snn1* susceptibility gene (92). The complexity of the interactions of ToxA, Tox1, and Tox3 with wheat belies the crude reputation of necrotrophic pathogens.

The NIP1 effector produced by the barley pathogen *Rhynchosporium secalis* is unusual because it is both an NE and an Avr factor (93–95). In the presence of the matching *Rrs1* gene, NIP1 is recognized and triggers defense responses and confers resistance. In the absence of *Rrs1*, NIP1 is a virulence factor, inducing necrosis (93–95). This is interesting, because both interactions induce necrosis but with different disease outcomes. Furthermore, different alleles of NIP1 induce differing levels of toxicity; however, the frequency of the different alleles in populations indicates that higher toxicity is not being selected for (93). This example hints at the complex nature of NEs, in that the timing and amount of necrosis may be important. Other NEs of *R. secalis*, namely NIP2 and NIP3, both induce necrosis but are not recognized as Avr factors.

NLPs AND SMALL RNAs SECRETED BY *BOTRYTIS* SPECIES

Botrytis species are pathogenic on both monocot and dicot plants. *B. cinerea* NLPs and homologous NLPs from other microorganisms are phytotoxic on many plant species. Two paralogous NLPs from *B. cinerea*, BcNEP1 and BcNEP2, produced in *Pichia pastoris* caused necrosis in many dicotyledonous plant species tested, but not in monocotyledons (95). Fluorescently labeled BcNEP1 and BcNEP2 proteins were associated with plasma membranes and the nuclear envelope, as well as in the nucleolus of responding plant cells. Strong accumulation of hydrogen peroxide was observed in chloroplasts. *Botrytis elliptica*, a pathogen of the monocot lily, also carries two *NLP* genes, *BeNLP1* and *BeNLP2*. Single knock-out mutants of *BeNLP1* and *BeNLP2* did not affect virulence of *B. elliptica* (96). Neither of the two BeNLPs produced in *P. pastoris* induced necrosis in lily. Because dicots but not monocots respond with necrosis after treatment with NLPs, these NLPs do not play a role in virulence on monocots. NLPs are under positive selection in *Botrytis* species, but their role in virulence on dicots remains to be elucidated (97).

sRNA effectors (98, 99) might play a role in the evolution of fungus-plant interactions. sRNAs are a new type of fungal effector that are delivered into host cells and suppress plant immunity by targeting *Argonaute 1* and thus disabling the host's RNA interference processes. Similar to effector genes, sRNAs are generated from repeat-rich regions of fungal genomes and appear to be subject to rapid evolutionary processes.

ORIGIN AND EVOLUTION OF EFFECTORS FROM FUNGAL PLANT PATHOGENS

Effector genes are subject to accelerated evolutionary processes we have termed "genomic tillage" (100). These evolutionary processes are selected because agri-ecological niches are subject to major and rapid (year-to-year) changes. New cultivars are regularly introduced and utilized in large monocultures to replace those whose resistance genes have been defeated. Furthermore, new agronomic techniques such as limited (or minimum or zero) tillage have had a major impact on crop diseases, and new fungicide classes are introduced about once every decade. Only those pathogens that can keep up with this rate of change remain able to cause significant diseases. The accelerated evolutionary processes include horizontal gene transfer, transposon activity, and RIP mutation, and they add to more familiar processes leading to point mutations and deletions.

It is no surprise, therefore, that many effector genes are located in repeat-rich regions that may have arisen through transposon activity and RIP mutation. This is most obviously illustrated by *Leptosphaeria maculans*, in which effector evolution is consistent with periodic episodes of transposon-induced RIP activity resulting in a highly compartmentalized genome (101, 102). Proximity to AT-rich repeats can increase gene mobility within the genome or between species (103) and could facilitate effector duplications, as are seen in the *PtrToxB* duplications in races of *P. tritici-repentis* associated with increased virulence (104) or the horizontal gene transfer of *ToxA* discussed above. Close proximity to AT-rich sequences has also been noted for some NEs. For example, *P. nodorum*'s *Tox3* gene is close to a region of AT-rich RIP-affected sequence around 10 kb long. Similarly, the genes required for the production of the *C. heterostrophus* secondary metabolite NE T-toxin exist within 1.2 Mb of AT-rich sequence (105).

As with Avrs, NEs have been observed to be under positive selection (97, 106, 107). In the *P. nodorum* wheat interaction, different ToxA isoforms vary in effector activity (108). This finding may be due to RIP activity, and it supported the hypothesis that variation at ToxA was due to selective pressure favoring increased virulence (108). In a similar manner to *Avr* and *R* genes, positive selection at NE and host recognition gene loci is probably indicative of the arms race between host and pathogen.

HGT was once thought to be an extremely rare occurrence or limited to species that were closely related and hence capable of normal gene-exchange processes. In addition to the HGT of the *ToxA* effector gene from *P. nodorum* into *P. tritici-repentis*, strong evidence exists that the *A. alternata* HST genes have transferred between the various pathotypes. Experimental demonstration of entire chromosome transfer between *F. oxysporum* f. sp. *lycopersici* and *Fusarium solani* f. sp. *pisi* has removed all doubt that this is a significant process. HGT has been shown to be more prevalent within the pathogen-rich *Pezizomycotina* subphylum than in other subphyla (109). Indeed, it seems certain that HGT has played a key role in the evolution of many pathogens and the recent emergence of certain crop diseases (110).

CONCLUSIONS AND FUTURE PERSPECTIVES

The first fungal protein effectors were discovered just over 2 decades ago (30, 77), although they were then called avirulence genes and host-specific toxins (65). Since then many more effectors have been discovered

together with their targets and recognizer genes. Estimates of the total number of effectors in a given species range from 20 to 200 (111), but given the somewhat arbitrary definition of effectors, the total number may be even higher.

Characterized effectors now include small RNAs, as well as small-molecular-weight compounds and proteins, and the latter are often posttranslationally modified (proteolytic cleavage, *N*-glycosylation, phosphorylation, etc.). They operate in the apoplast, the extrahaustorial matrix, the haustorium, the plant cytoplasm, or different cell organelles including chloroplast, mitochondrion, and nucleus. So far, we know they target plant antifungal compounds and antifungal defense pathways and camouflage fungal MAMPS, but this list of activities and targets is far from complete.

The isolation of effectors has significantly helped the identification of recognizer genes (31) and has also led to direct benefits to agriculture in a small number of cases (28). Knowledge of effector structure has been exploited to facilitate their discovery in related pathogens and in the selection of resistant host germplasm by plant breeders, but understanding and exploiting the overall complexity of the pathosystems remains a challenge (112).

Direct methods to exploit this knowledge for crop protection have so far proved rather elusive. While the general public's unease about genetically modified crops has not helped, the lack of broad-spectrum targets remains a real challenge. Effector families that are present in a wide range of pathogens, such as the Avr4 and Ecp6 families, may represent functions that could be targeted by a chemical, interfering RNA, or transgene. However, such families are rare, but we can expect that common functions will be found in more pathogens as more are studied. It is a fact of experimental life that many of the effectors cloned so far interact with resistance genes that are no longer effective in the field. The presence of both virulent and avirulent pathogens, and resistant and susceptible hosts, were essential experimental preconditions for the analyses. The ability of pathogens to evolve to overcome new *R* genes is well documented and is comparable to their ability to evolve resistance to fungicides (113). This ability is in part attributed to the location of effector genes in rapidly evolving parts of the genome (147) and in part to an unexpected propensity to acquire genes by horizontal transfer (100).

The identification of *L. maculans* effectors has enabled the rational deployment of resistance genes and has had a major impact on crop losses (114). Indeed, we can now acknowledge that our past practices of deploying resistance genes were as reckless as our deployment of antimicrobials directed against plant and animal pathogens. Knowledge of the structure of both effector and recognizer genes, coupled with vastly improved methods for the detection, differentiation, and quantification of pathogens, could be used in the stewardship of new *R* genes (whether genetically modified, genome edited, or conventional) (115). We can therefore conclude that the discovery of new effectors, their targets, and recognizer genes will all make major contributions to food security as well as reveal the exquisite complexity of plant fungal interactions.

Emerging Fungal Threats to Plants and Animals Challenge Agriculture and Ecosystem Resilience

38

Helen N. Fones,[1] Matthew C. Fisher,[2] and Sarah J. Gurr[1,3,4]

INTRODUCTION

While fungi can make positive contributions to ecosystems and agro-ecosystems, for example, in mycorrhizal associations, they can also have devastating impacts as pathogens of plants and animals. In undisturbed ecosystems, most such negative interactions will be limited through the coevolution of fungi with their hosts. In this article, we explore what happens when pathogenic fungi spread beyond their natural ecological range and become invasive on naïve hosts in new ecosystems. We will see that such invasive pathogens have been problematic to humans and their domesticated plant and animal species throughout history, and we will discuss some of the most pressing fungal threats of today.

Terms Used in This Article

Accessory chromosome: A chromosome additional to the basic karyotype complement, that is, the complete set of chromosomes, which is not necessarily present in all strains of a given species.

Adaptive potential: The capacity of an organism to adapt in response to changes in its environment.

Agro-ecosystem: The organisms coexisting on agriculturally managed land, along with the agricultural environment, as it affects those organisms.

Clonal spread: Movement of a group of genetically identical individuals.

Ecosystem services: Tangible and intangible benefits or consequences of ecosystem function.

Elite germplasm: Seeds (or equivalent) of an organism, specifically optimized to a particular environment, usually through commercial breeding.

Emerging pathogen: A pathogen responsible for a disease that is appearing in a new host or in a new place or increasing its occurrence in an existing host.

Endophyte: Used in this context to mean a fungus that lives within plant tissues for at least part of its life cycle without causing apparent disease.

Evolutionary potential: Capacity of an organism to acquire and retain new alleles, or to undergo shifts in allele frequency, in response to selection pressure.

Extinction/extirpation: Extinction is generally considered to be the death of the last individual of the species, while extirpation is the loss of a species in the chosen geographic area of study, though it still exists elsewhere.

Generalist pathogen: Generalists thrive in a wide variety of environmental conditions and can make use of a variety of different resources (for example, different host plants).

Heterothallic: Species which have sexes that reside in physically separate individuals.

Horizontal gene transfer (HGT): Acquisition of genetic material by one organism from a second, often nonrelated, organism. May be direct or via a vector such as a virus.

Hypervirulence: Unusually high virulence.

Hypovirulence: Decreased virulence.

Innate immunity: Nonspecific defense mechanisms against pathogen attack of animals or plants, usually most relevant during the initial phase of that attack.

[1]Department of Biosciences, University of Exeter, Exeter, EX4 4QD, United Kingdom; [2]Department of Infectious Disease Epidemiology, School of Public Health, Imperial College, London, St Mary's Hospital, London W2 1PG, United Kingdom; [3]University of Utrecht, 3584 CH, Utrecht, The Netherlands; [4]Rothamsted Research, North Wyke, Okehampton, EX20 2SB, United Kingdom.

Invasive species: An organism outside its native range, spreading rapidly and causing ecological and/or economic damage.

Long-distance dispersal: Spread of an organism to areas well beyond its current range, for example in international air currents.

Mycorrhiza: A symbiotic association between a fungus and the roots of a vascular plant.

Pandemic: An outbreak of infectious disease that spreads exceptionally widely: through populations, across countries, continents, or even globally.

Pathogenicity: The ability of an organism to cause disease in a particular host.

Obligate pathogen: Pathogens that must infect a host to survive, in contrast to other pathogens that are capable of survival independent of their host.

Saprophyte: A microbe that lives on dead or decaying organic matter.

Two-speed genome: A genome in which certain parts, which may range from specific, fairly small regions such as pathogenicity islands or entire (often accessory) chromosomes, are seen to evolve at a faster rate than the core genetic material.

Vertical transmission: "Inheritance" between generations; may refer to transmission of a pathogen or of genetic material (contrast to HGT).

Virulence: The severity of symptoms caused by a pathogen on a susceptible host.

Zoonoses: Disease of humans originating in animals and transmitted either directly or via a vector.

THE HISTORICAL IMPORTANCE OF FUNGAL DISEASE

Devastating fungal diseases of plants and animals can be identified throughout history. The decimation of harvests and ensuing famines, together with various efforts to prevent such outbreaks, are frequently described in early records. For example, wheat stem rust, caused by the fungus *Puccinia graminis* (still a problematic and invasive pathogen today; see "Current Examples of Emerging Infectious Fungal Diseases"), has been much feared for centuries (1). In the late 4th century BCE, in ancient Greece, Aristotle noted that this disease was favored by warmth and moisture (2). Meanwhile, the Romans held a festival, Robigalia, offering sacrifices to placate the god Robigo and protect cereal crops from such diseases (1). Around this time—circa 400 BCE—Hippocrates coined the words "endemic" and "epidemic" to distinguish between "normal" diseases such as coughs and colds and "abnormal" diseases such as plagues, in his Hippocratic corpus *Of the Epidemics*. References to plagues and pestilences of plants and peoples can also be found in the Bible as being heaven-sent curses or punishments.

Ergotism and Witchcraft

Fungal diseases of crops have, on occasion, led to some surprising social and political outcomes. A fascinating example is that of the ergot fungus, *Claviceps purpurea*. This pathogen of rye and other outbreeding cereal crops has a unique life cycle. Its sexual spores germinate on the stigmatic surface of its hosts' flowers, and its hyphae mimic pollen tube growth by extending downward to infect the ovary (3). The fungus then appropriates nutrients from the host to form a fruiting body, or sclerotium, in place of the developing seed. While fungal infection causes relatively little loss in yield, the grain quality is reduced due to the production of the fungal toxins ergotamine, ergine, and lysergic acid in the fruiting body (3). Ingestion of foodstuffs made from contaminated grain causes gastrointestinal symptoms followed by fatigue, depression, and painful muscular contractions. In more severe cases, vasoconstriction gives rise to "formication" (the feeling that the patient is covered in ants) and burning sensations and gangrene of the extremities, and psychoses may also occur (4). This suite of symptoms has long been recognized, with ergotism being dubbed "St. Anthony's fire" in the 11th century (5), but their source eluded mankind for centuries. The risk posed by ergot toxicity has diminished considerably since the identification of its fungal cause, with screening for contaminated seeds now in place. Nevertheless, there have still been isolated outbreaks, for example, in France in 1951 and in Ethiopia as recently as 2001 (6, 7). The most notorious case of ergot poisoning is perhaps that which triggered the 17th century witch trials in Salem, Massachusetts.

In a 17th century society dominated by political upheaval, puritanical Christianity, and social bickering, a group of young girls (aged 9 to 17) developed gastrointestinal symptoms, tingling and crawling sensations in the fingers, muscular contractions, mania, depression, and psychosis (4, 8). Unable to reach a diagnosis, a doctor suggested that the girls were bewitched (9). The patients then laid accusations of witchcraft against, initially, women on the fringes of the society (4, 8, 9). Fear and hysteria swept through the community and did not loosen its grip until 20 "witches" had been executed. At this time, similar symptoms were seen in Finnmark, Norway. Here, however, it was the patients themselves who were accused of witchcraft. A witch

hunt with even more tragic consequences than in Salem saw 137 people sent to trial, of whom around two-thirds were executed (10). In both Salem and Finnmark, it is thought that the illness which sparked the cycle of accusations, trials, and executions was due to ergotism (8, 9). Seasonal factors favoring the development of the fungus *C. purpurea*, including a cold winter followed by a humid spring, have been noted (4). Although other forces no doubt played a role in the extent of the accusations, it seems likely that *C. purpurea* triggered these ugly episodes, illustrating that fungi can influence human history in many ways.

Changing Landscapes: Chestnut Blight and Dutch Elm Disease

Emerging pathogens are those where the occurrence of the disease that they cause is entirely novel, or greatly increases, within a particular ecosystem. This may be due to the introduction of their host, either by man, due to a changed and newly permissive climate, or naturally; pathogen acquisition of new virulence genes or other traits allowing pathogenicity on a new host; or the appearance of a new genotype of a pathogen through hybridization, horizontal gene transfer, or other evolutionary events (discussed below in "Drivers for the Emergence of New Fungal Disease"). In the 20th century, two forest diseases emerged which destroyed large numbers of trees in Europe and North America. These serve as good examples of the damage done by emerging fungal pathogens in the recent past.

Chestnut blight is a disease of *Castanea* species, including the American chestnut *Castanea dentata*, the European *Castanea sativa*, and the Asian *Castanea crenata*. The causative fungus, *Cryphonectria parasitica*, is native to East Asia (11). Imports of *C. crenata* seedlings from Japan to North America appear to have been responsible for spreading *C. parasitica* to the United States (12). Once in North America, the fungus attacked native *C. dentata* trees. Within 50 years of the initial introduction of *C. parasitica*, mature *C. dentata* chestnut trees had been obliterated from the landscape. While uninfected rootstocks remain able to form new sprouts, these quickly become blighted, and no fruits are produced (11). *C. dentata* trees were previously the dominant canopy tree throughout the Appalachian forests (11), where their seas of white blossom held cultural importance. The loss of *C. dentata* trees also had profound ecological consequences, affecting both forest-floor and nearby aquatic habitats: chestnut leaves decompose easily and are of high nutritional value to invertebrates, compared to the leaves of the oak trees which largely replaced them (13). Impacts on mammal and bird species varied, with anecdotal accounts indicating a sharp drop in squirrel numbers due to the loss of mast production (14), while woodpeckers benefited from the increase in deadwood and insects therein (15). Meanwhile, seven moth species that lived or fed exclusively on chestnut became extinct (16). Thus, one fungus, *C. parasitica,* changed the forest landscape of the United States.

The spread of chestnut blight worldwide has been tracked by population genetic studies. In North America, genotypic data indicate that the source of the pathogen was Honshu, Japan, confirming the historical evidence of *C. crenata* seedling imports from this area in 1904. The American *C. parasitica* populations show considerable genetic divergence from the Asian populations; however, this is probably due to a small founder population, leading to random fixation of particular alleles in the emergent population (17). Overall, the data support a single or small number of introductions, followed by a rapid geographical spread. By contrast, *C. parasitica* spread slowly through Europe and without as marked destruction of the host *C. sativa* trees (17), which are less susceptible than American *C. dentata*. Additionally, European strains of *C. parasitica* themselves became infected with a virus, CHV-1, which caused fungal hypovirulence (17). Variation in the European fungal strains of *C. parasitica* is due to repeated introductions from both Japan and China. Despite the differences in spread pattern, American and European populations of the chestnut blight fungus show no genetic differentiation, indicating that there has been import and export of infected hosts between the two continents (17). Given the level of devastation the chestnut blight fungus unleashed in America—over 3 billion chestnut trees lost to disease—the fact that intercontinental trade in chestnuts was ongoing during this pandemic is, in retrospect, of grave concern.

A second fatal forest pathogen, which caused Dutch elm disease, spread across multiple continents in the 20th century, changing landscapes where grand elms once dominated the skyline. In contrast to chestnut blight, multiple pandemics of Dutch elm disease occurred. The final pandemic, in the 1970s, was the most damaging. Like the loss of American chestnuts, the loss of hundreds of millions of elm trees caused profound ecological changes, including the exposure of neighboring trees to storm damage and death and the creation of open woodland habitat that supported altered bird and mammal assemblages (11). The first pandemic, in the 1920s, was caused by the fungus *Ophiostoma ulmi*. This was a relatively weak pathogen, and it declined in disease severity naturally by the 1940s (18). However, a

second, more aggressive pathogen, *Ophiostoma novo-ulmi*, appeared during the 1970s (11, 19). This species has limited ability to interbreed with *O. ulmi*, and hybrid forms show reduced fitness. Nevertheless, transient hybrids occurred, and these provided a "genetic bridge" across which genes flowed between the species. These genes included a particular mating type allele, *MAT-1*, which increased the capacity of *O. novo-ulmi* to undergo sexual recombination, increasing its evolutionary potential (20). As we will see in "Natural Factors Promoting the Emergence of New Invasive Fungal Diseases," a high evolutionary potential is often important in the emergence and establishment of new infectious diseases.

Two subspecies of *O. novo-ulmi* exist, and both have invaded Europe: *O. novo-ulmi* subsp. *novo-ulmi* from the East and *O. novo-ulmi* subsp. *americana* from the West. These now hybridize freely (20). However, *O. ulmi* cannot coexist with the more aggressive *O. novo-ulmi*, so this pathogen is now locally extinct in many areas (20). As with chestnut blight, trade and transport are implicated in the spread of Dutch elm disease, with *O. novo-ulmi* subsp. *americana* reaching Europe in a consignment of logs sent from the United States to the United Kingdom in 1974 (20). In "Anthropogenic Factors Promoting the Emergence of New Invasive Fungal Diseases" we will discuss the importance of trade in plants and plant derivatives in the spread of agricultural and forest pathogens.

CURRENT EXAMPLES OF EMERGING INFECTIOUS FUNGAL DISEASES

Fungal diseases of plants have changed our landscapes and devastated our crops over the centuries. Since the Green Revolution, agricultural practices have favored intensive farming and the large-scale growing of hectare upon hectare of genetically uniform crops. Such plants are guarded from disease by one or two disease resistance genes or by the widespread spraying of fungicides. This plenitude of identical hosts has provoked widespread outbreaks of many known fungal foes on our major calorie crops. In this section, we focus on these emerging infectious diseases of domesticated crop plants and wild animals.

Diseases of Crop Plants

Soybean rust: *Phakopsora pachyrhizi* (Basidiomycete) (21–25)

What it infects

Soybean (*Glycine max*) and 95 other known legume species.

Becoming global

Sometimes called Asian soybean rust, this disease spread to Africa in the 1990s and then to South America and finally North America by 2004. Three main factors underlie its invasiveness: first, its asexual spores, which are produced in prolific numbers, can spread in global air currents. This includes cyclones and hurricanes, which cause unpredictability in terms of long-distance spread into new niches. These spores are then "rained out" of the atmosphere and deposited on wet leaves—ideal conditions for infection. Second, although *P. pachyrhizi* is a true obligate pathogen, it is a generalist: it can infect many different legume hosts. As well as soybean, it infects forage legumes such as vetch and lupin, as well as widely distributed weeds such as kudzu (*Pueraria lobata*), which is itself invasive. Third, *P. pachyrhizi* can rapidly generate new asexual spores by passing through its life cycle in as few as 9 days. Together, these factors ensure that the fungus spreads widely and finds a host readily. If soybean plants are absent, or only present seasonally, the pathogen sporulates on alternative hosts, repeatedly reinfecting newly planted soybean crops.

Why it matters

P. pachyrhizi causes an up to 80% reduction of soybean yields. This can lead to huge economic losses and social consequences, which have particularly affected parts of South America. An outbreak in 2001 in Paraguay caused severe losses and led to an outbreak in Brazil, in which up to 60% yield losses were reported. In 2002, over half a million metric tons of soybean were lost in Brazil alone. These losses, combined with the use of extra fungicides, cost Brazilian farmers 2 billion dollars during 2001 to 2003. The disease spread to Argentina in 2002 and Bolivia in 2003. In the United States, economic studies indicate that soybean rust could cause serious yield losses and increase production costs. In resource-poor farming areas, the resultant loss of livelihood leads to human suffering.

Mitigation

P. pachyrhizi is currently susceptible to treatment with azole and strobulurin fungicides. These target the fungal plasma membrane and interfere with mitochondrial electron transport, respectively. Prudent use of such chemicals, with careful monitoring, will hopefully lessen the risk of emergence of new, fungicide-resistant *P. pachyrhizi* strains. Moreover, meteorological monitoring and predictive modeling of global air currents and rainfall will aim to determine which crops are vulnerable and inform control measures.

Wheat stem rust: *Puccinia graminis* (Basidiomycete) (1, 26–32)

What it infects

Primarily a disease of wheat (*Triticum aestivum*), *P. graminis* can infect oats (*Avena sativa*), rye (*Secale cereale*), and barley (*Hordeum vulgare*), as well as the wild grasses *Festuca* and *Lolium* spp. The wheat stem rust fungus undergoes sexual reproduction on an alternative host, barberry (*Berberis vulgaris*).

Becoming global

Evidence suggests that the telial stage jumped onto grasses during their range expansion in the tertiary period, and the fungus was then further spread by agriculture. Barberry was identified as the alternative host in the 1780s. The fungus forms five spore types as it cycles between wheat and barberry. First, the teliospores, which have overwintered on wheat straw debris, germinate to form basidiospores which infect barberry, forming spermatia on the upper leaf surface. This triggers aeciospore formation on the lower leaf surface. These aeciospores are lifted into the boundary layer of the atmosphere and can travel thousands of kilometers before being deposited on wheat leaves, where they then form uredospores. These rust-red asexual uredospores are generated in prolific numbers and herald the start of epidemic disease levels. As the weather conditions deteriorate in autumn and the wheat harvests are gathered, the uredospore population declines in favor of the overwintering teliospores. Despite this complex dual-host life cycle, *P. graminis* is able to skip its telial stage to spread clonally in the absence of *Berberis*. Epidemics of wheat stem rust occurred in all wheat growing regions of the world during the 20th century; 60% of the U.S. wheat crop was lost in 1916, and eight more epidemics followed between 1920 and 1960. The popularity of Barberry as an ornamental in gardens and parks was implicated in these outbreaks. Meanwhile, Europe suffered epidemics in the 1930s, China in the 1950s, and Australia in the 1970s.

Why it matters

In addition to historical epidemics causing major yield losses worldwide, a new strain of *P. graminis*, known as Ug99, was discovered in Uganda in 1999. This new strain had spread to many African wheat growing countries, as well as Iran and Yemen, by 2005, and by 2014 had also been detected in Russia. There are now 11 known races of Ug99, each of which has broken the resistance offered by a different R gene bred into wheat. Ug99 is aggressive, causing significant yield losses, particularly to wheat varieties without effective disease resistance, and has shown itself to have high adaptive potential. It is feared that Ug99 will eventually reach other major wheat growing areas in Europe, Asia, and the Americas, causing catastrophic losses in global wheat yield.

Mitigation

Twentieth century epidemics were overcome by a combination of breeding for disease resistance in wheat and, in the United States, by the eradication of barberry plants. The former has mostly relied on gene-for-gene resistance, with durable protection derived from pyramiding of R genes. Destruction of over 50 million *Berberis* plants followed a major public education campaign ("Barberry or bread"), public participation, and legislation to make eradication compulsory.

Charcoal rot: *Macrophomina phaseolina* (Ascomycete) (21, 33–37)

What it infects

Over 500 host plant species are known. Individual strains show some degree of host specificity, but this is often incomplete, allowing the fungus to spread to infect other hosts. Crops infected by the charcoal rot fungus include soybean, sunflower, jute, cotton, cowpea, maize, sorghum, chickpea, peanut, canola, strawberry, guava, cassava, and melon. The fungus can also infect wild prairie grasses, as well as being an opportunistic human pathogen.

Becoming global

M. phaseolina was reported as the causal agent of guava wilt in India in 1990. It was identified as charcoal rot of strawberries in France in 1993 and of canola in the United States in 1994. In 1997, *M. phaseolina* was found causing stem rot of cassava in West Africa. In the 1990s, charcoal rot of soybean appeared in the United States. Charcoal rot of canola was found in Argentina in 2006 and Western Australia in 2009. Population genetics suggest this fungus spreads clonally, with its ability to infect wild species being important for its invasiveness.

Why it matters

M. phaseolina is a difficult fungus to identify. As such, it may have existed in many areas before it was first reported. However, charcoal rot began, more recently, to have to a serious impact on soybean yield in the United States. From 1996 to 2004, yield losses were estimated at around three quarters of a million metric

tons per year. Thus, *M. phaseolina* was the second most economically important disease of soybean at this time. In Africa's Sahel region over the same period, yield losses averaged around 10%; 100% yield loss is possible. The disease is most problematic in arid and semi-arid regions; the fungus thrives where soil nutrient content is low and temperatures are high. *M. phaseolina* is expected to become more geographically widespread under climate change models, and some host plants may be threatened with extinction. Increased occurrence of *M. phaseolina* is of further concern because it can act as an opportunistic mammalian pathogen.

Mitigation
M. phaseolina is hard to control, because its microsclerotia (hardened masses of fungal mycelium) persist in soil for up to 15 years. Soil treatment to mitigate the spread of fungal disease is problematic, not least because *M. phaseolina* shows resistance to many current fungicides. Moreover, antifungal prophylaxis does not prevent *M. phaseolina* infection in immunocompromised human patients, and the fungus can only be removed by wide surgical excision. Further research into this pathogen is needed, because its population genetic structure, life cycle, and manner of spread need to be better defined.

Leaf spot of barley: *Ramularia collo-cygni*, (Ascomycete) (38–41)

What it infects
This fungus primarily causes leaf spot disease on barley but is emerging as a pathogen of oats and wheat. It infects wild grasses including *Triticum, Festuca, Lolium, Elymus, Agropyron*, and *Brachypodium* spp.

Becoming global
R. collo-cygni was first described as a pathogen in 1893 in Italy, but rigorous scientific study of the fungus began in the 1980s. It was found in the United Kingdom in the late 1990s and detected in Europe, South and North America, the Middle East, Russia, Iceland, and Africa in the 2000s. This rapid emergence begs the question of whether it truly emerged or, instead, if improved recognition and detection led to its apparently sudden worldwide appearance. The latter seems a plausible explanation, because plants infected with *R. collo-cygni* remain symptomless while the fungus migrates to the awns (bristles on the glumes) and ears. The subsequent infection of the grains transmits the fungus from generation to generation and fuels further dispersal as infected germplasm is traded across the world.

Why it matters
This disease is largely symptomless in the early stages of infection, with symptoms appearing around the time of flowering and during grain set. This leads to low yield and low grain quality from a crop that appears uninfected until 3 weeks before the harvest is gathered. Recently, infections proved problematic in South America; high incidence and disease severity in Argentina in 2011 led to 70% grain yield losses, while in 2012, the fungus spread to six other South American barley growing areas, where it has now become a limiting factor in barley production. In 2002, widespread reports of barley leaf spot disease due to *R. collo-cygni* infection were reported in the United Kingdom. Hitherto, the fungus had been kept at bay by the use of strobilurin fungicides, but at this time, a point mutation known from related fungi rendered the fungus resistant to the quinone outside inhibitor fungicides. While the South American *R. collo-cygni* strain(s) has not yet acquired this mutation, if—or when—it does, grain costs and yield losses will rise.

Mitigation
Strobilurin fungicides are still in use in South America, but a limited lifetime should be expected and fungicide mixtures encouraged, given that fungicide resistance has arisen in *R. collo-cygni* elsewhere in the world. Trials have been conducted on seed treatments but without success, because the fungus behaves as a true endophyte, infecting the endosperm and embryo; treatments which kill the fungus are therefore detrimental to the seed itself.

Diseases of Animals

Amphibian chytridiomycosis: *Batrachochytrium dendrobatidis* and *Batrachochytrium salamandrivorans* (Chytridiomycota) (42–51)

What they infect
B. dendrobatidis has a broad host range, infecting all three classes of amphibian (anurans, caudates, and *Gymnophiona*). The fungus has a worldwide distribution occurring in 56 of 82 (68%) countries and infecting 42% of species. *B. salamandrivorans* has a more restricted range both in terms of its hosts, being found only in caudates (newts and salamanders), and geographic locations. Infection by these two chytrid fungi causes a cutaneous disease known as chytridiomycosis (Fig. 1).

Figure 1 Mass mortalities of midwife toads, *Alytes obstetricans*, caused by *Batrachochytrium dendrobatidis* (photo: Matthew C. Fisher).

Becoming global

Following the discovery in 1998 that *B. dendrobatidis* was a key driver of declines in amphibian species in Australia and the Americas, attention has focused on determining where outbreaks of chytridiomycosis have occurred and whether there are any underlying spatiotemporal patterns that indicate the original sources of infection, as well as pathways of spread. Phylogenomic analyses have shown that the worldwide emergence of chytridiomycosis is most likely explained by the rapid transmission of a hypervirulent lineage, called the global panzootic lineage (*Bd*GPL). This occurred on a global scale: this lineage has now been found in all continents alongside endemic lineages. Indeed, all mass-mortality and extinction events thus far attributed to chytridiomycosis caused by *B. dendrobatidis* are associated with the presence of *Bd*GPL. *In vivo* laboratory assessments of the virulence of *Bd*GPL have shown that this is indeed a hypervirulent lineage—a feature that confers "superbug" status on *Bd*GPL. However, the questions surrounding the origin of *Bd*GPL and the historical timing of this lineage's emergence across different continents remain elusive. In contrast, *B. salamandrivorans* is known to have emerged much more recently, having been most likely transported from Southeast Asia to Europe via the pet trade in infected amphibians.

Why it matters

Amphibians have long been recognized as being the most endangered vertebrate class on the planet, and chytridiomycosis is now recognized as a proximal driver of many amphibian die-offs worldwide. Indeed, chytridiomycosis has been described as "the worst infectious disease ever recorded amongst vertebrates, in terms of the numbers of species impacted and its propensity to drive them to extinction" (47). Thus, chytridiomycosis can result in widespread population decline, even extinction, in a subset of species and has contributed to the threatened status of almost 400 species of amphibian.

Mitigation

Countering disease-driven amphibian declines should consist of a multifaceted approach adapted to the stages of pathogen emergence. These include tackling the prearrival stage, the advancing invasion front, epidemic outbreaks, and established disease. Current approaches include prevention through restricting global trade in infected amphibians because it is clear that international movement of traded species is key to the spread of chytrids into naïve, disease-free ecosystems. Other short-term solutions include *ex situ* breeding programs known as "amphibian arks," alongside the cryopreservation of reproductive material. However, long-term, *in situ*, sustainable solutions are required if the goal of amphibian conservation is to be attained. This implies neutralizing the disease threat in wild populations using, for instance, antifungal compounds.

Bat white nose syndrome (WNS): *Pseudogymnoascus destructans* (Ascomycete) (52–55)

What it infects

First recognized in North America, *P. destructans* is now known to infect and cause clinical disease in at least six North American bat species. The fungus has also been described as infecting other species of bats in Eurasia and China.

Becoming global

WNS is a disease caused through infection of hibernating bats by *P. destructans*. First described following a cave die-off of little brown bats (*Myotis lucifugus*) in Schoharie County, New York, in the winter of 2006, the infection has since spread rapidly across eastern North America (Fig. 2). It was recently detected in Washington State, some 1,700 km from the index site. The mycosis is hypothesized to have been vectored into North America from Europe, where the fungus widely infects European bat species but where it does not cause observable mortality. Genetic analyses have confirmed that the North American variant of *P. destructans* is a single clone carrying a single mating type. This contrasts with the European genotypes, which are highly diverse and carry either one of the two heterothallic mating types.

Figure 2 Mass mortalities of little brown bats, *Myotis lucifugus* (photo: Alan Hicks).

Why it matters

P. destructans causes mass mortalities in North American hibernacula because the fungus destroys cutaneous membranes, including the wings, of hibernating bats. By 2015, four notable North American bat species' distributions had been entirely encompassed within the range of spread of *P. destructans*. As a result, species extirpations are predicted to occur in the near future.

Mitigation

Our current understanding suggests that the temperature of the bat hibernacula plays a role in WNS disease severity. Cooler and drier hibernacula appear to serve as refugia from disease impacts for some populations, because they carry lower fungal loads and thereby increase chances of bat survival. Indeed, it has been proposed that manipulating hibernacula entrances to create cooler and drier sites or restricting access to reduce bats' use of the warmer and wetter portions of hibernacula has potential as a single intervention in the management of WNS. Other approaches proposed include antifungal or biological (probiotic) interventions that could be used to reduce inoculum loads of *P. destructans* in the short term, thus allowing the bats time to adapt and evolve defensive/protective immunological responses to this pathogen.

Human cryptococcosis: *Cryptococcus neoformans* and *Cryptococcus gattii* (Basidiomycete) (56–60)

What it infects

Cryptococcus is a genus within the Tremellales, an order of fungi within the Basidiomycetes called "jelly fungi," due to their gelatinous fruiting bodies. They are commonly found growing on rotting wood as saprophytes. There are over 30 known species of *Cryptococcus*, of which two, *C. neoformans* and *C. gattii*, cause the majority of opportunistic human infections. Both species are readily recovered from the environment, where they can be isolated from the bark of a wide variety of tree species alongside other organic matter, most notably bird feces.

Becoming global

Genetic analysis has shown that *C. neoformans* and *C. gattii* have evolved independently from each other over the last approximately 30 to 40 million years. This separation has resulted in subtle variations in their virulence patterns. *C. neoformans* is the predominant species causing infection in immunocompromised individuals with HIV/AIDS. *C. neoformans* thus emerged in concert with the AIDS pandemic. *C. gattii*, however, causes rarer infections in putatively immunocompetent individuals. An unusual cluster of cryptococcal disease

in otherwise healthy individuals was seen on Vancouver Island, British Columbia, in 1999. This infection, caused by *C. gattii*, has now expanded into mainland Canada and the northwestern United States and is known as the Pacific Northwest outbreak. It was likely seeded by infectious inocula from South America.

Why it matters

The virulence attributes of *Cryptococcus* stem from various adaptations it has undergone that allow it to survive in the environment. An array of recognized "dual-use" survival/virulence factors is known. The most notable of these is the thick enveloping polysaccharide capsule, which in the environment defends against attack by parasitic amoebae but which also allows the fungus to survive macrophage assault and to disseminate as an intracellular parasite within the human body. Such adaptations have led to widespread human infection where the prevalence of HIV is high. In 2009, the CDC estimated that there are close to one million cases per year, with at least 100,000, and perhaps 500,000, deaths per year in sub-Saharan Africa alone, where cryptococcal meningitis accounts for around 17% of AIDS mortality.

Mitigation

The most important method of controlling cryptococcal meningitis is to control HIV. In Europe and North America, the numbers of cryptococcal patient cases fell dramatically after introduction of effective antiretroviral therapy. However, despite the widespread use of antiretroviral therapy in sub-Saharan Africa, there is no evidence of a reduction of cryptococcal infections. This may be due to the emergence of antiretroviral therapy resistance in target populations provoked by nonadherence to treatment regimes. The recent introduction of a cheap and easily used antibody-based disease diagnostic "dipstick" test that detects cryptococcal antigen holds much promise. This test has the potential to allow earlier treatment of the disease with potent antifungal drugs. It has triggered the widespread advocacy calling for the affected populations to have access to the most advanced antifungal drugs at an affordable cost.

Azole-resistant aspergillosis: *Aspergillus fumigatus* (Ascomycete) (61–63)

What it infects

The genus *Aspergillus* comprises a few hundred fungal species found in various climates worldwide. Certain *Aspergillus* species cause a variety of clinical diseases in humans and animals. The disease spectrum ranges from allergic conditions such as allergic bronchopulmonary aspergillosis through to invasive tissue disease in immunosuppressed tissue-transplant patients. Allergic bronchopulmonary aspergillosis is primarily seen in patients with chronic *Aspergillus* colonization suffering from cystic fibrosis and chronic granulomatous disease. Patients with lung diseases such as chronic obstructive pulmonary disease can develop chronic pulmonary aspergillosis when the fungus grows and becomes locally invasive, thus causing tissue damage.

Becoming global

The triazole antifungals, including itraconazole, voriconazole, isavuconazole, and posaconazole, are widely used to treat diseases caused by *Aspergillus* infection. However, azole-resistant strains have recently emerged across six continents and pose a significant new therapeutic challenge. Although *de novo* azole resistance is known to have arisen occasionally in patients during azole therapy, the main burden is now known to have been caused by the acquisition of resistance from environmental isolates. Here, the evolution of azole resistance in *A. fumigatus* is attributable to the widespread use of azole-based fungicides, which are widely deployed to control fungal disease in agriculture. The resistance phenotype is associated with particular key mutations in the fungal *cyp51A* gene. The occurrence of rapid selective sweeps associated with such new alleles has been documented.

Why it matters

cyp51A-mediated resistance is increasing rapidly; in some settings up to 10% of patients with *Aspergillus*-related disease do not respond to azole treatment. The prognosis for these patients is poor, with up to 80% mortality.

Mitigation

Azole fungicides are widely used in agriculture; they rank as the most important antifungal from a global perspective. Worldwide measures to curb their use should now be considered due to their attendant selection for antifungal resistance on nontarget pathogenic fungi such as *A. fumigatus*. But intervention is problematic, because azole use is so widespread in agriculture. A ban on azole use in crop disease prevention would alter reliance on other classes of fungicide, such as strobilurins and fast-forward emergence of new fungicide-resistant genotypes. However, this highlights the need either to reserve the antifungal azoles for the treatment of human fungal disease or to develop new antifungal drugs for human use.

DRIVERS FOR THE EMERGENCE OF NEW FUNGAL DISEASE

Natural Factors Promoting the Emergence of New Invasive Fungal Diseases

Most organisms are able to resist infection by most potential pathogens through innate immunity (e.g., 64). Pathogens, in turn, constantly evolve to overcome host defenses, creating selection pressure for hosts to withstand such pathogens. There is thus a classic evolutionary arms race between host and pathogen (65). While it is relatively easy to understand this process, it is considerably harder to predict when, where, and how new diseases will emerge.

The key factor determining the likelihood that a microbe will become pathogenic for the first time, on a new host or in a new place, is its "evolutionary potential." This is the organism's potential for genetic adaptability, and it is underpinned by a combination of the organism's biology, genomics, and population genetics. First, variability is a prerequisite for selection. A linked factor is effective population size, because more reproducing individuals generate more mutations on which selection can act. Second, reproductive mode affects evolutionary potential, because recombination creates new mixtures of genes (66, 67). Third, certain features of pathogen genomes may add to their evolutionary potential, increasing recombination, hybridization, variability, or rates of horizontal gene transfer (67, 68) (Fig. 3).

The biology and life cycle of the wheat pathogen *Zymoseptoria tritici* (Septoria leaf blotch disease) exemplifies all of these factors (Fig. 4). This fungus shows plentiful genetic variation, with evidence of gene flow between populations (69). It causes a polycyclic disease, with many cycles of asexual reproduction occurring within a wheat growing season, which allows selection for virulence (70). However, *Z. tritici* also reproduces sexually (71). The fungal genome consists of a core set of chromosomes and a suite of up to eight accessory chromosomes of unknown function, carrying genes which are largely silenced (72). The complement of these accessory chromosomes varies with fungal strain and can also change between generations. Further, there is evidence of multiple insertion and deletion events occurring in the accessory chromosomes. The changes in accessory chromosome number probably originate through nondisjunction at meiosis, followed by the fusion of sister chromatids. This leads to chromosomal degeneration and is probably the origin of the accessory chromosomes. The rapid evolution that takes place on accessory chromosomes (73) contributes to the pathogen's adaptive potential (74) and helps deleterious changes to be lost while advantageous ones are preserved. Other hallmarks attesting to the plasticity of this fungus are seen in its genome, which contains 17% repetitive DNA, 70% of which is enriched in class 1 transposable elements, which are associated with high mutation rates (75). *Z. tritici* poses a major threat to wheat production throughout the temperate world (71, 76; see "Threats to Agriculture from Emerging Fungi"). Its ability to evolve rapidly not only challenges our ability to breed for durable disease-resistant wheat cultivars but also promotes the emergence of fungicide resistance.

Genomes like that of *Z. tritici*, where accessory chromosomes are associated with high evolutionary potential, are often termed "two-speed" genomes. This refers to the separation of their core set of slowly evolving, essential genes from their accessory genes, genomic regions, or chromosomes, which are enriched in repetitive DNA, transposable elements, or other features which make them hot spots for mutation, recombination, and even for the introgression of genes from other species (77). These rapidly evolving genomic regions are frequently associated with pathogenicity and may be lineage-specific, determining host range (74). Examples can be seen in the genus *Fusarium*, a collection of saprophytic and pathogenic fungi which can infect both plants and animals, including humans. *Fusarium solani*, also called *Nectria haematococca*, carries up to three accessory chromosomes, which include genes more similar to *Aspergillus* genes than to the rest of the *F. solani* genome (76). One such accessory chromosome encodes pathogenicity factors that allow the strain which carries it to infect pea plants, having degraded a host defense compound (a phytoalexin) (76, 78). The related generalist *Fusarium oxysporum* (Fig. 5; see section on Panama disease) also carries accessory chromosomes containing many transposable elements and virulence genes which define its host range. These accessory chromosomes can be readily exchanged, even between fungal strains which are not sexually compatible and between strains of different species in the genus *Fusarium* (79). Not all *Fusarium* species carry accessory chromosomes, but even those lacking this feature have rapidly evolving genomic regions associated with pathogenicity and virulence determinants (80). The wheat pathogen *F. graminearum*, which has recently re-emerged to cause worldwide problems (69), has four chromosomes that show high single nucleotide polymorphisms and rapid recombination rates in the telomeric regions at the ends of chromosomes, reflecting ancient chromosome fusions (81).

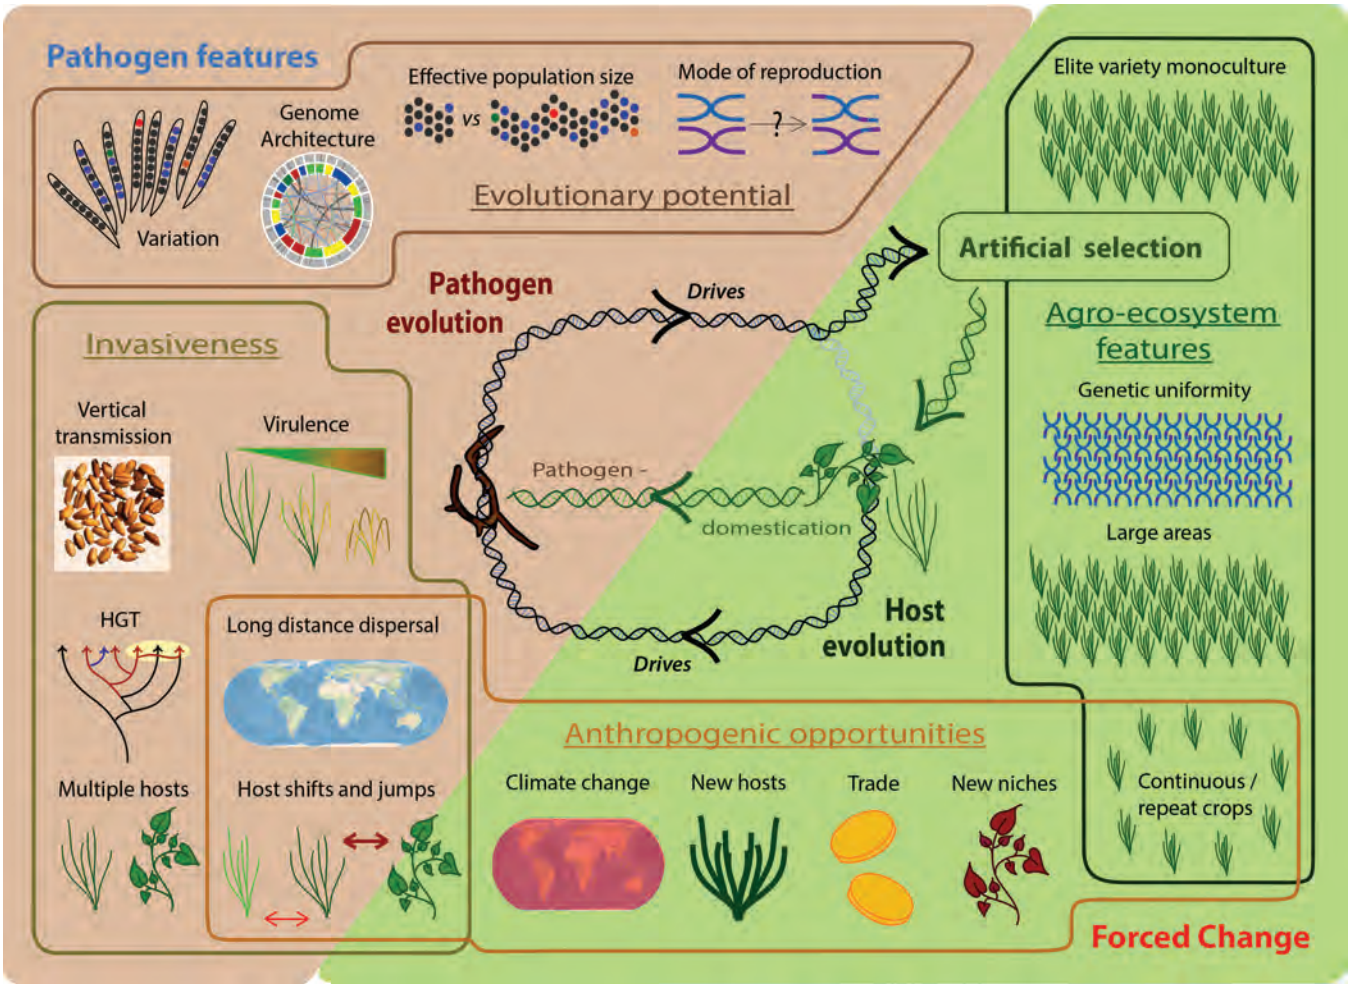

Figure 3 Factors influencing the emergence of infectious diseases of crop plants. These include features of the pathogens themselves as well as changes forced by the opportunities given to and pressures placed upon pathogens externally, as a result of human activity. Pathogen features prompting the emergence of new diseases include specialized genomes, sexual reproduction, large populations, and plentiful variation, which contribute to evolutionary potential. Invasiveness is key to the appearance of new emerging infectious diseases. This pathogen trait has natural components including high virulence and the capacity to infect multiple hosts and to transmit vertically, as well as such traits as long-distance dispersal and a propensity to undergo host shifts and jumps. Such traits may be natural or appear as a result of opportunities provided by anthropogenic changes to the environment. Such anthropogenic opportunities include climate change and trade and transport, introducing pathogens to new places, niches, and hosts. They may also take the form of pressures placed on pathogens by the continuous cultivation of a single crop year-round leading to genetic uniformity of available hosts over large areas. Such elite varieties are the product of artificial selection, which is the main driver of host evolution when the host is a domesticated crop. Host evolution can then drive pathogen evolution, leading to the appearance of new emerging infectious diseases and subsequent selection of new, resistant elite varieties. In addition, during the domestication of a crop, pathogens may be directly domesticated, short-cutting their adaptation to a particular host.

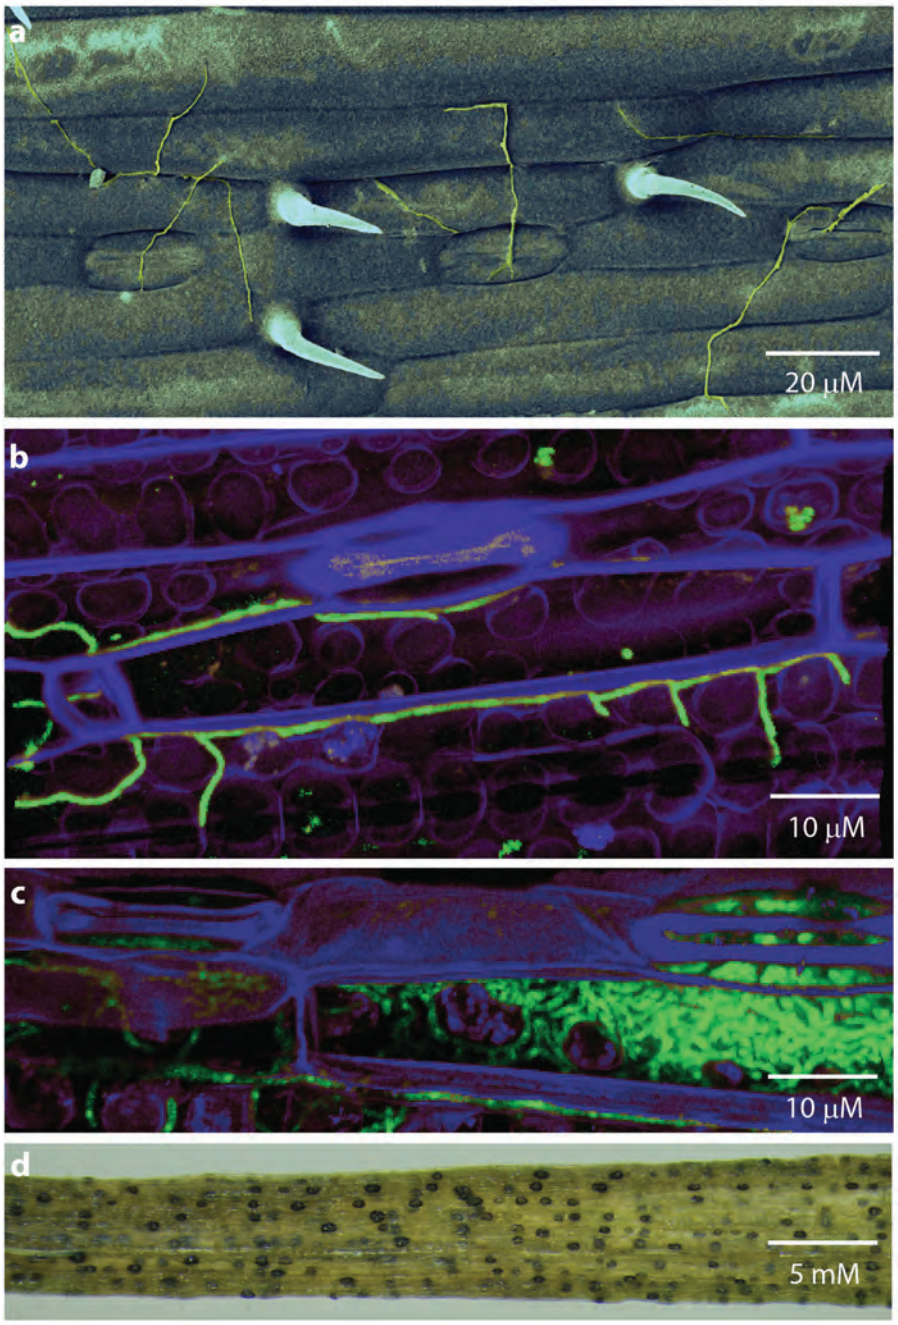

Figure 4 The wheat pathogen, *Zymoseptoria tritici*. (**a**) Scanning electron micrograph showing *Z. tritici* (green) on the surface of a wheat leaf. False color image. (**b**) Confocal fluorescence micrograph showing green-fluorescent protein-tagged *Z. tritici* (turquoise) beginning to colonize mesophyll tissues of a wheat leaf (purple). False-color image. (**c**) Confocal fluorescence micrograph showing *Z. tritici* (turquoise) proliferating with a wheat leaf at a late stage of infection. The fungal mass on the right of the image is a nascent pycnidium, the structure in which sporulation takes place. (**d**) Severely diseased wheat leaf showing *Z. tritici* symptoms, including mature pycnidia (black). Each black spot can release hundreds of spores. (Photos: Helen Fones; GFP-tagged *Z. tritici*: reference 127.)

The exchange of accessory chromosomes between *Fusarium* strains indicates that they undergo some form of HGT. HGT is common among bacteria and frequently allows the transfer of pathogenicity, virulence, or antibiotic resistance genes, creating "pathogenicity islands" in bacterial genomes. HGT had been assumed to be rare in eukaryotes, but new evidence concerning exchange of pathogenicity genes in particular suggests that it may be much more commonplace in filamentous fungi than realized. Such evidence usually comes from comparative genome data, the availability of which has recently exploded with the advent of rapid DNA sequencing technologies and analytical tools. Nucleotide sequences gained through HGT, including bacterial pathogenicity islands, can usually be recognized by a GC content different from the surrounding region of the genome and by a nearby abundance of transposase genes (encoding enzymes that move transposons). The *F. solani* chromosome containing the pea pathogenicity gene conforms to this pattern (76). There is a similar HGT footprint in the *toxA* gene of the notable wheat pathogen *Pyrenophora tritici-repentis*, which appears to have transferred from *Phaesosphaeria nodorum*, and in a cluster of pathogenicity-related genes in the maize smut pathogen *Ustilago maydis*. In the generalist plant pathogenic fungus *Alternaria alternata*, which provokes human allergies, such clusters are known to define host range (78).

So what are the endogenous attributes which favor the emergence of a new pathogen? Pathogens with large populations, high mutation rates, high rates of outcrossing and genetic recombination, and a high level of genomic plasticity, including the ability to exchange genetic material in a nonsexual manner such as HGT, are most likely to emerge as new pathogens: they have the evolutionary potential to overcome host defenses in a naïve plant or animal (79). Various routes have been identified for this emergence. Chief among these are host jumps and host shifts (82). It is relatively easy to see that the acquisition or loss of an accessory chromosome or a single or set of pathogenicity genes could lead to a host jump, by allowing a pathogen of one host suddenly to infect another. Historical examples of host jumps include the rice blast pathogen, *Magnaporthe oryzae*, which jumped from Setaria millet onto rice 7,000 years ago (78), and the ergot fungus, *C. purpurea* (see "Ergotism and Witchcraft"), whose closest relatives are symbionts of wild grasses and pathogens of arthropods (83, 84). More recently, the rice blast fungus jumped onto wheat in Brazil and, in 2016, onto wheat in Bangladesh (85, 86). Host shifts are smaller, between closely related hosts. Another route for the emergence of a new pathogen is through hybridization between two or more related fungal strains. An example of this mechanism was seen in Dutch elm disease (see "Changing Landscapes: Chestnut Blight and Dutch Elm Disease"), where hybridization between *O. ulmi* and the new, more aggressive *O. novo-ulmi* allowed the transfer of pathogenicity genes from the older species into the emergent, more devastating pathogen (20, 78). Other hybrid emerging fungal pathogens include poplar rust, *Melampsora columbiana*, and *Botrytis allii,* a postharvest disease of onions (20).

In addition to these factors, which promote the emergence of a new pathogen, there are also natural factors which play a role in determining pathogen invasiveness. Earlier in the article we saw that certain invasive plant pathogenic fungi share the ability to travel internationally in air currents (22, 23, 30). This allows worldwide spread of spores to infect any susceptible host population. In addition, it allows obligate pathogens to repeatedly reinvade areas where the host is not available year-round (87). Airflows are largely predictable, in both a local and global sense, allowing models to identify major risk areas based on pathogen source populations, spore release times, and prevailing air currents. But there are also unpredictable, extreme weather events such as cyclones or hurricanes (12, 87, 88) which can carry pathogens to new areas faster than expected. Interestingly, it now appears that for

foliar crop pathogens, this long-distance dispersal is not a special adaptation, but rather an extension of the processes involved in short-distance spread among hosts within a field, combined with turbulent airflow at small spatial scales (87). Fungal foliar crop pathogens appear to be uniquely successful at long-distance dispersal, which may be an exaptation derived from their usual modes of transmission (primarily rain splash and wind dispersal) (87). Similar processes are, however, also probably contributing to the aerosolization and contemporary dispersal of azole-resistant *A. fumigatus*, leading to the occurrence of the resistant *cyp51A* alleles in regions where there is little drug pressure (61).

An alternative—or additional—method of spread involves passage from one host generation to the next. For crop pathogens, this means transmission via the seed. This is particularly effective when both infected seeds and young plants appear healthy. Infected seeds allow the pathogen to use the host's own dispersal mechanisms while ensuring a susceptible host on arrival. International seed trade amplifies the effectiveness of this strategy (see "Anthropogenic Factors Promoting the Emergence of New Invasive Fungal Diseases"). An example of this vertical transmission is *R. collo-cygni*, which as we saw above, lives endophytically, causing no symptoms, until the plant begins to flower (40). There is a trade-off in virulence between intra- and interhost replication (78); endophytic growth is a solution which precludes any risk of host death before transmission.

Another feature of fungal pathogens which promotes their invasiveness is the ability to establish a year-round infection in a new area, often taking advantage of volunteer or wild plants. Such continuous infection means that there is a continuous inoculum source in the new location, even if the crop is not grown year-round. Alternatively, establishment of a year-round infection on crop plants in an area where they are grown year-round can provide year-round inoculum for invasion of nearby areas where the same crop is seasonal. Again, this ability is shared by many of the fungi discussed in "Current Examples of Emerging Infectious Fungal Diseases." There are a number of ways fungi achieve this. Broad host range, as seen in *M. phaseolina* and *Fusarium* spp., is one strategy; generalist pathogens dispersing to a new area have a range of potential hosts available and are thus likely to be able to become established. The same effect can be achieved, however, by more specialist fungi with narrower ranges of alternative hosts if those hosts are themselves widespread. The fungi *R. collo-cygni* and *P. graminis* exemplify this strategy, because they infect a number of wild grass genera whose species are found throughout temperate regions (1, 40, 41). Similarly, *P. pachyrhizi*, while primarily studied as a soybean pathogen, is able to infect many legumes, including the invasive weed kudzu, whose large, widespread populations greatly increase host availability (23, 24). Alternatively, fungi may form resting spores (such as the microsclerotia formed by *M. phaseolina*), which can survive cold winters or persist through hot or dry summer periods. Such a strategy increases the chances of infecting any hosts that become available in a new environment as the seasons change.

Anthropogenic Factors Promoting the Emergence of New Invasive Fungal Diseases

In addition to the factors outlined above, some human activities affect the likelihood of new invasive fungal diseases emerging. The most important of these is trade and transport (11), followed closely by agricultural practices that lead to wide distribution and high-density cultivation of genetically uniform plants or livestock, susceptible to the same diseases (66).

In "Changing Landscapes: Chestnut Blight and Dutch Elm Disease," we saw that the international trade in chestnut and elm continued during both the chestnut blight and Dutch elm disease epidemics. In agriculture and sylviculture, trade in products such as food or wood is commonplace, as is the worldwide trade in germplasm—including seeds, rhizomes, or cuttings of elite crop varieties. In "Natural Factors Promoting the Emergence of New Invasive Fungal Diseases," we saw that seed-borne fungi can exploit both natural and anthropogenic seed dispersal mechanisms. Live plants and animals are also traded and may carry a range of pests and pathogens undetected into new areas. Such trade is common in asexually propagated crops such as banana (see section on Panama disease). Trade in live plants is implicated in the spread of the ash die-back fungus (*Hymenoscyphus fraxineus*; see "Threats to Natural Ecosystems from Emerging Fungi") to the United Kingdom (89) and white pine blister rust fungus (*Cronartium ribicola*) to the United States, where the host, *Pinus albicaulis*, is now threatened, and Canada, where it is endangered (90, 91). Similarly, it is clear now that the international trade in Asian salamander species is enormous, with, for instance, over 2.3 million individuals of *Cynops orientalis* being imported into the United States from 2001 to 2009 (43). There has been much focus on how the transcontinental vectoring of *Bsal* in amphibians may have occurred. Molecular surveillance data have demonstrated

that *Bsal* is relatively widespread in European captive collections (45) and is associated with Asian species as well as with outbreaks of disease in captive European species of caudates. A clear case has therefore been made that the international movement of traded species of amphibians is a key mechanism that is contributing to the spread of *Bsal* and its invasion of naïve, disease-free ecosystems. These potent arguments have recently resulted in a ban on the importation of 201 salamander species into the United States (92).

When potential hosts are introduced to a new area, there are a number of associated risks. First, the imported organisms may be infected with a disease not occurring in the new location. Such introductions of deleterious organisms are sometimes termed "pathogen pollution" (11). Second, the introduced organism can carry a pathogen or commensal organism that has previously caused little or no disease but which may, in the new location, acquire new virulence or pathogenicity genes via HGT or hybridization, creating a new pathogen. Third, such fungi might possess or obtain genes for virulence in hosts endemic to the new area. These risks are compounded by the fact that closely related species of fungi which have diverged allopatrically (while occupying separate, nonoverlapping geographic areas) will not have experienced selection pressure toward perfect reproductive isolation. Thus, reproductive barriers may be leaky, allowing the formation of "hopeful monsters" (93)—hybrids which, while usually having lower fitness than the parents, occasionally bring together pathogenicity and virulence determinants in devastating new combinations. Backcrossing to either parent can then fix these genes in otherwise well-adapted local pathogen populations. Fourth, climatic factors might favor an imported pathogen or potential pathogen such that it is no longer limited by hot summers, cold winters, or drought. Finally, biotic factors may favor an introduced organism, because by invading new territories it may leave behind competitors, predators, or parasites, thus undergoing "enemy release." This allows the invader population to explode in numbers, further increasing the likelihood of favorable HGT, hybridization, recombination, or mutation events. Anthropogenic transport and mixing of pathogens can thus have serious consequences (11, 69, 87, 89–94).

Another anthropogenic factor in the emergence of fungal pathogens, particularly those of crop plants and, to a lesser extent, of livestock, is the unique cradle for pathogen evolution provided by agriculture. Agro-ecosystems are characterized by huge populations of genetically uniform individuals. A few varieties of one crop may constitute almost all of the host variability throughout particular climatic regions, or even worldwide (11, 78, 95). In contrast to the patchy distribution of hosts in natural ecosystems, large cropping areas mean that pathogen populations rarely experience bottlenecks or loss of diversity (87). Pathogen populations are enormous, and coinfection by multiple strains is the norm, increasing the rates of mutation, HGT, and hybridization (67). Similarly, intensive farming practices, with multiple crops per year, reduce the temporal diversity of host availability that is a feature of natural ecosystems. Moreover, fungal pathogens have no need for resting spores if the host is cultivated year-round and instead undergo extra cycles of asexual propagation and clonal spread, bolstering population sizes still further (76, 95). For example, the crop-destroying rice blast fungus *M. oryzae* is almost entirely clonal, while its wild relatives rely on sexual reproduction to produce the resting spores needed for persistence in natural ecosystems (11, 69). Similar processes are argued to have led to the extremely rapid emergence of *P. destructans* and WNS across North America, because bats disperse asexual conidia along their migratory routes (96).

Examples of the importance of agro-ecosystem uniformity in shaping the evolution of agricultural pathogens can be seen today in many economically important fungal crop pathogens. *Z. tritici*, for example, diverged from its nearest relatives around the time that wheat was domesticated and has its center of diversity in the same location—the Fertile Crescent—as wheat itself (78). The wild relatives of *Z. tritici* have a wider host range, which was lost in the genetic bottleneck that followed the initial jump by the ancestors of *Z. tritici* onto wheat. However, as wheat cultivation spread around the world, the pathogen went global too; there are signatures in its genome indicating rapid population growth and diversification (78, 95).

Similarly, many of the pathogens discussed in "Current Examples of Emerging Infectious Fungal Diseases" benefit from these features of agro-ecosystems. As seen in "Natural Factors Promoting the Emergence of New Invasive Fungal Diseases," these invasive, pathogenic fungi share the ability to establish year-round populations through infection of a range of hosts including wild species (21, 40, 81, 91, 97, 98), allowing spread through agricultural and unmanaged ecosystems. Such pathogens often have long-distance dispersal ability, bolstering genetic diversity during establishment (12, 21, 66, 87). Further, many are accidentally propagated on volunteer host plants, which appear between growing seasons, along roadsides or in other anthropogenic environments (1, 23, 24, 41, 66) (see Fig. 3).

Apart from crop plants, there is only one organism whose pathogens show such rapid evolution and propensity for host shifts, host jumps, and HGT events. This is because the density and uniformity of the agro-ecosystem, and high levels of pathogen pollution within it, are matched by only one species: the species supported by the agro-ecosystems—ourselves. With a huge, dense population, *Homo sapiens* has provided its pathogens with a similar evolutionary cradle. This means that lessons may be learned in interdisciplinary research into the evolution and epidemiology of crop and human pathogens (78).

A final anthropogenic factor influencing the emergence of invasive pathogens is climate change. This has both direct and indirect effects on the spread of fungi. One study found that pests and pathogens of crops are moving poleward as global temperatures increase, with fungi leading the charge (99, 100). Limitations imposed by cold winter temperatures, both on fungi themselves and on their hosts, are gradually lifting at higher latitudes, while perhaps, higher summer temperatures impose restrictions closer to the equator. This process is exemplified by the increasing severity of outbreaks of chytridiomycosis across amphibian populations in the high Pyrenees as the onset of spring arrives earlier in the year (101).

In addition to these direct effects, climate change influences agriculture, with crops increasingly grown outside of their natural ranges. With the spread of crop species comes pathogen pollution and all its attendant risks, including enemy release for pathogens which are noncompetitive in the hosts' home range. In addition, hosts will be exposed to pathogens native to the new location, which may adapt to them and eventually then spread into their original range (11, 78).

Panama disease as a case study concerning anthropogenic disease spread

Panama disease, also called *Fusarium* wilt, is an aggressive disease of banana first recorded in Australia in 1876. By 1950, it had spread throughout banana growing regions worldwide (102). Its spread was facilitated by the global monoculture of Gros Michel banana, the only variety grown for export at the time (102). Banana, a seedless triploid (three copies of every genome) resulting from hybridization of two *Musa* species, is propagated via rhizomes (103). Like infected seed (see "Anthropogenic Factors Promoting the Emergence of New Invasive Fungal Diseases"), symptomless but infected rhizomes can be transported around the world, carrying the disease with them (102). The disease can be soilborne, with microconidia entering roots and traveling through the vascular system, followed by further microconidation, allowing spread throughout the plant (104). Chlamydospores (thick-walled spores) survive in soil for up to 30 years. Gros Michel banana was first infected with this disease in Panama, providing its common name; the causal agent was identified in Cuba in 1910 and named *F. oxysporum* f. sp. *cubense* (*Foc*) (103). *F. oxysporum* causes vascular wilt disease in a wide range of plants, although individual *formae speciales* often show a restricted host range (see "Natural Factors Promoting the Emergence of New Invasive Fungal Diseases"). Within *Foc* are four races. Race 1 caused exceptional losses in Gros Michel plantations. Race 2 infects various varieties of cooking banana, whose fruits are not grown for export, and race 3 infects a different host species altogether (104). Abandoning Gros Michel, commercial growers turned to a new variety, Cavendish, which existed as a curiosity in collections in the United Kingdom and Honduras. Cavendish has appropriate qualities for export and resists *Foc* race 1 (103). Thus, trade in the world's favorite fruit was saved—for a time. In the late 1960s, reports appeared of a similar wilt disease infecting Cavendish banana, which in 1994, was confirmed as a new race of *Foc* (104). Race 4 also infects plantains, so it threatens two important crops. Initially, *Foc* Race 4 was confined to the Eastern hemisphere; its discovery in Jordan in 2014 (104) means that it is now likely to spread through Africa and, in time, will probably reach the banana plantations of the Americas. Treatment is problematic, because *Foc* is highly resistant to fungicide. A new, resistant banana variety will be needed if drastic losses in production are to be prevented.

THREATS TO NATURAL ECOSYSTEMS FROM EMERGING FUNGI

We have already seen that fungal diseases can have huge impacts on tree species, for example, in Dutch elm disease and chestnut blight. "Changing Landscapes: Chestnut Blight and Dutch Elm Disease" described the effect of the devastation of the Appalachian chestnut on biodiversity, as well as changes to landscapes and the resulting cultural impact. A similar example, which has received extensive attention, is the case of ash dieback in the United Kingdom and Europe. Ash dieback is a fatal disease of ash (*Fraxinus excelsior*). It is caused by *H. fraxineus* (previously *Chalara fraxinea*), an ascomycete native to Asia which is thought to have spread into and around Europe on infected but asymptomatic nursery stock (76, 105) (Fig. 6). *H. fraxineus* has devastated ash woodland throughout Europe, with up to

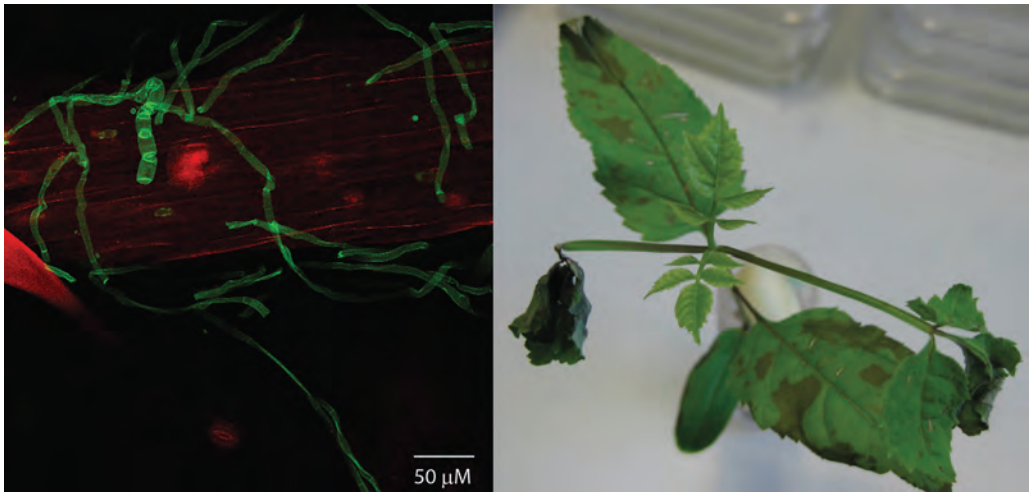

Figure 6 *Hymenoscyphus fraxineus* on ash. Left, hyphae (green; stained with fluorescein isothiocyanate-labeled wheat-germ agglutinin) of *H. fraxineus*, visualized by confocal microscopy, growing over and out of the vascular tissue of an ash leaf (red; stained with propidium iodide). Right, ash die-back symptoms on an ash seedling under laboratory conditions. (Photos: Helen Fones.)

100% of trees affected and with ash now considered a threatened species in several countries (106). This disease attracted public and scientific interest in the United Kingdom, where ash is common in woodlands and hedgerows. Studies indicate that around 45 species are dependent on ash, among a total of around 450 species associated with this tree (107). Ash is a pioneer of and keystone species in European riparian forests, as well as being a hedgerow plant and an urban amenity species (106).

H. fraxineus displays very high levels of outcrossing, resulting in rapid gene flow between populations (108–110). This means that even among emerging fungal diseases, *H. fraxineus* has high evolutionary potential. New genotypes with increased virulence or pathogenicity, whether arising by mutation, introgression, or recombination, quickly spread throughout European populations of this fungus. *H. fraxineus* shows much greater genetic diversity in Asia than in Europe, and Asian strains show higher virulence and pathogenicity to ash (111). With global trade and transport, it is only a matter of time until this destructive potential reaches Europe. Further, there are known to be various sympatric (species inhabiting the same geographic region) *Hymenoscyphus* species (112, 113) with which hybridization may ensue. As well as possible evolution of increased virulence, the possibility of host shifts onto additional *Fraxinus* or *Oleaceae* species, or even host jumps onto other trees entirely, is therefore high for this pathogen (113, 114, 128).

Another keystone species affected by an emerging fungal pathogen is the Hawaiian ʻŌhiʻa tree (*Metrosideros polymorpha*). This tree is threatened by the new disease rapid ʻŌhiʻa death, caused by the fungus *Ceratocystis fimbriata*. In this disease, the fungus infects the sapwood, causing death within weeks. Mortality rates are high: about 50% of infected trees die. Transmission may be by infected soil, cuttings, insect vectors, or windblown insect frass (powder produced by boring insects) (115, 116). The disease is of particular concern, because ʻŌhiʻa is a dominant species in the Hawaiian rainforest, determining succession and canopy structure and providing a habitat for many endangered species (115). Moreover, it is a key pioneer in the colonization of lava flows because it has a root system that is particularly able to penetrate cracks and is adapted to withstand toxic volcanic gases (117, 118).

Another ecosystem service provided by large tree species is carbon sequestration. American chestnut was an efficient carbon sink in its native range (119), capable of absorbing up to 35 metric megatons of CO_2 had the trees not been destroyed by *C. parasitica*. Similarly, Dutch elm disease is calculated to have prevented the absorption of a metric megaton of CO_2. These values do not include the vast potential carbon release from decaying wood of the dead trees (93).

Vertebrate biodiversity is an important component of food webs, and the losses of neotropical amphibian species have caused demonstrable changes in ecosystem functioning. This is compounded by the fact that

amphibians are both important grazers in their aquatic tadpole forms as well as insect-predators in their terrestrial adult morphs. In Central America, chytridiomycosis has changed patterns of amphibian biodiversity. Here, community composition across the region was severely disrupted by epidemics at multiple sites, and many of the unique species of these communities were eliminated, with disproportionate effects on endemic species. This resulted in a homogenization of the regional fauna and ecological homogenization of reproductive mode and habitat (120). Alongside the losses of biodiversity, economic consequences are starting to be attributed to emerging fungal diseases of vertebrates. While correctly attributing the economic cost of ecosystem functions is still in its infancy, valuations have estimated the losses to U.S. agriculture that are the result of declines in bat populations at more than $3.7 billion per year (121). Indeed, there are many ecosystem services which are hard to quantify but may be threatened or diminished when species are decimated by emerging fungal diseases. These include prevention of flooding, provision of clean air and water, pollination of crops and other plants, as well as the cultural, religious, and recreational significance of host species to humans. Where biodiversity is threatened, we are also at risk of losing potential pharmaceuticals and various other genetic resources which could be used to improve domestic species.

THREATS TO AGRICULTURE FROM EMERGING FUNGI

As well as their devastating effects on natural ecosystems and wild species, emerging fungal pathogens pose serious threats to agricultural production and food security. This is evident from "Current Examples of Emerging Infectious Fungal Diseases," where we saw the huge losses that can result from particular fungal pathogens. A recent, detailed study estimated that in the three major wheat growing countries of the European Union (United Kingdom, France, and Germany) losses caused by the fungus *Z. tritici* (Septoria leaf blotch of wheat) surpass €1,400 million yearly. This is despite deployment of the most resistant wheat varieties and application of fungicides at a further cost of over €900 million per growing season (70). These losses are due to just one disease, in conditions optimized for its control. It is clear that losses worldwide to fungal pathogens impact significantly on productivity and costs. Affordable food security will therefore depend on our ability to mitigate this threat.

Unfortunately, that ability is constantly challenged by the pathogens themselves. As we have discussed, emerging fungal pathogens are exceptionally adaptable. As well as increasing the risk that they will spread to new hosts and new places, this adaptability allows pathogens to repeatedly break the resistance provided by elite crop varieties. At least one wheat variety previously resistant to *Z. tritici* has failed due to new virulence acquisition by the pathogen (122); resistance breeding is complicated by linkage between *Z. tritici* resistance and low crop yield (123).

Not only do fungi have the ability to out-evolve and overcome the defenses of resistant hosts, but they can evolve or acquire genes for fungicide resistance, as we saw in "Azole-Resistant Aspergillosis." As such, these strains overcome our main mechanisms for protecting crops from disease and thus ensuring food security. The very traits that promote their becoming invasive pathogens also increase the risk of their developing fungicide resistance. For example, few curative fungicides exist for *Z. tritici* in wheat; there is reliance on azoles and strobilurins, to which the fungus is beginning to show resistance (70). Indeed, azole-resistant fungi are becoming increasingly common, a problem partly attributed to the persistence of azoles in soil (124). This increases incidental contact with fungi, creating selection pressure for resistance, which may be conferred by a single gene such as *Aspergillus nidulans atrB*, encoding a multidrug transporter conferring resistance to azoles and other fungicides (125). This is concerning not just because of the implications for agriculture, but also because many of these fungi or their close relatives cause mycoses in humans. Examples include *A. fumigatus*, the cause of invasive aspergillosis, a potentially fatal disease generally treated with triazole fungicides (see "Azole-Resistant Aspergillosis"). A single amino acid change and a 34-bp tandem repeat in the promoter region of the *Cyp51A* gene encoding the target protein are sufficient to provide resistance to various frontline triazoles that are used to treat severe human infection (61, 124).

Similarly, the generalist fungus *M. phaseolina* (see "Current Examples of Emerging Infectious Fungal Diseases"), which attacks immunocompromised patients, is treated with azole fungicides, but azole-resistant fungal strains are appearing (33). Given the environmental persistence of azoles and the high evolutionary potential of crossover pathogens such as *M. phaseolina* (126), it may be necessary to curb the agricultural use of azoles to maintain their medical efficacy, as discussed in "Azole-Resistant Aspergillosis." However, there are not yet effective replacements for azoles in agriculture.

CONCLUSIONS

Fungal infections have wreaked havoc with our harvests through the centuries. Fungi continue to cause widespread damage in crops. Recently, however, we have witnessed their growing impact on ecosystem resilience and on human health: there has been a dramatic decline in populations of amphibians and bats and an increased incidence of fungal infections in humans. Human activity and global climate change are intensifying fungal dispersal by modifying natural ecosystems and creating new opportunities for evolution. We must take steps to mitigate the risk of these infectious diseases spreading globally, for without action, fungal infections will lead to reduced crop yields, damaging food security. Increased agricultural reliance on fungicides will promote the evolution of fungicide resistance, which trait may then spread into pathogens of wild species and of ourselves. Biodiversity and human health will then suffer alongside agriculture, increasing the risk to ecosystems and ecosystem services at a time when pressures to exploit land to feed humans will be heightened. We must therefore ensure that research on the various host, pathogen, and environment interactions is fueled by adequate research funding and that disease detection is improved and then used to impose stricter global biosecurity protocols in the international trade of plant and animal species.

Fungi that Infect Humans

39

Julia R. Köhler,[1] Bernhard Hube,[2] Rosana Puccia,[3] Arturo Casadevall,[4] and John R. Perfect[5]

INTRODUCTION

In its short history of a century and a half, of which the last half-century brought the most dramatic advances, scientific medicine has found ways to cure or to treat millions of ill people who 200 years ago would have died early. Paradoxically, these successes of modern medicine have given rise to large groups of people at risk for fungal infections. Life-saving treatments may now breach normal immune functions, or susceptible patients such as premature newborns now survive long enough to become infected by a fungus. Invasive fungal infections have been very rare over most of our species' history (1), and the fungi that infect healthy humans are a small, if fascinating, group. Many more invasive fungal infections now occur in patients with an underlying serious illness.

Yet at the same time, less than 1/10,000 of the ~5 million fungal species estimated to currently inhabit the earth (2, 3) can infect and cause disease in a human being. The pathogenic fungi are not a monophyletic group, and the capacity for virulence appears to have emerged several times independently in evolutionary history (4). This article intends to illuminate the features by which some fungal species can infect humans and the evolutionary relationships that contributed to their development.

Fungi moved from the oceans onto land in a symbiotic relationship with plants (5–8) and maintain their most intricate host relationships with the plant kingdom. These comprise a spectrum from mutualistic symbiosis to biotrophy (acquiring nutrients from host tissues with specialized structures while downmodulating host immunity), necrotrophy (killing host tissues to feed from them), and saprotrophy (feeding from dead host tissues) (9–12). Among fungi incidentally infecting humans, plant necrotrophs such as *Fusarium* and *Alternaria* and saprotrophs such as *Aspergillus* and *Scedosporium* are common (13, 14). In contrast, plant mutualists such as mycorrhizal fungi and biotrophs such as *Erysiphe* and *Puccinia* are extremely rare agents of human infection, suggesting that an evolutionary strategy of lysing host tissue completely—dead or alive—can target hosts across two kingdoms of life.

Coevolution of animals with fungi shaped animal immune systems. In sponges, which are among the earliest metazoans, a cell surface protein recognizing (1,3)-β-D-glucan has been identified, whose ligand binding activates a tyrosine kinase pathway (15). (1,3)-β-D-Glucan, an abundant fungal cell wall component, thus acts as a fungal pathogen-associated molecular pattern in the earliest animals, demonstrating that defense against fungal attack was a requirement at the dawn of the metazoan era. Evolutionary latecomers such as humans had hundreds of millions of years to hone innate and adaptive immune systems to successfully keep potential fungal invaders in check.

Resistance to fungal infection increased during animal evolution. Insects possess the Toll pathway, by which fungal pattern-recognition receptors ultimately induce antimicrobial peptides, a pathway also used in human innate immunity to respond to fungal invaders (16). As a consequence, insects resist fungal infection more effectively than the early metazoans, yet they still succumb to fungi specialized to prey upon them (17). Infection with ~1,000 species of fungi across five clades kills insects (18).

Vertebrates added the adaptive immune system to their antifungal armamentarium, honing the capacity to

[1]Division of Infectious Disease, Boston Children's Hospital, Boston, MA 02115; [2]Department of Microbial Pathogenicity Mechanisms, Leibniz Institute for Natural Product Research and Infection Biology, Hans Knoell Institute Jena (HKI), Jena, Germany; [3]Disciplina de Biologia Celular, Departamento de Microbiologia, Imunologia e Parasitologia, Escola Paulista de Medicina-Universidade Federal de São Paulo, São Paulo, Brazil; [4]Department of Molecular Microbiology and Immunology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD 21205; [5]Division of Infectious Diseases, Duke University Medical Center, Durham, NC 27710.

distinguish self from nonself entities with the major histocompatibility complex, to respond quickly to invaders using memory and recall, and to iteratively increase affinity of soluble and cell-based receptor molecules for pathogens. Consequently, in fish, the first phylum to develop adaptive immunity, invasive fungal diseases due to, e.g., plant necrotrophs and saprophytes *Fusarium, Exophiala*, or *Paecilomyces* (19) are rare (20). Exceptions occur in situations of captivity in which fungal inocula may be overwhelming (21). The importance of the adaptive immune system in protecting humans from fungal infections is underscored by the diseases suffered by humans with defective adaptive immunity: cryptococcal meningoencephalitis, pneumocystis pneumonia, mucosal candidiasis, and massive dermatophyte skin and nail infections afflict individuals who are unable to mount adaptive immune responses.

Humans, endothermic mammals with highly sophisticated innate and adaptive immune systems, are naturally resistant to most invasive fungal infections. None but a small minority of fungi meet the four criteria required to establish invasive human infection: (i) the ability to grow at or above 37°C, (ii) the ability to reach internal tissues by penetrating or circumventing host barriers, e.g., through small airborne cells that directly enter air-filled spaces of lungs and sinuses, (iii) the ability to digest and absorb components of human tissues, and (iv) the ability to withstand the human immune system.

The stringency of these four criteria is demonstrated by the fact that an entire fungal lineage, the Chytridiomycota, is incapable of infecting humans. Chytridiomycota are an ancient lineage that live in watery environments and have preserved the flagellum of the basal fungi (22). These fungi are mainly saprotrophs and plant parasites (23), but their ability to infect animals is demonstrated by the ongoing decimation of amphibians. A chytrid species, *Batrachochytrium dendrobatidis*, has caused precipitous declines in frog populations around the world and is the cause of extinction of over 100 amphibian species (24). A distinct chytrid clade, the *Neocallimastigales*, demonstrates that chytrids can adapt to mammalian body temperatures by forming mutualistic relationships with ruminant mammals such as cattle and deer to which the fungi provide enzymes for digestion of cellulose (23, 25). But most chytrids grow only at cooler temperatures, and none are known to infect mammals.

The fungi that fulfill the four criteria to infect humans (thermal resistance, locomotion through or around host barriers, lysis and absorption of human tissue, and resistance to immune defenses) thus belong to only four lineages: the Zygomycota, Entomophthorales, Ascomycota, and Basidiomycota. They will be discussed in the following sections according to these phylogenetic categories. In addition, they will be divided by the clinically relevant category of primary versus opportunistic pathogens: have they evolved to confront healthy humans' immune systems, or do they infect only immunocompromised humans? While this distinction cannot be sharply drawn, in many cases it reflects an evolutionary history, because for important fungal opportunistic pathogens such as *Fusarium* and *Aspergillus*, humans are only an incidental host, accidentally encountered in their quest for live or dead plant tissue on which to grow.

Casadevall and colleagues have hypothesized that the stable elevated temperature of endothermic (warm-blooded) animals may have been one of the most potent developments in antifungal immunity (1, 26, 27). Protection from invasion by most fungi seems to be a major benefit of the energy expenditure on endothermy (control of body temperature by active balancing of metabolic heat production with heat loss) that drove its convergent evolution in at least two vertebrate lineages: birds and mammals (1).

Casadevall and colleagues proposed that evolution of endothermy and homeothermy produced a "thermal exclusionary zone" in which warmer hosts restrict fungal growth (1). These workers examined the temperature tolerance of over 4,800 fungal isolates of the Dutch national collection of fungi, which included 144 genera among the Dikarya (1). They found that most isolates grew well between 12 and 30°C, but with every 1° increase in temperature >30°C, around 6% fewer strains could grow (1). Calculations of the energetic cost versus infection-avoidance benefit of endothermic physiology arrived at an approximate temperature of many endothermic animals, ~36.5°C, as providing the most favorable balance (26). In fact, mammals have been proposed to have emerged as the dominant large animals at the end of the cretaceous period by selection through a "fungal filter" that prevented a second reptilian age (28), which could explain their remarkable resistance to fungal disease relative to other animals.

These considerations are supported by observations of "behavioral fever" among fungus-infected insects, which as mentioned, are susceptible to numerous fungi. Field observations and controlled experiments show that fungus-infected insects seek external heat sources and can survive longer when they are able to warm themselves (29, 30). Human fever is an even more energy-costly output of tumor necrosis factor-alpha signaling, which is potently induced by invading fungi, as shown for *Candida albicans* by several groups

(31, 32). The persistent fever response to invasive fungal infections is such a sensitive (if completely nonspecific) clinical marker that for over 3 decades since the studies of Pizzo and coworkers (33), it has been used as the sole indication for adding empiric antifungal to antibacterial therapy in neutropenic patients. Studies of the antifungal effect of human fever are lacking, but the general practice of aggressive antipyresis for fungus-infected patients may be questioned (34).

A capacity for locomotion to and through the human body is the second criterion for a fungus to infect a human. In the oceans, fungi originated as unicellular, oval cells propelled by flagella. Having lost their flagella, extant human fungal pathogens must use more indirect modes of movement to enter and spread through the body. Adhesion molecules are virulence factors related to fungal motion strategies because once a fungal cell has reached a favorable location, it needs to be able to stay at the site (35). Morphogenesis is another important virulence factor related to fungal movement. Yeast can readily disseminate to distant sites in the liquid environment of the bloodstream and extracellular fluid. Another advantage of a yeast form is its resistance to mechanical stress, such that most fungi encountered in deep-sea habitats, where hydrostatic pressures are in the range of 146 to 388 atmospheres, are yeast (36). Furthermore, yeasts are small enough to be readily ingested and spread by insects (37) and to become airborne in a desiccated state and act as infectious propagules (38). Primary fungal pathogens, once in the human body, proliferate almost exclusively in their yeast form.

Growth as a round or oval cell was a fundamental fungal trait. Lücking et al., in their comparison of fossil and molecular dating systems of fungal evolution, state that "all dating estimates show that the evolution of filamentous fungi occurred much later than the origin of the fungal lineage itself, suggesting that for a long time after their origin fungi were heterotrophic, unicellular, flagellate, aquatic organisms" (39). When fungi colonized land as plant symbionts (6, 39, 40), a growth form with a large surface area became necessary: mycelial fungal plant symbionts are able to absorb and concentrate essential nutrients which in soil are highly dilute, such as nitrogen and phosphate, and receive sugar from the plant in return (41).

Hyphae enable an active form of locomotion, as opposed to yeast or airborne propagules, which rely on passive transport. Growth at the hyphal tip propels the fungus into new territory, whether in the soil or in a human organ. Hyphae need adhesion molecules at their surface for their role in movement, because the growing tip could not move directionally if older hyphal cells were not tethered to their substratum. In *C. albicans*, hyphae possess unique adhesins that contribute to virulence (42–45).

Hyphal morphogenesis contributes to protection of fungi against ingestion and destruction by amoebae and phagocytes, e.g., in *Cryptococcus neoformans* (46). Amoebae are distant relatives of animals, and the basic mechanisms of phagocytosis, i.e., recognition of prey by cell-surface receptors and killing of ingested organisms by reactive oxygen species, are conserved between amoebae and the phagocytes which all metazoans possess (47–49). The opportunistic human pathogen *C. albicans* responds with hyphal growth when yeasts are ingested by macrophages (50), and *Candida* hyphae then induce macrophage pyroptosis (51–53), a form of apoptosis augmenting the immune response (54, 55).

Morphogenesis between two basic cell shapes, round or ovoid and detachable, or long, filamentous, and connected to multicellular mycelia, occurs among essentially all human pathogenic fungi. Airborne locomotion to reach distant substrates has evolved convergently in the form of dispersal cells among three fungal phyla: asexual sporangiospores among the Zygomycota, asexual conidia as well as meiotic ascospores among the Ascomycota, and meiotic basidiospores among the Basidiomycota. The effectiveness of this form of airborne locomotion is reflected in the continent-wide travel of fungal spores (56), their ubiquity out- and inside human habitations (57), and their isolation at stratospheric elevations up to 20 km (58). Few lineages have completely lost a round or a filamentous cell form. A highly successful human-associated fungus, *C. albicans*, is notable for the facility and frequency with which it switches among a broad spectrum of growth forms in the host (59).

Secretion of digestive enzymes appropriate to dissolve host tissue is the first step for a fungus to use the host as a nutritious substrate. *C. albicans*, a successful human commensal and pathogen, possesses 10 secreted acid proteinases known to contribute to virulence (60, 61). Its phospholipases (62, 63) and lipases (64–66) contribute to its pathogenesis. Infection of humans can be achieved only by fungi that secrete hydrolases suitable to digest human tissue, which include primary mammalian pathogens such as *Histoplasma capsulatum* (67, 68) and incidental, opportunistic pathogens such as *Fusarium* spp. (69) or *Aspergillus fumigatus* (70). A recent compelling genomic study comparing human-pathogenic Onygenales with five nonpathogenic, closely related species found that in the pathogens, gene families encoding plant-dissolving enzymes had dwindled, while those encoding hydrolases of animal tissues were enriched (71).

A. fumigatus is an interesting case of a saprotrophic fungus acting as a ferocious pathogen in specific immunocompromised populations. It is neither a plant necrotroph nor an amoeban or animal parasite. The features which turn *A. fumigatus* from a helpful recycler of plant carbon and nitrogen when it proliferates in our compost piles into a killer of patients with phagocyte defects, appear to be its high thermotolerance and its profuse production of hydrolases (72). These features lend it an edge among the microbial competition in decaying plant matter and by apparent coincidence enable it to withstand the human fever response and to rapidly lyse tissue in the absence of defending neutrophils when it happens to land in human lungs.

After hydrolysis of host macromolecules, possession of transporters to absorb the released oligo- and monomers of nitrogen, carbon, and phosphate sources, as well as micronutrients, is required of a human fungal pathogen. Acquisition and toxicity management of metallic micronutrients such as iron and zinc are especially critical because of their role as cofactors in enzymatic processes such as respiration and superoxide dismutation.

The host's withholding of these elements from bacterial pathogens has been termed "nutritional immunity" (73), and the same mechanisms limit growth of pathogenic fungi. For example, the human host actively sequesters iron during infection to withhold it from the pathogen (74–78). Conversely, pathogenic fungi such as *Candida*, *Histoplasma*, and *Paracoccidioides* deploy specific tools to wrest iron from the host (79–82). Interestingly, *A. fumigatus* utilizes siderophores, high-affinity iron chelators, to acquire environmental iron but has no uptake systems for host-specific iron sources such as heme and ferritin (83), consistent with its lifestyle as a plant saprobe and an only accidental pathogen of humans. The importance of iron sequestration in the host to defend against fungal growth was dramatically illustrated by an increased incidence of disseminated Mucorales infections in patients receiving the iron chelator deferoxamine (84).

In the micronutrient competition between pathogen and host, copper is a unique two-edged sword: while required for virulence of human fungal pathogens such as *Cryptococcus*, *Candida*, and *Paracoccidioides* (85–89), copper is also concentrated by activated host macrophages for lysosomal generation of reactive oxygen species to kill the ingested pathogen (90). Detoxification of copper has been shown to be required for virulence of *C. neoformans* (91, 92). Copper is a cofactor for a critical enzyme defending pathogens against reactive oxygen species, superoxide dismutase, and in a clever maneuver, *C. albicans* preempts rising ambient copper concentrations deployed by the host during infection: it decreases copper transporter expression and maintains activity of its superoxide dismutase by utilizing an alternative cofactor, manganese (93).

As Dzik emphasized in her superb review of the past half billion years' evolution of immunity (48), phagocytosis is a basal ability of unicellular eukaryotes such as amoebae and of the mobile cells of all metazoans. Macrophages, like amoebae, use cell surface receptors to recognize their prey (47) and reactive oxygen species to kill it (94). Fungal parasites of amoebae and of animals honed their strategies to evade these mechanisms over millions of years, and fungi that infect healthy humans devote a large portion of their physiology to evading or withstanding the immune system. Their strategies sometimes differ even between lineages of a single species.

The effectiveness of the human immune system against fungi can be judged by comparing the few fungal species that infect healthy humans with the hundreds of species that have been isolated from infections of immunocompromised patients. Conversely, the most effective fungal human parasites, as judged by the wideness of their distribution and the numbers of hosts they inhabit, are able to downmodulate human immune responses, thereby decreasing the risk to themselves that they will be immunologically eliminated. Additionally, unless a human-specialized fungal pathogen has a mode of transportation back from the soil to the next human host (as the Ajellomycetaceae do), killing the host is a dead end for the fungus, and the evolutionary winners manage to moderate host inflammation and disease. Among the pathogens that adopt these strategies are *Pneumocystis jirovecii* (Fig. 1A,B), the agent of pneumocystis pneumonia, the anthropophilic dermatophytes that cause ringworm and toenail fungus, and possibly the *Candida* colonizers of human mouths and guts which only invade systemically when normal defenses are breached (Fig. 1C).

Fungal cells use complex networks of sensing and signaling systems to fulfill these four criteria of pathogenicity. Experimental disruption of just one component leads to loss of virulence, including mechanosensor, calcineurin, protein kinase A, mitogen-activated protein kinase, target of rapamycin (TOR), and high-osmolarity signaling pathways (95–106).

FUNGI CAPABLE OF INFECTING HEALTHY HUMANS

Most of the fungi capable of infecting healthy humans evolved to infect other hosts such as amoebae, insects,

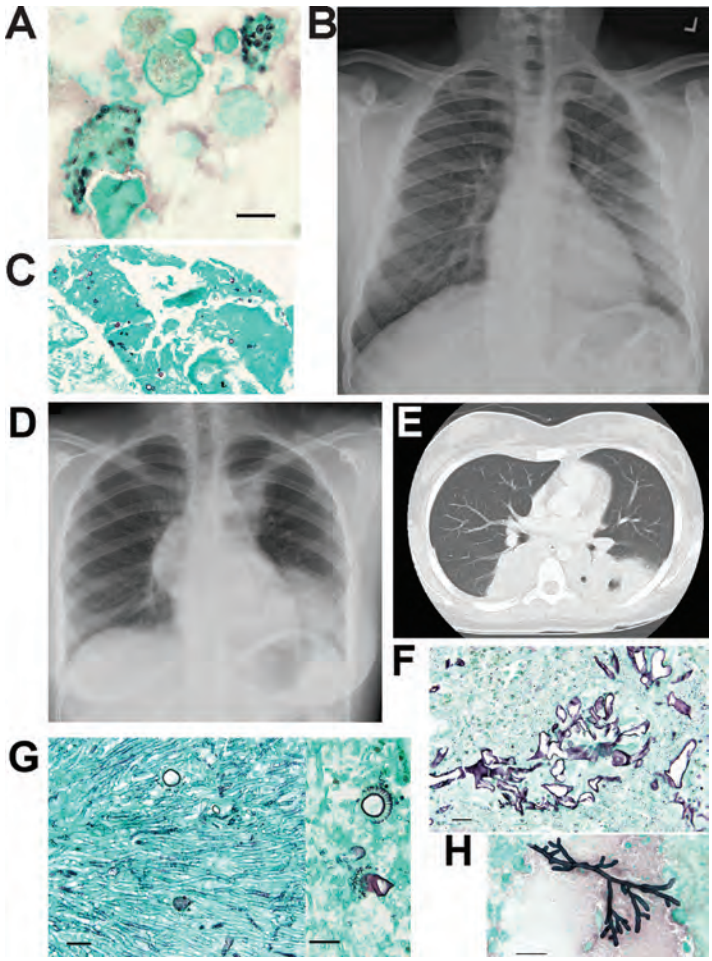

Figure 1 (**A**) Clusters of *Pneumocystis jirovecii* cells in brochoalveolar lavage fluid of an 8-year-old boy, post-lung transplant. Gomori methenamine silver (GMS) stain. Scale bar, 20 μm. Kozakewich, Department of Pathology, Boston Children's Hospital; Radiographs: Department of Radiology, Boston Children's Hospital.)

or small mammals. This is in contrast to bacteria such as *Streptococcus pyogenes* or *Mycobacterium tuberculosis*, whose virulence attributes directly target humans as their primary host. The ability to utilize healthy human hosts arose independently multiple times among three major fungal phyla: the Entomophthoromycota (107), the Ascomycota, and the Basidiomycota.

Entomophthoromycota

Entomophthoromycota are insect pathogens which have attracted the interest of mycologists since the 19th century because of their ability to decimate pests. They have been found as agents of invasive human infection only in subtropical and tropical regions despite their worldwide distribution. The species of genera

pathogenic for humans, *Basidiobolus* and *Conidiobolus*, are evolutionarily distant from each other as well as from the Mucorales, with whom they traditionally were classified in Zygomycota (107).

While the hyphae of Entomophthorales appear to be similar to those of the Mucorales, being broad, ribbony, with right-angle branches and sparse to no septa, their behavior is fundamentally different, in that they do not invade blood vessels (108). Thus, infarction and necrosis are not usual features, unlike in Mucorales infections. Their lytic enzymes, including elastases, collagenases, and lipases, kill arthropods (109–113) and are likely also to digest human tissue (114).

Conidiobolus spp. produce large ballistospores of 30 to 38 μm (115), which are forcibly launched up to 30 cm from their sporangiophores and presumably infect humans when they are inhaled and deposited on the mucosa of nasal air passages (116). Two species, *Conidiobolus coronatus* and *Conidiobolus incongruus*, have been isolated from central facial disease. Gradual progression causes swelling of submucosal and subcutaneous tissue, disfigurement, breathing difficulties, and chronic bacterial sinusitis due to blockage of ostia. Unlike the Mucorales that cause sinus disease, *Conidiobolus* does not usually penetrate into the central nervous system (CNS) (108).

Basidiobolus ranarum causes subcutaneous disease primarily in children in tropical and subtropical Africa, Asia, and the Americas. The fungus can be attached to plant matter in feces of amphibians and reptiles that ingested *Basidiobolus*-infected insects (117) and can be accidentally inoculated under the skin, e.g., by thorns. Nodules appear at inoculation sites (117), sometimes resembling malignancies (118). *Basidiobolus* can also cause gastrointestinal disease, presumably after ingestion, mimicking inflammatory bowel disease or cancer (119–121). Its inability to invade deep organs is likely related to limited thermotolerance: 37°C may be its maximal growth temperature (117).

Neutrophils, eosinophils, and histiocytes respond to the fungal invasion, forming ordered cellular arrays, granulomas, to contain the fungus. Dense eosinophilic material surrounding the hyphae, the Splendore-Hoeppli phenomenon, which is thought to consist of antigen-antibody precipitate (115), is a classical histologic finding.

Ascomycota

Subcutaneous infections of healthy hosts, through traumatic inoculation of fungal elements, e.g., on thorns, is also initiated by a few dozen members of the Ascomycota, which cause chromoblastomycosis and mycetoma of the extremities and trunk. These neglected tropical diseases cause much suffering but only very rarely directly cause death, and they afflict poor people in rural areas, which may explain the limited research attention they have enjoyed and the as yet limited understanding of their pathogenesis.

Chromoblastomycosis is caused by several genera of filamentous pigmented plant saprotrophs, including *Fonsecaea* and *Cladophialophora* and, more rarely, *Phialophora, Rhinocladiella*, and *Exophiala* (122). These fungi convert to growth as chambered round structures called "muriform cells" in the host, which are pathognomonic for the disease. Their melanin-coated cell walls are thought to protect against reactive oxygen species (123). As the superficial infection extends in depth and breadth, verrucous and nodular lesions develop which become intensely pruritic. Chronic inflammation gives rise to lymphedema and squamous cell carcinomas (122). The incidence of chromoblastosis in Brazil is estimated at 3/100,000 (124) and in Madagascar at 14/100,000 (122), though accurate counts are not available. Treatment is difficult and requires months to years of antifungals, of which the most commonly used have been itraconazole and terbinafine (122).

Mycetoma is a destructive subcutaneous infection that spreads by extension to bone and vital organs including the lungs. Amputation of the affected limb is in many cases the final common pathway of treatment courses that failed because of drug toxicity (e.g., in the case of ketoconazole), inability to purchase the years' worth of drugs required, difficulty adhering to such long treatment courses, and poor efficacy of the drugs (125). The syndrome is characterized by nodule formation, sinus tracts, and discharge of macroscopic granules which consist of masses of the pathogenic agent. While actinomycetes including *Nocardia* spp. cause similar clinical syndromes, the disease is often caused by fungi and then termed "eumycetoma." Fungi involved in this infection include *Pseudallescheria boydii*, a feared opportunistic pathogen of neutropenic patients in other contexts, *Fusarium* spp., discussed below, and most commonly, *Madurella mycetomatis*, a member of the Sordariales (126). This melanin-producing species typically does not produce conidiophores in culture, contributing to difficulties in precise identification except when molecular diagnostics are available (127).

Mycetoma occurs around the globe in regions between 30°N and 15°S of the equator, termed the "mycetoma belt," which includes Mexico, Sudan, and India. Risk factors for acquisition of this crippling infection are agricultural work and lack of shoes. A recent genomic study positioning *M. mycetomatis* among Sordariales

species growing in dung of mammals suggests that this agent of mycetoma may reside in dung of domestic animals and enter the subcutaneous space by traumatic inoculation (127). Why only a fraction of the at-risk individuals develop the infection is the subject of studies that have variously implicated polymorphisms in CC chemokine ligand 5 and interleukin-10 promoter regions (128), in the promoter of tissue inhibitor of metalloproteinases (129), and in chitotriosidase, a macrophage enzyme required to break down cell wall chitin of *M. mycetomatis* (130).

More urgent is the question of prevention and treatment: protective clothing, including closed shoes, could do much to avert new mycetoma cases, if at-risk individuals could afford them. Because ketoconazole has unacceptable hepatotoxicity, and itraconazole is only erratically absorbed, a recent finding of remarkably low *in vitro* MICs of ravuconazole for *M. mycetomatis* is highly encouraging, if confirmed clinically, and if this drug or other extended triazoles such as voriconazole, posaconazole, and isavuconazole will be made available to those who need it (131), treatment outcomes might substantially improve. As with most neglected tropical diseases, an improvement of the socioeconomic situation of at-risk people will be the most effective means of prevention.

Pathogenic Onygenales comprise a group of ascomycetous soil dwellers that parasitize mammals and cause systemic infection. Most belong to the family Ajellomycetaceae (132, 133), which includes *Blastomyces dermatitidis* (teleomorph, *Ajellomyces dermatitidis*) *H. capsulatum* (teleomorph, *Ajellomyces capsulatus*), *Paracoccidioides brasiliensis*, *Paracoccidioides lutzii*, and *Lacazia loboi*. *Coccidioides immitis* and *Coccidioides posadasii* in the family Onygenaceae possess similar properties. Ajellomycetaceae are the only phylogenetically related fungal group whose members all cause systemic disease in otherwise healthy humans. As mentioned, phylogenomic analyses show that the pathogenic clades of Onygenales switched from vegetarian to carnivorous lifestyles, losing cellulases and pectinases and gaining proteinases and keratinases (71).

Most genera occur in defined geographic areas, which follow particular soil consistencies, e.g., dry and alkaline for the *Coccidioides* spp. and acidic for *Histoplasma*, and possibly specific host mammals, e.g., rodents for *Coccidioides* (134), bats for *Histoplasma* (135), and armadillo species for *Paracoccidioides* (136, 137). In the soil, they grow as a branched network of hyphal filaments, a mycelium, and utilize dead plant or animal matter for nutrition. Their airborne dispersal cells are produced as conidia from specialized hyphae in *Histoplasma* and *Blastomyces* or as arthrospores from regulated fragmentation of hyphal compartments, in *Coccidioides* and *Paracoccidioides*. *Paracoccidioides* additionally produces aleuroconidia budding directly from hyphae.

Once a mammal inhales conidia or arthrospores, they convert into parasitic yeasts (or spherules in the case of *Coccidioides* spp.) and initiate an infection. The principal signal for their conversion to the yeast or spherule form is mammalian body temperature as their cue to initiate an entire alternative pathogenic growth program. In immunocompromised hosts, the infections are more clinically apparent, more severe, and more likely to disseminate to multiple organs with different organ disease propensities among different genera: *Paracoccidioides* in oral and respiratory mucous membranes (138, 139); *Blastomyces* in bones, joints, and skin (140); *Histoplasma* in multiple organs including the gastrointestinal tract and adrenals, as well as in bones and skin (141); and *Coccidioides* spp. in lungs, skin, deep organs, and in rare worst cases, in the CNS.

Adaptive cellular immunity is required to control the infection with these fungi. For this reason, clinically apparent infections with some members of this group, e.g., *H. capsulatum*, became much more common with the rising prevalence of AIDS. Close relatives within this order pursue very different pathogenic strategies in the same habitat. For example, the teleomorph genus *Ajellomyces* comprises anamorph sister species *H. capsulatum* and *B. dermatitidis*, of which one, *H. capsulatum*, evolved mechanisms to thrive within macrophage phagolysosomes, while the other, *B. dermatitidis*, is a successful extracellular pathogen.

Other thermally dimorphic fungi are rare animal-pathogenic species within orders comprising plant saprobes and pathogens. They are *Sporothrix schenckii* (order Ophiostomatales), which is primarily introduced into the host through skin injuries, and *Talaromyces* (*Penicillium*) *marneffei* (order Eurotiales), which does not infect healthy hosts but due to the AIDS epidemic has become a prevalent and important invasive pathogen in Southeast Asia.

The fact that these evolutionarily distant fungi convert from saprobic hyphal to pathogenic yeast-growth at the temperatures of endothermic animals suggests that an ability to access large nutrient stores of a mammalian host is an advantageous lifestyle option for a soil dweller and is a result of convergent evolution in several phyla. It is also a testament to the suitability of the yeast form for accessing and spreading through a human host.

H. capsulatum hyphae produce macro- and microconidia. The latter are small enough to penetrate into the alveoli of mammalian lungs, where they are phagocytized by alveolar macrophages and convert to yeasts which proliferate in the hostile environment of the phagolysosome. This conversion entails differential transcription of 6 to 20% of the genome (142–144) and is controlled by a network of transcriptional regulators in response to a histidine kinase signal (145–148).

Regulation of translational efficiency of specific transcripts has recently been found to play a role in cell-type interconversions of *H. capsulatum* (149). Differential lengths of upstream leader sequences of cell-type enriched transcripts specify distinct translational activity of the transcripts in the two different cell types, adding a layer of translational regulation to the previously known transcriptional regulation of cell fate. In addition to the transcriptional regulators Ryp2 and Ryp3 that induce yeast-enriched transcripts, expression of a homolog of the *Aspergillus nidulans* WetA conidial regulator is repressed by differential translation in yeast, and its dysregulated expression at 37°C induces inappropriate hyphal growth at mammalian body temperature (149).

Histoplasma thrives in soil enriched with bird and bat droppings. While birds are very rarely infected with *H. capsulatum* (150), bats are frequently infected but respond with minimal inflammation (135), suggesting active repression of the host immune response by the fungus. A broad variety of other infected mammals including humans develop granulomatous inflammation in response to *Histoplasma* yeast (151–153). The fungus may have developed specific mechanisms to repress the host immune response of bats, thereby establishing an efficient amplification cycle by which its mycelial form grows in droppings under bat roosting places, e.g., in caves, and its microconidia are released into the air to be inhaled by the bats that fertilize its soil substrate (135).

Other pathogenic Onygenales, all of which associate with mammals, have equally distinctive ecology and pathobiology. The genus *Coccidioides* comprises the species *C. immitis*, distributed through California into Utah and eastern Washington (154), and *C. posadasii* (155, 156), which is present in Arizona, Texas, Mexico, Central America (157, 158), and South America including Brazil (159), Argentina, Colombia, Paraguay, and Venezuela (160, 161). The human disease was first described by Alejandro Posadas in Argentina, who reported finding large cysts in the widespread skin lesions, which he called "psorospermias," of a cavalry soldier returning from the Chaco (162).

Mycelia of the *Coccidioides* spp. grow ~20 cm below the surface near rodent burrows in hot, arid soils (161, 163). They are thought to remain limited to the surface area in which a mammalian carcass is decaying (164), because they have lost the plant-degrading enzymes such as cellulase and tannase of their ancestral lineages, while acquiring animal tissue-digesting keratinases and metalloproteinases (165). The morphogenetic repertoire of *Coccidioides* is unique in that the parasitic, round form of the fungus in the mammalian host, the spherule, does not bud to the exterior, but produces daughter endospores in the enlarging mother. The maturing spherule protects its progeny from host phagocytic attack through its sheer size of 60 to 100 μm (166), which not even a macrophage of 20 to 80 μm could engulf. The spherule eventually ruptures to release its daughters into host tissue for local replication or hematogenous dissemination.

Coccidioides arthroconidia arise by regulated fragmentation of subsurface hyphae and become airborne when the soil is disturbed by wind or by human or animal activity. Inhalation of arthroconidia begins the infectious process, in which conidia convert to spherules at mammalian body temperatures and begin infecting the lungs. In ~60% of cases, the infection causes no symptoms or a mild respiratory syndrome, but in 40%, febrile pneumonia ensues, among whom a small percentage develop dissemination to the skin, skeletal system, and deep organs including the CNS (167).

Much of our current understanding of *Coccidioides* spp. pathobiology originated with Charles Edward Smith's epidemiologic studies of soldiers stationed in Californian Army airfields during World War II and of 432 patients with erythema nodosum, then considered a hallmark of coccidioidomycosis, in Kern and Tulare Counties of the San Joaquin Valley (168, 169). Smith showed the association of infection with field work such as potato digging and cotton chopping and the absence of human-to-human transmission as well as silent infection in a majority of cases (168, 169). He also demonstrated the role of adaptive immunity in preventing reinfection once the coccidiodin skin test turned positive, i.e., cellular memory had developed, inspiring contemporary vaccine development efforts (168, 170, 171). These findings also explain a possible protective role of long-term low-level exposures, given the increased risk of recent arrivals to endemic areas developing valley fever (168) and given the link with tuberculosis, which can coexist in *Coccidioides* infections and amplify their severity (161).

Coccidioides spp. evolved in North America before formation of the isthmus of Panama connected that

continent with South America ~3 million years ago (172). The genetically homogeneous South American strains, derived from populations in present-day Texas, reached their current distribution 8,940 to 134,000 years ago (172). This timespan coincides with the migration of humans into South America, and it is conceivable that latently infected humans carried *C. posadasii* to their new homes on this continent (173). In addition, other mammals such as migrating bats could contribute to its ongoing spread (174).

Though a mating-competent form has not been observed, meiotic genes are expressed in *Coccidioides* spp. (71, 163), and there is much genetic diversity and little clonality, to the point that within a 10-m^2 area in Tucson, Arizona, multiple genotypes were found (175). Recent hybridization events between the species have been documented: gene flows from *C. posadasii* to *C. immitis*, enriched for genes associated with immune evasion and with cell walls, suggest selective advantages conferred by the introduced genes (176).

Recent sharp increases in human coccidiodomycosis in the United States have been attributed to several factors, including the large numbers of immunologically naive retirees moving to Sunbelt endemic areas and construction in previously undisturbed desert (177). Human incidence and prevalence studies of *Coccidioides* south of the United States are sparse, but exposure studies from Argentina (178) and Mexico suggest a substantial prevalence (179). A concerning factor is the effect of drought and rainfall cycles on *Coccidioides* growth in the soil (180, 181), which may become more pronounced given current climate shifts.

Another unique member of the Ajellomycetaceae, *L. loboi*, a sister genus to *Paracoccidioides*, has been found only in subcutaneous infections of previously healthy humans in the Amazon basin and in dolphins of the Atlantic Ocean and of the Amazon (182, 183). It can (analogously to *M. leprae*) be amplified only in a mouse model but cannot be grown in culture. In contrast, *P. brasiliensis* and *P. lutzii*, prevalent fungal pathogens that cause pneumonia, systemic disease of the monocyte-macrophage system, and destructive lesions of skin and oral mucous membranes (138, 139, 184, 185), occur in Central and South America mainly outside the Amazon region (183).

In Brazil, *Paracoccidioides* was the major cause of deaths from invasive fungal infection between 1996 and 2006 (186). Though millions of people are thought to be infected, only ~2% will develop disease. As in tuberculosis, most disease results from reactivation of the latent pathogen many years after infection, leading to chronic pulmonary forms that can be uni- or multifocal and affect mainly 30- to 50-year-old agricultural workers. Acute or subacute lymphatic forms of paracoccidiosis are less common; they develop in children and young adults weeks to months after infection and are associated with high mortality rates (187). *Paracoccidioides* causes clinical disease in many more men than women, in a ratio up to 13:1, possibly because estrogen blocks the conversion of inhaled arthroconidia to the tissue-invasive yeast form (188). This fungus frequently infects armadillos, and its virulence factors such as the immunodominant adhesin glycoprotein 43 (gp43) (184, 189–191) may have evolved in its coevolution with these ancient mammals (192, 193). Hence, *Paracoccidioides* may be the member of the pathogenic Onygenales (194) to have evolved targeting a mammalian host in South America during that continent's isolation from the other land masses between 130 and 3 million years ago (194, 195).

In experimental systems, gp43 is partially responsible for yeast cell adherence to Vero cells and to extracellular matrix components such as laminin and fibronectin (196). *P. brasiliensis* adheres to and then is taken up by epithelial cells through endocytosis, with the aid of microfilaments and microtubules, triggering host cell apoptosis (196). Proteases subsequently support nutrient acquisition and dissemination of the fungus, e.g., an extracellular thiol-dependent serine protease, which selectively cleaves extracellular matrix-associated proteins *in vitro* and has a unique kind of positive modulation by fungal polysaccharides. Another serine protease (PbSP) interacts with proteins related to folding processes, protein trafficking, and cytoskeleton reorganization (197). A secreted aspartyl protease (Sap) was detected in the fungal cell wall and is highly expressed in a virulent isolate (198).

Some members of the Onygenales infect healthy humans only superficially: the dermatophytes. They cause invasive disease very rarely, e.g., in individuals who cannot induce dectin 1-dependent innate responses to (1,3)-β-D-glucan as a result of homozygous CARD9 mutations (199, 200). Dermatophytes of the family *Arthrodermataceae* specialize in degrading keratins, important structural proteins in vertebrate skin whose extensive cross-linking by disulfide bonds makes them proteinase-resistant (201). Reptilian amniotes had evolved keratin, so the basis for this specialization was available as a fungal substrate 300 million years ago (202).

Analysis of the mitochondrial genomes of six dermatophytes comprising the three morphologically defined anamorphic genera *Trichophyton*, *Microsporum*, and *Epidermophyton*, together with 29 other members of the Ascomycota, confirmed that the dermatophytes are

descended from a common ancestor (are monophyletic) and separated from other fungi only 32 to 50 million years ago (203). Molecular phylogenetic studies have confirmed the grouping of dermatophytes by their ecologic and clinical features, including the distinct sites of the human body they tend to infect (204, 205), but not by their traditional morphology-based taxonomy.

Anthropophilic dermatophytes travel over the world with their human hosts. While many species are endemic to specific geographic regions, some occur worldwide. Their prevalence varies with the lifestyle and socioeconomic conditions of their human hosts and is undergoing continuous epidemiologic changes (206). Unlike their thermally dimorphic Onygenales relatives, they can reach a new host by person-to-person transmission, and their access to new human substrate is made even easier by the ability of their arthroconidia to persist for years in fomites (207). Anthropophilic dermatophytes, relying on person-to-person access to new hosts, can forgo long-distance travel via airborne conidia, which their geophilic relatives produce in larger profusion to reach distant deposits of animal keratin (207).

Coevolution with their animal hosts presumably allowed dermatophytes to evade or resist the evolutionarily more ancient innate immune mechanisms, so that today their control requires adaptive cellular immunity (208). By restricting their usual habitat to the most superficial keratinized layer of the skin and its appendages, dermatophytes reduce their contact with immune cells. Human-specific dermatophytes (anthropophiles) are able to downregulate host inflammation to establish a chronic infection (209, 210). In contrast, humans eliminate soil-dwelling (geophilic) and animal-specific (zoophilic) dermatophytes by a vigorous inflammatory response.

Basidiomycota

Cryptococcus

Cryptococcus (Fig. 1D,E) is a genus containing diverse environmental saprophytes worldwide, among which two species infect humans: *C. neoformans* and *Cryptococcus gattii*. Only in the past few decades have their phylogeny, genetics, cell and sexual biology, and virulence been elucidated, because before the AIDS epidemic they were rare human pathogens (211). Until the international medical community's goal of an AIDS-free generation by 2030 is reached, e.g., through implementation of UNAIDS' 90-90-90 goals (212, 213), cryptococcus will continue to cause lethal infections: for 2006, 957,900 cases of cryptococcal meningoencephalitis associated with AIDS were estimated, resulting in 624,700 deaths (214). Most of these deaths occur in Africa and are caused by *C. neoformans* var. *grubii*. Its sister species, *C. gattii*, has recently emerged in the American Northwest as a cause of pneumonia and other deep organ infections in apparently healthy people and in animals. Hence, in addition to expanding its geographic range (215), the fungus may also be undergoing continued evolution toward increased virulence (216–218).

C. gattii causes invasive disease and death in wild and domestic land mammals, ocean mammals, and birds, as well as pneumonia and meningoencephalitis in previously healthy people (219–223). A wealth of analyses of pathogenic cryptococci over the past several decades have shown that *C. gattii* in many settings is a more common primary pathogen than *C. neoformans* (218, 224), and new reports continue to blur the artificial boundaries between primary and opportunistic pathogens among the *Cryptococcus* species (225–227), illustrating the limited utility of these terms (228). A recent report has indicated that the presence of anti-granulocyte-macrophage colony-stimulating factor (GM-CSF) auto-antibody is a risk factor for *C. gattii* CNS infection in otherwise healthy individuals (229). It suggests that patients with cryptococcal CNS infection considered "immunocompetent" may carry immune defects which cannot yet be identified by routine immunological screening.

C. neoformans and *C. gattii* are believed to have separated ~40 million years ago (230, 231), diverging from saprobic cryptococcal phyla most likely in Africa (230) and subsequently spreading around the world in waves of clonal expansion punctuated by interbreeding events (232). Their broad and flexible sexual repertoire allows for genetic diversification and hybridization, introducing hybrid vigor, as well as an extremely efficient form of inbreeding: same-sex mating (233–235).

The nomenclature of cryptococcal subtypes continues to evolve as more genomic data are analyzed, but presently *C. neoformans* var. *grubii* has at least three distinct genotypes, VNI, VNII, and VNB (236), and *C. gattii* has been organized into four major genotypes, VGI, VGII, VGIII, and VGIV (235), which contain further subtypes such as VGIIa-c. Therefore, there are numerous lineages within each species, as well as hybrids between them, with distinct virulence properties that have been demonstrated worldwide (237). It is important to emphasize that even the standard H99 (*C. neoformans* var. *grubii*) strain can micro-evolve in the laboratory over short periods of time with measurable consequences for its virulence (238).

An origin of *C. neoformans* var. *grubii* in southern Africa is supported by the finding that this is the site of its highest genotypic diversity, and a collection of strains from Botswana contained 12% isolates of the a mating type, which in other sites is extremely rare (236). Enrichment of *C. neoformans* in bird droppings (236) and its ability to mate on pigeon droppings (239) are consistent with the idea that birds may have been one of its vectors of spread; another travel mode, with ocean currents, is suggested by survival of cryptococci for at least a year in fresh- and seawater (240).

C. gattii has a similar focus of unique symmetry of alpha and a cells in South America. While clinical and environmental isolates of the alpha mating type vastly predominate in other parts of the world, and isolates of the a type are almost never encountered, the South American distribution is 0.8 a to 1.0 alpha (241). *C. gattii* has been isolated from dozens of tree species, especially from sites of wood decay and insect consumption of vegetable matter (242–245). Could migrating insects rather than birds have expanded *C. gattii*'s range? In any case, its culture from a tree in the midst of a pristine Amazon rainforest (243) supports the idea of its longstanding presence in South America.

The pathogenic cryptococci enter a human by inhalation of infectious cells: dried yeast or possibly basidiospores, the products of meiosis after mating. When these small airborne cells, <5 μm in size, are inhaled, pneumonia can ensue in susceptible hosts, and upon gaining access to the bloodstream, the yeast can disseminate to all organs including skin. *Cryptococcus* has a special predilection for the CNS and causes subacute meningoencephalitis, in which high intracranial pressure plays an especially deleterious role and which, left untreated, is lethal. The fungus can persist for years in the lung or in sites of previous dissemination and reactivates only upon weakened immune surveillance.

C. neoformans and *C. gattii* have classically been shown to share important virulence traits lacking in their rarely pathogenic sister species: a thick capsule composed of glucurono- and galactoxylomannan which, by analogy to encapsulated bacteria such as *Streptococcus pneumoniae*, blocks phagocytosis of the organism unless it is opsonized (246, 247); cell wall melanin which shields the fungal cell from oxidative and other chemical stress (248, 249); and the ability to grow at endothermic mammals' temperature range (250).

The cryptococcal capsule is a unique organelle with many roles in infection. Capsular glucuronoxylomannan and other macromolecules, as well as virulence-associated proteins, are carried through the cell wall by vesicles that originate from the late endosome (multivesicular body) and are targeted to the extracellular space (251, 252). Upon phagocytosis, large amounts of capsular polysaccharide are shed to fill the phagocytic cells' cytoplasm (253, 254).

Further protective mechanisms against phagocyte attack are disruption of phagolysosome membranes and interference with full acidification of this organelle (253); detoxification of oxidative and nitrosative stressors with neutralizing enzymes such as superoxide dismutase, glutathione reductase, and thioredoxins (255); and a highly sophisticated system to detoxify the copper wielded by host macrophages against the fungus while acquiring sufficient amounts of this critical micronutrient (91, 256).

Cryptococci can promote their own extrusion from the intracellular environment with a process called nonlytic exocytosis (vomocytosis). In this process the vesicle with the yeast and its potentially important extracellular "virulence factors" is expelled from a phagocytic cell without the latter's demise (257). It is apparent that cryptococci can live and move around in both an intracellular and extracellular lifestyle within the host.

Diversification of a population is an important survival mechanism in stress situations like the host interaction. Cryptococci can physically diversify by size in the host, producing large Titan cells and small drop cells. Titan cells are giant cells of up to 50 μm in diameter that are too large to be phagocytosed (258, 259) and in which DNA replication and growth are not followed by mitosis (259). There is some evidence of a dormant cell population in hosts latently infected with *Cryptococcus* (260). Cryptococci further diversify by age, in that senescent cells are more resistant to phagocytosis, oxidative stress, and killing by antifungals than younger cells (261) and are more likely to undergo phenotypic switching (262).

The transcriptome of *Cryptococcus* in the human host demonstrates a stress reaction (263). Furthermore, under *in vivo* stress conditions the genome shows plasticity with changes in genes and chromosome structure (264), which has implications for antifungal drug resistance and its stability (265). Many antiphagocytic mechanisms are controlled by two GATA transcription factors and are likely to involve coordinated regulation of numerous physiologic processes, because hundreds of genes are differentially expressed in their mutants (266, 267). Hypothetically, global restructuring of the transcriptional landscape during the encounter with the host, by positive feedback loops of chromatin modifications uniquely discovered in the fungal kingdom,

may lead to a global "pathogenic" versus "saprobic" chromatin state (268).

How did cryptococci, for which humans are only incidental hosts, evolve their extensive repertoire of virulence factors? As mentioned above, amoebae use essentially the same mechanisms for engulfment and digestion of nonself cells as the phagocytes of metazoans (48). A prolific line of experimentation has shown that cryptococci utilize the same mechanisms against amoebae as against mammalian hosts and put them to use to proliferate in amoebae (253, 269), suggesting coevolution with amoeboid predators in the soil (253).

The recent development of a lateral flow assay for detection of cryptococcal antigen in blood and cerebrospinal fluid has importantly allowed a sensitive, specific, inexpensive and technologically facile test to be used effectively in resource-limited environments for clinical care (270). Clearer understanding of the ecology, epidemiology, and evolution of cryptococci will emerge with the availability of more microbiological capacity in resource-poor countries: cultures of blood and cerebrospinal fluid currently cannot be performed in medical settings where most patients with cryptococcosis seek help.

OPPORTUNISTIC FUNGAL PATHOGENS OF HUMANS

A sufficiently immunocompromised host can be infected by hundreds of environmental fungal species that grow at human core temperatures. However, a predictable set of actors among Mucorales (Fig. 1F), Ascomycota, and Basidiomycota is known to cause the most common invasive infections in immunocompromised individuals, and they will be discussed next according to their phylogenetic affiliations, which predict important parameters of their physiology.

Basidiomycota

Besides the *Cryptococcus* spp. discussed above, other Basidiomycota that grow predominantly as yeast in the host, including *Malassezia* spp., *Trichosporon asahii*, and other members of the human skin microbiota, are opportunists for patients with venous catheters and certain immunosuppressed patients.

Ascomycota

Candida

Candida spp. are among the most common human pathogenic fungi (Fig. 1C), because the majority of the human population carries members of the genus *Candida* on their mucous membranes. The genus consists of approximately 150 species, but the overwhelming majority (>90%) of *Candida* infections are caused by only four species: *C. albicans* (>50% of all cases), *Candida glabrata*, *Candida parapsilosis*, and *Candida tropicalis*. *C. albicans*, *C. parapsilosis*, and *C. tropicalis* belong to the CTG clade, a phylogenetic group that translates the CTG codon into serine instead of leucine (271), while *C. glabrata*, the second most common species in many studies, is more closely related to the baker's yeast *Saccharomyces cerevisiae*. These *Candida* species are commensals and natural members of the microbiota of mucosal surfaces (*C. albicans*, *C. parapsilosis*, and *C. glabrata*) and the skin (*C. parapsilosis*), and *C. tropicalis* is also an environmental fungus.

Until the 1950s, humans survived only briefly with diseases during which *C. albicans* could significantly invade the host. Invasive candidiasis was very rare (272, 273). Yet paradoxically, *C. albicans* is an efficient invasive pathogen in humans with immune defects, causing mucous membrane infections in individuals with ineffective adaptive cellular immunity and fatal disseminated infections in patients lacking functional innate immune cells (neutrophils). Humans so prevalently acquire adaptive immunity against *Candida* during childhood that for decades, a skin test containing *Candida* antigens was used as an anergy control in tuberculin skin testing for *M. tuberculosis* with the purified protein derivative (274). Given the rarity of invasive candidiasis until very recently, it is unlikely that *C. albicans*' pathogenic repertoire evolved to enable invasive disease. Moreover, unlike the pathogenic Onygenales, which produce airborne conidia from the soil-growing mycelia nourished on lethally infected animals, *Candida* has no mechanism to return to other human hosts once it has caused lethal infection. However, every human community has a population of individuals with temporary deficits of adaptive immunity: infants and young children.

Children are the community reservoirs of numerous human-adapted pathogens before they, naturally or by vaccination, develop specific adaptive immunity. This pervasive principle was recently dramatically illustrated when novel pneumococcal vaccinations for children were implemented, leading to decreased pneumococcal disease of adults over 65 (275). Before they develop anticandidal adaptive immunity, healthy children are susceptible to candidal infection of the oral mucous membranes, popularly termed thrush. We posit that the pathogenic repertoire of *C. albicans*, including biofilm formation and disruption of epithelial barriers, evolved for temporary mucosal infection of infants, which provides the fungus with the opportunity to replicate to

substantial numbers and, via infants' uncontrolled oral secretions, to easily spread to and colonize their adult contacts. While *C. albicans* biofilms at present are most troubling in patients with implanted foreign material including vascular catheters, and negatively impact quality of life in millions of denture wearers, this species' capacity for biofilm formation did not evolve in interactions with man-made plastic materials. A comprehensive study of *C. albicans* transcriptional networks controlling biofilm formation has found that genes upregulated in biofilms arose relatively recently during the evolution of *C. albicans*, after divergence of the CTG clade (276), consistent with the idea that mucous membrane biofilms are an evolutionary hallmark of this species and its close relatives.

Due to the medical relevance of *C. albicans*, the biology, genetics, and pathogenicity mechanisms of this organism have been particularly well studied. In most cases, infections with *C. albicans* are endogenous infections. Therefore, pathogenicity includes a shift from harmless colonization to overgrowth on superficial tissues and invasion into deeper tissue. The major reservoir of *C. albicans* is the human gut, and recent studies have begun to focus on its interaction with bacteria and on the commensal lifestyle, because the evolutionary selection pressure on this fungus has likely been as a commensal organism (277, 278). It has been shown that certain bacterial populations can prevent outgrowth of *C. albicans* and that the presence of *C. albicans* influences community reassembly after treatment with antibiotics (reviewed in 279). Of note, emergence of *C. albicans* and *C. glabrata* has been shown in ≈75% of cases with ultra-low-diversity microbial populations during prolonged stays in intensive care units, providing further indirect evidence for frequent colonization of *Candida* species in the gut (280). Depending on the degree of host immunocompromise, all four human-associated *Candida* species can cause life-threatening disseminated and systemic infections.

While traditionally described as dimorphic, *C. albicans* is in fact a polymorphic fungus and can grow as a spherical yeast, filamentous pseudohyphae or true hyphae, chlamydospores, and in various switching morphologies. All morphologies have a distinct but flexible cell wall structure with key functions in pathogenicity, such as adhesion, invasion and host recognition. Key components are glycoproteins, (1,3)- and (1,6)-β-D-glucan, and chitin.

While the role of chlamydospores remains mysterious, all other *C. albicans* morphologies are associated with distinct biological and pathogenic functions. Switching between opaque and white budding yeast has been linked to mating and biofilm formation; the yeast form is thought to be critical for disseminated infections (281) and spread via the bloodstream (282), and the filamentous form has been shown to be essential for invasion into epithelial cells.

Pathogenicity mechanisms differ between superficial and invasive infections, but in all stages the four fungal virulence properties are required. Initially, attachment to epithelial cells is required and mediated by cell surface adhesins, some of which, such as Hwp1 and Als3, are linked to hyphal morphology (42, 283). Damage of epithelial cells is due to the physical force of hyphal extension, as well as to secreted hydrolytic enzymes and toxins.

Recently, the first peptide toxin of a human-pathogenic fungus was discovered in *C. albicans* (284). This toxin, candidalysin, is a proteolytic product of the strictly hypha-associated polypeptide Ece1. Once hyphae are produced, the *ECE1* gene is expressed and Ece1 is produced, processed by the Golgi proteases Kex2 and Kex1, and secreted. The third of eight peptides in total, candidalysin integrates into host membranes and causes pore-like lesions and damage. Intriguingly, candidalysin is also a key signal for the host to activate the danger response pathway, which has been identified as the signaling pathway that is characteristic for the commensal-to-pathogen shift of *C. albicans* on epithelial surfaces (285).

Adaptation to the different host niches from mucosal surfaces to deeper tissue, blood, and organs is a crucial part of *C. albicans* pathogenicity. This includes metabolic adaptation, and the metabolism of *C. albicans* is known to be very flexible. This is also true for nutrient uptake strategies, in particular, metal acquisition mechanisms (76, 286). Within the several niches and during confrontation with the host immune system, the fungus can adapt to various stresses such as osmolarity, reactive oxygen species, or pH (287). The latter includes not only cellular adaptation, but also active manipulation of the environmental pH (288).

Furthermore, immune evasion strategies to avoid or overcome the immune response of the host are critical. For example, *C. albicans* and *C. glabrata* can survive phagocytosis by macrophages, proliferate intracellularly, and escape (289). Another mechanism of immune evasion and drug resistance strategy is the production of biofilms, which also occurs on medical devices such as catheters.

Although *C. albicans* was originally described as a member of the artificial group of "fungi imperfecti" due to the proposed lack of a sexual cycle, recent studies discovered complete sets of genes required for sexual

reproduction, which led to the discovery of (i) parasexual cycles which permit recombination in the absence of meiosis and (ii) a haploid form of *C. albicans* (290, 291). Much recent work, led by the Berman laboratory, has emphasized the importance of *C. albicans* genomic diversification as its strategy to adapt to shifting environments, including drug exposure. *C. albicans* is able to diversify a population exposed to drugs and other stressors by generating unbalanced chromosomal duplications and deletions (292) and by generating tetra- and aneuploid cells through its parasexual cycle and random chromosome loss (293).

Aspergillus

Aspergillus spp. have distinct abilities to infect humans. Among them, the opportunistic pathogen par excellence *A. fumigatus* initiates infection in air-filled spaces such as the sinuses and lungs (Fig. 1G,H). When unchecked in these sites by phagocytes of innate immunity, its proliferation causes foci of necrotizing pneumonia that may coalesce and destroy the lung. Given its septated hyphae whose compartments can survive fragmentation, it can also hematogenously disseminate to highly perfused organs including the brain, the eyes, and the kidneys. Upon encountering blood vessels, *Aspergillus* hyphae tend to enter and follow their course, clogging the vessel and causing infarction of downstream tissue. This angioinvasive behavior may be attributable to thigmotropism, the ability to sense and follow contours, which aspergilli have in common with fungi of diverse phyla (294, 295).

A. fumigatus causes ~90% of invasive aspergillosis (296), so it will be discussed here for the diverse *Aspergillus* spp. involved in human disease. *A. fumigatus* evolved as a thermophilic plant saprobe. It is well-adapted to the high temperatures that occur during bacterial decomposition of dead plants and tolerates thermophilic bacteria's optimum temperature of around 55°C (297). Clearly, its evolution of virulence factors including secretion of a very broad and redundant range of hydrolases (298, 299) is unrelated to humans because the only significant humans susceptible to invasive aspergillosis before the advent of iatrogenic immunosuppression were those born with mutations in NADPH oxidase, i.e., with chronic granulomatous disease.

Among *A. fumigatus* virulence attributes are pyomelanin and dihydroxynaphthalene melanin, with which it coats its airborne dispersal spores, the conidia (300). Melanin protects conidia from sunlight and oxidative stress in the environment, and in human alveolar macrophages it blocks phagolysosomal acidification (300) and pyroptosis (301). Other secondary metabolites that interfere with phagocyte function are fumagillin, helvolic acid, and gliotoxin (300, 302). Sophisticated biosynthetic pathways for these toxins evolved presumably to defend the fungus against protozoans or small metazoans such as nematodes encountered in its environment. Nevertheless, once conidia germinate and produce a hypha, they are recognized by alveolar macrophages and subsequently destroyed by neutrophils (303–307). Human defenses against aspergilli are very effective: the average person is estimated to inhale between hundreds and tens of thousands of *A. fumigatus* conidia each day without developing infection (308–310).

Non-*fumigatus* aspergilli, *Fusarium*, *Pseudallescheria*, and other opportunistic ascomycetous fungal pathogens

These pathogens cause invasive disease during profound immunosuppression. They were historically divided into hyalohyphomycetes (lacking cell wall pigment) and phaeohyphomycetes (with melanized cell walls), but these distinctions have no taxonomic or prognostic significance. Among the nonpigmented genera are the non-*fumigatus Aspergillus* spp. (311), *Fusarium* spp. and their teleomorph *Nectria* spp. (312), and *P. boydii* and its *Scedosporium* anamorphs (313). *Scedosporium*, a species complex currently being redefined by molecular studies (234), is a saprotroph in watery environments and a cause of devastating pneumonia with occasional dissemination to the CNS after near-drowning incidents. These fungi tend to be resistant to older antifungals, in particular, amphotericin B; newer triazoles are the preferred therapeutic option (314).

Fusarium spp. have evolved to infect plants, and the genomes of certain lineages contain one or more dispensable chromosomes encoding plant pathogenicity factors that may be horizontally transferred within the genus (315). Genes encoding pathogenicity-associated proteins such as secreted hydrolytic enzymes and signaling molecules appear to be evolving at an increased rate compared with other parts of the genomes of three distinct plant-pathogenic *Fusarium* spp., suggesting ongoing coevolution of plant host and fungal pathogen (316).

A recent exquisite study of *Fusarium graminearum* infecting maize stalks (317) identified both plant host-specific and nonspecific induction of virulence factors: early upregulation of plant-directed enzymes such as pectinases, which hydrolyze plant extracellular matrix, as well as induction of genes required for growth during phosphate starvation (317). During early growth between plant cells, *F. graminearum* cells upregulate phosphatases and phosphate transporters and induce synthesis of membrane lipids lacking phosphate (318),

thus freeing up phosphate for ribosome biosynthesis and DNA replication (317). Given the many links between bacterial virulence and phosphate homeostasis (319), these responses of *Fusarium* cells upon encountering a plant host are likely to contribute to virulence in humans as well. In *Fusarium*, morphogenesis additionally contributes to virulence for humans, because yeast-like (adventitious) cells are produced from hyphae in the host (320) and typically spread widely through the bloodstream to cause numerous foci of infection in the skin.

Pigmented filamentous ascomycetes, also called dematiaceous fungi, infect immunocompromised and, rarely, immunocompetent individuals to cause phaeohyphomycosis. Some are also among the agents of chromoblastomycosis. The melanin these fungi elaborate in their cell walls protects them against reactive oxygen species in the environment and in the host. Their pathobiology includes brain abscesses (*Cladophialophora bantianum*, *Ramichloridium* spp., *Dactylaria gallopava*), keratitis, sinus or soft tissue infections, ulcers, and cysts (*Exophiala jeanselmei*, *Exophiala dermatitidis*, *Curvularia*, *Bipolaris*, or *Alternaria* spp.). When directly inoculated into tissue, these fungi such as *Exserohilum rostratum* can cause devastating disease, as evidenced by a tragic meningitis outbreak due to contaminated injectable steroids (321).

Pneumocystis

P. jirovecii belongs to the subphylum Taphrinomycotina, a clade of distinct fungi thought to have diverged at the separation of Ascomycota from Basidiomycota; it is the human-adapted member of the genus *Pneumocystis*, in which each species is able to infect only one specific mammalian host. *Pneumocystis* was first described in 1909 by Carlos Chagas (the discoverer of *Trypanosoma cruzi*, after whom the disease caused by this flagellate parasite is named) in a remarkable 70-page paper on trypanosomiasis published in Portuguese and German, the two languages arranged side-by-side on the page (322). In this paper he described inoculating the blood of three ill children into guinea pigs. After some days, he observed "parasitic forms" in the lungs of guinea pigs from two of the children, which he interpreted as a developmental stage of the flagellate. This lung-residing organism was renamed *Pneumocystis* when husband-and-wife team P. and M. Delanoë, researchers at the Institut Pasteur in Paris, found it in the lungs of local sewer rats that had never been infected with flagellates (323).

The numerous species of the large genus *Pneumocystis* are now known to have coevolved in such close association with their specific mammalian hosts (324) that their mitochondrial rRNA sequences have been used as markers for the phylogeny and phylogeography of the bats and rodents they inhabit (325–327). The human-specific *Pneumocystis* species was renamed *jirovecii* once it was understood to be completely distinct (328) from the rat-specific *P. carinii* identified by the Delanoës in Parisian rats (329–331), with no possibility of host cross-infection (328).

In the 1940s and 1950s, epidemics of "interstitial plasma cell pneumonia" among malnourished infants occurred in Central European countries, particularly Germany, Czechoslovakia, and Austria, which subsided when nutrition improved as the continent recovered from World War II (332). High incidence in orphanages was reported from Iran in the 1960s (333), and sporadic cases among malnourished or immunocompromised children and adults were then also reported in the English literature (332). In 1981, the CDC reported five cases of pneumocystis pneumonia in Los Angeles in the first description of the syndrome that was to be called AIDS (334). Since then, pneumocystis pneumonia incidence has exploded (335)—a devastating disease, occasionally outside the lung, with high mortality among HIV-infected people and among the large and varied immunocompromised patient populations emerging over the past 4 decades.

Into the late 1980s, it was unclear to which kingdom of life *Pneumocystis* belonged: protozoa or fungi? rRNA sequencing resolved the issue (336). But still the unique life cycle of *Pneumocystis* as an obligate biotrophic parasite of mammals (337), seen growing in lungs as amoeboid cells with thin cell walls ("trophic forms") much more abundantly than as oval forms with thick walls ("cystic forms," now known to be asci), poses numerous mysteries, especially because no *in vitro* system of culture has been reproducibly established.

The trophic forms are extracellularly attached to alveolar epithelial cells in so tight an association that interdigitations arise (338), and are generally in a haploid state, but may have to undergo mating and meiosis to proliferate (339). If mating and meiosis are obligatory stages of the *Pneumocystis* life cycle, primary homothallism as indicated by genome structures of *P. carinii* and *P. jirovecii* recently described by Almeida et al. (340) would indeed be an efficient strategy: a haploid cell can then mate with its direct offspring and avoid the trouble of switching mating types or awaiting the appearance of a partner of the opposite mating type (341).

Remarkably, while it remains extracellular, *Pneumocystis* relies on the host for a broad range of metabolic functions and hence has lost a large complement of

metabolic and transporter-encoding genes, as determined in a recent landmark genome analysis (342). It lacks ~80% of the genes for amino acid synthesis that are present in yeast, is not able to assimilate inorganic nitrogen or sulfur, and is missing nearly all genes of the nucleotide salvage pathways (342). In addition, its lipid metabolism is limited, it lacks fatty acid beta-oxidation, and it does not synthesize ergosterol (342). Lack of ergosterol explains its resistance to classical antifungals such as amphotericin B and azoles.

The cysts are thought to be the infective forms, transmitted by the airborne route from an asymptomatically colonized or an ill, infected person to an uninfected one, so that infants acquire the infection from their caretakers (343). Primary infection seems to occur throughout early childhood, with increased prevalence of antibodies in healthy children over time (344), marking the development of acquired immunity whose cellular component is the decisive defense against proliferation of *Pneumocystis* in the human host. Primary infection may not always be asymptomatic, because *Pneumocystis* may cause upper respiratory tract infection in infants (345). It may also contribute to progression of chronic obstructive pulmonary disease in adults (346).

The main defense of *Pneumocystis* against host immunity seems to be a very large family of major surface glycoproteins, of which up to 179 unique genes were found per species (342). It also avoids activating some innate immune responses by forgoing N-linked mannans on the outer chains of its surface proteins and is the only fungal genus not found to encode chitin synthases (342). These strategies seem to be strikingly successful: because *Pneumocystis* has not experienced on an evolutionary timescale a need to respond to host immune defenses such as oxidative stress or nutrient limitation, it has lost genes required in pH sensing, osmotic and oxidative stress responses, cyclic AMP signaling, and the glyoxylate cycle (342).

Prevalence of colonization of immunocompetent humans is thus much higher than was suspected before the advent of detection by PCR. One study showed, e.g., that 62% of people autopsied after dying suddenly of accidents, homicides, and suicides in the streets of Santiago, Chile, were found to carry *Pneumocystis* (347). Apparently, its long coevolution with its mammalian hosts has fine-tuned a "live-and-let-live" relationship in which the fungus does not significantly damage a normal host, and the host provides a deluxe niche for the fungus.

This equilibrium apparently breaks down only when cellular adaptive immunity fails, as in HIV-infected patients not receiving antiretroviral therapy or in patients undergoing iatrogenic immunosuppression. Then the fungus proliferates in the lung and elicits a strong inflammatory response which is the primary cause of failing gas exchange and may require corticosteroid therapy along with direct antipneumocystis treatments to reverse respiratory failure. While its stripped-down metabolic functions allow only for a very slow replication cycle of 5 to 8 days (342, 348), the ineffective host immune response leads to a cycle of fungal replication and futile inflammation that despite appropriate therapy can be fatal.

Mucorales

Mucorales cause invasive disease in specific hosts, among whom the most numerous are diabetics. The number of diabetic adults has more than doubled over 3 decades (349) in a slow-motion explosion of diabetes following adoption of processed, high-glycemic-load foods around the world; disease-controlling medication and equipment are out of reach for millions of poor diabetics (350). Within this development is embedded an unexplained rise of type 1 diabetes incidence of 3 to 4% per year (351), which with its potential for diabetic ketoacidosis is putting large numbers of people newly at risk for devastating infections with a group of ancient fungi: the Mucorales.

Additionally, Mucorales infect neutropenic and otherwise profoundly immunosuppressed people and patients with elevated serum iron due to hemochromatosis or excessive blood transfusions, as described in the excellent series by Roden at al. (352). The infection begins with entry of airborne sporangiospores into air-filled spaces, i.e., sinuses and lungs. Infections with Mucorales progress rapidly as the fungus grows quickly and relentlessly through tissue planes and blood vessels, causing widespread infarction and necrosis due to its angioinvasive behavior. Angioinvasion is likely due to thigmotropism, the ability to sense and follow the curvature of a surface, which has been experimentally demonstrated for *Mucor mucedo* (294), and distinguishes the Mucorales from its sister clade Entomophthorales, which neither invade blood vessels nor usually cause necrosis. To avoid fatal outcomes (353), management requires three factors: control of underlying disease, surgical debridement, and antifungal therapy with lipid formulations of amphotericin B or, provided the pathogen tests as being susceptible, new extended-spectrum azoles such as posaconazole or isavuconazole (354).

The Mucorales are soil saprotrophs with occasional parasitic behavior toward plants and animals. They comprise an ancient lineage whose evolutionary dis-

tance from the phyla of other human parasitic fungi is apparent in the structure of their hyphae, which are fragile, thin-walled, and lack septa, and in the composition of their cell walls, in which chitin and chitosan play the structural roles that glucans fulfill in the Dikarya (355, 356). Some species such as *Mucor circillenoides* are dimorphic and form yeast in the host (357–359), contributing to dissemination. Spread to distant sites is rare in the monomorphic species because fragments of the coenocytic hyphae, small enough to travel in the bloodstream, are likely to leak cytoplasm and become inviable, but when it occurs, the brain is a common target organ in a usually terminal stage of the infection (353).

Thermotolerance has experimentally been shown to be correlated with virulence among *Rhizopus* species (360) (Fig. 1E). Thermotolerant *Rhizopus microsporum* produces a secreted toxin, rhizoxin, in collaboration with a bacterial endosymbiont, *Burkholderia rhizoxinica* (361). Rhizoxin inhibits mitotic spindle formation in eukaryotes and is known to kill, for example, rice seedlings which then provide nutrients for the fungus as well as for the bacterium. Recent work shows that a *Burkholderia* type 2 secretion system extrudes chitinase to gradually melt the fungal cell wall at sites of bacterial attachment, enabling the *Burkholderia* to gently enter *Rhizopus* hyphae and move to the growing hyphal tip, where they induce spore formation so that each vegetative fungal progeny (sporangiospore) is guaranteed its own bacterial endosymbiont (362, 363). In a meticulous study using murine and *Drosophila* models, a contribution of rhizoxin to *Rhizopus* spp. pathogenesis in animal infection was not found (364). This study suggests that pathogenicity for a human is likely to be an unexpected accident for *Rhizopus* landing in a human alveolus, for which this fungus is evolutionarily unprepared. Conversely, the activity of rhizoxin against human cells (365) suggests a potential for discovery of other endosymbiont-produced toxins of broad specificity that may contribute to Mucorales' production of necrosis.

Another *Rhizopus* species, *R. oryzae*, is responsible for ~70% of human disease (366). One of its important virulence factors is the ability to scavenge iron from the host (367–371). As mentioned, procuring micronutrients such as iron is a basic requirement for a fungal pathogen. In the Mucorales this ability is likely to have evolved in their interaction with bacteria: deferoxamine, a compound used in chelation therapy in patients with iron overload, from which *Rhizopus* notoriously can acquire iron (74), is a bacterial siderophore. The importance of iron homeostasis is also reflected in the recently described genome of a representative of the ancient Mucorales lineage *Lichtheimia*, in which zinc/iron permeases, heme oxygenases and siderophore transporters not present in *Rhizopu*s were discovered, and a link between iron limitation and calcineurin signaling was found (372).

CONCLUSION

Humans are endowed by evolution with robust defenses against invasive fungal disease. Yet our species' social evolution has reached a stage where scientific medicine, in the process of successfully treating many serious diseases, renders their survivors newly vulnerable to invasive fungal infections. We have not yet developed sufficient antifungal diagnostic and treatment modalities to meet the needs of this epidemic, and these are clear tasks for our time. In addition, human social evolution has reached an initial threshold of recognizing that if all lives are equally precious, we must provide available prophylactic, diagnostic, and therapeutic efforts to all who need them. Over the past 20 years, since effective treatment became available, the AIDS pandemic has highlighted this imperative. Monumental efforts of bench science and clinical research synergized to bring an end to AIDS within our reach. The goal set by the United Nations Program on HIV/AIDS (UNAIDS) to end the AIDS pandemic by 2030 is achievable with currently available approaches (373), though its implementation is lagging because sufficient resources are not yet available (374), demonstrating a continued need for advocacy which will ultimately benefit all suffering from treatable infections, or from those that could be treatable if research resources were provided. People suffering from opportunistic as well as from primary invasive fungal infections urgently need resources and research efforts to bring them new diagnostics and treatments regardless of commercial potential. Enormous work over the past 3 decades has opened vast new vistas in fungal biology; we can expand upon them to ultimately fulfill the promises of modern medical advances.

The Mycobiome: Impact on Health and Disease States

40

Najla El-Jurdi[1] and Mahmoud A. Ghannoum[2]

INTRODUCTION

Research efforts by mycologists over the past few years finally established the fungal community and its previously overlooked members as crucial components of the microbiome. It is now undeniable that the commensal fungal microorganisms, alongside the other components of the microbiota, play a central role in association with the human host. Ongoing research is describing the fungal community and is providing new insights into biological mechanisms by which multidirectional interactions between the microbiome, their genomes (metagenome), metabolites (metabolome), and the human host ultimately affect health and/or disease states.

The term "microbiome" refers to microorganisms (microbiota) and their genomes coexisting with their hosts, including millions of bacteria, fungi, viruses, protozoa, and parasites. "Mycobiome" is a term coined to refer specifically to the fungal component of the microbiome. This microbial consortium starts developing during childbirth as a result of environmental exposures, dietary habits, host genome, and other exogenous and endogenous factors. The microbiome is unique to each individual, much like a fingerprint, and establishes a symbiotic relationship with the human host with various effects on the nutritional, metabolic, immunologic, and physiologic state(s) of the host (1). A disruption of this fine balance leads to imbalance, or "dysbiosis," and has been associated with several disease states.

In a national and international attempt to highlight the role of the microbiome and to unify efforts to describe its role in human health and disease states, the National Institutes of Health and the European Commission launched the Human Microbiome Project to characterize the human microbiota and their genomes (2). Here, we will highlight the role of the fungal community as an indispensable component of the microbiome.

CHARACTERIZATION OF THE HUMAN FUNGAL MICROBIOTA (MYCOBIOME) IN HEALTH STATES

Maintaining a Symbiosis

During the first 3 years of life, starting from birth, the human body codevelops with commensal microorganisms, primarily bacteria and fungi. It is hypothesized that these microbiota and their metabolites interact with the human host in a balanced, or symbiotic, bidirectional manner. The composition of the microbiome in each individual varies among body sites and develops as a result of complex endogenous and exogenous exposures including breast feeding, nutrition, medication exposure, and host genetic factors (3). As much as this healthy host-microbiota interaction is fundamental to the different host body functions and maintaining a "normal" state, any disruption of this balance leads to dysbiosis with contribution to disease states.

Early research efforts in the Human Microbiome Project described the bacteriome in "health states," with more focus on describing the bacteria inhabiting various body sites, in particular the skin, oral cavity, and gastrointestinal tract (the gut). The gastrointestinal microbiome historically attracted the most attention due to its intimate association with the human host and direct impact on the development of the immune system from birth through the secretion of various cyto-

[1]Department of Medicine, Division of Hematology-Oncology, University Hospitals Cleveland Medical Center, Case Western Reserve University, Cleveland, OH 44106; [2]Center For Medical Mycology, Department of Dermatology, Case Western Reserve University, and University Hospitals Cleveland Medical Center, Cleveland, OH 44106.

kines, metabolites, and neurohormones (4). Research describing the role of the bacterial component of the microbiome has established its association with several disease states including but not limited to metabolism, obesity, type 2 diabetes mellitus, atopic dermatitis, allergy, wounds, cystic fibrosis, chronic kidney disease, rheumatoid arthritis, neurodevelopmental disorders, HIV, liver cirrhosis, inflammatory bowel disease, autism, Parkinson's disease, pancreatic cancer, colorectal cancer, esophageal cancer, graft-versus-host disease (GVHD), and others (5–18).

In comparison, relatively little effort has been dedicated to characterizing the mycobiome in health and disease states. It was not until 2010 that serious attempts were initiated to characterize the fungal component of the human microbiome. Accurate description of the mycobiome was made possible by using high-throughput, next-generation sequencing (NGS) approaches (multitag pyrosequencing approach and ion-torrent personal genome medicine) to characterize the oral fungal mycobiome in healthy individuals using pan-fungal internal transcribed spacer primers (19) instead of depending on culture-based techniques.

The Oral Mycobiome

In the first study of its kind, by Ghannoum et al. (19), the investigators used multitag pyrosequencing and internal transcribed spacer primers to analyze oral rinse samples from 20 healthy, nonsmoking adults, and data analysis revealed the presence of 11 nonculturable and 74 culturable (capable of growing on a culture medium) genera. In total, 101 culturable species were detected, and on average each individual was found to have between 9 to 23 species. The core oral mycobiome (COM) and bacteriome were defined as organisms present in ≥20% of investigated subjects. The fungal genera representing the COM of the oral cavity were *Candida* species (75% of individuals), *Cladosporium* species (60%), *Aureobasidium* species (50%), members of the Saccharomycetales (50%), *Aspergillus* species (35%), *Fusarium* species (30%), and *Cryptococcus* species (20%). Interestingly, principle component analysis revealed significant individual mycobiome variations between white and Asian men. Using an advanced NGS approach, this study emphasized (i) the complex nature of the mycobiome that results from an interplay between several genetic and environmental factors and (ii) that one-third of the oral fungi in healthy individuals are not culturable on a culture medium in the laboratory and otherwise could not be identified without the use of high-throughput NGS approaches (19).

The Gastrointestinal Mycobiome

The gastrointestinal mycobiome has been of interest in many studies that characterized the fungal component of the intestinal tract in mice, pigs, rabbits, dogs, and humans in addition to other mammals (20). The growing body of evidence continues to reveal complex and multidirectional interactions between the host gastrointestinal tract and fungi, influencing health and disease states. In healthy individuals, the gastrointestinal mycobiome is thought to include 66 fungal genera, with *Candida* being the predominant one, in addition to 184 species. Some of the most common nonpathogenic genera inhabiting the gastrointestinal tract include *Cladosporium*, *Penicillium*, *Mucor*, and *Saccharomyces*; potentially pathogenic genera include *Aspergillus*, *Candida*, *Cryptococcus*, *Fusarium*, and *Pneumocystis*. In the following sections, we will describe in detail the difference in the mycobiome composition in several gastrointestinal diseases and the possible association between these changes and the development of disease (15, 21–24).

The Skin Mycobiome

It is now established that the human skin microbiome consists of millions of organisms, particularly yeast and dermatophytes. To characterize the "basal" skin mycobiome, Findley et al. (25) sampled 14 skin sites from 10 healthy adults. Interestingly, sample analysis revealed that fungal diversity depends on the body site. *Malassezia* was the most common fungal genus, identified in 11/14 sampled body sites. A high fungal diversity was described in the plantar heel, toenail, and toe web foot sites. Sample analysis from arm sites revealed higher bacterial diversity and lower fungal diversity than core-body (i.e., excluding the arm and foot sites) and foot sites. The plantar heel was the most diverse site, with prevalence of *Malassezia*, *Aspergillus*, *Cryptococcus*, *Rhodotorula*, *Epicoccum*, and others. The investigators described both the bacterial and fungal communities at all of these sites and highlighted a few important points: (i) bacterial and fungal diversities are grouped into clusters, with the same core-body site having similar bacterial and fungal richness; (ii) skin topography and tissue structure are key determinants of the microbiome composition; and (iii) the skin mycobiome is highly variable among body sites.

More recently, Jo et al. (26) compared the skin mycobiomes of healthy children and adults. The child group (age <14 years) had more diverse fungal species, while in the adult group (age range 18 to 39 years), *Malassezia* was the most prevalent fungal species and was identified on the trunk, head, and arm skin sites.

The investigators hypothesized that the fungal communities change in individuals through puberty alongside changes in the skin composition and increases in sebaceous glands. The fact that adults have a more sebaceous skin than children could explain the prevalence of the lipophilic fungi *Malassezia* in this group (26). Leung et al. (27) characterized the skin bacteriome and mycobiome in healthy individuals from Hong Kong and compared them to a Western population, showing that the major fungal species were common among the two cohorts. Nonetheless, they demonstrated that outdoor environments and lifestyles may contribute to the difference in the other mycobiome composition between populations (27).

A STATE OF DYSBIOSIS: ROLE OF THE MYCOBIOME IN DISEASE STATES

Human Immunodeficiency Virus (HIV)

The oral bacteriome and mycobiome in HIV-positive individuals were investigated by Brown et al. and Mukherjee et al. (21, 28). The investigators used high-throughput NGS/multitag pyrosequencing approaches to identify the oral bacteriome and mycobiome in 12 HIV-positive individuals compared with HIV-negative matched controls (28). In the core oral bacteriome, 13 of 14 genera were common between the two cohorts, whereas the COM was different and *Candida* was the most common fungus in both cohorts. When further classifying the *Candida* species, *Candida albicans* was the most prevalent, identified in 58% and 83% of HIV-negative and positive individuals, respectively. In addition, the investigators wanted to further describe any correlation between the oral bacteriome and mycobiome in the two cohorts. By conducting correlation analysis, they were able to identify the presence of 12 and 15 bacterial-fungal pairs in the HIV-positive and HIV-negative cohorts, respectively (28). Furthermore, they identified a nonpathogenic member of the COM, *Pichia*, that exhibits an antagonistic (inhibitory) effect against pathogenic fungi including *Candida*, *Cryptococcus*, *Aspergillus*, and *Fusarium* (28). Adding either *Pichia* cells or the medium they were grown in, referred to as *Pichia* spent medium (PSM), inhibited the growth of *Aspergillus*, *Fusarium*, and *Candida*, in addition to inhibiting *Candida* biofilm formation. Importantly, this study was the first to identify an interaction among different members of the oral mycobiome that was postulated to occur via nutrient limitation or the secretion of a product that modulates growth and interferes with virulence factors.

These *in vitro* results were further tested and validated in an experimental murine model of oral candidiasis (28). When compared with the untreated group, mice treated with PSM had a statistically significant lower fungal burden and infection score. When the investigators examined the tongues of PSM-treated mice, they identified an intact epithelium and few hyphae, whereas nystatin and control (saline-treated) mice had epithelial disruption and extensive fungal growth (28). The inhibitory effect of PSM was proteinaceous in nature and not a secretory metabolite. This is an especially important finding because it identifies a potential novel antifungal agent and a new approach for the management of fungal infections.

The same group conducted a subsequent study using a systems biology approach to correlate the bacteriome, mycobiome, and metabolome data between HIV-positive and -negative individuals (21). Correlation difference network analysis showed that *Rothia*, *Candida*, and certain metabolites, namely phenylacetate, sorbitol, and histamine, demonstrate a statistically significant correlation difference between HIV-positive and -negative cohorts. This study highlights the importance of conducting more studies to further investigate the role of cyclic mono- and dipeptides as key metabolites in quorum sensing or cross-talk between oral bacterial and fungal genera and their functional implications in HIV and other patient populations.

Hepatitis B Virus (HBV)

The microbiome composition of individuals infected with HBV has been described to include both the bacterial and fungal communities. Chen et al. (29) studied the gastrointestinal mycobiome in 161 HBV-positive individuals and healthy volunteers using culture-dependent and -independent (18S rDNA gene amplification-based PCR) techniques. The 161 participants in this study were divided into 4 groups: group 1, HBV cirrhosis patients (n = 38); group 2, chronic HBV patients (n = 35); group 3, HBV carriers (n = 33); and group 4, healthy controls (n = 55). The culture-dependent method identified *Saccharomyces cerevisiae* and four *Candida* species (*C. albicans*, *Candida glabrata*, *Candida krusei*, and *Candida tropicalis*). The culture-independent PCR-based method identified 37 operational taxonomic units, which are clusters of nearly identical sequence tags or phylotypes with a predefined similarity threshold (usually 97%), commonly used to define microbial taxa. Thirty-one different fungal operational taxonomic units were identified, including *Cryptococcus*, *Saccharomyces*, *Penicillium*, and *Galactomyces* species. The investigators identified a higher

abundance of *Candida* and *Saccharomyces* with increased severity of HBV infection, and patients with HBV-cirrhosis or chronic HBV infection had greater fungal diversity than HBV carriers and healthy controls. The results of this study were similar to previous findings linking increased HBV disease severity with an increase in fungal burden and proposing an immune-meditated mechanism. One mechanism proposed by Thomas et al. (30) is related to the deficiency or dysfunction in the mannose binding protein (MBP) during HBV infection. Mannose binding protein is a pattern recognition receptor that binds to fungal cell walls and triggers a host immune response against fungal pathogens. Persistent HBV infection has been linked to mutation in the mannose binding protein leading to an attenuated immune activation and increased colonization by fungal pathogens. Further research is required to confirm the underlying mechanisms.

Inflammatory Bowel Disease

The gastrointestinal microbiome has attracted a lot of researchers in an attempt to identify an association between its bacterial and fungal communities and various diseases. The mycobiome has been described in healthy individuals (31–34), and alternations or symbiosis of its fungal components have been implicated in several gastrointestinal disorders, including peptic ulcer disease (35), irritable bowel syndrome (36), antibiotic-associated diarrhea (37), chemotherapy-induced gastrointestinal mucositis (38), and inflammatory bowel disease (IBD) (39).

IBD refers to a group of inflammatory disorders that affect various anatomic locations of the gastrointestinal tract. IBD includes two major disorders: Crohn's disease (CD), which can affect any part of the gastrointestinal tract from the mouth to the anus, and ulcerative colitis (UC), which primarily affects the colon and the rectum (40–42). Although the pathogenesis of these disorders is not completely understood, they have been related to immune dysfunction in a genetically susceptible host. In fact, gastrointestinal microbiota have been implicated to possibly trigger this inflammatory immune response. The initial discovery of anti-*S. cerevisiae* antibodies in the sera of patients with CD triggered further interest in studying the possible association between various components of the mycobiome and IBD.

Using an 18S rRNA PCR-based method, Ott et al. (39) described the mycobiome present in the fecal samples and intestinal mucosa of patients with CD and UC and healthy controls. The fungal profile was significantly different between the fecal and mucosal samples across the three groups. Nevertheless, Ascomycota and Basidiomycota constituted the majority of the fungal taxa identified in the fecal samples across the three groups, accounting for 92.3% and 7.7% of the recovered fungi, respectively.

Standaert-Vitse et al. studied patients with familial CD and noted a higher colonization rate by *C. albicans* in this population (43). To compare the *Candida* profile in the upper gastrointestinal tract (oral cavity) and lower gastrointestinal tract in patients with IBD, Trojanowska et al. (44) studied samples obtained from patients with UC (n = 72), CD (n = 18) and healthy controls (n = 36). The samples were obtained from throat swabs, colonic aspirates, and biopsies, as well as fecal samples, and analyzed using PCR-based and conventional culture-based methods which favor the growth of predominant fungi. The investigators reported a similar alteration in the profile of non-*albicans Candida* species in both the UC and CD groups. Whereas healthy controls were colonized by *C. tropicalis*, IBD patients had a higher diversity of *Candida* and other species, namely *C. tropicalis*, *C. glabrata*, *C. krusei*, *Candida guilliermondii*, *Candida kefyr*, and *Geotrichium candidum* (44). The results of these experiments highlight that (i) *C. albicans* strains isolated from the oral cavity and different sections share a similar genotype, implicating fungal transmission from the upper to the lower gastrointestinal tract, and (ii) the mycobiome of the oral cavity can act as a future diagnostic marker for the development of IBD. *C. albicans* appears to be more common among patients with CD (43).

Jawhara et al. (45) used experimental murine models of CD and induced colonic inflammation using dextran sodium sulfate. The investigators showed that colonic inflammation promotes *C. albicans* colonization (45) and triggers an immune response leading to the production of antibodies against *C. albicans* and *S. cerevisiae* antigens. After these findings, Iliev et al. (20) performed studies using dextran sodium sulfate to chemically induce inflammation in an experimental murine model deficient in dectin-1, a key receptor encoded by *Clec7a* that mediates the biological effects of fungal (1, 3) β-D-glucans. Compared to wild-type mice, dectin-1-deficient mice had more severe IBD symptoms, histologic alterations, production of proinflammatory cytokines, and weight loss (20). The mycobiome profile of dectin-1-deficient mice was characterized by an increase in the prevalence of pathogenic fungi, *Candida*, and *Trichosporon* accompanied by an increase in inflamed intestinal tissue and a decrease in the nonpathogenic fungi *Saccharomyces* (20). In contrast, the bacterial profile was noted to be similar in the wild-type and dectin-1-deficient mice, suggesting that the mycobiome rather than the bacteriome is a key con-

tributor to initiation of inflammation and pathogenesis of IBD (20). The investigators were also able to show that *C. tropicalis* exacerbates colitis severity in dectin-1-deficient mice, as demonstrated by more weight loss and pathologic evidence of crypt loss and inflammatory cell infiltration (20). However, the mycobiome alone is not sufficient to trigger inflammation or reduce disease severity. Transplanting fecal samples from the wild-type to dectin-1-deficient mice did not affect the severity of IBD, suggesting a more complex mechanism for the development of IBD that includes other host-related factors.

More recently, Hoarau et al. (46) characterized the bacteriome and mycobiome of families with CD, their nondiseased first-degree relatives, and healthy non-CD unrelated volunteers from the same geographic area in northern France-Belgium. In this study, the investigators used next-generation ion-torrent sequencing techniques. The microbiome diversity and abundance analysis revealed a distinct microbiome profile in the CD and nondiseased first-degree relative samples compared to the non-CD unrelated samples (46). Interestingly, the CD and nondiseased first-degree relative groups clustered together and had similar mycobiome but not bacteriome profiles. Additionally, microbial interaction analysis using single and mixed-species biofilms revealed a higher abundance of *Serratia marcescens* and *Escherichia coli* in the CD group as well as *C. tropicalis*. The positive correlation between the three organisms suggests that they interact and form a triple-species biofilm, which was further confirmed by the study investigators (46) and illustrated in Fig. 1. These findings are supported by other studies showing that CD family members have a more similar microbiome profile compared to unrelated healthy volunteers (47, 48). This important paper was the first to identify key intra- and interkingdom microbial interactions and associations that are implicated in disease states (46). The proposed hypothesis for such interkingdom microbial interactions is that the mixed-species biofilms represent a cooperative evolutionary strategy for these organisms to survive the host's immune surveillance (49). As such, the fungal components develop virulence factors including extracellular enzymes and hyphae, while bacteria find shelter in the fungal matrix, escaping antibiotics and immune attack (49).

Based on the knowledge that patients with IBD have a higher abundance of and colonization with *C. albicans*, several studies tested the efficiency of antifungals to manipulate the gut microbiome and decrease disease severity. In one study by Zwolinska-Wcislo et al., treatment with fluconazole or probiotic decreased the severity of UC (50). Samuel et al. retrospectively observed that four of six patients with active IBD who were treated for histoplasmosis with itraconazole achieved clinical and endoscopic remission at the end of the treatment duration (51). These data provide evidence that the fungal community plays an important role in IBD and that approaches to control this component of the microbiota through the use of antifungal and/or probiotics may be a very promising option to control IBD.

ROLE OF THE MYCOBIOME IN CANCER

Given that several environmental, genetic, and dietary factors have been implicated in the initiation and progression of carcinogenesis, it is no surprise that the host microbiome and metabolome have recently been at the forefront as potential modulators of cancer metabolism and targets for cancer therapies. To date, the vast majority, if not all, of the literature investigating the role of the microbiome in carcinogenesis and cancer therapy has focused on the bacterial component. We have growing evidence that the microbiome is implicated in colorectal (18, 52, 53), esophageal (54), and pancreatic cancer (17, 55). In addition, some investigators have focused on the association between certain bacteria and the host's response to chemoimmunotherapy (56–58) and checkpoint inhibitors such as programmed death-ligand 1 (59–61). To our knowledge, there is no dedicated research on the implication of the mycobiome in the initiation and/or progression of carcinogenesis. Further investigations are warranted to describe the fungal profile in different cancers in an attempt to start understanding the role of fungi and their metabolites on carcinogenesis and response to cancer chemoimmunotherapies.

ROLE OF THE MYCOBIOME IN HEMATOPOIETIC CELL TRANSPLANTATION (HCT)

Despite all the advances in the treatment of hematological malignancies, HCT continues to be an effective treatment modality and sometimes the only chance for cure. However, these procedures are associated with significant toxicities that increase morbidity and mortality. The major toxicities related to HCT include opportunistic infections, gastrointestinal toxicities, and GVHD.

Scientists have been investigating the role of the microbiome in HCT outcomes for more than 40 years. Several studies have established an association between the microbiota and HCT outcomes including GVHD, infections, transplant-related mortality, relapse rates,

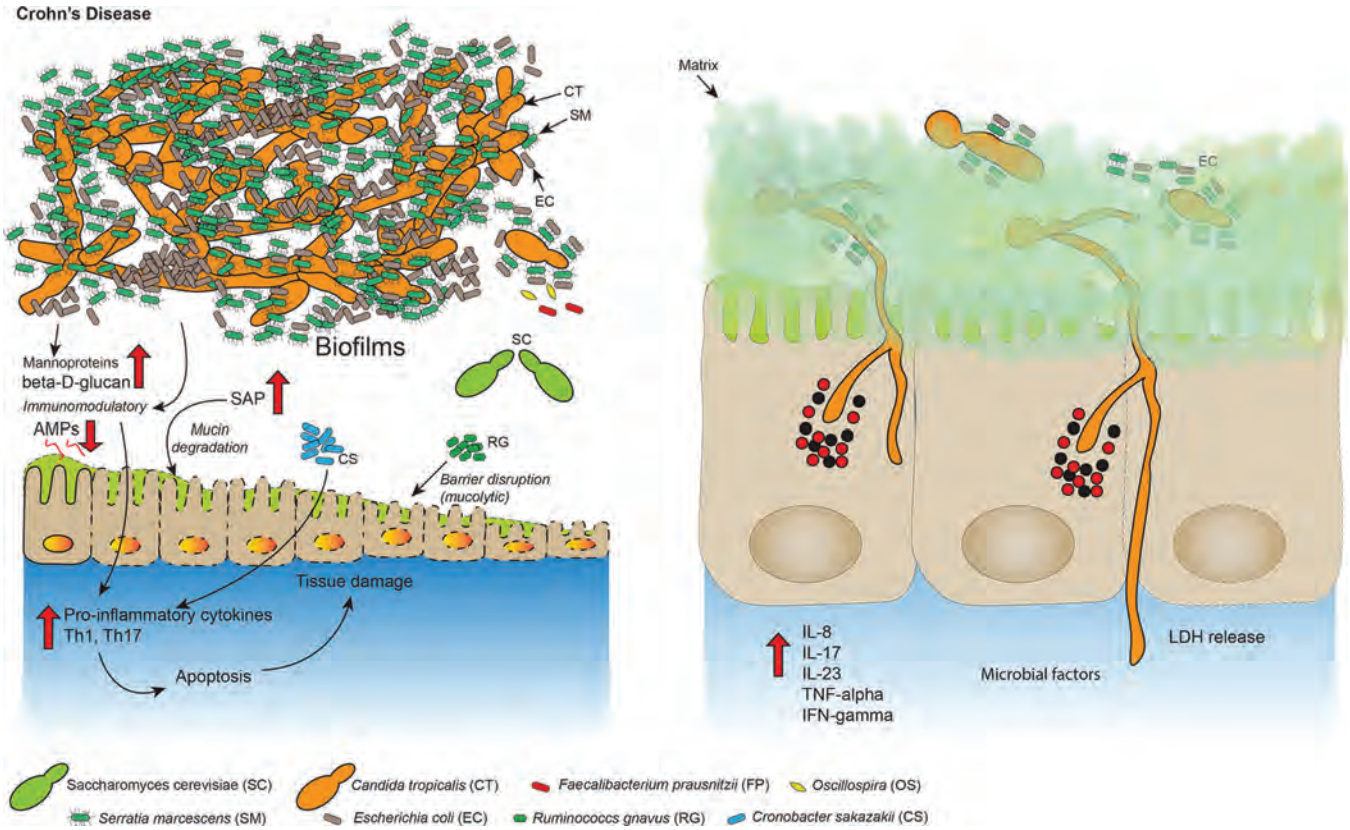

Figure 1 Schema showing potential interactions between bacteria, fungi, and the host in the gut in Crohn's disease (CD). Inter- and intrakingdom interactions impact the host immune system in the setting of CD, resulting in increased levels of proinflammatory cytokines (e.g., Th17 cytokines) under the influence of enteric pathogens and immunomodulatory components of biofilms (e.g., fungal β-glucans, bacterial lipopolysaccharides), causing increased oxidative damage and apoptotic cell death. Additionally, microbial-induced production of mucolytic enzymes may lead to barrier dysfunction, resulting in tissue damage and lesion formation. (**Left**) Interactions between fungi, bacteria, and the host in the gut of CD patients, showing an increase in the levels of *C. tropicalis*, *E. coli*, and *S. marcescens*. (**Right**) Biofilm formation by gut microbiota can influence host response to microbial dysbiosis (71).

and overall survival. Early studies of murine allogeneic HCT models involved gut decontamination in an attempt to prevent gastrointestinal GVHD. However, this strategy fell out of favor in humans due to contradicting results, and it was replaced by the current belief that a more diverse microbiome is associated with better HCT outcomes (62–64). Many studies revealed the role of the microbiome in GVHD (64–68) and mortality post-HCT (62, 69). Similar to oncological malignancies, the majority of the studies have focused on the role of the bacterial rather than the fungal component of the microbiome in HCT. In this article we will highlight the literature focusing on the fungal component, or mycobiome, and its potential contribution to GVHD and other transplant outcomes.

GVHD is a result of a complex process of "immune dysregulation" mediated by allogeneic donor T-cells attacking normal recipient cells. A group at the Fred Hutchinson Cancer Research Center conducted a randomized controlled trial using either fluconazole or placebo for 75 days post-HCT (70). After 8 years of follow-up, patients who were in the fluconazole arm had a statistically significant lower incidence of invasive candidiasis and candidiasis-related death, better overall survival, and lower incidence of severe GVHD (70). This was among the first studies to clearly demonstrate an association between the mycobiome and GVHD along with other transplant outcomes.

Following experiments conducted in mice by Iliev et al. (20) that demonstrated an important role of

dectin-1 in chemically induced colitis and *Candida* colonization, van der Velden and his colleagues investigated whether dectin-1 function and *Candida* colonization in humans had any implications for gastrointestinal GVHD (67). To achieve this objective, the investigators conducted a retrospective analysis on patients undergoing allogeneic HCT who were evaluated for *Candida* colonization and dectin-1 polymorphism on prospectively collected DNA samples (67). Analysis showed that *Candida*-colonized patients had a statistically significant higher incidence of severe grade II to IV GVHD as well as gastrointestinal GVHD (67). Interestingly, *Candida* colonization was more prevalent in patients who had a single nucleotide polymorphism Y238X loss of function polymorphism in the dectin-1 gene. More research is certainly needed to understand the mechanism by which *Candida* and other members of the mycobiome are associated with increased susceptibility and/or protection from gastrointestinal GVHD and other transplant-related outcomes, as is the case with the bacterial component of the microbiome, which has a firmly established role in the pathogenesis of GVHD.

CONCLUSION AND FUTURE DIRECTIONS

Some researchers coined the term "second genome" to underscore the importance of the microbiota and its collective metagenome on their host's health and/or disease. Regardless of the accuracy of this terminology, the message behind it is that the potential magnitude of the microbiome, both bacteriome and mycobiome, is too large to be overlooked. In recognition of this, the Human Microbiome Project was launched nationally and internationally, unifying efforts to characterize the microbiome and to elucidate the functional role of the microbiota and the mechanism(s) by which these organisms and their metabolites (matabolome) may affect health and disease states. Despite recent recognition, more research is needed to characterize the role of the mycobiome component of the microbiome.

Skin Fungi from Colonization to Infection

41

Sybren de Hoog,[1] Michel Monod,[2] Tom Dawson,[3] Teun Boekhout,[1] Peter Mayser,[4] and Yvonne Gräser[5]

INTRODUCTION

Humans are exceptional among vertebrates in that their living tissue is directly exposed to the outside world. In the absence of protective scales, feathers, or fur, the skin has to be highly effective in defending the organism against a gamut of opportunistic fungi surrounding us. Most (sub)cutaneous infections enter the body by implantation through the skin barrier. On intact skin, two types of fungal expansion are noted: (A) colonization by commensals, i.e., growth enabled by conditions prevailing on the skin surface without degradation of tissue, and (B) infection by superficial pathogens that assimilate epidermal keratin and interact with the cellular immune system. In a response-damage framework (1), all fungi are potentially able to cause disease, as a balance between their natural predilection and the immune status of the host. For this reason we will not attribute a fixed ecological term to each species, but rather describe them as growing in a commensal state (A) or in a pathogenic state (B).

Colonization of human skin by allochthonous (i.e., having their preferred niche outside the human host) commensals is coincidental (Fig. 1A). The conditions provided on the skin resemble some essential factors of their natural niche in the environment. The fungi have a "sloppy fitness space" (2); i.e., as long as these factors are met, the fungi are able to survive in habitats that are otherwise unsuitable. Mechanisms for transmission are lacking and thus the infection is a spillover with negative impact on fitness of the etiologic agent. A typical example is the black yeast *Hortaea werneckii*. The species causes tinea nigra, characterized by blackish patches on excessively salty skin of hyperhydrotic individuals acquired, for example, after a holiday at the beach (3). Coastal waters are the natural habitat of the fungus (4). It is a halophile, its ecology being determined by Hog1 homologues of the mitogen-activated protein kinase of *Saccharomyces cerevisiae* (5), being able to grow even in near-saturated NaCl solutions.

Malassezia species have their natural niche on humans, living on human products, i.e., they are autochthonous commensals (Fig. 1B). Clinically, they are recognizable in several common skin disorders including seborrheic dermatitis as pityriasis versicolor (PV), a common skin disorder associated with hyper- or hypopigmentation caused by *Malassezia* (6–8). The lipid-dependent fungi are also part of the benign residential skin flora of most warm-blooded animals including humans (9).

Dermatophytes cause cutaneous infections. The evolutionary history of dermatophytes is determined by their ability to degrade keratin. In humans, they are highly specialized, infecting almost exclusively nails, hair, and epidermis. Three broad ecological groups can be distinguished (Fig. 1C). Ancestral species are geophilic, having a saprobic life cycle in the soil and digesting remains of vertebrate keratin such as feathers and hair. Human infection is sporadic and decreases the fungus' fitness. Zoophilic species reside in closer association with the mammalian host, being carried in pelts and feathers, mostly without causing inflammatory reactions. Anthropophilic species are the most derived dermatophytes, naturally growing on naked human skin. The fungi have developed an intimate interplay with innate and acquired immunity.

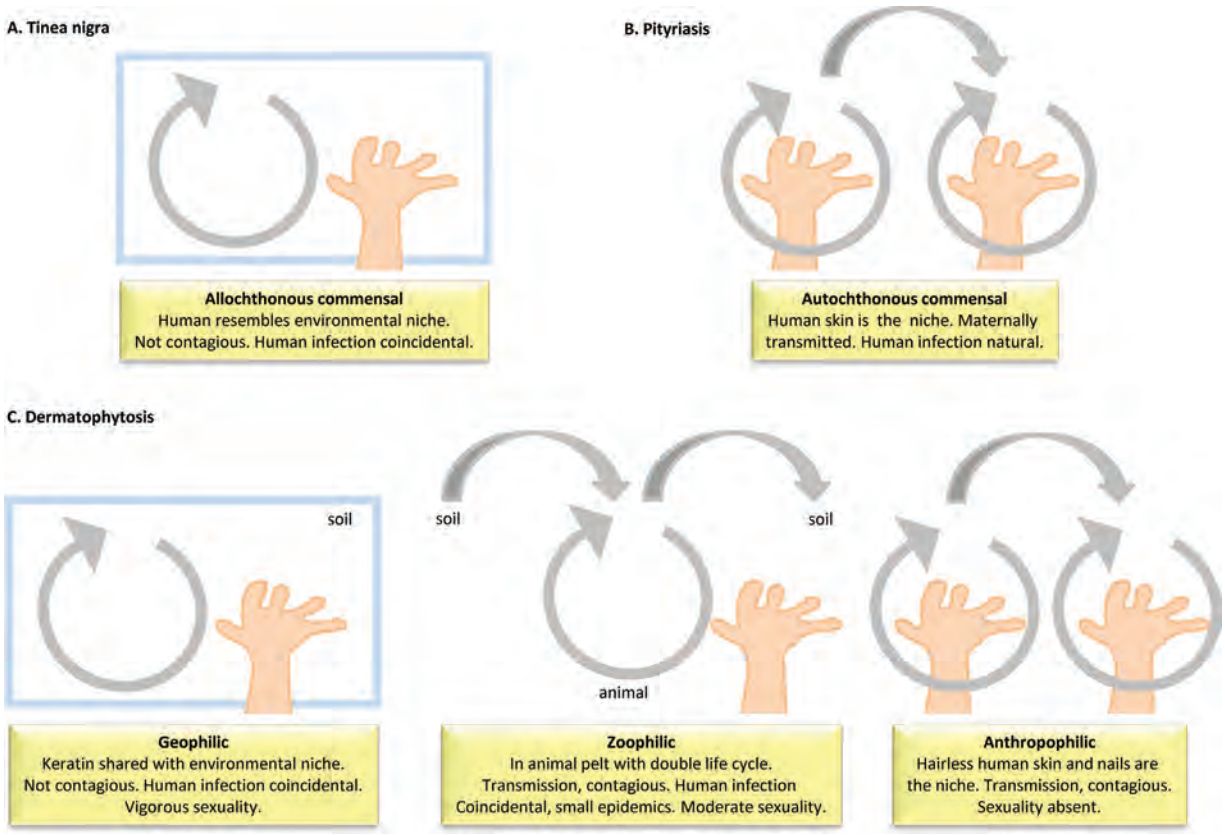

Figure 1 Overview of basic types of fungal occurrence on human skin and modes of transmission.

This review focuses on the natural eukaryotic skin flora: i.e., dermatophytes and *Malassezia*.

DERMATOPHYTES

Biodiversity

Common dermatophytes on humans are classically identified by clinical presentation and macro- and micromorphology. Today, methods of choice to display the total biodiversity and the coherence of species in a phylogenetic system involve multilocus sequencing. Polymorphisms of the rDNA internal transcribed spacer (ITS) region were able to resolve a large number of species (10). The topology of their phylogenetic tree has repeatedly been confirmed by other molecular markers such as *BT2* (11), *TEF1* (12), and *TEF3* (13), and thus the taxonomy of *Arthrodermataceae* seems to have reached stability. In all trees, *Trichophyton* is polyphyletic, containing clinically and ecologically widely different species. Therefore de Hoog et al. (13) confined *Trichophyton* and *Epidermophyton* to mainly anthropophilic species located in derived clusters. Zoophilic species were located at the top and around the middle of the tree and were classified in *Trichophyton*, *Microsporum*, and *Nannizzia*, while the highly diverse geophilic species were located in an ancestral position and were mainly classified in *Arthroderma*, *Lophophyton*, and *Nannizzia* (Fig. 2).

Virulence Factors

Because dermatophytes are almost exclusively localized in keratinized tissues, research on mechanisms of invasion primarily focuses on secreted proteases. All dermatophytes grow well in a medium containing hard keratin as the sole source of carbon and nitrogen. The spectrum of proteases secreted by dermatophytes is similar to that of *Aspergillus*, but differs by multiple endoprotease members of the S8 (subtilisins), M35 (deuterolysin), and M36 (fungalysins) families (14, 15). These belong to endoprotease gene families that have expanded in the *Onygenales*, and to exopeptidases of the M14 family (metallocarboxypeptidases) and M28 (aminopeptidases). At neutral or alkaline pH, dermatophytes secrete two major subtilisins, Sub3 and Sub4,

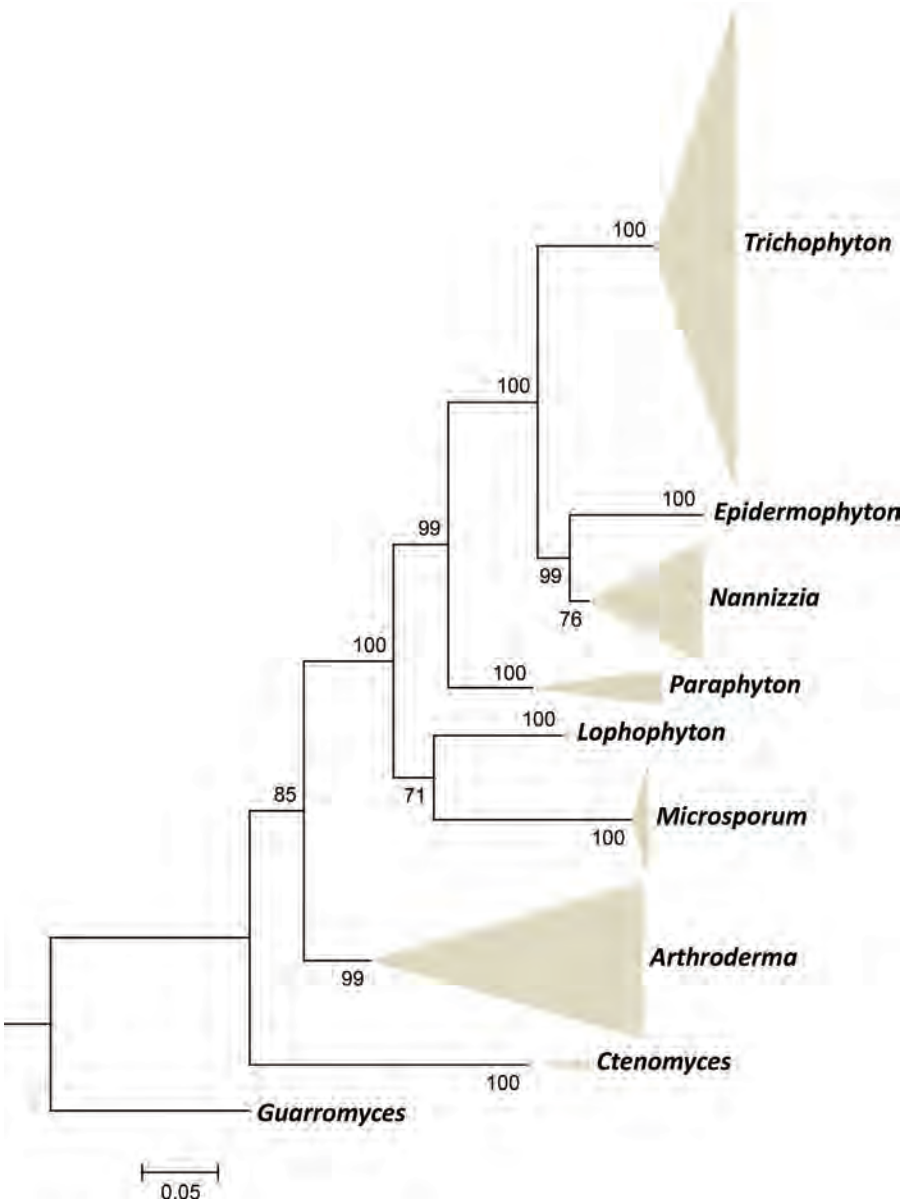

Figure 2 Maximum likelihood phylogenetic tree (RAxML v.8.0.0) based on ITS and partial LSU, TUB, and 60S L10 sequences of *Arthrodermataceae* species using GTRCAT as model, with 1,000 bootstrap replications, shown as collapsed when bootstrap values >70%. *Guarromyces ceretanicus* was selected as outgroup. Reprinted from de Hoog et al. (13).

and two major fungalysins, Mep3 and Mep4, as endopeptidases (14, 16–19). In comparison with proteinase K and subtilisin Carlsberg, *Trichophyton rubrum* secretes subtilisins Sub3 and Sub4, which are more active on keratin azure than on other protein sources such as elastin, suggesting specificity toward hard keratin substrates (17). In addition, dermatophytes secrete various aminopeptidases, e.g., leucine aminopeptidases (Lap1 and Lap2) and dipeptidyl-peptidases (DppIV and DppV). These enzymes show activities similar to *Aspergillus fumigatus* orthologues (20). Dermatophytes were also found to secrete a carboxypeptidase of the MEROPS M14A subfamily that is homologous to the human pancreatic carboxypeptidase A (21).

In a protein medium at acidic pH, dermatophytes secrete an aspartic protease of the pepsin family (Pep1) as an endoprotease, as well as tripeptidyl peptidases of the sedolisin family, prolyl peptidases and carboxypepti-

dases of the S10 family, and exoproteases (14). Analysis of the repertoire of secreted exoproteases in dermatophytes suggests basic mechanisms of extracellular proteolysis similar to those known in *Aspergillus* species at acidic and neutral pH (22, 23).

The proteases secreted *in vitro* are considered as virulence factors. However, transcriptome analysis performed with RNA from guinea pigs infected by the dermatophyte *Trichophyton benhamiae* and proteomic analyses of proteins extracted from infected nail beds of patients with onychomycosis revealed that a particular subtilisin (Sub6), not detected *in vitro*, was the major protease during infection (24, 25). Additional secreted proteins were detected, including the closely related Sub7 and the dipeptidyl peptidase DppV. Surprisingly, most of the proteases secreted *in vitro* during keratin digestion were not detected during the establishment of an infection. The results from *in vivo* experiments are of interest because Sub6 and DppV in *T. rubrum* were previously identified and described as major dermatophyte allergens, Tri r 2 and Tri r 4, respectively (26).

Other secreted hydrolases, e.g., ceramidases and lipases, are also putatively involved in degradation of the skin barrier. Microarray analysis revealed upregulation of genes such as heat shock proteins and transporters during *Arthroderma benhamiae* infection in guinea pigs, but the precise role of these genes in pathogenicity remains unclear (24). Marked upregulation of genes encoding enzymes of the glyoxylate cycle (i.e., isocitrate lyase and malate synthase) focused attention because this cycle was found to be necessary for virulence in *Candida albicans* (27) and for persistence in macrophages in *Mycobacterium tuberculosis* (28). However, virulence of deletion mutants defective in malate synthase was not attenuated in guinea pigs (29). The effects of the absence of the glyoxylate pathway might be suppressed by other metabolic pathways during infection.

Clinical Manifestations Distant from Dermatophyte Infections: Asthma and Skin Dermatophytides

Dermatophyte infections can provoke secondary immune reactions such as severe asthma and eczematous skin reactions (dermatophytids) in susceptible individuals. Dermatophytids, like *Trichophyton*-related asthma, can be controlled with systemic antifungal therapy.

Dyshidrotic and vesicular eczema on the hands (palms and/or fingers) associated with tinea pedis and/or tinea unguium in adults (generally caused by *T. rubrum* and *Trichophyton interdigitale*) are common dermatophytids (30). Eczema on the chest, trunk, and back associated with scalp ringworm due to zoophilic and anthropophilic species is less frequent but has been reported (31–33). A set of diagnostic criteria was developed to identify a dermatophytid reaction (33, 34): (i) there is a proven dermatophytic infection in a body site other than the locus of the eczematous skin reaction; (ii) the eczema appeared after the dermatophyte infection. The fungus is not present in the site of the cutaneous eruption. From this site, culture assays remain sterile and direct mycological examination is negative; (iii) the dermatophytid symptoms only resolve after eradication of the primary focus of fungal infection; (iv) the patients are sensitized to dermatophyte antigens and show a positive skin test response to fungal extracts (termed "Trichophytin"). In contrast to knowledge on *Trichophyton* asthma (35–37), individual antigens involved in dermatophytids have not been identified. Proteins secreted *in vivo* by dermatophytes are the best candidates as antigens involved in the host immune response.

Comparative Genomics

Genomes of dermatophytes are somewhat smaller than usual in filamentous ascomycetes, ranging from 22.5 Mb for *T. rubrum* to 24.1 Mb for *Trichophyton equinum* (38). Important functions concern secondary metabolism, proteases, and LysM binding domains, i.e., motifs that bind to various types of peptidoglycan and chitin. In contrast, genes involved in sugar metabolism and plant cell wall degradation are relatively depleted. There are only a few low-GC (31 to 36%) transposable elements, representing 1.3 to 7.2% of the genome (38), with low GC. Genomes of dermatophytes are colinear among each other, with only a few inversions. The core set comprises 6,168 orthologous groups of which 308 are unique to the dermatophytes. Species-specific genes have little functional information, and, hence, different clinical predilections between species cannot be explained with genome data alone. Three orthologous groups of the glycosyltransferase family (GT54) may be involved in immunomodulation of mannan upon infection. Burmester et al. (15) analyzed the global secretome during keratin degradation by growth with human keratinocytes. Dermatophytes produce a broad repertoire of genes encoding hydrolytic enzymes, lipases for cutaneous lipid degradation, and an exceptionally large number of proteases. Proteases do not differ significantly between species, indicating that proteolytic abilities are ancestral. Dermatophytes have an unusually high degree of nonreducing

polyketide synthases. Possibly this is linked to the often striking colony colors due to extracellular metabolites of the polyketide synthase pathway, such as the mycotoxin xanthomegnin, the red color of *T. rubrum*, which has been detected in clinical samples of epidermal material infected by *T. rubrum*, in contrast to noninfected controls.

Sexuality

Many geophilic and zoophilic species produce sexual phases on suitable media after confrontation of strains of opposite mating types, and, in such species, mating type distribution is balanced. Li et al. (39) matched molecular structure of the mating type locus idiomorphs (alpha and high-mobility group [HMG] domains) with *in vitro* mating results. Symoens et al. (40) showed balanced frequencies of + and − mating types in strains of the zoophilic species *T. benhamiae*. Anzawa et al. (41) showed mating of a highly competent *Arthroderma simii* tester strain producing a fertile F1 generation with a strain of *T. rubrum*, although, with a hybridization depression, only 1 of 35 ascospores was a real recombinant of the two species. On the basis of mating alone, some authors maintain rather wide species concepts uniting entities that are clinically and phenotypically different from each other (42). Another approach is a hypothesis of an atavistic ability to undergo genetic exchange via sexual reproduction/hybridization in response, e.g., the stressful conditions of a newly inhabited environment (13).

Over the phylogenetic tree, a gradual loss of sexual vigor can be observed. Kano et al. (43) confirmed that in the zoophilic species *Trichophyton verrucosum* idiomorphs of the mating type locus (alpha domain and HMG domain genes) exhibited only a single molecular mating type. Gräser et al. (Kosanke S, Hamann L, Gräser Y, unpublished data) noticed that this is the prevalent situation in several other zoophilic and most anthropophilic species. This suggests that anthropophilic species do not have an environmental niche where sexuality could take place, being transmitted between hosts. It may be hypothesized that clonal offshoots of interbreeding species are ecologically specialized and may be in danger of extinction upon changes in their niche on the human host (44).

Host Defense Mechanisms

Zoophilic and geophilic species of dermatophytes (e.g., *T. benhamiae*, *Trichophyton erinacei*, *T. verrucosum*, and *Microsporum canis*) cause highly inflamed lesions in humans. A dermatophyte provokes a more intense inflammatory reaction on a host to which it is not adapted than to its natural host; but on the other hand such lesions more rapidly lead to spontaneous resolution. Both innate and adaptive immunity are involved in host defense mechanisms against dermatophytes.

Innate immunity

Innate immunity in superficial dermatophytosis implies the action of keratinocytes and neutrophils. A broad spectrum of cytokines is produced by keratinocytes upon exposure to a dermatophyte (45), including interleukin-8 (IL-8), a potent chemoattractant for neutrophils that can kill dermatophytes, and the proinflammatory tumor necrosis factor α (TNF-α) (46). Production is higher in zoophilic than in anthropophilic dermatophytes (45, 47), which is consistent with the clinical features by the respective dermatophyte groups. Keratinocytes also secrete a wide variety of antimicrobial peptides with antifungal properties. Human β-defensin (48), cathelicidin LL-37 (49), psoriasin (50), and disulfide-reduced psoriasin (51) were proven to be either fungistatic or fungicidal *in vitro* against *T. rubrum*. Disulfide-reduced psoriasin was isolated from psoriatic lesions and confers resistance to fungal infections (51).

Zoonotic dermatophyte infections tend to be more inflammatory than those caused by anthropophilic species (52). Rare cases of deep dermatophytosis have been described in HIV and immunosuppressed patients (53, 54), but also in immunocompetent people, mainly from North African families with consanguinity (55). These patients were found to bear homozygous mutations in the gene coding for a caspase recruitment domain containing protein (CARD9). A stop codon mutation (Q289*) was detected in 15 patients from seven Algerian and Tunisian families (55). Two missense mutations, R101C and R101L, were detected in two Moroccan siblings and a Brazilian patient, respectively (55, 56). The mutation Q289* was also detected in a patient of Egyptian origin with extensive skin and nail dermatophytosis (57). CARD9 is an adaptor protein in the signaling pathway downstream from lectin receptors, such as dectin 1 and dectin 2 involved in the recognition of pathogenic fungi, and plays an important role in the innate immune response against fungal pathogens. The gene is expressed mainly in myeloid cells and is involved in the stimulation of proinflammatory responses. CARD9-deficient cells show low levels of IL-6 production after stimulation with zymosan, an agonist of dectin 1 (55).

Adaptive immunity

Zoophilic and geophilic dermatophytes induce a delayed type hypersensitivity (DTH) cell-mediated response,

which usually results in recovery and subsequent protection against reinfection. The response is characterized by elevated levels of the key cytokines IL-12 and gamma interferon (IFN-γ), which trigger T-helper 1 (Th1) cells for the activation of macrophages as effector cells. The overexpression of transforming growth factor β, IL-1β, and IL-6 mRNA during infection of *T. benhamiae* in a mouse model also suggests a role of the Th17 pathway in the establishment of immunity with recruitment of polymorphonuclear neutrophils (58). In contrast, anthropophilic species (e.g., *T. rubrum*, *T. interdigitale*, and *Trichophyton tonsurans*) tend to be associated with less inflammatory, but more chronic and persistent infections. These infections are correlated with poor specific DTH, elevated specific IgE and IgG4, and IgE-mediated immediate hypersensitivity, with the production of Th2 cytokines by mononuclear leukocytes (37, 59). While a cell-mediated Th1 response to dermatophytes is effective in eradicating the infection, Th2-mediated immediate hypersensitivity responses are not protective.

MALASSEZIA

Biodiversity

Malassezia species are among the most prominent microorganisms growing on human skin, where they form a significant part of the skin microbiome (60) thus corroborating older culture-based studies (61 and references therein). Because *Malassezia* spp. are extremely fastidious in culture, culture-based studies are potentially biased for the fast-growing and more robust species including *M. furfur*, *M. sympodialis*, and allies and against slower and fastidious species such as *M. restricta*, *M. globosa*, or *M. obtusa*. As such, in this review, we will focus on more recent DNA-based studies and point out specific differences where relevant.

It has long been known that all *Malassezia* species are lipophilic, and it has recently been shown that all species, including *M. pachydermatis*, are actually fully lipid dependent and lack a fatty acid synthase (9). They require long-chain fatty acid (e.g., C12 or longer) supplementation for growth (62). Within the Fungi, the genus *Malassezia* occupies a rather isolated phylogenetic position. Recent multigene phylogenetic studies placed the genus in its own class, *Malasseziomycetes* in the phylum *Basidiomycota*, subphylum *Ustilaginomycotina*, that otherwise mainly comprises plant pathogens (63). Taxonomically, the genus has been significantly enlarged during the last decades and currently contains 15 species (Fig. 3) (64–66). For a long time, only two species were recognized, namely the lipid-dependent and human-associated *M. furfur* and the then considered non-lipid-dependent and animal-associated *M. pachydermatis*. Major improvements in our understanding of the diversity and phylogenetic relationships of the *Malassezia* species resulted from molecular phylogenetic studies, especially those initiated by Guého et al. (67). The initial studies used the D1/D2 domains of the large subunit ribosomal DNA (LSU rDNA) and were later followed by the addition of the ITS (61, 68 and references therein). Improved phylogenetic insights based on these rDNA domains presently identify 14 species (66, 69). A recent phylogenomic study resulted in a fully resolved, well-supported phylogenetic tree in which four subclades were apparent (Fig. 4; 9). The most basal lineage is formed by *M. slooffiae* and *M. cuniculi* (clade C), with two larger terminal sister clades, namely clade A with *M. japonica*, *M. yamatoensis*, *M. obtusa*, and *M. furfur*, and clade B with two subclades, namely B1 with *M. pachydermatis*, *M. nana*, *M. caprae*, *M. dermatis*, and *M. sympodialis*, and B2 with the most common human skin commensal organisms, *M. restricta* and *M. globosa* (9). This core-eukaryotic gene tree, in general, agrees with a previous four-gene tree (70) and an amplified fragment length polymorphism (AFLP)-based tree (71).

Occurrence on Healthy Human Skin

Malassezia species have been considered commensal skin-inhabiting fungi that may be implicated in skin diseases (72). Their ubiquitous presence on humans has implied early maternal transmission, which is supported by a combination of culture and molecular studies (73). Recent advances in human mycobiome studies revealed that *Malassezia* species represent a commonly occurring group of fungi on and in the human body. When compared to bacteria, the abundance of fungi was generally lower, but *M. globosa* and *M. restricta* were more abundant near the ears and forehead (60). *Malassezia* species predominated on 11 body and arm sites of healthy individuals, namely the antecubital crease, back, external auditory canal, glabella, hypothenar palm, inguinal crease, manubrium, nare, occiput, retroauricular crease, and volar forearm. Eleven species were found to occur on various body sites (74), and a reanalysis of available metagenomics data from 12 individuals revealed that at least 12 *Malassezia* species can occur on skin. In terms of both frequency and abundance, in all individuals, *M. restricta* and *M. globosa* were the nondisputed numbers 1 and 2, with *M. sympodialis* ranking third (9).

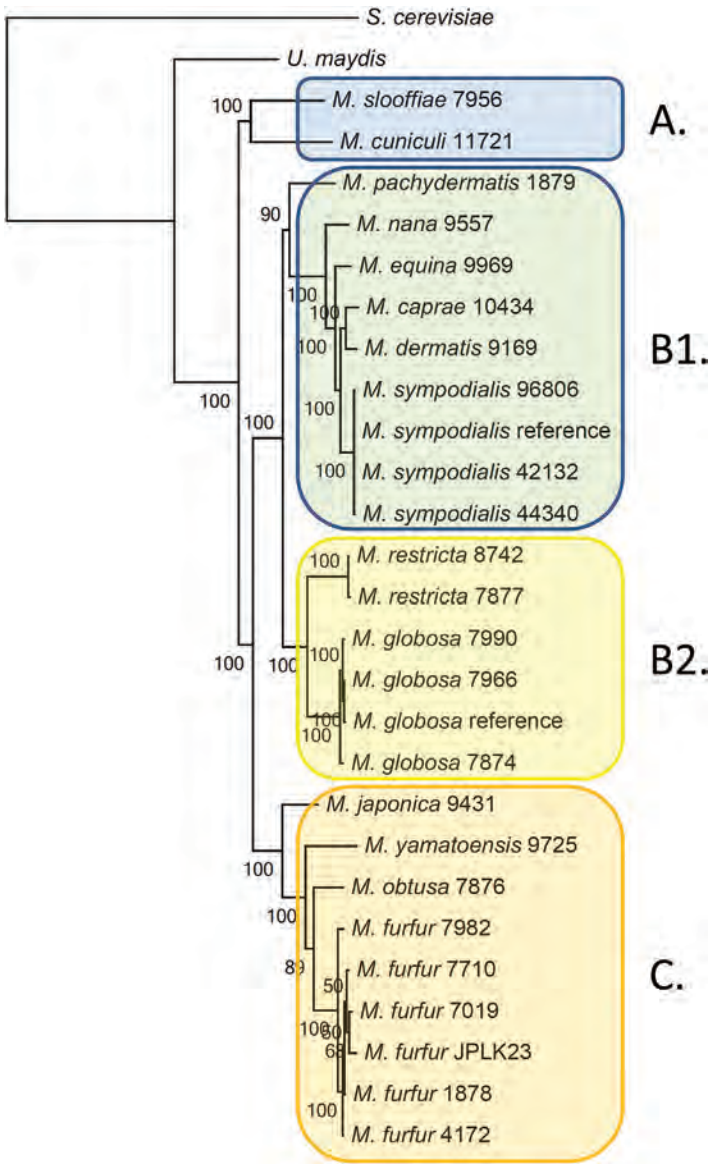

Figure 3 *Malassezia* species tree was constructed using concatenated sequences of 164 core eukaryotic genes that are present in all *Malassezia*, *U. maydis*, and *S. cerevisiae* genomes. Sequences were aligned using MUSCLE and the phylogeny constructed using a maximum likelihood (ML) approach by RAxML. RAxML was run using "–f a –m PROTGAMMAJTT" with 400 bootstraps.

Topological differences were observed. On the back, *M. globosa* was found to be most abundant on most individuals, with the exception of a single individual where *M. sympodialis* was dominant. The latter occurs in almost all cases as the second most abundant species on the back. In the antecubital or alar crease, *M. restricta* was most abundant in all subjects. Two of these species, and in many cases all three, were present in all individuals and also at most body sites sampled, but differences between individuals are observed. *M. slooffiae* occurred as a rather abundant species on one individual, whereas *M. obtusa*, *M. pachydermatis*, *M. caprae*, and *M. equina* were much less abundant. The occurrence of these latter species seems largely dependent on the individual. Interestingly, individuals showed the same spectrum of species present over a 3-month period (60). The factors that determine the presence of the rarer species are unknown. Many

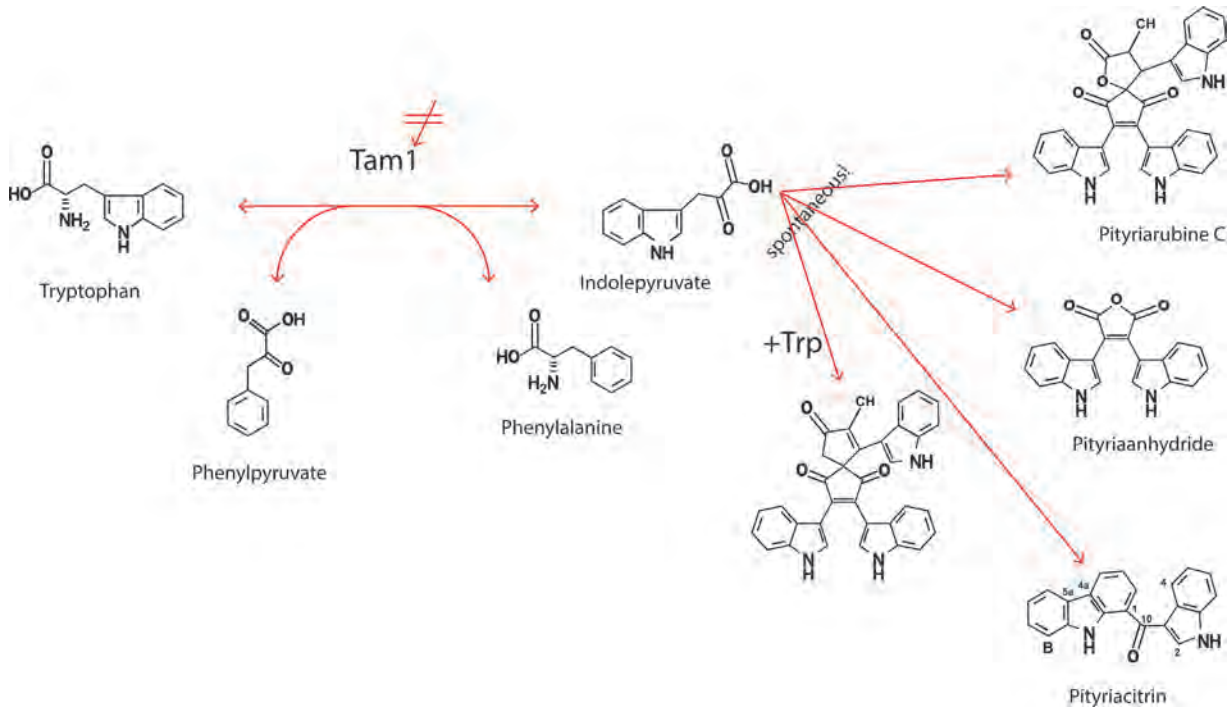

Figure 4 Synthesis of indole-derived pigments by one enzymatic step (TAM1) and possible intervention by TAM inhibitors.

more individuals from different ethnic and geographic origins, together with large-scale assessment of their skin conditions and other associated metadata, probably have to be investigated to understand any causal relationships. Furthermore, data as yet are primarily in Caucasians of Western descent and location, and more data will be required to understand the breadth of *Malassezia* diversity in other ethnicities and from people residing in different climates and geographies.

Occurrence in Human Skin Disorders

Malassezia spp. were found to be the most abundantly occurring fungi on both healthy and diseased skin with *M. restricta*, *M. globosa*, *M. sympodialis*, and *M. furfur* occurring on both and *M. slooffiae* only on nonlesional skin (75). The number of sequence reads of *M. restricta* and *M. globosa* differed significantly between both types of skin, with *M. restricta* being more dominant at lesional skin and *M. globosa* on nonlesional skin. No differences were observed in colonization of both skin types for *M. furfur*, *M. sympodialis*, or *M. slooffiae* (75). A French study that compared dandruff versus nondandruff scalp reported that the presence of dandruff correlated with a disequilibrium between *M. restricta* and *Staphylococcus epidermidis* or *Propionibacterium acnes* (63, 76). With the use of ITS and D1/D2 of LSU rDNA, it was found that *M. restricta* was the major fungus on both types of scalp with 97% of sequence reads from healthy scalp and 84% from scalp with dandruff (76). The difference in healthy versus dandruff scalp may also be due to intrinsic host factors separate from fungal metabolism, termed "individual susceptibility" (77).

M. globosa is a diverse species, the species most highly correlated with human disease and containing multiple genotypes (78). Four IGS1 genotypes have been described, and it has been suggested that one of those may be related to atopic dermatitis (79). The species is known from healthy skin, but also from lesions of PV and seborrheic dermatitis (SD) patients and animal skin (64, 80). Skin mycobiome studies revealed that *M. globosa* occurs on the back, occiput, and inguinal crease. The species may co-occur with *M. restricta* in SD/dandruff and atopic dermatitis patients (81). The abundance of *M. globosa* was significantly higher on SD than on healthy skin (75).

The second most important species on healthy and diseased skin, particularly of the head, including scalp, neck, face, and ears, is *M. restricta* (61). This species is known from the skin of healthy subjects, SD, dandruff, and atopic dermatitis patients (6, 81). It occurs abundantly on both SD and healthy skin (75), being isolated

from approximately 52% of SD patients compared to 64% in healthy humans (82).

M. sympodialis (83) is known from healthy human skin, in particular, the back and chest, but also from human PV, atopic dermatitis, skin, auditory tract, and various animals (64, 84). A recent Polish study using a culturing approach found that it was the most abundant *Malassezia* species on skin (85), but these results differ from many other studies that found *M. restricta* or *M. globosa* as the most common skin inhabitants. The discrepancy may have been caused by more ready isolation of *M. sympodialis* than of *M. globosa* and *M. restricta*.

Less commonly isolated species from human skin are *M. caprae*, previously known from healthy skin of goats and horses (86), and *M. dermatis*, known from lesions of atopic dermatitis and healthy skin (61). *M. furfur* has been reported from deep-seated infections, blood, urine, and vagina, and from septicemia in neonates that receive lipid supplementation via catheters (87, 88). Eight AFLP subtypes have been reported (68) that, however, did not fully coincide with subtypes based on sequences of the D1/D2 domains of the LSU rDNA. It has been suggested that isolates of AFLP genotype 4 may be more frequently involved in deep-seated infections, but the numbers that have been reported are low, hampering statistical analysis (71).

M. japonica is known from the skin of healthy Japanese women, but also from skin of atopic dermatitis patients (79). *M. obtusa* is known from the human groin, dermatitis skin, the nasal vestibule, but also from animals, such as goat, horse, and dog, and from canine otitis (89). *M. yamatoensis* is known from lesions of seborrheic and atopic dermatitis patients, but also from healthy human skin (64). It has also been suggested that several *Malassezia* species may be involved in skin carcinogenesis because of the production of aryl-hydrocarbon receptor ligands (90).

Occurrence Outside Human Skin

The mycobiome of the nasal vestibule of healthy humans and those suffering from allergic rhinitis is dominated by *Malassezia* species and comprises at least eight species with *M. restricta* as the most abundant and with *M. globosa* ranking as number 2. Further species observed were *M. cuniculi*, *M. dermatis*, *M. obtusa*, *M. pachydermatis*, *M. slooffiae*, and *M. sympodialis* (89). *Malassezia* species were found to be present with 100% colonization (91) and may also occur in the human gut, where five species were demonstrated using pyrosequencing of rDNA ITS (92). However, this approach is very sensitive and cannot discriminate between live resident flora and dead transient DNA. Using a PCR approach, *M. restricta*, *M. globosa*, and *M. pachydermatis* were found in stool of various individuals from different geographic locations, i.e., Amazonia, Polynesia, India, and Senegal (93). Another condition that has attracted interest is the prevalence of fungi in cystic fibrosis patients. *Malassezia* species, including *M. globosa* and *M. restricta*, were present in all sputum samples investigated, but with 10- to 50-fold lower levels than the more abundantly present *Candida* species (94). Finally, *Malassezia* species have been demonstrated to occur in the oral cavity where they have been suggested to be part of the basal oral mycobiome (95, 96).

A study using pyrosequencing of part of the small subunit ribosomal DNA (SSU rDNA) of sputum from asthma and nonatopic humans suggested that *M. pachydermatis* occurred commonly in asthmatic patients but was absent from healthy humans. A similar trend was seen for *M. furfur*, but the number of reads was much lower than that for *M. pachydermatis* (97). *M. pachydermatis* was also found in the nasal vestibules of healthy humans as well as those with allergic rhinitis (89).

Importantly, *M. pachydermatis* may cause catheter-related septicemia in neonates who receive lipid supplementation (98), and it also may cause sepsis in immune-suppressed adults. Domestic pet animals, especially dogs, have been identified as a source for transmission to neonates (99).

Occurrence Outside Humans

Many animals, such as cats, dogs, but also birds, horses, goats, cows, and pigs, may be infected by *Malassezia* species (65). *Malassezia* sequences have also been demonstrated from diverse terrestrial and marine ecosystems (100). Diverse *M. pachydermatis* isolates populate animal skin, including seven D1/D2 LSU rDNA genotypes that are known to exhibit some host specificity (101). Sequevar *a* originated from humans, sequevar *b* occurred in various animals, sequevar *c* came from rhinoceros, and cats and dogs were colonized by two and three genotypes, respectively.

M. equina was reported from healthy skin of a horse (anus) and cow in Spain (86), and *M. nana* from the otitis externa of cats, but also from cows in Brazil with or without otitis externa (102). *M. pachydermatis* is especially known from the external ear canal of many warm-blooded animals, especially dogs and cats, but also from bears, fox, rhinoceros, California sea lion, and many more (103 and references therein).

M. globosa is known from animal skin as well as from ears of healthy and diseased bovines and, for

the latter, a link with nematodes has been suggested (104). DNA of the species was detected in *Malenchus* nematodes in a European forest soil (105), and also in Antarctic soils where a connection with nematodes has been further postulated (106).

Biochemistry

Of the 15 currently recognized *Malassezia* species, *M. globosa* is thought to play a key role in the pathogenesis of PV (80). However, PV characteristics such as pigmentation alterations, fluorescence of PV lesions, or minimal signs of inflammation despite high fungal load (107) cannot be explained just by occurrence of *M. globosa*, which is also the predominant species on healthy skin. Instead, it was shown that, with tryptophan as a nitrogen source, *M. furfur* produces a number of indole pigments and alkaloids, which might be related to the clinical appearance of PV (Table 1) (108). Despite its complex biochemistry, the pathway does not represent secondary metabolism, as is the case with most of the mycotoxins. In the related and completely sequenced organism *Ustilago maydis*, it was shown that tryptophan and keto acids are converted to indole-3-pyruvic acid (IPyA) and the corresponding amino acids involving a tryptophan aminotransferase (Tam1; UM01804, XM_752858) as the initial and only enzymatic step. The indole pigments and alkaloids are then formed spontaneously from IPyA (109; Fig. 1). Tam1 of *M. furfur* (MfTam1) was shown to be differentially expressed under pigment-producing and nonproducing conditions (110, 111). The *mftam1* gene (1,431 bp) was cloned by a reversed PCR strategy (112). MfTam1 (molecular weight [MW] 52,500; JX 453496, EC 2.6.1.27) is specific for transamination of L-tryptophan with K_m values for the substrate and α-ketoglutarate in the low millimolar range (~7 mM). Its activity is highly dependent on pyridoxal phosphate (PLP) and compounds interfering with PLP, such as cycloserine (CS) and aminooxyacetate (AOA), inhibit the MfTam1 reaction. Mayser and Rieche (113) showed that a 200 mM CS solution topically applied for 5 days on PV lesions reversed the hyperpigmentation, and found with AOA tests the same effect as for CS on PV. However, AOA was more potent than CS (P. Mayser, unpublished data). Interestingly, comparison with the genome of *M. globosa* showed that the gene is also present in this species (MGL_2601, XM_001730167) (111). However, MgTam (MW ~35,500) shows a weaker activity *in vitro* than MfTam (Mayser, unpublished data). For CS and AOA inhibition of MgTam1 is expected, because the sequence is similar to the one of *M. furfur* and the inhibitors target PLP-dependent enzymes.

PV is very common in tropical climates and is associated with sweating and hyperhidrosis (114). The tryptophan concentration in sweat, however, is very low (~70 μM). It was shown that glycine metabolism of *M. furfur* results in *Malassezia* growth (115). However, metabolism of tryptophan is responsible for pigment production. When glycine and tryptophan are present, the fungi first grow and then, after a growth plateau is reached, start producing pigments. These data indicate that *M. furfur* preferentially metabolizes glycine. When the glycine concentration decreases, the metabolism switches to deamination of tryptophan with pigment formation as a by-product. In light of the fact that glycine is highly abundant in sweat (~2 to 4 mM) (116), it was hypothesized that severe sweating changes the local amino acid concentrations, resulting in an enrichment of the poorly water-soluble tryptophan on the skin. Thus, *M. furfur* (and probably *M. globosa*) might convert Trp to IP in a situation that lacks other nitrogen sources. The subsequently spontaneously generated indole pigments could be responsible for the clinical course of this common skin disease. TAM 1 inhibitors might represent a new approach in the therapy of this widespread disease.

Table 1 Selected Trp-derived indole compounds and their potential relationship to clinical phenomena in PV

Isolated compound	Pharmacological property	Phenomenon in PV
Pityriacitrin	UV protection	Lack of sunburn in depigmented areas of PV alba
Fluorescent metabolites (e.g., pityrialactone)	Fluorescence	Fluorescence of lesions in PV
Pityriarubins	Inhibition of oxidative burst in granulocytes	Lack of inflammation in lesions of PV
Malassezin	Induction of apoptosis in human melanocytes	Depigmentation in PV alba
AHR[a]-agonists (e.g., malassezin, pityriazepin, indolo[3,2-b]carbazole)	Activation of cytochrome, activation of AHR	Immunomodulation, effects on cell differentiation and homeostasis, depigmentation? desquamation?
Diversity of pigmented compounds	Pigmentation	Brick-red to brownish pigmentation of lesions in PV

[a]AHR, aryl hydrocarbon receptor.

Malassezia biology is also implicated in the common skin disorders dandruff and SD (9). These disorders are thought to be downstream of *Malassezia* lipid metabolism. In brief, *Malassezia* lacks the enzymes necessary to generate required fatty acids (no fatty acid synthase) or to assimilate unsaturated fatty acids (lacking a Δ9-desaturase). These deficiencies are compensated by the secretion of a number of hydrolytic enzymes that break down human sebaceous lipids. The *Malassezia* cells then assimilate the saturated fatty acids for survival (117), and leave behind irritating fatty acids that have been shown to induce dandruff-like desquamation in susceptible individuals (77).

Comparative Genomics

Twenty-four *Malassezia* isolates have been fully sequenced (Table 2), including all 14 currently accepted species and multiple isolates of the most common inhabitants of human skin (*M. globosa*, *M. restricta*, and *M. sympodialis*) and the most common human pathogenic species, *M. furfur* (9). The *Malassezia* genomes were compared with widely divergent fungal genomes, which identified features defining *Malassezia*. A large set of common fungal genes has been lost, corresponding to the compactness of the genome and adaptation to the skin environment. *Malassezia* genomics shows the genus has a propensity for gene turnover and highlights the importance of gathering nutrients from a sparse environment via secretion of large families of lipases, phospholipases, aspartyl proteases, and other peptidases. Recently, multiple genomes of *M. sympodialis* were generated via long read sequencing, and the genomes annotated via proteogenomics. This has significantly increased the reliability of the *M. sympodialis* genome annotation (118).

Several important facets of *Malassezia* warrant consideration. *Malassezia* produces a set of secreted hydrolases similar to *C. albicans*, a human skin pathogen, but is phylogenetically more closely related to the plant pathogen *U. maydis*. *Ustilago* produces a different set of secreted hydrolases, adapted for life on plants. The set of secreted enzymes utilized by each genus is likely

Table 2 *Malassezia* genome statistics[a]

adaptation to the host niche and may be involved in pathogenicity (9, 72, 119). *Malassezia* species are all missing multiple enzymes required for robust lipid metabolism, including fatty acid synthase, Δ9-desaturase, and $\Delta^{2,3}$-enoyl-CoA isomerase. These gene losses likely explain their lipid dependence. Genuswide variation in these families also likely supports each species' niche specificity. *Malassezia* species have multiple gene duplications into several families. These genes have undergone lineage-specific duplications since divergence from *Ustilago* (9, 119). *Malassezia* species all encode proteins similar to the *M. sympodialis* allergens, supporting a role in skin and inhalational allergy. *Malassezia* genomes all have genes associated with mating, although mating has not been observed. They are likely among the first recorded fungi with a pseudobipolar mating phenotype (83, 120, 121).

Malassezia species have been shown to have gained and lost many specific gene families during their complex evolution. Of particular note is the likely gain of a single gene, conserved in all *Malassezia* but absent in any other sequenced basidiomycetes, suggesting a gene transfer at the very root of the *Malassezia*. The gene is likely functional, as it was found in *M. globosa* to be both transcribed and its transcription regulated. A second important potentially horizontally transferred gene family was located at the root of clades B1/B2 and was shown to be related to a catalase, which could adaptively protect *Malassezia* from a group of their own secreted proteins that generate hydrogen peroxide (9). Another example of *Malassezia* receiving genes via horizontal gene transfer is acquisition of a flavohemoglobin A from the *Corynebacterium* of *Actinobacteria*, potentially adding nitric oxide resistance into *Malassezia* (118).

Malassezia genomics also has revealed that they are likely to mate (9, 119). Fungal mating may be involved in pathogenesis, by increasing genetic diversity (122, 123). The mating loci suggest bipolar or pseudobipolar mating may be present in all *Malassezia* species. Studies using sequencing technology to build larger contiguous regions will be needed to define the mating systems in *Malassezia*, and further gene deletion or model systems to study any role in pathogenesis. Now that transformation and genetic engineering of *Malassezia* have been shown to be possible (124, 125), it is likely that the roles of these and other genes and pathways will be clarified.

Host Defense Mechanisms

As residents of the skin of all animals, and by definition then all human beings, *Malassezia* represents a unique opportunity to study the interaction of commensal microorganisms with the human immune system. As such, *Malassezia* has been shown to directly modulate cytokine expression by isolated human peripheral blood mononuclear cells (126). This report indicates that the *Malassezia* species most commonly found on human skin (*M. globosa*, *M. restricta*) downregulate expression of IL-6 or IL-1β, while the less common *M. sympodialis* does not. It was also indicated that the ability to modulate immune cells may be related to lipid metabolism, because extraction of *Malassezia* lipids via chloroform: methanol abrogated this effect. *Malassezia* lipids are further implicated in their relationship with the immune system in that the overall hydrophobicity of isolates correlates with their ability to stimulate secretion of proinflammatory cytokines from isolated human keratinocytes. An additional report further implicates a direct interaction with human monocyte-derived dendritic cells (127), where human NK cells activated monocyte-derived dendritic cells and induced an even stronger activation when *Malassezia* was present. Upregulation of CD83 and CD86 indicates that NK cells mature DCs and improve their costimulatory capacity.

M. sympodialis is able to directly elicit a human immune response, shown by the presence of human antibodies that cross-react with a group of *Malassezia*-secreted proteins termed "allergens" (128). In this series of reports, it was shown that individuals with specific forms of atopic dermatitis had serum IgG that could react with protein lysates from *M. sympodialis* and that subjects with head and neck atopic dermatitis had higher levels of anti-*Malassezia* IgG (129, 130). The allergens were identified, cloned, and sequenced, and later shown to be present and likely secreted in all *Malassezia* species (9). The *Malassezia* allergens are contained and secreted in nanovesicles, and the secretion and activity are modulated by skin pH (72).

Fungal Biofilms: Inside Out

42

Katherine Lagree and Aaron P. Mitchell

INTRODUCTION

We focus this article on turning a biofilm inside out. The "inside" of the biofilm comprises the individual biofilm-related phenotypes, their environmental drivers and genetic determinants, and the coordination of gene functions through transcriptional regulators. Investigators have viewed the inside of the biofilm through diverse approaches, and this article will attempt to capture the essence of many. The ultimate goal is to connect the inside to the "outside," which we view as biofilm structure, development, pharmacological attributes, and medical impact.

Biofilms are surface-associated microbial communities, encased in self-produced extracellular material, that exhibit phenotypes distinct from those of planktonic (free-living) cells. Microbes are thought to grow predominantly as biofilms in nature (1). The surfaces with which biofilm cells are associated may be diverse and include solid abiotic materials, tissues and cells, and air-water interfaces. In fact, a colony growing on an agar plate is a biofilm.

Biofilm cells are quite different from the mid-logarithmic-phase planktonic cells that modern microbiologists were trained to study (see reference 2). Biofilm populations are invariably heterogeneous (Fig. 1A). Cells at the periphery of the biofilm are bathed in the external medium; cells at the base of the biofilm may have limited nutrients and oxygen and are surrounded by their neighbors' waste products. Cells at the periphery may be exposed to a rapidly fluctuating environment; cells at the base are buffered from many abrupt changes. Thus, a mature biofilm may include cells exposed to a range of nutrients, and the biofilm cell population may be growing at a range of rates.

Our focus on biofilms stems from their central role in infection biology (3). Biofilms are medically relevant in two major contexts: device-associated infection and *in vivo* growth. Device-associated infection is the phenomenon of the presence of an implanted medical device being a significant risk factor for bloodstream or deep-tissue infection. The specific risk factor and the likely types of infecting organisms vary with the kind of device and its location. The connection to biofilm formation was first elucidated by Costerton and colleagues (3), who found biofilms of infecting organisms on the devices that were removed from infected patients. In the vast majority of cases, the devices are sterile when implanted and later become colonized by microbes that enter the bloodstream. The biofilm on a device serves as a reservoir that continually seeds the infection. Unfortunately, as detailed later in this article, biofilm cells are generally recalcitrant to antimicrobials; thus, device removal may be the only therapeutic option. Because the usage of implanted devices continues to increase worldwide, the problem of device-associated infection will only grow in the future.

The second connection between biofilms and infection has to do with the nature of growth *in vivo*. Some infections are obviously surface-associated growth. Examples include mucosal infections such as thrush and vaginitis. Invasion of the surface may follow initial infection, and the surface itself may change over the course of infection due to inflammation and tissue damage. Other infections are not associated with host surfaces, but the infecting organisms grow as an aggregate encased in extracellular matrix (ECM) material. The aggregates may be considered self-contained biofilms, analogous to the flocs that form at the end of industrial fermentations (4).

We now look inside fungal biofilms at the major biofilm-relevant phenotypes and, where known, the molecular mechanisms that govern those properties. We focus primarily on *Candida albicans*, the biofilms of which have been studied extensively, as well as on *Aspergillus fumigatus*.

Department of Biological Sciences, Carnegie Mellon University, Pittsburgh, PA 15213.

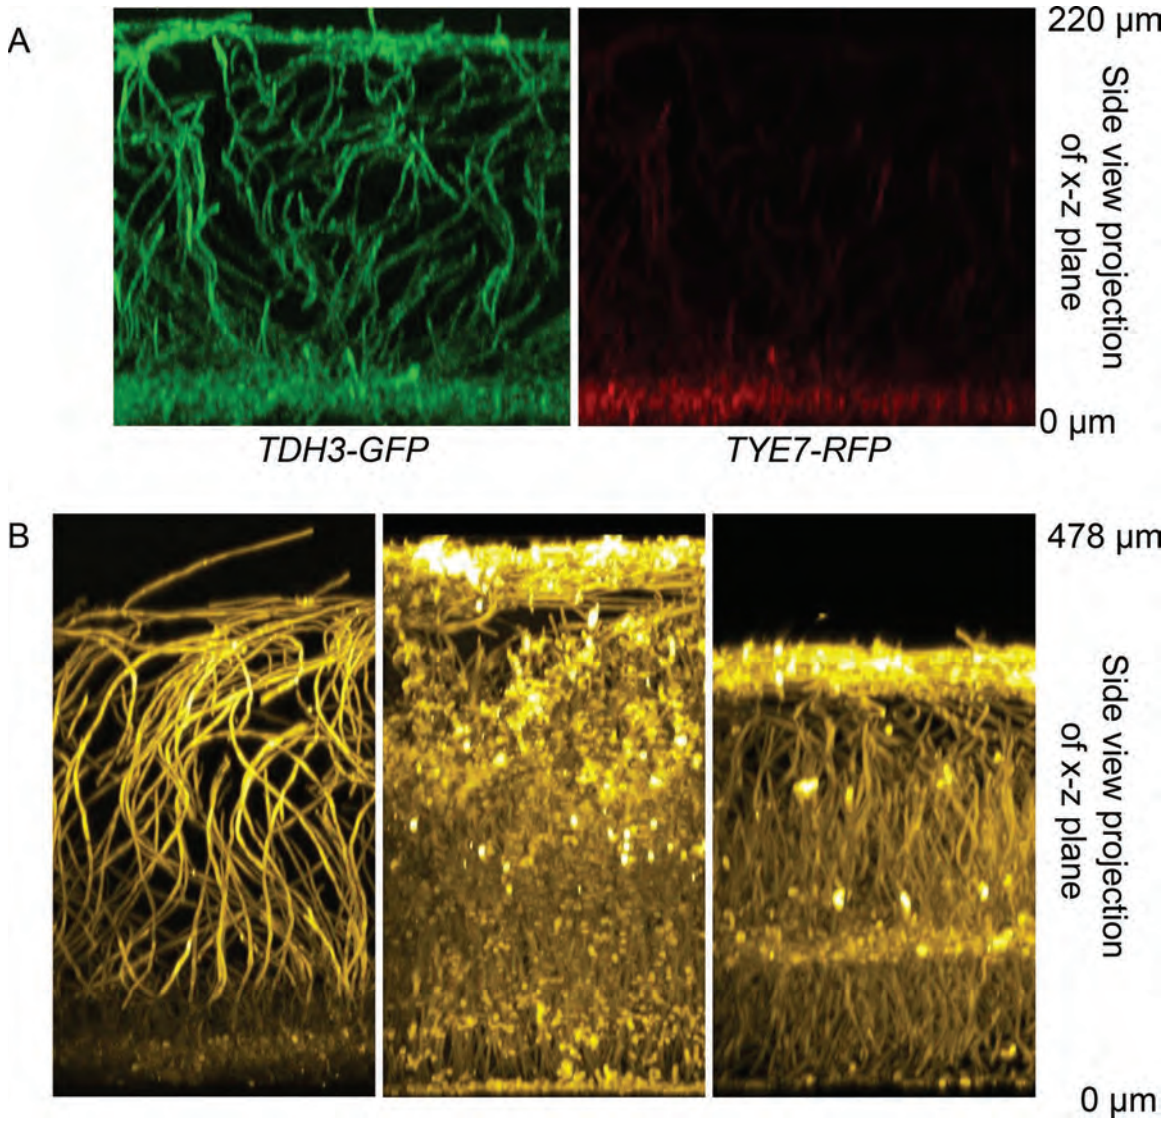

Figure 1 Confocal imaging of *C. albicans* biofilms. (**A**) Images show the heterogeneity of biofilms at the level of gene expression using a GFP construct fused to the *TDH3* promoter that is constitutively expressed throughout the biofilm and an RFP construct fused to the *TYE7* promoter showing greater expression at the basal layer of the biofilm, respectively. (**B**) Images show the phenotypic diversity of biofilms based on the growth medium in RPMI, YPD, and RPMI plus 10% serum, respectively. Biofilms were fixed and imaged using a Zeiss DuoScan confocal microscope. Side view projections were generated by reslicing and then z-projecting the stack using ImageJ software from the National Institutes of Health.

ADHERENCE

A necessary step in biofilm formation is attachment to a biotic or abiotic surface. For *C. albicans* biofilms, the attachment step is achieved through adhesive proteins expressed on the cell surface that are usually in the category of glycosyl phosphatidyl inositol (GPI)-anchored proteins. This kind of cell wall protein makes up a large portion of the total cell wall protein complement in *C. albicans*. Indeed, 115 putative GPI-anchored proteins have been identified, though more than half of these have no assigned function (5). The general structure of GPI-anchored proteins includes an N-terminal signal sequence, which traffics the protein to the endoplasmic reticulum, and a C-terminal hydrophobic domain site that allows the attachment of a preformed GPI anchor (6). A third structural part of GPI-anchored

proteins is the central region, which varies among proteins. Often, the central region contains repeats of conserved, functional units.

The Als (agglutinin-like sequence) family of adhesins is the most well-known category of GPI-anchored proteins in *C. albicans*. We use Als proteins to illustrate many general principles of fungal adhesins. Mutants defective in expression of *ALS1* and *ALS3* have decreased adherence to host and abiotic substrates (7–9). Due to their cell surface expression and role in virulence, recombinant Als1 and Als3 have been investigated for use as vaccines, with considerable success in mice (10). Als proteins contain the canonical GPI-anchor components along with an immunoglobulin-like region near the N-terminal domain, a conserved threonine-rich region, tandem repeats of a threonine-rich sequence, and a serine- and threonine-rich stalk that is often highly glycosylated near the C terminus (Fig. 2). Each of these domains has been studied in detail and has been shown to be functionally important (11).

The Als immunoglobulin-like region has two immunoglobulin-like domains and a peptide-binding cavity. This domain is responsible for binding to a broad range of host substrates such as E-cadherins, ECM proteins, or fucose-containing glycans (11–13). Although ligand binding by Als proteins in solution is relatively weak, the loss of a highly expressed Als protein has a very dramatic effect on adherence. This conundrum spurred further structural and biochemical analysis of the N-terminal regions of several Als proteins. Three Als regions are critical for substrate binding: the peptide-binding cavity, the threonine-rich region, and the tandem repeat region (Fig. 2). The peptide-binding cavity interacts directly with ligands (14, 15), and the other regions mediate Als protein aggregation, as discussed below.

Following the N terminus, there is a threonine-rich region (T). One function of this region is to promote secretion, though the mechanistic basis for this role is not understood (13). The second function is related to a highly conserved amyloid-forming domain within this region that mediates Als protein association, yielding polyvalent Als protein aggregates. This domain has been explored in detail by the Lipke group (16). Using atomic force microscopy and amyloid binding dyes such as thioflavin T, amyloid formation was observed with surface-expressed Als5. Following the discovery of amyloid formation in the Als proteins, Chan and Lipke made the connection that the adherence of fungal cells to surfaces is mediated through a process called "catch-bonding" (17). The process of catch-bonding seems to be broadly utilized by other organisms to mediate adhesion, because it has been described to occur with other systems such as mammalian selectins and bacterial adhesins (18). Chan and Lipke showed that the domains are activated through sheer force. The force causes nanodomains to form, comprising Als protein aggregates. This mechanism accounts for the strong adherence exhibited by *C. albicans* when it adheres and forms a biofilm compared to the relatively weak binding of adhesins to specific ligands in solution (17, 19).

The threonine-rich amyloid-forming region is followed by threonine-rich tandem repeats (TR). These repeats have been shown to be heavily glycosylated (13) and are predicted to form antiparallel β-sheets (20). Expression of Als5 derivatives that differed in the numbers of TR repeats in the heterologous host *Saccharomyces cerevisiae* has shown that they mediate cell-cell aggregation (13). This cell-cell aggregation function was independent of the immunoglobulin-like domain (13). Several modeling approaches argue that aggregation of the TR is mediated primarily by hydrophobic interactions (20). In addition, the TR region increases the affinity of the Als5 immunoglobulin-like region for at least one substrate, fibronectin (13). Spectroscopic analysis argues that this TR function is mediated by an effect on the folding of the immunoglobulin-like domain (13). It is remarkable that a region of such simple
