Disclaimer

Health care is a complex and constantly evolving field. No publication can be assumed to encompass the full scope of information that an individual practitioner brings to his or her practice and, therefore, this book is not intended to be used as a clinical manual recommending specific treatments for individual patients. It is intended for use as an educational tool, to broaden the knowledge and perspective of the practitioner. It is the responsibility of the healthcare practitioner to make his or her own determination of the usefulness and applicability of any information contained herein. Neither the publisher, the editors, authors, nor reviewers assume any liability for any injury and/or damage to persons or property arising from the use of information to be found in this publication.

Preface

Clinicians who focus on the management of complex, chronic disease have not chosen an easy path. This book describes an approach to improving patient outcomes across a wide range of chronic health conditions through careful analysis of common underlying pathways that interact to produce disease and dysfunction or health and vitality. Outstanding content has been contributed by experts from diverse disciplines that traditionally do not integrate their knowledge within a single text. The approach to disease management and health promotion described herein represents the evolution of the functional medicine model over the past fifteen years through the voices of its leaders.

Functional medicine reflects a systems biology approach to health care: a comprehensive analysis of the manner in which all components of the human biological system interact functionally with the environment over time.¹ Over the past century, biology and medicine have focused heavily upon understanding the physiology and biochemistry of individual organs, cells, and molecules. Traditionally, researchers and clinicians have explored one component of various biological systems at a time.² In clinical practice, this process usually leads to the differential diagnosis. In drug discovery, it helps us understand how individual compounds interact with a specific drug target in human physiology. From these investigations has emerged an exceptional knowledge base. We are now poised to comprehend the common underlying pathways of health and disease as never before. We can acknowledge that most diseases are rarely the result of a single physiological problem localized to a single organ.³ Rather, most chronic disease results from the complex interactions of multiple organ systems and multiple physiological and biochemical pathways with environmental influences and genetic predispositions. This knowledge demands a new clinical approach to prevention and treatment.

Two challenging questions that have stimulated the development of functional medicine have emerged over

the past two decades: *How are the body's physiological systems linked together? And how is their function influenced by both environment and genetics?* The recognition that these two questions are inextricably linked to each other has become much clearer with the discovery that the human genome contains far fewer genes than expected and that much of our biological uniqueness is related to the “non-coding” region of the genome—the region that controls systems of gene expression.⁴ In essence, we have learned that our complex phenotype cannot be adequately understood by exploring one gene at a time (although that exploration is a vital part of building our knowledge). *Systems of genetic expression* give rise to our biological complexity and they need to be understood from an integrated perspective.

Health care is an enterprise focused on the alleviation of human suffering caused by disease and dysfunction. Disease has its start as a functional impairment (a *dysfunction*) that, left untreated, becomes a diagnosable disease that later can become the cause of death. Each disease has a past, a present, and a future tied to the progressive loss of function and vitality. James Fries in his landmark article on aging, morbidity, and natural death termed this the “loss of organ reserve.”⁵

This functional systems biology approach to understanding the origin of disease is now being encouraged by the National Institutes of Health under the new program, *NIH Roadmap*, as a route to accelerate medical discoveries that will improve health.⁶ “In this set of NIH Roadmap initiatives, researchers will focus on the development of new technologies to accelerate discovery and facilitate comprehensive study of biological pathways and networks.” It is presently driving research in immunology, neurology, cardiology, endocrinology, and radiology.

Three characteristics define the systems biology approach to medicine: emergence, robustness, and modularity.⁷ *Emergence* represents the specific characteristics that are displayed in a complex system that are not demonstrated by its individual parts and cannot be predicted

from an understanding of the individual parts alone. In the functional medicine model, this has been termed the “web-like interconnections” of physiological processes and biochemical pathways. *Robustness* is the ability that complex biological systems have to maintain homeostasis in the face of changing environmental conditions. In functional medicine, this is termed “homeodynamics.” The greater the degrees of physiological freedom individuals have, the more robust their health. For example, very simple EKG patterns are indicative of cardiac disease, whereas the more chaotic fine structure of heart rhythm (i.e., a homeodynamic pattern) is associated with cardiovascular fitness. *Modularity* refers to a system that is comprised of functional units working together to produce an outcome that cannot be produced by any of the units working independently. An example of this concept in functional medicine is the view of the immune, endocrine, and nervous systems as parts of one super-system, the neuroendocrineimmune system. Only by looking at that system as a whole, and not at each of its units in isolation, can the practitioner fully understand the complex presentation of multiple signs and symptoms that patients so often exhibit.

Seventy-eight percent of healthcare expenditures are now for the treatment of chronic diseases, and most physicians are not adequately trained to deal with these complex problems.⁸ In functional medicine, it is our conviction that developing a healthcare system that *effectively* manages (and prevents) chronic disease will depend upon our ability to apply a systems biology approach to medicine. Functional medicine incorporates many aspects of this approach, each of which plays a vital role.

Identifying and following biomarkers of function that can be used as indicators of the onset of disease, and also as markers of the success of interventions, is an extremely important activity in functional medicine. Using a patient-centered rather than a disease-centered model emphasizes the importance of eliciting the patient’s story, and incorporates mindfulness and the narrative tradition.⁹ Recognizing that the extent and severity of chronic conditions in middle to late life are, to a large extent, the outcome of environmental insults received at any point from conception forward allows for a focus on long-term prevention to be integrated into clinical practice.¹⁰ Harnessing the healing power of the mind-body interaction is also important to func-

tional medicine clinicians, as developed from scientific progress in the field of psychoneuroimmunology.¹¹

In looking back at the history of medicine in the 20th century, the origin of this concept of function can be credited to a large degree to the work of Dr. Hans Selye.¹² His pioneering work related to the functional endocrinology of what he termed “stress” and its relationship to chronic diseases as diverse as peptic ulcer, hypertension, and heart disease created a new medical model for disease arising out of dysfunction, rather than from infectious organisms or inborn errors of metabolism. He put a physiological mechanism behind the concept that “it is more important to know what kind of person has the disease, than what disease the person has.”¹³

Voices from all aspects of our society are merging into a unified call for a new model to address chronic health conditions. A 2005 article in *The New England Journal of Medicine* pointed out that children being born today may be the first generation in the history of the United States with a lower life expectancy than their parents.¹⁴ This prediction comes at a time when the United States spends twice as much per capita for health as any other country, but is 37th in the world in terms of health outcomes. Another 2005 *NEJM* study reported that Medicare is in great danger from the increasing prevalence of age-related chronic diseases, which it does not have the resources to address.¹⁵ The former chairman of Intel Corporation, Dr. Andrew Grove, recently commented in the *Journal of the American Medical Association* that innovation in medicine is slow and that a new model is needed to address the serious health concerns of the country.¹⁶

Functional medicine is an effective response to this call for a new model of care. It was born out of collaborations among clinicians of many different disciplines and specialties, clinical laboratory specialists, health sciences researchers, health educators, health policy professionals, and healthcare administrators to address the rising incidence and cost of chronic disease. Over the past fifteen years, functional medicine has become an experienced voice in these discussions.

This textbook is the result of our belief that a teaching tool is necessary to assist dedicated practitioners to develop competency with the functional medicine model, and to stimulate and support the emergence of new approaches to the education of future clinicians in all healthcare disciplines. It is our hope that this text-

book is but the first edition of what will be an evolving chronicle of the successful development and implementation of the functional medicine model for the effective prevention and treatment of chronic diseases.

Many individuals and organizations provided financial support for the development of this book, and many clinicians, educators, and scientists contributed to the content. For their vision, their commitment to excellence, and their generosity, we dedicate this book to them.

Foreword: Textbook of Functional Medicine

July 1, 2010

Mark Hyman, MD

Chairman, The Institute for Functional Medicine

Shifts in thinking do not come easily in science. Thomas Kuhn, in *The Structure of Scientific Revolutions*, warns that changes of “normative” science rarely come from within. We are at a moment in medical history that requires a new way of interpreting and processing data, a new operating system to successfully address our global epidemic of chronic disease.¹ Practitioners need a new set of lenses through which to interpret and act on clinical information.

The *Textbook of Functional Medicine* presents those new lenses, and the science that validates them. In this groundbreaking text, we learn:

- a new way of seeing the epidemic of chronic disease based on underlying causes, and
- a focus on developing treatment models that can restore balance within dysfunctional biological systems and networks.

Current medical models are reductionist in nature, producing fragmented, organ-based, specialist-focused care that results in increased costs and poor outcomes.² Disastrously, primary care is a dying field^{3,4,5} at the same time that primary care diseases are increasing at dramatic rates. Applied in practice, functional medicine can reinvigorate primary care by training practitioners to prevent, treat, and often cure chronic conditions more effectively and at lower cost than the conventional medical paradigm.⁶

The urgency for practitioners to learn and adopt more effective clinical tools for prevention, treatment, and management of chronic disease is underscored by the fact that more than 75% of healthcare costs—\$2.3 trillion—is now spent on chronic disease.⁷ By 2040 (at current growth rates and if we don’t act soon), health care costs will absorb 34% of our GDP⁸ and nearly 80%

of all federal spending will be allocated to Social Security, Medicare, and Medicaid.⁹

As the science and practice of medicine transition from the acute-care, reductionist model that evolved from the germ theory of disease to a systems model based on networks of biologic function—a model that has emerged from the genomic revolution—clinical practice, medical education, and health research must all evolve and adapt to make the transition successful.¹⁰ A fundamental re-orientation of clinical problem solving is required, expanding the diagnostic focus from the disease-based ICD-9 classification system to include assessment of patterns of dysfunction within complex networks of biologic systems, which are at the root of all disease.¹¹

Functional medicine provides a new model of healthcare delivery and practice that addresses the drivers of chronic diseases such as cardiovascular disease, diabetes, obesity, cancer, autoimmune and allergic conditions, digestive, mood, and cognitive disorders by translating existing research into clinical practice through the lens of systems biology. Most chronic disease is preventable, and much of it is reversible, if a comprehensive, individualized approach addressing genetics, diet, nutrition, environmental exposures, stress, exercise, and psychospiritual needs is implemented through integrated clinical teams and based on emerging research.¹² Functional medicine provides a practical clinical framework for understanding how the body’s physiologic systems are linked together and how their function is influenced by both environment and genetics.¹³ Clinical medicine can and must shift to an applied systems medicine—personalized, predictive, preventive, and participatory.¹⁴

The *Textbook of Functional Medicine* shifts our paradigm from organ-based diseases to functional dynamic systems. It is the first robust clinical model that effectively applies the promise of systems biology. Arising from direct observation and assimilation of seemingly

disparate scientific evidence, a view of biology emerges that delivers a new operating system for the maintenance of health and the prevention of disease. It is essential reading for any practitioner or scientist involved in health care in the 21st century.

**21st Century Medicine:
A New Model for Medical Education and Practice 897**

Section I

Introduction

The background of the page is a vibrant blue. The lower portion features a complex, abstract pattern of white and light blue lines that flow and swirl, resembling a close-up of a fan or a dynamic, fluid motion. A sharp, bright white diagonal streak cuts across the lower right area, adding a sense of energy and direction to the overall design.

Chapter 1

The Vision and Mission of The Institute for Functional Medicine

David S. Jones, MD, and Sheila Quinn

The Institute for Functional Medicine is a nonprofit, tax-exempt 501(c)3 educational organization that educates physicians and other healthcare practitioners in improving the management of complex, chronic disease through the use of functional medicine. IFM is accredited by the Accreditation Council for Continuing Medical Education (ACCME) to provide continuing medical education for physicians. In addition to live CME courses, IFM publishes books, course syllabus and audio recordings from live courses, and hosts an online Member Forum. Detailed information about the Institute and its educational activities can be found at www.functionalmedicine.org.

IFM's long-term goals are perfectly described in a statement by Peter F. Drucker: "The product (*of the non-profit organization*) is neither a pair of shoes nor an effective regulation. Its product is a changed human being. The nonprofit institutions are human-change agents."¹

Vision Statement

The vision of the Institute for Functional Medicine is to improve the health of individuals worldwide by continuous improvement in healthcare practices.

Mission Statement

The mission of the Institute is to improve patient outcomes through prevention, early assessment, and comprehensive management of complex, chronic disease. We achieve this mission by:

1. Developing the functional medicine knowledge base as a bridge between research (both emerging and established) and clinical practice;

2. Teaching physicians and other healthcare providers the basic science and clinical applications of functional medicine;
3. Communicating with policy makers, practitioners, educators, researchers, and the public to disseminate the functional medicine knowledge base more widely.

Purpose Statement

The Institute provides continuing medical education for physicians and other healthcare professionals, publishes books and other educational materials, and offers clinicians a Forum for the shared exploration of emerging research and clinical applications to improve patient care and outcomes.

Statement of Need

The U.S. healthcare system fails to address the needs of many of our citizens. Many physicians have lost their passion for patient care;² patients are disenchanted sufficiently with the focus of their health care to seek alternatives to conventional care in steadily increasing numbers;^{3,4} the numbers of uninsured grow as employers reduce their premium share or opt out of providing employee health insurance because of costs;^{5,6} and the U.S. ranks 37th in quality of health outcomes⁷ despite spending \$1.6 trillion per year on health care.⁸

Research suggests that the sense of futility experienced by many healthcare providers stems from a loss of meaning and empowerment in the therapeutic relationship, created (in part) as our chaotic healthcare system has shifted focus from quality issues to cost issues.^{9,10,11,12,13} A paradigm shift is required to

re-enchant the practice of medicine for both the healthcare provider and the patient (the consumer of health care).¹⁴ It has been suggested that the holism inherent in the therapeutic relationship, plus an expansion of medical thinking beyond the diagnosis and the prescription pad, will re-involve the healthcare provider in the dual function of critical thinking and mindful involvement with the whole life of the patient.^{15,16,17}

The Institute for Functional Medicine is committed to helping practitioners and patients achieve this important goal. Since IFM's first incorporation in 1996, it has been dedicated to reducing the fragmentation of health care with a rigorous, science-based continuing educational program whose primary focus is on improving patient outcomes through more effective prevention, early assessment, and comprehensive management of complex, chronic disease. As our mission statement indicates, IFM intends to be just such a change agent as Drucker described, helping to better the health of people worldwide by changing the way health care is practiced.

This textbook represents an important step in achieving IFM's mission—putting into the hands of healthcare providers around the world a consistent, documented view of the philosophy, concepts, underlying science, and clinical applications of functional medicine so that, together, we can work toward the continued development of this extremely important approach to patient care.

Chapter 2

What is Functional Medicine?

- *Introduction to Functional Medicine*
- *History of Functional Medicine*

Introduction to Functional Medicine

David S. Jones, MD, Jeffrey S. Bland, PhD, and Sheila Quinn

A 2003 article in the *British Medical Journal*¹ generated the following editorial comment: “It is almost a daily occurrence for primary care doctors to encounter patients whose symptoms are probably not due to discernible organic cause.” Many of these symptoms appear to be related to chronic inflammatory complaints of unknown origin. Because no specific disease can unequivocally be attached to these complaints, the following question arises: What physiological processes/mechanisms result in the expression of these signs and symptoms? Could their underlying “organic cause” be related to altered function in the absence of observed pathology?

A major challenge for medicine in the 21st century will be to move toward a thorough understanding of physiological mechanisms that underlie disease rather than simply labeling later-stage effects with the names of diseases. “What should we say to patients with symptoms unexplained by disease?” asks the article associated with the editorial comment quoted above. The authors suggest that, for most patients, using the term “functional,” as in “functional illness,” would be more socially acceptable than “medically unexplained symptoms.”

Historically, the term “functional” has been used pejoratively in medicine. It has implied either a disability associated with geriatric medicine or a psychiatric problem. Now, the term “functional” is being used to describe a manifestation of changes in basic physiological processes that produce symptoms of increasing duration, intensity, and frequency. These symptoms often

represent the first signs of a later-stage, pathophysiological definable disease. So, the term becomes applicable not only to diseases of unknown origin, but to early alterations in function that clearly move a patient toward chronic disease over the course of a lifetime.

A new model of medicine is emerging to describe these altered physiological processes that presage the onset of histopathologically defined disease. This model takes the term “functional” beyond psychosomatic illness to define a state of chronic dysfunction associated with altered physiological processes that create a physiological alarm state.

What is Functional Medicine?

Functional medicine is a dynamic approach to assessing, preventing, and treating complex chronic disease. Functional medicine helps clinicians identify and ameliorate dysfunctions in the physiology and biochemistry of the human body as a primary method of improving patient health. Functional medicine acknowledges that chronic disease is almost always preceded by a lengthy period of declining function in one or more of the body's systems. Returning patients to health requires reversing (or substantially improving) the specific dysfunctions that have contributed to the disease state. Those dysfunctions are, for each of us, the result of lifelong interactions among our environment, our lifestyle, and our genetic predispositions. Each patient, therefore, represents a unique, complex, and interwoven set of influences on

intrinsic functionality that have set the stage for the development of disease or the maintenance of health.

The Functional Medicine Domain

One way to conceptualize where functional medicine falls in the continuum of health and health care is to examine the functional medicine “tree.”

In its approach to a patient care model for complex, chronic disease, functional medicine encompasses the whole domain represented by the graphic shown in Figure 2.1, but concentrates on the section below Organ System Diagnosis, which differentiates it from the conventional medical model. Assessment and treatment *first* address the patient’s core clinical imbalances, fundamental physiological processes, environmental inputs, and genetic predispositions, rather than heading straight for the diagnosis. (These elements are explored in detail and thoroughly documented in separate sections of this book. Here in the *Introduction*, we provide an overview of the content and concepts.) Diagnosis is not excluded from the functional medicine model, but the emphasis is on understanding and improving the functional core of the human being as the starting point for intervention. Functional medicine practitioners reason that scientific evidence strongly indicates that impaired physiological processes, if not corrected, lead to significant clinical imbalances in essential body systems. If left in a dysfunctional state, those clinical imbalances often progress to more significant signs and symptoms that may be the precursors or actual indicators of a disease state that can be diagnosed. Improving balance and functionality in these basic processes creates momentum toward health.

Conventional medicine normally acts either when a diagnosis can be made, or when signs and symptoms are severe enough (or the patient is persistent enough) to demand a clinical intervention. Functional medicine practitioners certainly do intervene when a diagnosis has already been made, but they also evaluate functionality at a much earlier stage, often averting (or deferring for a substantial period of time) the disease outcome or its secondary effects. And, in all cases, functional medicine clinicians focus on restoring balance to the dysfunctional systems by strengthening the fundamental physiological processes that underlie them, and by adjusting the environmental inputs that nurture or impair them. This approach leads to therapies that

focus on restoring health and function, rather than simply controlling signs and symptoms.

Functional medicine could be characterized, therefore, as “upstream medicine” or “back to basics”—back to the patient’s life story, back to the processes wherein disease originates, and definitely back to the desire of healthcare practitioners to make people well, not just manage symptoms.

Principles

These basic principles characterize the functional medicine paradigm:

- An understanding of the *biochemical individuality* of each human being, based on the concepts of genetic and environmental uniqueness;
- Awareness of the evidence that supports a *patient-centered* rather than a disease-centered approach to treatment;
- The search for a *dynamic balance* among the internal and external factors in a patient’s body, mind, and spirit;
- Familiarity with the *web-like interconnections* of internal physiological factors;
- Identification of *health as a positive vitality*—not merely the absence of disease—emphasizing those factors that encourage the enhancement of a vigorous physiology; and
- *Promotion of organ reserve* as the means to enhance the health span, not just the life span, of each patient.

Each of these principles is discussed in depth in the *Principles* section, and the evidence supporting their inclusion is presented there.

Environmental Inputs

Environmental inputs (at the base of the medicine tree graphic) include the basic building blocks of life, as well as the primary influences on them. When we talk about influencing “gene expression,” we are interested in the interaction between “environment” in the broadest sense and any genetic predispositions with which a person may have been born. Many environmental factors that affect genetic expression are (or appear to be) a matter of choice (such as diet and exercise), but others are very difficult for the individual patient to alter or escape (air and water quality, toxic exposures), and still

others may be the result of unavoidable accidents (trauma, exposure to harmful microorganisms in the food supply through travel). Some factors that may appear modifiable are heavily influenced by the patient's

economic status—if you are poor, for example, it may be impossible to choose more healthful food, decrease stress in the workplace and at home, or take the time to exercise and rest properly.

Figure 2.1 The continuum of health and health care

Section I

Introduction

Whatever the nature of these “inputs,” their influence on the human organism is indisputable, and they are often powerful agents in the search for health. Ignoring them in favor of the “quick fix” of writing a prescription means the cause of the underlying dysfunction may be obscured, but is usually not eliminated. The functional medicine practitioner takes the elements listed below into consideration when working with a patient to reverse dysfunction or disease and restore health:

- Diet (type and quantity of food, food preparation, calories, fats, proteins, carbohydrates)
- Nutrients (both dietary and supplemental)
- Air
- Water
- Microorganisms (and the general condition of the soil in which food is grown)
- Physical exercise
- Trauma
- Psycho-social factors (including family, work, community, economic status, stress)
- Xenobiotics
- Radiation

Environmental inputs are intimately connected with the functional medicine principle of *dynamic balance* mentioned above. The importance of this critical interweaving between internal and external factors in a patient’s body, mind and spirit is fully explored later in the book.

Fundamental Physiological Processes

The fundamental physiological processes that ultimately determine health or disease include:

- communication, both outside and inside the cell;
- bioenergetics, or the transformation of food, air, and water into energy;
- replication, repair, and maintenance of structural integrity, from the cellular to the whole body level;
- elimination of waste;
- protection and defense; and
- transport and circulation.

These fundamental physiological processes are usually taught in the first two years of medical training, where they are appropriately presented as the foundation of modern, scientific medical care. However, subsequent training in the clinical sciences often fails to fully inte-

grate this rich understanding of the underlying functional mechanisms of disease with therapeutics and prevention. In the second two years, conventional clinical training heavily emphasizes teaching/learning based on organ system diagnosis.² This approach—aggregating the patient’s signs and symptoms into groupings that follow organ system declensions—has given us both the power and the weakness of specialization (e.g., the breakdown of medicine into cardiology, neurology, gastroenterology, pulmonology, nephrology, dermatology, hematology, hepatology, endocrinology, the surgical specialties, and so forth). Specialists become exceedingly knowledgeable in a well-defined subset of the human organism, but they often evaluate and treat diseases within their specialty area as though the inevitable cross-talk among all organ systems does not occur.

Focusing predominantly on organ system diagnosis without examining the underlying physiology that produced the patient’s signs, symptoms, and disease often leads to managing patient care by matching diagnosis to pharmacology. The job of the healthcare provider then becomes a cookbook exercise in finding the right “recipe”—the drug or procedure that best fits the diagnosis (not necessarily the patient). Every medical problem thus becomes a personal health issue in search of a pharmacological agent or surgical procedure³ and that leads to a significant curtailment of the critical thinking pathways: “Medicine, it seems, has little regard for a complete description of how a myriad of pathways result in any clinical state.”⁴

Even more important, the pharmacologic treatments specific to each specialty are often implemented without careful consideration of the physiological effects across all organ systems and physiological processes (and genetic variations).⁵ Pharmaceutical companies have exploited this weakness. Did you ever see a drug ad that urges the practitioner to carefully consider the impact of all other drugs being taken by the patient before prescribing a new one? The marketing of drugs to specific specialty niches and the use of sound-bite sales pitches that suggest discrete effects skew healthcare thinking toward this narrow, linear logic, as notably exemplified by the COX-2 inhibitor drugs that were so wildly successful on their introduction, only to be subsequently withdrawn or substantially narrowed in use due to collateral damage.^{6,7}

Pharmacological and medical hardware interests also strongly influence the research that is done and the

information that reaches physicians about new drugs and procedures.^{8,9,10} Our national research establishment—both private and governmental—is heavily focused on drug development and medical devices technology, rather than multifactorial, individualized, lifestyle-focused interventions. Physicians (and now patients as well) are subjected to the disproportionate impact the drug industry's ad campaigns have on information about treatment approaches for disease—everything is centered on taking a drug,¹¹ rather than helping patients change behavior. By controlling research topics,¹² selecting what data will be published,^{13,14} and dominating continuing medical education programs,^{15,16,17} the pharmaceutical industry often replaces complex thinking with more simplistic approaches relying on pharmaceuticals.¹⁸ Even our less commercial research models (at NIH, for example) all too often concentrate on “single disease–single agent–single outcome” methodologies. Examination of lifestyle and the attendant physiological and health consequences seldom receive needed research support because the medical-industrial complex that surrounds conventional training and practice is driven by these powerful commercial interests. (Lifestyle approaches are also more difficult to study prospectively, but the work certainly can be done with the will and the resources.)

Fortunately, a stronger voice from within the ranks of medical educators and practitioners is emerging on behalf of re-evaluating the influence of commercial interests on our healthcare system—from education to research to clinical practice.^{19,20} Many mainstream publications are including articles by leading medical thinkers that patient-centered health care requires a broader focus than simply labeling the problem (diagnosis) and selecting the right drug.²¹

The functional medicine approach to assessment, both before and after diagnosis, charts a course using different navigational assumptions. Every health condition instigates a quest for information centered on understanding when and how the specific biological system(s) under examination spun out of control to begin manifesting dysfunction and/or disease. Analyzing all the elements (information from the patient's story, signs, symptoms, and laboratory assessment) through a matrix focused on functionality requires critical thinking that is quite different than matching diagnosis with drug and hardware interventions. A deeper understanding of biochemistry and physiology is required of a functional

medicine practitioner. The foundational principles of how the human organism functions—and how its systems communicate and interact—are essential to the process of linking ideas about multifactorial causation with the perceptible effects we call disease or dysfunction.

To assist clinicians in this process, functional medicine has adapted and organized a set of *core clinical imbalances* that function as the intellectual bridge between the rich basic science literature delineating physiological mechanisms of disease (first two years of medical training) and the clinical studies, clinical experience, and clinical diagnoses of the second two years of medical training. The core clinical imbalances serve to marry the mechanisms of disease with the manifestations and diagnoses of disease. (Re-examine the medicine tree graphic to appreciate how the core clinical imbalances fit within the total framework of health care.)

Core Clinical Imbalances

The practice of functional medicine is characterized by an examination of the core clinical imbalances that underlie the expression of disease. Those imbalances arise as *environmental inputs* such as diet, nutrients (including air and water), exercise, toxins, and trauma *are processed* (see above list of the fundamental processes involved) through a unique set of *genetic predispositions*, attitudes, and beliefs. The *core clinical imbalances* that arise from malfunctions within this complex system include:

- *Hormonal and neurotransmitter imbalances*
- *Oxidation-reduction imbalances and mitochondriopathy*
- *Detoxification and biotransformational imbalances*
- *Immune and inflammatory imbalances*
- *Digestive, absorptive, and microbiological imbalances*
- *Structural imbalances* from cellular membrane function to the musculoskeletal system

Imbalances such as these are the precursors to the signs and symptoms by which we detect and label (diagnose) organ system disease. These imbalances arise from dysfunction or defect within the fundamental physiological processes that cut across all organ systems, and they alert the healthcare provider to pay attention to the full expression of disease and dysfunction. Each of these imbalances is explored in considerable detail later in the book, and the underlying evidence supporting this approach to patient care is thoroughly discussed.

The most important precept to remember about functional medicine is that restoring balance—in the

patient's environmental inputs and in the body's fundamental physiological processes—can be both a precursor and a concomitant activity to evaluating and treating chronic illness, and to improving health. It involves much more than treating symptoms.

Short Description of Functional Medicine

Functional medicine is dedicated to prevention, early assessment, and improved management of complex, chronic disease by intervening at multiple levels to correct core clinical imbalances and thereby restore each patient's functionality and health to the greatest extent possible.

History of Functional Medicine

David S. Jones, MD, and Jeffrey S. Bland, PhD

If contrast is the essence of vision, then clearly delineating the differences between present-day conventional medicine and functional medicine will help improve our understanding of the road being pioneered by functional medicine.

In his commentary in 2003, *The Medicine We Are Evolving*,²² Sidney MacDonald Baker, MD, postulates that current conventional medicine rests on two primary principles:

1. The fundamental subject of medical concern is disease;
2. The inquiry as to health rests first on the naming of the patient's disease.

He points out that treatment is then prescribed for the disease without rigorous consideration of the patient's unique individual needs, which may include the need to be rid of something toxic, allergenic or infectious, or the need to add something vital that is missing, or both.

Dr. Baker describes the difference between the acute-illness legacy of conventional medicine and today's functional medicine model that is focused on prevention and treatment of chronic, complex illnesses (the dominant medical problems experienced in our modern, industrialized, hygienic society):

How do we think differently? The emerging school of thought [*functional medicine*] does not deny the usefulness to the patient and physician of diagnostic groups that allow us the comfort of knowing "what you've got." We are careful to keep in mind that a diagnosis is an idea we form about groups of people and properly belongs to the group, not an individual. Making a diag-

nosis in the realm of chronic illness—such as the many conditions of chronic inflammation whose proud names end in "-itis," and autism, schizophrenia, depression, anxiety, cardiovascular disease, and a host of otherwise eponymous, classical, and respectable diseases—is for us not the end of a diagnostic road, but the first step, to be followed by the ... [*consideration of unique individual needs*]. These questions are not applied to "curing the disease" but to healing the person.

This approach is based on the recognition that individuality ... [*has*] a spiritual as well as a biological foundation in the sense that each of us is a unique creature. Hence our patients are denied dignity when given a group identity (diagnosis) and a group treatment (the "treatment of choice" for that diagnosis).²³

Functional medicine evolved from a medical paradigm that, instead of emphasizing the primacy of diagnosis and pathology, focuses on the antecedent events that precede the onset of diagnosis (*cf.* the notion of "upstream medicine," discussed above under *The Functional Medicine Domain*). Leo Galland, MD, elaborated this principle first in the early 1990s in his unpublished, but widely disseminated paper, *Patient-Centered Diagnosis: A Guide to the Rational Treatment of Patients as Individuals*,²⁴ later expanded and published in 1997 as *The Four Pillars of Healing*.²⁵ Patient-centered diagnosis depends on knowledge of the mediators, triggers, and antecedents of the patient's specific disease (discussed in detail in Chapter 8). According to Dr. Galland, arriving at an accurate, detailed, structured assessment of the patient requires a collaborative context within which the patient's story includes:

aspects of the patient that had previously been ignored. We were interested in the effects of the common components of life: a patient's thoughts and beliefs, home or work environment, exposure to potential toxins, and allergens, food and drink, stressful life events, social interactions, patterns of physical activity.

The evaluation investigates the patient's history, including family history and clues regarding genetic and social inheritance, the environmental/emotional conditions affecting the patient's health, and those factors that continue to mediate the dysfunction and/or disease. The patient's narrative always includes clues that will eventually inform the physician about the underlying mechanisms of dysfunction, without "segregation of biological and psychosocial dimensions."²⁶ This model derives from the integration of research in molecular biology and behavioral psychology about the influences that lead to the clinical manifestation of disease. One approach of this kind has been labeled the "biopsychosocial model,"

and it helps clinicians understand “how suffering, disease, and illness are affected by multiple levels of organization, from the societal to the molecular.”²⁷

Starting in the early 1980s, Jeffrey Bland, PhD, first developed the fully elaborated model of functional medicine that now includes both the *six principles* and the *fundamental clinical imbalances* that underlie the dysfunctional devolution of health into disease. Writing in the preface of his 2004 seminar series syllabus,²⁸ Dr. Bland states:

It amazes me that this accumulated body of information ... now comprises more than 2000 pages and 5000 referenced articles demonstrating the importance of diet, nutritional intervention, lifestyle and environment on both the prevention and management of virtually every chronic disease We are involved in what Thomas Kuhn termed a “paradigm shift” in our understanding of the origin and treatment of age-related chronic diseases. The discovery of the code of the human genome and the recognition that our function is determined by much more than just our genome is a revolution in thinking. Our health and disease patterns after infancy are not “hardwired” deterministically by our genes, but rather a consequence of the interaction of genetic uniqueness with environmental factors. Our experiences wash over our genes to give rise over time to how we look, act, feel and our disease pattern. This is truly a change in thinking about the origin of disease that requires a similarly bold change in how we treat disease.

This model emerges from the groundwork of six great innovators who carved out from the domain of molecular medicine the foundational concepts underpinning functional medicine. The six pioneers of this new medical paradigm are Archibald Garrod (1902), Linus Pauling (1949), Roger Williams (1956), Abram Hoffer (1957), Hans Selye (1979), and Bruce Ames (2002). Let us pause and reflect on the contributions of these six pioneers who have improved our understanding of the human organism and the factors that contribute either to ongoing health or to the progression toward chronic, degenerative diseases.

Archibald Garrod, MD

Dr. Garrod was first to discover the diseases of genetic metabolism in the early 20th century. (He investigated the genetic metabolism diseases of infancy.) Although those diseases originated in the genes, he said, the ultimate expression of the diseases depended on the exposure of those genes to factors in the envi-

ronment. He discovered alkaptonuria, which led to the understanding of phenylketonuria and the role of the phenylalanine-restricted diet in its management. In 1902, Dr. Garrod wrote, “It might be claimed that what used to be spoken of as a diathesis of a disease is nothing else but chemical individuality. It is nearly true to say that the factors which confer upon us our predisposition and immunities from disease are inherent in our very chemical structure, and even in the molecular groupings which went to the making of the chromosomes from which we sprang.”²⁹

Linus Pauling, PhD

Dr. Pauling made extraordinary contributions to the way we view the origin of disease. His article in *Science* magazine in 1949 on the origin of sickle cell anemia taught us that single gene mutations could contribute to disorders that cut across organ systems and produce multiple symptoms. In this article he introduced the term “molecular medicine.”³⁰ Dr. Pauling explained that in sickle cell anemia, a single point gene mutation on the heavy chain of the globin molecule of hemoglobin could contribute to a conformational change in the way the hemoglobin molecule was structured in three dimensions. That conformational change affected the way oxygen bound to the heme portion of the hemoglobin molecule and changed the relationship between the molecule and its oxygen absorption/desorption. The change in shape of that molecule changed the shape of the red cell, because hemoglobin made up about three-quarters of the volume of a red cell. The red cell then became sickle-shaped, and this sickle would “cut” its way through the vasculature, creating the pain and disability of sickle cell crisis.³¹

Dr. Pauling predicted in 1949 that the molecular origin of disease would have extraordinary implications. As we learned more about the origin of these diseases, he believed, we would find ways to modify the expression and function of these genes to prevent the expression of disease. In 1997, 48 years after Dr. Pauling proposed this model of the potential power of molecular medicine, a paper in *The New England Journal of Medicine* validated his thesis. That article explained that administering hydroxy urea intravenously to patients who carried the genetic trait of sickle cell anemia could prevent the hemoglobinopathies associated with this genetic disorder.³² Hydroxy urea upregulated the

Section I

Introduction

expression of fetal hemoglobin in these patients and “diluted” the amount of sickle cell hemoglobin, resulting in a reduction of sickle cell crisis.

Roger Williams, PhD

Dr. Roger Williams, a professor of biochemistry at University of Texas at Austin and past President of the American Chemical Society, discovered members of the B-complex vitamin family, including pantothenic acid. Dr. Williams’ book, *Biochemical Individuality*, published in 1956, proposed a role of various nutrients in preventing what he called “genetotrophic diseases.”³³ Genetotrophic diseases are those for which genetic uniqueness creates demands for specific nutrients beyond the average to facilitate optimal function and prevent premature disease. Dr. Williams theorized that when those specific needs are not met in a given individual, disease results.

Dr. Williams believed the major chronic degenerative diseases of aging—heart disease, stroke, cancer, diabetes, and arthritis—were related to genetotrophic imperfections. In his model, the unique genes of each individual require different levels of nutrition and a specific lifestyle for optimal health. The consequences of not meeting the specific needs of the individual are expressed, over several decades, as degenerative disease “of unknown origin.” In the category of what he called genetotrophic diseases, Dr. Williams even included diseases of mental illness, childhood diseases, behavior disorders, and alcoholism. He believed they all were related to the mismatch of genes and environment. At a genetic level, the individual needed a different level of nutrients to promote proper phenotypic expression. If that need was not met, the resulting undernutrition would manifest as chronic disease in midlife. This very powerful concept revolutionized our thinking about the origin of age-related diseases.³⁴

In defending his concept of biochemical individuality, Dr. Roger Williams said, “Nutrition is for real people. Statistical humans are of little interest. People are unique. We must treat real people with respect to their biochemical uniqueness.”

Abram Hoffer, MD, PhD

As a psychiatrist who also held a doctorate in organic chemistry, Dr. Hoffer in the 1950s provided a unique perspective on mental illness. He discovered in the urine

of schizophrenics unique chemicals that represented the oxidative byproducts of adrenaline.³⁵ He found that these substances produced central nervous system toxicity. As a result of these discoveries, Dr. Hoffer proposed that certain forms of mental illness resulted not from bad early childhood experiences, but as a consequence of altered brain chemistry.³⁶ He found that increased doses of the common B vitamins, niacin and pyridoxine, could treat these conditions in some schizophrenic patients.³⁷ Dr. Hoffer, with the synthesis of a new idea that incorporated biochemical genetic individuality, nutritional modulation of gene expression, and functional physiology, provided the bridge that allowed psychiatry to enter the field of biologically based, functional therapy.

Hans Selye, MD, PhD

As the father of the physiological definition of the word “stress,” Dr. Selye introduced to both medical professionals and healthcare consumers the role of the mind in the function of the body.³⁸ Dr. Selye’s tremendous insight gave birth to the rapidly evolving field of psychoneuroimmunology, which is redefining the way health practitioners view the impact of lifestyle and behavior on health. The combination of the physiology of stress and the understanding of the influence of perceived stress on genetic expression served as a powerful driver for the evolution of functional medicine.

Although Dr. Selye was never awarded a Nobel Prize for his contributions, many historians of 20th century medicine believe his insights on the role of behavior and environment in health represent one of the most important factors shaping the new medicine.

Bruce Ames, PhD

Dr. Bruce Ames, Professor of Biochemistry and Molecular Biology, and Director of the National Institute of Environmental Health Science Center, University of California, Berkeley, published his landmark paper in 2001.³⁹ His team’s research provides the bench science to substantiate Williams’ postulates on genetotrophic diseases. Ames shows in his encyclopedic review paper that “as many as one-third of mutations in a gene result in the corresponding enzyme having an increased Michaelis constant, or K_m (decreased binding affinity), for a coenzyme, resulting in a lower rate of reaction.” Some

people carry polymorphisms¹ that are more critical in determining the outcome of their health history. He goes on to argue that studies have shown that administration of higher than dietary reference intake (DRI) levels of cofactors (specific vitamins and minerals) to these polymorphic genes restores activity to near-normal and even normal levels. He concludes, “Nutritional interventions to improve health are likely to be a major benefit of the genomics era.”

The functional medicine model rests on the stout shoulders of these worthy researchers and clinicians. They pioneered the concepts that postulated that many agents modify gene expression in such a way as to create different phenotypes. They provided the breakthrough science that demonstrates that significant influences in this process include diet, exercise, stress, environmental, and lifestyle factors.

Molecules of functional importance transmit messages and receptors receive them. The transmitters are the molecules we call the mediators. The receivers are the membrane receptor binding and soluble receptor sites that translate the messages into altered gene expression and altered function. It is possible to manipulate both the messages and their reception on the basis of things we do every day, by the way we think, act, eat, and feel, by where we live, and by the nature of our relationships and our spiritual belief systems. All these factors influence the mediating molecules and can lead to an expanding health paradigm. An informational rubric encompasses communicating and receiving the right messages to be in synchrony with our genes to give rise to healthy function.

These six individuals pioneered the new medicine for the 21st century by establishing the scientific basis for recognizing that our genes generally do not determine our disease. The awareness that our environments are powerful agents influencing the genetic expression of both health and disease represents a major shift in medical thinking.⁴⁰ The utility of this model within the medi-

cal paradigm is no longer in question. It is just a question of how long it will take for this model to be fully integrated within the standard practice of medicine.

¹ A polymorphic gene is an alternate form of a *wild* gene present in >1% of the population. The most common polymorphic genes are single nucleotide polymorphisms (SNPs) that result in translational proteins and enzymes with decreased functionality. We all share at least 99.9% of the nucleotide code of our species’ genome. The SNPs are what make us unique within our species. The translation of our genome message that includes our SNPs results in our individual phenotype. [Burghes, et al. *Science*. 2001;293: 2213-14.]

Importance of Improving Management of Complex, Chronic Disease

David S. Jones, MD, and Sheila Quinn

The Larger Context

Despite the fact that non-genetic factors that are *modifiable*—including diet, overweight, inactivity, and environmental exposures such as smoking—account for 70–90% of mortality in the U.S.,¹ physician education, training, and reimbursement are most often focused on treating disease using drugs and surgery rather than comprehensive patient-centered treatments focused on the individual. For example, as reported in a study published in the *British Medical Journal*,² clinical questions in primary care can be categorized into a limited number of generic types and frequency. The four most common question types were:

1. What is the drug of choice for condition x?
2. What is the cause of symptom x?
3. What test is indicated in situation x?
4. What is the dose of drug x?

This shortsighted approach to health care should give us all cause for serious concern, because it is perpetuating a system that is far too costly and increasingly ineffective for the prevention and management of chronic diseases whose root causes are to be found in a much more complex perspective on patients' lives.

A Critical Problem

The gap between emerging research in basic sciences and integration of new knowledge into clinical

practice is often astonishingly large—particularly in the area of complex, chronic illness.³ This is one of the reasons that today's healthcare providers are not adequately trained to manage the increasing burden of complex, chronic disease.

The 20th century took on—and, to a great extent mastered—the challenges of providing health care for acute conditions (injury and life-threatening illness). Knowledge and technology grew apace, and so did costs; measures no one thought possible 100 years ago have become readily available. Organ transplants, re-attachment of severed limbs, life-support systems, new drugs, infection control procedures, laparoscopic explorations and surgeries—the list is extensive. But at the same time that our healthcare system was becoming dependent on advances in acute care, other influences were superseding acute conditions as the greatest threats to American health: increasingly stressful and sedentary lifestyles,^{4,5,6} industrial pollution⁷ of air, water, and earth⁸ leading to devitalized (and sometimes dangerous^{9,10,11}) food, overconsumption (rising rates of obesity) but undernutrition,¹² and fragmented family and community ties (social isolation^{13,14,15}). These influences have helped to create an overwhelming burden of chronic disease that we do not yet train our healthcare providers to treat or prevent effectively.¹⁶ Among other contributing factors:

- Disease prevention has too often been conceptualized as immunization and early diagnosis, an approach that is far too limited. Effective prevention

of chronic disease today requires understanding individual genetic vulnerabilities (20–30% of chronic disease risk) and the effect of lifestyle upon those individual variations (70–80% of the risk).

- Physicians highly trained primarily in conventional diagnosis and treatment (drugs, surgery, radiation) are not well qualified to apply prevention-focused interventions such as nutrition, diet, and exercise to help patients minimize their risk of suffering from one or more of the major chronic diseases in America (heart disease, diabetes, autoimmune disease, mental illness, and cancer).¹⁷
- In addition to prevention strategies, many complex, chronic diseases are very responsive to dietary and various lifestyle interventions.¹⁸ But clinicians without these skills are literally at the mercy of the pharmaceutical industry. “Doctors are taught about drugs by agents of the pharmaceutical industry, which works hard to persuade them to select the newest and most expensive medications—even in the absence of scientific evidence that they are any better than older, less costly ones.”¹⁹ Or, we would add, even in the presence of evidence that many non-drug interventions are therapeutically effective and significantly less expensive.^{20,21}

Increasing Economic Burden

The American healthcare system is predicated on a huge myth—that the more a society spends on health care, the better the health of its population will be. We justify having—*by far*—the costliest healthcare system in the world by deluding ourselves that we therefore also have the best health in the world. However, our romance with ever newer and more expensive drugs, technology, and surgeries has not achieved what we have been led to expect. Consider just a few of the many significant statistics available on this subject:

National health expenditures:

- increased 69% between 1990 and 2000, to a per capita cost of \$4,637, which is 68.5% higher than our closest competitor (Germany) and more than 2½ times as much as the UK;^{22,23}
- increased at a rate 4–5 times that of inflation in most years of that decade (a time of relatively low inflation in other industries);²⁴
- were disproportionately affected by the cost of prescription drugs, which were responsible for 21% of

the cost increases in Year 2000, while representing only 9% of total spending;²⁵ and

- are expected to rise to \$3.1 trillion over the next 10 years (from a level of \$1.4 trillion in 2001).²⁶

What does the American public get for this exorbitant price tag?

- A nation with 43.6 million uninsured in 2002²⁷ (while every other Westernized nation provides basic coverage to all its citizens).
- An excessively high serious medical error rate (highest among the U.S., Canada, the UK, Australia, and New Zealand), including (in 1994) 160,000 deaths from adverse drug reactions (ADRs).²⁸
- An unacceptable portion (45%) of Americans failing to receive “indicated care”²⁹ including, notably, preventive care.
- A healthcare system that is thought by many to be “in imminent danger of collapse.”³⁰

Add to this volatile mix the projection that one-third of the people born in the year 2000 will eventually have diabetes³¹—perhaps the most costly of the chronic diseases when all its comorbidities and secondary complications are considered³²—and we believe that no further evidence is necessary to justify a sea change in our approach to health care. There will be many ideas about the best changes to consider, but this textbook is being written, in part, to ensure that all those who are interested in the assessment, prevention, and treatment of chronic disease know what functional medicine has to offer.

There are, of course, other powerful societal drivers for the problems described above. Among them are the demand for fast and easy, high-fat, high-sugar foods; the demand for expensive testing (such as CAT scans or MRIs) and expensive drugs; and the increasingly sedentary nature of most jobs (tied to a desk) and personal lifestyles (centered around television and other passive entertainment experiences). It is important that all sectors share the responsibility for empowering healthful choices—the individual and his/her family, the workplace, the residential and civic communities, the marketplace, and the healthcare system. This book addresses needs that exist within the healthcare system, but does not in any way discount the vital influence of other elements of society. We do, however, call upon clinicians to let their voices and their work be stronger and more insistent in the call for prevention and health, rather

than concentrating their formidable knowledge, intelligence, and skills on after-the-fact interventions.

Functional Medicine and the Chronic Care Model

In the inaugural issue of the *Annals of Family Medicine*,³³ the lead editorial focused on the need for a new paradigm for the primary care disciplines. The present intellectual framework¹ taught in our medical education system fails to address the web-like interactions of multiple comorbidities for chronically ill patients. The power of organ-system medicine and the scientific research based on this model have brought us to the doorstep of the 21st century where, despite huge advances in disease detection, pharmacology, and surgical interventions, we are ill-equipped for the century's greatest challenge—an aging population with ever-increasing rates of (largely preventable, often reversible) chronic disease. The dominance of the existing heuristic (rule of thumb and experience) and reductionist model has fragmented medical care into specialty and sub-specialty care, which drives costs upward³⁴ and conflicts with the need for a comprehensive, integrated approach to chronically ill patients with multiple comorbidities.

In Grumbach's insightful editorial, *Chronic Illness, Comorbidities, and the Need for Medical Generalism*,³⁵ he opens: "It is said that when students enter medical school, they care about the whole person, and by the time they graduate, all they care about is the hole in the person. Current medical education inculcates many of the dominant values of modern medicine, reductionism, specialization, mechanistic models of disease and faith in a definitive cure." He suggests that the dominant paradigm now being taught is most applicable in the context of acute illness (e.g., trauma and infection). However, the dominant illnesses of the 21st century are and will be the chronic diseases (e.g., diabetes, heart disease, arthritis, and dementia, among others). In this context, the reductionist model fails to address (what he believes is) the most germane issue: "Cure is rarely possible, but improved functional status with amelioration of symptoms of pain and dysfunction and longer life (health span) through a thorough understanding of secondary prevention is possible." He goes on to describe the para-

digm shift in the intellectual matrix needed for integrated care for the chronically ill:

These studies demonstrate the futility of reductionistically carving up patients on the basis of individual conditions and sending them to the diabetes program on Monday, the cardiac program on Tuesday, the arthritis program on Wednesday, and the depression program on Thursday. What is needed is a model of care that addresses the whole person and integrates care for the person's entire constellation of comorbidities. This generalist approach does not deny the value of specialty care, which can offer expertise and unique services to the care of patients with chronic illness. But the generalist approach affirms a central role for the primary care clinician as the coordinator and integrator of specialty care and other referral services, working in partnership with the patient and other health care personnel to optimize overall physical functioning, mental health, and well-being.³⁶

IFM has been an innovator in this field for more than two decades. Functional medicine is not a unique and separate body of knowledge, but it does represent a different way of applying the scientific and clinical information that emerges from the research literature and from the clinical practices of many disciplines. Functional medicine emphasizes a definable and teachable *process* of integrating multiple knowledge bases within a pragmatic intellectual matrix that focuses on functionality at several levels as the key to health. Functional medicine uses the patient's story as an essential tool for integrating diagnosis, signs and symptoms, and evidence of clinical imbalances into a comprehensive approach to improve both the patient's environmental inputs and his or her physiological function. It is a clinician's discipline, and it directly addresses the need to transform the practice of primary care.

Functional medicine can substantially improve the existing Chronic Care Model,³⁷ which comprises six basic elements to foster productive interactions between patients and providers:

1. Patient self-management support;
2. Delivery system design (team-based delivery of care);
3. Decision support (consistent with scientific evidence and patient preferences);
4. Clinical information system (organizes individual patients and patient populations to receive appropriate levels of care);
5. Organizational support; and
6. Community support.

¹The intellectual framework and filter taught and then used by primary care practitioners will, from here on, be called the intellectual matrix.

The strength of the Chronic Care Model is the acknowledgment that optimal care relies on healthcare team building involving the top levels of the organization as well as the caregivers, and integrating support for patient self-management. However, what is missing and central to success in this effort is an intellectual matrix that can filter research and clinical evidence to achieve a coherent focus applicable to the *unique* set of signs and symptoms presented by the *individual* patient. No such matrix now exists outside of the functional medicine model. The Chronic Care Model is still grounded in the heuristic, organ-system based, reductionist thinking that is inadequate to the task.³⁸ As presently configured, that model will run into the same wall: chronic illness and multiple comorbidities are difficult to handle because the *fundamental, underlying clinical imbalances* have not been clearly delineated as the starting point for understanding chronic, complex illness. Even the coordination of resources as described in the Chronic Care Model will inevitably fall significantly short of the goal if the focus of this integrated collaboration is not properly identified. Functional medicine helps to identify the proper focus from a multidisciplinary, patient-centered model that all caregivers can learn and apply.

The Chronic Care Model appears to assume that the best we can do for a patient with chronic disease and comorbidities is to minimize the progression of the disease through the consistent and complete application of existing standards of care. There's no implicit or explicit anticipation of actually restoring health, and no recognition that unless we can restore health (to varying degrees in different patients), the huge impact of chronic disease on the healthcare system and the economy will be virtually unchecked. One might summarize the problem in this manner:

- if assessment and treatment are not fully integrated with prevention,
- if therapeutic interventions are not expanded to include a primary emphasis on diet, exercise, and lifestyle,
- and if health and disease are not perceived as existing on a continuum, along which the patient's placement can move towards health (even in the presence of significant chronic disease and comorbidities),
- then the emphasis is always going to be on palliative care, and the costs are always going to be excessive.

Functional medicine directly addresses the restoration of health, looking for common factors among various symptoms, diagnoses, and comorbidities that can be affected by intervening to improve function at the cellular level and the organ level. The functional medicine matrix takes into direct consideration the patient's lifestyle and diet, genetic predispositions, and core clinical imbalances, seeking a multifactorial and individualized approach that will reach beneath symptoms to restore function and generate momentum toward health. Too often the patient care process is seen as complete when a diagnosis is achieved and a drug is prescribed. In functional medicine, the diagnosis is the beginning of the journey, and the patient's past and continuing story is the central driver.

Our Aging Population and the Centrality of Diet, Lifestyle, and Environment David S. Jones, MD, and Sheila Quinn

Healthy Aging Matters

Researchers have estimated "the cost to our society resulting solely from the triad of coronary heart disease, diabetes, and obesity alone is nearly half a trillion dollars!"³⁹ Since most of the chronic disease burden occurs in the last decades of life, the importance of healthy aging can, therefore, hardly be overstated. However, it isn't an aging population, per se, that increases the economic burden on the healthcare system. It's an older population that has either more disease, or more years of life with disease, or both. Booth et al.⁴⁰ point out that "the advances made against modern chronic diseases over the past 30 years have come to a halt." Today in North America and most of the Westernized world, people are living longer, and, for many, those additional years are filled with the cost and effort of managing multiple chronic diseases. We have no idea whether or not there is an upper limit to life expectancy—all past predictions about such limits have been exceeded, in a steady, linear climb of about 2.5 years per decade for the past 150 years.⁴¹ So, we may as well assume that the upper boundary will continue to advance, which means we will be providing expensive, intensive healthcare services to a growing number of older citizens who will be living with more heart disease, more diabetes, and

more arthritis, cancer, and other complex chronic diseases for 30–40 years, rather than 10–20.

At least, that's what current projections indicate. There are many who believe, however, that a different goal is within our reach: "In the ideal case, the healthy citizens of a modern society will survive to an advanced age with their vigor and functional independence maintained, and morbidity and disability will be compressed into a relatively short period before death occurs" ⁴² There is research to support this hypothesis: "Not only do persons with better health habits survive longer, but in such persons, disability is postponed and compressed into fewer years at the end of life." ⁴³ And, even more to the point, successful aging is often the result of factors under at least some personal control: "our weight, our exercise, our education ... our abuse of cigarettes and alcohol ... our relationship with our spouse, and our coping styles can [all] be modified. A successful old age ... may lie not so much in our stars and genes as in ourselves." ⁴⁴

To be sure, there is much about the process of aging that we cannot yet understand or control. Aging is certainly associated with increasing incidence of disease and disability on a population-wide basis. However, research is making it increasingly clear that there are many behaviors (diet, exercise, stress reduction) ^{45,46,47,48} and treatments (antioxidants, essential fatty acids, minerals, certain amino acids, the B vitamins, and much more) ^{49,50,51} that can counteract the functional decline that leaves us vulnerable to disease and disability as we age. ⁵² Functional medicine helps to bring this knowledge into clinical practice, both for prevention and for treatment.

Centrality of Diet and Exercise in Prevention and Treatment

A healthcare system that is primarily dependent on the prescription pad for therapeutic success will inevitably be far more costly in the long run ⁵³ than one that brings lifestyle and environment to the fore. Diet, exercise, stress reduction, and active lifestyles are the most effective—and least costly—tools for lifelong disease prevention; there are numerous studies that validate this assertion, providing data on everything from pancreatic cancer ⁵⁴ to sarcopenia ⁵⁵ to very costly diseases such as heart disease and diabetes. ^{56,57} (We do not mean to discount the huge impact of broad societal influences such

as a strong economy, an educated and well-compensated workforce, and supportive communities, but discussion of those issues is beyond the scope of this book.) Research is emerging in a continuous and expanding stream to demonstrate the therapeutic effectiveness of lifestyle interventions for the treatment of many chronic diseases.

Using type 2 diabetes as an example can help us understand more clearly what's at stake. Consider the following facts:

- The incidence of diabetes is rising rapidly—it's a red flag bearing the message that something important has gone awry. ⁵⁸
- "100% of the increase in prevalence of type 2 diabetes and obesity in the U.S. during the latter half of the 20th century must be attributed to a changing environment interacting with genes, since 0% of the human genome has changed during this time period." ⁵⁹
- Diabetes is being diagnosed in ever younger patients—so we will be paying for their care for many, many more years if we don't act now. ^{60,61}
- It is a very costly disease. In 2002, the total cost of diabetes was \$132 billion/year—\$92 billion in direct medical costs and \$40 billion in disability, work loss, and premature mortality. ⁶² This is a 35% increase over the 1997 total. ⁶³ In just five years, we added \$34 billion/year to the healthcare budget from diabetes alone. (If this doesn't scare us, what will?)
- Diabetes has many genetic links and new information is emerging all the time about how those can be identified. ^{64,65,66} Clinicians will increasingly be paying attention to genes at risk through ethnicity and family history, thus bringing genomics (environment acting on genes) into play. ⁶⁷
- Diabetes increases the risk of many other chronic diseases, including various neurological conditions, ^{68,69} heart disease, ^{70,71} kidney disease, ^{72,73} stroke, ⁷⁴ and cancer. ^{75,76} Today's growth in the incidence of diabetes will lead directly to increases in many other diseases as the diabetic population ages.
- For most type 2 diabetics, the disease can be prevented, delayed, or reversed. ^{77,78}

It's hard to read this condensed set of facts about diabetes and not wonder, "What's gone wrong?" This is a (mostly) preventable disease, about which a great deal is known; it causes great human suffering if not prevented;

it costs us tens of billions of dollars each year; and it's now hitting our children. What is standing in the way of turning this around? It's certainly not a lack of information—even a quick search of the literature turns up hundreds of relevant research articles in every field from endocrinology to epidemiology to psychology.

At the risk of offering an oversimplified explanation, one reason seems intuitively obvious: We do not have a healthcare system, or healthcare practitioners, with the skills, time, and will to do what needs to be done. We have a healthcare system that forces practitioners to focus on seeing the most patients in a day, for the smallest investment of professional time and effort, with quick access to drugs (and highly vulnerable to pharmaceutical industry pressure and patient demands). This scenario cannot help but obscure the real answers to the problem.

Functional medicine offers a way to change this scenario. Practitioners can begin approaching patient care from a different perspective, with a broader set of tools, and with an empowered patient as ally and partner. Helping the doctor—and the patient—to fully understand the critical factors that affect functionality, aging, disease, and health over a lifetime will help create a more cost-effective healthcare system, and lead to longer health spans for our citizens.

Functional Medicine Incorporates Genomics Jeffrey S. Bland, PhD

Genomics—The Genetics-Environment Interface

April 25, 2003, represented the 50th anniversary of the publication describing the structure of DNA, in the journal *Nature*, by Watson and Crick.⁷⁹ That classic paper contained the prophetic comment, “It has not escaped our attention that the specific pairing (of the DNA bases) we have postulated immediately suggests a possible coping mechanism for the genetic material.” This paper (and companion papers that appeared in the same issue of *Nature* by Wilkins, Strokes, and Wilson, and by Franklin and Gosling) created a paradigm shift in medicine that has taken 50 years to be integrated into its curriculum. **The concept that disease mechanisms originate at the molecular biological level and are related to intricacies of interaction between the environment and genes and their expression her-**

alded a new age in medicine. The seeds that were planted then are only now coming into bloom.

Rabinowitz and Poljak commented in 2003 that we are seeing the emergence of a new primary-care model built on the molecular medicine discoveries of the last 50 years.⁸⁰ This primary-care model integrates the concept of host/environment interaction in framing a better understanding of the origin of disease and its potential treatment, individualized to the patient. Until very recently, we have tended to believe that diseases are “hard-wired” into our genes as a consequence of genetic uniqueness. This belief has caused us to forget or overlook the important variable of environment and its role in modulating the expression of genes. As these authors point out:

These (molecular genetic) developments, however, raise the concern that both physicians and patients could fall into a trap of biological determinism, believing that one's genetic and metabolic makeup far outweighs the role of environmental factors in disease. Such thinking fails to acknowledge that most health outcomes are the result of interactions between host factors and environmental factors.⁸¹

Although the human genome contains only between 30,000 and 35,000 genes, millions of variations of these genes, called single nucleotide polymorphisms (SNPs), exist within the gene pool. These polymorphisms occur as variations in which the least common allele is present in at least 1% or more of the population. Researchers have found that when these SNPs are present in a gene it means a person has two different genes coding for the same function. Only recently have we understood that many of these SNPs lead to differences in the phenotype of an individual, and that how these differences may be expressed depends upon environmental factors.

One major environmental factor that modifies gene expression is the individual's nutritional status. Both macro- and micronutrients can influence the expression of genes, the translation of the genetic message into active protein, and that protein's ultimate influence in controlling metabolic function.^{82,83,84,85,86}

The effective integration of these concepts into the educational model so that patient assessment and treatment can be personalized to the patient's own genetic uniqueness represents a great challenge for modern medicine. It has been postulated that medical nutrition education is very near a “tipping point” that will herald rapid changes in the existing system vis-à-vis these exciting concepts.⁸⁷ Functional medicine has been addressing

these issues and training clinicians to understand and use the concepts for many years.

(According to Gladwell, the tipping point is the moment when an idea, trend, or social behavior crosses a threshold, “tips,” and spreads like wildfire.⁸⁸ Broad examples from medicine include the discovery of the polio vaccine, the identification of insulin as a treatment for type 1 diabetes, the 1964 Surgeon General’s Report on the health effects of cigarette smoking, and the McGovern Committee and the 1979 Surgeon General’s Report on Health Promotion and Disease Prevention. Another tipping point may be the changes stemming from the Human Genome Project that are leading to a new definition of medical nutrition education.)

As evidence that we are near the tipping point in medical education, Tel Aviv University recently incorporated into its medical curriculum a course titled “Introduction to Pharmacogenomics: Towards Personalized Medicine.”⁸⁹ As investigators learn how different individuals metabolize substances based on their genetic uniqueness, we learn more about the important roles specific nutrients play in modifying the expression of metabolic patterns in the individual. Diet, lifestyle, and environment have significant influence on the way an individual can metabolize specific substances based upon his or her genetic uniqueness. We are seeing the first applications of genomic medicine in the area of pharmacogenomics. Pharmacogenomics is defined as the unique metabolism of various substances based on an individual’s genetic uniqueness. A great deal of research is being done to study individual variations in reactions to drugs and that body of research will contribute enormously to our understanding of personalized medicine.

Nutrigenomics

Linus Pauling was a pioneer in alerting physicians to the importance of nutrients in modulating physiological processes at the biomolecular level and ultimately giving rise to the phenotype of health or disease. The interface between genomics and nutrition is now defined as the field of “nutrigenomics.” As Kozma observed:

Information from the Human Genome Project will dramatically change health care for the dietetic and nutrition discipline. Approaches to risk assessment including obtaining family history, diagnosis, prevention, early intervention, and management of nutritional issues will evolve through the application of nutritional genomics. Dietetic and nutrition specialists

will increasingly require knowledge of genomics, gene-environment interactions, the expanding role of pharmacogenomics in drug and food therapies, and genetic applications to clinical practice.⁹⁰

The development of nutrigenomic concepts will assist clinicians in understanding the varied responses of different patients to specific nutritional therapies. An example is the wide inter-individual variation in blood lipid and lipoprotein responses to dietary change.⁹¹ A diet that is low in fat and high in unrefined complex carbohydrate may in one individual be effective in lowering total blood lipids. In another individual with a different genotype, however, the same diet may actually increase specific members of the lipid and lipoprotein families. Similarly, some individuals, when placed on a higher-protein, low-carbohydrate diet, may have reductions in their blood lipid profiles, while others may have elevations of blood lipids on the same diet.

Fogg-Johnson and Kaput provide a good restatement for us to consider:

Effects of the Human Genome Project are surfacing in anticipated and unanticipated areas. One of the key discoveries from the project is the existence of individual differences in gene sequences that result in differential response to environmental factors, such as diet. Those genetic differences, single nucleotide polymorphisms (SNPs, pronounced snips), are the key genetic enabler of the emerging scientific discipline called nutrigenomics or nutritional genomics. ... The science of nutrigenomics is the study of how naturally occurring chemicals in foods alter molecular expression of genetic information in each individual.⁹²

Since approximately 1990, nutrition research has undergone a gradual shift in focus from epidemiology and physiology to molecular biology and genetics. This shift has resulted in a growing realization that we cannot understand the effects of nutrition on health and disease without determining how nutrients act at the molecular level. Müller and Kersten note: “There has been a growing recognition that both macronutrients and micronutrients can be potent dietary signals that influence the metabolic programming of cells and have an important role in the control of homeostasis.”⁹³

In every respect, the transition occurring within medical nutrition is epic in its impact and scope. Nutrition-focused practitioners are at a pivotal point in the history of their practice. Kauwell’s observations are particularly pertinent: “Armed with the findings of the Human Genome Project and related research, dietetics practitioners will have the potential to implement more

efficient and effective nutrition intervention strategies aimed at preventing and delaying the progression of common chronic diseases.”⁹⁴

Genomics and Proteomics: Importance for the Future of Nutrition Intervention

A central feature of this paradigm shift in medical nutrition is the recognition that not all genes within the human genome are expressed in every cell simultaneously. Instead, the expression is selective to the cell type and cell environment. The study of the synchronous activation of families of genes to yield various proteins that ultimately regulate metabolic function is called “proteomics.”

A large body of information exists about the number of genes, chromosomal localization, gene structure, and gene function. Scientists are only now beginning to understand the orchestrated way the proteins expressed from these genes control metabolism.⁹⁵ For example, researchers have found that in some cells only 50% (approximately) of the genes transcribed to form the specific messenger RNA (mRNA) are translated into active proteins. The action point in the control of cellular physiology is therefore the combination of genetic transcription (expression), active protein formation, and control of metabolism that has been termed the “phenome.”

The phenotype of the cell is a complex process or system of interacting events related to genetic expression, protein synthesis, protein activation, and metabolic regulation. By evaluating genetic expression through the production of specific mRNAs, the synthesis of specific proteins from those mRNAs, and ultimately the effect of those proteins on metabolic function, we can establish biomarkers of health and disease. From this understanding, we can evaluate the role of specific nutrients on this process in the individual patient. Although this may at first seem to be a daunting task, new screening technologies and powerful systems of bioinformation analysis are emerging to hasten the day when such interventions are a real option in clinical care.

Toward a Systems Biology Approach

As we write in 2005, the systems biology approachⁱⁱ for analyzing individual effects of nutrients on function is not yet available, but a number of clearly identified relationships that connect specific SNPs, nutrient sensitivity, and disease risk are now understood. Petricoin and Liotta predicted in 2003 that clinical applications of proteomics, which involve the use of molecular genetic technologies at the bedside, will result in patient-tailored therapies.⁹⁶

Work at the Institute for Systems Biology in Seattle, Washington, has demonstrated the success of an integrated system for understanding cellular physiology based on the interaction of genomic expression, proteomics influences, and their role in controlling metabolism.⁹⁷ Although this work is in its early stages, the “proof of concept” that a systems biology approach can be used for evaluating the impact of genetic expression, proteomic activity, and their roles in controlling metabolism, supports an optimistic perspective for the future of personalized and functional medicine.

Upstream vs. Downstream Medicine

In the last few decades, much medical research has focused primarily on discovering specific molecules that inhibit enzyme function “downstream” in a complex physiological process. The search for molecules with the selective ability to inhibit specific enzyme-mediated steps, such as angiotensin-converting enzyme inhibitors (ACE inhibitors), selective serotonin reuptake inhibitors (SSRIs), H2 blockers, and selective cyclooxygenase-2 inhibitors (COX-2 inhibitors), has succeeded in fueling the growth of the multibillion-dollar pharmaceutical industry (not without serious consequences for some patients with some of these drugs).

Genomic and proteomic research has begun to demonstrate, however, that rather than blocking specific enzymes downstream in a complex biological system associated with a specific disease, it can be even more effective to develop new approaches that would selectively regulate the expression of various alarm molecules upstream in the metabolic process that are associated with the disease. The emphasis of such research is to identify tissue-selective “upstream” modulators of

ⁱⁱ Systems biology seeks to explain complex biological systems, such as the cell, through the integration of many different types of information.

genomic and proteomic expression. The objective is to identify ways to normalize the functional changes associated with early disease risk without adversely affecting other tissues engaged in similar metabolic processes.

The Rise of Personalized Medicine

This revolutionary shift in thinking suggests that substances consumed in the diets of various cultures for thousands of years may have profound influence on gene expression and proteomic outcome. It may also help explain the epidemiological observations that certain diets are associated with reduced disease risk. As Willett pointed out, the integration of extensive epidemiological research with the discoveries being made in nutrigenomics will give rise to a new personalized medicine using diet, lifestyle, and environment as principal tools in both prevention and treatment of specific chronic diseases.⁹⁸ Burke wrote, "Evidence is now emerging of the complex interactions between genes and the environment in the causation of many diseases, and the study of the interactions represents the next important step in genomic research. Efforts to understand the molecular mechanisms that underlie complex diseases will build on insights and strategies developed in the study of single-gene diseases."⁹⁹

From these concepts, new clinical tools and programs are emerging to help apply medical nutrition in ways that will make it more effective in improving patient outcomes, and that approach is a key component of the functional medicine model, and thus an urgently needed element in modern clinical care.

Chapter 4

Training Clinicians in New Approaches to Care

Sheila Quinn and David S. Jones, MD

Functional Medicine: A Model of Integrated Care to Address Systemic Health Issues

Functional Medicine Can Be Taught

Functional medicine synthesizes and applies scientific evidence from the biomedical research literature in fields such as biochemistry, physiology, immunology, and nutrition. Unlike alternative medical disciplines (such as acupuncture or chiropractic or naturopathic medicine), it does not require that conventional providers master different languages/tools of health care, nor does it require that alternative providers give up the tenets of their respective disciplines. It can be taught to, and used by, all healthcare providers with a background in the basic medical and clinical sciences, regardless of the particular profession a practitioner belongs to (within the limits of specific training and licensure, of course). This makes functional medicine uniquely suited to multidisciplinary, integrated clinical settings, as well as to use by individual practitioners.

This textbook is organized around the information and approach that IFM uses to teach clinicians, and exemplifies the kind of clinical thinking and patient management that characterize many functional medicine practitioners:

- A thorough understanding of the core context and concepts of functional medicine (*Principles Section*) helps to distinguish the functional medicine approach.
- Teaching functional medicine often requires refreshing and expanding the clinician's knowledge of biochemistry and physiology (*Fundamental Physiological Processes Section*).
- A strong appreciation for the importance of environmental inputs (*Building Blocks Section*) is vital to

an understanding of functional medicine, for we are equally concerned with whether the raw materials of health (or disease), including genetic predispositions, are present in the patient's life.

- An emphasis is placed on learning to assess and improve underlying functional imbalances in six core areas that comprise the “engines” that drive the patient toward health or disease (*Fundamental Clinical Imbalances Section*).
- The more didactic information presented in the first five sections is brought into context for the provider in *A Practical Clinical Approach*. Here the functional medicine matrix—a tool for simplifying the complex science into a manageable clinical approach—is the underlying structure. This section demonstrates how to obtain, sort, and qualify the different kinds of patient information so as to generate a strong indicator to the clinician of the most useful way to “pull on the web” of interconnecting issues presented by the patient.
- Finally, the last section, *Putting it All Together*, helps clinicians understand some of the most important patient care issues that are commonly experienced in functional medicine.

Thus, functional medicine can be taught to any clinician who has an open mind and an eagerness to twist the kaleidoscope and look at patient care from new angles. It is a matter of acquiring, analyzing, classifying, and prioritizing information in different ways, and then applying therapeutic (or preventive) measures that are aimed at correcting the imbalances that underlie organ-system disease. If the clinician doesn't address the underlying imbalances—and understand how they arise and how they can be ameliorated—it is much less likely that restoration of health will be the ultimate

outcome. Functional medicine approaches patient care with the confidence that restoring and maintaining health are achievable goals.

Functional Medicine is Discipline-Neutral

Functional medicine is discipline-neutral—the field is accessible to any health practitioner who has a fairly standard Western medical science background. There are significant advantages to this “neutrality,” particularly as the nation’s healthcare system becomes more and more open and adaptive to integrated care concepts:

- Patients with chronic disease often use multiple care-givers from a variety of fields. It is extremely valuable to the patient (and to the efficient delivery of care) when those practitioners have a common “language” for discussing patient health. Functional medicine creates a unifying mind-set and information architecture about health and disease, regardless of widely varied clinician training and skills.
- Although the science underlying functional medicine is complex, the application of therapeutic and prevention-oriented approaches is often relatively straightforward; patients can understand it and so can practitioners from many different backgrounds. Functional medicine creates a more level playing field between and among patients and providers.
- We have had a very hierarchical healthcare system for many years in the United States; as a result, turf battles between professions are common and patients often get caught in the crossfire. With the cross-disciplinary nature of functional medicine, those problems can be minimized or eliminated.

Functional medicine is firmly grounded in scientific principles and data but adopts a flexible, eclectic perspective on medicine. The use of dietary interventions, clinical nutrition, exercise therapy, mind-body-spirit issues, botanical medicines, physical medicine, and even energy medicine (e.g., acupuncture) can all be integrated into functional medicine teaching and practice when the science warrants it. The use of drugs and/or surgery does not disappear, but lifestyle interventions assume a certain primacy (where appropriate)—both because of their lower cost and because of their long-term role in restoration of health and prevention of disease (or complications of disease).

Conventional providers and alternative providers alike are able to integrate functional medicine thinking into their existing knowledge base because underneath the superstructures created by the many professions, an abiding interest in “functionality”—how things work and what to do when they don’t—is a shared terrain. Some learners may not have a strong science background, and may thus need to intensify their knowledge of biochemistry and physiology, but some with a strong science education may have to learn clinical nutrition and to appreciate the contributions of (for example) botanicals and chiropractic.

In these diverse ways, functional medicine helps create a bridge between conventional and alternative practitioners and approaches—a place where there is mutuality of ideas and interests, and where the patient’s needs can come first. This common meeting ground will enhance the delivery of integrated care and contribute to the development of respectful and productive professional relationships among healthcare providers.

Focused Training is Needed to Change the Existing Model of Care

The postgraduate healthcare education industry encompasses many different methods of delivering information to clinicians: textbooks, journal articles, and professional conferences are among the most common. The sizable investment made in these activities year after year ought to create a significant obligation to demonstrate that they substantially improve the care that patients receive. Unfortunately, emerging research is demonstrating quite convincingly that the changes created by conventional continuing medical education or CME (journal articles and conferences) are much less significant than most practitioners realize. Consider just a few selected quotations:

- “lecture results in only the lowest level of behavioral change.”¹
- “the best predictor of knowledge of blood pressure treatment [for example] is a physician’s year of graduation from medical school.”²
- “Unfortunately, most of the clinical questions generated at the point of care go unanswered.”³
- “traditional medical care delivery methods are failing to adapt by responding too slowly to rapidly changing new medical evidence.”⁴

- “[M]any of the implications from research, although black and white to the researcher, are not immediately compelling to the practitioner”⁵
- “Uneven uptake of research findings—and thus inappropriate care—occurs across different health care settings, countries and specialties”⁶
- “Didactic sessions do not appear to be effective in changing physician performance.”⁷

And, very significantly:

- “In addition to being disconnected temporally and spatially from the actual delivery of care, CME has too often failed to deliver the most important and useful information to clinicians: patient-oriented evidence on common or important problems that has the potential to change practice.”⁸

This disconnection from “evidence that matters” is of great concern to IFM and to functional medicine leaders and practitioners. We spend a lot of time and effort—unsupported by the deep pockets of the pharmaceutical industry or the organizational backing of medical schools, societies, or hospitals—developing courses and symposia that deliver information. We work diligently to ensure the clinical relevance of that information and to focus on the problems that cost the healthcare system the most in dollars and cost patients the most long-term distress—complex, chronic disease. But if this is not the most effective way to deliver “patient-oriented evidence that matters” (POEMs) then we want to change it.

Meeting that challenge head-on has brought us to this book. While information alone may not change clinician behavior very significantly, high quality information is an absolutely essential ingredient in the mix—necessary, but not sufficient. Developing a comprehensive textbook—where the evidence base is clearly demonstrated and the clinical connections to that evidence are made clear—seems an important step. Delivering this comprehensive information base so that clinicians can learn at their own pace, in their own homes and offices, and in response to clinical questions that arise at the point of care, may enable us to increase our effectiveness and—a prime consideration—perhaps redirect the focus of our onsite courses to more interactive, clinically specific education.

We hope that the book’s users will take on a personal “commitment to change.” There is evidence to show that “physicians who expressed a commitment to change were significantly more likely to change”⁹ their

actual behavior. We offer help with understanding how to change in Chapter 36—it may be structured as “helping patients to change unhealthy behaviors,” but it is just as useful in making any kind of personal change, in one’s life or one’s practice.

We think of you—the current and future functional medicine practitioners—as our partners in developing the information base and improving the effectiveness of the training. Please stay in communication with us about what really does—and does not—make a difference in the way you actually practice and how your patients have fared.

Mentoring and Follow-Up Are Needed in Addition to CME

If it can be established, as we believe and have expounded on at some length in earlier in this section, that certain changes are urgently needed in our current healthcare system, particularly for complex chronic disease, then the question immediately arises, “If information alone is insufficient, how can such change be achieved?” There are several important pathways to address:

1. **Change the way physicians and other practitioners are taught.** As noted above, we do know that how a physician is taught is often an extremely powerful predictor of how he/she will practice. A lot of CME effort is devoted to trying to change and update what was learned in medical school. New practitioners should be emerging from their training already prepared to practice effective, integrated care in multidisciplinary settings. The *Textbook of Functional Medicine* can contribute by providing a broader view of the underlying mechanisms of health (and disease prevention), by linking the basic sciences and the research literature with effective clinical approaches, and by strengthening the priority that is placed upon understanding the key influences on gene expression.
2. **Find ways to make continuing medical education more effective.** While the research on effectiveness of CME is not voluminous, it does present a rather alarming assessment of CME effectiveness in changing physician behavior (see above). The picture goes something like this: didactic presentations may improve knowledge but are unlikely to change behavior;¹⁰ single interventions on a particular subject are much less likely to change behavior

than multiple, varied interventions (rare);¹¹ complex changes are more difficult than simple ones;¹² information that is not relevant to questions that arise at the point of care is unlikely to change behavior;¹³ even CME that changes physician behaviors with some efficacy may not change patient outcomes;¹⁴ practitioners may find change difficult if the system within which they practice is not proactive and responsive;¹⁵ and yet physicians still like CME.¹⁶ They attend it with great regularity and frequency, rely on it for their continued learning, and are often quite willing to make a commitment—in the moment of learning—to change.¹⁷

How can this massive, nationwide (costly) effort to bring good continuing education to the fore, and to use information as an effective change agent, be enhanced? There are certainly many more questions than answers on this vital topic, but two findings that have emerged with some consistency are these: mentoring is an important element and follow-up is critical. Practitioners need continuing contact with skilled and respected colleagues who can give feedback on new information and ideas, and whose collaboration can be sought about key clinical questions that directly affect patients.¹⁸

IFM provides you—the reader of this book—and other interested practitioners considerable support for the effective integration of functional medicine into practice through its vibrant, interactive online community (www.functionalmedicine.org). On the fully searchable IFM Member Forum (information about membership is available at <http://www.functionalmedicine.org/membercommunity/becomemember.asp>), you can participate in a variety of ways:

- **Engage with the experts** who post as Forum Hosts on “Topic of the Week.” Cases are presented, emerging evidence is discussed, and stimulating questions are posed. Some discussions involve dozens of respondents and are highly interactive. Forum Hosts are a valuable resource for all functional medicine practitioners, even experienced ones.
- **Post a question or issue of your own.** Is a particular patient troubling you, or are there conditions or approaches you want clinical guidance on? Any member can initiate a post (although you may want to search the Forum first to see whether the topic has been explored before). You are likely to receive very thoughtful and generous responses from your colleagues. Over time, you will get to know these professionals, and you can begin independent dialogues by emailing directly to those whose expertise is most helpful to you.
- **Review the regular “Article of the Week”** postings by the Forum Consultant, who will also chime in on Forum Host or member postings by offering links to key research or relevant articles.
- **Speak up about functional medicine.** Share your education and clinical experiences with colleagues and patients. If you are an experienced functional medicine practitioner, offer to mentor a colleague who is new to the field. Recommend this book to your local hospital library, or buy an extra copy and donate it to the school where you received your professional training. In other words, expand the functional medicine community through your own efforts. The opinion of a respected colleague can be very influential.

- *Clinical Decision Making—A Functional Medicine Perspective*

Functional Medicine and the Emerging Research Base

David S. Jones, MD

Understanding the Limitations of the Randomized Controlled Trial (RCT)

The scientific method disciplines the creative process of human inquiry. In the applied biological sciences (e.g., clinical medicine) prior to World War II, evaluation of emerging therapeutics was mainly the purview of recognized leaders in the medical profession, based primarily on their clinical impressions, without the touchstone of any systematic controls.¹ To temper the quality of evidence and render a “truer” judgment with less personal bias, elite postwar researchers developed the randomized controlled trial (RCT) protocol. The major characteristics of this method include blinded assessment (of subjects, investigators, or both) in the presence of a placebo control, random assignment to comparable groups, and inferential statistics as a surrogate for establishing causation.²

This methodology (RCT) found its most ardent advocates in the sphere of pharmacological therapeutic interventions, specifically drug studies (using, most often, single agents). With development of powerful pharmaceuticals, the imperative for a scientifically rigorous methodology for asking systematic questions about efficacy, benefits, risks, and causation has proved ever more important (*cf.* the thalidomide tragedy of the late 1950s and the early 1960s³ and the unpredicted results of the more recent HERS RCT research vis-à-vis female hormone replacement therapy⁴). In the ensuing 60 years, the advocates for the RCT model have worked

assiduously to understand RCT study designs, including identification of pitfalls and types of bias.^{5,6,7,8,9}

The proponents of the RCT as the gold standard for unbiased research results have moved forward in the applied medical fields, both in primary and specialty care. They have developed systems for grading recommendations based on a “research quality scale” that ranks methodologies in descending order of accepted best evidence:^{10,11}

- Systematic reviews and meta-analyses of RCTs
- RCTs
- Non-randomized intervention studies
- Non-experimental studies
- Expert opinion

The very influential schema called *evidence-based medicine* (EBM) has emerged using these hierarchical assumptions as foundational suppositions:

A new paradigm for medical practice is emerging. Evidence-based medicine de-emphasizes intuition, unsystematic clinical experience, and pathophysiologic rationale as sufficient grounds for clinical decision making and stresses the examination of evidence from clinical research. Evidence-based medicine requires new skills of the physician including efficient literature searching and the application of formal rules of evidence evaluating the clinical literature.¹²

Evidence-based practice requires the integration, patient by patient, of the physician’s clinical expertise and judgment with the best available relevant external evidence. Sackett in 1996 described EBM in this way: “Evidence based medicine is the conscientious, explicit,

Section I

Introduction

and judicious use of current best evidence in making decisions about the care of individual patients. The practice of evidence based medicine means integrating individual clinical expertise with the best available external clinical evidence from systematic research. ... Good doctors use both individual clinical expertise and the best available external evidence and neither alone is enough."¹³ The process of evidence-based medicine is summarized below.^{14,15}

- Select specific clinical questions from the patient's problem(s).
- Search the literature or databases for relevant clinical information.
- Appraise the evidence for validity and usefulness to the patient and practice.
- Implement useful findings in everyday practice.

As discussed in several of the aforementioned papers, the combining of these elements can be viewed as a Venn diagram (Figure 5.1), where the best outcomes occur when all three elements are represented.

Figure 5.1 Optimal outcomes: Applying evidence-based medicine to the real world

Arguments in favor of evidence-based medicine include the following:^{16,17}

- Increasingly available new evidence can and should lead to major changes in patient care.

- Practicing physicians often fail to obtain available relevant evidence.
- Medical knowledge and clinical performance deteriorate over time without the leavening of newer evidence influencing clinical decisions.
- Traditional continuing medical education (CME) is inefficient and generally does not improve clinical performance without a disciplined methodology of inclusion of new evidence into clinical practice.
- The discipline of evidence-based medicine can keep the physician up-to-date.

The clinical application of basic research has been slowed by two major issues. The *first problem* that has impeded the successful application of EBM to the daily specifics of patient care is the complex nature of the translation of research studies to the individual patient's unique clinical problem(s)—what Larry Weed called knowledge coupling.^{18,19,20} John Hampton, Professor of Cardiology, University Hospital, Nottingham, England, in a review titled "Evidence-based Medicine, Opinion-based Medicine, and Real-world Medicine," reasons: "Clinical trials will tell us what treatments are effective, but not necessarily which patients should receive them Treatment must always be tailored to the individual patient."²¹ Added to this methodologic conundrum are the real-world exigencies of daily clinical practice that make it virtually impossible to collate and filter all relevant evidence prior to direct application to the unique needs of the patient. Imagine a clinic where, after each therapeutic encounter—thorough history taking accompanied by a complete physical exam—a problem list is developed that is then carefully subjected to a medical literature search and analysis. The practice of clinical medicine will not tolerate the inertia of such a process.²² These practicalities of real-time clinical practice have slowed the integration of new research into the clinical care of patients who are often in desperate need of interventions based on emerging evidence.

To assist the practicing physician's effective inclusion of new evidence into daily practice, both government-sponsored and commercially affiliated organizations have moved EBM forward with a collation of filtered studies called *Patient-Oriented Evidence that Matters* (POEMs).²³ It is now possible to search these specific databases, or self-developed relevant databases that review groups of studies that directly link research findings with specific clinical problems. The development of

robust and thorough databases of POEMs is an ongoing commitment of institutions throughout the industrialized world.^{24,25}

A *second major issue* has proved to be a Gordian knot that has not yet been unraveled. If medical care were as simple as identifying the clinical problem followed by the prescription of an appropriate single pharmacologic agent, then the EBM system, as presently configured and applied, would work if appropriate POEMs were available for each medical problem. However, the dream and heritage from half a century of medicalization of the daily health problems of our patients have *not* proved remedial to the widely accepted notion of “better living through chemistry.”²⁶ (Most POEMs and most studies in the Cochrane Collection are research trials of pharmacologic therapeutic interventions.) In fact, acute medical problems are the only medical problems that appear to predictably respond as envisioned by the conventional medical paradigm. However, greater than 70% of health problems presenting to clinicians today are chronic, complex medical issues²⁷ for which the underlying assumptions of the RCT and medical education based on this assumption simply fail to provide satisfactory answers.

Halsted Holman, MD, of Stanford Medical School, editorialized in *JAMA* in 2004: “Chronic disease is now the principal cause of disability and use of health services and consumes 78% of health expenditures.”²⁸ Within this population with chronic, complex illness, non-genetic factors that are *modifiable* by lifestyle changes—including diet, overweight, inactivity and environmental exposures such as smoking—account for 70–90% of mortality in the U.S.²⁹ Add to this the projection from the Centers for Disease Control and Prevention (CDC) that one-third of the people born in the year 2000 will eventually have diabetes,³⁰ which is probably the most costly of the chronic diseases when all of its comorbidities and secondary complications are considered.³¹ With similar disturbing statistics in hand, Holman goes on to point out that, “Chronic disease requires a practice of medicine quite different from that used for acute disease ... Unfortunately, few if any schools are preparing their students adequately for the roles they and their patients need to play.”

Despite these sobering facts, physician education, training, and reimbursement, as well as research designs for clinical studies that physicians will depend upon for clinical decision making, continue to be

focused on treating chronic disease using drugs and surgery rather than comprehensive patient-centered treatments focused on the individual. It becomes easier to see that the *second major issue* impeding the application of emerging research is the absence of an adequate filtering system (evidence design) and application architecture (or information matrix) for the focus of 21st century medical needs: complex, chronic illness. Funding of research continues to be primarily focused on pharmacologic answers to these complex, chronic problems, leaving discerning clinicians without the EBM tools and information for addressing their patients’ complex needs.

In a cogent paper in *The Lancet* (van Weel and Knottnerus, 1999),³² the difficulties of using evidence in the context of the individual patient with complex, chronic illness are discussed and specific obstacles are identified:

- EBM tends to concentrate on research methodology and reduce clinical practice to the technical implementation of research findings.
- Comorbid conditions are the usual justified reason for the exclusion of patients from RCTs, so the very patients most in need of usable evidence (e.g., those with complex, chronic conditions) are often not in the cohorts of patients being studied, leaving the findings from the research trials very limited in their applicability.
- In general practice, treatment usually consists of various elementary interventions. Combinations of evidence-based interventions do not sum to a plan that is evidence-based. Interactions between single interventions may increase or decrease their efficacy (even under ideal trial conditions) when cobbled together into a comprehensive plan.
- Clinical research does not focus on the overall outcome of composite interventions because of the complexity of such studies and the absence of well-developed tools for studying such approaches.
- Drug interventions have been studied more extensively than non-pharmacological interventions, in part due to the technical and methodological difficulties in the design of RCTs for non-drug interventions.
- This situation is a particular problem in general practice, where the use of educational, dietary, and lifestyle interventions is attractive because of their resonance with the principle of “maximum effect using minimum resources.”

- The structure of RCT methodology assumes the consequences of individual variability in response to treatment will “wash out” if the subject pool is large enough and the statistical analyses sophisticated enough. While this may be true for populations, it seriously limits the applicability of the research in primary care, which is delivered one patient at a time.

According to van Weel and Knottnerus, the driving force behind EBM should be a coherent system of fundamental research of pathophysiology *and* humanities, combined with careful clinical observations, on which systematic (RCT-based) evidence of effectiveness is superimposed. Existing clinical practice should be supported or, if erroneous, corrected on the basis of this coherent system.

They go on to propose that “two complementary approaches are needed to strengthen the evidence base of non-pharmacological interventions and complex multifaceted strategies. First, the generic characteristics of complex interventions must be acknowledged as essential for its evaluation. Second, a methodology to allow the assessment of complex effects should be further developed.”³³ They share the concern that EBM has de-evolved into primarily a discussion of “research methodology and [has] reduce[d] clinical practice to the technical implementation of research findings.”

Dr. David Mant in his seminal paper, “Can Randomized Trials Inform Clinical Decisions about Individual Patients?” takes a slightly different tack in exploring the irony that the RCT combines strength of concept for the population being studied with weakness of specific application to the individual patient:³⁴

The paradox of the clinical trial is that it is the best way to assess whether an intervention works, but is arguably the worst way to assess who will benefit from it. ... However, the nub of the argument for me is that randomized controlled trials are primarily about medical interventions and not patients. In clinical trials, patients are randomized to allow a comparison of intervention efficacy unbiased by the individuality of the patient. This methodological approach provides society with powerful protection against witch-doctoring, and helps us eliminate the inefficiencies in the provision of medical care described by Cochrane. But the methodological minimization of information on effectiveness in relation to the individual patient leaves an evidence gap for clinicians.

Dr. Alan Feinstein, from the Department of Medicine, Yale University, in his article, “Problems in the

‘Evidence’ of ‘Evidence-based Medicine,’” echoes similar reservations.³⁵ Larry Culpepper and Thomas Gilbert, in their *Lancet* commentary, “Evidence and Ethics,” focus this same reservation in the primary care arena of patient care.³⁶ In summation, the reductionist simplicity of the double-blind, placebo-controlled trial frequently does not work for the significant questions now facing 21st century primary care practitioners in the one-on-one decision making characteristic of clinical medicine. The statistical and mathematical sophistication needed for multi-variable analysis of the clinical context of patients with complex, chronic illness, in the interface between the patient’s unique environmental context and genomic card catalog of possibilities, simply does not now exist. We are in the transitional stage of realizing that our tools of evidence are inadequate to the challenge posed by emerging evidence from our scientific community that demonstrates that the world works through complex mechanisms operating simultaneously. These complex questions cannot be reduced to the relatively simple single-agent, single-condition research for which the RCT methodology is so well suited.^{37,38,39}

We cannot continue to ignore where the truly significant questions reside, regardless of the difficulty and elusiveness of the answers needed to address the problems inherent in chronic, complex diseases. The RCT tool was developed during a specific period in our medical history and worked well to adjudicate between the traditionalists who claimed that clinical experience trumped bench science and the scientists who perceived the value in systematic inquiry. Major strides in treatment have occurred in the intervening 50 to 60 years as a result of the shift in opinion toward the use of RCT methodology. But we are now at another nodal decision point, unique to our cultural and medical evolution. We need a more sophisticated tool to shed light on the nature of the web-like interweaving of mechanisms at work in the chronic, complex illnesses under scrutiny.^{40,41}

Complex Conditions, Complex Models

The emerging research on underlying mechanisms of dysfunctional processes that lead to diagnosable disease has outpaced the ability of existing clinical research methods to keep up with useful evaluation of the information. The complexity of the developing “explanatory models” has been serially addressed in the *Annals of Fam-*

ily *Medicine*, a peer-reviewed medical journal “dedicated to advancing knowledge essential to understanding and improving health and primary care,” including the development of methodology and theory for addressing this conundrum.⁴² In the article, “The Biopsychosocial Model 25 Years Later: Principles, Practice, and Scientific Inquiry,”⁴³ the authors critique the limitations of the conventional biomedical model and the research methodologies that evolve from this model, and preview the evolving model of “complexity and causality” and the nested model of “structural causality”:

Few morbid conditions could be interpreted as being of the nature “one microbe, one illness”; rather, there are usually multiple interacting causes and contributing factors. Thus, obesity leads to both diabetes and arthritis; both obesity and arthritis limit exercise capacity, adversely affecting blood pressure and cholesterol levels; and all of the above, except perhaps arthritis, contribute to both stroke and coronary artery disease. Some effects (depression after a heart attack or stroke) can then become causal (greater likelihood of a second similar event). ... These observations set the stage for models of circular causality that describe how a series of feedback loops sustain a specific pattern of behavior over time.^{44,45,46} Complexity science is an attempt to understand these complex recursive and emergent properties of systems^{47,48} and to find interrelated proximal causes that might be changed with the right set of interventions.⁴⁹

David Deutsch, in *The Fabric of Reality*, describes the need for a next step in using the science of underlying mechanisms of disease in the clinical setting of medicine:

The science of medicine is perhaps the most frequently cited case of increasing specialization seeming to follow inevitably from increasing knowledge, as new cures and better treatments for more diseases are discovered. But as medical and biochemical research comes up with deeper explanations of disease processes (and healthy processes) in the body, understanding is also on the increase. More general concepts are replacing more specific ones as common, underlying molecular mechanisms are found for dissimilar diseases in different parts of the body. Once a disease can be understood as fitting into a general framework, the role of the specialist diminishes. ... Physicians ... can look up such facts as are known. But [more importantly] they may be able to apply a general theory to work out the required treatment, and expect it to be effective even if it has never been used before.⁵⁰

The real question facing every discerning, informed clinician in a patient-oriented clinic⁵¹ is how to bring relevant, graded, emerging scientific evidence to the complex list of problems made unique by the patient’s

gene map of susceptibilities/potentialities that, in turn, communicates constantly with the ever-changing environment within which the patient lives. No RCT can possibly inform, *in a specific way*, the appropriate clinical roadmap for assessment and planning for therapeutic interventions in this complex environment.⁵²

Dr. Richard Horton, editor-in-chief of *The Lancet*, addressed this issue in an editorial titled, “The Precautionary Principle”:

We must act on facts, and on the most accurate interpretation of them, using the best scientific information. That does not mean we must sit back until we have 100% evidence about everything. Where the state of the health of the people is at stake, the risks can be so high and the cost of corrective action so great, that prevention is better than cure. We must analyze the possible benefits and cost of action and inaction. Where there are significant risks of damage to the public health, we should be prepared to take action to diminish those risks even when the scientific knowledge is not conclusive, if the balance of likely costs and benefits justifies it.⁵³

One such intermediate tool that addresses this second major problem in applying emerging scientific evidence to clinical problems has been developed. This algorithm for critically assessing interventions in the context of complex, chronic illness has the mnemonic “STEPed Care”:

Safety (an analysis of adverse effects that patients and providers care about),

Tolerability (pooled drop-out rates from large clinical trials),

Effectiveness (how well the intervention[s] work and in what patient population[s]), and

Price (costs of intervention, but also cost-effectiveness of therapy).⁵⁴

Clinicians who are armed with this tool can arrange the emerging evidence about underlying mechanisms of disease in the clinical context of their patients’ problems and can apply this matrix of STEPed Care, bringing the best of new evidence to the unique needs of their patients.

To do more is to place patients in danger, teetering on the insubstantial edge of research, but to do less is unconscionable. For example, starting in the 1970s emerging research suggested that public health measures to ensure folate nutriture for women in the childbearing years, especially prior to conception, could markedly affect the incidence of spina bifida as well as other congenital neural tube anomalies in newborns.^{55,56,57,58,59}

However, it was not until March 1996 that the U.S. Food and Drug Administration (FDA) authorized addition of folic acid to enriched grain products. By 2001, a report in *JAMA* substantiated a 19% reduction in the birth prevalence of neural tube defects following the FDA's decision.⁶⁰ This delay of over two decades was and is unjustified. Discerning practitioners were applying the principles inherent in the STEPed Care process 15 years before the mandated action of the FDA, bringing to their patients of childbearing age and to their newborns the critical benefits of emerging research about folic acid at a much earlier actionable point.

Drs. Mark Hyman, Joseph Pizzorno, and Andrew Weil wrestled with this dilemma in the reconfiguration of the medical research perspective at this branching point in our evolution of medical technologies. In their 2004 commentary in *Alternative Therapies*, they propose a middle-ground approach for best addressing the real problems both clinicians and patients face at this time:⁶¹

Medical science is imprecise and the tools of analysis and research are imperfect despite our best intentions. No statistical model or research methodology can accurately predict the outcome in all humans who vary greatly in habits and genes. Medicine has in recent years been humbled in its hunger to help by its mistakes including hormone replacement therapy,⁶² which in the end hurt rather than helped the heart, the "lipids only hypothesis" of cardiovascular disease that ignores the important role of inflammation,⁶³ and the belated,⁶⁴ sober end to our love affair with COX-2 inhibitors.

Uncertainty is common in medicine. In the face of uncertainty, we must take a broader view, step back from the canvas of individual studies and meta-analyses and view the landscape of medicine and scientific inquiry as a whole, while understanding the limitations and value of different tools of research. We require all the tools in order to create sense and be sensible in a shifting sea of data points. The goal of seeking an informed balanced overview is to help us create understanding from knowledge, to sort through the facts and place them in the context of biologic principles, against the backdrop of all we know. Then we ask ourselves if the new data fit into the landscape or appear like a polar bear in a desert. We must also recognize that the questions we ask, how we ask them, and why, all inform the answers we receive.

The responsibility of the scientist is to filter the research, place it in context, provide hope where appropriate and caution where necessary, but most importantly to be an informed, measured guide to a public seeking to gain health and ameliorate suffering.

We are also at a branch point in the evolution of clinical medicine where the "dissonance that exists between

public and profession is intensifying."⁶⁵ Horton describes his answer to this dilemma as follows: "Application, synthesis, and reflection—these are my personal wishes for a renaissance in clinical medicine. It is not concerned with hierarchies of evidence; it is not dependent on up-to-date literature alone as the arbiter of clinical decision making; it does not proselytize a bottom-line approach to the reading of new research. Rather, it is about preferring interpretations to conclusions, external validity to internal validity, context to the highly controlled—and artificial—experimental environment."⁶⁶ Our patients are clamoring for this "renaissance" and the "largely skeptical and indifferent response to them has isolated physicians within an unattractive provincial and narrow island of medicine, a medicine that has become intellectually self-admiring of its scientific purity and, as a consequence, self-deluding and self-defeating."⁶⁷

We are again facing a paradigm shift,⁶⁸ ironically birthed by the original attempt to construct an evidence-based medical system. Thomas Kuhn⁶⁹ has described scientific paradigms as ways of looking at the world that define both the problems that can legitimately be addressed and the range of admissible evidence that may bear on their solution.

When defects in an existing paradigm accumulate to the extent that the paradigm is no longer tenable, the paradigm is challenged and replaced by a new way of looking at the world. Medical practice is changing, and the change, which involves using the medical literature more effectively in guiding medical practice, is profound enough that it can appropriately be called a paradigm shift.⁷⁰

The practice of EBM needs to return to its original mission of integrating evidence to inform clinical experience and to expand the understanding of basic mechanisms of health and disease.^{71,72} This will help to reverse the decade-long plunge into the narrow focus on "the discussion of research methodology, reducing clinical practice to the technical implementation of research findings."^{73,74} Alternate study designs and statistical methodologies are now being evaluated for analyzing complex data sets.⁷⁵

A middle ground has been defined, creating a broader appreciation for the clarity that RCTs can bring without the obsequious and inappropriate hegemony that has characterized the debate over the last decade.⁷⁶ As concluded by Larry Dossey in his "Notes on the Journey": "One of the greatest impediments to progress in science

is to assume that our fundamental concepts are basically complete. They have never been.”⁷⁷

We still have miles to go in our journey to understand the appropriate scientific methods that can reliably discipline the creative process of human curiosity about efficacy, benefits, risks, and causation of human suffering and its remediation. The new paradigm will recursively inform and redirect the EBM paradigm shift developed during the 1990s. IFM and functional medicine are already adapted to this changing model, making use of both existing and emerging research, and educating clinicians to bring the best of both worlds to their patients. It is our hope that this textbook will provide convincing evidence of the value of that mission.

Clinical Decision Making—A Functional Medicine Perspective

Joseph E. Pizzorno, Jr., ND

Introduction

As 21st century health care moves from a disease-based approach to a more patient-centric system that can address biochemical individuality to improve health and function (see Chapter 8), clinical decision making becomes more complex. Accentuating the problem is the lack of a clear standard for this more complex functional medicine approach. While there is relatively broad agreement in Western medicine for what constitutes competent assessment of disease and identification of related treatment approaches, the complex functional medicine model posits multiple and individualized diagnostic and therapeutic approaches, most or many of which have reasonable underlying science and principles, but which have not been rigorously tested in a research or clinical setting. (For a discussion of the limitations of the current RCT model in testing multifactorial and individualized approaches, see the preceding discussion in this chapter.) This has led to non-rigorous thinking and sometimes to uncritical acceptance of both poorly documented diagnostic procedures and ineffective therapies, resulting in less than optimal clinical care.

In this discussion, we will address the challenges of clinical decision making in a functional medicine practice, looking at various models of human decision making and identifying strategies to improve their application in the healthcare setting.

Challenges for the Functional Medicine Clinician

The personalization of care achievable through the functional medicine approach is the only real solution to the crisis of chronic disease facing us today. (This subject has been explored deeply in Chapters 1 through 4.) However, to practice this form of medicine is difficult, complex, and requires higher standards of decision making by clinicians. The functional medicine approach to diagnosis demands not only that we determine what disease the patient is suffering from, which can be challenging, but also what the patient's underlying physiological dysfunctions are, and the underlying cause(s), which is a complex process.

Sumatriptan or Magnesium?

Consider the clinician who wants to practice the best medicine and therefore reads not only standard medical journals but also the nutrition research. The clinician decides to compare sumatriptan to magnesium for a patient suffering migraine headache. Looking at a meta-analysis of various triptans in the treatment of migraine patients, the clinician would conclude that 100 mg of sumatriptan is likely effective in 59% of patients.⁷⁸ (Efficacy is defined as relief of headache pain within two hours.) Being a responsible clinician, he/she would also consider adverse drug reactions and would see that the placebo-subtracted proportion for patients with at least one adverse drug reaction (ADR) is 13%; for at least one central nervous system symptom, 6% (3.0–9.0%); and for at least one chest symptom, 1.9% (1.0–2.7%). The clinician might compare these data with other triptans, and choose rizatriptan instead, since it shows somewhat better efficacy and consistency, and similar tolerability.

In contrast, looking at the research for magnesium, the clinician would find a response of 41.6% from oral magnesium. This reduction in attack frequency in the magnesium group compared to 15.8% in the placebo group might be compelling, but the incidence of ADRs of diarrhea (18.6%) and gastric irritation (4.7%) would likely preclude use.⁷⁹ Not surprisingly, the conventional practitioner would very likely make an EBM decision and choose rizatriptan over magnesium.

However, digging deeper would show a dramatic difference in response to magnesium based on serum ionized magnesium levels (IMg²⁺). Eighty-nine percent of those responding to intravenous magnesium showed

low pretreatment serum magnesium levels, while only 37.5% of non-responders had a low IMg^{2+} level.⁸⁰ Digging even deeper, the clinician would notice that magnesium is twice as effective if the patient also suffers a prodromal aura.⁸¹

Conventional diagnosis of migraine is pretty straightforward, although atypical presentations are probably more common than previously recognized.⁸² The causes, however, are myriad. A research team at SaluGenecists, Inc., performed a comprehensive review of the research literature (over 10,000 research articles studied; 1,000 cited) and identified at least 27 different physiological dysfunctions that can lead to the clinical presentation of migraine headache. Patients get to migraine via complex, individual pathways. Further, there are research reports to be studied concerning approximately 40 different “natural medicine” approaches to migraine (nutritional, herbal, and lifestyle therapies). And 20 environmental toxins may need to be evaluated in order to normalize physiological dysfunctions. The clinical decision-making process has now become far more complex than simply diagnosing migraine and prescribing a triptan! This two orders of magnitude increase in complexity dramatically increases the need for rigorous decision making.

Considering a human’s approximately 4,000 enzyme systems, 1,000 chemical mediators (these two numbers are my estimates, I could not find an actual count), 2,000,000 possible single nucleotide polymorphisms (SNPs), approximately 250 nutrients known to be important in human health, and several thousand endogenous and exogenous xenobiotics, the true size of the challenge becomes readily apparent.

Clinical Decision Making

How Good Are We at Critical Thinking?

How do we expand upon the current disease-based diagnosis and treatment model to achieve a clinically effective understanding of the biochemical, physiological, and environmental uniqueness of our patients? What diagnostic challenges does this expanded model create for clinicians? One of the most important services a clinician provides his or her patients is decision making. Disease diagnosis, physiological function assessment, determining optimal treatment, limiting adverse drug reactions—all involve critical thinking skills.

How do clinicians make diagnostic and therapeutic decisions? What influences clinical decision making? What data contribute to accurate decisions? What induces errors into a clinician’s decisions? How can we improve the accuracy and reliability of clinical thinking? What happens when the complexity becomes too great? While we seldom think about the *process* of decision making, our ability to do it efficiently and accurately impacts our every interaction with patients. Unfortunately, research has shown that clinical critical thinking skills need more attention in order to avoid systematic logic errors and misinterpretation of the actual predictive value of various types of patient information.

Improving the reliability of the information clinicians use to make decisions is obviously critical. To that end, evidence-based medicine has become a recurrent theme in the medical research and academic literature. A recent survey showed that virtually all (122 of 126) LCME-accredited (Liaison Committee on Medical Education) medical schools included EBM as a required course of at least 20 hours.⁸³ However, formal courses devoted specifically to critical thinking are rare. Utilizing the AAMC (American Association of Medical Schools) curriculum search tools found only six institutions with courses that included one of the terms “decision” or “critical” or “analytic,” and the hour allocations were low. Obviously, critical thinking is informally taught in many courses and clinical rotations. Nonetheless, it seems to receive limited formal attention. A survey of 417 U.S. internal medicine residency programs found formal clinical decision making training (critical appraisal, searching for evidence, posing a question, and applying it in decision making) in only 99 of 269 (37%) institutions that responded.⁸⁴

A Cochrane review of the research evaluating the effect of teaching critical thinking skills to healthcare professionals already caring for patients found a remarkable 25% improvement in clinical accuracy.⁸⁵ However, the Cochrane review also said there were too few properly designed and conducted studies to be confident in the size of the improvement or its actual clinical significance. Nonetheless, the well-documented evidence of frequent clinician error and its role in the incidence of suboptimal care and adverse clinical outcomes is compelling. One widely reported epidemiological study that reviewed published reports found that 4 to 18% of consecutive outpatient visits result in adverse effects, with

one study asserting that up to 69% of the adverse events were preventable with better decision making.⁸⁶

It appears undeniable that patients receive a lower quality of care than would be expected considering the high level of practitioner training and the huge body of research now available. The need for accurate decision making is even more critical when clinicians adopt the principles and practices of functional medicine.

What Can We Learn From Artificial Intelligence (A.I.) Research?

One way to improve critical thinking skills is to better understand how humans make decisions. As computers became available with enough power to mimic human thinking processes, researchers had to rigorously dissect how humans make decisions. While most of the early research centered on the creation of chess programs that could match human masters, of particular relevance here is the effort to duplicate the thinking processes of healthcare professionals.

Interest in this area increased dramatically with the publication of MYCIN (1980), an “expert system” that came out of research at Stanford University in the late 1970s. What caught the imagination of the A.I. and healthcare communities was that, for blood-borne infections, MYCIN outperformed not only medical students and residents, but also infectious disease fellows and medical school faculty (see Table 5.1). How did it do this? By having logicians and programmers work with a group of infectious disease experts to exhaustively determine all the “rules” they used to determine which bacterial species caused a blood-borne infection and the optimal intervention for its eradication. Converting their knowledge into software logic required that the clinicians exhaustively think through how they make decisions. This level of rigor resulted in better decision making, not only because the model was able to incorporate the best thinking of many experts, but also because it applied those rules consistently with every patient.

According to Enrico Coiera (Foundation Chair in Medical Informatics, Faculty of Medicine, University of New South Wales, Australia), “If physiology literally means ‘the logic of life,’ and pathology is ‘the logic of disease,’ then health informatics is the ‘logic of healthcare.’”⁸⁷

Table 5.1 MYCIN vs. Students and Clinicians (1980)

Healthcare expert	Score
Perfect score	80
Medical student	24
Resident	36
Actual hospital outcome	46
Infectious disease fellow	48
Medical school faculty	34–50
MYCIN	52

There are now over 70 A.I. tools in use in conventional medicine to improve diagnosis (actually outperforming clinicians in some areas), avoid drug interactions, interpret x-rays and laboratory tests, teach medical students, and perform other tasks (see Judith Federhofer’s excellent review at www.computer.privatweb.at/judith). We can continue to learn much about the mechanics of medical decision making and areas of potential error by formally coding our decision-making processes into computer programs. These programs consistently reproduce our thinking processes so that they can be subjected to evaluation. By identifying where our decisions lead to correct or incorrect outcomes, we can refine our thinking and improve our use of evidence and patient data.

Artificial Intelligence—Many Ways of Thinking

Studying the types and diversity of artificial intelligence systems (called expert systems when they are used to duplicate experts in a field of study) that have been developed to mimic human thinking is very informative. In general, five types have been used in medicine (there are actually many more types of A.I., but these are the most common in health care):

- Rules-based systems
- Case-based reasoning (CBR)
- Neural networks
- Fuzzy logic
- Bayesian networks

This discussion may appear daunting, but we will draw from it some straightforward guidance. Busy clinicians can't be expected to calculate all the probabilities before making recommendations for each patient, but their critical thinking skills can be improved by understanding better how decisions are made.

Rules-based Systems

Rules-based systems are fairly straightforward. They look like flowcharts with "If ... then" statements. Many clinical guidelines are based on this model. Figure 5.2 shows a diagram modified from a flowchart developed by Herb Joiner-Bey, ND, for Nancy Sudak, MD's article on a functional medicine approach to migraine headache, published in volume 2.6 of *Integrative Medicine: A Clinician's Journal*. Each branch point is simply an "If ... then" logic statement. This matches human reasoning well in simple cases, especially when pathognomonic decision points are available (like Koplik's spots in measles).

Figure 5.2 Migraine flowchart

Case-based Reasoning

Case-based reasoning (CBR) starts by accumulating and evaluating a large number of "solved" cases to determine the characteristics of the successfully treated patients. It then tries to match new patients with patients

in the database. This method duplicates human pattern matching pretty well, i.e., once you've seen a patient with classic migraine, others are easy to recognize.

Neural Networks

Neural networks make no effort at understanding how humans think nor do they develop algorithms. Rather, they look at human decision making as a "black box." By using a large number of examples of desired behaviors, they attempt to match input (signs and symptoms) to outputs (diagnoses or therapies). The computer software is set up to be similar to the parallel processing architecture of the brain. This process may match human thinking at a very early age, but does not help us much when trying to understand adult reasoning processes.

Fuzzy Logic

The concept of fuzzy logic puts me in awe of human creativity. The idea here is to look at particular information and attempt to determine the level of uncertainty. It could be described simply as a rules system with probabilities or uncertainties added.

Bayes Inference

An expert system used frequently in medical diagnostic systems is Bayesian inference, based on the probability theory of the Rev. Thomas Bayes, an 18th century mathematician. This heuristic reasoning system makes inferences based on the rigorous mathematics of the predictive value of information. His formula for determining the predictive value of information can be simply stated as:

$$P(D|F) = P(F|D) * P(D) / P(F)$$

where:

D = Decision (e.g., disease)

F = Finding (e.g., symptom)

P(D) = The *a priori* probability of the decision (e.g., the incidence of a disease in the general population)

P(F) = The *a priori* probability of the finding (e.g., the incidence of a symptom in the general population)

P(D|F) = Probability of the decision given the finding

P(F|D) = Probability of the finding, given the presence of the decision

The Bayes formula can be restated in terms of sensitivity and specificity:

$$P(D|F) = P(D) \cdot TP / (P(D) \cdot TP + (1 - P(D)) \cdot FP)$$

Or

$$P(D|F) = P(D) \cdot TP / P(F)$$

That looks pretty complicated, but the main take-away is that the probability of the decision's accuracy is inversely proportional to the *a priori* probability of the finding. In other words, the more prevalent a piece of information (a finding or symptom) is in the population, the less predictive it is in a specific patient. Intuitively, this makes sense.

As you may recall from your study of statistics long ago, the issues of sensitivity and specificity are extremely important. They are frequently used in laboratory medicine where they provide us guidance on the usefulness of specific tests. For example, a lab test may be very sensitive, i.e., is abnormal very frequently when the disease is present. However, if it has a high false positive (low specificity, where $FP = 1 - \text{specificity}$), meaning the result is frequently abnormal even when the disease is *not* present, it is not very useful.

The value of this kind of an inference-based expert system is that it mimics human thinking well (human brains are remarkably effective inference engines). If the mathematically rigorous Bayes thinking is used, decisions can be more accurate, and long chains of logic can be used (see Figure 5.3). This is the method used by casinos to calculate odds and by the Mars Lander to pick a site and land on it safely. Equally important, this system can be used to map human biochemistry, and we can learn a lot from it about the strengths and weaknesses of human thinking processes.

The Role of Uncertainty in Medical Error

A strong case can be made that underappreciation of uncertainty is a major cause of error in medicine.⁸⁸ McNeil has argued that the major hidden barriers to better health care result from a lack of discussion about the impact of uncertainty in medicine.⁸⁹ She enumerates three sources of uncertainty that cloud decision making:

1. uncertainty as a result of lack of convincing evidence,
2. uncertainty about the applicability of research evidence to clinical care, and
3. uncertainty about interpretation of data.

Figure 5.3 Bayesian inference network

Note: Each arrow indicates a Bayesian inference.

Others have asserted that the failure to learn how to make decisions under uncertainty is the leading cause of excessive diagnostic testing and inappropriate treatments.⁹⁰ Obviously, reliable evidence is critical for effective decision making. *However, too often evidence is confused with decision making.* The quality of evidence is now evaluated (several EBM scales exist, typically ranking evidence from 1 for meta-analysis to 5 for anecdotal evidence), which may be helpful, but clinical decision making is not only about the ranking of evidence; it is also about making choices in the face of uncertainty. The failure to train doctors about clinical uncertainty has been called “the greatest deficiency of medical education throughout the twentieth century.”⁹¹

Lessons from the Reverend Bayes

Rigorously dealing with uncertainty is exactly the problem addressed by the Bayes probability formulas. Consciously utilizing the false positive to balance the true positive in order to accurately portray the true level of uncertainty significantly improves the reliability of decision making. It does this by removing our overestimation of the certainty of decisions, pointing to the need for more information to improve accuracy. Through the use of the true positive (sensitivity) and false positive (1-specificity), the mathematically correct strength of an inference can be determined—that is, the clinician can better understand the true predictive value of evidence.

The Bayes formula may look daunting, but its use can be surprisingly easy. In fact, there are available on the Internet simple Bayes calculators (I have one that runs in Excel that I am happy to share; contact me at: drpizzorno@salugenecists.com). However, the clinician does not need to make the calculation every time. After using the formula a few times, the needed modifications to decision making become more intuitive.

Let's look again at that migraine patient. It appears that 41.6% of migraine patients respond to oral magnesium. How do you determine which ones will respond? What evidence is most predictive?

Muscle cramps are a common sign of magnesium deficiency. The true positive (TP) is 48%. If the patient is experiencing muscle cramps with the migraine, the clinician might then assume that magnesium is very likely to work. However, muscle cramps are common in the general population (27.5%⁹²) so the false positive (FP) is actually quite high, 25%. Therefore, the predictive value using the Bayes formula is that we've only increased the true confidence in magnesium being useful for the patient from 41.6% to 62%. This is still not very good, considering the potential for side effects.

Consider, instead, mitral valve prolapse as an indication of magnesium deficiency. Its TP is only 14%, which on the surface seems less compelling than muscle cramps. However, its prevalence in the population is low (4%⁹³) so its FP is also low, only 3%. Therefore its predictive value is significantly higher—using the Bayes calculation, our confidence is now 80%—much more compelling! In addition, the incidence of an adverse reaction is now much less because we are now unlikely to be giving magnesium to a patient who does not need it.

This comparison is useful because we can see clearly that one piece of evidence appears on the surface to be more useful since it has high sensitivity, but it is actually much less useful than lower sensitivity evidence that has a much lower false positive.

The simple rule: If the prevalence in the general population of a piece of evidence (a symptom or other finding) is high, even though it may be highly associated, its predictive value is actually weak. Therefore, before the clinician can confidently make a recommendation, the **right kind of evidence**, i.e., that with a high ratio of TP to FP, needs to be gathered (e.g., discovering whether the patient suffers a prodromal aura, measuring magnesium levels, and so forth).

The Bayesian calculations required for accurate inferential information highlight a vulnerability in the human thinking process that is relevant to functional medicine: using only the true positive and ignoring the false positive when making complex decisions in an area of high uncertainty skews the decision making. Stated differently, failing to consider the population prevalence of the evidence and the intervention leads to false confidence on the part of the clinician.

Summary

Uncertainty is a fact of life in health care. It arises from many sources: incomplete or inaccurate patient data; evidence that is not as good as we would like; and making inaccurate inferences from the evidence and data. Lack of awareness about this uncertainty principle leads to excessive confidence in our conclusions. Erroneously believing we have made a good decision results in stopping the evidence-gathering process prematurely. The clinical impact, then, is greater frequency of ineffective therapies and increased risk of ADRs.

What can clinicians do? There are three relatively straightforward steps that all healthcare practitioners can take:

1. Improve the quality of the evidence we use (the evidence to be considered ranges from more accurate eliciting of patient data to better understanding of underlying physiology and biochemistry, the influence of environment on gene expression, and the effectiveness of assessment tools and therapeutic strategies).
2. Understand the true predictive value of evidence by considering not only the true positive but also the critical false positive, i.e., become more aware of the population prevalence of the evidence and data we use and learn how to calculate their effect upon certainty.
3. Continue evidence gathering (especially evidence with a high true-positive to false-positive ratio) until the level of certainty supports a reasonable level of confidence in the efficacy and safety of the intervention.

Removing overassessment of accuracy from clinical decision making helps us prioritize where additional information has to be gathered so that we can provide the best possible care for our patients.

Principles of Functional Medicine

The background of the page is a vibrant blue. The lower portion of the page features a complex, abstract pattern of flowing, wavy lines that create a sense of movement and depth. A bright, white, diagonal streak of light cuts across the lower right quadrant, adding a dynamic element to the design.

Chapter 6

Functional Medicine is Science-Based

DeAnn Liska, PhD

Introduction

Lewis Thomas, the eminent physician essayist, called medicine “the youngest science” in his 1983 book of the same title. He observed at that time that such discoveries as antibiotics and the structure of DNA had made medicine more of a science, in which it could conduct experiments that test hypotheses about disease-causing agents and their curative interventions.¹ He clearly identified the 20th century promise of the “science of medicine”—suggesting that we would not only have absolute answers to what causes disease and dysfunction, but we would also be able to “cure” disease. Indeed, the 20th century did see an influx of new technologies, new pharmaceuticals, and a deeper understanding of the biochemical underpinnings of disease. Furthermore, the promise of the “cure” has been enhanced by such findings as the frank vitamin deficiency diseases that are cured by nutrient repletion and the bacterial-based infectious diseases that can be eradicated by antibiotic treatment.²

Western medicine, in particular, is driven by technological advances and built upon the notion that everything that is relevant can be tested, proved (or disproved), and, with those results, a direct solution can be found. However, this new “science of medicine” has not been able, so far, to stem the rising pandemic of chronic disease. Likewise, scientific literature is accumulating more and more evidence that the promise of directly curing conditions such as rheumatoid arthritis, type 2 diabetes, cancers, and Alzheimer’s with a simple approach is not realistic. Moreover, the influx of new scientific information over the past several decades has continued to increase, while the ability of the average clinician to review that information and understand its relevance to a real-life patient is limited by time constraints and the sheer volume of material. The multifac-

torial nature of chronic conditions, along with the emerging understanding of just how biochemically unique we all are, has collided with our model of basing clinical decisions primarily, if not solely, on a narrow definition of science.

In Chapter 5 of this book, a very detailed and carefully documented analysis of the history and limitations of the current scientific research model was presented. Here, as we open our discussion of the principles of functional medicine, we will look at how one of the basic principles—that functional medicine is science based—plays out against that background.

Functional medicine embraces the challenge of incorporating the newest scientific literature into its model of clinical care; advances in our understanding of fundamental physiological and biochemical processes can only enhance the clinician’s ability to treat patients with complex, chronic disease. Science is a critical tool for improving our understanding of the underlying clinical imbalances that lead to disease, and also a lens through which we can examine, describe, and adapt to the biochemical individuality of each patient. It is by understanding these imbalances that clinicians can help patients change the course of a disease. Therefore, a functional medicine practitioner must stay abreast of the current literature and be willing to challenge beliefs and current dogma.

Functional medicine does not identify a single gold-standard method for considering something relevant or useful. Functional medicine practitioners incorporate many different sources of scientific information into the medical decision-making process: basic science, clinical experience, and the principles explored in this section are all important elements in the model. Using this approach requires a paradigm shift from the focus

Section II

Principles of Functional Medicine

of the late 20th century—that there is a single valid model for useful evidence—to the broader view that all the relevant science and information should be reviewed and understood. Overall, that's the mission of this text—to help all of us make that leap to a new approach, wherein science and evidence in many forms are valuable to an innovative and clinically relevant model of care.

Science and Evidence-based Medicine (EBM)

The emergence of the scientific method as central to medicine has changed the face of health care. Clinical trials have become the primary method of establishing medical benefit. The randomized, placebo-controlled, double-blind clinical trial (DB/PC RCT) has come to dominate the field. Without data from an RCT showing a statistically significant effect, an intervention is considered unproved, which many take to mean “not beneficial.” This has led to the attempt to find the “best” medicine from the “perfect” data: an evidence-based approach to medicine.

Certainly, the testing of many approaches that were in common practice has made a strong and highly beneficial impact on medical practice. For example, estrogen replacement therapy (ERT) was considered a standard practice for decades. Maintaining estrogen levels in women over 50 at levels similar to those for younger women was thought to be beneficial, and early observational studies suggested that the benefit extended to the cardiovascular system. However, more recent investigations of ERT, utilizing the RCT, did not support the findings from those early observational studies, indicating instead that some women on ERT may be at increased risk for thrombotic events and stroke, especially within the first two years of beginning ERT.^{3,4} The trials that showed increased risk of ERT generally included postmenopausal women who were not exhibiting symptoms of the menopause transition, such as hot flashes, whereas the benefit of exogenous hormones was observed in studies with younger women. As noted by Rosano et al.,⁵ “several biological reasons may have contributed to the divergent findings from observational studies and RCTs.” Older women may have fewer estrogen receptors, or a different pattern of expression of these receptors, and also may be more susceptible to inflammation and thrombotic events, factors that could

alter their response to exogenous hormones, when compared to younger women.^{6,7,8}

Testing a single, defined intervention is, however, different than managing a patient with one or more chronic, complex, multifactorial conditions. A comprehensive approach to preventing and treating such conditions has not been amenable to study through the RCT model. Moreover, most often, a statistically significant, “successful” therapy is effective in barely more than 50% of patients.^{9,10,11,12} Even if the therapy is highly successful in a trial, studies indicate that patients in randomized controlled trials are often not typical of those seen in clinical practice.^{13,14} (Indeed, with data indicating that adverse drug reactions from properly prescribed drugs rate as the fourth most common cause of death in hospitalized patients, consumers, government agencies, and practitioners are often left to question whether medicine does more harm than good.¹⁵)

In 2002, David Brown asserted in a *Washington Post* article that “Evidence-based medicine is likely to transform the entire field.”¹⁶ The actual definition of EBM varies, but the Centre for Evidence-Based Medicine at the University of Toronto defines it as “the integration of best research evidence with clinical expertise and patient values.”¹⁷ Much of the literature about EBM, however, has centered on how best to score the evidence, creating a hierarchy in which some evidence has great value and other evidence has much less value. Although the definition of EBM includes the words “clinical expertise” and “patient values,” the evidence base used is primarily, if not exclusively, drawn from RCT data. This focus on finding the “best” data often disregards the needs of the individual patient. For example, in a 1997 discussion on evidence-based disease management published in *JAMA*,¹⁸ the relevant skills for employing EBM were described as “precisely defining a patient problem, proficiently searching and critically appraising relevant information from the literature, and then deciding whether, and how, to use this information in practice.” Not only does this description focus on “precisely defining a patient problem,” which is often difficult to do for multifactorial, complex conditions, but the implication that the “evidence” comes primarily (or only) from the literature directly “relevant” to that problem. The web-like nature of physiological processes seems a misfit in this type of evidence model.

While the goal of EBM is laudable (to improve clinical practice by using interventions that have stood the test of thorough investigation), the actual practice is not clear. In a study on why general practitioners do not implement so-called “best evidence” from research studies, Freeman and Sweeney¹⁹ found the doctor-patient relationship to be particularly relevant. “Evidence is not implemented in a simple linear way, as some definitions of evidence based practice imply, but in an evolving process whereby reciprocal contributions from the doctor and the patient over time influence how evidence ultimately is used.”

The following excerpts from a 1997 editorial in the *British Medical Journal* clarify some of the issues that are still with us today:²⁰

We face the problem that criteria for internal and external validity (that is, clinical applicability) may conflict. Clinical studies are usually performed on a homogeneous study population and exclude clinically complex cases for the sake of internal validity. Such selection may not, however, match the type of patients for whom the studied intervention will be considered Studies on the effectiveness of clinical care may also not easily attain internal validity. An example is the evaluation of the many interventions that cannot be blinded, such as many non-pharmacological procedures Thus, in seeking internally valid evidence that is externally valid for clinical practice, we need “medicine based” studies that include, not ignore, clinical reality and its inherent difficulties In reviewing clinical evidence we must be reluctant to adopt too detailed criteria for good and bad science and to freeze criteria for validity. Study methods themselves need to evolve.

Science and the Patient-centered Approach

Studying the body’s function from a scientific perspective is a demanding process; bringing in the patient’s perspective makes it even more complex. To bring these issues into clearer focus, we will examine a real-life case that is a matter of public record.

A Case of Chronic Fatigue Syndrome

In an essay titled “A Sudden Illness,” Laura Hillenbrand, author of the best-selling book *Seabiscuit: An American Legend*, describes her continuing battle with chronic fatigue syndrome, which began in 1987 before the syndrome was accepted by mainstream medicine.²¹ One of her symptoms was a chronic strep infection. After a year in which she had seen several internists and

a psychiatrist, and had several courses of antibiotics, she found an internist who again changed her antibiotics and, eventually, her strep appeared to improve. Her other symptoms, including debilitating, unremitting fatigue, did not. In her own words:

I kept returning to see this doctor, hoping she could find some way to make me feel better. She couldn’t, and I could see that it was wearing on her. In September, I was so weak that on a ride over to her office I had to drop my head to my knees to avoid passing out. When the nurse entered, I was lying down, holding my head, the room swimming around me. She took my blood pressure: 70/50. The doctor came in. She wouldn’t look at me. “I don’t know why you keep coming here,” she said, her lips tight.

I told her that I felt faint and asked about my blood pressure. She said that it was normal and left, saying nothing else. She then went to see my mother, who was in the waiting room. “When is she going to realize that her problems are all in her head?” the doctor said.

I returned home, lay down, and tried to figure out what to do. My psychiatrist had found me to be mentally healthy, but my physicians had concluded that if my symptoms and the results of a few conventional tests didn’t fit a disease they knew of, my problem had to be psychological. Rather than admit that they didn’t know what I had, they made a diagnosis they weren’t qualified to make.

Without my physician’s support, it was almost impossible to find support from others. People told me I was lazy and selfish. Someone lamented how unfortunate Borden was to have a girlfriend who demanded coddling. Some of Borden’s friends suggested that he was foolish and weak to stand by me. “The best thing my parents ever did for my deadbeat brother,” a former professor of his told him, “was to throw him out.” I was ashamed and angry and indescribably lonely.

Hillenbrand’s condition had begun suddenly, with symptoms assumed to be from food poisoning. These were soon followed by swollen lymph nodes and a persistent strep infection. At the time, chronic fatigue was not recognized as a diagnosable condition by mainstream medicine. There was no “evidence base” to explain her condition, but there was science.

Patients having symptom complexes consistent with what we now call chronic fatigue syndrome have been described in the medical literature for centuries and have, at various times, been categorized with names such as post-viral fatigue and chronic Epstein-Barr virus (EBV) syndrome.²² In fact, a few years before Hillenbrand first experienced symptoms, Behan et al.²³ published an analysis of 50 cases of post-viral fatigue and concluded: “A metabolic disorder, caused by persistent virus infection

Section II

Principles of Functional Medicine

and associated with defective immunoregulation, is suggested as the pathogenetic mechanism.” The year in which her symptoms began, Buchwald, Komaroff and colleagues published a report in which they found abnormalities in immune cells of chronic fatigue patients.²⁴ In March of 1988, the first working definition of chronic fatigue syndrome was published in the *Annals of Internal Medicine*.²⁵ While Hillenbrand was experiencing debilitating symptoms, being treated only with antibiotics for her chronic strep, and feeling very much alone, the literature available at the time actually showed that she was, in fact, not alone.

When faced with a patient such as Hillenbrand (one of the “walking wounded,” so familiar to clinicians everywhere), where the research base does not yet offer clear answers, it is important to remember that science is still there to help. Exploring the underlying physiological pathways that appear to be involved would be a functional medicine approach. The therapeutic plan could then be designed to support the healthy, balanced function of those pathways, while also removing any known or postulated triggers (e.g., strep infection) that are acting upon those pathways to exacerbate symptoms. A patient may not be “cured,” but can have improved function. A clinician may not know the answers, but can have a place to start. In this particular case, the association with immune function was deducible from the symptom pattern experienced by Hillenbrand, as well as from the available literature. The science was there in terms of indicating that a possible connection between these symptoms and immune dysfunction could exist. Unfortunately, to this date, an indisputable evidence base describing the underlying immune imbalances in chronic fatigue syndrome is still not available. Waiting for that level of evidence before treating the patient would leave many a patient still hearing their clinician say, “I don’t know why you keep coming here.”

Data are accumulating to show how complex these chronic conditions are. Not only do syndromes such as chronic fatigue and fibromyalgia have significant overlap in symptoms and biochemistry, but gene expression profiles indicate that differential expression patterns can be identified; these conditions may well represent sub-groups of specific metabolic imbalances.^{26,27,28} In fact, in 1996, the Royal Colleges of Physicians, Psychiatrists, and General Practitioners provided this summary of the evidence:²⁹

Chronic Fatigue Syndrome (CFS) is not a single diagnostic entity. It is a symptom complex which can be reached by many different routes. The conceptual model of CFS needs to be changed from one determined by a single cause/agent to one in which dysfunction is the end stage of a multifactorial process. Although it is important to recognize the role of factors that precipitate the condition, greater understanding is required of factors that predispose individuals to develop the illness, and those that perpetuate disability.

Simply stated, not every CFS patient will be the same and the focus on underlying pathways is now being seen as the way to medically manage CFS. In the functional medicine approach, the focus on those sciences that elucidate underlying pathways and clusters of symptoms is absolutely critical to prevention and treatment of complex, chronic disease. These “functionalities” in physiology and biochemistry help us to identify varying patterns within a given diagnostic category and undertake a search for common underlying factors in patients with a number of different debilitating symptoms, conditions, or diseases.

Applying Science in Clinical Practice

Many evidence-based evaluations target whether a single intervention works. This is a different question than evaluating whether a patient improves in a clinical practice. Therefore, although published research is helpful as a guide, it is often not directly reflective of what a clinician faces when working with an individual patient. Moreover, the development of research methodologies has focused heavily on single-agent interventions, such as pharmaceuticals. Many of the integrative approaches that take into account the entirety of a patient’s experience (e.g., diet, lifestyle, environmental exposure) are not amenable to being studied using these methodologies. As stated in a discussion in *The Lancet*:³⁰

Drug interventions have been studied more extensively than non-pharmacological interventions, because of requirements for drug registration and the technical and methodological difficulties in the design of RCTs for non-drug interventions. This situation is a particular problem for general practice. According to the principle of “maximum effect, minimum resources,” patients’ education, diets, and lifestyles are, in theory, particularly attractive. Generally, such interventions cannot be assessed under adequately masked conditions, so “contamination” of trial groups will threaten internal validity. So, it is not surprising that a literature search fails to find convincing evidence of effectiveness of avoidance of house-

dust mite allergens. However, absence of proof of effect is different from proof of lack of effect. Even if there is insufficient clinical research available to support its case, exposure to allergen has a key role in the pathophysiology of airways inflammation. Consequently, the concept of asthma makes avoidance of allergens a logical measure even in the absence of direct support from a RCT.

Advances in our understanding of how the body functions at the most basic level are integral to functional medicine. Science-based functional medicine, then, is the incorporation of science within the context of the patient's experiences and biochemical individuality. It is not a prescription that can be tested in a simple RCT; it is not a clinical algorithm directing that each patient with condition X is treated with a clearly defined therapy. Functional medicine urges the practitioner to become adept at the art of reviewing the best and most recent scientific research, both basic and clinical sciences, as part of the process of developing a personalized approach for a patient-centered practice of medicine. As stated by Aaron and Buchwald:³¹

Finally, describing an illness as “unexplained” should not be taken to mean “unexplainable” or “imaginary.” Researchers and providers involved with patients who have unexplained clinical conditions would do well to remember Osler's statement that the study of medicine “begins with the patient, continues with the patient and ends ... with the patient.”

Summary

Functional medicine looks at the emerging science, and digs deep into the way these findings influence our ideas about how the body functions at the physiological and biochemical level. Functional medicine uses the core clinical imbalances as the matrix upon which to organize the science, and includes basic science, clinical trials, case reports, and clinical experience (anecdotal data) to understand a patient's situation. In functional medicine, clinical trials are one piece of the puzzle, not the only source of evidence.

Functional medicine requires an active interaction with the scientific literature. It requires a clinician to keep up with new findings in human physiology and biochemistry; it requires a clinician to integrate the current findings into the model of how problems begin and where the imbalances may lie; it requires a thought process that cannot be directly correlated to an evidence-scoring system. It requires science to continue

deepening our understanding about the complexities of life and the various effects of our actions. Functional medicine relies on science and incorporates it deeply into patient-centered care in an analytical and integrative model.

*Discovery consists of seeing what everybody
has seen and thinking what nobody has thought.*

—Albert Szent-Györgyi,
1937 Nobel Laureate in Physiology
and Medicine: the scientist
who isolated vitamin C

Introduction¹

In the *Structure of Scientific Revolutions*,¹ Thomas Kuhn analyzed the process of changing scientific paradigms. He described how in each discipline of science, new advances and theories are slow to be adopted but, once accepted, they assume the position of “normal science.” They become foundational to collective beliefs and theories in a new iteration of scientific leaders. Overturning “normal science” often requires decades of accumulated evidence to succeed against the old theories that wane as their ability to explain new data is eroded. Medicine is replete with examples of “normal science” becoming obsolete in retrospect. With change, the newer theories that have been ignored—not because of lack of merit but because of their poor fit with the established paradigm—clearly present a more robust model of explanation.²

There are many examples of resistance to change in the history of medicine. A few medical vignettes can

serve to illustrate the unnecessary delays common to incorporating new discoveries into practice:

- When Edward Jenner developed the therapeutic technique of vaccinating against smallpox in 1797, the Royal Society of London scolded him for risking his reputation on something “so much at variance with established knowledge, and withal so incredible.”
- When the Hungarian physician Ignaz Semmelweis discovered that physicians’ unwashed hands caused fatal infections among new mothers at the University of Vienna in the 1850s, he lost his academic position, dying disgraced.
- When the American writer and physician Oliver Wendall Holmes published an article on the prevention, through hand washing, of “childbed fever,” his observations brought him bitter abuse.
- Alexander Fleming discovered penicillin in 1929. But there was a delay of 12 years before he, W.H. Florey, and E.B. Chain first used it therapeutically.³ Together, with their scientific teams, they changed the concept of *anti-biotics*.
- Kilmer McCully, the prodigy pathologist from Harvard, first proposed the role of folate deficiency and the resultant homocysteinemia connection to cardiovascular disease in the late 1960s.⁴ His hypothesis caused his banishment from the pathology department at Harvard Medical School and Massachusetts General Hospital because of the clear conflict his theory represented to the then-dominant

¹This part of Chapter 7 was adapted by David Jones, MD, from two articles: Hyman M. Paradigm shift: The end of “normal science” in medicine; Understanding function in nutrition, health, and disease. *Alt Ther.* 2004;10(5):10-93. Baker SM. The medicine we are evolving. *Integrative Med.* Dec 2002/Jan 2003;1(1):14-15. Many thanks to Doctors Hyman and Baker, and to both journals, for permission to adapt these publications.

cholesterol model of atherosclerosis. Fortunately, he endured, working in relative obscurity at a small Veterans Administration hospital in Rhode Island, eventually vindicated by research from Europe. His model, in the current context of cardiovascular disease as primarily an expression of inflammation, has added to our understanding of metabolic and immunological connections to the development of atheromatous plaque, as well as other diseases associated with aging.

Medicine is also replete with discarded therapies that were well accepted at the time, such as the removal of the colon or all the teeth to treat chronic disease, or, more recently, low-fat diets for weight loss and the prevention of cardiovascular disease,⁵ and/or conventional hormone therapy for prevention of heart disease in postmenopausal women.^{6,7} We are again at the edge of a major transitional period.

Chronic Disease and the Failure of the Current Medical Paradigm

One of the most compelling, current problems in medicine is the failure of the conventional model of medical diagnosis and treatment to successfully address the burden of *chronic disease* that affects 125 million Americans in our society. Our current approach does not attempt, in a systematic manner, to effectively diagnose and treat the underlying causes of chronic disease, found in the complex interaction of genes, lifestyle, and environment. As a nation, we spend \$1.6 trillion on health care each year. This represents 15% of our gross national product (GNP) or approximately \$5,000 per person per year, or more than double the percent of GNP spent by any other nation on health care. Despite this, we are 12th out of 13 industrialized nations in 16 major indicators of the health status of a population, such as life expectancy and infant mortality.^{8,9} In fact we are 27th in life expectancy; Cuba is 28th.

Yet that may not be the most problematic issue. Recent data point to the dangers of the medical care that evolves from our current paradigm. Our own healthcare system can do great harm. Our system of disease management has been estimated to be anywhere from the 1st to the 3rd *leading cause of death* in our hospitalized patient population,¹⁰ resulting from hospital infections,^{11,12} atypical drug reactions,¹³ bedsores,¹⁴ medical errors,¹⁵ negligence,¹⁶ unnecessary procedures,

and surgery.¹⁷ The cost attributed to the harm caused by the chaos in our medical system has been estimated at over \$200 billion.

There are other significant problems endemic to our medical system and conventional medical paradigm:

1. The randomized controlled trial (RCT) is fundamentally ill suited to the assessment of lifestyle and nutritional interventions, individualized therapies, and long-latency deficiency diseases.¹⁸ (This topic is addressed, from a variety of perspectives, in both Chapter 5 and Chapter 6.)
2. The lack of publication of negative medical trials¹⁹ promotes a positive bias in the medical literature, suggesting an unrealistic proportion of successes and supporting the primacy of pharmacological interventions.
3. Direct-to-consumer pharmaceutical marketing,^{20,21} and heavy marketing of off-label uses of medications to physicians, including conventional hormone replacement therapy,²² create misinformation and encourage inappropriate prescribing practices by healthcare providers.^{23,24}
4. The many financial conflicts of interest^{25,26} inherent in the practice of funding research by private industry skew the emphasis on what should be studied and lead to suppression of conclusions that don't suit the funding source.^{27,28,29,30} One of the well-known examples of the latter was the research-based comparison between generic thyroxine and Synthroid. The pharmaceutical company prevented the publication of the study that it had funded because the outcome was not favorable to the trade name drug.^{31,32} With the exception of the National Institutes of Health and some private foundations, most of the research agenda is set by the pharmaceutical industry.
5. The funding, control and orchestration of most postgraduate education for physicians by the pharmaceutical industry^{33,34} lead to a clear bias for the primacy of pharmacologic interventions.^{35,36,37}

In addition, recent research suggests that more of the same care is not necessarily better. In areas where there are more physicians, there is a higher cost of care. There is also less patient satisfaction and worse outcomes than comparable areas with a lower cost of care.^{38,39} Studies of compliance with agreed-upon standards for care and prevention show that, in spite of higher costs of medical

care within the U.S., these standards are not met. There is a frequent lack of implementation of clinical science to clinical practice. For example, only 40% of patients receive aspirin after myocardial infarction.⁴⁰ A recent study of adults in 12 metropolitan areas found that only 54.9% of patients received the recommended preventive, acute, or chronic care, using 439 indicators in 30 acute and chronic conditions. The authors conclude, *"The deficits we have identified in adherence to recommended processes for basic care pose serious threats to the health of the American public. Strategies to reduce these deficits in care are warranted."*⁴¹

The Fallacy of Misplaced Concreteness

Lara Pizzorno, MA Div, MA Lit, LMT

Alfred North Whitehead's "fallacy of misplaced concreteness" is essentially a more logically rigorous statement of the common saying that "we err when we mistake the map for the territory." When humans interact with the world, we interpret the full experience via abstraction; we generalize from the specific observation (the "concrete") to create an idea. This is essential and logically acceptable, so long as we do not equate, and therefore significantly diminish, the actual experience with our working conception of it.

Unfortunately, we often do confound the concrete experience with the abstract idea, assuming our abstractions equal the totality of the reality. The tunnel vision which results prevents us from seeing more of what is actually before us. Science is not free of this error, with the result that new insights are typically met with hostility, and their application and benefits suppressed an average of 50 years before joining the ranks of what is considered the "standard of care."

As Whitehead cautions, "It is impossible to over-emphasize the point that the key to the process of induction [the *sine qua non* of scientific reasoning], as used either in science or our ordinary life, is to be found in the right understanding of the immediate occasion of knowledge in its full concreteness We find ourselves amid insoluble difficulties when we substitute for this concrete occasion a mere abstract"*

Avoiding the fallacy of misplaced concreteness is not a task to be underrated by even the most scientifically adept. Such assumptions "appear so obvious that people do not know what they are assuming because no other way of putting things has ever occurred to them."

Whitehead reminds us that "Almost all really new ideas have a certain aspect of foolishness when they are first produced," possibly due to the fact that we form our systems of thought "by the rough and ready method of suppressing what appear to be irrelevant details. But when we attempt to justify this suppression of irrele-

Many professionals within conventional medicine feel that the most important single reason for the deficits in our healthcare system is that we are locked into an old paradigm in medicine, "normal medicine."^{42,43} The model we use to diagnose and treat disease is based on "normal" science; the single-invader, single-disease, and single-drug model of medicine. While practitioners of the healing arts are schooled in the basic sciences of anatomy, physiology, biochemistry, cell biology, genetics, epidemiology, pathology, and pharmacology—each of which encompasses its own science—no body of knowledge exists within the dominant medical culture that can be construed as "medical science."⁴⁴

vance, we find that, though there are entities left corresponding to the entities we talk about, yet these entities are of a high degree of abstraction." Whitehead identified this problem as the primary obstacle to the advancement of science; it occurs when we allow our paradigm to limit our powers of observation.

In medical terms, the fallacy of misplaced concreteness appears in the form of the abstract entities called "diseases," which are simply a constellation of symptoms that often appear together, not an actual entity. While grouping symptoms in this manner is convenient, if the abstraction controls the interaction we have with the patient, we hamper our ability to see the individual who exhibits any symptom or grouping of symptoms (disease) in his or her unique way. In addition, by narrowing our focus to an abstract entity we call "migraine" or "irritable bowel syndrome" or "diabetes," we limit our inspection of the individual's dysfunctions to a predefined set of details, thus potentially missing what may be crucial for that person.

Scientific studies that regress to the mean exemplify this fallacy. The data based on the "representative sample," having lost all the specificity that defines a real human being, are then used to provide recommendations most applicable to an equally "representative" individual, in other words, to no one at all. Such findings tell us everything we need to know about someone who doesn't exist.

Functional medicine offers us both an awareness of how the fallacy of misplaced concreteness operates to limit the effectiveness of medicine, and a way to cut through it. Only the integration of (necessarily) abstract science with concrete individual specificity—the patient-centered, individualized approach that is the hallmark of functional medicine—will enable us to provide a much more accurate and effective assessment.

*All quotations from Whitehead AN. *Process and Reality*.

Section II

Principles of Functional Medicine

We have yet to embrace the new paradigm that, for the first time, allows us to personalize medicine. We have the opportunity to focus on optimizing function and enhancing health by understanding the complex high-order functioning of the human being. The new paradigm allows us to remediate disease, not by symptom suppression, but by assessing and treating the cause of dysfunction and illness. Van Ommen, in “The Human Genome Project and the Future of Diagnostics, Treatment and Prevention,” published in *The Lancet* in 1999, foretells this paradigm transition in medicine:

The combination of large-scale gene-expression analysis with pharmacological and nutritional studies will ultimately allow the stratification of individuals by their genetically determined abilities for drug and nutrient metabolism. Tailor-made treatments and lifestyle regimens will improve the effectiveness of therapies and reduce side effects. This will apply equally to monogenic disease and more complex gene-environment interaction disorders, like cardiovascular disease, cancer, hypertension, arthritis, migraine, epilepsy, Parkinson's disease, and Alzheimer's disease.⁴⁵

How Do We Change Paradigms?

In order to move today's model toward the future, we need to think differently. This functional school of thought does not deny the usefulness to the patient and physician of diagnostic groups that allow us to identify in some codified way “what the patient has.” We are careful to keep in mind, however, that a diagnosis is an idea we form about groups of people and properly belongs to the group, not to an individual. Making a diagnosis in the realm of chronic illness—such as the many conditions of chronic inflammation whose names end in “itis,” as well as autism, schizophrenia, depression, anxiety, cardiovascular disease, and a host of other recognized diseases—is for us not the end of a diagnostic road, *but only the first step*. The fundamental subject of medical concern is the human individual. The logic of inquiry rests on two questions of need:

- Does this person have an unmet individual need?
- Does this person need to be rid of something toxic, allergic, or infectious?

These principles are antithetical to the implicit emphasis of the current conventional medical paradigm, which could be described as follows:

- The fundamental subject of medical concern is disease.

- The inquiry as to health rests first on the naming of the patient's disease.
- Treatment is prescribed for the disease.

In the past, the legacy and momentum of our focus on acute illness have permitted us to remain disease-focused long after chronic illness replaced acute illness as the dominant problem in our modern, industrialized, hygienic society.⁴⁶ The medicine we are developing begins to address the following linguistic, statistical, and logical errors of the present paradigm of conventional medicine:

1. The concept that diseases are entities and can cause symptoms is entirely without scientific support. It is a linguistic error that forges a false map in the imagination of professionals and lay people.⁴⁷
2. The idea that each patient's diagnostic and treatment options can be based on determinations of averages is a misuse of statistics when it serves as a diagnostic and therapeutic guide for each unique individual.
3. The maxim that assumptions to explain an event should not be multiplied beyond necessity (Occam's razor) is the logical partner of the one-disease, one-treatment approach of mainstream medicine, particularly in the framework of chronic illness.
4. Medicine is the only field claiming a scientific basis in which general systems theory⁴⁸—i.e., that everything is interconnected—has not become the acknowledged basis for inquiry. Linear causality remains the accepted basis for medical etiology.

Despite the crumbling of the healthcare system around us,^{49,50} we have held onto this system of differential diagnosis, biochemical homogeneity, and pharmaceutical therapy as the answer to most chronic lifestyle and long-latency nutritional deficiency diseases. However, there is an alternative model for organizing and perceiving the problems in modern terms. There are a number of organizing principles and themes that underlie nearly all disease (see Chapter 2). This new medical paradigm emerges from the basic and clinical sciences literature. The exploration of the needed shift from our current model to the origins of illness and the maintenance of health, as well as the identification of appropriate investigations, interventions, and therapies for chronic, complex illnesses, both require a new intellectual architecture. The explication of a functional methodology is the central mission for this textbook.

A New Paradigm: Understanding and Enhancing Function

The science of medicine is perhaps the most frequently cited case of increasing specialization seeming to follow inevitably from increasing knowledge, as new cures and better treatments for many diseases are discovered. But as medical biochemical research comes up with deeper explanations of disease processes (and healthy processes) in the body, understanding is also on the increase. More general concepts are replacing more specific ones as common, underlying molecular mechanisms are found for dissimilar diseases in different parts of the body. Once a disease can be understood as fitting into a general framework, the role of the specialist diminishes. Physicians ... may be able to apply a general theory to work out the required treatment, and expect it to be effective even if it has never been used before.⁵¹

There is much in medicine and science that we cannot perceive with our current way of seeing. A new framework and new organizational concepts are needed in a science with very few true “theories.”⁵² Linus Pauling remarked years ago that “although medicine is largely based on the sciences, it has not yet become a science.”⁵³ We need a unifying theory of health and disease. We are only now on the verge of forming a clear picture of what that might look like.

A theory can be defined as “a set of facts, propositions, or principles analyzed in their relation to one another and used, especially in science, to explain phenomena.”⁵⁴ Scientific theory, unlike hypothesis, is most often the result of years of investigation. Medicine has come of age and we are at the transitional edge of development of an entirely different gestalt and theory of health and disease. The science of medicine today is maturing and the old concept of the single agent (bacterium) causing a single disease (infection) treated with a single molecule (antibiotic) is being replaced by our understanding of complex, higher-order functions. We are finally able to peer into the underlying mechanisms of disease and aging, illuminated by the light of genomics, proteomics, metabolomics, and nutrigenomics.

Medicine is nearly ready to discard the old descriptive, phenomenological approach that emerged from the exigencies of medical practice in the early 20th century, where infectious disease was primary and the Pasteur model of outside invaders ruled. The organization of medicine into sub-specialties is an artifact of descriptive medicine that bears little relevance to biological principles. The current classification of diseases (ICD-9)

is now less useful in understanding mechanisms and guiding innovative therapies in health and illness. Finally, we can move toward understanding and treating disease with a dynamic, functional model based on an intricate understanding of the nature of the interaction of the genome with the environment, especially in the field of nutrigenomics.⁵⁵

The story of the role of nutrients in health and disease is a useful model to help us shift from a medical model based on pathology to one based on deviations from optimal function, with an understanding of the process of de-volution of health into chronic, complex illnesses. A fundamental change in perspective has occurred with the development of genomics, proteomics, metabolomics, and the evolution of nutrigenomics.⁵⁶ Nutrigenomics is the use of nutrients of varying and sometimes high doses to influence gene expression, with the goal of not simply treating disease, but also of optimizing function.⁵⁷ The development of the “-omics” and the applications of nutrigenomics are poised to change medicine forever from a pathology-based science to a function-based science.⁵⁸

Example of the New Paradigm: Nutrients Beyond Deficiency Diseases

The old paradigm of diagnosis and classification of diseases into organ system pathologies (corresponding fairly closely to medical specialties) becomes less meaningful in the light of our understanding of the basic mechanisms of dysfunction in the human body. One disease may have multiple causes, and one initiating factor may cause multiple diseases. Atherosclerotic cardiovascular disease (CVD) and celiac disease provide clear examples of this concept.

We recognize cardiovascular disease by its pathology: atherosclerotic plaques. However, the development of plaques can be triggered by multiple factors. These include insulin resistance,⁵⁹ folate deficiency and hyperhomocysteinemia,⁶⁰ occult infections,⁶¹ heavy metal toxicity,^{62,63} inherited dyslipidemias, stress, and other factors that increase inflammation.⁶⁴

The diagnosis and treatment of each of these antecedent conditions varies, and the success of medical therapy rests on making the proper assessment of the etiologic factors involved (and they are often multiple).⁶⁵ Prescribing the classic low-fat diet, usually high in refined carbohydrates, along with a beta-blocker and a statin for CVD can—counter to expectation—actually

Section II

Principles of Functional Medicine

exacerbate the underlying problem in the patient with insulin resistance, or may miss entirely the key underlying mechanism (e.g., occult infection) in a different patient. Both are precursor conditions that can lead to the end point of CV dysfunction. Let's illustrate this point with some patient stories.

A 56-year-old patient with severe CVD, after interventions including two angioplasties and a CABG (coronary artery bypass graft), suffered a stroke. The evaluations and treatments he experienced prior to his stroke were considered "standard of care" for his diagnosis. However, with further evaluation after his stroke, through the lens of functional assessment, he was found to have a marked elevation of homocysteine (22 mmol/L with normal 6–8 mmol/L). He was tested genetically and found to have a specific genetic uniqueness, homozygous 677C to T polymorphism of MTHFR (methylentetrahydrofolate reductase). This SNP (single nucleotide polymorphism) produces a variant enzyme that requires extraordinarily high doses of folate to facilitate coenzyme binding and MTHFR enzyme activity. His treatment plan focused on his genetic, proteomic, and metabolomic uniqueness. With appropriate nutrient intervention, his serum homocysteine equilibrated into the normal range, and he had no further demonstrable progression of his atherosclerosis.⁶⁶

Another patient report exemplifies both the functional medicine methodology as well as the problems inherent in our current disease classification system. At 57, the patient described himself in general good health, eagerly planning a climb of Mt. Kilimanjaro. However, it was noted in his comprehensive workup that he took 15 different medications: prescriptions for colitis, asthma, alopecia areata, and hypertension. He was being treated in a standard manner by an internist, a gastroenterologist, a pulmonologist, and a dermatologist, all of whom made the correct "diagnosis" and provided the appropriate medications for each diagnosis. However, by filtering the patient's signs and symptoms through the lens of underlying pathways, it was apparent that all of the patient's "diseases" had an inflammatory component that manifested across organ systems (and specialty domains). None of his physicians had searched for the underlying mechanism, nor apparently considered this assessment (an across-systems inflammatory process) relevant. Their treatments were based solely on diagnoses relevant to their specialties. An eval-

uation program ensued, looking for underlying mechanisms of dysfunction that could explain his disorders. With appropriate investigation, it was found that most of his diagnoses could be explained by something he was eating—gluten-containing foods—that caused the "many-headed hydra" of his inflammatory disorders.^{67,68} Tests confirmed the diagnosis of celiac disease, that had been missed for over 40 years. Within six months, he was off most of his medications, lost 25 pounds, and stabilized his blood pressure. He had no more symptoms of asthma, his bowel movements normalized, and his hair grew back. A 2002 review of celiac disease in *The New England Journal of Medicine*⁶⁹ catalogued the myriad diseases that can be caused by immune-mediated gluten sensitivity, including anemia, osteoporosis, autoimmune diseases, thyroid dysfunction, schizophrenia, and psoriasis. Each of the patient's conditions could have been triggered by multiple factors; but, for him, eating gluten-containing foods was the cause of his symptoms. His genetic susceptibilities required that he not eat a particular food protein in order to maintain health and prevent triggering his symptoms.

The Diverse Roles of Nutrients

How we think about essential nutrients in general has been shaped by the vitamin deficiency diseases through which they were historically discovered. Vitamins are still defined by single deficiency diseases, such as pellagra, beriberi, scurvy, and rickets. That thinking is the basis for the current dietary reference intakes (DRIs), which recommend the minimum amount to prevent deficiency diseases, not the variable amounts needed by a polymorphic population for optimal health—sometimes hundreds of times the DRIs. Most physicians and consumers do not realize that DRIs are based simply on the minimum amount of a nutrient necessary to prevent an index deficiency disease. Applied clinical medicine has failed to recognize that nutrients are multifunctional substances with many roles. For example, in recent reviews,^{70,71} vitamin D has not only been implicated in prevention of rickets, but may have a role in treating or preventing heart disease, multiple sclerosis, polycystic ovary syndrome, depression, epilepsy, type 1 diabetes, and cancer. Folate not only prevents megaloblastic anemia, but also prevents neural tube defects, and is a key factor in preventing many cases of cardiovascular disease, dementia, depres-

sion, and colon and breast cancer.⁷² Magnesium plays a role in over 300 enzyme reactions.

Conventional thinking has been biased against the therapeutic use of vitamins in disease and has avoided the question of whether vitamins have a role in optimizing health.⁷³ Study of nutrients over the long term has been complicated by the fact that the desired outcomes being tracked involve primarily the absence of problems rather than a defined dysfunction or remediation. This is in direct opposition to pharmaceutical agents, which are meant to alter pathology. Nutrients restore normal function; they do so by optimizing normal biological functions, mostly through their actions as coenzymes in biochemical reactions.

We have approximately 30,000 genes. The most common type of variation in the human genome is the SNP, where a single base differs between individuals (being A instead of G, for example). SNPs occur about once every 1000 base pairs in the genome, making up the bulk of the 3 million variations found in the genome. The frequency of a particular polymorphism tends to remain stable in the population. (Genome information from genome.wellcome.ac.uk.) These SNPs create unique biochemical needs within the population. One-third or more of them affect coenzyme-binding sites for vitamins or nutrients, and therefore have a role in disease and dysfunction.⁷⁴ Bruce Ames, in his landmark review of genetic variant enzymes and vitamin therapy, stated: "Our analysis of metabolic disease that affects cofactor binding, particularly as a result of polymorphic mutations, may present a novel rationale for high-dose vitamin therapy, perhaps hundreds of times the normal dietary reference intakes (DRI) in some cases."⁷⁵

Our current nutritional recommendations do not accommodate the broad and varied roles of nutrients in human biology. Also absent is the consistent clinical question: "What does this individual need that she or he has failed to get?" For example, the person may need to add vitamins, minerals, essential amino acids and essential fatty acids, accessory and conditionally essential nutrients.⁷⁶ In many cases, a single nutrient may catalyze hundreds of biochemical reactions; suboptimal levels may lead to cellular and molecular dysfunction that is not recognized as a "deficiency" disease.⁷⁷ The notion that higher doses may be needed for the optimal functioning of the total organism is not widely taught, despite new evidence that suboptimal nutrient status may contribute to "long-latency" defi-

ciency diseases that are epidemic, such as cardiovascular disease, cancer, osteoporosis, neurodegenerative disease, and immune dysfunction.⁷⁸

Nutritional science has been seen as a secondary factor in health, something best left to the dietitian.⁷⁹ Historically, nutrition was taught at the state agricultural schools in the department of home economics. The "real" science was, of course, being pursued by the scientists at the universities, in the departments of chemistry, physics, and biology. Until recently, physicians educated within this biased system of learning have abdicated their responsibility to study the science and practice of nutrition. Clear nutritional guidelines and consensus have been hard to achieve despite emerging evidence of importance. We need to cultivate different tools of assessment and research that allow us to better answer questions about nutrition and nutraceutical therapies.⁸⁰

Long-latency Disease: A Further Example of the New Medicine

Dr. Robert Heaney is a Professor of Medicine at Creighton University in Omaha, Nebraska. He won the 2003 E.V. McCollum Award of the American Society for Clinical Nutrition in recognition of his contributions to nutritional science and medicine, particularly in the field of osteoporosis and calcium physiology. In his E.V. McCollum Award lecture, he stated that the fundamental flaw in the establishment of recommended nutrient intakes is the presumption that if a nutrient intake is sufficient to prevent the index deficiency disease, then it is adequate for the optimal functioning of the total organism. He suggested that this narrow viewpoint overlooks two important facts. First, there are long-term consequences of lesser degrees of deficiency that may operate through similar mechanisms as the index disease; and second, there may be very different mechanisms involved in the development of long-latency deficiency diseases.

In his lecture, he also tackled the difficult question of the adequacy of the standard research tools in this area of multi-factorial causality (see also Chapters 5 and 6, plus this chapter's discussion, *How Do We Change Paradigms?*). He suggested the increased use of observational research to better infer causality in nutrition. The appropriate methodology for ferreting out the causal agents for the absence of a problem—research for benefit rather than harm—runs straight into the controversy surrounding the belief that double-blind RCTs are the

gold-standard methodology for *all* scientific studies. He proposed that we can safely use the usual principles for causal inference from observational data in the nutritional context:⁸¹

... biological plausibility, correct temporal sequence, dose-response relations, experiments of nature found in inborn errors of metabolism and demonstration of causal connection in animal models. These principles are all well understood in a general way, and what ... may have been lacking up till now was the conviction within the field of nutrition that long-latency deficiency diseases exist, that they are nutritional problems, and that the use of such inferential and investigative stratagems may be both appropriate and necessary.

In the paper he adapted from his E.V. McCollum Award Lecture ("Long-latency Deficiency Disease: Insights from Calcium and Vitamin D"),⁸² he lays the groundwork for a new conceptualization of the role of nutrients in health and disease. In effect, he turns nutritional science on its head by saying, "Prove to me that we *don't* need higher levels of nutrients for health."

Because the current recommendations are based on the prevention of the index disease only, they can no longer be said to be biologically defensible. The pre-agricultural human diet, insofar as it can be reconstructed, may well be a better starting point for policy. ... Such a diet would have had at least some of the following features: high protein intake, low glycemic index, high calcium intake, high folic acid intake, an alkaline ash residue and high vitamin D input. It is in this nutritional context that human physiology is adapted. The burden of proof should fall on those who say that these more natural conditions are not needed and that lower intakes are safe.

He laments that nutritional science has been largely ignored by practicing physicians. His perspective finds support in Dr. Jim Kaput's more recent paper, "Nutritional Genomics: The Next Frontier in the Post Genomic Era."⁸³

Dr. Heaney used the examples of calcium, vitamin D, and folate to illuminate the multi-functional nature of nutrients in complex, higher-order functioning in biology. Vitamin D has been classically associated with the prevention of rickets and osteoporosis. Current recommended levels for vitamin D intake are benchmarked to the prevention of rickets, the presumption being that if patients do not have rickets or osteomalacia, then their vitamin D intake is adequate. Evidence indicates otherwise; increasing vitamin D levels in the blood to the upper levels of the reference range improves calcium absorption efficacy by two-thirds,

reducing osteoporotic fracture risk by one-third. Additionally, vitamin D has other roles. It has been shown that serum 25(OH) vitamin D concentrations are inversely associated with prostate and squamous cell cancers. The underlying mechanism for this effect appears to be as follows: people with low sun exposure or increased skin pigmentation are less able to make calcitriol (biologically active 1,25-dihydroxyvitamin D) within tissues in an amount adequate to control cell proliferation and reduce oncogenesis. Heaney hypothesizes that protective serum levels of 25(OH) vitamin D, for prevention of oncogenesis, may be much greater than current reference values.

In that same paper, he describes the multiple conditions that may arise from a single nutrient deficiency, the multifunctional nature of nutrients, and the need for higher intakes for optimal health: "*Inadequate intake of specific nutrients may produce more than one disease, may produce them by more than one mechanism, and may require several years for the consequent morbidity and mortality to be sufficiently evident to be clinically recognizable as 'disease.'*" He also suggests that the intakes of nutrients required to prevent the non-index diseases are often higher than required to prevent the index disease; for example, preventing osteoporosis requires four times the vitamin D needed to prevent rickets; similarly, preventing neural tube defects requires four times the intake of folate needed to prevent anemia.

Nutrigenomics: An Organizing Principle of the New Paradigm

Imagine a drug that could cure within days or weeks a fatal disease using a very small dose, without toxicity, and with a 100% success rate. Such a drug does not exist and probably will never exist; but this is the power and potential of nutrients. They function within the genetic and evolutionary necessities of the cell to enhance and facilitate optimal biological functioning. They are vital to our very survival. Their effectiveness in curing deficiency diseases is dramatic, but their role in the prevention and management of long-latency chronic diseases is more frequently relevant to most daily clinical practice.

Many patients worry about the dangers of medications; their compliance with pharmaceuticals is disturbingly low, as 20% of prescriptions go unfilled and 85% are never refilled.⁸⁴ The decision to see a doctor should not be measured by concern for risk and danger,

but by the opportunity and anticipation of enhanced health and well-being. Herein lies the potential of nutrigenomics and the new medical paradigm that allows us to understand the integrative function of complex organisms, and the essential and primary role of nutrition in maintaining that function. This new paradigm shifts us from disease treatment and disease prevention to health promotion.⁸⁵

The study of nutrigenomics⁸⁶ spearheads a radical transformation in medicine akin to the change in physics that occurred when the deficiencies of Newtonian physics were illuminated by discoveries in quantum mechanical physics and Albert Einstein's theory of relativity. We have entered an era where genetic predisposition replaces Mendelian genetic determinism, where biochemical individuality replaces biochemical homogeneity, and where the importance of the biological terrain or internal milieu exceeds that of the external invader. However, acceptance of the change, seeing what is right in front of us, is difficult. As R.D. Laing states in *The Voice of Experience*,⁸⁷ "Our way of looking is not easily disturbed by what it sees, let alone by what it cannot see."

Kaput summarizes the concepts of nutrigenomics, a foundational component of the new functional paradigm of medicine, in a way that should give us pause and cause us to examine our outdated beliefs:

The interface between the nutritional environment and cellular/genetic processes is being referred to as "nutrigenomics." Nutrigenomics seeks to provide a molecular genetic understanding for how common dietary chemicals (i.e., nutrition) affect health by altering the expression and/or structure of an individual's genetic makeup. The fundamental concepts of the field are that the progression from a healthy phenotype to a chronic disease phenotype must occur by changes in gene expression or by differences in activities of proteins and enzymes, and that dietary chemicals directly or indirectly regulate the expression of genomic information. We present a conceptual basis and specific examples for this new branch of genomic research that focuses on the tenets of nutritional genomics: 1) common dietary chemicals act on the human genome, either directly or indirectly, to alter gene expression or structure; 2) under certain circumstances and in some individuals, diet can be a serious risk factor for a number of diseases; 3) some diet-regulated genes (and their normal, common variants) are likely to play a role in the onset, incidence, progression, and/or severity of chronic diseases; 4) the degree to which diet influences the balance between healthy and disease states may depend on an individual's genetic makeup; and 5)

dietary intervention based on knowledge of nutritional requirement, nutritional status, and genotype (i.e., "individualized nutrition") can be used to prevent, mitigate, or cure chronic disease.⁸⁸

Nutrigenomics is a fulcrum point for placing a lever of change in our current medical paradigm. Kaput describes the robustness of this paradigm ("the next frontier in the post genomic era") as having the potential to radically change our approach to health and disease. In fact, for the first time in medicine, we have the opportunity to not only treat disease but to create a context for health. The adoption of new organizing principles and concepts that form the basis of the new medical paradigm can help us successfully navigate health and illness in the 21st century.

Development of the Knowledge Base in Biochemical Individuality

DeAnn Liska, PhD

Introduction

Our ideas of health and disease have changed dramatically in the past several decades. Once, we talked of illness as something we *caught* and could *control*; now, we talk about being susceptible to the forces around us because of our genes. Once, we understood the role of genetics in disease as important only with respect to the defined "inherited diseases of metabolism," in which a dysfunctional gene that directly leads to a disease (such as maple syrup disease, or phenylalaninemia) is passed on from generation to generation. An inherited disease of metabolism is discrete: you either have it or you don't. And, if you have it, you can manage it but you can't eradicate it.

As seen in the *Cathy* cartoon on page 64, our understanding of "genetic predisposition" has been influenced by the concept of genetic determinism. We have believed that the genes we inherit are static and, like flood waters that grab us and pull us downstream against our will, we must succumb to a more powerful force. However (and fortunately), the emerging data from investigations that focus on understanding the integration of environmental triggers with genetic constitution indicate that we can manage most of these predispositions. Once we know where and how we are susceptible, we can improve the match between our

CATHY © 2001 Cathy Guisewite. Reprinted with permission of UNIVERSAL PRESS SYNDICATE. All rights reserved.

environmental exposures and our own unique profiles to improve health outcome and longevity. This is the promise of 21st century medicine. And, since our genetic constitution is unique, this is the historical and scientific basis for biochemical individuality.

Biochemical Individuality in Functional Medicine

Biochemical individuality is not a new topic in functional medicine; it has been one of the underlying principles since the early 1980s. Although the unique genetic profile of an individual may be the most obvious way in which we are all “biochemically individual,” in functional medicine this concept has long been defined as comprising the interaction of genetics and environment. We understand biochemical individuality to mean that each individual has a unique physiological and biochemical composition, based upon his or her individual genetic make-up, that interacts with the

individual’s specific environment—that continuous exposure to “inputs” (experiences, nutrients, activity, toxins, medications, etc.) that influences our genes. It is this combination of factors that accounts for the endless variety of phenotypic responses—those biochemically unique individuals we see every day in our offices and clinics. Biochemical individuality is dependent upon the DNA that is present at the moment of conception in each individual and, therefore, a discussion of biochemical individuality includes understanding how DNA is expressed and influenced.

A Brief Look at the History of Biochemical Individuality

The first work upon which the field of genetics is based came from the Augustinian monk, Gregor Mendel, who found that phenotypic traits in peas could be

passed down from generation to generation. His work was published in 1866, but remained in obscurity until around 1900, when it was rediscovered and promoted by several scientists. Although the concept of genes and inheritance was taking a forefront at the time, Archibald Garrod cautioned in 1902 that the chemical behavior (metabolism) of different individuals varied in ways that were independent of genetics. Dr. Garrod discovered alkaptonuria, which led to the understanding of phenylketonuria and the role of phenylalanine-restricted diets in its management. Although he studied a classic model of inherited disease, he noted that “variations of chemical behavior ... are probably present everywhere in minor degrees” and stated “as no two individuals of a species are absolutely identical in bodily structure neither are their chemical processes carried out on exactly the same lines.”⁸⁹

The renowned biochemist, Roger Williams, PhD, was the first to use the term “biochemical individuality” in his classic book of the same name, published in 1956.⁹⁰ In this work, he described how the anatomical and physiological variations among people are related to their varied responses to the environment and to their differing nutritional needs. He pointed out that even identical twins could differ in their requirements for optimal function, based upon the fact that they developed in different environments *in utero*, a concept that is beginning to accumulate scientific support (discussed further below). In addition, he noted that although identical twins share the same genes their differing nutritional and developmental environments also can contribute to different expression of these genes as they grow older.

Dr. Williams came upon the idea of biochemical individuality in his work with nutrition and chronic disease. In 1950, he published an article in *The Lancet* titled “The Concept of Genetotrophic Disease,” in which he proposed a role for nutrients in the prevention of chronic disease.⁹¹ Genetotrophic diseases are those for which genetic uniqueness creates a demand for specific nutrients beyond the average intake to facilitate optimal function and prevent premature disease. Dr. Williams theorized that when those specific needs are not met in a given individual, disease results. He further proposed that the major chronic degenerative diseases of aging are genetotrophic. That is, the unique genes of each individual require different levels of nutrition and a specific lifestyle for optimal health. The con-

sequences of not meeting the specific needs of the individual are expressed, over several decades, as degenerative disease “of unknown origin.” In his model, at the genetic level, an individual has a need for a different level of nutrients to promote proper phenotypic expression. If that need is not met, the resulting “under-nutrition” will manifest as chronic disease in midlife.

Although medicine did not initially embrace the concepts of genetotrophic disease and biochemical individuality, they have consistently gained more attention since the 1980s. It is now fashionable within science to talk about “individual responses.” Much of this progress has come as a result of the technological advances that have allowed us to dissect DNA. Over the past two decades, individual genes have been identified and many of their functions have been described. The dogma of gene expression (Figure 7.1) was defined. The understanding of viral integration into the genes in specific cells, and the identification of mitochondrial DNA as separate but integrated in every cell have also enhanced our realization that each and every person is unique at the level of DNA.

Figure 7.1 Dogma of gene expression

A schematic from the chromosome to gene in a cell. A gene comprises a small section of DNA on a chromosome. Each gene has two alleles (the two copies, one from each parent). A person can have two different alleles (polymorphisms), which is called a heterozygote. If the two alleles are the same, it is called a homozygote.

Section II

Principles of Functional Medicine

The Human Genome Project represented a major international commitment among scientists and provided the human genome sequence for 99% of the gene-coding DNA in April 2003, which corresponded with the 50-year celebration of Watson, Crick, and Franklin's discovery of the structure of DNA. The implications of this work, especially as they relate to medicine, are still unfolding, but they have already begun to change the way we view health and disease. As discussed in a 2003 review in the *Archives of Internal Medicine*:⁹²

The individualization of treatments has been one of the strongest therapeutic tools, while also one of the greatest challenges of the pregenomic era. Individuals with apparently identical clinical problems may respond very differently to a specific treatment, and this has generally been accepted as an insoluble problem. However, with the availability of comprehensive genetic and molecular profiles, it will probably become possible to respond to disease with individualized strategies based on genetic profiles.

The promise is to be able to fully use genetic information for individualized clinical management plans; the challenge remains to understand the multiple connections and patterns that are emerging from these data. This field is extremely active, and new findings continue to emerge each day. The areas most developed to date are briefly reviewed below, but the reader is encouraged to stay abreast of the emerging research on a regular basis.

The Human Genome and Single Nucleotide Polymorphisms

DNA is described by its base pair composition. DNA is composed of four molecules called bases: A (adenine), G (guanine), T (thymine), and C (cytosine). A strand of DNA is composed of these four bases in different orders, like beads on a string. Each strand of DNA has a complement strand (its pair), and the bases pair off as A to T, and C to G. Therefore, the complement or pair strand of DNA is like a mirror copy that is used to provide a copy within the cell. The primary strand is the one that provides the blueprint for mRNA through a process called transcription. The mRNA is then transported to the cytoplasm, where protein is made in a process called protein translation (see Figure 7.2). The process of reading the DNA is called gene expression. Common definitions in the field of genetics and molecular biology are provided in Table 7.1.

Figure 7.2 mRNA to protein

A schematic showing the general dogma of gene transcription and translation. A gene is transcribed into RNA, which is transported to the cytoplasm as mRNA. The mRNA carries the information of one gene, and is translated to make protein in the cell's cytoplasm.

Today, we know that the human genome is composed of approximately 3,164.7 million base pairs, which contrasts to the smallest bacterium genome of 600,000 DNA base pairs. Human DNA is arranged into 23 (physically separate) chromosomes, each of which contains between 50 million and 250 million base pairs. The human genome is estimated to encode 30,000 genes. An average gene-encoding region on human DNA is around 3,000 base pairs, but gene size can vary greatly from very small to extremely large (over 2 million base pairs). The gene density of DNA is about one gene per every 100 kilobases. The functions associated with over 50% of the discovered genes are unknown. Updates on the human genome can be obtained at the Human Genome Project Information site on the internet: http://www.ornl.gov/sci/techresources/Human_Genome/project/info.shtml.

Much of the DNA within the gene contains information that isn't transcribed, but acts to regulate the expression of the gene. This non-coding DNA is particularly important for signal transduction pathways. The amount of DNA in the human genome that directly encodes protein is only about 2% and each gene contains several areas of non-coding DNA that are involved

Table 7.1 Definitions for Common Terminology in the Study of Genes

Gene	The functional and physical unit of heredity passed from parent to offspring. Genes are pieces of DNA that contain the information necessary for making a cell, such as the information to make structural proteins and enzymes.
Genome	The DNA code that comprises the complete genetic composition of an organism. As an analogy, this would be the entire encyclopedia of information, or DNA, to encode one person. Each cell contains a genome, but a cell only uses the portions of the genome relevant for its specific functions.
DNA (deoxyribonucleic acid)	The chemical substance that forms the genome. DNA is composed of four specific compounds, or nucleotides: guanine (G), adenine (A), cytosine (C), and thymine (T).
mRNA (messenger RNA)	A fragment of RNA that is read from the genome (or DNA blueprint). An mRNA carries with it only the information related to one gene, so it is the molecule within the cell that transfers the information from the DNA, which contains the blueprint of all genes, for one specific gene that can then be transported to the site where the protein will be made. As an analogy, if DNA is the encyclopedia of a person's genotype, the mRNA is a photocopy of one page of that encyclopedia.
Gene expression	The process of making proteins from DNA, or reading the DNA.
Genotype	The internally encoded information of an organism (or genome).
Phenotype	The outward, physical manifestation of an organism (the interplay of environment and genotype).
Transcription	The process of making an mRNA from DNA that occurs within the nucleus of the cell. For example, during transcription, the section of DNA that contains the information for a specific gene is copied into an mRNA molecule, which is much smaller and can be transported to the site where proteins are made within the cell.
Translation	The process that occurs within the cell in which a protein is generated from mRNA. In this process, the mRNA is read by the cell's protein generation machinery to make a specific protein that can be used within the cell or transported to another site, where it will affect function.
Wild-type	The most common DNA sequence for a specific gene. This term is mainly used for comparative purposes in scientific literature to identify a standard sequence that can be compared to other sequences for identification of DNA mutations.
Mutation	A general term to describe a change in an individual's DNA sequence (genotype) from the defined wild type (the most common sequence, considered the standard for that gene). This change may or may not lead to a change in phenotype (e.g., point mutations, multiple mutations, deletions, duplications, somatic mutations).
Polymorphism	A difference in DNA sequence from the most common sequence that occurs at a consistent frequency and is maintained in the population. To be considered a polymorphism, a DNA sequence must be present in at least 1% of the population. Many polymorphisms result in proteins that are still active, but the activity differs (slower or faster) than the most common sequence.
SNPs (Single Nucleotide Polymorphisms)	A change at a single site (single base pair) in a DNA sequence as compared to the most common sequence that occurs in at least 1% of the population. SNPs can lead to proteins that are more or less active than those from the most common sequence, and are considered to account for much of the variability seen among different individuals (i.e., biochemical individuality).

Section II

Principles of Functional Medicine

in gene regulation (see Figure 7.3). The DNA that is not contained within the genes is known to function in managing structure and conformation of the DNA, which also influence whether a gene is recognized and transcribed within a cell; however, the specific function of much of the DNA in our cells is unknown.

Figure 7.3 Noncoding regions of DNA

A schematic showing the structure of a gene. Each gene in the DNA has exons (segments that will be included in the mRNA), and introns (segments that will be selectively removed before the RNA leaves the nucleus). The role of introns in gene expression is not fully understood, but they are thought to play a role in regulation of gene expression. Some polymorphisms that affect phenotype have been shown to occur in intron sections of genes, thereby altering a protein's activity by influencing how well the gene is expressed and ultimately how much protein is actually made.

Defining the structure and sequence of the human genome has helped us understand the genetic differences that occur as mutations. A mutation is any change in DNA over the most common sequence, called the wild type. A mutation can come in many forms: a whole section of DNA may be deleted; a large section may be inserted where it doesn't belong; a small deletion or insertion can also occur. Most of these, if they are large changes, lead to observed differences in structure or function, or even death *in utero*, and they occur in less than 1% of the population. Very small changes that alter the function of an enzyme, making it more active or less able to function, but not obliterating its function completely, occur more regularly. These types of changes are generally at one base site, and so they are called single nucleotide polymorphisms; they occur in at least 1% of the population.

Because SNPs are not an embryonic lethal mutation, or an inherited single-gene mutation that leads to a

severe disease or alteration of structure, they are maintained in the population and passed from generation to generation. It is estimated that around 3 million SNPs will eventually be identified; 1.8 million have already been found. SNPs can occur anywhere in the DNA, but the ones that occur on or around genes hold the most interest for researchers. Associating a SNP with a specific functional outcome holds promise for helping to personalize health care and prevention for individual patients; we may be able to intervene before a condition becomes established. [Note: Updates on SNPs can be found at the International HapMap Project Web site at: <http://snp.cshl.org/>.]

How SNPs Alter Function

SNPs can affect the phenotype of an individual in a variety of ways. A SNP in the body of a gene may encode a protein, such as an enzyme, leading to what seems to be a minor change in structure of the protein. In many cases, this is only one amino acid change, but the change can alter the activity of the protein such that it is more active (e.g., binds its substrate more tightly) or less active. The protein may have lower stability (so that it is present but at an apparently lower concentration), or higher stability (so the protein is at an increased concentration because it is broken down less quickly). SNPs can also occur in areas of the DNA that are involved in gene regulation but may not directly alter the protein, so that the gene is transcribed more or less readily. The ultimate effect of these SNPs can be seen as “tweaks” in the metabolic pathway functions. Individuals having these SNPs may not process and excrete a toxin as quickly as the general population, or their need for a nutrient cofactor may be higher because of lowered ability to bind a specific nutrient and maintain activity.

Not all SNPs have medical significance; determining those that most influence various conditions or responses to interventions is a challenge. Moreover, most of the SNPs that are relevant will lead to only a small change, such as a decrease in an enzyme's activity, but not the on-off type of change seen with heritable disorders of metabolism. Taken together with the multifactorial nature of metabolic pathways and the myriad influences on chronic diseases, the combined effects of different SNP patterns are likely to be of greatest value in understanding susceptibility to particular diseases or conditions.

Analyzing many SNPs at once can be done using microarray technology, but understanding the myriad patterns that emerge from this analysis will take many years of work. Therefore, the integration of these new findings is being seen first in cases in which one particular change (one SNP) is found to influence a response, such as in the metabolism of a drug that occurs primarily through one specific pathway. A few areas have led the way to integrating individualized genetic information in ways that are influencing medicine today, and those are reviewed below.

Adverse Drug Reactions and Pharmacogenomics

A widely cited study published in *JAMA* in 1998⁹³ brought to the fore a key issue in medicine: that pharmaceutical agents are one of the most commonly identified causes of adverse events. The pharmaceutical companies develop products based on the notion that one drug will work for everyone at the same dose, the “one-size-fits-all” model. However, the meta-analysis presented in the *JAMA* article indicated that 2.2 million patients (6.7%) had adverse drug reactions (ADRs) in 1994, and 106,000 patients (0.32%) died as a result of them. Moreover, the analysis used a conservative method to reduce any contribution from errors in administration, overdose, drug abuse, therapeutic failures, and “possible ADRs” and, therefore, the findings represent only drug reactions from properly prescribed and administered drugs. The conclusion was that adverse drug reactions from properly prescribed medications represent between the fourth and sixth leading cause of death in the United States. Although this publication spurred much comment after it appeared,⁹⁴ it identified a key area of concern that had not yet been fully accepted: adverse drug reactions occur in a high number of individuals with no direct explanation.

For several years after publication of this study, a number of articles on the mechanisms of ADRs were published. Researchers began to recognize that a key factor in ADRs is biochemical individuality—specifically, variability in drug metabolism due to polymorphisms in genes for drug metabolizing enzymes.⁹⁵ At a given dose of drug, the range in variability of patient responses is 4-fold to 40-fold (i.e., 400% to 4000%).⁹⁶ The president and CEO of New Jersey-based Orchid BioSciences has been quoted as saying that “more money is spent on adverse drug response than on drug development.”⁹⁷

Not only is the issue of adverse events a major concern, but drug efficacy is also influenced by biochemical individuality and is becoming a focus of discussion in medicine. For example, in a 2003 news story, Allen Roses, the worldwide vice-president of genetics at GlaxoSmithKline, observed: “The vast majority of drugs—more than 90%—only work in 30 or 50% of the people. I wouldn’t say that most drugs don’t work. I would say that most drugs work in 30 to 50% of people. Drugs out there on the market work, but they don’t work in everybody.”⁹⁸ For example, it is known that codeine is ineffective for pain relief in about 10% of the population. In order to be efficacious, codeine must first be converted to morphine in the body, a reaction that requires the cytochrome P450 enzyme CYP2D6, and 10% of the population has a SNP in the CYP2D6 gene that results in a less active protein.⁹⁹

The issue, then, is how to predetermine who will respond and who won’t and—even more immediate—who will respond with an ADR that may be fatal. This has led to the definition of the field of pharmacogenomics or pharmacogenetics. Research in pharmacogenetics began by identifying allelic variations in genes (primarily SNPs) and has expanded to include identifying new drug targets. All definitions for pharmacogenetics revolve around how the body uses and metabolizes pharmacologic agents.

A specific example of biochemical individuality and drug response can be shown with the thiopurine S-methyltransferase (TPMT) protein, which is the enzyme that breaks down the drug 6-mercaptopurine. This drug is a chemotherapeutic agent used for acute lymphoblastic leukemia, a deadly form of cancer that afflicts approximately 2,400 children in the United States every year. Between 10 and 15% of people metabolize this drug either too quickly (resulting in lowered efficacy of a standard dose of the drug) or too slowly (resulting in accumulation of lethal levels), based upon the presence of a mutation in the TPMT gene. A genetic test now exists to determine whether this mutation is present before the drug is given to a patient.

Warfarin is a narrow-spectrum anticoagulant drug with a wide interindividual variation in dosage. The risk of serious hemorrhage during warfarin therapy ranges from 1.3 to 4.2 per 100 patient years of exposure. Therefore, it is important to find ways to quickly and effectively determine the best dosage for a patient. Warfarin is composed of two enantiomers—R-warfarin

and S-warfarin—which are metabolized differently. The S-warfarin is metabolized by the 2C9 cytochrome P450 (CYP2C9), whereas the R-form is metabolized by the CYP1A2 and CYP3A4 enzymes. The CYP2C9 gene is known to have two relatively common SNPs, one resulting in an enzyme that is only 5% as active as the wild type, and another that leads to an enzyme that is 12% as active as the wild type.

To understand the role of these polymorphisms in warfarin therapy, Aithal et al.¹⁰⁰ compared the SNP pattern in low-dose patients (1.5 mg per day or less) with control patients and found patients in the low-dose group were six times more likely to have a low-activity SNP than the control patients. Moreover, further studies have demonstrated that using the common 5 mg per day dose initially in patients with the SNP that leads to the most compromised 2C9 activity causes an increase in the international normalized ratio and a significant risk of bleeding.¹⁰¹ Patients with SNPs in 2C9 have been shown to be at greater risk for major bleeding complications in some studies, but not in all.^{102,103,104} It is becoming prudent practice to genotype for CYP2C9 before beginning warfarin therapy to reduce the risk of ADRs and to decrease medical expenditures.^{105,106}

These examples illustrate how findings in pharmacogenomics support the concept of biochemical individuality. The benefit to patients today is great; the potential benefit, as the knowledge base grows, is huge. In a systematic review of ADRs, Phillips et al.¹⁰⁷ published a list of the most common pharmaceuticals that are involved in ADRs (see Table 7.2). In this growing field, many more examples become available every year. The best resources for up-to-date information are the internet, product manufacturers, and specific laboratories that test for SNPs.

Role of Environment in Shaping Biochemical Individuality

Detoxification and Biochemical Individuality

A 2001 report suggested that between \$568 billion and \$793 billion is spent per year in Canada and the United States on environmentally caused disease.¹⁰⁸ We are exposed to a great number of environmental compounds during the course of our lifetime (see Chapter 13 for a discussion of xenobiotics), and many of these compounds show little relationship to previ-

ously encountered compounds or metabolites. Our bodies have an extensive network of responses to manage these new and unknown substances and, because the environment is unique to each individual, these responses are at the core of what we mean by “biochemical individuality.”

Table 7.2 Commonly Identified Drugs in Adverse Drug Reactions

Category	Name(s) of Drug
Beta-blockers	Atenolol, metoprolol
Angiotensin-converting enzyme inhibitor	Lisinopril
Diuretic	Furosemide, hydrochlorothiazide
Calcium channel blocker	Diltiazem, verapamil
Inotropic agent/pressor	Digoxin
NSAID	Aspirin, ibuprofen, naproxen, piroxicam
Tricyclic antidepressants	Imipramine HCl, nortriptyline HCl
Selective serotonin reuptake inhibitor	Fluoxetine
Antibiotics, antitubercular agents	Amoxicillin, erythromycin, isoniazid, rifampin
Anticoagulant	Warfarin sodium
Corticosteroid	Prednisone
Anticonvulsants	Carbamazepine, phenytoin
Antidiabetic agent	Insulin
Bronchodilators	Theophylline
Electrolytes	Potassium
Antiemetic or antihistamine	Meclizine HCl

Table was compiled from Phillips et al., JAMA. 2001;286(18):2273.

The pathways that have received the most attention to date are the phase I and phase II detoxification

enzyme systems, in part because they are involved in drug metabolism and are, therefore, the focus of pharmacogenomics, but also because they are the first-line enzyme defense systems for our interaction with the environment.^{109,110} Since these systems are designed to manage environmental exposure, they are also regulated by the environment. Specific detoxification pathways may be induced or inhibited depending on the presence of various dietary or exogenous compounds.¹¹¹ Gender, lifestyle habits, nutriture, and health status also influence the relative activities of various detoxification enzymes. Moreover, the detoxification enzymes show a wide variety of polymorphisms. A number of other genes are also involved with management of environmental compounds as well. (Please see Chapters 22 and 31 for more detailed discussions of the mechanisms and clinical implications of detoxification.)

Polymorphisms in phase I or phase II enzymes have been associated with increased prevalence and/or risk of many conditions including asthma; cancers of the breast, prostate, lungs, esophagus, stomach, and pancreas; multiple chemical sensitivity; and cardiovascular disease.^{112,113,114,115,116,117,118} Other enzymes also play important roles in our environmental exposure risks. For example, a polymorphism in the human paraoxonase (PON1) gene—which encodes a high-density lipoprotein-associated enzyme that exerts an antiatherogenic effect by protecting low-density lipoproteins (LDL) against oxidation—has been found to influence both sensitivity to specific insecticides or nerve agents, and the risk of cardiovascular disease.¹¹⁹ The PON1 polymorphism has also been associated with neurological symptoms in Gulf War syndrome.¹²⁰

Lung cancer mortality is related to smoking; however, only about 15% of the individuals who smoke will be afflicted with this cancer.¹²¹ Tobacco smoke contains a multitude of carcinogens, but many of these carcinogens must be metabolized before they are damaging to the body. It is apparent that much variability exists in these processes.¹²² For example, polymorphisms in the glutathione S-transferase (GST) gene have received much attention with respect to health risks from smoking. This enzyme is involved in detoxification of tobacco carcinogens, and studies have found that specific polymorphisms in the GST gene are related to the risk of developing coronary heart disease for smokers.¹²³

Although we can cite many examples showing how the environment and specific genetic composition inter-

act, variation in sulfur-dependent pathways is a particularly intriguing area of study. A significant number of individuals who display sensitivity to environmental compounds have impaired sulfation of endogenous compounds, particularly phenolic compounds. In addition, impairment in the sulfation detoxification pathway is associated with such conditions as Alzheimer's disease, Parkinson's disease, motor neuron disease, rheumatoid arthritis, and delayed food sensitivity.¹²⁴ Because the sulfur-dependent detoxification pathway depends upon the availability of the sulfur cofactor, and this cofactor is obtained from precursors in the diet, such as methionine, cysteine, and inorganic sulfur, this is an example of a critical interaction involving the environment, nutrition, and genetics.

Biochemical Individuality and Nutrition

Diet is known to have a major impact on chronic disease prevention and management, so it may be no surprise that the diet-gene interaction is the object of much interest from the research community. A new field of study—nutritional genomics (or nutrigenomics)—has been identified to help us understand the effect of nutrients on DNA:

The link between diet and health is well established, but renewed interest in which dietary components are biologically active and how they exert their effects is being fuelled by the development of nutritional genomics Such techniques can facilitate the definition of optimal nutrition at the level of populations, particular groups, and individuals. This in turn should promote the development of food derived treatments and functionally enhanced foods to improve health.¹²⁵

So prevalent is this understanding that it has even found its way onto the front page of consumer magazines such as *Newsweek*, which had a cover story on “Diet and Genes” in January 2005 that included discussions of the role of ingredients in broccoli (e.g., indole-3-carbinol), green tea catechins, and components of soy on gene expression.¹²⁶ Unfortunately, many of these discussions still focus on a one-size-fits-all model for nutrition. However, the impact that the human genome project has had on the scientific knowledge underlying individualization of pharmaceutical interventions is also encompassing nutrition. Emerging data indicate we will soon be able to individualize nutrient interventions, as well as gain a much better understanding of the implications of biochemical individuality for nutrition-oriented public policy.^{127,128}

Section II

Principles of Functional Medicine

Known genetic polymorphisms that affect nutrition include the hereditary hemochromatosis-linked gene (HFE), which is associated with iron overload; transferrin receptor polymorphisms that influence iron requirements; SNPs in the vitamin D receptor that are associated with bone integrity; SNPs that influence lipid metabolism and cardiovascular health, such as the apolipoproteins and LDL-receptor lipoprotein lipase; and the relationship among PPAR polymorphisms, saturated fat intake, and insulin.^{129,130} Presence of specific SNPs can alter the body's metabolism in ways that can be directly observed (as with a disease like hemochromatosis or elevated lipids), or the effects can be more subtle. For example, the ability to observe what is happening at the DNA level has provided evidence that subclinical deficiencies are involved in genome instability, leading to increased DNA damage.¹³¹ The carotenoids, vitamins C, E, and B12, folate, niacin, and zinc appear to be particularly important for genome stability.¹³²

Bruce Ames, who has studied the effect of nutrients on oxidative stress and DNA integrity, has noted that as many as one-third of all mutations in a gene result in the corresponding enzyme having an increased Michaelis constant (K_m) for a coenzyme, which means the enzyme has a decreased affinity for its vitamin cofactor.¹³³ A decreased binding affinity results in a lower rate of reaction and, as noted by Ames, many of these effects can be ameliorated by administration of high doses of the cofactor. (Chapter 26 contains a discussion by Ames on micronutrient insufficiency.)

Perhaps the best understood example integrating findings in nutrition, genetics, and metabolism is that of folate and methylation. Folate is involved in generation of the methylation cofactor S-adenosylmethionine (SAM). A deficiency in SAM is associated with congenital abnormalities, certain cancers, cardiovascular disease, neural tube defects, and peripheral neuropathies. A deficiency in SAM results from disruption in folate metabolism. Cells are highly susceptible to folate deficiency during states of increased folate turnover since they do not accumulate excess folate. Impaired folate metabolism results from insufficient folate intake; gastrointestinal disorders that result in malabsorption; SNPs in genes encoding key pathway enzymes, especially methylenetetrahydrofolate reductase (MTHFR); increased folate catabolism; and deficiencies in vitamins B6, B12, or iron, which are also necessary in the folate-methylation pathway.¹³⁴ Of these, a SNP in the

MTHFR gene has received much research attention (see Figure 7.4).

Figure 7.4 MTHFR SNP

Function of methylenetetrahydrofolate reductase (MTHFR). MTHFR is required for reduction of 5,10-methylenetetrahydrofolate (5,10-CH₂-THF) to 5-methyltetrahydrofolate (5-CH₃-THF) which serves as a methyl donor for the remethylation of homocysteine to methionine through methylation of cobalamin (vitamin B12) to methylcobalamin (CH₃-B12). The most common SNP in this pathway is in the MTHFR, which results in a decreased activity of the MTHFR enzyme, thus influencing the balance of the homocysteine cycle.

The MTHFR polymorphism results in a thermolabile enzyme that is about 50% less active than the wild-type enzyme. Epidemiological studies have shown that this polymorphism, in the presence of low folate intake, results in elevated blood homocysteine levels and is associated with a higher risk of cardiovascular disease.¹³⁵ Silaste et al.¹³⁶ investigated the plasma homocysteine effects of a low-folate versus a high-folate diet on individuals with SNPs related to metabolism of homocysteine, including the MTHFR gene and the methionine synthase gene. The groups did not initially vary in baseline homocysteine levels. However, after the high-folate diet, although the individuals with the SNP in the MTHFR gene had a smaller increase in serum folate than those with the wild-type gene (55% compared to 85%, respectively), their blood homocysteine levels decreased more (18%) than those without the SNP (11%). A similar effect was also noted with the methionine synthase gene.

A study on the effect of diet on MTHFR polymorphisms, in which 322 men and 252 women participated, noted that about 41% of the individuals had wild-type genes at both alleles (the same gene site on each of the two chromosomes), whereas 48% had one wild-type gene and one with the SNP (heterozygotes), and 11% had SNPs on both alleles (homozygote polymorphism). The group that was homozygous for the polymorphism had higher homocysteine concentrations initially ($15.8 \pm 9 \mu\text{mol/L}$) than either of the other two groups (11.3 ± 8

and $10.8 \pm 9 \mu\text{mol/L}$).¹³⁷ The study found that adherence to a Mediterranean diet was associated with reduced homocysteine in individuals with either of the alleles containing the SNP for the MTHFR, but not in those individuals who had only the wild-type genes. This study suggests that some individuals may be more responsive to specific dietary interventions than others, based upon the presence of specific DNA sequences.

Effects of Early Life on Biochemical Individuality

An intriguing area of research is the effect of early life on gene expression patterns. In a research review published in the journal *Science* in September 2004,¹³⁸ Gluckman and Hanson discuss the hypothesis that some chronic diseases in adulthood are influenced by environmental factors in the periconceptual, fetal, and infant phases of early life, a model called the “development origins of health and disease.” We often think that chronic degenerative disease appears in mid-life as a consequence of something we did in mid-life, but this model suggests that very early life can influence patterns of gene expression and the risk of developing certain diseases.¹³⁹ In particular, studies in several mammalian species demonstrate that manipulation of the periconceptual, embryonic, fetal, or neonatal environment can lead to altered postnatal cardiovascular and/or metabolic function.^{140,141,142} Most of these influences appear to be related to diet and include maternal undernutrition, low-protein diet, or high-fat diet. Factors such as nutrition, stress, and environmental toxins in early phases of life may combine to set in motion a trajectory leading toward dysfunction in middle age. This presents an entirely different responsibility for the healthcare system (and for all of us, as future patients); rather than just waiting until disease develops, a patient’s health plan needs to begin at the time of (or even before) conception.

Epigenetic Effects

We now know that biochemical individuality is more than just a difference in gene sequence. One can easily postulate today that two fertilized eggs placed in different *in utero* environments will develop into individuals with different physiology. In a fascinating twist, studies with identical twins have also shown us that biochemical individuality can occur even when the genetics are the same and the environment is presum-

ably the same for both individuals. This introduces the concept of epigenetic effects.

Epigenetics is the study of heritable changes in DNA function without a change in DNA sequence. Epigenetics includes mechanisms that alter activation and expression of genes, such as methylation at specific sites on DNA, histone acetylation, and modification of DNA function by RNA. Therefore, although a major focus of today’s research is on identifying gene sequences and polymorphisms, it is important to heed the following caution expressed eloquently by Walter Willett,¹⁴³ from the Harvard School of Public Health:

Genetic and environmental factors, including diet and life-style, both contribute to cardiovascular disease, cancers, and other major causes of mortality, but various lines of evidence indicate that environmental factors are most important. Overly enthusiastic expectations regarding the benefits of genetic research for disease prevention have the potential to distort research priorities and spending for health. However, integration of new genetic information into epidemiologic studies can help clarify causal relations between both life-style and genetic factors and risks of disease. Thus, a balanced approach should provide the best data to make informed choices about the most effective means to prevent disease.

Proteomics and Metabolomics

In a concept paper in the journal *Nature*, Paul Nurse,¹⁴⁴ from the Cell Cycle Laboratory at Lincoln’s Inn Fields Laboratories, London, wrote:

Many of the properties that characterize living organisms are also exhibited by individual cells. These include communication, homeostasis, spatial and temporal organization, reproduction, and adaptation to external stimuli. Biological explanations of these complex phenomena are often based on the logical and informational processes that underpin the mechanisms involved Most experimental investigations of cells, however, do not readily yield such explanations, because they usually put greater emphasis on molecular and biochemical descriptions of phenomena. To explain logical and informational processes on a cellular level, therefore, we need to devise new ways to obtain and analyze data, particularly those generated by genomic and post-genomic studies.

Clearly, today’s understanding of genomics represents just the tip of the proverbial iceberg with respect to a full understanding of how the body functions and, from that, the differences among us. The genome may be the blueprint for the proteins and structures in our

Section II

Principles of Functional Medicine

body, but it is the proteins that carry out functions, and the small molecules that result from protein activities that are the pillars of the signaling and communication activities throughout our bodies. Since many changes occur at once, and specific interactions or patterns can result in different outcomes, new technologies have been developed to look at multiple genes at one time. These are collectively called “microarray analysis technology” or the “gene array.” These different gene expression patterns can result in a variety of different protein activity patterns. “Proteomics” is the term that has been coined to describe the study of multiple proteins at once, or protein expression/activity patterns. Proteomics is more difficult to perform from a technological standpoint, since each protein is chemically different. DNA is chemically the same; it’s the pattern of bases in the DNA that changes. Gene array technology and large-scale genotyping are increasing our knowledge base every day.¹⁴⁵ Likewise, although proteomics is still in its infancy, technologies are also changing how medical research is being conducted.^{146,147}

The greatest promise for understanding biochemical uniqueness is likely to manifest through a deeper understanding at the level of the metabolome. The scientific community is in the process of developing the technologies to quantify entire classes of metabolites; understanding the pattern of these metabolites is called “metabolomics.”¹⁴⁸ The metabolome looks at entire biochemical pathways to understand the integrated effects of environment, toxins, nutrients, and genetics on complex metabolic regulation and tissue composition. Through the use of genomics, proteomics, and metabolomics, we can better understand, for example, the 50% concordance rate in identical twins for developing diseases such as type 1 diabetes, or the complexity of establishing breast cancer risk.¹⁴⁹ These technologies may even change how we look at disease. As stated by Gerling et al. in the January 2003 issue of *Archives of Internal Medicine*:¹⁵⁰

Since many different genetic defects and molecular pathways may produce clinically indistinguishable disease presentations, many disorders currently viewed as single entities may become divided into large numbers of distinct molecular diseases, with treatment increasingly targeted at the unique primary molecular defect. This will challenge currently accepted definitions of terms such as *disease*, *disorder*, and *syndrome*, as each may come to denote particular genetic components or signature molecular abnormalities, or imply an optimal mode of genetically based and/or conventional

treatment. Indeed, our present difficulties in defining the gene(s) involved in many of the major diseases may be because we are studying large pools of very divergent molecular “syndromes” with the same clinical presentation. This may also explain why many treatments are only effective in certain patients.

Biochemical Individuality and the Future

Biochemical individuality is not such a new concept; it’s our understanding of what it really means that is continuing to evolve. The concept of genetic predisposition is a way of indicating that we are all different, that we may have a gene that “predisposes” us to some particular condition, but the condition may not be realized unless certain other factors are also present. We are already seeing that the success of the Human Genome Project is creating a better understanding of biochemical individuality and how it can be used to improve disease prevention and management. However, fully implementing this knowledge to improve health outcomes depends on several further developments in research technology. In particular, we must develop the following technical capacities:

1. the ability to detect genetic variation that is silent or undetectable at the level of the phenotype;
2. the ability to analyze the role of epigenetics in genetic variation;
3. the ability to quantify the impact of environment on specific genetic variation patterns;
4. the ability to identify patterns of protein activities through proteomics; and
5. the ability to fully integrate changes in metabolism and entire metabolic pathways by pattern analysis.

As stated eloquently by Robert Eckhardt¹⁵¹ in a review on genetics and nutritional individuality:

The latest nutritional guidelines (Murphy 2001)ⁱⁱ incorporate recommended daily allowance for some 30 nutrients. If the metabolic pathway influencing nutritional requirements for each of these nutrients was affected independently by only two alternative alleles at a single genetic locus (almost certainly a substantial underestimate of systemic complexity), then we should expect that the number of alternative genotypes would be 3^{30} or in excess of 200 trillion; three alternative alleles would raise the level of potential diversity to 6^{30} , i.e., over a billion times higher. The advancing wave of

ⁱⁱ Murphy SP. How consideration of population variance and individuality affects our understanding of nutritional requirements in human health and disease. *J Nutr.* 2001;131:361S-65S.

knowledge about the human genome has confirmed the idea that each of us must be genetically unique in our nutritional needs.

Furthermore, although much of the initial focus of genomics, proteomics, and metabolomics has been on ADRs, drug metabolism, environmental interactions, and nutrient needs, research in inflammation and immune system function is also finding distinct, important differences that affect health.^{152,153,154,155} Taken together, the differential effects of the genomics, environment, nutrition, and epigenetic influences indicates that we are all, clearly, biochemically individual.

Chapter 8

Patient-centered Care: Antecedents, Triggers, and Mediators

Leo Galland, MD

*It is more important to know what person has
the disease than which disease the person has.*
—William Osler

The purpose of this chapter is to present an **organizational structure** for assessment of patients as unique individuals, an approach I have called person-centered diagnosis.¹ The goal of person-centered diagnosis is to enable healers to develop individualized treatment plans that are based upon an understanding of the physiological, environmental, and psychosocial contexts within which each person's illnesses or dysfunctions occur. The information you need to effectively apply this organizational structure fills the remainder of this textbook. My goal here is to describe and illustrate the structure. To create it, you must start by eliciting all of the patient's concerns. In actively listening to the patient's story, you attempt to discover the **antecedents, triggers** and **mediators** that underlie symptoms, signs, illness behaviors, and demonstrable pathology. Functional medicine is based upon treatment that is collaborative, flexible, and focused on the control or reversal of each person's individual antecedents, triggers and mediators, rather than the treatment of disease entities.

Eliciting the Patient's Story

The first step in patient-centered care is eliciting the patient's story in a comprehensive manner. It is the functional medicine practitioner's job to know not just the ailments or their diagnoses, but the physical and social environment in which sickness occurs, the dietary habits of the person who is sick (present diet and pre-illness diet), his beliefs about the illness, the

impact of illness on social and psychological function, factors that aggravate or ameliorate symptoms, and factors that predispose to illness or facilitate recovery. This information is necessary for establishing a functional treatment plan.

The importance of understanding the patient's experience of his/her illness cannot be overemphasized. Extensive research on doctor-patient interactions indicates that doctors who fail to pay attention to the patient's concerns miss important clinical information. The conventional diagnostic paradigm, differential diagnosis, leads doctors to ignore or denigrate information that patients consider important, or that influences individual prognosis.^{2,3,4} Not only does this ignorance impair the effectiveness of treatment,⁵ it generates considerable dissatisfaction among patients.^{6,7,8}

Extensive research done within the context of conventional medical care reveals what most patients know: doctors do not pay enough attention to what their patients have to say. A study done at the University of Rochester found that most patients have three reasons for visiting a physician, are interrupted within 18 seconds of starting to tell their stories, and never get the chance to finish.⁹ Although doctors excuse this behavior by citing lack of time, it would have taken an average of one minute and rarely more than three minutes for a complete list of problems to be elicited.

Even when doctors know what their patients' concerns are, they typically ignore them.¹⁰ Most patients have different ideas about their illnesses than their doctors and some form of clarification or negotiation is needed for an effective therapeutic alliance to be established.¹¹ A study that carefully analyzed taped transcripts of visits to a medical clinic found that patients attempted

Section II

Principles of Functional Medicine

to clarify or challenge what their doctor had said in 85% of the visits. Their requests were usually ignored or interrupted.¹² Understanding the patient's perspective allows the doctor to work in a collaborative way with patients, giving information that helps the patient make healthful choices.¹³ The more information the patient receives from the doctor and the more actively the patient is involved in making decisions about treatment, the higher the level of mutual satisfaction, and the better the clinical outcome.^{14,15,16,17,18} A systematic review of randomized clinical trials and analytic studies of physician-patient communication confirmed a positive influence of quality communication on health outcomes.¹⁹ Such a collaborative relationship depends upon the practitioner recognizing and acknowledging the patient's experience of the illness. Useful questions to ask include:

- How are you hoping that I can help you today?
- What do you believe is the source of your problems?
- What kind of treatment are you looking for?
- What do you most fear about your illness?
- What impact have your symptoms had on your life?

Organizing and Analyzing the Patient's Story

What modern science has taught us about the genesis of disease can be represented by three words: triggers, mediators, and antecedents. Triggers are discrete entities or events that provoke disease or its symptoms. Microbes are an example. The greatest scientific discovery of the 19th century was the microbial etiology of the major epidemic diseases. Triggers are usually insufficient in and of themselves for disease formation, however. Host response is an essential component. Identifying the biochemical mediators that underlie host responses was the most productive field of biomedical research during the second half of the 20th century. Mediators, as the word implies, do not "cause" disease. They are intermediaries that contribute to the manifestations of disease. Antecedents are factors that predispose to acute or chronic illness. For a person who is ill, they form the illness diathesis. From the perspective of prevention, they are risk factors. Knowledge of antecedents has provided a rational structure for the organization of preventive medicine and public health. Medical genomics seeks to better understand disease by identifying the phenotypic expression of disease-related genes and their products. The application of genomic science to clinical medicine requires the inte-

gration of antecedents (genes and the factors controlling their expression) with mediators (the downstream products of gene activation). Mediators, triggers, and antecedents are not only key biomedical concepts, they are also important psychosocial concepts. In person-centered diagnosis, the mediators, triggers, and antecedents for each person's illness form the focus of clinical investigation.

Antecedents and the Origins of Illness

Understanding the antecedents of illness helps the physician understand the unique characteristics of each patient as they relate to his or her current health status. Antecedents may be thought of as congenital or developmental. The most important congenital factor is gender: women and men differ markedly in susceptibility to many disorders. The most important developmental factor is age; what ails children is rarely the same as what ails the elderly. Beyond these obvious factors lies a diversity as complex as the genetic differences and separate life experiences that distinguish one person from another.

Congenital factors may be inherited or acquired *in utero*. They can most readily be evaluated from a comprehensive family history, including mother's health before and during pregnancy. Genomic analysis, which is now commercially available, can supplement the family health history as a tool for investigating unique nutritional needs or individual variability in sensitivity to environmental toxins.^{20,21} The most common single gene disorders in North America, celiac disease and hemochromatosis, may be confirmed by the presence of genetic markers, but should first be suspected from abnormalities in routine lab tests. Elevated serum ferritin concentration or transferrin saturation should prompt genetic testing for the alleles associated with hereditary hemochromatosis.²² Increased small intestinal permeability, as measured by the inexpensive, non-invasive and under-utilized lactulose/mannitol challenge test, has a sensitivity approaching 100% for untreated celiac disease.²³ Abnormal intestinal permeability should prompt the measurement of celiac-specific immune markers in patients with chronic fatigue, autoimmune disorders, or chronic gastrointestinal complaints of any type.

Normal intestinal permeability in patients consuming gluten almost always excludes celiac disease as a consideration; however, this may not necessarily be the

case for other gluten-sensitive disorders. Because celiac disease and gluten-sensitive disorders are common, have protean manifestations, and can be well controlled by nutritional interventions, intestinal permeability should be a routine component of the laboratory testing for antecedents of illness. The treatment of choice for frank hemochromatosis is phlebotomy, but mild iron overload without frank hemochromatosis is more common than the full-blown disease. These patients generally have only one of the alleles associated with the disease, but have elevated transferrin saturation and/or ferritin. They are not treated with phlebotomy, and should be treated with dietary interventions. They should not take iron or vitamin C supplements, because vitamin C reduces iron to its more toxic form.

Some familial disorders may reflect intra-uterine rather than genetic influences. Twin studies of hypertension, for example, indicate a higher concordance for blood pressure between identical twins with a common placenta than identical twins with separate placentas.²⁴ Presumably, the shared placenta mediates subtle nutritional influences that affect a tendency toward chronic illness in adulthood.

Post-natal developmental factors that govern the predisposition to illness include nutrition, exposure to toxins, trauma, learned patterns of behavior, and the microbial ecology of the body. Sexual abuse in childhood, for example, is associated with an increased risk of abdominal and pelvic pain syndromes among women.^{25,26} Recurrent otitis media increases the risk of a child developing attention deficit disorder,^{27,28} an effect that is not associated with hearing loss but may result from the effects of antibiotics on the microbial ecology of the gut.

Precipitating events are critical antecedents that closely precede the development of chronic illness. They represent a boundary in time: before this event, the person was considered healthy; since the event, the person has become a patient. Understanding the nature of the precipitating event may aid in unraveling the triggers and mediators that maintain the state of illness. The most common precipitating events among my patients are a period of severe psychosocial distress, an acute infection (sometimes treated with antibiotics), exposure to environmental toxins at work or home, or severe nutrient depletion related to illness or crash dieting. Useful questions for uncovering precipitating events include:

- When is the last time you felt really well for more than a few days at a time?
- During the six months preceding that date, did you experience any illness or major stress, change your use of medication or dietary supplements, or make any significant life changes?

Other publications of this author present cases in which cryptogenic illness was found to be precipitated by foreign travel, antibiotic use, dietary changes,²⁹ smoldering infection, or the illness of a spouse.³⁰

Triggers and the Provocation of Illness

A trigger is anything that initiates an acute illness or the emergence of symptoms. The distinction between a trigger and a precipitating event is relative, not absolute; the distinction helps organize the patient's story. As a general rule, triggers only provoke illness as long as the person is exposed to them (or for a short while afterward), whereas a precipitating event initiates a change in health status that persists long after the exposure ends. Common triggers include physical or psychic trauma, microbes, drugs, allergens, foods (or even the act of eating or drinking), environmental toxins, temperature change, stressful life events, adverse social interactions, and powerful memories. For some conditions, the trigger is such an essential part of our concept of the disease that the two cannot be separated; the disease is either named after the trigger (e.g., "strep throat") or the absence of the trigger negates the diagnosis (e.g., concussion cannot occur without head trauma). For chronic ailments like asthma, arthritis, or migraine headaches, multiple interacting triggers may be present. All triggers, however, exert their effects through the activation of host-derived mediators. In closed-head trauma, for example, activation of NMDA receptors, induction of nitric oxide synthase (iNOS), and liberation of free intra-neuronal calcium determine the late effects. Intravenous magnesium at the time of trauma attenuates severity by altering the mediator response.^{31,32} Sensitivity to different triggers often varies among persons with similar ailments. A prime task of the functional practitioner is to help patients identify important triggers for their ailments and develop strategies for eliminating them or diminishing their virulence.

Although the identification and elimination of triggers is not a foreign concept in conventional medicine, many physicians neglect the search. A study was

conducted by telephone in which practicing physicians were asked how they would treat a new patient with abdominal pain, who had a recent diagnosis of gastritis made by a specialist in another town. Almost half were ready to put the patient on acid-lowering therapy without asking about the patient’s use of aspirin, alcohol or tobacco, all of which are potential triggers for gastritis. The authors of the study concluded, “In actual practice, ignoring these aspects of the patient may well have reduced or even negated the efficacy of other therapeutic plans implemented.”³³

Mediators and the Formation of Illness

A mediator is anything that produces symptoms, damage to tissues of the body, or the types of behaviors associated with being sick. Mediators vary in form and substance. They may be biochemical (like prostanoids and cytokines), ionic (like hydrogen ions), social (like reinforcement for staying ill), psychological (like fear), or cultural (like beliefs about the nature of illness). A list of common mediators is presented in Table 8.1. Illness in any single person usually involves multiple interacting mediators. Biochemical, psychosocial, and cultural mediators interact continuously in the formation of illness.

Cognitive/emotional mediators determine how patients appraise symptoms and what actions they take in response to that appraisal.³⁴ They may even modulate the symptoms themselves. People in pain, for example, experience more pain when they fear that pain control will be inadequate than when they believe that ample pain management is available.³⁵

Perceived self-efficacy (the belief in one’s ability to cope successfully with specific problems) is a cognitive mediator that determines coping with illness. People with a high degree of health self-efficacy usually adapt better to chronic disease, maintaining higher levels of activity, requiring lower doses of pain medication, adopting healthier lifestyles, and cooperating with prescribed therapies, compared to people with low self-efficacy.³⁶ Self-management education is designed to enhance self-efficacy,³⁷ and has been shown to improve the clinical outcome for patients with several types of chronic disease, including asthma,³⁸ arthritis,^{39,40,41} and diabetes.⁴²

The biochemical mediators of disease listed in Table 8.1 are best known for their ability to promote cellular damage. Most are organized into circuits and cascades that sub-serve homeostasis and allostasis. In these networks, each mediator is multi-functional and most

functions involve multiple mediators, so that redundancy is the rule, not the exception. The most striking characteristic of biochemical mediators is their lack of disease specificity. Each mediator can be implicated in many different, apparently unrelated diseases, and every disease involves multiple chemical mediators in its formation.

Table 8.1 Common Illness Mediators

Biochemical	Hormones Neurotransmitters Neuropeptides Cytokines Free radicals Transcription factors
Subatomic	Ions Electrons Electrical and magnetic fields
Cognitive/emotional	Fear of pain or loss Feelings or personal beliefs about illness Poor self-esteem, low perceived self-efficacy Learned helplessness Lack of relevant health information
Social/cultural	Reinforcement for staying sick Behavioral conditioning Lack of resources due to social isolation or poverty The nature of the sick role and the doctor/patient relationship

Mediator networks that regulate inflammatory and neuroendocrine stress responses have been the subject of intensive research with important clinical implications. A detailed discussion of these networks is outside the scope of this chapter, but they are addressed in Chapters 19, 23, 27, and 32; see the index for further cross-referencing. Comprehensive reviews have appeared elsewhere.^{43,44,45,46} Within the framework of functional medicine, a key feature of biochemical mediators is the natural rhythm of mediator activity, which is strongly influenced by the common components of life: diet, sleep, exercise, hygiene, social interactions, solar and lunar cycles, age, and sex. Aging, illness, and chronic psychological distress upregulate activity of the inflammatory and neuroendocrine-stress response networks. Regular physical activity downregulates both.

Integrating the Patient's Story

After listening to the concerns that led each patient to seek a consultation in functional medicine, the clinician makes a series of distinctions:

1. For patients whose main concern is optimal health and prevention, ask about present and past health problems and the family health history. If these supply no indication of illness susceptibility, then turn your attention to risk factors for future illness: weight, fitness, type and level of physical activity, dietary pattern, sleep habits, use of alcohol, drugs, tobacco, firearms, environmental exposures at home and work, travel, sources of stress and pleasure, degree of involvement with others, spiritual beliefs and practices, sexual relationships, hopes and fears for the future.
2. For patients with an active health problem, always ask, "What was your health like before this problem began?" An intake questionnaire that asks about previous health problems is also helpful, because it gathers information in a different fashion concerning what the patient was like prior to the present illness. Such a tool is condition-specific, not open-ended. The two approaches complement one another.
 - a. Some patients will say that they were really healthy prior to their present illness. In that case, look for a precipitating event. If you or the patient can identify one, then ask about ongoing triggers that bear some relationship to the precipitating event. For example: if the precipitating event was marital or job stress, focus on stress-related psychological triggers. If the precipitating event was an environmental exposure, focus on ongoing exposures to volatile chemicals or mold.
 - b. The most challenging patients will usually indicate that their health was poor even before their present illness. In that case, take a detailed, chronological history from birth to the present that includes information about early life experience (including illness, injury and abuse), school and work performance, diet, drug and medication use, leisure activities, travel, family life, sexual experiences, habits, life stressors, and places of residence. Because gathering this data can be very time consum-

ing, a self-administered questionnaire completed by the patient before the interview may help to prompt responses and improve memory of remote events. For many patients with complex, chronic health problems, it may be useful to take a detailed life history **before** seeking detailed information about present symptoms. Problems that emerge from such a review have to be addressed for a successful outcome of treatment. Dealing with the present concerns by themselves almost never succeeds for patients in this group.

Whatever rapport you establish with patients initially, maintaining the therapeutic relationship usually depends upon significant improvement in symptoms or in a sense of well-being within a few days to a few weeks of the initial evaluation. This is most efficiently achieved by addressing the triggers that provoke symptoms and helping the patient decrease exposure to them. When triggers cannot be identified or avoided, then symptomatic improvement must rest on control of mediator activation. A combination of the two will usually produce the most satisfactory long-term benefits.

Assessment of Triggers

A comprehensive search for triggers requires that you know the following about your patient: each drug—prescription, over-the-counter or recreational—that the patient has used and when; nutritional habits and each dietary supplement used and when; what effects the patient noted from the use of each substance; sources of stress—life events, environmental exposures, thoughts or memories, and social interactions—and when they occurred in relation to symptoms. Elicit the patient's own ideas about possible triggers by asking, "What do you think causes or aggravates your symptoms?" The patient's observations may be insightful and accurate in ascribing causality. Of course the patient's—and the clinician's—observations can also mislead, or focus on non-essential factors. Teach patients to challenge their own observations by looking for consistency and replicability, wherever possible. Suggest alternative theories for the patient to consider and explain that the search for triggers works best as a collaborative effort between patient and doctor. The patient's ability to recognize triggers is an important step in self-care.

Food and environment supply important triggers for the practice of functional medicine. Food intolerance is a very common phenomenon, reported by 33% of the population in one large study.⁴⁷ Relatively few of these reactions (4–14%) are due to true food allergies. Most food intolerance has no clear immunologic basis. Mechanisms include sensitivity to the pharmacological effect of alkaloids, amines or salicylates in food.^{48,49,50,51} Histamine poisoning from scombroid fish and tyramine-induced headache are dramatic examples.⁵² Although most food intolerance is short-lived, severe chronic illness can occur, and the food trigger may elude identification unless the physician starts the investigation with a high index of suspicion. Gluten intolerance, with its protean manifestations, is probably the best example. Affecting about 2% of people of European ancestry,⁵³ gluten intolerance is common and often unrecognized. In addition to being the essential trigger for celiac disease, gluten sensitivity may be manifest in patients with neurological disorders of unknown cause,⁵⁴ cerebellar degeneration,⁵⁵ dermatitis herpetiformis,⁵⁶ failure to thrive,⁵⁷ pervasive developmental delay,⁵⁸ inflammatory arthritis,^{59,60,61,62,63} psoriasis,^{64,65} Sjögren's syndrome,^{66,67} and schizophrenia.^{68,69} The different presentations of gluten sensitivity may derive from genetic differences among affected patients.⁷⁰

Published studies on food intolerance and your patients' symptoms may be found through the National Library of Medicine. If the patient has a disease diagnosis, an internet search may reveal previously observed associations between specific foods and the patient's condition. Access PubMed over the internet (www.pubmed.gov) and run a search that cross-references the name of the patient's condition with "Hypersensitivity, food" and also with "Food, adverse reactions." Both of these are Medline Subject Headings (MeSH). There is no MeSH listing for "food allergy" or "food intolerance." Your search will be more efficient if you list the patient's condition as it appears in MeSH. A negative search does not eliminate food intolerance as a trigger for the condition being searched, but the number of positive findings may surprise you.¹

Health effects of ambient air quality are as important as those of foods. Numerous studies conducted in U.S. cities demonstrate a close correlation between fine-

particle air pollution and daily mortality rates, even at levels of pollution considered safe by the World Health Organization.⁷¹ In the industrialized world, most people spend most of their time indoors, and indoor air pollution has become a serious cause of morbidity. Studies using experimental chambers have shown that volatile organic compounds (VOCs) released from building materials, furnishings, office machines, and cleaning products can cause irritation of the respiratory system in humans and animals at levels 100 times weaker than permissible exposure levels or the World Health Organization Indoor Air Guidelines.^{72,73,74} Controlled experiments with people who describe themselves as sensitive to VOCs confirm that VOC exposure causes headache, fatigue, and difficulty concentrating. People who deny such sensitivity also experience symptoms, but do not experience mental impairment when exposed. Air samples of buildings with and without "sick building" complaints have established an association between VOC exposure and human sickness.^{75,76,77,78}

A questionnaire can elicit important information about environmental exposures at home and at work. The open-ended question, "Has your work or home environment been a concern to you?" should be accompanied by a checklist of potential exposures.

Microbial triggers for chronic illness present a particular challenge, as exemplified by the many facets of *Helicobacter pylori* infection. Originally isolated from the gastric mucosa of patients with gastritis and peptic ulcer disease, *H. pylori* has been implicated in the pathogenesis of NSAID gastropathy,⁷⁹ gastric carcinoma,⁸⁰ lymphoma,⁸¹ and a variety of extra-digestive disorders, including ischemic heart disease,⁸² ischemic cerebrovascular disorders,⁸³ rosacea,⁸⁴ Sjögren's syndrome,⁸⁵ Raynaud's syndrome,⁸⁶ food allergy,⁸⁷ vitamin B12 deficiency,⁸⁸ and open-angle glaucoma.⁸⁹ For elderly patients with open-angle glaucoma and incidental *H. pylori* infection of the stomach, eradication of *H. pylori* by antibiotics was associated with improved control of glaucoma parameters at two years.⁹⁰ The mechanism by which *H. pylori* aggravates open-angle glaucoma is unknown, but may result from the ability of *H. pylori* colonization of the gastric tract to trigger the local and systemic release of platelet-activating factor, inflammatory cytokines, and vasoactive substances.

In the case of untreated *H. pylori* infection, non-invasive screening tests, including serum antibodies, stool antigens, and C-14 breath testing, are available. For

¹ Medical cybrarian Valerie Rankow (vr99@optonline.net) has assisted the author with this search strategy and with numerous other, more complex searches.

other types of infection, inquiring about the previous response of a given symptom or symptom complex to antibiotics may be useful. In 1988, physicians at the University of Minnesota conducted a study in which they administered intravenous cephalosporins to patients with various types of arthritis who also manifested antibodies to *Borrelia burgdorferi*. Most of these patients were not thought to have Lyme disease. Some met diagnostic criteria for rheumatoid arthritis, some for osteoarthritis, and some for spondyloarthropathies. The response to antibiotics was quite variable and ranged from no response to dramatic and sustained improvement. The authors noted that improvement in arthritis following antibiotics was not related to the patient's clinical diagnosis or the level of anti-*Borrelia* antibody. The best predictor of a positive response to the experimental treatment was a previous history of improvement of arthritis associated with the use of antibiotics.⁹¹

The most comprehensive way to ask the antibiotic question is: "During the time you have had symptom X, have you taken antibiotics for any reason? Which antibiotic? Did symptom X change while you were taking the drug?" Among patients with chronic diarrhea of unknown cause, for example, some will report that their gastrointestinal symptoms improved when taking a specific antibiotic; others will report that they worsened. The first case suggests that bacteria or protozoa sensitive to the antibiotic may be causally related to the patient's gastrointestinal problems. Repeating the antibiotic prescription can establish if this response is replicable. If so, therapy can focus on treating the microbe and understanding why a single course of antibiotics was ineffective. The second case suggests that depletion of bacteria by antibiotics and concomitant increase in antibiotic-resistant organisms, including yeasts, may be contributing to diarrhea, and treatment can focus on restoration of normal intestinal flora.

Assessment of Psychosocial Mediators

Useful questions for eliciting a person's beliefs about his/her illness are:

- What do you think has caused your problem?
- What do you most fear about your problem?
- How much control do you think you have over your symptoms?

Useful questions for eliciting information about the nature and sources of social support include:

- Are there people in whom you can confide?
- How satisfied are you with your marriage/family/friends/social life?
- How much support do you receive in dealing with your health problems?
- How often do you feel loved or cared for?

Assessment of Biochemical Mediators

Understanding the biochemical alterations associated with a conventional disease diagnosis can be helpful in understanding the biochemical mediators of each person's illness. Inflammation is believed to play a critical role not only in response to infection and in the classic inflammatory diseases, but also in the pathogenesis of coronary artery disease, diabetes, cancer, depression, and the negative health effects associated with obesity and with aging.^{92,93,94,95,96,97,98} The orchestration of mediator signals in the inflammation and neuroendocrine-stress networks, as they interact with one another, is critical for normal physiological functions (e.g., the architecture of sleep, the repair of injury, and the response to infection), and for the dysfunctional physiology central to the pathogenesis of most of the major chronic diseases.^{99,100,101}

Most chronic disease is associated with chronic inflammation, but the patterns of immune response that underlie inflammation are not always the same. Patients with type 1 diabetes mellitus, Crohn's disease or any other disorder categorized by granuloma formation or excessive cell-mediated immune responses are likely to have an immune response to common triggers in which the Th1 component is upregulated and not subject to the normal downregulation provided by Th2 activity. Their mediator response to inflammatory stimulation produces excessive levels of gamma interferon and interleukin-12 (IL-12), key Th1-related cytokines.¹⁰² Patients with severe depression often show a loss of negative feedback in the HPA axis. Urinary free cortisol is elevated; the diurnal pattern may be disrupted, with increased PM cortisol secretion and blunting of dexamethasone suppression. This phenomenon appears to be driven at the level of the hypothalamus, not the adrenals, because spinal fluid corticotropin-releasing hormone (CRH) is elevated.¹⁰³ Several groups of researchers in the late 1990s speculated that impaired synaptic function due to a deficit of omega-3 fatty acids may contribute to the CNS dysfunction of patients with depressive illness^{104,105,106,107} (although some large recent

Section II

Principles of Functional Medicine

studies do not show the same patterns^{108,109}). Omega-3 fatty acid levels tend to be lower in blood samples than in control populations. The key component appears to be eicosapentaenoic acid (EPA).

To utilize the vast database of available information about biochemical disease mediators, integrative clinicians should consider three strategies. First, maintain up-to-date knowledge of disease pathophysiology by reading reviews in mainstream journals on mechanisms of disease or on specific mediators. In reading these, pay special attention to the types of mediators mentioned and their functions within the networks that involve inflammation, oxidative stress, and neuroendocrine balance. Second, attend workshops and courses that emphasize integrative physiology, sponsored by institutions like IFM, the New York Academy of Sciences, the Center for Mind-Body Medicine, and the American College for Advancement in Medicine.¹¹⁰ Third, employ knowledge of the most common biochemical imbalances in chronically ill North Americans and the influence of diet, nutrition, and dietary supplements on these imbalances.

Treatment Planning

A functional medicine treatment plan should be collaborative and dynamic. Collaborative means that patient and practitioner work together to set goals and priorities. Dynamic means that the treatment plan is adjusted as needed in response to feedback. Your knowledge of the patient's beliefs about his/her illness and perceived self-efficacy are essential for collaborative treatment. An appropriate therapeutic intervention for dysfunctional beliefs is the giving of information. Patients have an intense need for explanations about the causes of their diseases.¹¹¹ They want to know how they came to be sick, so that they can attach some meaning to the illness,¹¹² what to expect from the illness, and what they can do to relieve symptoms or speed recovery. Information of this type can reduce anxiety (even when the diagnosis itself is frightening), increase feelings of personal control, and improve the ability to cope with pain. People change their behaviors more readily when they receive information about the importance and the nature of the changes they need to make, help with setting goals, and measuring progress. The kind of information needed is personal, not statistical. It must answer the question, "What can I do?"

The physician can help patients who are suffering from isolation by calling this isolation to the attention of family members or friends, or by attempting to connect the patient with a support group or community agency. Possibly, there is nothing that can be done to relieve the patient's isolation, but the doctor's awareness and acknowledgment of it can be important to the patient and serve to enhance the therapeutic relationship.¹¹³

If potential triggers have been identified, an assessment of the patient's ability to control exposure to them is important. For patients who are reluctant to make major dietary or environmental changes, explain that each avoidance is an experiment that the patient can direct with your guidance. If eliminating foods (and reintroducing those foods as a challenge) has no effect on symptoms or measurable physiologic parameters, do not encourage the patient to persist in the avoidance of those foods, whatever the results of *in vitro* allergy tests may be. The patient will have enough work to do following a healthy diet. Food intolerance is only meaningful if its effects can be demonstrated in real life.

For microbial triggers, the decision to use prescription antimicrobial drugs or natural products with antimicrobial activity may require negotiation. If the situation is not critical, it is usually worthwhile honoring the patient's preferences and intuition.

Understanding the ways in which mediators are modulated by diet enables creative nutritional therapies to be applied. Salicylic acid, the major metabolite of aspirin, suppresses activation of the nuclear transcription factor NFκB, an anti-inflammatory effect that is independent of cyclooxygenase inhibition¹¹⁴ and may be responsible for some effects of low-dose aspirin therapy.¹¹⁵ Vegetables are rich sources of natural salicylates and vegetarians may have serum concentrations of salicylic acid as high as those of people ingesting 75 mg of aspirin a day.¹¹⁶

Dietary fatty acids may have profound effects on the network of inflammatory mediators, altering prostanoïd synthesis, PPAR activity, and the response to cytokines like IL-1.^{117,118,119} They have subtler effects on the neuroendocrine-stress response network, modulating neuronal responses to serotonergic and adrenergic transmission.¹²⁰ Therapy with omega-3 fatty acids provides an excellent example of nutritional modulation of disease activity through alteration of biochemical mediators.¹²¹ Three principles can guide this type of therapy. The first utilizes knowledge of the pathophysi-

ology of specific inflammatory and CNS disorders. Using this model, omega-3 therapy has been successfully applied to the treatment of patients with rheumatoid arthritis,¹²² inflammatory bowel disease,¹²³ coronary artery disease,¹²⁴ peripheral vascular disease,¹²⁵ dysmenorrhea,¹²⁶ cystic fibrosis,¹²⁷ migraine headaches,¹²⁸ schizophrenia,^{129,130} atopic eczema,¹³¹ and multiple sclerosis.^{132,133} Because the fatty acid composition of the contemporary Western diet differs significantly from Paleolithic and ancestral diets, reflecting a marked decrease in omega-3 consumption relative to total fat, the response of so many unrelated disorders to EFA supplementation may indicate that EFAs are not merely working as nutraceutical agents, but that EFA dietary status is important for disease pathogenesis.

The second method rests upon the clinical evaluation of an individual's fatty acid status using clinical parameters that are independent of disease activity. Prasad has stated that the best test for nutritional adequacy is a functional test.¹³⁴ Determine a parameter to follow and measure how administration of the nutrient(s) in question affects that parameter. This method can be applied to the use of EFA therapy in clinical practice. Stevens et al., studying boys with ADHD and a randomly selected population of schoolchildren, found a correlation between low concentrations of omega-3 EFAs, learning and behavior problems, and symptoms associated with EFA deficiency (thirst, dry skin, and dry hair).^{135,136} Evaluating the presence of these symptoms in patients and observing how they change with EFA supplementation is a quick guide to EFA status that may be used clinically to evaluate the EFA contribution to mediator imbalance. This author's method for doing this has been described elsewhere.¹³⁷ Finally, it is possible to measure the levels of fatty acids in plasma and erythrocyte phospholipids, although guidelines for the level of change in fatty acid profiles needed to produce a known clinical effect have only been reported for patients with rheumatoid arthritis, in whom clinical improvement requires that eicosapentaenoic acid (EPA) account for 5% of fatty acids in plasma phospholipids.¹³⁸

The successful application of nutritional therapies, especially dietary interventions, and other self-care practices, as part of a therapeutic plan is very helpful in enhancing self-efficacy among patients. Enhancement of self-efficacy should always be a cardinal goal of treatment in functional medicine.

Summary

Functional medicine is essentially patient centered, rather than disease centered. A structure is presented for uniting a patient-centered approach to diagnosis and treatment with the fruits of modern clinical science (which evolved primarily to serve the prevailing model of disease-centered care). The core scientific concepts of disease pathogenesis are antecedents, triggers, and mediators. Antecedents are factors, genetic or acquired, that predispose to illness; triggers are factors that provoke the symptoms and signs of illness; and mediators are factors, biochemical or psychosocial, that contribute to pathological changes and dysfunctional responses. Understanding the antecedents, triggers, and mediators that underlie illness or dysfunction in each patient permits therapy to be targeted to the needs of the individual. The conventional diagnosis assigned to the patient may be of value in identifying plausible antecedents, triggers or mediators for each patient, but is not adequate by itself for the designing of patient-centered care.

Applying the model of person-centered diagnosis to patients facilitates the recognition of disturbances that are common in people with chronic illness. Diet, nutrition, and exposure to environmental toxins play central roles in functional medicine because they may predispose to illness, provoke symptoms, and modulate the activity of biochemical mediators through a complex and diverse set of mechanisms. Explaining those mechanisms is a key objective of this textbook.

A patient's beliefs about health and illness are critically important for self-care and may influence both behavioral and physiological responses to illness. Perceived self-efficacy is an important mediator of health and healing. Enhancement of patients' self-efficacy through information, education, and the development of a collaborative relationship between patient and healer is a cardinal goal in all clinical encounters.

Chapter 9

Homeostasis: A Dynamic Balance

Joseph J. Lamb, MD

Introduction

The next principle of the functional medicine paradigm is the importance of the search for *dynamic balance* among the internal and external factors in a patient's body, mind, and spirit.

Human life is dependent upon an intricate balance of minerals,¹ water,² organic molecules, and high-energy chemical bonds. Ever since the coalescing of the first molecules capable of replication, and the development of the first cells capable of creating an internal environment, organisms have been characterized by cellular organization, growth and metabolism, reproduction, and heredity. They have also interacted with the external environment. From these simple beginnings have come the great diversity of all plant and animal life and the majesty of human life. Despite the vast complexity inherent in the organization of a human being, the system operates within relatively narrow limits for healthy balance, as dictated by our biochemistry.

Homeostasis and Homeodynamics

Of necessity, the cells of our bodies, with their own unique intracellular environment, are also bathed in a unique external environment: the extracellular fluid. One of the first to explore the concept of balance, the 19th century French physiologist, Claude Bernard, described the extracellular fluid as the “milieu interieur” or internal environment.³ In 1929, Walter Cannon, the noted Harvard physiologist who first advanced the “fight vs. flight” hypothesis, formally suggested “the name homeostasis for the functional organization by which an organism will retain its original condition after a transient perturbation that is not actually damaging.”⁴

Homeostasis is defined in *Stedman's Medical Dictionary* as:

1. The state of equilibrium (balance between opposing pressures) in the body with respect to various functions and to the chemical compositions of the fluids and tissues.
2. The processes through which such bodily equilibrium is maintained.⁵

This balance of chemical interactions defines how well and how long our bodies function. In their classic *Textbook of Medical Physiology*, Guyton and Hall describe this automatic process:

The very fact that we remain alive is almost beyond our own control, for hunger makes us seek food and fear makes us seek refuge. Sensations of cold make us provide warmth. Other forces cause us to seek fellowship and to reproduce. Thus, the human being is actually an automaton, and the fact that we are sensing, feeling and knowledgeable beings is part of this automatic sequence of life ...⁶

In the conventional model, this equilibrium is often viewed at its simplest solely as a balance of internal factors alone. However, our understanding of these unique forces has evolved as our understanding of human genomics, cell signaling pathways, and the mind-body connection has developed. C.H. Waddington in 1968 “introduced the term homeorrhexis to capture the idea that what living things really hold ‘constant is not a single parameter, but a time extended course of change, that is to say, a trajectory.’”⁷ And in a series of papers beginning in 1979, J.E. Yates described a physical biology model for the description of motion and changes at all biological levels of organization which he called homeodynamics.⁸

And yet, functional medicine envisions an even more vibrant and active dynamic. Taking into account

Section II

Principles of Functional Medicine

the concepts of biochemical individuality and health as a positive vitality (not the simple absence of disease), homeodynamics is the constant and vital process of balancing external and internal factors to achieve a healthy functional state.⁹

Indeed, as described in the *Textbook of Natural Medicine*,¹⁰

The term “homeodynamic” describes a range of continuously occurring metabolic and physiologic activities that enable an individual to adapt to changing circumstances, stresses, and experiences. The homeodynamics of one’s health are constantly at work to enable a person to function as a unique individual. Supporting health at a homeodynamic level may require one to focus attention on cellular processes or organ function at sites that seem to be far removed from the patient’s area of discomfort, and at levels that may be unusual from a conventional point of view.

The recent focus on energy production and mitochondrial dysfunction, oxidative stress, neuroexcitotoxicity, and inflammation manifested by glial activation as causes of neurodegenerative diseases provides an excellent example of this model.¹¹

Inherent in this sense of balance are the mechanisms by which the organism controls and maintains this homeodynamic stability and flexibility. Classically, we know of the negative and positive feedback cycles of allopathic and functional medicine. Naturopathic and functional medicines also acknowledge that there are two internal forces, a higher and a lower drive, which maintain this unique individual internal balance. These two forces together constitute the profound self-generated ability to heal, classically known in the naturopathic tradition as *vis medicatrix naturae*. The lower drive is, in many ways, the classic automatic balance described by Guyton and Hall. This inherent internal healing mechanism can be augmented greatly by the higher drive. “The higher drive is the power of the mind and emotions to intervene and affect the course of health and disease by depressing or stimulating the internal capacities.”¹²

Thus, the great diversity that creates biochemical individuality is not the simple genetically determined outcome of biochemical interactions written into our genotypes at birth. Instead, this welcome diversity is a reflection of the interaction of genetic, environmental, and mind-body factors that allow each human to have the unique breadth of experience that characterizes human life.

A pivotal study by Lichtenstein et al., exploring the causation of cancer in a pooled cohort of monozygotic and dizygotic twins from Sweden, Denmark, and Finland, found that “statistically significant effects of heritable factors were observed for prostate cancer (42%), colorectal cancer (35%), and breast cancer (27%).”¹³ While they found familial (hereditary or nonhereditary) factors for many types of cancer, the rates of concordance between twins were generally below 10%. They estimated the contribution of non-shared environmental factors for different cancers to range from 58% to 82%.

This study demonstrates that environmental inputs, including diet and nutrients, air and water, exercise, toxic load from the environment, and psychosocial factors and how we interpret them, contribute significantly to our phenotypic expression. This freedom from genetic determinism is a liberating concept of functional medicine. We are thus given the wonderful opportunity to provide our patients with patient centered, biochemically individualized lifestyle and nutritional interventions to assist them in maintaining their unique homeodynamic balance.

Homeodynamic Balance: Physiological Processes

The maintenance of this unique balance of pathophysiological processes is coordinated by a variety of communication systems, both neural and hormonal. Classically, these systems involve the secretion of a chemical messenger or hormone to act either locally (both on an intracellular as well as an intercellular level) or more distantly (intercellular level).

These chemical messengers and hormones can be classified into two distinct groups by the site of action in the target cell. The first group, including polypeptide hormones as well as monoamines and prostaglandins, does not enter the cell, but instead interacts with cell membrane receptors to signal change via second-level messengers such as cyclic adenosine monophosphate, inositol triphosphate, and diacylglycerol, and also by stimulation of the nucleotide regulatory peptides (G-proteins) that bind guanosine triphosphate.¹⁴ The second group enters the cell and interacts with a diverse collection of nuclear receptors. These receptors, for thyroid and steroid hormones, vitamin A and D derivatives, endogenous metabolites, phytonutrients, and xenobiotics, “are structurally related and collectively

referred to as the nuclear receptor super family.”¹⁵ As many of the ligands for these receptors have not been identified, these undefined receptors have been labeled the orphan nuclear receptors.

The peroxisome proliferator-activated receptors (PPARs) are one subfamily of nuclear receptors and are activated by endogenous intermediate metabolites of polyunsaturated fatty acids. PPAR γ , expressed primarily in adipocytes, has a crucial role in adipocyte differentiation as well as a probable role in modulating insulin sensitivity.¹⁶ Memisglu and his colleagues have investigated the link between a PPAR γ polymorphism and dietary fat intake in relation to body mass.¹⁷ They showed that total dietary fat intake was positively associated with body mass index (BMI) among homozygous wild-type individuals but not among carriers of a variant allele. Additionally, they demonstrated that monounsaturated fat was inversely related to BMI among carriers of the variant allele. They concluded that the PPAR γ genotype modulates physiological responses to dietary fat. Conversely, environment—in the form of dietary fat intake—has direct influence on our genotype, pushing the resultant phenotype toward obesity.

Vitamins have been shown to have central roles in metabolism both as substrate and important cofactors in enzymatic conversions. Two vitamins, specifically vitamins A and D, are also messengers with specific nuclear receptors. Cantorna and her colleagues have explored the effect of vitamin D in experimental autoimmune encephalomyelitis (EAE), a mouse model for multiple sclerosis (MS).¹⁸ They showed that development of EAE was completely prevented by pretreatment with 1,25-dihydroxyvitamin D₃ and that disease progression was also prevented by treatment with 1,25-dihydroxyvitamin D₃. They conclude that their findings “provide strong evidence that vitamin D status may be an important factor in determining the incidence of MS and that it is a physiologically important immune system modulator.”¹⁹

Another example of environmental influence on metabolism and disease expression is indole-3-carbinol (I3C). I3C is an endogenous metabolite of glucosinolates in the *Brassica* family of vegetables—specifically broccoli, cauliflower, cabbage, kale, and Brussels sprouts. I3C has been found to exert a chemopreventive effect on breast cancer by inducing tumor cell apoptosis²⁰ and by stimulation of tumor-suppression genes.²¹

Certainly, one of the most interesting recent advances is the recognition of the diverse group of phytonutrient and environmental influences that provide information through the orphan nuclear receptors. These receptors may have developed for these specific molecules because their presence in the external environment was a measure of the safety of this outer environment. When our hunter-gatherer ancestors ate a diet rich in the appropriate phytonutrients and fatty acids, these messages of bounty signaled that it was safe to grow, to reproduce, indeed to come out of the sheltering caves. When the diet shifted, orphan nuclear receptors may have recognized the changing pattern of nutrient-based information and secreted messages of alarm and inflammation that instead stimulated pathways of conservation as they sought shelter for the dark winter months.

Further research will offer functional medicine practitioners a broader understanding of the influence of environment on our genotype and new opportunities to modulate this interaction.

Summary

Each individual is much more than the simple product of genetic expression directing the construction of shared building blocks. Instead, phenotypic expression is the unique product of an ever-changing dance between genes and environment as the individual strives to create a unique, harmonious balance.

Homeodynamic physiologic processes modulate the constant interplay of environmental inputs with our genetic programming. Modifiable lifestyle choices and nutritional choices can influence the expression of wellness or disease by our biochemically unique metabolisms.

Web-like Interconnections of Physiological Factors

DeAnn Liska, PhD, and Dan Lukaczer, ND

Introduction

Science is a process of unraveling a phenomenon; persistence in the process, until the phenomenon is understood at deeper levels, is absolutely necessary. The body, however, isn't like a mystery novel; there isn't one villain to be found among a number of innocent bystanders caught up in the action. The body is much more complex, continually interacting with the environment and responding in minute ways. Take something as simple as the breath we take thousands of times a day. The rhythm of breath is affected by a brief noise, stopping it for a moment, or a smell, making us take a shorter quick huff or a longer, deep inhalation. All of this we may do with little conscious awareness.

Looking in a mirror, it's easy to think that the body is solid and formed, with little change in any given moment. But we are not statues. Our bodies are fully interconnected, complex, functioning organisms in which we have a constant flow of air, fluids, and energy upon a mutable matrix; nothing is ever still inside our bodies. Every twitch, every thought, every touch of the world around us on our skin elicits a response, causing a biochemical change that influences another change and then another. This is the web of our being, and in functional medicine, we use the model of a web to understand this complexity. The web model can explain the situations in which one major imbalance influences

many different functions and systems, and the situations in which no major imbalance can be found, but several pathways seem to be off-center, or skewed enough to affect overall the pattern of health. The web is multidirectional—multiple factors can underlie a single condition, and multiple conditions can be influenced by a single dysfunctional process or imbalanced system.

Therefore, instead of looking for a single “root cause” of a disease and finding the “cure” from a single pill, in functional medicine we ask what is unbalanced, what has shifted the flow of biochemical information, energy, physical structure, and emotions too far to one side or the other of a healthy range, thus skewing the web. For many conditions, especially conditions associated with aging—like Alzheimer's disease, heart disease, or various arthritic conditions—finding a single root cause that will explain all the occurrences in all people is not possible. No single culprit exists and no single pill will cure these conditions in every patient. Instead, there are many influences, and there may be many imbalances, each contributing something to the outcome. Scientists and clinicians unraveling the web are likely to find a very complex set of interrelationships among myriad factors for each of these conditions.

In functional medicine, we ask about the patterns that are present and how these patterns are aiding or taking away from optimal function. Although every person is unique, with a unique set of genes interacting with the

Section II

Principles of Functional Medicine

environment in a distinct, personal way, there are some major pathways we can monitor that will help us see where the imbalances are most likely to be found. Fundamentally, we look for the major points of activity on the web that, when skewed, are likely to influence many different parts of a person's biochemistry and physiology. The applications of this principle—web-like interconnections—are deeply explored throughout the chapters in Section VI: A Practical Clinical Approach. Here, we simply present the principle for your consideration.

Web-like Interconnections of Cellular Insensitivity to Insulin Signaling

Let's look at one example of a complex underlying physiological dysfunction that can manifest in a variety of ways: the dysfunction of cellular insensitivity to insulin signaling. It is an excellent model for visualizing the interconnections of complex, chronic disease. Commonly referred to as the insulin resistance syndrome or metabolic syndrome, this multifaceted condition weaves its way through a web of interactions that manifest in a multitude of dysfunctions. Over 60 years ago, Dr. H.P. Himsworth used the term "insulin insensitivity" to describe his observation that diabetes was not generally associated with low insulin levels but with cellular insensitivity to insulin.¹ It took another 40 years until a consensus was reached on this radical notion. It is now clear that the vast majority of patients with type 2 diabetes have an insulin insensitivity that impairs their ability to adequately dispose of glucose; further, this defect—if discovered before frank diabetes is present—is predictive of the development of the disease.^{2,3} As prescient an observation as it was, Himsworth probably did not fully understand the broader implications of his discovery. There is now a substantial and growing body of evidence that suggests insulin resistance is an underlying biochemical imbalance in not only type 2 diabetes, but cardiovascular disease (CVD), hypertension, polycystic ovary syndrome (PCOS), and even colon and some breast cancers.

How does insulin insensitivity relate to diabetes? Fundamentally, individuals who develop type 2 diabetes have a decline in the insulin secretory response. With insulin levels declining, circulating free fatty acids (FFAs)—which are normally suppressed by insulin—then rise. FFAs, in turn, stimulate hepatic glucose production. Without the normal insulin inhibitory signal, hypergly-

cemia occurs as the liver continues to secrete normal amounts of glucose into a greatly expanded plasma glucose pool.⁴ With increasing hyperglycemia, there is a further reduction in beta cell function (possibly as a result of glucotoxicity) and a further drop in insulin.

It is estimated that the vast majority of the 16 million people diagnosed with type 2 diabetes in the U.S. carry the underlying pathophysiology of insulin resistance.⁵ Many factors play into that situation: overweight, sedentary lifestyle, dietary choices, stress, and genetics are some of the most important. While muscle and adipose tissue are generally resistant to the imbalanced insulin signal, other tissues are not, and a cascading host of metabolic consequences and dysfunction ensues. Elevated insulin directly stimulates lipogenesis in arterial tissue and enhances the growth and proliferation of arterial smooth muscle cells; hyperinsulinemia decreases fibrinolysis by stimulating plasminogen activator inhibitor-1 (PAI-1),^{6,7} which is associated with an increased risk for coronary thrombosis; and hyperinsulinemia leads to increased hepatic production of triglycerides (TG) and inhibition of high-density lipoproteins (HDL). Elevated TG and depressed HDL are important risk factors for coronary heart disease (CHD). These skewed pathways ultimately result in an increased incidence of CHD.^{8,9,10}

Insulin resistance also plays a key role in hypertension; as much as 50% of the hypertensive population appears to be insulin resistant.¹¹ It has been proposed that a large segment of essential hypertension is caused by enhanced renal sodium reabsorption in the distal tubule, which is promoted by hyperinsulinemia.¹² Hyperinsulinemia may also play a role by altering internal sodium and potassium distribution in a direction that is associated with increased peripheral vascular resistance.¹³ Insulin appears to work through other mechanisms as well to increase sympathetic nervous system activity and thus peripheral resistance.¹⁴

Furthermore, insulin resistance and hyperinsulinemia appear to have a critical relationship to androgen hormonal modulation. Research over the past 10 years has linked insulin with PCOS.¹⁵ Studies have shown that high circulating insulin may stimulate ovarian cytochrome P450c17 α and 17,20-lyase enzymes in predisposed women, resulting in elevations in serum and free unbound testosterone, which are associated with the signs and symptoms seen in PCOS. Insulin influences the androgenic state, not only by directly affecting the metabolism of ovarian androgens, but also indirectly by

regulating circulating levels of sex hormone-binding globulin (SHBG). Insulin has been shown to lower the production of SHBG.¹⁶ SHBG binds to testosterone and estrogens, making them biologically unavailable and thus lowered SHBG indirectly increases the delivery of unbound and bioavailable testosterone to tissues.¹⁷

Insulin resistance also appears to be related to certain forms of cancer. One hypothesis has postulated a link between colorectal cancer, insulin resistance, and hyperinsulinemia.¹⁸ While the epidemiological data are not completely consistent, the two largest prospective studies to date do support a modest correlation between colorectal cancer risk and diabetes.^{19,20} Even more recently, speculation has centered on the link between hyperinsulinemia and breast cancer.²¹ It has been known for some time that exposure of breast tissue to estrogens increases the risk of estrogen receptor-positive breast cancers. It is also well established that only the estrogens that are unbound to SHBG are biologically available to receptors on target cells. As mentioned, insulin inhibits the formation of SHBG. While SHBG binds to both testosterone and estrogen, it binds preferentially to testosterone, so decreased levels of SHBG result in increased levels of free unbound estrogen.²² A more graphic representation of these and other relationships can be seen in Figure 10.1.

Summary

As can be seen in this brief analysis, a specific dysfunction can result in myriad symptoms and can be caused by myriad factors. In this example, the imbalance is not confined to the single molecule, insulin; rather, it manifests in how the body secretes and responds to insulin. Promoting a healthy insulin response may involve many different factors. It is only by examining the web-like interconnections among these symptoms and factors that we can achieve a comprehensive assessment for the patient. As functional medicine clinicians, we examine the underlying imbalances; we ask ourselves what preceded and what triggered them; we look at upstream and downstream effects; and then we search for interventions that can affect the underlying interconnected pathways so that normal and even optimal function can be restored. Understanding how to rebalance important pathways in the body—establishing healthy and balanced web-like interconnections—is the key to reestablishing a healthy pattern of function.

Organ System Function and Underlying Mechanisms: The Interconnected Web

Alex Vasquez, DC, ND

Introduction

Understanding the scientific basis and clinical applications of functional medicine and a “whole patient” approach to health care requires that clinicians fully appreciate the interconnectedness of organ system function with biochemical and physiological processes. Simplistic models of health and disease developed decades ago may no longer be accurate or clinically useful insofar as they fail to reflect the more recently discovered complex and multifaceted interrelationships. (Figure 10.2 uses the functional medicine matrix to depict some of this complexity.) As discussed earlier in this chapter, numerous mechanisms mediate these interrelationships, including, but not limited to, those that can be described as biochemical, hormonal, neurological, immunological, piezoelectric, and physical or mechanical. Ultimately, we are forced to dissolve the artificial intellectual boundaries we have created between organ systems and expand our appreciation

Figure 10.1 Web-like interconnections: Insulin resistance syndrome

Section II

Principles of Functional Medicine

of individual molecules, cellular messengers, and the physiologic mechanisms that mediate intercellular communication and coordinate inter-organ function.

Figure 10.2 Web-like interconnections of the functional medicine matrix

The following discussion provides some specific examples of this profound interconnectedness that is a foundational principle of functional medicine. In this section, we will survey current research literature documenting the interconnected nature of some key organ systems and disease processes. With these examples, clinicians will better appreciate how the gastrointestinal, immune, cardiac, neurologic, and other systems interact with and depend upon each other for optimal physiologic function. Likewise, clinicians will understand more completely how essentially any dysfunction or lesion in the body can have clinically significant implications and distant adverse effects. From this perspective, individualized clinical interventions can be designed and employed to deliver better health outcomes.

Gastrointestinal Tract and Liver

While the liver and the gastrointestinal tract share an obvious anatomic connection via the portal circulation, the functional clinical implications of this connection are often not fully appreciated. Not only is the gastrointestinal tract the recipient of massive amounts of “external information” in the form of nutrients, toxins, and allergens that weigh in at more than 1,538 pounds (700 kilograms) per year, but the gastrointestinal tract is also a reservoir for the several hundred species and subspecies of yeast, bacteria, and other microbes with the potential to modify hepatic function (e.g.,

detoxification) and overall health (e.g., immune response) by numerous mechanisms and with positive effects or negative consequences. (See Chapter 13 for a detailed discussion of microorganisms.)

The various organs and tissues of the gastrointestinal tract perform the complex functions of digestion, absorption, exclusion, excretion, immunologic defense, antigen sampling, and temporary storage of food residues and other substances that have been ingested. The mucosa is selectively permeable and allows the absorption of nutrients and other molecules via transcellular and paracellular routes. Compromise of mucosal integrity due to injury from antigens, infection, systemic inflammation, or toxicants such as ethanol or nonsteroidal anti-inflammatory drugs, increases absorption of potentially harmful substances that are normally excluded when mucosal integrity has not been breached. Materials that are harmless when rejected by the selectivity of the intestinal mucosa can, when inappropriately absorbed, serve as a source of inflammatory and immunogenic stimuli for the embedded macrophages in the liver (Kupffer cells) and also for the systemic immune system and the brain’s embedded astrocytes and microglia. This phenomenon is clearly demonstrated by the neurological complications and focal white-matter lesions seen in the brains of patients sensitized to the dietary antigen gluten; in this scenario, it appears that dietary antigens cross a damaged mucosal lining and escape filtration by the liver to produce a systemic inflammatory response that manifests clinically as neurologic disease.^{23,24} It seems likely that other antigens are also capable of inducing a systemic inflammatory response in susceptible individuals.

The two most voluminous substances in the gastrointestinal tract are food antigens and microbial metabolites and debris, notably lipopolysaccharides (LPS, endotoxin) from gram-negative bacteria. These foreign substances normally excluded by an intact mucosa can serve as mediators of physiologic disruption (hence the importance of their exclusion), and indeed this is what has been observed in experimental and clinical data. For example, in patients with autism, increases in inflammatory mediator production are seen following exposure of monocytes to dietary allergens and LPS.²⁵ We also note that LPS is a potent inhibitor of numerous cytochrome P450 biotransformation pathways, thus leading to impaired drug metabolism as demonstrated in recent clinical trials.^{26,27} The implica-

tions of these data are profound and correlate closely with phenomena observed in clinical practice, namely that patients with irritable bowel syndrome—a condition causatively associated with both food intolerance and bacterial overgrowth of the small bowel—commonly report environmental sensitivity and medication intolerance. One plausible answer to the conundrum of the chronically unwell patient—typified by the patient with chronic fatigue or environmental illness—now becomes clear: overgrowth of the small bowel with LPS-producing bacteria leads directly to the gastrointestinal symptoms of gas and bloating, with immune system activation,²⁸ and also reduces hepatic clearance of metabolites, toxicants, and xenobiotics to which the patient eventually becomes sensitized (immunologically and/or non-immunologically). This explains, at least in part, the rationale for and impressive clinical efficacy associated with the implementation of clinical therapeutics that simultaneously improve intestinal microecology, improve mucosal integrity, and provide biochemical/nutritional support for the processes of detoxification.^{29,30}

Gastrointestinal Tract and Immune System

Any discussion of the role of the gastrointestinal tract in relation to the immune system must include a view of the gut that is inclusive of its contents of food antigens, intraluminal microbes, and their debris and metabolic products. When the gut is simply pictured as a passive semi-sterile tube with food entering one end and feces exiting the other, then it would appear an unlikely locus of immunogenic stimulation and neurogenic inflammation that can have systemic health consequences.^{31,32,33,34,35} Conversely, appreciation of the manifold quantitative and qualitative variables that can exist hidden from both the clinician's external view and the endoscopist's internal camera enables practitioners to have a more realistic perspective on the influence that gastrointestinal function, dietary antigens, and microflora can have on extra-gastrointestinal processes and overall health.^{36,37}

The combination of a hypersensitive/dysregulated immune system and exposure to dietary antigens sets the stage for the clinical phenomenon commonly described as "food allergy." Diverse in frequency, duration, severity, and quality, these immune-mediated adverse reactions to foods can precipitate or exacerbate

a wide range of clinical manifestations including rhinoconjunctivitis, chronic sinusitis, dermatitis, epilepsy, migraine, hypertension, joint inflammation, and mental depression.^{38,39} The immunopathogenesis generally includes multiple mechanisms and is not limited to mediation via IgE antibodies and histamine. Indeed, the pathophysiology of "food allergy" is commonly seen with numerous (not singular) aberrations in physiologic function, including responses mediated by or resultant from antibodies (including IgE, IgG, and/or possibly IgA classes of antibodies), cytokine-mediated responses (e.g., TNF- α), increased intestinal permeability, occult gastrointestinal inflammation, and alterations in gastrointestinal microflora.⁴⁰ To be more complete, our conceptualization of "food allergy" must also include awareness of enterometabolic disorders (i.e., the interconnections between food, intestinal flora, and systemic health⁴¹) as well as contributions from neurogenic inflammation (i.e., the translation of immunogenic inflammation to a neurologic signal with systemic proinflammatory effects⁴²).

Aberrations in gastrointestinal microflora can provoke a cascade of physiologic responses that may lead to widespread physiologic imbalances and result in a variety of clinical manifestations that may or may not conform to a recognized pattern or named disease even though the patient is highly symptomatic.⁴³ Furthermore, we can conclude from recent literature that the concept of molecular mimicry is now well established and that it provides us a model with which to apprehend the induction of immune dysfunction (especially autoimmunity) by microorganisms with immunogenic epitopes that are structurally similar to those in human tissues.⁴⁴ Thus, the link between "dysbiotic" gastrointestinal flora such as *Klebsiella pneumoniae* and systemic immune-mediated inflammatory disorders such as ankylosing spondylitis and chronic uveitis has a biological and scientific basis. Individualized assessment and treatment of such dysbiotic loci, whether in the gut, genitourinary tract, or nasopharynx, are likewise supported by current research and offer the hope of cure rather than an endless and additive cycle of anti-inflammatory and anti-rheumatic drugs. For example, evidence now shows that the systemic autoimmune disease Wegener's granulomatosis may be triggered and perpetuated by molecular mimicry with occult respiratory infections caused by *Staphylococcus aureus*, and that eradication of the infection can result in clinical improvement and

Section II

Principles of Functional Medicine

reduced need for ongoing anti-rheumatic medication.^{45,46,47} In addition to molecular mimicry, microbes (i.e., occult infections and environmental exposures) can also alter immune regulation by serving as a source of superantigens, which cause widespread and multifaceted immune dysfunction with resultant proinflammatory effects contributing to the exacerbation of allergy and autoimmune disease.⁴⁸

Immune System and Cardiovascular System

The role of subclinical inflammation in the etiology of atherosclerosis is no longer an issue of conjecture, as it has become a well-established aspect of the disease process. Even slight elevations in high-sensitivity C-reactive protein are associated with a significantly increased risk for cardiovascular morbidity and mortality in otherwise “apparently healthy” individuals.⁴⁹ With the increasing irrefutability of these data, pharmaceutical companies have scrambled to develop and sell drugs that can reduce this low-level inflammation, while physicians with a broader perspective have directed their energies toward intensifying their patient-centered search for the source(s) of inflammation in each individual patient. For example, subclinical inflammation can result from dietary indiscretion,⁵⁰ disturbed sleep,⁵¹ and vitamin D deficiency;⁵² in any of these situations, addressing the underlying causes of the inflammation with multicomponent nutritional/lifestyle interventions may deliver more effective health improvement than can the long-term use of inflammation-suppressing medications.^{53,54,55}

Gastrointestinal Tract, Liver, and Neurologic System

The last several years have witnessed an increased appreciation for the influence that the gut and liver have on the brain, and advancements in functional assessments are now documenting analytically what was at one point known only clinically—that the status of the gut and liver have profound effects on the functioning of the brain. Evidence supporting the existence of a clinically important gut-brain interconnection has been published consistently over many decades and in major journals; see Chapters 28 (discussion by Gershon) and 31 (discussion by James) for analyses of these complex interactions. Today, among the most poignant

examples are Parkinson’s disease and the autistic spectrum disorders. Indeed, the strength of evidence supporting the hepato-gastrointestinal link with these “neurologic” conditions is so strong that it could be logically argued that any treatment of these conditions that does not address the hepatic and enteric aspects of these diseases is therapeutically incomplete.

Although Parkinson’s disease was once considered idiopathic, we now recognize it as being a multifaceted disorder associated with defective mitochondrial function, impaired xenobiotic detoxification, and occupational and/or recreational exposure to toxicants, particularly pesticides. These associations align to create a new model for the illness based on exposure to neurotoxins such as pesticides,⁵⁶ which are ineffectively detoxified⁵⁷ and then accumulate in the brain,⁵⁸ inducing mitochondrial dysfunction⁵⁹ and oxidative stress,⁶⁰ and leading to the death of dopaminergic neurons. Therefore, from the perspective of both prevention and treatment, the clinical approach to Parkinson’s disease must include pesticide avoidance and optimization of detoxification to prevent the neuronal accumulation of neurotoxic mitochondrial poisons. The plan must also include optimization of nutritional status, antioxidant capacity, and mitochondrial function.⁶¹

The view that autism is a behavioral problem unfortunately continues to permeate present-day medical treatment of this condition, and many pediatricians and psychiatrists still advise only behavioral therapy and medicalization with psychoactive pharmaceuticals, particularly selective serotonin reuptake inhibitors (SSRIs).^{62,63} While these interventions produce modest improvements over those seen in control groups, neither intervention remotely addresses the complex underlying physiology nor offers the possibility of cure, and SSRI use in children is highly controversial due to the association with increased incidence of suicide.⁶⁴ We now know that autism is a multifaceted disorder associated with gastrointestinal inflammation, nutritional deficiencies,⁶⁵ multiple food allergies and intolerances,⁶⁶ impairments in liver detoxification and resultant accumulation of xenobiotics, the majority of which have neurotoxic and/or immunotoxic effects.⁶⁷ Thus, autism is not a behavioral disorder *per se*; rather, it is a gastrointestinal-allergic-immunological-toxicant-nutritional-environmental disorder, and the behavioral/cognitive abnormalities are symptoms of the underlying complex and interconnected pathophysiology. See

Chapter 30 (discussion by McGinnis) for an in-depth analysis of autism and oxidative stress.

Musculoskeletal System, Neurologic System, and Immune System

The adverse effects of a dysregulated immune system upon the musculoskeletal system are well known for their contributions to autoimmune diseases such as rheumatoid arthritis. In this classic scenario, the immune system is the effector, and periarticular structures, synovium, and joint surfaces are the targets of inflammatory and destructive processes that result in joint destruction and pain that affect the musculoskeletal and neurologic systems, respectively. This model holds that the direction of events flows from the immune system (autoimmunity) to the musculoskeletal system (target site) to the nervous system (perception of pain). This popular model must be updated in light of current research.

The phenomena of neurogenic inflammation and neuronal plasticity demonstrate the active, effector functions of the sensory nervous system and exemplify the extent to which the Cartesian model of the sensory nervous system (i.e., as exclusively afferent and passively receptive) is no longer valid.^{68,69} Much of the musculoskeletal inflammation seen in clinical practice appears due, in large part, to inflammation that originates from and is mediated by the sensory nervous system through the release of proinflammatory mediators from sensory nerves in periarticular tissues.^{70,71} Furthermore, evidence is accumulating that neurogenic inflammation can result from a heterogeneous group of diverse stimuli, including allergens, environmental chemicals, and pain distant from the site of arthritis.^{72,73} Likewise, evidence that intentional relaxation⁷⁴ as well as acupuncture⁷⁵ can modulate inflammatory pathophysiology indicates that psycho-emotional variables and nonbiochemical therapeutics are important clinical considerations for patients with inflammatory diseases.

Evidence also suggests that musculoskeletal therapeutics such as spinal manipulation may influence immune responsiveness. Brennan et al.^{76,77} showed that chiropractic spinal manipulation resulted in an acute increase in phagocytic capacity of polymorphonuclear neutrophils, and that this result was seen only following authentic (versus sham) manipulation, and that the effect was proportional to the increase in serum levels of substance P, a

multifunctional molecule that acts as a neurotransmitter as well as a proinflammatory messenger. While the clinical implications of these data are yet to be clarified, they clearly demonstrate that the immune system is sensitive to mechanical stimuli.

Beyond Biochemistry and Neurophysiology: Piezoelectricity as a Mechanism for Intersystem Connectedness

Piezoelectricity, the continuum between mechanical stress and bioelectric conduction, is a well-established aspect of organic matter, affecting all vertebrates and, therefore, humans. Notably, the nervous system in general and the spinal cord in particular demonstrate an intrinsic dipole moment that is demonstrable across species of vertebrates.^{78,79} In 1977, Lipinski from Tufts University School of Medicine⁸⁰ summarized the current research of the day and speculated on the effects of spinal manipulation, yoga, and acupuncture as mediated via the body's inherent pyroelectric and piezoelectric properties. Lipinski's literature review (particularly including the work of Bassett⁸¹) suggests that "piezoelectricity present in many biological systems may theoretically control cell nutrition, local pH, enzyme activation and inhibition, orientation of intra- and extra-cellular macromolecules, migratory and proliferative activity of cells, contractility of permeability of cell membranes, and energy transfer." With these concepts and possibilities considered, we can construct a conceptual bridge linking mechanical stimuli such as massage, manipulation, exercise, and yoga, and (neuro)electrical stimuli such as acupuncture, meditation, prayer and intentionality, to plausible biochemical/physiological effects that translate into observed clinical benefits. This integrated model helps to explain the effects of "energetic" therapeutics such as moxibustion, acupuncture, and yoga that may be mediated by nonbiochemical physiologic mechanisms. Furthermore, this model also helps us to understand hitherto unexplainable phenomena such as the well-reported sensitivity that some people display to changes in the weather and the positioning of their bodies in relation to electromagnetic fields of the planet, electrical equipment, and power lines. Piezoelectricity may also be the physiologic conduit that transmits the effects of "distance healing," prayer, and intentionality.^{82,83,84}

Summary

Human physiology is complex and treatment plans must be multifaceted to reflect this complexity. Cells, tissues, and organ systems work in concert—not in isolation—and therefore effective intervention generally requires improvement in numerous organ systems. As the artificial boundaries between organ systems dissolve, a unifying theme emerges, namely that the attainment, preservation, and re-establishment of health must be all-encompassing. Programs and paradigms related to the treatment of disease and the attainment of optimal health must reflect appreciation of environmental, physical, mental/emotional, nutritional, biochemical, hormonal, immunologic, neurologic, and gastrointestinal components of our existence that coalesce without boundaries to make the human body and our experience of life itself. Thus, new frontiers in health care will be reached not solely when new discoveries occur, but also when the integration of these discoveries into a cohesive, multifaceted, unified healthcare model prepares the way for more accurate understanding and more effective interventions. Healthcare providers of diverse backgrounds (ND, DC, MD, DO, RD, RN, LAc, and others) can and must work together to offer scientifically based, multifactorial interventions that are adapted to the specific needs of individual patients.

Chapter 11

Health as a Positive Vitality

Nancy Sudak, MD

The Goal of Health is More than the Absence of Frank Disease

The disease model is compatible with a managed care setting, in which insurance reimbursement for services is predicated upon codified diagnoses. The problem with this practice is that it fails to acknowledge the zone of dysfunction that occurs between optimal health and diagnosable disease. Although a working understanding of disease is both critical and useful, it can be enlightening to acknowledge that a disease is not a bona fide entity, but rather a label we affix to clinical patterns of signs and symptoms. When no “disease” can be found, this model becomes less relevant, and clinicians are often at a loss to identify effective treatments beyond palliative pharmaceuticals. We lose the opportunity to transform health and move the patient back toward wellness when we adhere to this model; regenerative potential is diminished as one advances further toward chronic disease on this continuum. Clearly, waiting until disease identifies itself before developing meaningful therapeutic strategies is detrimental to our patients and costly for our healthcare system overall.

An unfortunate result of employing the disease model is that the concept of health has come to be equated with the absence of disease. Patients who return from medical evaluations relative to symptoms frequently report, “The doctor said there’s nothing wrong with me.” Though patients tend to be relieved when no major disease is discovered, they may also be distressed by the discrepancy between their sensation of being unwell and the physician’s assertion that all findings are normal. Significant morbidity and psychological distress may ensue,¹ particularly if the physician’s attitude is dismissive. Because the focus of medical education is on disease, not wellness, physicians are not specifically

trained to be qualified surveyors of vitality. A comprehensive medical history should include inquiry about habits that establish health as well as behaviors that erode it. Functional medicine practitioners evaluate patients through physical findings, objective laboratory measures, and a comprehensive appraisal of an individual’s environmental inputs, which typically include: dietary habits, quality of air, water and soil, toxic and infectious exposures, exercise patterns, social relationships, behavior, stress management techniques, and spiritual centering practices.

The word “health” is derived from the Old English “*hal*,” meaning wholeness, being whole, hale, sound, or well.² In current parlance, we recognize that wholeness signifies full function of the body-mind-spirit. In this light, it is not extreme to expect to feel fully alive, vibrant, and even joyful when healthy. Since much of the population reports chronic symptoms in the absence of authenticated disease,³ patients are led to believe that it is normal to feel unwell in the face of a clean bill of health. It is now evident that the overweight adult population in the U.S. constitutes the majority;⁴ thus, it has become standard to be overweight. Obviously, the solution is not to rework our height and weight charts to accommodate an obese population, but to become conscious that what appears to be most common in our culture is not necessarily healthy. By adopting a more optimistic and functional approach to wellness, we define health as positive vitality, rather than mere absence of disease. This attitude promotes consideration of features that fortify our physiology to promote wellness, instead of concentrating on negative factors that give rise to illness.

We are aware of literally thousands of highly useful disease markers. However, ruling out disease by using

laboratory measures doesn't necessarily rule in good health. Positive indicators of wellness may be found to some degree on objective testing (e.g., cellular nutrient levels, beneficial flora cultures, antioxidant levels, hormone metabolites). A diagnosis of being truly healthy will depend on favorable physical exam findings and laboratory evaluations, of course, but the patient's story of how vital and fully functional he or she feels must figure prominently in the clinician's assessment. Patients who report feeling unwell despite unrevealing evaluations tend to benefit from a functional medicine approach since broad areas of dysfunction are identifiable and treatable through supportive and restorative measures.

Importance of Functionality to Quality of Life

Illnesses and symptoms, whether acute or chronic, may generally be traced to one or more functional disturbances within the functional medicine "web." Functional status is characteristically diminished in keeping with the magnitude of symptoms. To use a simple example of immune system dysregulation, a person with an itchy patch of atopic dermatitis on one ankle is less likely to experience a decline in functionality than someone with generalized urticaria. When we are highly symptomatic, discomfort becomes a leading influence from which we cannot be readily distracted, and a greater degree of debility is anticipated. When functional capacity weakens, we can also expect quality of life to decline. Health-related quality of life is a multifaceted concept that reflects the outcome of an illness on a patient's evaluation of his or her functional status and emotional well-being. Abundant reports in the medical literature confirm the harmful impact of illness or chronic symptoms on quality of life observed in conditions such as: osteoarthritis,⁵ chronic fatigue syndrome,⁶ obesity,⁷ insomnia,⁸ childhood migraines,⁹ and hip fractures.¹⁰

Good health—full functionality on every level—is achieved by favorable interactions between our genes and our environment. When we understand that our genes have not changed substantially from those of our Paleolithic progenitors, but that our modern environment has been radically altered since that era, we appreciate that our journey to maintain positive vitality must involve manipulating our environment advantageously to match the physiology of our genes. No two people share identical genetic activity; each individual is con-

stantly experiencing his or her environment to produce a certain quality of life. Our daily behaviors are fundamental to the production of our internal and external environments, and represent the most powerful influences upon our physiology. These daily choices contribute directly to biochemical function and may include: diet quality and quantity, micronutrient adequacy, level of physical exercise, action of the hypothalamic-pituitary-thyroid-adrenal axis, toxic or infectious exposures, and emotional experiences of joy, fear, hostility, connectedness, etc. Negative influences include frequent application of lawn pesticides, regular ingestion of *trans*-fatty acids, frequently skipping meals, and excessive activation of the stress response, whereas positive influences are exemplified by purposeful avoidance of xenobiotics, adequate daily intake of pure water, essential fatty acids, antioxidants, and regular use of stress management techniques.

When we refer to an individual as being "highly functional," we are often making a judgment of someone's ability to be physically or intellectually industrious. A principal driving force behind feeling energetic, creative, and productive is vigorous cellular and biochemical function. Assessing the core clinical imbalances of a patient is predicated upon understanding the body's major molecular mediators (e.g., cytokines, immunoglobulins, antioxidants, stress hormones, neurotransmitters, fatty acids). Our health is determined by the complex interplay of these biologic modifiers as they cut across multiple organs. (See sections IV and V of this book for detailed information about these important influences.) The further we depart from daily healthy lifestyle practices, the less molecular support we provide to our metabolic functions, and if this process continues, cellular resiliency declines and we have begun to pave the road toward dysfunction and disease. We may feel less physically and emotionally lively as this path unfolds.

We can easily think of instances of how the mind affects the body. A classic example of this concept is the well-documented effect of mindfulness meditation in reducing chronic pain.¹¹ Another common example is the association between hostility and increased risk for myocardial infarction.¹² The effect of the body on the mind is equally observable, since physiologic variables clearly contribute to emotional and cognitive welfare. Straightforward examples of molecular mediators that modulate brain function include: blood glucose levels,

neurotransmitters, essential fatty acids, and B vitamins.¹³ However, less obvious biochemical mediators may have a profound impact on function. For example, if dietary intake of gluten is inappropriate for a given individual's physiology, psychiatric and emotional disturbances may be seen.^{14,15} Certain people may become sluggish and unmotivated after succumbing to a carbohydrate craving. Many patients who implement a comprehensive elimination diet experience unanticipated abatement of chronic symptoms long considered part of their normal physiologic landscape. In this way, they learn that diet is an environmental input that is critically important in determining function and vigor.

Spiritual connection represents another dimension of being that affects quality of life. Though difficult to quantify in research, the role of spirituality in health care has been receiving increasing attention.¹⁶ Geriatric patients reporting greater degrees of spirituality tended to more highly appraise their health status.¹⁷ The American Psychiatric Association's Board of Trustees has passed a resolution stating that "it is useful for clinicians to obtain information on the religious or ideologic orientation and beliefs of their patients so that they may properly attend to them in the course of treatment." Religious commitment appears to be correlated with decreased risk for depression, substance abuse, hypertension, and other chronic health problems.¹⁸ In a recent survey, greater than 75% of patients believed that spiritual issues should be addressed routinely in clinical care.¹⁹ Practitioners who engage with patients' spirituality will bring more meaning to healthcare delivery and the therapeutic relationship. A practical approach to accomplishing this goal is discussed in Chapter 33.

Though conventional medicine seems to have partitioned mind and spirit from body, the functional medicine approach embraces these essential elements of wholeness as they affect one another within the matrix of core areas of function. Quality of physiologic function is generated by the performance of daily behaviors, by and large within the sphere of our control. We maximize wellness of body-mind-spirit when we consistently implement practices that strengthen our unique constitutions, and learn to reject those that seem to impair vitality and optimal function. As biochemically unique individuals, we must each determine which environmental inputs are ideal in defining our personal health.

The functional medicine model embraces the old adage "If you don't take time for your health, you'll have

to take time for your illness." We understand that our daily actions collectively represent the most significant factor of control over our health. Decision making in this regard occurs many times within a 24-hour period. When we become mindful of our immediate options to produce better health outcomes, we may ask ourselves many questions as we navigate through the day:

- Shall I eat a full breakfast or just have a doughnut during my break?
- Shall I walk to work or drive?
- Should I exercise today or sleep later?
- Which would suit my needs better—a slice of pizza on-the-run or a meal of lean protein, fresh vegetables, and whole grains that I actually sit down to eat?
- Should I watch a rerun of my favorite sit-com or go to bed earlier?
- Should I try to remain gluten-free for a few weeks to see if my headaches improve?
- Will application of lawn pesticides to kill the dandelions on my lawn affect my health and that of the planet adversely?

Once it becomes habitual to ask these questions and to mindfully implement the healthier options, making optimal choices becomes self-perpetuating. If we are paying attention, we can quickly realize how much better we feel when we show a preference for those selections better matched to our physiology.

The functional medicine paradigm illustrates the art of living well as the basis for health and well-being. Symptoms or impairment of vitality will prompt a trained practitioner to investigate for functional imbalances. Functional medicine has the potential to revolutionize healthcare delivery, not only as a result of its anticipatory and preventive nature, but because the identification and supportive treatment of underlying contributing factors is the most effective means of addressing the health of the individual. By recognizing and treating functional disturbances, physicians can guide patients toward more advantageous environmental inputs, thereby saving millions of dollars in healthcare expenditures. Functional medicine physicians routinely state that they have become re-enchanted with medical practice; once they have learned the application of nutritional biochemistry and functional physiology, they have at their disposal an extensive array of tools that are quite satisfying to implement.

Chapter 12

Healthy Aging: The Promotion of Organ Reserve

David S. Jones, MD, Jeffrey S. Bland, PhD, and Sheila Quinn

Introductionⁱ

For nearly 20 years, we have used the term “organ reserve” in functional medicine as a marker for healthy aging. Our assumption has been that if we enable our patients to reduce oxidative stress and inflammation, improve the match of genes to environment, support healthy lifestyles, and improve micronutrient repletion, we will be creating greater flexibility and adaptability (degrees of freedom) in the aging human organism, enabling people to live out their years with longer periods of health and vitality and shorter periods of disease and debility prior to death. The research base, however, has yet to precisely define “organ reserve”; nor are we yet able to measure or specify the effects of all these preventive measures on the reserve capacity of our organs (hearts, lungs, livers, kidneys, brains, etc.) to respond to life’s insults—illness, trauma, loss, chronic stress, and poor lifestyles. It is difficult, therefore, to describe a causal link between the concept of organ reserve and the phenomenon of healthy aging. It is, however, a useful concept—a kind of shorthand term that encompasses the physiological benefits of the functional medicine approach to health. With that caveat, let’s explore some aspects of theories about aging and how we can help patients to more years of optimal health.

ⁱThis chapter was adapted from “Healthy aging and the origins of illness: Improving the expression of genetic potential,” which was published by the authors in *Integrative Medicine: A Clinician’s Journal*. Dec 2003/Jan 2004;2(6):16-25. Many thanks to the journal for permission to adapt this article.

Aging and Disease: Rectangularizing the Morbidity Curve

Suggestions from anthropological data estimate that our earliest ancestors lived on average only about 18 years, and that by the time of the Roman Empire, life expectancy was still not much over 22 years. In the interval from that point to the start of the 20th century, life expectancy at birth doubled to 45 years.^{1,2} “Throughout most of the 20th century, death rates declined dramatically at every age in developed nations, and life expectancy at birth rose rapidly. For example, life expectancy at birth for U.S. females increased from 48.9 years in 1900 to 79.0 in 1995.”³

Ageing [sic] is a biological puzzle of long standing, particularly because it manifests itself over a wide range of biological systems, tissues and functions. ... But ageing is not a function. Ageing can be defined as an endogenous progressive deterioration in age-specific components of fitness.⁴ It is not actively selected for. It is instead a secondary effect of the decline in the force of natural selection with age.^{5,6} From such theory it follows that many loci, and many biochemical pathways, are expected to produce the deleterious effects of ageing, because it is a secondary side-effect of normal evolution.”⁷

If it is true that the forces of natural selection lose hegemony in the years following fecundity (the aging years), but that the forces of selection have set in place the genetic mechanisms that define the biologic context of adaptive possibilities, then new models for understanding aging and constructive interventions, in terms of both public health recommendations and individual healthcare strategies, are required.

In 1980, James Fries discussed in *The New England Journal of Medicine* “a set of predictions” on aging, natural death, and the compression of morbidity.⁸ In his

paper, he challenged the popular notion that aging is necessarily associated with increased morbidity and disability. He also suggested that, in developed countries, with substantial improvements in public health measures, nutrition, and medical care, people would approach greater parity between “expected biological life span” and actual years of functional life. As summarized in a reflective editorial published in the same journal 18 years later: “In the ideal case, the healthy citizens of a modern society will survive to an advanced age with their vigor and functional independence maintained, and morbidity and disability will be compressed into a relatively short period before death occurs at around the age of 85 years.”⁹ This has become known as the *Fries hypothesis* and as the rectangularizing of the morbidity curve based on *maintenance of organ reserve*.

In 1998, again in the *NEJM*, Anthony Vita and colleagues (including James Fries) presented evidence collected from a study of 1,741 University of Pennsylvania alumni over a period of 32 years.¹⁰ Their extensive data supported the notion that *healthful lifestyle activities* were associated with less loss of function (disability) and fewer chronic illnesses during the life span. In this study, the lifestyle factors showing the greatest correlation with differences between the upper and lower levels of risk were: (1) smoking, (2) body mass index, and (3) patterns of exercise. An accompanying editorial summarized the findings: “In the group with the lowest level of risk, the onset of functional disability was postponed by about five years. In the group with the highest level of risk—those who had a body mass index of 26 or higher, smoked 30 or more cigarettes per day, and got no regular vigorous exercise—there was both an earlier onset of disability and a greater level of cumulative disability, as well as more disability in the final year of life for the 10% of the cohort that had died.”¹¹ In the Harvard Study of Adult Development, George E. Vailant corroborated the importance of the same risk factors—smoking, obesity, and exercise—but added two emotional components, stable marriage and “mature defenses,” as important differentiating factors of successful aging.^{12,13}

However, subsequent analyses of the Fries hypothesis have demonstrated that the rectangularization Fries described is actually composed of two elements, mortality and morbidity, and they should be analyzed separately. Compression of *mortality* refers to an increasing concentration of *ages at death* (decreased variability of

ages at death); whereas compression of *morbidity* refers to increasing concentration of illness and disability into the latter years of life.¹⁴

The calculations of life expectancy contain statistical Gordian knots that preoccupy many researchers in the field of aging. Behind the pure intellectual interest in aging and life expectancy lurk important public policy issues that will not be explored here.¹¹ The fundamental debate is between those who believe increases in longevity will proceed more slowly in the future than they have in the past, eventually stopping entirely, and those who believe the data do not support such a conclusion. The hypothesis presented by Carnes and Olshansky,¹⁵ postulating that animal and human data suggest that species “possess an *intrinsic mortality signature*,” falls into the first category:

Imagine a population completely protected from extrinsic causes of death, but denied access to any medical intervention that might influence (i.e., postpone the age of death) intrinsic processes—the goal for most control groups in studies involving laboratory animals. Assuming the population is representative of the species from which it came, the life expectancy for this hypothetical population is an estimate of the upper limit for the average life span of individuals within this species—an upper limit imposed by the intrinsic mortality signature.

The conundrum of *life expectancy* or *species-specific intrinsic mortality signature* rests squarely on the implicative enfolding of the natural processes of aging occurring always in real time within an incalculably complex environment that interacts with the inherent genetics and biological processes of each individual within the species. We are learning that risks of disease and age-related decline are unique to each patient, and that phenotypic expression appears to be more vulnerable to environmental pressures than to genetic influences.¹⁶ Many in this field assert that the extension of *functional life span*ⁱⁱⁱ and *life expectancy*^{iv} as seen in the 20th century is unlikely to be duplicated in the 21st century. The large incremental improvements in public health measures, nutrition, and medical care associated with the increases in life expectancy in the 20th century are not reproducible in the 21st century without “modifying endogenous

¹¹ The U.S. Social Security Administration, for example, must predict the size of future beneficiary populations. If, as some researchers believe, the agency is underestimating future increases in longevity, the Social Security system will be subject to some very significant unplanned-for financial burdens. [Roush W. Live long and prosper? *Science*. 1996;273:42-46.]

biological processes inherent to aging."¹⁷ Olshansky and Carnes go on to assert: "There are no life-style changes, surgical procedures, vitamins, antioxidants, hormones, or techniques of genetic engineering available today with the capacity to repeat the gains in life expectancy that were achieved during the 20th century."

However, a 2002 article by Oeppen and Vaupel¹⁸ disputes their contentions. Using life expectancy data for the world's most long-lived populations, they show evidence of a "regular stream of continuing progress" as represented by a linear climb from 1840 to 2000. During that period, record life expectancy broke every prediction advanced, usually within just a few years: "Best-practice life expectancy has increased by 2.5 years per decade for a century and a half." Not to mince words, Oeppen and Vaupel conclude: "This mortality research has exposed the empirical misconceptions and specious theories that underlie the pernicious belief that the expectation of life cannot rise much further."

Wilmoth¹⁹ concurs: "Extrapolation rides the steady course of past mortality trends, whereas popular and scientific discussions of mortality often buck those historical trends, in either an optimistic or pessimistic direction ... [E]arlier arguments about an imminent end to gains in human longevity have often been overturned, sometimes quite soon after they were put forth." In another paper published in 2000, he argued further that this contrarian view is based on data that show that "the most significant trend now affecting longevity in industrialized societies is the decline of death rates among the elderly."^{20,21}

In 1999, Wilmoth and Horiuchi also demonstrated through demographic statistical methods that *rectangularization of mortality* is not a necessary and concomitant association with mortality decline.²² Myers and Manton, in 1984, had shown that the standard deviation of deaths above age 60 in the United States increased rather than decreased between 1962 and 1979, in spite of the decline in death rates.²³ In the old-

est-old populations in developed countries there has been an unexplained expansion, rather than a compression of mortality (greater variability of the *ages at death*).^{24,25,26} Also, the overall rectangularity of the survival curve and the *limits of longevity* are not irrevocably linked as initially postulated by Fries in 1980. In the original theory, as the survival curve rectangularized, the limits of longevity would be substantially revealed. As shown by James Vaupel and associates,²⁷ as well as others,²⁸ as early as the 1950s and into the 1990s, there was a general loss in the rectangularization of the survival curve as the limits of longevity came very much into question due to the well-documented rise in improved survival at older ages.^{29,30,31} For example, the number of centenarians has doubled approximately every 10 years since 1950.³²

We enter the 21st century in need of a *general theory on population aging*,^{33,34} and humbled by the awareness that "our understanding of the complex interactions of social and biological factors that determine mortality levels is still imprecise."³⁵ It is clear that the present sustained increase in life expectancy from birth is now due to the mortality decline at the highest ages,³⁶ even if as yet unexplained. We have entered a transition in population biodemographics within the developed countries where fecundity and mortality are lower and causes of death are less associated with infectious diseases and/or accidental death, and more associated with degenerative and age-related causes. Research is ongoing to delineate the subtle differences and causes of (a) life expectancy, (b) disease-free life expectancy, and (c) disability-free life expectancy.

Contemporary research has substantiated Fries' 1980 prediction that chronic illness can be postponed by changes in lifestyle, contradicting the anticipated forecast of an ever older, ever more feeble, and ever more expensive-to-care-for populace. Although his first prediction that the length of human life is fixed has proved erroneous, his second prediction that many of the "markers" of aging can be modified, has proved prescient.³⁷ His charge that "acute illness has ceased to be the major medical problem in the United States," and that "chronic illness now is responsible for more than 80% of all deaths and for an even higher fraction of cases of total disability" has only recently received the attention it deserved.³⁸

Fries challenged the medical establishment to focus on both the elements of aging (senescence) and a strategy

ⁱⁱⁱ *Life span* refers to a specific individual's length of life. For example, the verified oldest-age-at-death of a member of a species establishes the *maximum* life span for that species. Therefore, maximum life span is always greater than life expectancy. The oldest fully authenticated age to which any human has ever lived is 122 years and 164 days, by Jeanne-Louise Calment. She was born in France on February 21, 1875 and died at a nursing home in Arles, southern France on August 4, 1997 (*Guinness Book of Records*).

^{iv} *Life expectancy* is a statistical measure of a population; it is actuarially derived and is especially sensitive to improvements in life expectancy at birth rather than later improvements in survival.

of postponement, rather than cure, for the chronic diseases. In order to construct therapeutic interventions around validated elements that can enhance healthy aging and the compression of morbidity, researchers are teasing out those mechanisms that are associated with death from natural aging, as well as those consequent to chronic illness.

For most of us, death will be preceded by a decline in function, and we would all like that period of decline to be as brief as possible. Achieving that goal requires that physicians and patients alike understand what contributes to age-related decline and disease, and what mitigates against the involution of physical, psychological, and social vigor. We need a deeper understanding of the complex interaction of aging and decreased functional reserve, and the interwoven associations with illness, so that—as clinicians—we do not fail to give our patients the best possible chance for maximum health and function as they age.

Mechanisms of Aging

A number of models^v have been proposed to account for the observable effects of aging on living organisms.^{39,40,41,42,43,44,45} The model proposed by Denham Harman, MD, PhD, in 1956,⁴⁶ has developed in the intervening half century the greatest number of advocates and the most robust repository of research.^{47,48} Dr. Harman proposed that the accumulated effects of oxidative damage from normal metabolism create mischief for members of all sex-dependent species after the reproductive years, although, as mentioned earlier, there may also exist extenuating factors in the oldest-old.^{49,50}

A number of lines of thinking converge around Harman's *free radical theory of aging*.^{51,52,53} The evolutionary biologists explain aging as a sidebar to the underlying mechanisms and processes of natural selection. As explained by Michael Rose in 1999:

Heritable traits persist and become prevalent in a population—they are selected, in evolutionary terms—if those properties help their bearers to survive into reproductive age and produce offspring. The most useful traits result in the most offspring and hence in the greatest perpetuation of the genes controlling those properties. Meanwhile traits that diminish survival in

youth become uncommon—are selected against—because their possessors often die before reproducing. ... (However) in contrast to deleterious genes that act early, those that sap vitality in later years would be expected to accumulate readily in a population, because parents with those genes will pass them to the next generation before their bad effects interfere with reproduction. (The later the genes lead to disability, the more they will spread, because the possessors will be able to reproduce longer.)⁵⁴

These ideas have produced some very interesting research into the mitigation of the inevitable ravages of oxidative damage as the organism ages. For example, rat studies performed by Dr. Ames and his associates showed that feeding “old rats” the normal mitochondrial metabolites *acetylcarnitine*^{vi} and *lipoic acid*^{vii} for a few weeks restores mitochondrial function, lowers oxidants to the level of a young rat, and increases ambulatory activity to a level usually seen only in young rats.^{55,56,57}

These animal studies suggest plausible underlying mechanisms of aging as well as possible restorative interventions. Dr. Ames summarizes: “With age, increased oxidative damage to proteins and lipid membranes, particularly in mitochondria, causes a deformation of structure of key enzymes, with a consequent lessening of affinity (Km) for the enzyme substrate; an increased level of the substrate restores the velocity of the reaction, and thus restores function.”⁵⁸

Studies are now being conducted with human subjects using DNA microarray technology as an assay.⁵⁹ Young and old rat lymphocytes and young and old human leukocytes will be compared as a measure of interventional success. Ames and his associates have termed this research *searching for the metabolic tune-up*. They hope to determine the levels of micronutrients that mitigate against DNA damage. By using DNA microarray technology, the experimental interventions can be assayed for enhanced or worsened *genomic stability*. They are presently working their way through all of the established micronutrients that have shown an association between deficiency and DNA damage. However, in the end, tuning-up the metabolism will require an understanding of the cross-connections between the

^v Not covered here are the models based on the arrays of alleles differentiating long-lived from shorter-lived individuals within species populations, programmed aging as a specific development end point (the aging gene model), and the role of telomerase in cellular aging. (See endnotes associated with the referenced sentence.)

^{vi} Carnitine is an amino acid that facilitates transport of free fatty acids across the cell membrane of the mitochondria.

^{vii} Lipoic acid (a powerful antioxidant), CoQ10, tetrahydrofolate, and glutathione are part of the mitochondrial multi-enzyme complexes intricately involved with oxidative phosphorylation, cellular respiration, and Krebs cycle-derived cellular ATP/energy production within mitochondria.

unique genetic constitution and the unique nutrient needs of the individual.⁶⁰ The thrust of this present research was presaged by Ames' proposal in his 1998 paper that micronutrient inadequacy is genotoxic:⁶¹

Micronutrient deficiency may explain, in good part, why the quarter of the population that eats the fewest fruits and vegetables (5 portions a day is advised) has about double the cancer rate for most types of cancer when compared to the quarter with the highest intake Eighty percent of American children and adolescents and 68% of adults do not eat five portions a day. Common micronutrient deficiencies are likely to damage DNA by the same mechanism as radiation and many chemicals, [and] appear to be orders of magnitude more important. Remedying micronutrient deficiencies is likely to lead to a major improvement in health and an increase in longevity at low cost.

The Origins of Illness: A Mismatch Between Genes and Environment

"Most of us believe we age by genetically predetermined processes that are beyond our control ... and hope we have gotten the genetic luck of the draw."⁶² For many years, medical professionals and the lay public alike believed that we could do little to prevent the associated illnesses of aging, as they were thought to be principally a deterministic result of our genetic inheritance.

In the past 15 years, however, as researchers have deciphered the genome locked into *Homo sapiens'* 23 pairs of chromosomes, this deterministic model of sickness has been found by most scientists in the field to be incorrect.⁶³ Genes do not code for specific diseases of aging.⁶⁴ Instead, they code for various strengths and weaknesses in the human constitution that give rise to resistance or susceptibility factors for age-related diseases. Some people get the "luck of the draw" and have more resistance genes to factors associated with 21st century living. For most people, however, the occurrence of illness as we age is a result of the blending of genetic susceptibility factors with environmental exposures.⁶⁵

The multifactorial "genes for heart disease" or "genes for cancer" may never be translated into actual disease expression unless the individual plunges these less resistant genes into an environment that triggers his or her unique constitution. For example, the susceptibility within the array of "genes for heart disease" may not result in heart disease until the person eats a diet rich in saturated fat, smokes, lives a lifestyle that enhances frequent high tides of his/her stress hormones, and/or has

inadequate levels of the B vitamins in his/her diet to appropriately respond to these environmental stressors.⁶⁶ As Nada Abumrad pointed out, "Nutritional support can be tailored to the individual genotype to favor beneficial phenotypic expression or to suppress processes that lead to later pathology."⁶⁷ This recognition gives individuals much greater control over their health as they age than they would have if all sickness were simply a natural consequence of advancing age. *The pluri-potential qualities of our life depend on the vast array of information within our genome and how/what signals are—and have been—generated to induce expression from our genome.*^{viii}

When Watson and Crick⁶⁸ published their benchmark research on the structure of DNA in 1953, they little suspected their discovery would initiate a revolution in medicine. They could not know it would empower a *revolution of choice* for the kind of "health probability" an individual can select, as he/she grows older.⁶⁹ Watson and Crick's discovery heralded the dawn of what has been called "genomic medicine." For clinicians it represents the age of *personalized medicine*.⁷⁰ We now know that even diseases (like cancer) that we once thought were "all in the genes" are caused by interactions between our gene matrix and environmentally derived signals transduced at the cell membrane interface and then translated through genetic processing.

From Genotype to Phenotype: The Role of Individual Susceptibility

In an article published in the *NEJM* in 2000, investigators from the Karolinska Institute in Sweden reported on 44,788 pairs of twins from their extensive health and human services registries. (One of the benefits of the socialized medical system in Sweden, Denmark, and Finland is the huge databases of patients' demographics and health outcome histories.) This specific study showed that identical twins do not experience cancer at the same rate. In fact, the study reported, "Inherited genetic factors make a minor contribution to susceptibility to most types of neoplasms. This finding indicates that the environment has the principal role in causing sporadic cancer."⁷¹

^{viii} In Matt Ridley's (1999) *GENOME: The Autobiography of a Species In 23 Chapters*, he uses the analogy of a book of life in 23 chapters to highlight the connection between what has been found in the gene mapping discoveries to this point in the genome project (30,000 to 35,000 gene sequences derived from 2.9 billion nucleotide codes in the 23 paired chromosomes).

In 1950, Roger Williams wrote a paper titled “The Concept of Genetotrophic Disease.”⁷² In this *Lancet* article, Williams advanced the bold concept that a number of diseases whose origins were unknown at that time could be understood as conditions associated not with malnutrition, but with *undernutrition* based on the individual’s unique genetic needs. He postulated that heart disease, cancer, diabetes, arthritis, schizophrenia, and even alcoholism could be considered to have “genetotrophic origin.” Williams’ concept, rooted in genetics and biochemistry, proposed that undernutrition would result in suboptimal metabolisms within susceptible individuals, which would, in turn, increase the potential for chronic illness developing over decades of living.

Medicine did not at that time embrace the genetotrophic model for the origin of disease, and the concept remained dormant for 50 years. The results of the Human Genome Project in the late 20th century and the revolution in understanding how diet and specific macro- and micronutrients influence gene expression have recently made Williams’ concepts seem prescient. He appears to have predicted the transition in medicine from a largely empirical meta-science to a predictive science based on unified mechanisms of disease. We now know that the mechanisms that result in the initiation and progression of most age-related chronic illnesses have their origin, at least in part, in the genetotrophic concept.^{73,74}

The recent publication of a landmark paper by Ames et al.⁷⁵ provides the bench-science substantiation needed to flesh out Williams’ postulates. Ames shows in his encyclopedic review paper that “as many as one-third of mutations in a gene result in the corresponding enzyme having an increased Michaelis constant, or *K_m* (decreased binding affinity), for a coenzyme, resulting in a lower rate of reaction.” Some people carry polymorphisms^{ix} that are more critical in determining the outcome of their health history. He goes on to argue that studies have shown that administration of higher than dietary reference intake (DRI) levels of cofactors (specific vitamins and minerals) to these polymorphic genes

restores activity to near-normal and even normal levels. He concludes that “nutritional interventions to improve health are likely to be a major benefit of the genomics era.”

It is also recognized now that nutritional status and specific nutrients modify drug metabolism, and the impact is unique to the genotype of the individual. Researchers have recently discovered that specific nutrients modify the expression and function of detoxification genes.^{76,77,78} Cruciferous vegetables, which include broccoli, cauliflower, Brussels sprouts, and cabbage, contain nutrients called glucosinolates. These substances break down in the digestive tract to produce chemicals such as indole-3-carbinol, sulforaphane, and phenylisothiocyanate. These chemicals, in their turn, activate specific genes that help detoxify cancer-producing substances.⁷⁹ The mechanism by which specific nutrients help protect individuals with certain genotypes is just now being fully explored.

Other nutrients, such as glutathione, CoQ₁₀, vitamins C and E, the B-complex nutrients (including folic acid, B12, and B6), and the essential minerals zinc, copper, and selenium, all assist the genes in protecting against heart disease, stroke, dementias, cancer, and diabetes.^{80,81,82,83,84} Genetic uniqueness may cause some individuals to require 100 times as much of a particular vitamin, mineral, or accessory nutrient as another for good health.⁸⁵ For example, “a common polymorphism exists for the gene that encodes the methylene tetrahydrofolate reductase (MTHFR) enzyme, which converts 5,10-methylene tetrahydrofolate to 5-methyltetrahydrofolate, required for conversion of homocysteine to methionine Individuals with the MTHFR 677 TT genotype had a significantly higher risk of CHD, particularly in the setting of low folate status.”⁸⁶ Elevated homocysteine is associated with depression, heart disease, stroke, colon and breast cancers, and dementia.⁸⁷ If susceptible individuals consume a diet that for most people would be “adequate” in these nutrients, they run the risk of developing a disease of aging such as heart disease. Kilmer McCully recently wrote: “There is an urgency to this matter. There are 500,000 people dying every year from heart disease, and millions more suffering.”⁸⁸ As Willett and Stampfer pointed out in a December 2001 article in the *NEJM*, the daily consumption of a well-balanced multivitamin and mineral supplement now makes sense from a number of lines of research.⁸⁹

^{ix} A polymorphic gene is an alternate form of a *wild* gene present in >1% of the population. The most common polymorphic genes are single nucleotide polymorphisms (SNPs) that result in translational proteins and enzymes with decreased functionality. We all share at least 99.9% of the nucleotide code of our species’ genome. The SNPs are what make us unique within our species. The translation of our genome message that includes our SNPs results in our individual phenotype. [Burghes, et al. *Science*. 2001;293:2213-14.]

We inherit more than our genes. Through custom, habit, and patterning, we also inherit nutrition and life-style habits. The interaction of genetic uniqueness with lifestyle results in the illnesses many people associate with aging. A dramatic example can be seen today in the stunning increase in cases of type 2 diabetes^{90,x} and the estimate that “as many as 1 in 4 apparently healthy Americans are at risk of developing ‘Syndrome X,’ a metabolic derangement that is a major contributor to coronary artery disease”⁹¹ and a likely precursor to type 2 diabetes. There is clear and compelling evidence from many sources that diet and lifestyle are the culprits, since (as noted above) the human genome itself has not changed in this period of time.

Summary

People *are* living longer—that’s indisputable. We know that how we live those extra years is an abiding issue. Medical education, research, and practice need to shift focus, looking at the complex issues involved in the origins of illness and healthy aging. The evidence is very strong that illness is not a predetermined consequence of aging^{92,93} and that age-related decline can probably be substantially compressed (in length and in severity) by better management of the interaction between our genetic uniqueness and the overall environment to which we expose our genes throughout our lifetimes.⁹⁴ Ongoing research will help us understand the mechanisms by which the environment affects our genes, and we will be able to intervene sooner, targeting very specific risks and vulnerabilities inherent to the individual. Tailored recommendations for diet, nutritional pharmacology,⁹⁵ pharmacogenomics, lifestyle change (including “mind-body” issues), structural and physical medicine, and exercise^{96,96,97} are already important in improving the expression of genetic potential, and will become more clinically useful and focused as the evidence base expands.

The doctors of the 21st century will need to understand how to assess patients’ genotypes,^{98,99,100} how to personalize treatment for their individual needs, configuring patient interventions to improve lifestyle and

environment to minimize the risks of age-related chronic disease. We hope that this book will help the readers to do just that.

Diet and Nutrients

Jeffrey S. Bland, PhD

Introduction

A historical review of our understanding of chronic diseases affirms that we now know these are primarily “lifestyle diseases.” This gene-environment connection, in which certain genetic strengths and weaknesses are powerfully influenced by environmental choices, gives rise to the patient’s health phenotype. The phenotype is a result of the interaction of the genotype with environmental factors: genomics influence proteomics,¹ which influence metabolomics, which ultimately give rise to phenomics, or how an individual looks, acts, and feels. Genes are expressed as a consequence of the environment in which they are immersed. Environment-gene interactions give rise to the expression of the diseases of the culture. No medicine or therapy can prevent the interaction between genes and environment. Unfortun-

¹Proteomics applies the techniques of molecular biology, biochemistry, and genetics to analyzing the structure, function, and interactions of the proteins produced by the genes. Metabolomics provides an overview of the metabolic status and biochemical events associated with a cellular or biological system, describing their dynamic responses to genetic and environmental modulation. Phenomics attempts to integrate the information provided by these areas of study into a holistic picture of the complete organism (individual).

nately, it is not possible to attack causality in many chronic diseases without dealing with multiple environmental factors. Fortunately, we do know that the outcome, or phenotype, can be affected by modifying the environment. Yet, we are not using this information effectively to modify our approach to health care. We need this new, primary model for addressing both the prevention and management of chronic disease. That is the central theme of functional medicine.

Diet and Nutrients: The Emerging Evidence

An editorial about the relationship among environmental “inputs” such as diet, lifestyle, and longevity appeared in the *Journal of the American Medical Association*, authored by Drs. Eric Rimm and Meir Stampfer, well-respected epidemiologists at the Departments of Epidemiology and Nutrition at the Harvard School of Public Health.¹ They discussed the work of Ancel Keys, who worked at the University of Minnesota and was a pioneer in the discovery of new research methods linking nutrition and disease. He is credited with discovering that saturated fat intake is a risk factor for cardiovascular disease (CVD) and that unsaturated fat intake

is associated with a lower risk of CVD. Rimm and Stampfer state:

Nearly 50 years ago, Keys recognized the enormously divergent rates of heart disease around the world, even after adjusting for differences in age. Although coronary disease was and remains the leading cause of death in the United States and many developed and developing countries, it was almost non-existent in the traditional cultures of Crete and Japan. Rates of cancer at various sites also differ enormously—up to 100-fold—in different populations. The rapid changes in rates of many of these diseases over time and studies that show increases in chronic disease rates among migrants from traditional to Westernized cultures demonstrate that relatively swift changes in disease rates cannot be attributed solely to genetic differences between populations. Instead, they are likely due to differences in lifestyle, with dietary factors and physical activity the leading candidates Although understanding of the relation of lifestyle and health outcomes will continue to be refined, information available now is sufficient to take action.

Rimm and Stampfer conclude by saying that studies on positive lifestyle practices and their mechanisms tend to be supported by the historical research record: “As a society, the United States spends billions on chronic disease treatments and interventions for risk factors. Although these are useful and important, a fraction of that investment to promote healthful lifestyles for primary prevention among individuals at all ages would yield greater benefit.”²

Many studies from the 1990s through today emphasize the importance of diet and the environment in the prevention and management of heart disease. Pertinent studies are reported in two 2004 *JAMA* papers linking specific diets to heart disease prevention. The first is titled “Mediterranean Diet, Lifestyle Factors, and 10-year Mortality in Elderly European Men and Women.”³ This HALE Project (Healthy Ageing: a Longitudinal Study in Europe) is an interesting study. It comprises individuals enrolled in the Survey in Europe on Nutrition and the Elderly: a Concerned Action (SENeca) and the Finland, Italy, and the Netherlands Elderly (FINE) studies. It included 1,507 apparently healthy men and 832 women, aged 70 to 90 years in 11 European countries. This cohort study was conducted between 1988 and 2000. After looking at hazard ratios of various lifestyle and diet considerations, the authors concluded that, “**among individuals aged 70 to 90 years, adherence to a Mediterranean diet and healthful lifestyle is associated with a more than 50% lower rate of all-**

cause and cause-specific mortality.” (If we could prescribe a drug that would lower mortality of all causes by 50%, with virtually no side effects, wouldn’t we all jump on that bandwagon? One has to wonder why we are not hearing a clarion call from all stakeholders for a major shift in our thinking about health care.)

A companion paper is titled “Effect of a Mediterranean-style Diet on Endothelial Dysfunction and Markers of Vascular Inflammation in the Metabolic Syndrome.”⁴ This study analyzed work done in the outpatient department of the Division of Metabolic Diseases at the Second University of Naples in Italy. The investigators assessed the effect of a Mediterranean-style diet on endothelial function and vascular inflammatory markers in patients with metabolic syndrome. “After 2 years, patients following the Mediterranean-style diet consumed more foods rich in monounsaturated fat, polyunsaturated fat, and fiber and had a lower ratio of omega-6 to omega-3 fatty acids. Total fruit, vegetable, and nut intake, whole grain intake, and olive oil consumption were also significantly higher in the intervention group. The levels of physical activity increased in both groups by approximately 60%,” mainly by walking for a minimum of 30 minutes per day. The researchers concluded that “a Mediterranean-style diet might be effective in reducing the prevalence of the metabolic syndrome and its associated cardiovascular risk.” Reductions in high-sensitivity C-reactive protein (hs-CRP), interleukin-6 (IL-6), interleukin-7 (IL-7), and interleukin-18 (IL-18), markers for immunological functional changes, were also realized (for hs-CRP levels, $p=.01$ and for IL-6, $p=.04$). The conclusion is that implementation of an improved diet and lifestyle program results in remarkable changes in inflammatory patterns and improved insulin sensitivity. The recent “demonstration by epidemiological studies that an elevated serum IGF-1 level is associated with an increased relative risk of developing a number of epithelial cancers”⁵ broadens the scope of concern.

Diet and the Importance of Carbohydrate Type

When we speak of the Mediterranean diet, we are not necessarily talking about a diet high in protein and low in carbohydrate. In fact, this style of diet is reasonably high in carbohydrate. However, the carbohydrate is highly unrefined, fiber-rich, and plant-phytonutrient-rich, which has a different physiological effect on function than does carbohydrate in white starch or sugar. Carbohydrate is not the villain here; rather, the *type* of

carbohydrate is what's important. "White" in carbohydrate (to simplify) is devoid of all the agents necessary for appropriate metabolism and physiochemical control—gastric emptying, release of glucose in a time-release fashion, and the rhythmic effect it has on the neuroendocrine-immune system through the proper release of energy molecules such as glucose and fatty acids. We should be speaking more about glycemic load and glycemic response than simply talking about percentages of protein, fat, or carbohydrate. Glucose and insulin levels can be raised postprandially by giving protein at high levels. The important feature in the construction of a diet that manages chronic disease is to balance both amount and type of macronutrients, micronutrients, and phytochemicals so that they impact the genomics of the individual with an improved health phenotype. While that balance may vary from person to person, depending on genetics and environment, there are some factors that are important for all of us; one of them is the glycemic response of the diet.⁶

Glycemic Index, Glycemic Load, Dietary Fiber Intake, and the Incidence of Type 2 Diabetes

The glycemic and insulin response after eating (more information on this can be found in Chapter 32) plays an important role in determining long-term risk of CVD. The concept that individuals carry different metabolic sensitivities to the glycemic load of the diet is supported in an article that appeared in 2004 in the *American Journal of Clinical Nutrition* ("Glycemic Index, Glycemic Load, and Dietary Fiber Intake and Incidence of Type 2 Diabetes in Younger and Middle-aged Women").⁷ This is one of many papers with the same theme, documenting that a diet high in rapidly absorbed carbohydrate and low in cereal fiber is associated with increased risk of type 2 diabetes. A diet high in fiber-rich carbohydrate from cereal fiber is associated with a lower risk of heart disease. It promotes a reduction in the relative risk of type 2 diabetes, metabolic syndrome, and insulin resistance.

Whole Grain Intake and Insulin Sensitivity

Whole grain intake is more than just carbohydrate. Grains contain a rich array of soluble and insoluble fiber, as well as hundreds of different phytochemicals. All of these influence insulin and glucose control through their effects on absorption, liver enzyme activities related to gluconeogenesis, glycogen synthesis, adi-

pocyte physiology, centrally mediated appetite, and peripheral cells such as muscle cells. It is a much more complex story than just getting glucose from starch. We are talking about the metabolic signaling events that occur through the consumption of complex, unrefined, or minimally refined food that is high in complex carbohydrate. Quoting from a 2004 review paper that appeared in *Nutrition Reviews*:

The apparent paradox that ad-libitum intake of high-fat foods produces weight loss might be due to severe restriction of carbohydrate depleting glycogen stores, leading to excretion of found water, the ketogenic nature of the diet being appetite suppressing, the high protein-content being highly satiating and reducing spontaneous food intake, or limited food choices leading to decreased energy intake. Long-term studies are needed to measure changes in nutritional status and body composition during the low-carbohydrate diet, and to assess fasting and postprandial cardiovascular risk factors and adverse effects.⁸

To compress morbidity, rectangularize the survival curve, and develop an effective chronic disease prevention and management program, diet must be used in an intelligent manner, and personalized to the patient's needs so as to result in an improved health phenotype.

Gluten Contamination of Commercial Oat Products

As we change environmental inputs to introduce a higher complex-carbohydrate, minimally processed type of dietary regime, what about the relative effect that the potentially allergenic component of grains might have, including gluten and other reactive proteins? (Issues of gluten sensitivity arise throughout this book; see the index for cross-referencing.) There are certain grain-related products that are low in or devoid of gluten, such as oats. An interesting article published in *The New England Journal of Medicine* ("Gluten Contamination of Commercial Oat Products in the United States")⁹ suggests, however, that certain commercially available oats are not, in fact, gluten-free. The author states that while there is quite a bit of published literature suggesting that people with celiac disease or gluten sensitivity can consume moderate amounts of uncontaminated oats, because they are low in or devoid of gluten, high variability in gluten content has been reported in batches of oats, suggesting contamination with gluten not native to oats, probably as a consequence of being processed in the same plant where

wheat is processed. Gluten-sensitive individuals are urged to recognize that contamination of commercial oats in the United States with gluten grains such as wheat, barley, and rye is a legitimate concern. We should not assume that all oats are gluten-free. While they would be low in gluten relative to wheat, there may be some contamination. (This may explain why some people with gluten sensitivity have experienced a reaction to oats.)

Glycemia, Insulinemia, and Food Proteins

What about the argument that eating more protein leads to improved glucose tolerance? One paper which represents current thought is titled “Glycemia and Insulinemia in Healthy Subjects after Lactose-equivalent Meals of Milk and Other Food Proteins: The Role of Plasma Amino Acids and Incretins.”¹⁰ The authors of this paper conclude that food proteins differ in their capacity to stimulate insulin release, possibly by differentially affecting the early release of a messenger molecule called incretin. Incretin hormones and insulinotropic amino acids may stimulate higher insulin output, insulin resistance, and glycemia. This paper demonstrates that differing food proteins may have remarkably different effects on postprandial insulin and glucose levels. Those that appear to have the lowest influence on postprandial glucose are foods containing milk and soy proteins (although casein has been shown to raise postprandial insulin¹¹). Food proteins that have higher postprandial glycemic responses include beef proteins and some meat and fish proteins. We need to keep in mind that the macronutrient ratio alone of carbohydrate, fat, and protein does not really tell us what we need to know clinically about how individual foods affect particular glucose and insulin responses and, therefore, influence chronic disease risk.

Tailoring the Diet to Genetic Risk

Tailoring the diet to the patient’s need can have significant positive benefits in improving the translation of the genotype into a healthy phenotype. Personalization of the diet can result in reduced inflammatory potential through normalization of neuroendocrine-immune system function (see Chapter 26 for an in-depth discussion of using diet and nutrients to reduce inflammation). The outcome of this strategy is to reduce the risk and progression of chronic disease. Here

are just two examples that should alert us to the power of such an approach. Throughout the rest of this book, you will come across many more.

The 219G→T polymorphism and a diet rich in saturated fat. Certain people have specific single nucleotide polymorphisms (SNPs) and are more susceptible to the oxidative types of reactions and lipoprotein abnormalities associated with the inflammatory profile. For instance, individuals with the 219G→T polymorphism carry a much higher sensitivity to saturated fat in the diet, increasing susceptibility to inflammation and increasing the relative risk of coronary atherosclerosis, metabolic syndrome, and type 2 diabetes. Such individuals need to pay special attention to the kind of fat they ingest. They can be thought of as “yellow canaries,” alerting us to the presence of higher susceptibilities in the human genome to certain types of environmental inputs.¹²

Positive role of essential fatty acids. The literature is replete with studies indicating the positive role that omega-3 balanced diets or omega-3 supplemented diets have on reestablishing proper function of the neuroendocrine-immune system and the inflammation profile. For instance, a paper in the *Journal of Nutrition* described how an α -linolenic acid-rich diet reduced inflammatory and lipid cardiovascular risk factors in hypercholesterolemic men and women.¹³ DHA, as well as EPA, also has a positive role in reducing cardiovascular risk and lowering inflammatory potential in women.¹⁴ Chronic inflammation does not result in increased risk of CVD alone, but rather relates to the whole family of chronic diseases. (A detailed discussion of essential fatty acids can be found in Chapter 27.)

Summary

At this time, we are witnessing a virtual epidemic in the increase of metabolic syndrome, type 2 diabetes, obesity, CAD, hypertension, and the epithelial cancers. The increased incidence of these conditions arises from a change in the functional metabolic state of the individual due to changing diet and lifestyle factors. One compelling perspective on these issues has been provided by Dr. Loren Cordain (and others), whose work focuses on the “growing awareness that the profound changes in the environment (e.g., in diet and other lifestyle conditions) that began with the introduction of agriculture and animal husbandry ~10,000 years ago

occurred too recently on an evolutionary time scale for the human genome to adjust.”¹⁵ The challenge for today’s clinicians and patients is how to create a different gene expression pattern so that good health and a rectangularizing of the survival curve can be achieved in a 21st century environment. To begin with, we must apply the same level of effort to these issues that we applied in the last 100 years to acute care, with its myriad (and often miraculous) drug and surgical interventions. Nothing less will suffice.

When the wrong information is delivered to the genes in the form of a diet or lifestyle poorly matched to a person’s needs, or from a toxic exposure, those genes create an environment in the body (the so-called phenotype, the phenomics of the individual) that is unwary, ill at ease, uncomfortable, and prepared to do battle. This results in chronic immunological activation or imbalance. This shift from acute threats to chronic dysfunction is the challenge of 21st century medicine. Many variables are influential—not only diet, but stress, toxins in the environment, endotoxins in the gut, chronic infection, and mechanical trauma, such as over-training in athletes. Myriad environmental factors can shift the balance in the immunological system, creating in various tissues the message of inflammation which, in turn, is related to the etiology of most chronic disease.

Air and Water

Jeffrey S. Bland, PhD

From a functional medicine perspective, physiology is in a homeodynamic state of interaction with the environment. What may appear to be “homeostasis” is, in actuality, very dynamic. An analogy is the flight of a humming bird. It can hold itself stationary, or in “stasis,” at the flower to sip the nectar but, as we know from time-lapse photography, it is actually flapping its wings “dynamically” to overcome gravity. So it is with human physiology. We assume that, because blood sugar, pH, osmolarity, and cellular redox potential don’t change much in the healthy individual, homeostasis is a natural set point for physiology.

At the cell biological and molecular levels, however, there is significant dynamic function going on at any one time in order to maintain what is perceived as homeostasis. Blood gases are constantly being exchanged, glucose and fats are being taken up by the

cell and metabolized, hydrogen ions are moving at rapid rates across membranes, ions are being transported against gradients, and oxidation-reduction reactions are occurring at diffusion-controlled rates. All of these dynamic processes are regulated by master switches at the executive level in the control of metabolism, both locally and at the whole-person levels. This system is fueled by nutrients that support the energetics necessary to maintain homeodynamic flexibility, or “degrees of freedom.”¹⁶

The most stable physiological system is the system with the greatest homeodynamic flexibility.^{17,18} This is the state that might be defined as having the greatest potential for functional health. Redundancy is built into physiology to allow multiple processes to provide routes to the maintenance of homeostasis. The more pathways available, the greater the metabolic degrees of freedom, and the more resilient the functional physiology. As a person loses metabolic degrees of freedom, it results in the loss of “organ reserve,” as defined by James Fries,¹⁹ and increases the risk or severity of illness. An example of this is the electrocardiogram (EKG). The most complex EKG is found in the fine structure (i.e., physiological degrees of freedom) of the fit, young athlete.²⁰ The simplest EKG is the flat-line of a person who has lost all physiological resiliency.

The task of the functional medicine practitioner is to find ways of increasing the patient’s physiological degrees of freedom which, in turn, increase functional reserve of the patient. Two environmental factors that have great impact on homeodynamic control of physiology are air and water.

Oxygen as a Limiting Nutrient

The air we breathe is composed of approximately 20% diatomic molecular oxygen. This oxygen supports aerobic metabolism. In the absence of proper oxygen delivery to the cell, metabolic degrees of freedom are significantly reduced and functional reserve is compromised. The cell, tissue, or organ that is oxygen-deprived loses its homeodynamic potential and shifts to the primitive state of anaerobic metabolism, or fermentation. In this case, the cells become more acidic and pH drops, electrolytes are disturbed, and reduction-oxidation chemistry is modified. In clinical medicine, we associate these conditions with ischemic hypoxia or, in the extreme, anoxia.²¹ In these cases, oxygen becomes the limiting nutrient for function and new homeostatic

Section III

The Building Blocks

levels of blood sugar, blood gases, osmolarity, and redox result that are associated with degrees of ill health or disease.^{22,23}

Conditions that can result in oxygen becoming the limiting nutrient include, as examples:

- anemia
- vascular injury
- ischemic events due to vasoconstriction
- poisoning
- respiratory depression
- pulmonary dysfunction
- compromised musculoskeletal fitness

Historically, most cultures have had a traditional activity (a “therapy”) designed to improve oxygen delivery to tissues, and a number of these activities have been investigated for their health effects.^{24,25,26}

Examples include:

- deep-breathing exercises
- yoga
- rebreathing
- dance
- physical therapy
- stress reduction (meditation)
- dietary factors to improve blood chemistry
- physical fitness training and athletic competition

At the Institutes for the Achievement of Human Potential in Philadelphia, parents of brain-injured children are taught exercises for their children that improve oxygen delivery to the brain.²⁷ The positive impact these therapies have on improving function in brain-injured children has been documented from hundreds of thousands of examples around the world.

Water as a Limiting Nutrient

The second most important substance in maintaining homeodynamics and functional reserve is water. The majority of the human body is composed of water. The water that makes up our body composition plays a very important role within cells in maintaining structure and function. Intercellular water binds to proteins, carbohydrates, and nucleic acids to maintain their proper function. When dehydrated, the structure of critical cellular biomolecules is adversely affected, reducing their function.^{28,29} All systems are influenced by dehydration, resulting in reduced energy production, neurotoxicity, and alteration in the function of every organ. As water is lost and not replaced, the con-

centration of substances within cells increases, pH changes, and enzyme function is altered. Muscle cramping, sore muscles, reduced mental clarity, constipation, fatigue, and increased sensitivity to toxic substances all increase during states of dehydration. In these cases, water becomes the limiting nutrient for support of functional physiology.

The Importance of Assessing Air and Water Adequacy

In a functional medicine assessment, the adequacy of air (i.e., oxygen) and water to maintain functional organ reserve should be a first-stage priority. The use of body composition measurements using bioimpedance analysis³⁰ can provide information about both intra- and intercellular water status. Pulse and heart rate, along with physical assessment of oxygen saturation and tissue-specific signs of ischemia, can provide information concerning the adequacy of oxygen.

Often, clinicians assume adequacy of both oxygen and water because they are so readily available, and if the patient doesn't display overt symptoms of hypoxia or dehydration, no further evaluation is done. By concentrating on the signs and symptoms of chronic tissue deprivation of either oxygen or water, clinicians can identify many patients in need of therapy in these areas. Proper intervention to improve tissue oxygen and water delivery will improve homeodynamic control and functional physiological reserve.

Health Effects of Air and Water Pollution

An extensive literature on health effects of environmental pollution is available to the interested reader. This short introduction to air and water as building blocks of health would be incomplete, however, without at least mentioning the significant impact that industrialization has had on the quality of air and water.

Water. From the fish we eat, which are now significant sources of toxins such as mercury³¹ and pesticides (see, for example, the discussion on xenobiotics to be found further on in this chapter), to substances we add to water as a function of general public use³² (chlorine, fluoride, softening agents), to bacterial or parasitic agents found as a result of contamination or overuse,³³ pure water on this planet has become a diminished resource. All of these problems have significant health implications, ranging from neurological damage³⁴ to res-

piratory problems³⁵ to gastrointestinal ailments.³⁶ Access to safe water for drinking, bathing, and normal household use is a very important part of a healthy life—one of which we are most aware when it no longer exists.

Air. “Increased levels of particulate air pollution are associated with increased respiratory and cardiovascular mortality and morbidity as well as worsening of asthma.”³⁷ One of the most distressing aspects of air pollution is its disproportionate effect on babies and children. One study reported that “studies on infant mortality and exposure to particles show an outstanding consistency in the magnitude of the effects, despite the different designs used”; the effect is estimated to be about a 5% increase in post-neonatal mortality for all causes and around 22% for respiratory diseases.³⁸ That’s a heavy price to pay, and it’s paid by our youngest and most vulnerable patients. That is not to imply that adults are somehow protected. A 2005 study suggested that particulate air pollutants in Scandinavia are responsible for approximately 3,500 deaths per year.³⁹ “The annual cost of human exposure to outdoor air pollutants from all sources is estimated to be between \$40 to \$50 billion The death toll from exposure to particulate air pollution generated by motor vehicles, burning coal, fuel oil, and wood is estimated to be responsible for as many as 100,000 fatalities annually in the United States.”⁴⁰

Summary

It can be easy to lose sight of the critical importance of adequate oxygenation and hydration of tissues as key factors in health. Air and water are taken for granted, particularly in industrialized countries and particularly by people who are mostly healthy—we breathe, we drink fluids, we give it little thought. Unfortunately, in today’s world, we must pay attention to the sufficiency and quality of our air and water, and clinicians must consider whether a patient may be suffering from deprivation or contamination of these most vital building blocks to health, even when the effects may be diffuse and difficult to detect. With problems this pervasive, we cannot afford to take anything for granted.

Physical Exercise

William J. Evans, PhD

Introduction

Virtually every system in the human body is affected in some way by increasing levels of physical activity. Exercise encompasses a broad range of activities; it can be defined as increased (above resting) muscular activity and may be categorized as anaerobic (sprinting), endurance (aerobic), or resistive (weight lifting). Resistive exercise is defined as muscle contracting a few times against a heavy load or with high tension. This type of exercise is also termed progressive resistance training (PRT) when the load or intensity is progressively increased as an individual becomes stronger. PRT is distinctly different from aerobic or endurance exercise, in which muscles contract against little or no resistance. Anaerobic exercise makes use of phosphocreatine and/or glycogenolysis for energy production. This type of exercise is generally thought of as a sprinting type of exercise; however, an extremely deconditioned patient, such as an individual with chronic obstructive pulmonary disease or heart failure may perform anaerobic exercise simply by getting out of bed and walking across a room.

The adaptive response to regularly performed exercise has been repeatedly demonstrated to have remarkably beneficial effects. The list of these adaptive responses is extensive. The Centers for Disease Control and Prevention, along with the American College of Sports Medicine, has suggested that everyone should accumulate at least 30 minutes of exercise on most (preferably all) days.⁴¹ This recommendation is based on evidence of a substantial decrease in all-cause mortality resulting from a moderate amount of increased physical activity.^{42,43} The American Heart Association has stated that inactivity is a primary risk factor for cardiovascular disease.^{44,45,46} Because far more Americans are inactive than those who have elevated cholesterol or who smoke, it is the predominant risk factor for heart disease in the United States. This review will focus on the acute and chronic adaptations to exercise with particular attention to substrate use and effects on risk factors for chronic disease and aging.

Aerobic Exercise

Maximal aerobic exercise capacity is termed $\text{VO}_{2\text{max}}$. VO_2 (volume of oxygen consumed during maximal aerobic exercise) is defined by the Fick equation:

$\text{VO}_2 = \text{Cardiac Output} \cdot \text{Arterio-venous oxygen difference}$.

$\text{VO}_{2\text{max}}$ is expressed as either:

$\text{ml O}_2 \text{ consumed} \cdot \text{kg}^{-1} \text{ body weight} \cdot \text{min}^{-1}$ or
 $\text{L O}_2 \text{ consumed} \cdot \text{min}^{-1} \cdot \text{ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$

The latter formula is most often used to define an individual's aerobic capacity, as differences in body weight are controlled for.

The Fick equation demonstrates that there are two important determiners of $\text{VO}_{2\text{max}}$: central factors that control the delivery of oxygen to skeletal muscle and the capacity of skeletal muscle to extract and utilize oxygen for ATP during exercise. Regularly performed aerobic exercise increases $\text{VO}_{2\text{max}}$ through the following mechanisms:

1. increased cardiac output resulting from a plasma volume expansion (approximately 15%);
2. increased stroke volume as a result of cardiac hypertrophy; and
3. improved capacity to extract and use oxygen by skeletal muscle.

This enhanced oxidative capacity of muscle is due to increased capillarization, mitochondrial density, and myoglobin content. Under most conditions, the delivery of oxygen limits maximal aerobic performance. Increasing blood hemoglobin concentration (from anemic to normal or from normal to super-normal) has been demonstrated to increase $\text{VO}_{2\text{max}}$ and submaximal exercise performance.^{47,48,49,50} Anemia due to malnutrition has been demonstrated to limit functional status and work capacity. On the other hand, aerobic exercise performance in athletes can be substantially improved by increasing hemoglobin levels above normal through the use of recombinant human erythropoietin.⁵¹

Maximal aerobic capacity ($\text{VO}_{2\text{max}}$) declines with advancing age.⁵² This age-associated decrease in $\text{VO}_{2\text{max}}$ has been shown to be approximately 1%/yr between the ages of 20 and 70 years old. This decline is likely due to a number of factors including decreased levels of physical activity, changing cardiac function (including decreased maximal cardiac output), and reduced muscle mass. Flegg and Lakatta⁵³ determined that skeletal muscle mass accounted for most of the variability in $\text{VO}_{2\text{max}}$ in men

and women above the age of 60 years old. A number of studies have demonstrated that the age-related decline in $\text{VO}_{2\text{max}}$ is ameliorated by physical activity.^{54,55,56,57} Bortz and Bortz⁵⁸ reviewed endurance event data from master athletes up to age 85 and noted that the decline in performance occurred at a rate of 0.5%/yr. They concluded that this decline of 0.5%/year may represent the effects of age (or "biological" aging) on $\text{VO}_{2\text{max}}$, and the remainder of the decline may be the result of an increasingly sedentary lifestyle. However, Rosen et al.⁵⁹ examined predictors of this age-associated decline in $\text{VO}_{2\text{max}}$ and concluded that $\text{VO}_{2\text{max}}$ declines at the same rate in athletic and sedentary men and that 35% of this decline is due to sarcopenia.

Aerobic exercise has long been an important recommendation for the prevention and treatment of many of the chronic diseases typically associated with old age. These include type 2 diabetes mellitus (and impaired glucose tolerance), hypertension, heart disease, and osteoporosis. Emerging research is also demonstrating an important role for exercise in treatment and prevention of certain cancers and neurodegenerative diseases.^{60,61,62,63,64,65,66}

Regularly performed aerobic exercise increases insulin action. The responses of initially sedentary young (age 20–30) and older (age 60–70) men and women to three months of aerobic conditioning (70% of maximal heart rate, 45 minutes/day, three days per week) were examined by Meredith et al.⁶⁷ They found that the absolute gains in aerobic capacity were similar between the two age groups. However, the mechanism for adaptation to regular submaximal exercise appears to be different between old and young people. Muscle biopsies taken before and after training showed a more than two-fold increase in oxidative capacity of the muscles of the older subjects, while that of the young subjects showed smaller improvements. Another study found that "exercise training exerts antioxidative effects in the skeletal muscle in chronic heart failure, in particular, due to an augmentation in activity of radical scavenger enzymes."⁶⁸ In addition, skeletal muscle glycogen stores in the older subjects, significantly lower than those of the young men and women initially, increased significantly. The degree to which the elderly demonstrate increases in maximal cardiac output in response to endurance training is still largely unanswered. Seals and co-workers⁶⁹ found no increases after one year of endurance training while, more recently, Spina et al.⁷⁰ observed that older

men increased maximal cardiac output while healthy older women demonstrated no change in response to endurance exercise training. If these gender-related differences in cardiovascular response are real, it may explain the lack of response in maximal cardiac output when older men and women are included in the same study population.⁷¹

Aerobic Exercise and Carbohydrate Metabolism

The two-hour plasma glucose level measured during an oral glucose tolerance test increases by an average of 5.3 mg/dL per decade, and fasting plasma glucose increases by an average of 1 mg/dL per decade.⁷² The NHANES II study demonstrated a progressive increase of about 0.4 mM/decade of life in mean plasma glucose value 2h after a 75 g oral glucose tolerance test (OGTT, providing a specific amount of glucose drink in a solution and measuring the changes in plasma glucose over a 2 to 3 hour period) (n = 1,678 men and 1,892 women).⁷³ Shimokata and coworkers⁷⁴ examined glucose tolerance in community-dwelling men and women ranging in age from 17 to 92. By assessing level of obesity, pattern of body fat distribution, activity and fitness levels, they attempted to examine the independent effect of age on glucose tolerance. They found no significant differences between the young and middle-aged groups; however, the old groups had significantly higher glucose and insulin values (following a glucose challenge) than the young or middle-aged groups. They concluded: "The major finding of this study is that the decline in glucose tolerance from the early-adult to the middle-age years is entirely explained by secondary influences (fatness and fitness), whereas the decline from mid-life to old age still is also influenced by chronological age. This finding is unique. It is also unexplained." However, it must be pointed out that anthropometric determination of body fatness becomes increasingly less accurate with advancing age and does not reflect the intra-abdominal and intramuscular accumulation of fat that occurs with aging.⁷⁵ The results of this study may be due more to an underestimate of true body fat levels than age, *per se*. These age-associated changes in glucose tolerance can result in type 2 diabetes and the broad array of associated abnormalities. In 1995, in a large population of elderly men and women (older than 55 years), serum glucose and fructosamine levels were seen to be higher in subjects with retinopathy compared with those without and, within the

groups with retinopathy, serum glucose was significantly associated with the number of hemorrhages.⁷⁶ These relationships were independent of body composition, abdominal obesity or the presence of type 2 diabetes.

The relationship between aging, body composition, activity, and glucose tolerance was also examined in 270 female and 462 male factory workers aged 22 to 73 years, none of whom were retired.⁷⁷ Plasma glucose levels, both fasting and after a glucose load, increased with age, but the correlation between age and total integrated glucose response following a glucose load was weak: in women only 3% of the variance could be attributed to age. When activity levels and drug use were factored in, age accounted for only 1% of the variance in women and 6.25% in men.

The fact that aerobic exercise has significant effects on skeletal muscle may help explain its importance in the treatment of glucose intolerance and type 2 diabetes. Seals and co-workers⁷⁸ found that a high-intensity training program showed greater improvements in the insulin response to an oral glucose load compared to lower intensity aerobic exercise. However, their subjects began the study with normal glucose tolerance. Kirwan and co-workers⁷⁹ found that nine months of endurance training at 80% of the maximal heart rate (4 d/wk) resulted in reduced glucose-stimulated insulin levels; however, no comparison was made to a lower intensity exercise group. Hughes and co-workers⁸⁰ demonstrated that regularly performed aerobic exercise without weight loss resulted in improved glucose tolerance and rate of insulin-stimulated glucose disposal, as well as increased GLUT4 levels in older subjects with impaired glucose tolerance. GLUT4 is the glucose transporter protein found in skeletal muscle. The amount and/or the activation of this transporter protein is thought to be a rate-limiting step in the transport of glucose into muscle cells. In this investigation, a moderate intensity aerobic exercise program was compared to a higher intensity program (50 vs. 75% of maximal heart rate reserve, 55 min/day, 4 day/wk, for 12 weeks). No differences were seen between the moderate and higher intensity aerobic exercise on glucose tolerance, insulin sensitivity, or muscle GLUT4 (the glucose transporter protein in skeletal muscle) levels, indicating perhaps that a prescription of moderate aerobic exercise should be recommended for older men or women with type 2 diabetes (or at high risk for type 2 diabetes) to help to ensure compliance with the program.

Endurance training and dietary modifications are generally recommended as the primary treatment in the non-insulin-dependent diabetic. Cross-sectional analysis of dietary intake supports the hypothesis that a low-carbohydrate/high-fat diet is associated with the onset of type 2 diabetes.⁸¹ This evidence, however, is not supported by prospective studies in which dietary habits were not related to the development of type 2 diabetes.^{82,83} The effects of a high-carbohydrate diet on glucose tolerance and lipoproteins have been equivocal.^{84,85,86,87} Hughes et al.⁸⁸ compared the effects of a high-carbohydrate (60% CHO and 20% fat)/high-fiber (25g dietary fiber/1000 kcal) diet with and without three months of high intensity (75% max heart rate reserve, 50 min/day, 4 d/wk) endurance exercise in older, glucose-intolerant men and women. Subjects were fed all of their food on a metabolic ward during the three-month study and were not allowed to lose weight. These investigators observed no improvement in glucose tolerance or insulin-stimulated glucose uptake in either the diet or the diet plus exercise group. The exercise plus high-carbohydrate diet group demonstrated a significant and substantial increase in skeletal muscle glycogen content and, at the end of the training, the muscle glycogen stores would be considered to be saturated. Since the primary site of glucose disposal is skeletal muscle glycogen stores, the extremely high muscle glycogen content associated with exercise and a high-carbohydrate diet likely limited the rate of glucose disposal. Thus, when combined with exercise and a weight maintenance diet, a high-carbohydrate diet had a counter-regulatory effect. It is likely that the value of a high-carbohydrate/high-fiber diet lies in its effect on reducing excess body fat, which may be an important cause of the impaired glucose tolerance. Recently, Schaefer and co-workers⁸⁹ demonstrated that older subjects consuming an ad libitum high-carbohydrate diet lost weight.

There appears to be no attenuation of the response of elderly men and women to regularly performed aerobic exercise when compared to those seen in young subjects. Increased fitness levels are associated with reduced mortality and increased life expectancy. A 2005 review pointed out that these effects appear to be primarily as a result of protection against cardiovascular disease and type 2 diabetes. The authors suggest that "regular exercise induces suppression of TNF- α and thereby offers protection against TNF α -induced insulin resistance."⁹⁰ Increased fitness has been shown to prevent the occur-

rence of type 2 diabetes in those who are at the greatest risk for developing this disease.⁹¹ Thus, regularly performed aerobic exercise is an important way for older people to improve their glucose tolerance.

Exercise and Weight Loss

Aerobic exercise is generally prescribed as an important adjunct to a weight loss program. Aerobic exercise combined with weight loss has been demonstrated to increase insulin action to a greater extent than weight loss through diet restriction alone. In the study by Bogardus et al.,⁹² diet therapy alone improved glucose tolerance, mainly by reducing basal endogenous glucose production and improving hepatic sensitivity to insulin. Aerobic exercise training, on the other hand, increased carbohydrate storage rates and, therefore, "diet therapy plus physical training produced a more significant approach toward normal." However, aerobic exercise (as opposed to resistance training) combined with a hypocaloric diet has been demonstrated to result in a greater reduction in resting metabolic rate (RMR) than diet alone.⁹³ Heymsfield and co-workers⁹⁴ found aerobic exercise combined with caloric restriction did not preserve fat-free mass (FFM) and did not further accelerate weight loss when compared with diet alone. This lack of an effect of aerobic exercise may have been due to a greater decrease in RMR in the exercising group. In perhaps the most comprehensive study of its kind, Goran and Poehlman⁹⁵ examined components of energy metabolism in older men and women engaged in regular endurance training. They found that endurance training did not increase total daily energy expenditure due to a compensatory decline in physical activity during the remainder of the day. In other words, when elderly subjects participated in a regular walking program, they rested more, so that activities outside of walking decreased and thus 24-hour calorie expenditure was unchanged. However, older individuals who had been participating in endurance exercise for most of their lives have been shown to have a greater RMR and total daily energy expenditure than did age-matched sedentary controls.⁹⁶ Ballor et al.⁹⁷ compared the effects of resistance training to that of diet restriction alone in obese women. They found that resistance exercise training results in increased strength and gains in muscle size as well as preservation of FFM during weight loss. These data are similar to the results

of Pavlou et al.⁹⁸ who used both aerobic and resistance training as an adjunct to a weight loss program in obese men and demonstrated preservation of FFM.

Two important studies were carried out by Jakicic and co-workers,^{99,100} examining exercise intensity and duration and their effects on weight loss. In the first study, exercise advice was provided to three groups of overweight women losing weight. All three groups were told to exercise for a total of 40 minutes each day. One group was told to perform all 40 minutes of exercise in one bout; a second group was told to perform 40 minutes of exercise in four 10-minute bouts throughout the day; and the members of the third group were given the same advice as the second group (intermittent exercise) but were provided with a motorized treadmill for their homes. The study found that the duration of the exercise bout was not important. However the total number of minutes exercised per week, irrespective of the group, had the most important effect on total weight loss and maintenance of the weight loss. The second study¹⁰¹ examined the effects of exercise intensity on weight loss (high vs. moderate aerobic exercise). Researchers found that intensity had very little effect on total weight loss, but that, once again, total number of minutes exercised/week was the most important factor. These studies suggest that 150 minutes/wk may be a threshold for exercise having a significant effect on weight loss and maintenance.

Strength Training

While endurance exercise has been the more traditional means of increasing cardiovascular fitness, the American College of Sports Medicine currently recommends strength or resistance training as an important component of an overall fitness program. This is particularly important in the elderly where loss of muscle mass and weakness are prominent deficits.

Strength conditioning or progressive resistance training (PRT) is generally defined as training in which the resistance against which a muscle generates force is progressively increased over time. PRT involves few contractions against a heavy load. The metabolic and morphological adaptations resulting from resistance and endurance exercise are quite different. Muscle strength has been shown to increase in response to training between 60 and 100% of the 1 repetition maximum (1RM).¹⁰² 1 RM is the maximum amount of

weight that can be lifted with one contraction. Strength conditioning results in an increase in muscle size, and this increase in size is largely the result of increased contractile proteins. The mechanisms by which the mechanical events stimulate an increase in RNA synthesis and subsequent protein synthesis are not well understood. Lifting weight requires that a muscle shorten as it produces force. This is called a concentric contraction. Lowering the weight, on the other hand, forces the muscle to lengthen as it produces force. This is an eccentric muscle contraction. These lengthening muscle contractions have been shown to produce ultrastructural damage (microscopic tears in contractile proteins muscle cells) that may stimulate increased muscle protein turnover.¹⁰³

Effects of Resistance Exercise and Insulin on Protein Metabolism

Hormonal and nutritional factors, particularly the availability of insulin and amino acids, have important effects in the control of muscle protein synthesis.^{104,105} For example, starvation reduces the rate of protein synthesis in skeletal muscle by more than 50% compared to the rate seen in fed animals. This inhibition of protein synthesis (also seen in muscle from diabetic animals) is a result of an impairment in the initiation phase of protein synthesis.^{106,107} The mechanism through which insulin regulates protein synthesis initiation involves phosphorylation of the translational regulator eukaryotic initiation factor 4E (eIF-4E)-binding protein 1 (4E-BP1).¹⁰⁸ Insulin-like growth factor 1 (IGF-1) results in the phosphorylation of 4E-BP1 and dissociation of the 4E-BP1 • eIF-4E complex in cells in culture (muscle cells that are grown in a medium containing appropriate nutrients and growth factors).¹⁰⁹ IGF-1 has also been shown to stimulate protein synthesis in rats *in vivo*¹¹⁰ and in muscle in perfused hind limb preparations.¹¹¹ These studies also suggest that insulin plays a permissive role in the effect of IGF-1 in stimulating muscle protein synthesis.

Studies of insulin secretion after resistance, but not endurance, exercise provide evidence for insulin's role in maintaining muscle mass. King et al.¹¹² and Dela et al.¹¹³ showed that arginine-stimulated insulin secretion is decreased with endurance training. In contrast, acute resistance exercise in rats has been shown to increase insulin secretion.¹¹⁴ As reviewed above, regular aerobic exercise is known to increase insulin sensitivity and glucose tolerance. In addition to its effects on insulin

action, aerobic exercise training results in decreased insulin secretion.¹¹⁵ Regularly performed endurance exercise in young men is associated with an insulin pulse profile in the resting fasted state characterized by less insulin secreted per burst but a similar number of bursts over a 90-minute period. These researchers suggested that training-induced elevations in target-tissue sensitivity to insulin may reduce the requirement for pulsatile insulin secretion. This coordinated response keeps glucose concentrations constant. Dela et al.¹¹⁶ demonstrated that aerobic exercise training decreases both arginine- and glucose-stimulated insulin secretion, indicating, they conclude, a profound β -cell adaptation.

A single bout of concentric exercise is a recognized enhancer of insulin action, while eccentric exercise transiently impairs whole body insulin action for at least two days after the bout.¹¹⁷ We have demonstrated that eccentric exercise can result in a long-term delay in the rate of glycogen synthesis.¹¹⁸ The decreased insulin action and delayed glycogen synthetic rate have been shown to result from decreased rate of glucose transport rather than decreased glycogen synthase activity.¹¹⁹ This transient resistance to insulin and impaired resynthesis of glycogen can result in a systemic hyperinsulinemia that may result in an increase in the rate of muscle protein synthesis. Our laboratory has demonstrated age-related differences in the insulin response to hyperglycemia following a single bout of eccentric exercise.¹²⁰ Two days following upper and lower body eccentric exercise, younger subjects demonstrated a pronounced pancreatic insulin response during a hyperglycemic clamp, while this response was blunted in healthy elderly men.

The effects of resistance exercise on insulin availability appear to be opposite those of endurance exercise and, thus, net protein accretion is stimulated with resistance exercise. Insulin has been demonstrated to have profoundly anabolic effects on skeletal muscle. In the resting state, insulin has been demonstrated to decrease the rate of muscle protein degradation. Stable isotope amino acid studies in humans^{121,122} clearly demonstrate that insulin inhibits whole body protein breakdown *in vivo* and stimulates muscle protein synthesis rate in human skeletal muscle¹²³ and in insulin-deficient rats. However, in non-diabetic animals, this effect was not seen. Fluckey et al.^{124,125} have argued that insulin is not likely to stimulate muscle protein synthesis in quiescent muscle. We have demonstrated that an insulin infusion

does not increase the rate of protein synthesis in non-exercised muscle; using a resistance exercise model, we have also demonstrated that resistance exercise does not stimulate an increase in the rate of protein synthesis. It was only with the addition of insulin that an exercise-induced increase in the rate of soleus and gastrocnemius protein synthesis was seen. This effect of insulin stimulation on the rate of protein synthesis was preserved with advancing age.

Protein Requirements and Exercise

High-intensity resistance training is clearly anabolic in both young and older individuals. Data from our laboratory demonstrate a 10 to 15% decrease in N-excretion at the initiation of training that persists for 12 weeks. That is, progressive resistance training improved N-balance; thus, older subjects performing resistance training have a lower mean protein requirement than do sedentary subjects. This effect was seen at a protein intake of 0.8g and 1.6g, indicating that the effect of resistance training on protein retention may not be related to dietary protein intake. These results are somewhat at variance with our previous research demonstrating that regularly performed aerobic exercise causes an increase in the mean protein requirement of middle-aged and young endurance athletes.¹²⁶ This difference likely results from increased oxidation of amino acids during aerobic exercise that may not be present during resistance training.

Strawford et al.¹²⁷ also demonstrated similar effects of resistance exercise training on nitrogen balance in patients with HIV-related weight loss. The investigators examined the effects of an anabolic steroid (oxandrolone, 20 mg/d, and placebo) and high-intensity resistance training in 24 eugonadal men with HIV-associated weight loss (mean = 9% body weight loss). Both groups showed significant nitrogen retention and increases in LBM, weight, and strength. The mean gains were significantly greater in the oxandrolone group than in the placebo group in nitrogen balance, accrual of FFM, and strength. Results were similar whether or not patients were taking protease inhibitors. These results confirm the positive effects of resistance exercise on nitrogen retention and protein requirements.

These studies, taken as a whole, demonstrate the powerful effects of resistance exercise training on protein nutriture. The anabolic effects have important implications in the treatment of many wasting diseases

and conditions such as cancer, HIV infection, aging, chronic renal failure, and undernutrition seen in many very old men and women. By effectively lowering dietary protein needs, resistance exercise can limit further losses of skeletal muscle mass while simultaneously increasing muscle strength and functional capacity.

Resistance Exercise and Aging

Our laboratory examined the effects of high-intensity resistance training on the knee extensors and flexors (80% of 1RM, 3 days/week) in older men (age 60–72 years). The average increases in knee flexor and extensor strength were 227% and 107% respectively. CT scans and muscle biopsies were used to determine muscle size. Total muscle area by CT analysis increased by 11.4% while the muscle biopsies showed an increase of 33.5% in type I fiber area and 27.5% increase in type II fiber area. In addition, lower body $\text{VO}_{2\text{max}}$ increased significantly while upper body $\text{VO}_{2\text{max}}$ did not, indicating that increased muscle mass can increase maximal aerobic power. It appears that age-related loss in muscle mass may be an important determinant in the reduced maximal aerobic capacity seen in elderly men and women.¹²⁸ Improving muscle strength can enhance the capacity of many older men and women to perform many activities such as climbing stairs, carrying packages, and even walking.

We applied this same training program to a group of frail, institutionalized elderly men and women (mean age 90 ± 3 years, range 87–96).¹²⁹ After eight weeks of training, the 10 subjects in this study increased muscle strength by almost 180% and muscle size by 11%. More recently, a similar intervention on frail nursing home residents demonstrated not only increases in muscle strength and size, but increased gait speed, stair climbing power, and balance.¹³⁰ In addition, spontaneous activity levels increased significantly while the activity of a non-exercised control group was unchanged. In this study, the effects of a protein/calorie supplement combined with exercise were also examined. The supplement consisted of a 240 mL liquid supplying 360 kcal in the form of carbohydrate (60%), fat (23%), and soy-based protein (17%), and was designed to augment caloric intake by about 20%, and provide one-third of the RDA for vitamins and minerals. The men and women who consumed the supplement and exercised gained weight compared to the three other groups examined (exercise/control, non-exercise supplement,

and non-exercise control). The non-exercising subjects who received the supplement reduced their habitual dietary energy intake so that total energy intake was unchanged. In other words, the supplement did not add to total energy intake, but rather substituted one source of energy (the supplement) for another (their meals). More recently (in the same study population), we demonstrated that combined weight lifting and nutritional supplementation increased strength by $257 \pm 62\%$ ($p = 0.0001$) and type II fiber area by $10.1 \pm 9.0\%$ ($p = 0.033$), with a similar trend for type I fiber area ($+12.8 \pm 22.2\%$).¹³¹ Exercise was associated with a 2.5-fold increase in neonatal myosin (a form of myosin found in growing muscle) staining ($p = 0.0009$) and an increase of $491 \pm 137\%$ ($p < 0.0001$) in IGF-1 staining. Ultrastructural damage increased by $141 \pm 59\%$ after exercise training ($p = 0.034$). Strength increases were largest in those with the greatest increases in myosin, IGF-1, damage, and caloric intake during the trial. Frail, very old elders respond robustly to resistance training with musculoskeletal remodeling, and significant increases in muscle area are possible with resistance training in combination with adequate energy intakes. It should be pointed out that this was a very old, very frail population with diagnoses of multiple chronic diseases. The increase in overall levels of physical activity have been a common observation in our studies.^{132,133,134} Since muscle weakness is a primary deficit in many older individuals, increased strength may stimulate more aerobic activities like walking and cycling.

Strength training may increase balance through improvement in the strength of the muscles involved in walking. Indeed, ankle weakness has been demonstrated to be associated with increased risk of falling in nursing home patients.¹³⁵ However, balance training, which may demonstrate very little improvement in muscle strength, size, or cardiovascular changes, has also been demonstrated to decrease the risk of falls in older people.¹³⁶ Tai Chi, a form of dynamic balance training that requires no new technology or equipment, has been demonstrated to reduce the risk of falling in older people by almost 50%.¹³⁷ As a component of the National Institute on Aging FICSIT trials (Frailty and Injuries: Cooperative Studies of Intervention Techniques), individuals aged 70+ were randomized to Tai Chi (TC), individualized balance training (BT), and exercise control education (ED) groups for 15 weeks.¹³⁸ In a follow-up assessment four months post-intervention, 130 subjects responded

to exit interview questions asking about perceived benefits of participation. Both TC and BT subjects reported increased confidence in balance and movement, but only TC subjects reported that their daily activities and their overall life had been affected; many of these subjects had changed their normal physical activity to incorporate ongoing TC practice. The data suggest that when mental as well as physical control is perceived to be enhanced, with a generalized sense of improvement in overall well-being, older persons' motivation to continue exercising also increases.

Province et al.¹³⁹ examined the overall effect of many different exercise interventions on reducing falls in the FICSIT trials. While separate interventions were not powered to make conclusions about their effects on the incidence of falls in an elderly population, the researchers concluded that "all training domains, taken together under the heading of 'general exercise' showed an effect on falls, this probably demonstrates the 'rising tide raises all boats' principle, in which training that targets one domain may improve performance somewhat in other domains as a consequence. If this is so, then the differences seen on fall risk due to the exact nature of the training may not be as critical compared with ... not training at all." It's important to note that in addition to regular strength and balance training, other elements play an important role in bone health and preventing falls; specifically, reducing psychotropic medication and diet supplementation with vitamin D and calcium (discussed further below) have also been shown to be effective.^{140,141}

The use of a community-based exercise program for frail older people was examined in a group of predominantly sedentary women over age 70 with multiple chronic conditions.¹⁴² The program was conducted with peer leaders to facilitate its continuation after the research demonstration phase. In addition to positive health outcomes related to functional mobility, blood pressure maintenance, and overall well-being, this intervention was successful in sustaining active participation in regular physical activity through the use of peer leaders selected by the program participants.

In addition to its effect on increasing muscle mass and function, resistance training can also have an important effect on energy balance.¹⁴³ Men and women participating in a resistance training program of the upper and lower body muscles required approximately 15% more calories to maintain body weight after 12

weeks of training when compared to their pre-training energy requirements. This increase in energy needs came about as a result of an increased resting metabolic rate, the small energy cost of the exercise, and what was presumed to be an increase in activity levels. While endurance training has been demonstrated to be an important adjunct to weight loss programs in young men and women by increasing their daily energy expenditure, its utility in treating obesity in the elderly may not be great. This is because many sedentary older men and women do not spend many calories when they perform endurance exercise, due to their low fitness levels. Thirty to 40 minutes of exercise may increase energy expenditure by only 100 to 200 kcals with very little residual effect on calorie expenditure. Aerobic exercise training will not preserve lean body mass to any great extent during weight loss. Resistance training *can* preserve or even increase muscle mass during weight loss and, therefore, may be of genuine benefit for those older men and women who must lose weight.

Bone Health

The increased calorie need resulting from strength training may be a way for the elderly to improve their overall nutritional intake when the calories chosen are nutrient-dense foods. In particular, calcium is an important nutrient to increase. Calcium intake was found to be a limiting nutrient in the diet of free-living elderly men and women in the Boston Nutritional Status Survey, which assessed free-living and institutionalized elderly men and women.¹⁴⁴ Careful nutritional planning is needed to reach the recommended calcium levels of 1500 mg/d for postmenopausal women with osteoporosis or using hormone replacement therapy, and 1000 mg/d for postmenopausal women taking estrogen. An increased calorie intake from calcium-containing food is one method to help achieve this goal.

In one of the very few studies to examine the interaction of dietary calcium and exercise, we studied 41 postmenopausal women consuming either high-calcium (1462 mg/d) or moderate-calcium (761 mg) diets. Half of these women participated in a year-long walking program (45 min/d, 4 d/wk, 75% of heart rate reserve). Independent effects of the exercise and dietary calcium were seen. Compared with the moderate-calcium group, the women consuming a high-calcium diet displayed reduced bone loss from the femoral neck, independent of whether the women exercised.

The walking prevented a loss of trabecular bone mineral density seen in the non-exercising women after one year. Thus, it appears that calcium intake and aerobic exercise are both independently beneficial to bone mineral density at different sites.

The effects of 52 weeks of high-intensity resistance exercise training were examined in a group of 39 postmenopausal women.¹⁴⁵ Twenty were randomly assigned to the strength training group (2 days/week, 80% of 1RM for upper and lower body muscle groups). At the end of the year, significant differences were seen in lumbar spine and femoral bone density between the strength-trained and sedentary women. However, unlike other pharmacological and nutritional strategies for preventing bone loss and osteoporosis, resistance exercise affects more than just bone density. The women who strength trained improved their muscle mass, strength, balance and overall levels of physical activity. Thus, resistance training can be an important way to decrease the risk for an osteoporotic bone fracture in postmenopausal women.

Muscle strength training can be accomplished by virtually anyone. Many healthcare professionals have directed their patients away from strength training in the mistaken belief that it can cause undesirable elevations in blood pressure. With proper technique, the systolic pressure elevation during aerobic exercise is far greater than that seen during resistance training. Muscle strengthening exercises are rapidly becoming a critical component of cardiac rehabilitation programs, as clinicians realize the need for strength and endurance for many activities of daily living. There is no other group in our society that can benefit more from regularly performed exercise than the elderly. While both aerobic and strength conditioning are highly recommended, only strength training can stop or reverse sarcopenia. Increased muscle strength and mass in the elderly can be the first step toward increased physical activity and a realistic strategy for maintaining functional status and independence for the remaining life span.

Exercise in the Treatment of Chronic Disease

The effects of exercise in treating chronic debilitating disease are largely unexplored. For example, fatigue is the most common complaint of patients with cancer, yet the most common advice provided by oncologists is for increased rest. Just as cardiac rehabilitation has been

demonstrated to provide an important mechanism for the post-myocardial infarction patient to improve fitness and reduce the risk of a second event, exercise can greatly improve fitness and reduce much of the fatigue associated with cancer and its treatment. The proven effects of resistance training to enhance nitrogen retention and increase muscle size and strength can provide positive benefits for patients with wasting diseases such as HIV infection and cachexia. Resistance exercise may prove to have powerful effects on patients with chronic renal failure who must consume low-protein diets to slow the progression of their disease. Exercise therapy for those patients forced to undergo extended periods of inactivity during dialysis could also improve functional status and decrease the fatigue associated with disuse. The potential value of a reasonable and well thought out exercise program is great, and the exploration of this value should be a high priority for researchers.

Summary

Exercise exerts a powerful acute and chronic effect on virtually every system in the human body. In assessing these effects and prescribing exercise, it is important to keep in mind the very different effects of aerobic vs. resistance exercise. Both forms of exercise are recommended and should be a component of a comprehensive program of disease prevention and health promotion. Chapter 29 presents information on helping patients structure and maintain a balanced exercise program.

Psychosocial Influences

John Tatum, MD

Introduction

An examination of the building blocks of health would be incomplete without an evaluation of the pivotal role played by psychosocial influences. Even in ancient times, this view was not unknown: Hippocrates (460–377 BC) is thought to have said, “It is better to know the patient who has the disease than it is to know the disease which the patient has.” A substantial part of “knowing the patient” includes understanding the psychosocial influences that have shaped, and continue to influence, our patients (and ourselves). While this material is not

intended to review extensively the factors and theories underlying psychological well-being (there is, after all, substantial literature devoted to the field and readily accessible to the reader), we do want to emphasize the importance of the clinician's continuing attention to the subject. A further discussion of mind/body issues, including the effects of spirituality, community, and poverty on health, can be found in Chapter 33. Here, we undertake a brief review of stress, as a marker for the profound effects that psychosocial influences have on the development of each human being.

Historical Emergence of Stress as a Recognized Factor in Health

In the modern age, the first to write extensively about stress and use the term was Walter Cannon, whose work during World War I, and on into the 1930s, helped to establish the "groundwork for understanding the physiology of mind-body interactions."^{146,147} Hans Selye (1907–1982), who gave full credit to Cannon's work, reintroduced the term and is considered the "father of stress," although the term was not actually used in the original short article in 1936.¹⁴⁸ His use of the word stress was derived from the physical sciences and engineering; through his work, the term evolved from a description of purely physical influences to encompass the biologic sphere as well.¹⁴⁹ His final definition of the term became: "Stress is the nonspecific response of the body to any demand made upon it."¹⁵⁰ In the words of one writer, "Selye's last main contribution to the stress concept was the recognition that, despite our different psychologic and cerebral reactions, both negative and positive stressors (i.e., distress and eustress) elicit virtually identical corticoid/catecholamine responses."¹⁵¹ Even more specifically, "different stressors elicit different patterns of activation of the sympathetic, nervous, and adrenomedullary hormonal systems."¹⁵² As both scientists and clinicians know, activation of those systems eventually involves the entire mind-body of the patient. The fact that thinking and psychosocial influences affect genetic expression and have long-term neurochemical consequences was demonstrated by the work of Nobel Laureate Eric Kandel, who said, "Stated simply, the regulation of gene expression by social factors makes all bodily functions, including all functions of the brain, susceptible to social influences."¹⁵³

Selye first noticed in medical school that patients with various illnesses had many symptoms in common, such as "coated tongues, aches and pains, loss of appetite, and inflamed tonsils."¹⁵⁴ He later noticed a generalized syndrome in laboratory animals exposed to various noxious agents, which he described as the "general adaptation syndrome."¹⁵⁵ Selye distinguished distress from eustress, stating, "the fact that eustress causes much less damage than distress graphically demonstrates that it is 'how you take it' that determines, ultimately, whether you can adapt successfully to change."^{156,157}

Chronic vs. Acute Stress

Since the word stress has been used in so many different ways, describing external events and internal reactions, Bruce McEwen suggested the term allostasis, as opposed to homeostasis, to describe the physiologic response of the body in the face of a challenge.¹⁵⁸ Robert Sapolsky, in his well-received book, *Why Zebras Don't Get Ulcers*, explains that, unlike us, the zebra has an episode of stress only when the lion is in pursuit; otherwise, he is physiologically calm.¹⁵⁹ Chronic stress (which most people experience) and its cumulative effects comprise what McEwen terms allostatic load. "Allostatic load does not always denote a failure of the body's efforts to cope with change or emergency. We can create it for ourselves by living in a way that makes for internal imbalance." Some examples of self-generated stress are not getting enough sleep, eating an unhealthy diet, and not getting enough exercise.¹⁶⁰ The importance of cumulative stress, or the allostatic load, was illustrated by the Holms and Rahe Social Readjustment Rating Scale. Points were assigned to life stressors, both positive and negative, and the higher the total number of points, the greater the likelihood of illness.¹⁶¹ Further discussion of allostatic load and its effects can be found in the following section on trauma.

Health Effects of Stress

Increased stress has been associated with many health conditions that are widely discussed in the medical literature and readily accessible to the reader. Some of the most familiar (with a few interesting recent citations) include cardiovascular disease,^{162,163} gastrointestinal disease,¹⁶⁴ and hormone dysfunctions,¹⁶⁵ all of which have active, ongoing explorations that continue to produce interesting data.

The etiological role of stress in disease was demonstrated in a well-designed prospective study of first-year medical students who were followed for a year. The prediction that there would be a measurable weakening of the immune system and an increase in illness at exam time was confirmed.¹⁶⁶ The proinflammatory cytokine IL-6 has been shown to be one mediator of stress-induced illness. The daily burden of caregivers has been recognized as particularly stressful, and the effects of that stress, including elevated IL-6 levels, have been shown to continue after the loss of the loved one.¹⁶⁷ Chronic stress also raises cortisol levels,¹⁶⁸ which have been shown to damage the brain.¹⁶⁹ Studies on psychosocial factors and cancer risk are inconclusive at this time.¹⁷⁰ Individuals under stress show less DNA repair, animals show decreases in the DNA repair enzyme methyltransferase, and examination stress increases the ability of a tumor-promoting agent to block apoptosis.^{171,172}

Stress prepares the organism for an emergency, but chronic stress impairs health through a complex array of physiologic functions initiated by the release in the hypothalamus of corticotropin-releasing factor (CRF). CRF triggers the release of adrenocorticotrophic hormone, or ACTH, from the pituitary, which in turn causes the release of cortisol from the adrenal cortex. Cortisol helps maintain blood glucose levels but (as noted above) chronic stress or chronic administration of pharmacological cortisol preparations causes insulin resistance, hypertension, redistribution of fat in the body, decreased protein synthesis, and decreased DNA repair. Furthermore, the immune system is weakened through a decrease in the production of blood cells, antibodies, and gamma globulins, but also through an inhibition of the production of the proinflammatory interleukins IL-1, IL-2, and IL-6; tumor necrosis factor; and gamma interferon. This shift in resources from ongoing maintenance and repair of the organism to all-out defense is understandable when fleeing the lion, but harmful when chronic, as discussed eloquently by Sapolsky in *Why Zebras Don't Get Ulcers*.

Some Determinants of Individual Responses to Stress

Although chronic stress and total cumulative stress increase the chance of illness, genetic, psychological, and social factors also play important modifying roles. For example, not all rats of the same strain suffer the

same degree of ill effects from the same stress. Sapolsky, professor of biology and neuroscience at Stanford University, and recipient of a McArthur Foundation "genius grant," describes a series of experiments with rats in which a second rat receives the same electric shock as the first. The second rat does not develop an ulcer if:

- there is a companion rat it can bite,
- it has a piece of wood it can gnaw on,
- it has a warning before the shock,
- it can press a lever it thinks will reduce its shock,
- the shocks are fewer than expected, and/or
- it is accompanied by a second rat it likes.¹⁷³

Sapolsky translates these studies to humans, observing that stress-related illness is less likely to happen if:

- we have an outlet for our frustration,
- we have "a hobby" or diversion,
- we have predictive information,
- we have a real or imagined sense of control,
- we can interpret a stress favorably, and/or
- we have social connectedness.

Thus, more important than the amount of stress is one's reaction to it, and that reaction is influenced by many factors.

In his review article, "How the Mind Hurts and Heals the Body," Oakley Ray describes four classes of coping skills that improve one's ability to handle stress.¹⁷⁴ The first of these is knowledge. "With knowledge [or] information, comes an empowerment, a belief that the world is understandable, controllable, and friendly. Perhaps the most stressful situation is the ambiguity that comes from an awareness that one has inadequate and incomplete information."¹⁷⁵ If education can be seen as a measure of knowledge, and perhaps the ability to acquire knowledge, increased years of education should be associated with longevity,¹⁷⁶ and indeed they are. Interestingly, however, subsequent research has shown that the association with education is "explained in full by the strong association between education and income."¹⁷⁷ As the authors go on to point out, with a strong match to Sapolsky's list (shown above):

Persons in lower socioeconomic strata have increased exposure to a broad range of psychosocial variables predictive of morbidity and mortality. This includes (1) a lack of social relationships and social supports; (2) personality dispositions, such as a lost sense of mastery, optimism, sense of control, and self-esteem or heightened levels of anger and hostility; and (3) chronic and acute stress in life and work, including the stress of racism, classism, and other

Section III

The Building Blocks

phenomena related to the social distribution of power and resources.

The second coping skill Ray describes is “inner resources.” This refers to the “beliefs, assumptions, and predictions” one learns growing up, including whether life is seen positively or negatively.¹⁷⁸ Valliant and Mukamal spoke of “involuntary mental mechanisms that adaptively alter inner or outer reality in order to minimize distress.”¹⁷⁹ Rotter introduced the important concept of locus of control,¹⁸⁰ and Kamen and Seligman talked of explanatory style.¹⁸¹ Again, these elements map back to Sapolsky’s list in a very substantive way.

Ray’s third class of coping skills is social support. “In general, ... the larger the social support system is, the lower the mortality rate.”^{182,183} (More on this subject can be found in Chapter 33.)

The fourth class of coping skills Ray describes is spirituality (also discussed further in Chapter 33). He refers to Oxman, Freeman, and Manheimer’s 1995 study. “Those who professed no strength and comfort from religion were three times as likely to die in this six-month period [after elective open heart surgery] as those who said they drew strength and comfort from religion. Those who did not participate in group activities were four times more likely to die than those who did.”¹⁸⁴ Other studies have shown similar findings.¹⁸⁵

There are many other psychosocial influences on health in modern life that the clinician needs to be cognizant of. Among the many that have been studied, some pertinent ones in today’s highly mobile, globalized world include natural catastrophe,^{186,187,188} disaster,¹⁸⁹ terrorism,^{190,191} and immigrant status (acculturation).¹⁹² Common experiences such as loss of a loved one, relocation, and loss of employment have been researched for decades.

Summary

This brief examination of psychosocial influences as key building blocks in patient health reveals that we cannot overemphasize the importance of taking a thorough psychosocial history as part of routine health care. Psychosocial factors influence health through the interconnected information systems of the mind, the endocrine system, the nervous system, and the immune system,¹⁹³ so the clinician cannot discount the possibility that the physical effects that brought the patient to the office may have been initiated by (triggers) and/or

influenced by (mediators) psychosocial experiences. The psychosocial portion of a comprehensive traditional medical history would include birthplace and subsequent moves, parental information including parenting style, sibling information, history of abuse or neglect, academic history, sexual history, marital history, children (including miscarriages and abortions), occupational history, and history of substance abuse. Research suggests the importance of paying particular attention to stress, loss, attitude, knowledge, beliefs, social support, and spirituality, as they have a direct impact on health and outcome, as described above.

Trauma

Jayne Alexander, DO

Introduction

When a rock is dropped to the bottom of a lake it not only disrupts the column of water through which it falls, but it also alters the dynamics of the entire body of water. Similarly, trauma, typically a directed force, not only disrupts or distorts the human body along the path of impact, but also potentially alters the dynamics of the entire organism.

This discussion will consider some of the physiologic and mechanical principles involved in trauma. Clinical considerations relevant to the post-stabilization, office-based patient will be presented.

Anatomic and Physiologic Response to Trauma

Starting with embryonic development and continuing throughout life, the living human body functions in part as a spatially oriented metabolic field engaged in the conduct of spatially ordered metabolic processes.¹⁹⁴ Trauma can be viewed as a force that distorts or disrupts the body’s spatial organization, or anatomy, to an extent that exceeds its ability to immediately return to its normal orientation and function.

The dominant physiologic concerns in the stabilized trauma patient are the effects of distortion mechanics, cellular breakdown secondary to frank tissue disruption, and consequent local and systemic responses. Non-incisive trauma, such as strain, spares its recipient the frank tissue disruption that occurs in

incisive trauma. However, neural, vascular, and lymphatic elements that course within strained tissues are, themselves, subject to the forces of strain.¹⁹⁵ The resulting distortion sets the stage for mechanical compromise that can manifest as pain, swelling, and functional impairment.

Incisive and non-incisive trauma that frankly disrupts tissue integrity initiates the process of inflammation, beginning with the release of substances such as neuropeptides from peripheral nerve terminals, histamine from mast cells, prostaglandins from capillary endothelial cells, and cytokines from white blood cells.¹⁹⁶ Consequent increased local blood flow and increased capillary permeability contribute to fluid pooling in the extravascular space, or interstitium, and to the manifestation of edema. The presence of fibrinogen in the interstitial fluid and the infiltration of leukocytes leads to clotting, phagocytosis, and lysosomal degradation.¹⁹⁷

Within three to five days of disruptive trauma, granulation tissue, which is rich in fibroblasts and small, budding blood vessels, typically begins to form. Granulation tissue fibroblasts, some of which have characteristics of smooth muscle cells, are involved in the synthesis of glycosaminoglycans and collagen, favoring the former in the early stages of healing and the latter as healing advances.¹⁹⁸ The neovasculature's loosely constructed interendothelial junctions allow extravasation of yet more proteins into the already protein-rich interstitium, a process that further contributes to the formation of interstitial edema.¹⁹⁹

It is the critically important task of the lymphatics to remove inflammatory exudate from the interstitium.^{ii,200,201} The efficiency with which that task is performed governs the length of time that the interstitium is exposed to lysosomes, proinflammatory cytokines, and other irritants. Their persistence in the interstitium can contribute to pain, via stimulation of primary afferent nociceptors, to delayed healing, and eventually to fibrosis.²⁰² Additionally, under conditions of venous stasis, the efficiency of lymphatic drainage inevitably affects the rate of delivery of nutriture and medication to the site of injury, as well as the rate of presentation of

antigens to lymph nodes and the vigor of the subsequent immune response.^{iii,203,204}

The body's response to trauma involves both the peripheral and central nervous systems. The peripheral nervous system (PNS) has two components: a somatic component, the efferent fibers of which innervate skeletal muscle, and an autonomic component which innervates most other tissues and organs.^{iv} Both components carry sensory fibers, or primary afferent fibers, from somatic or visceral tissues to the central nervous system (CNS) via the dorsal horn of the spinal cord. These primary afferents are of two types—myelinated, large-caliber fibers, or A afferents, and non-myelinated, small-caliber fibers, or B afferents. The large-fiber system is typically involved in discriminative touch and proprioception, and the small-fiber system is involved in nociception, the detection of damaging or noxious stimuli. The small-caliber fibers, commonly referred to as primary afferent nociceptors, or PANs, are responsive to mechanical, chemical, and thermal stimulation. Low-level stimulation of PANs is perceived as crude touch or contact, whereas more intense stimulation is perceived as pain. Under conditions of repetitive stimuli, PANs are subject to sensitization—a lowering of the threshold of activation, which leads to the development of facilitation and hyperalgesia.²⁰⁵

Nociceptive information is conveyed by somatic and visceral afferents to the dorsal horn of the spinal cord, and then ascends the cord to the midbrain, primarily via the anterolateral system. The forebrain limbic system, which processes emotional content, has descending projections to the midbrain. A major area of convergence of this ascending nociceptive and descending emotional information is a cluster of norepinephrine-producing

ⁱⁱ Among the substances found in lymph are proteins, histaminase, neutrophilic lysosomes, prostaglandin E, interleukin-1, and antigens [References 200, 201 (p. 937), and Atkinson, TP. Histamine and serotonin. In Gallin JI, et al. *Inflammation: Basic Principles and Clinical Correlates*. New York: Raven Press, 1992, p. 196.]

ⁱⁱⁱ Of clinical significance is the understanding that osmotic and hydrostatic gradients do not account for the uptake of exudates from the interstitium by initial lymphatics. Rather, pulsatile fluid waves, consistent with arteriolar vasomotion, pass through the interstitial fluid and contribute to the opening and closing of the initial lymphatic. [Intaglietta M, Gross JF. Vasomotion, tissue fluid flow and the formation of lymph. *Intl J Microcirc: Clin and Exper*. 1982;1:55-65.] Once within the lymphatic vessels, the movement of lymph is supported *intrinsically* by a distension-sensitive myogenic pump, and *extrinsically* by such mechanical forces as intestinal peristalsis and thoracic respiration as well as by neural and humoral mediators. [Schmid-Schonbein GW. Microlymphatics and lymph flow. *Physiol Rev*. 1990;70(4):987-1028.]

^{iv} The autonomic nervous system (ANS) sends fibers to all tissues except hyaline cartilage, centers of intervertebral discs, and parenchymal tissues of the CNS. [Willard, FH. Autonomic nervous system. In Ward RC, ed. *Foundations for Osteopathic Medicine*. 2nd Ed. Philadelphia: Lippincott Williams and Wilkins, 2003.]

Section III

The Building Blocks

cells called the locus coeruleus (see Figure 13.1). The locus coeruleus releases norepinephrine through projections to the forebrain, the spinal cord, the hippocampus, the hypothalamus, and to cardiovascular and respiratory centers located in the brain stem.²⁰⁶

When the hypothalamus, which also receives emotional input, is stimulated by norepinephrine from the locus coeruleus, it responds by releasing both corticotropin-releasing hormone (CRH) and norepinephrine. CRH, in turn, stimulates the locus coeruleus to release more norepinephrine, thereby establishing a feed-forward loop between the locus coeruleus and the hypothalamus. Additionally, CRH causes the anterior pituitary to release adrenocorticotropin (ACTH). ACTH, via systemic circulation, stimulates the release of glucocorticoids such as cortisol from the adrenal cortex, resulting in, among other things, gluconeogenesis and suppression of the release of cytokines.²⁰⁷ Under normal conditions, following short-term physical or emotional stress, elevated cortisol levels will serve to downregulate this hypothalamic-pituitary-adrenal (HPA) axis. In addition to being activated by emotional stress, hormonal stimulation, and nociceptive impulses, the HPA axis is also activated by cytokines released in response to trauma, infection, histamine, and inflammation.²⁰⁸ This intersystemic integration is designated as the neuroendocrine immune system.

Figure 13.1 Generalized schema of effect of noxious or emotionally charged input to the central nervous system

Release of norepinephrine from the hypothalamus increases the activity of the sympathetic nervous system (SNS). This has the effect of increasing heart rate, respiratory rate, blood pressure and cardiac output, dilating large muscular arteries and bronchioles, decreasing gastrointestinal system activity, and mediating numerous other changes that prepare the body for aggressive or defensive action.²⁰⁹ Sympathetic fibers follow blood vessels to all lymphoid organs and surround T-cells, many of which have receptors for norepinephrine. Norepinephrine has the effect of increasing the rate of T-cell differentiation, enabling a short-term response to a broad array of antigens. The rate of cell division, however, is decreased, compromising the long-term effectiveness of the response.²¹⁰

Analogous to the distorting effect that a falling rock has on the entire body of water into which it falls is the effect of trauma on the entire human organism. Various researchers and clinicians have considered the living human body as a single metabolic field,^v a matrix field²¹¹ or a fluid field,²¹² and have considered the effects of distortion on the field as a whole. In his later years, Nobel laureate Albert Szent-Györgyi stated, “Whenever we separate two things, we lose something, something which may have been the most essential feature.”²¹³ To the physician trained in subtle manual sensing, distortions of the whole, when present, are manually perceptible and reveal essential organizational qualities of the entire organism.

The Patient with a History of Trauma

Obtaining the History

Obtaining the history of a stabilized, office-based patient has various components. One should consider the type of trauma and the mechanical forces involved, predisposing factors or antecedents, the duration or “age” of the trauma, and the patient’s overall state of health and metabolic reserve.

^v German embryologist E. Blechschmidt describes metabolic fields as “those morphologically definable regions, at all levels of spatial resolution, which contain spatially ordered metabolic movements.” This he applies to cells, tissues, organs, and the whole organism at any stage of development. [Blechschmidt, E. *The Ontogenetic Basis of Human Anatomy*. Berkeley: North Atlantic Books, 2004, p22.].

Type of trauma. Patients who are seen in the office have often experienced trauma of the momentum-inertia type, wherein a moving body or object has impacted the patient's body, exemplified by an object falling on the head; or the moving patient has impacted a stationary object, as in hitting one's head on the overhead storage compartment of an airliner. Information regarding the direction and degree of force should be obtained. Knowledge of individual vectors of force is fundamental to the diagnosis of contrecoup injuries, whiplash, and complex impact injuries. Determination of resultant vectors can guide the discerning clinician to consider areas of occult or asymptomatic trauma and potential functional compromise. Traumas that are not of the momentum-inertia type involve a variety of forces that will be addressed in subsequent sections.

Common sources of trauma that may precipitate a patient's visit to the office, and that should be solicited as part of any new patient's history, include the following:

- Birth
- Motor vehicle, pedestrian, and bicycle accidents
- Falls, sports injuries, and blows to the head
- Dental and orthodontic procedures
- Surgical procedures and wounds
- Physical, sexual, and emotional abuse including domestic violence, child and elder abuse, abusive child-rearing practices, and exposure to abuse in the role of a witness
- Loss

In obtaining a birth history, one should ascertain the duration and mechanism of labor, whether cesarean section was necessary, and whether forceps or vacuum extraction was used.^{214,215} Prolonged engagement in the maternal pelvis during a long and difficult labor subjects the infant cranium to considerable compressive force, potentially resulting in cranial nerve dysfunction or plagiocephaly.^{216,217,218,219} Difficulty sucking, for example, is typically the result of hypoglossal nerve irritation, a condition which can be promptly corrected by the skillful application of a decompressive manual procedure.²²⁰ In the event of cesarean section, presurgical engagement in the birth canal requiring forceful retraction into the uterus is a scenario which, in this author's experience, has been associated with neonatal torticollis. Since, among other things, maternal HPA axis activation is associated with intrauterine growth retardation,²²¹ the physical and emotional health of the mother during

pregnancy and her attitude toward the pregnancy should be solicited. APGAR scores and knowledge of the quality, or robustness, of the first cry are additional meaningful indicators of anatomic and physiologic health or compromise.

Auto, pedestrian and bicycle accidents, sports injuries, and falls can potentially involve open or closed head injury, fractures, sprains, and strains. Consideration of vectors of force as well as distribution of force is particularly pertinent in this form of trauma.^{222,223,224} Becker states,

"In circumstances of trauma, thousands of cells have had their inertial patterns suddenly disturbed ... into new patterns that include force factors Thereafter, the central nervous system must include this new data in every voluntary and involuntary use of the local areas involved and in varying degrees throughout the entire body physiology This is in addition to the local injuries that have been endured by the body, which are usually the only thing treated by the physician."²²⁵

A history of participation in ice skating, gymnastics, horseback riding, or contact sports should automatically put the physician on the lookout for the effects of trauma. Fracture need not occur for falls, blows, and other momentum-inertia type injuries to be functionally significant. Intraosseous strain typically precedes, but does not always result in, fracture. In the experience of this author, the presence of strain—interosseous, intraosseous, and that involving soft tissue—can contribute to delayed healing and to pain that persists beyond apparent healing. It therefore behooves the physician to solicit the mechanical details of even those falls and accidents that the patient appends with the assuring comment that "nothing was broken."

Many dental procedures (for example, extractions and applications of prostheses) involve the use of compressive, distractive, or torsional force, and orthodontia relies on low-grade force sustained over time to accomplish its goals. Even in the most skilled professional hands, the use of some force is inevitable. The force of extraction, for instance, may be transmitted to the mandible, maxilla, or pre-maxilla from which a tooth is removed, and with the use of excess force or torsion, the force may extend to one of the many bones with which these three articulate, potentially affecting sinus, vestibular, and cranial nerve function, and precipitating cephalgia.²²⁶ Having a potentially similar effect is the commonly used orthodontic palate expander, which, in

decompressing the maxillary arch, inevitably transmits compression to other areas of the cranium.

Surgical procedures are inherently disruptive to anatomy and physiology. A clean surgical incision in a healthy patient should undergo healing by first intention with minimal loss of tissue. Nonetheless, collagenous scars are avascular and acellular and do represent an interruption in tissue continuity. Large wounds involving extensive loss of cells undergo healing by second intention, a process that involves a more intense inflammatory reaction and more extensive wound contraction than does healing by first intention. Predictably, this process sets the stage for more extensive scarring and fibrosis.²²⁷

Obtaining a history of abuse and the witnessing thereof requires sensitivity and an understanding that such history may be compensatorily suppressed, unavailable to the patient's consciousness, or literally lacking in verbal narrative.²²⁸ A tempo of interviewing should be adopted that affords patients the opportunity to assess the intent and integrity of the clinician before being called upon to reveal sensitive personal information. Once the physician is entrusted with such information, it is imperative that referral, if necessary, be made with a clearly conveyed attitude of support and respect, lest patients feel abandoned in the wake of their disclosure. Often overlooked are those who witness abuse. Witnesses are, themselves, traumatized, being caught in the psychological conflict of affiliation with either the perpetrator or the victim.²²⁹ Of diagnosing the psychological and behavioral aftermath of abusive trauma, Herman admonishes that:

Concepts of personality organization developed under ordinary circumstances are applied to victims, without any understanding of the corrosion of personality that occurs under conditions of prolonged terror. Thus, patients who suffer from the complex aftereffects of chronic trauma still commonly risk being misdiagnosed as having personality disorders.²³⁰

Loss, in the context of trauma, is unique. Unlike other forms of trauma in which the integrity of the organism is disrupted by an added force, the integrity of the organism, in loss, is disrupted by virtue of absence. In this author's experience, patients have reported pain in the midepigastria area for a number of days following loss, perhaps harkening to the "severing of heart-strings." Others having lost a spouse or intimate partner have reported a feeling of "irregularity" or concavity on the side of their body next to which the loved one slept.

Clinical observations correlate. In the clinical experience of the author and her colleagues, the fluid field in patients who have experienced physical or psychological attack is often perceived as being compressed or regressed toward the physiologic midline. By contrast, in loss, there may be an actual perceived absence in an aspect of the fluid field with a compensatory shift of the midline, giving physiologic corroboration to the affectionate aphorism "my other half."

Antecedents. It is incumbent upon the physician to endeavor to determine the etiology or background related to the patient's trauma. Trauma can be preceded and precipitated by cardiovascular and cerebrovascular events, neurological phenomena such as tumor and seizure, visual impairment, and alcohol intoxication. Trauma can result from inattention secondary to fatigue, anxiety, or preoccupation. Trauma can also be a potential consequence of occupation, lifestyle, and familial or interpersonal relationships. Determining and addressing with the patient those factors which are causal or predisposing to trauma is a valuable and sometimes critical contribution of the clinician.

Long-term Consequences of Unresolved Trauma

The persistent effects of unresolved trauma manifest through a variety of mechanisms which operate locally, intersystemically, and within the patient as a whole.

Compensatory structural changes. Asymmetric falls on the buttocks, one-legged falls in holes, and forced "splits" in dance classes can dramatically shift the plane of orientation of both the body of the sacrum and the sacral base. Compensatory structural changes in the form of scoliosis can be the result.

Fibrosis. Trauma that is incisive or disruptive to tissues leads to fibrosis, the extent of which is affected in part by the efficiency of drainage of inflammatory exudate by the lymphatics in the post-traumatic period.²³¹ Fibrotic tissue interrupts the integrity and function of the tissues it transects, and limits the range or freedom of motion of the tissues involved. Functional impairment and discomfort, as exemplified by adhesive capsulitis and post-surgical, intra-abdominal adhesions, can ensue.

Facilitation. Spinal facilitation, a state of sensitization of the interneuronal pool, occurs as a result of prolonged or excessive stimulation of primary afferent nociceptors, as well as from direct neuronal injury or inhibitory interneuron death, and is a mechanism underlying chronic pain.²³² Maintained in a state of

constant partial or subthreshold excitation, and responsive to subnormal levels of input from peripheral and autonomic PANs, facilitated levels of the spinal cord are easily stimulated. Once stimulated, signals are sent to the locus coeruleus, which invokes the locus coeruleus-norepinephrine-HPA axis and results in increased sympathetic tone and cortisol output.

Under conditions of facilitation, norepinephrine, released from the locus coeruleus in response to input from a facilitated level of the spinal cord, stimulates the hypothalamus, overpowering the normal downregulatory effect of cortisol.²³³ This results in unmitigated stimulation of the hypothalamus which leads to its sustained release of norepinephrine and CRH and the consequent increase in both sympathetic tone and adrenal elaboration of cortisol.

Peripherally, the effects of facilitation may be identified by the presence of tissue texture changes, hyperalgesia, altered ease or range of motion, and anatomic asymmetry of the affected region—a constellation of findings referred to in osteopathic literature as somatic dysfunction.²³⁴ Although a facilitated level of the cord may interact with higher centers as previously described, the facilitated reflex arc can also operate independently of higher input. Resolution of the somatic dysfunction associated with facilitation, which can be accomplished manually, allows normalization of somatic afferent input, and, barring persistent visceral input, enables normalization of HPA and autonomic function.²³⁵

Viscerosomatic and somatovisceral reflexes. In addition to potentially subjecting the patient to sympathetic and HPA overdrive, facilitation also predisposes the body to the establishment of viscerosomatic and somatovisceral reflexes. Facilitation of an interneuronal pool affects outflow to both visceral and somatic structures innervated by the facilitated level of the cord.²³⁶ Thereby, facilitation that was originally established in response to persistent inflammation or mechanical irritation from an unresolved visceral trauma can, via somatic efferents, affect the skeletal muscle innervated by the same spinal level. Conversely, facilitation secondary to unresolved musculoskeletal injury can result in chronic increased autonomic stimulation of segmentally related viscera.

Allostatic load. The cumulative, long-term effect or toll taken on the body by frequent, repetitive activation of the autonomic nervous system, HPA axis, and cardiovascular, metabolic, and immune systems, or by their

persistent low-grade activation to a chronically elevated baseline, is termed allostatic load.^{vi,237,238} (This concept is also discussed in the preceding essay on psychosocial influences on health.) In the present discussion, it was established that somatic and visceral trauma, psychological trauma, chronic pain, inflammation, and facilitation all serve to activate the locus coeruleus-norepinephrine-HPA axis. Unresolved trauma clearly places a significant demand on the body and, over time, is a major contributor to the development of allostatic load.

The effects of allostatic load established to date are multiple. In a study involving 1,189 men and women, aged 70–79 years at outset, participants were assessed with respect to allostatic load, cognitive functioning, and physical functioning.²³⁹ Participants with highest allostatic load scores performed most poorly with respect to cognitive and physical functioning and, on eight-year follow-up, higher baseline allostatic load scores predicted greatest loss in cognitive and physical functioning.²⁴⁰ Related to an aspect of cognitive functioning is the hippocampus, which is involved in verbal and contextual memory. The hippocampus is rich in cortisol receptors, and normally participates in a feedback loop controlling release of CRH from the hypothalamus.^{241,242} Persistently elevated levels of cortisol are toxic to hippocampal neurons, and lead to neuronal atrophy or death and loss of memory.^{243,244}

Prolonged HPA axis activation in infancy and childhood takes its toll, inhibiting the production of growth hormone and somatomedin C.²⁴⁵ This contributes to the condition of “failure to thrive,” in which caloric intake does not promote weight gain. Early loss of a parent (due primarily to parental separation) and physical and sexual abuse during childhood both carry an increased risk of major depression during adulthood.²⁴⁶ A history of major depression is among the strongest predictors of cardiovascular risk, depression being associated with increased resting heart rate, decreased heart rate variability, and increased plasma norepinephrine.²⁴⁷ Chronic elevation of cortisol inhibits bone formation,

^{vi} Based on the word *allostasis*, which is akin to the term *homeodynamics*. The term refers to the coordinated, broad intersystemic (particularly neuroendocrine immune) range of variability that enables the body to maintain stability in the face of protracted challenge. This is distinguished from *homeostasis*, which maintains discrete, physiologic parameters such as pH and electrolyte balance within a more finite operating range. (The principles of dynamic balance and homeostasis are discussed in Chapter 9.)

and women with a history of depressive illness have a greater frequency of decreased bone mineral density.²⁴⁸

Childhood abuse additionally predisposes to adult anxiety disorders, panic disorder, attempted suicide, post-traumatic stress disorder (PTSD), and likelihood of developing PTSD^{vii} in response to other traumas.²⁴⁹ Sensitization or hyperactivity of CRH circuits secondary to stress early in development is hypothesized to explain the psychological sequelae.²⁵⁰ Females who experience PTSD from childhood sexual abuse demonstrate daily elevation of norepinephrine, epinephrine, dopamine and cortisol levels, and have a tendency toward obesity.²⁵¹ Abused females additionally have an increased rate of premenstrual syndrome, asthma, spastic colitis, and dysmenorrhea.²⁵² Male veterans, by comparison, who developed PTSD in combat, demonstrate an elevated norepinephrine-to-cortisol ratio, and an increased incidence of cardiovascular disease, gastrointestinal symptoms, chronic pain, and rheumatism.²⁵³

Chronically elevated cortisol and catecholamine levels lead to immunosuppression and decreased cellular immunity, which, in turn, leads to increased severity of the common cold and increased titers of cold-virus antibody.²⁵⁴ Elevated cortisol also promotes insulin resistance.²⁵⁵ This results in increased output of insulin, which has been shown to be excitatory to the sympathetic nervous system.²⁵⁶ (For discussion of the inflammatory effects of increased insulin output, see Chapter 30.)

Chronic sympathetic hyperactivity elevates blood pressure and increases cardiac workload, thereby contributing to endothelial dysfunction, coronary spasm, left ventricular (LV) hypertrophy, and serious dysrhythmias. Persistently elevated blood pressure accelerates atherosclerosis, which increases the risk of myocardial infarction.²⁵⁷ When coexistent with LV dysfunction, increased sympathetic tone is the most sensitive predictor of cardiac and arrhythmic mortality.²⁵⁸ Increased sympathetic tone impedes development of collateral circulation following arterial occlusion.²⁵⁹

Supporting the Patient's Health

Details of treatment are not within the purview of this chapter, and clinicians of varying backgrounds will

approach treatment differently. However, common goals of treatment and principles to apply in planning treatment will likely apply to most clinicians and should be addressed.

Promoting efficient exchange of all the fluids of the body is of fundamental importance. Healing is supported and adverse inflammatory and degenerative effects are averted by efficient fluid exchange. Nutrients, both endogenous and exogenous, are delivered and wastes are removed via the fluids of the body. Nutrients will not arrive at their desired destination if the destination or its access routes are in a state of stasis. Similarly, waste products and inflammatory exudates will not be removed if the routes of egress are not open and functioning.

Also fundamental to the resolution of trauma is the downregulation of afferent input. Attenuation of facilitation and elimination of the sources of nociceptive stimulation can contribute significantly to normalization by reducing input to the SNS and HPA axis. In this author's experience, this can often be accomplished by manually engaging and augmenting the corrective and generative physiologic processes that are operant in the patient's body. Ultimately, it must be acknowledged that the physician is an assistant, and the capacity for healing is inherent to the patient.

Case Studies

The following cases from the author's experience are offered in abbreviated form to illustrate potential and uncommonly considered consequences of trauma.

Case 1. Concussion and macroscopic distortion.

During the winter of my freshman year in osteopathic school, one of my classmates fell on the ice, landing hard on his back and hitting the back of his head. His glasses went flying. When he retrieved them, they fit poorly, and he presumed they had been bent in the fall. In the following hours, he experienced headache, difficulty focusing, unsteadiness on his feet, and "did not feel like himself." Later that day he reported his symptoms to one of his clinical professors who, on examination, found evidence of the impact, and administered an osteopathic treatment aimed at reestablishing structural balance. Following the treatment, my classmate "felt like himself," and when he donned his glasses, they fit perfectly, indicating that it was not his glasses that had been warped, but his head. This illustrated to those of us present the capacity of the living cranium to

^{vii} PTSD is characterized by hyperarousal, intrusion (vivid flashbacks and nightmares of the traumatic event), and constriction (anesthesia, detachment, passivity). [Reference 227, p35.]

deform on impact. We were left by the professor, as I will leave the reader, to consider the potential consequences of sudden distortion, or “warping,” of the human cranium on such phenomena as extraocular muscle function, vestibular function, occlusion, venous sinus drainage, cranial nerve function, etc.

Case 2. Hyperthyroidism. Prior to arriving at my office, this 34-year-old mother of five was anticipating an ablative procedure for symptoms of hyperthyroidism of sudden onset two months earlier. Her history revealed that prior to, and within the same month of, her symptoms’ onset she had fallen head over heels down a flight of stairs with her six-month-old daughter in her arms. On exam, her pulse was 110, speech was rapid and voice high-pitched, thyroid was palpably enlarged and she had lost 15 pounds. She complained of headache, feeling hot, “rubber legs,” dyspnea, and dysarthria. Potentially relevant findings included sternoclavicular and acromioclavicular compression, upper left costovertebral compression, segmental cervical restriction and paracervical hypertonicity, occipito-temporal compression, and positional asymmetry of the temporals. Manual osteopathic treatment was administered to restore ease and function to the involved area. On follow-up four days later, the patient reported no recurrence of dyspnea, no “rubber legs,” fewer headaches and improved energy; pulse was 90. Over the following weeks her condition improved and resolved.

Clinical Pearls

1. Attend to areas *where forces accumulate*, e.g., a fall on an outstretched hand may give rise to upper arm or shoulder symptoms if compressive forces are not resolved.
2. When a patient requires a boot-type cast, attempt to match its height in the other shoe. This will help to avoid low back pain and the initiation of scoliotic mechanics.
3. In managing fractures, treatment *prior* to casting aimed at decreasing or eliminating strain in interosseous, intraosseous, and soft tissues can potentially reduce the development of pain and dependent edema.
4. Solicit a history of trauma from every new patient, and consider trauma as an etiologic or contributing factor in illnesses of unknown or “idiopathic” etiology. Symptoms not typically associated with trauma may, in fact, have a traumatic etiology.

Summary

Trauma is one of many challenges presented to our patients. Its proper identification and thorough resolution can have effects that reach beyond the individual. When unresolved, trauma can dampen and defeat the human spirit. However, when resolved, trauma has the potential to impart understanding and can augment the human capacity for compassion.

Xenobiotics

John Cline, MD

Introduction

The building blocks of health include both harmful and beneficial influences upon human biology and individual genetic and biochemical uniqueness. One of the harmful environmental inputs that clinicians must pay increasing attention to is xenobiotic exposure. The word xenobiotic is defined as “a chemical substance that is foreign, and usually harmful, to living organisms.”²⁶⁰ Xenobiotics are also known as persistent organic pollutants (POPs), which are carbon-containing chemicals that have been introduced into the environment in ever-increasing numbers. In fact, it has been estimated that there have been over 80,000 of these chemicals introduced into the environment since World War II.²⁶¹ There is a growing body of scientific evidence documenting serious health problems that arise secondary to the exposure and accumulation of POPs in humans.²⁶² There are few environmental issues that have aroused more public concern than the harmful effects of POPs in the general population, especially when it concerns the health and welfare of children. Despite the volume of scientific literature published, this subject remains controversial as there are huge financial issues at stake.

History

It is interesting to note that pesticides as we know them today did not exist before World War II. Organophosphate pesticides were developed as nerve gases, and the phenoxyherbicides such as 2,4-D were designed to destroy the Japanese rice crops (with later use as a component of Agent Orange, a substance used to defoliate large areas in jungle warfare).²⁶³ Following World

War II, these chemicals were put to use in many applications, including agricultural production, spraying of neighborhoods for mosquito eradication, and home and garden use. In the 1950s and onward, epidemiologists became concerned about the health effects of exposure to POPs. Initially, studies of wildlife communities demonstrated reproductive, developmental, endocrine, immunologic, and carcinogenic effects.^{264,265,266} There were high rates of malformed genitalia, aberrant mating behavior, sterility, cancer, and immune system and thyroid dysfunction. United States epidemiologists began to notice a rise in the incidence of non-Hodgkin's lymphoma (NHL), observing that these cases were clustered in agricultural areas. This phenomenon paralleled pesticide use, causing some researchers to postulate that there was a causal link.

In 1962, Rachel Carson's book, *Silent Spring*, was truly revolutionary in bringing this issue into political and public awareness.²⁶⁷ It was followed in 1996 by *Our Stolen Future*, which documented the health effects of these endocrine-disrupting chemicals.²⁶⁸ In 1996, a number of governments participated in the Intergovernmental Forum on Chemical Safety and agreed upon a list of 12 POPs to be eliminated from the environment. These 12 have been dubbed the "Dirty Dozen." In 2001, the United Nations Environment Program sponsored the Binding Convention on Persistent Organic Pollutants held in Stockholm, Sweden, and there was a call for an immediate ban on 11 of the Dirty Dozen. The list of these dozen POPs and their sources are found in Table 13.1. It should be noted that DDT was still allowed to be used in developing countries to control mosquitoes in malaria prevention.

Properties of POPs

POPs are persistent because they resist photolytic, biological, and chemical degradation. They can take as long as one century to biodegrade.²⁶⁹ They are carbon containing and hence organic. They are lipophilic pollutants accumulating in the fatty tissues of organisms. Furthermore, they bioaccumulate up the food chain leaving those at the top with high concentrations in their tissues. Most of the POPs are semivolatile which allows them to travel thousands of miles in the air before they settle.²⁷⁰ An example of this is the Inuit of

Nunavik in northern Canada. These aboriginal people consume the fat of seals, beluga and narwhal whales. These people have been found to have high body burdens of POPs.²⁷¹

Health Effects of POPs

The available epidemiological evidence suggests that the health effects of POPs in humans are similar to those in animals in the same range of exposures. Human studies have demonstrated negative effects of POPs on neurodevelopmental, thyroid, estrogen, and immune function.^{272,273,274,275} Exposures to all of the commonly used pesticides, such as phenoxyherbicides, organophosphates, carbamates, and pyrethrins, have shown positive associations with adverse health effects. Furthermore, the carcinogenic effects of certain POPs have been well demonstrated. Triazine herbicides increase breast cancer risk; carbamate and phenoxyherbicides increase lung cancer risk; use of indoor insecticides is associated with brain cancer and lymphocytic leukemia in children.²⁷⁶

In pregnant women, higher levels of polychlorinated biphenyls (PCBs) have been shown to adversely affect the brain development of their children. The affected children were initially found to have decreased visual recognition scores,²⁷⁷ followed by decreased performance on short-term memory testing.²⁷⁸ By age 11, these children were found to have lower average IQ scores and were delayed in reading comprehension.²⁷⁹ Furthermore, there was evidence of altered gender-typical play behavior, with less masculinized play in boys and more in girls.²⁸⁰ There was also decreased ability to control inappropriate responses, as is found in children with attention deficit hyperactivity disorder.²⁸¹

There is also growing concern about the impact of flame retardants on human health. There are 175 types of flame retardants and the brominated flame retardants (BFRs) make up the majority. Tetrabromobisphenol A is the most widely used BFR. *In vitro* studies have demonstrated that it is hepatotoxic, immunotoxic, and neurotoxic. In addition, it acts as an endocrine disruptor with estrogen-like properties. The primary toxic effect is as a disruptor of thyroid homeostasis.²⁸² Furthermore, the level of polybrominated diphenyl ethers (PBDEs, another type of flame retardant) is rising in humans, as recently demonstrated in a study of people

Table 13.1 Environmental and Dietary Sources of Persistent Organic Pollutants (the “Dirty Dozen”)

Type	Environmental Sources	Examples of Dietary Sources
Dioxins, furans	Byproducts of petrochemical industry and chlorine bleaching in pulp and paper mills; hospital and municipal incinerators	Meat, poultry, and dairy products; sport fish (e.g., lake trout, salmon, walleye); wildlife (e.g., waterfowl and waterfowl eggs, muskrat, otter, moose, deer)
PCBs	“Fire resistant” synthetic products made before 1977, old electrical equipment, leaky containers in PCB disposal sites	Great Lakes fish (e.g., lake trout, salmon), Arctic marine mammals, breast milk
Aldrin	Pesticide used against insects in the soil to protect crops such as corn and potatoes	Dairy products, meat, fish, oils and fats, potatoes, root vegetables
Chlordane	Broad-spectrum contact insecticide used on vegetables, grains, maize, oilseed, potatoes, sugar cane, beets, fruits, nuts, cotton, and jute	Use has been severely restricted, so food does not appear to be a major pathway of exposure now; air may be a pathway because of past use in termite control (in the United States)
DDT	Pesticide widely used during World War II to protect soldiers and civilians against diseases spread by insects	Fish, dairy products, fat of cattle, hogs, poultry and sheep, eggs, vegetables, breast milk
Dieldrin	Insecticide used to control insects in soil	Same as for aldrin
Endrin	Foliar (leaf) insecticide used on field crops such as cotton	Current dietary exposure thought to be minimal because of restricted use
Heptachlor	Nonsystemic stomach and contact insecticide used to control insects in soil	Detected in the blood of U.S. and Australian cattle in 1990; current dietary exposure thought to be minimal because of restricted use
HCB	Fungicide used for seed treatment	HCB-treated grain; current dietary exposure thought to be very low because of severely restricted use
Mirex	Stomach insecticide used to control ants, termites, and mealy bugs	Meat, fish, wild game, marine bird eggs, sea mammals
Toxaphene	Contact insecticide used primarily on cotton, cereal, grains, fruits, nuts, and vegetables and used to control ticks and mites in livestock	Dietary exposure thought to be very low because of restricted use; however, there is a local problem with some fish in Lake Superior

Legend:

PCBs = polychlorinated biphenyls

DDT = dichlorodiphenyltrichloroethane

HCB = hexachlorobenzene

living in the remote Faroe Islands. The concentration of PBDEs in human breast milk rose threefold between 1987 and 1999.²⁸³ Breastfed Faroese children were also found to be 0.59 kg lighter and 1.5 cm shorter than non-breastfed children. The transfer through the breast milk of the contaminants methylmercury and PCBs fully explained the attenuated growth parameters.²⁸⁴

Recommendations and Summary

One of the most comprehensive reviews of the subject of xenobiotics is the document, *Systematic Review of Pesticide Human Health Effects*.²⁸⁵ The conclusions are as follows:

- The scientific literature does not support the concept that some pesticides are safer than others.
- Reducing exposure is the best advice. Given the wide range of commonly used home and garden products associated with adverse health effects, the focus should be on reduction of exposure to all pesticides.

Furthermore, low-dose exposure is not necessarily safe exposure; “no evidence of harm” is not equivalent to “evidence of no harm.” We are currently able to characterize the risks for only a small number of the 80,000+ POPs that have been released into our environment. There are incalculable combinations of chemicals, environmental breakdown molecules, and metabolites that need to be evaluated for safety in humans. Unfortunately, we presently have a knowledge void, and the phrase “no evidence of harmful effects” can hide the greater truth that there is simply no evidence at all.²⁸⁶

Each one of us needs to avoid exposure to POPs as much as possible and have intact and healthy detoxification systems. For the clinician, it is imperative to help patients understand this diffuse, but increasingly heavy burden our bodies are being asked to handle because it is one of the environmental inputs that has significant effects upon health. Further discussion of the clinical implications of the toxic burden, including detoxification (its processes and applications) and polymorphisms that can predispose to more significant problems, can be found in Chapter 22 and Chapter 31.

Microorganisms

Patrick Hanaway, MD

*A mighty creature is the germ,
Though smaller than the pachyderm,
His strange delight he often pleases,
By giving people strange diseases.*
—Ogden Nash

Introduction

Microorganisms include viruses, bacteria, fungi, protozoa, algae, and nematodes, roughly in increasing order of size. They are the oldest form of life on earth and are found virtually everywhere. Bacteria have been present on earth for more than 2.5 billion years. The combined weight of all microbial life is thought to be about 25 times more than all animal life combined.²⁸⁷ Thus, humans have evolved fully in the presence of bacteria. Not only are we not alone, but we are required to live in mutual balance with this vast array of microorganisms. This relationship can be defined as symbiotic (at least one partner profits without hurting the other), commensal (partners that coexist without detriment but without obvious benefit), and pathogenic (in which there is damage to the host).

The critical interface between the human body and its internal and external environments manifests itself on many levels: the food we eat, the air we breathe, and the lifestyle we choose are all “environmental inputs” that influence our genetic material continuously. The interaction between the body (through the epidermal, respiratory, oropharyngeal, and gastrointestinal interfaces) and the myriad microbes in the environment provides benefits to both parties.

The biologic terrain where humans and microorganisms interact must remain in homeostatic balance to provide the correct milieu for the body to function optimally. In this model, bacteria and other microorganisms are not usually considered dangerous, invasive, and pathogenic. Pathogenicity among microorganisms is the exception, not the rule. Considering the huge population of bacteria and viruses in our environment and in our own bodies, it is a relatively rare occurrence that these typically symbiotic relationships become harmful. Rather, imbalanced microbial growth may be indicative of an alteration in the biologic terrain.

The symbiotic organisms living in and on us have more than 100 times the amount of genetic material that the entire human genome has.²⁸⁸ The Human Genome Project tells us that at least 223 human proteins have significant homology with bacterial proteins, suggesting direct horizontal transfer from bacterial genes.²⁸⁹ While the age of antibiotics has led us to focus on microbes (and bacteria in particular) as pathogens, an understanding of the co-evolution of humans and microorganisms is critical for our health and well-being.

Discussions on this point date back to ancient medical systems, but the most well-known debate on this matter was between Pasteur and Béchamp. Pasteur postulated that “germs” were the primary cause of illness, while Béchamp argued that the “inner terrain” was the most important factor.²⁹⁰ Noted 19th century pathologist Rudolph Virchow is reported to have said, “mosquitoes seek the stagnant water, but do not cause the pool to become stagnant.”²⁹¹

Microorganisms are ubiquitous and nowhere is this more important than the critical role of the large and dynamic bacterial community present within the gastrointestinal tract. Evidence demonstrates that bacteria have co-evolved to support digestion, absorption, metabolism, and development of the immune system. Disruption of this mutual balance between the physical body and these commensal microorganisms leads to both acute and chronic disease.

Commensal Flora in the Gastrointestinal Tract

At birth, the human body is sterile. Colonization of the skin epithelia and the mucosal membranes starts immediately after birth and evolves quickly over the first days of life.²⁹² These species play a critical role in the dynamic education of the adaptive immune system, promoting balance and strength in the under-developed immune system.

More than a century ago, the Russian scientist Eli Metchnikov discussed the clinical importance of gastrointestinal flora. He promoted the health benefits of taking live bacterial cultures as a means of supporting the colonic microflora. Research on microbial ecology has grown rapidly since the early 1990s, particularly because of the inherent role of the gastrointestinal flora in the development of the immune system. It appears that our co-evolutionary relationship with these organisms is used as a primer for regulation of the immune system.

Colonization of gut flora begins immediately after birth and is nearly complete after the first week of life, but quantity and species vary markedly over the first six months of life.²⁹³ More than 500 species have been noted, each with numerous strains identified by molecular probes.²⁹⁴ Overall, the number of bacteria present in the gastrointestinal lumen is 10-fold greater than the number of cells in the human body,²⁹⁵ with more than 100 times the human genome's DNA content.²⁹⁶ Studies demonstrate that bacteria differentially colonize the neonatal and infant gastrointestinal tract based upon a number of environmental factors, including the mode of delivery (Cesarean section or vaginal delivery),²⁹⁷ hygiene measures, environmental contaminants, maternal flora, age at birth, and type of feeding.²⁹⁸

Nutritional inputs from breastfeeding, bottle feeding, and introduction of solid food provide the initial substrate for growth of varying species of bacteria within the gut.²⁹⁹ Other environmental factors, including more aggressive standards of hygiene, have led to a delayed development pattern and even an absence of certain groups of bacteria in the commensal flora of neonates.³⁰⁰

Hygiene Hypothesis

In 1989, Strachan³⁰¹ coined the term “hygiene hypothesis.” As stated, the theory is that increased prevalence of allergy and atopic illness in industrialized countries is a result of the decrease in exposure to common infections during early life, secondary to smaller family size. A number of studies have confirmed this relationship, but there is no direct evidence for a protective role of infections. Many have attempted to extend this hypothesis, based upon epidemiologic evidence, to include the role of antibiotics, vaccines, and anti-microbial soaps, but their effects have not been proved.³⁰² Immunologically plausible explanations have been demonstrated.³⁰³ Current research focuses on the role of nutrition, timing, and gut flora maturation on immunologic development.³⁰⁴

Breastfeeding has been recognized to have an important role in the nutrition of the infant. Nutritive and immunologic components of breast milk have been studied for years, but the effects of essential fatty acids and oligosaccharides as stimulants for commensal flora are now better understood. From an evolutionary perspective, the gut has been finely tuned to develop based upon the dietary presence of breast milk over the first 1–3 years of life. The immunoregulatory role of breast milk and infant nutrition has come to the fore.³⁰⁵

Colonization of Gastrointestinal Flora

There is a significant alteration in the gut flora of the neonate over the first week of life, depending upon the food source. Classically, we see the introduction of *E. coli* and strep species during the first few days of life, giving way to bifidobacteria, bacteroides, and clostridium. Breast-fed infants then develop a predominance of bifidobacteria, first noted by Tissier in 1905.³⁰⁶ Bottle-fed infants show a more diverse pattern of colonization.³⁰⁷ A number of internal and external factors influence the adherence and succession of microbes within the gastrointestinal tract, including feeding habits,³⁰⁸ hygiene,³⁰⁹ stress,³¹⁰ antibiotics,³¹¹ bacteria-host communication, and gene expression.³¹²

Many species have evolved to peacefully co-exist within the gastrointestinal tract. With more than 500 species identified and more than 100 trillion bacteria “in residence,” the necessity of a mutually beneficial relationship is clear. While the sub-species and quantities of bacteria will vary over time, the families and species of commensal flora remain relatively constant within an individual over the course of a lifetime. The gastrointestinal microflora can, however, be modified by diet and environmental factors, and those changes can significantly affect health.

Humans and bacteria have co-evolved to offer mutual benefit. The positive health effects of these bacteria include: energy salvage from carbohydrate fermentation, synthesis of B and K vitamins, production of short-chain fatty acids (SCFAs) such as n-butyrate to act as metabolic substrate for colonocytes, lowering pH, producing anti-microbial compounds, and stimulating the immune system.³¹³

Nearly 70% of the human immune system is localized in the digestive tract. The mucosal surface of the gastrointestinal tract would cover the area of a doubles tennis court (if stretched out flat), and is approximately 200x the surface area of the skin. Defense against microbes is mediated by the early reactions of innate immunity, followed by the reaction of adaptive immunity. Innate immunity includes the skin, mucosal epithelia, cytokines, and phagocytes. These non-specific defense mechanisms provide defense against common pathogens, but the innate immune response *stimulates* the adaptive immune system and influences the nature of the adaptive response.³¹⁴ The process of “oral tolerance” is an important example of this.³¹⁵ The semi-

permeable gastrointestinal epithelium identifies and responds to pathogens, while minimizing the immune reaction to food antigens and commensal flora.

Through the process of co-evolution, the body has mastered a number of methods to identify microbes and develop the adaptive immune system, based upon the proper timing and presence of the bacterial stimuli. The body responds differentially to bacterial stimuli and responds to a variety of structural components on each bacterium. Recent evidence demonstrates that immunostimulatory DNA³¹⁶ may derive from the copious amounts of bacterial DNA present in the gastrointestinal tract. The epithelial mucosa is equipped with pattern recognition receptors (PRRs) that recognize bacterial DNA from commensal bacteria and modulate immune function.³¹⁷

Thus, our immune system is dynamically educated by the presence of commensal, symbiotic, and pathogenic bacteria at the interface of the intestinal epithelium. The gut flora interacts with our innate immunity and influences the adaptive immune response in an important dialogue between our immune system and the environment. Commensal bacteria are also able to modulate expression of host genes involved in important intestinal functions, including nutrient absorption, mucosal stimulation, xenobiotic metabolism, and intestinal maturation.³¹⁸ Understanding the “cross-talk” between bacteria and the immune system helps us better understand the relative continuum between pathogenic and non-pathogenic relationships.

Altered Balance in the Human Micro-Organism Environment

Hooper and Gordon³¹⁹ have highlighted the effects of imbalance within this complex ecosystem. The increasing prevalence of allergy and atopy are associated with alterations of intestinal colonization and decreased tolerance to common food proteins and inhaled allergens. Treatment with probiotics can help to shift these symptoms back to normal.³²⁰ The pathogenesis of inflammatory bowel disease (IBD), a condition that is becoming substantially more common, appears to involve an abnormal activation of the immune system. IBD results from an inappropriate and exaggerated mucosal immune response to normal constituents of the mucosal microflora. Host genetic background may determine the susceptibility to intestinal inflammation

and normal mucosal microflora appears to maintain the inflammatory process.³²¹

Overall, we see that these critical gene-environment interactions highlight immunologic dysregulation arising from the combination of varied bacterial species (commensal and pathogenic), altered adaptive immune system activation, and multiple antigenic stimuli. It appears that diet (as prebiotics and antigens) plays an important role with each of these factors.

Summary

From an evolutionary perspective, our genome has not changed over the past 50 years, but the incidence of chronic disease has become epidemic. Playing a vital role in the development of chronic diseases are the changes in our diet and various other environmental factors (see, for example, the discussion on Diet and Nutrients at the head of this chapter) that no longer provide the proper milieu for the gastrointestinal tract to properly activate the immune system. Our genetic predispositions have not prepared us to successfully manage the current lifestyle, dietary, and environmental patterns we face today. We must work to balance each of these inputs to re-align our immune systems for optimal function. As we explore the foundations of normal physiology, we must develop new therapeutic strategies to re-establish a proper relationship with our “old friends,” because microorganisms are one of the key environmental inputs to health.

Radiation

Carol R. McMakin, MA, DC

Introduction

To understand the effects of environmental radiation exposure on the human system, it is important to understand that, from a biophysics perspective, the human body is an electromagnetic semiconductor matrix that allows for instantaneous communication among all cells and tissues in the system. Every physiologic process and biochemical reaction takes place in this semiconductor matrix. Every cell in the body is filled with a cytoplasmic matrix or cytoskeleton that is connected by integrins across the cell surface to every other cell surface and membrane in the body. The

enzymes that create every physiologic function do not float in an intracellular soup; they are attached to the cytoplasmic matrix and perform their chemistry in a solid state context created by this intracellular structure. Water molecules line the matrix forming a system that functions as a semiconductor, sharing electrons and allowing the transmission of energy and information throughout the system.³²²

Understanding this model becomes important when considering the influences that create damage or constitute a threat to the health of the system, as well as those that may have the potential to heal.

Ionizing Radiation

The health risks of environmental x-ray exposure are well documented and easy to understand. Ionizing radioactive energy (x-rays) includes a spectrum of high-energy unseen particles that move through the cell, creating physical damage to intracellular structures. DNA seems particularly sensitive to such damage, and different organs may have different responses to exposure.³²³ X-rays are useful for medical imaging because the bone and more dense body structures absorb x-rays that pass through less dense structures. The x-rays that pass through the softer tissues create the images on film that we see as diagnostic x-rays. The damaging intracellular effects of x-rays are used therapeutically in cancer treatment to destroy the DNA of malignant cells. Environmental exposure to x-rays includes the ionizing radiation produced by the sun and exposure to altitudes at which the atmospheric protection against x-ray exposure is reduced (e.g., during activities such as mountain climbing and air travel). Radon gas and natural radioactivity found in certain types of rock and brick create residential exposure risk.

Ionizing radiation is a potent carcinogen and injures living cells by damaging the DNA. X-rays create some direct damage to the DNA by splitting bonds, but most of the damage is indirectly generated by free radicals that create intracellular injury and DNA damage. Hydroxyl radicals (OH) are considered to be the most damaging of all free radicals and are created by splitting the water molecules that line the intracellular and extracellular matrix.

Immune system cells seem particularly vulnerable, as do bone marrow cells.³²⁴ Exposure to x-rays increases the risk of breast, colon, lung and ovarian cancer, basal cell

carcinoma, and leukemia. Radiation exposure reduces the level of both vitamin E and vitamin C in bone marrow.³²⁵ The reduction may be either a direct or an indirect effect, as these vitamins are used to counteract the free radicals produced by the x-ray exposure.

Protecting the Patient

How can the clinician help patients to protect themselves from the effects of exposure to ionizing radiation? There is evidence to suggest that antioxidants and other natural substances are protective against the damaging effects of ionizing radiation.

Beta carotene: Serum concentrations of oxidized conjugated dienes (an index of lipid peroxidation) were significantly increased in children who were exposed to high levels of irradiation, as compared to children in low radiation areas, following the Chernobyl (nuclear reactor) disaster in Russia. Supplementation with natural beta carotene 40 mg per day for three months resulted in a significant decrease in serum conjugated diene levels after one and three months.³²⁶

Lycopene: An animal study using mice demonstrated the ability of lycopene to protect against the detrimental effects of radioactivity exposure. This protection was double that of beta carotene. This effect is likely attributable to lycopene's antioxidant properties.³²⁷

Lipoic acid: This study involved radiation victims in Chernobyl. Lipoic acid reduced free radical damage caused by radiation exposure. One group of 16 children given 400 mg of lipoic acid daily for 28 days showed significant reductions in both white blood cell free radical activity and urinary excretion of radioactive isotopes, compared to a control group of 12 children.³²⁸

Vitamin E: A second group of 14 children given 400 mg lipoic acid plus 200 mg vitamin E daily for 28 days showed an even greater reduction in urinary excretion as compared to both the lipoic acid and control groups.

Vitamin C improves the ability of the body to resist the toxic effects of exposure to radioactivity. Guinea pigs that were supplemented with large dosages of vitamin C (10 gram equivalent) combined with bioflavonoids were able to withstand twice the known lethal dosages of radioactivity.³²⁹

Cabbage, broccoli: Cabbage and broccoli were protective in reducing radiation damage and mortality from radiation exposure in animal studies. Guinea pigs exposed to whole-body x-radiation demonstrated a

lower death rate and bleeding incidence when they were pre-fed on cabbage prior to receiving x-ray exposure.³³⁰

Ginkgo biloba: When *Ginkgo biloba* was administered to Chernobyl recovery workers, it protected them from further chromosomal damage.³³¹

Melatonin is an antioxidant that protects DNA, lipids, and proteins from free-radical damage. It works by stimulating the activities of antioxidant enzymes and scavenging free radicals directly or indirectly. Among known antioxidants, melatonin is a highly effective scavenger of (OH), hydroxyl free radicals. Melatonin is distributed widely in organisms and in all cellular compartments, and it quickly passes through all biological membranes. Lymphocytes that were pre-treated with melatonin exhibited a significant and concentration-dependent decrease in the frequency of radiation-induced chromosome damage, as compared with irradiated cells that did not receive the pre-treatment.³³²

Siberian and Korean ginseng doubled the life span of rats exposed to prolonged x-rays at a total dose of 1,620 to 7,000 rads.³³³

Nonionizing Radiation

The risks of nonionizing radiation exposure are less clearly documented. The controversy arising from Robert Becker's research in the 1980s (and his books, *The Body Electric*³³⁴ and *Cross Currents*³³⁵) still reverberates through the research community. Becker stated that the ever-increasing spectra of electromagnetic exposure—"electro-pollution," including FM radio waves, microwaves, and other electromagnetic fields to which humans are being exposed—create biological effects. Animal studies show chronic stress responses in animals exposed to increased levels of electromagnetic fields (EMF), demonstrated by increased body weight and alterations in neuroendocrine function. (Becker claimed that the Department of Defense interfered with research funding aimed at finding any detrimental effects from radio waves or electromagnetic fields. The military uses these EMF bands for communication and tracking.)

The commercial, legal, and financial consequences of any documented link between electromagnetic exposure and cancer are enormous. It is no wonder that researchers (such as Becker) who discover such links find themselves attacked in the public and even in the scientific press.

Robert P. Liburdy published a number of papers between 1984 and 1993 documenting the effects of electromagnetic fields on cells. In 1984 he found that radiofrequency radiation affects the immune system by altering human immunoglobulin on T and B lymphocytes. The effect takes place at power levels below the current OSHA recommended safety limit of 0.4 WKg⁻¹.^{336,337}

He published several papers documenting the effects of 12 mg, 60Hz fields, such as those found in the home and workplace, on breast cancer cells. Both tamoxifen and melatonin inhibit the growth of cultured human breast cancer cells. He found that the 12 mg, 60Hz field blocked melatonin's natural oncostatic action on estrogen positive MCF-7 human breast cancer cells grown in cell culture. The next study showed the same environmental electromagnetic fields inhibit the oncostatic action of tamoxifen as well as melatonin, which implicates the estrogen receptor. The negative effect could be overridden by increasing the dose of melatonin and tamoxifen.

There is some controversy over the effects of microwave radiation (from cell phones, FM radio stations, and television transmissions) and its ability to produce specific cancers. As long as there are such huge financial and liability issues involved in the funding and publication of research on this topic, sorting out the real risks on a true scientific basis seems difficult, if not impossible, at the current time. James Oschman observes that, "the Russian standard for maximum safe microwave exposure to avoid changes in brain activity is 1000 times less than the U.S. legal maximum." Until further research is available, the reader is advised to be cautious and judicious in the selection of home and workplace locations relative to microwave and FM transmission towers, and in the use of cell phones. It has not been documented that the use of antioxidants serves the same protective function in EMF exposure as is seen in radiation exposure.

Beneficial Effects of Electromagnetic Therapies

The beneficial and therapeutic effects of electromagnetic therapies have been studied since the early 1900s. The Albert Abrams Medical Clinic in San Francisco successfully treated tuberculosis, cancer, influenza and syphilis in 1920 using frequency-specific electromagnetic

therapies. Upton Sinclair expected to write an exposé on Abrams's "quackery" for *Pearson's Magazine* in 1922, but the published article was titled "House of Wonders." Sinclair was impressed by the clinical results and the hope they offered to patients. In 1934, the American Medical Association declared that electromagnetic therapies were "unscientific" and moved medicine toward the use of drugs and surgery. The study of electromagnetic therapies and the beneficial effects of electromagnetic therapeutic fields on biological systems dropped out of medical research and into the realm of biophysics.

Robert Becker's ground-breaking work (described above) on the electromagnetic nature of biological tissue and the beneficial effects of direct current (DC) fields in tissue regeneration revolutionized the treatment of non-union fractures and wound healing. The current author resurrected frequencies used in the 1920s by Abrams and others, using a battery-operated (DC) microcurrent device as a frequency generator, and began using those frequencies to treat myofascial pain and nerve pain with a technique called "frequency specific microcurrent" in 1997.^{338,339} Very specific clinical responses to over 100 frequencies have been noted, including those thought to remove inflammation, remodel scar tissue, alleviate concussion, eliminate the herpes virus, and stop bleeding. Two frequencies used simultaneously produced unprecedented log scale reductions in inflammatory peptides during a 90-minute treatment in fibromyalgia patients. The changes in cytokines correlated directly with reductions in pain scores.³⁴⁰

Blinded animal research conducted at the University of Sydney by Vivienne Reeve, PhD demonstrated that the frequency to "remove inflammation" (40hz) in the "immune system" reduced lipoxygenase-mediated inflammation by 62% in four minutes in a mouse model. The reduction was time dependent and all animals responded. Three other frequency combinations tested produced no reduction in inflammation. Prescription and non-prescription anti-inflammatory medications tested with this same model reduced swelling by 45%.³⁴¹

The research and early clinical experiences in this area are promising and suggest there is potential therapeutic benefit of electromagnetic and frequency-specific therapies.

Summary

The pervasiveness of radiation, both in the natural environment and from manmade sources, makes it a key environmental input in today's world. There are important distinctions between the effects of ionizing vs. nonionizing radiation, but overall it seems clear that less is better than more. There are foods and supplements that can help patients protect themselves from radiation damage; clinicians should become familiar with these and assist patients with known high levels of radiation exposure to take precautionary measures.

Chapter 14

Influence of Mind and Spirit

DeAnn Liska, PhD

Introduction

This chapter is the final entry in our Building Blocks section. We have given our attention to the effects on human health of various well-known and often well-researched biological and physical factors, and their interaction with individual genetic predispositions: diet, nutrients, air, water, exercise, trauma, xenobiotics, microorganisms, and radiation. The psychosocial realm has also been discussed, and is a source of prolific research and myriad books and articles written about common (and uncommon) clinical approaches. We now turn our attention to the impact of spirituality as one of the key building blocks of health. Here, we will briefly introduce the subject, which is just beginning to make itself felt in research and scientific writing. (Further discussion can be found in Chapter 33.)

Understanding the role of biochemical individuality (that is, genetic predisposition influenced by environment) is a cornerstone of functional medicine and has been demonstrated by such examples as the variety of differentially regulated detoxification enzymes,^{1,2,3} the relationship among body fat composition, blood pressure, and insulin resistance,^{4,5,6} and the myriad influences that determine risk of conditions such as CVD.^{7,8,9,10} All of these examples (and a great deal of this book) are about the physical nature of our being—the mechanisms that connect us with the physical world around us. Because these are physical, matter-based examples, we can test them. We can do genetic testing; we can devise assays to detect the result of a specific intervention. But the medicine of today involves more than just the physical, matter-based body; it also includes the spiritual experience of the patient.

Emerging Research on Spirituality and Health

As the changing research record indicates, an understanding of the role of spirituality in health and healing is attracting considerable attention of late. For example, a search of the National Library of Medicine database (PubMed) using the word “spirituality” shows that only 62 articles were published on this subject in the 20 years between 1970 and 1990, compared to 477 articles between 1990 and 2000, and more than double that number, 1226 articles, from 2000 to 2004. This increased interest was triggered by studies such as that of King and Bushwick, in which it was noted that 94% of patients admitted to hospitals believe that spiritual health is as important as physical health, and 77% believe that physicians should consider their patients’ spiritual needs, but only 20% of patients reported their physicians addressing spiritual issues with them in more than just a passing fashion.¹¹ A 2003 study in which physicians were asked about their attitudes and preferences regarding spirituality in the medical encounter found that, of the 84.5% who indicated they should be aware of patients’ spirituality, most would not ask about spiritual issues unless a patient were dying.¹² In a discussion on the role of spirituality and health, Levin makes this assertion:

By excluding matters of spirit from clinical research and practice, physicians run the risk of leaving out a large piece of what it means to be a human being. If physicians sincerely wish to treat the whole person, they first will have to see their patients as more than just a body and a personality, or, worse, a collection of isolated organ systems.¹³

Researching the Spirituality and Health Connection: Challenges and Early Findings

Given the importance of this subject to patients and practitioners alike, it is valuable to spend a little time exploring some new findings that suggest there may be a physical, biochemical basis for spirituality. Interestingly, as with all other building blocks to health, this biochemical connection appears to be experienced differently by each of us; that is, spirituality (our experience of the divine) is another example of how we all show biochemical individuality. Moreover, the research is showing more clearly how our spirituality, life experience, and physical bodies (biochemistry) are all entwined in such a manner that ignoring one means leaving out part of the web.

First, it is beneficial to define spirituality and religion, since these terms can be interpreted differently. The Oxford dictionary defines spirituality as “of the human spirit or soul, not physical or worldly.”¹⁴ Religion, in contrast, is more limited and means “a particular system of faith and worship.”¹⁵ Therefore, spirituality is the non-physical component of a person, whereas religion is the institutional practice, or how spirituality is codified and acted on by a group or society. These definitions help to clarify why it is often easier to observe, report on, and quantify religion than it is to assess spirituality. In fact, this is one of the primary challenges in incorporating spirituality into a science-based discussion.

There are other roadblocks as well. A primary issue is the historical conflict between “science” and “religion.” Many scientists and clinicians have been taught that spirituality is unscientific, not logical, and, therefore, not relevant to a Western, science-based approach to health and disease. Certainly, history is filled with examples of how science can challenge religious beliefs, and how religion can limit scientific progress. The tone of recent research, however, is showing that the 21st century may find a way to heal the rift between science and the spiritual—or, at least, to begin examining it objectively. Even when this relationship between “science” and “religion” is difficult, a functional medicine approach of treating the patient, not just the disease, means finding ways to incorporate attention to spirituality into clinical practice in a science-based manner.

The difficulty of “measuring” spirituality challenges our current research models. Much work performed in the 1990s and early 2000s focused on spiritual practices

like meditation, prayer, yoga, and quigong because those can be seen (that is, the activities can be observed, recorded, and their before-and-after effects can be assessed). For example, in a controlled trial, specific daily practice of yoga was shown to increase plasma melatonin after three months.¹⁶ Intrinsic religiosity has also been associated with diurnal cortisol rhythm, as compared to subjects with low religiosity, who show apparent flattened cortisol patterns.¹⁷ Davidson et al.¹⁸ reported in 2003 that an eight-week program of mindfulness meditation before influenza vaccination led to an increase in antibody titer, as compared to non-meditating controls, which suggests an improvement in immune function with meditation.

These are but a few of many fascinating examples of the general effect spiritual practices can have on health indicators. Should we expect that each patient can benefit similarly from these practices? In functional medicine, we would say that such practices will be filtered through the patient’s genetic predispositions and overall environment, so perhaps the answer is “no.”

We know that stress hormone pathways and behaviors like anxiety are, at least in part, determined by certain genetic polymorphisms—that is, the polymorphic pattern of genes we inherit from our parents influences our response to stress and our susceptibility to conditions such as post-traumatic stress disorder. Continuing that train of thought, it is intriguing to speculate that at least some of these polymorphisms might also be involved in how responsive individual patients are to spiritual practices such as mindfulness meditation. Consider the finding that parallel polymorphisms in the acetylcholinesterase and paraoxonase 1 gene loci have been associated with anxiety scores.¹⁹ Research has also documented that psychosocial stress can lead to alteration in how the acetylcholinesterase gene is spliced, which then leads to different levels of acetylcholinesterase activity in the cell.²⁰ Another study has reported an association between certain polymorphisms in the cytochrome P450 2D6 gene and harm avoidance; it has been postulated that this detoxification system may impact personality by influencing the generation of endogenous neurotransmitters in the brain.²¹

From these examples, it is not too far-reaching to suggest that many spiritual practices that are now being shown to influence the body’s biochemistry will be experienced differently by patients with different

genetic propensities. Thus, we begin to perceive the biochemical individuality of spirituality.

Possibly the most intriguing work on the interplay between biochemical individuality and spirituality has emerged from Thomas Bouchard's group at the Department of Psychology, University of Minnesota, MN. Bouchard has investigated genetics and behavior by focusing on twins reared together or apart, and has concluded that there is now strong evidence that virtually all individual psychological differences are moderately to substantially heritable.²² In particular, he used a validated scale of intrinsic and extrinsic religiosity with 35 pairs of monozygous twins and 37 pairs of dizygotic twins reared apart and found that twin similarity could not be explained by environmental factors alone, but was only explained by a model containing genetic plus environmental factors.²³ (Note that both genetics and environmental factors must be included for the model to be effective.)

The Temperament and Character Inventory (TCI)—a 240-question, standardized, validated, personality assessment that scores such behaviors as self-transcendence, transpersonal identification, and mysticism—has also been used to explore the interrelationship among genetics, biochemistry, and behavior. In an interesting report, Comings and colleagues obtained results suggesting an association between a polymorphism in the D4 dopamine receptor gene (DRD4) and scores on the self-transcendence scale of the TCI ($p < 0.02$),²⁴ although this observation has not been reproduced.²⁵ Still, it is interesting to compare these findings with those of Newberg and colleagues, who have used neuroimaging techniques to understand the changes in brain activity during meditation. While observing cerebral blood flow during meditation in trained meditators (Buddhist monks), these researchers found an overall increase in cortical activity and suggested that this change might be related to the altered sense of space and connectedness experienced by the monks during meditation.²⁶ In a follow-up review of the physiology of meditation, Newberg and Iversen summarized the many studies that indicate meditation influences neurotransmitters, including increasing dopamine in the striatum, as well as increasing serum concentrations of arginine, vasopressin, GABA, melatonin and serotonin, and decreasing serum cortisol and norepinephrine.²⁷

Dr. Dean Hamer, chief of gene structure at the National Cancer Institute, has published a book called "The God Gene,"²⁸ in which he describes studies on

spirituality. He reviews a study initially targeted to better understand smoking addiction, in which he recruited 1,000 men and women and obtained TCI questionnaire scores. He reports finding a large variation among the subjects in the subscore for spirituality on the TCI. Moreover, although some have suggested that patients who are more influenced by spiritual experiences are likely to be more "temperamental" or "anxious," Hamer and colleagues found just the opposite. Subjects also provided biological samples, from which Hamer and his colleagues looked for a genetic explanation for the variation in the spiritual score on the questionnaire and keyed in on the vesicular monoamine transporter 2 gene (VMAT2). Although his work is intriguing, it has not been reproduced or thoroughly assessed by the scientific community. Furthermore, Hamer is the first to admit:

Human behaviors, and the brain circuits that produce them, are undoubtedly the product of intricate networks involving hundreds to thousands of genes working in concert with multiple developmental and environmental events. Further advances in the field will require the development of microarray analysis that measures the activity of many different genes simultaneously. Only then will the gene hunters have a shot at achieving the promises held out by the past century of classical behavior genetics research.²⁹

Spirituality as a Clinical Intervention

Integrating the spiritual into the everyday practice of medicine can be difficult. Anadarajah and Hight³⁰ reviewed tools for such formal assessment and integration of spirituality into medical practice and found the majority were developed for use by pastoral counselors and nurses, or as research instruments. They further commented: "Little has been written about approaches developed for use by practicing physicians in a routine medical encounter." Therefore, they designed a tool that can be incorporated into general practice: the HOPE questionnaire. A more comprehensive discussion of spiritual assessment tools can be found at <http://www.gwu.edu/~cicd/toolkit/spiritual.htm> (accessed Dec. 30, 2004). It is anticipated that this increased interest in the spiritual component of health will lead to many more useful tools for assessment of spirituality and, ultimately, to the ability to individualize a health plan for patients that includes the entirety of the human experience. For now, it is clear that "one size does not fit all" is true even for such practices as

meditation, relaxation, and prayer; in reality, these practices will be experienced differently by each of us.

Summary

The relationship between genes, genetic expression, and spirituality is a new, intriguing area of research. Although we know that different life experiences can affect our spiritual selves, these new areas of research are showing how our unique genetic, physical selves also influence our sense of spirit and the divine (and vice versa). These studies also help us understand that patients may need different types of intervention and spiritual support; for example, some may find meditation easy to perform on their own, with a more successful result on such physical parameters as blood pressure, whereas some patients may require designated teachers or programs, not because they aren't trying hard enough, but because they aren't as "biochemically susceptible" to the effects of meditation. Clinicians will need to adapt research findings to their clinical practices—never an easy task. But surely we are all better off—patients and practitioners alike—for bringing knowledge and awareness of this important subject into both scientific inquiry and clinical practice.

Section IV

Fundamental Physiological Processes

Chapter 15

Communications: Intracellular and Extracellular

Gary Darland, PhD

Introduction

The Hippocratic concept of the four humors (phlegm, blood, black and yellow bile) may have been the first widely accepted concept of homeostasis. Imbalance among the four was thought to result in what today we call disease. Much more recently, homeostasis has been defined in *Dorland's Medical Dictionary* as “a tendency to stability in the normal body states (internal environment) of the organism.” The definition goes on to mention that this is achieved by a system of negative feedbacks. Although implied in the latter definition, it is often overlooked that the maintenance of stability is an active process. A constant flow of information is necessary to determine the appropriate response, and energy is required to generate the response. Cells are continually monitoring both the intra- and extra-cellular environment and adjusting their biochemical processes accordingly. Unlike the implication in Dorland's definition, the responses can be either negative or positive. It's becoming increasingly apparent that many chronic diseases result from failures in these regulatory processes.

All cells, whether they are the simple prokaryotic bacteria, or the highly differentiated eukaryotic cells that comprise the human body, must be able to sense and respond to their environment. Within the eukaryotic kingdom, the biochemical mechanisms underlying these processes are nearly ubiquitous. The basics can be described rather simply, but the combinations and permutations of the interactions lead to an often bewildering complexity. It is probably not much of an exaggeration to say that at this level the “web of life” metaphor becomes reality.

There are two (at least) methods of approaching the concept of homeostasis from the standpoint of signal recognition and response. One can discuss either multi-

ple examples briefly or go deeper into a few selected mechanisms. We have chosen the second method, and will use this space to discuss two examples of cellular communications in some detail: redox and energy sensing. We hope that these discussions will enhance the reader's understanding of similar physiological processes in other areas.

In multicellular organisms, cellular communication occurs over varying distances. Autocrine signals are used to monitor the intracellular environment. Paracrine signals are transferred between adjacent cells. Finally, endocrine signals are produced by the endocrine glands and transmitted throughout the body. Regardless of the type of signaling, the basic molecular mechanisms are conserved. Protein receptors bind to specific molecules termed ligands and undergo a conformational change resulting in the acquisition of some biochemical activity. The acquired activity results in the transduction from the receptor to one or more effector molecules. The specifics of the process can be simple, such as opening an ion channel, but typically a cascade of reactions is involved. The term *signal transduction* is often applied to this process. In common with electronic circuitry from which the analogy is drawn, amplification, distribution, and feedback are all part of the process. Feedback is particularly important and at least one of the effector molecules can be counted upon to turn off the pathway. It is becoming increasingly apparent that one of the characteristics of many chronic diseases is defective feedback circuitry.

Signal Transduction

At the heart of signal transduction are the cellular receptors that respond to changes in the environment. Three general classes of cellular receptors exist and are

Section IV

Fundamental Physiological Processes

described briefly below. A prerequisite for all receptors is that binding to specific ligands is necessary to affect signal transduction; in the absence of a receptor-ligand complex, the receptors are effectively shut off.

Receptor tyrosine kinases (RTKs) represent a class of receptor proteins that share four general features. They are transmembrane proteins with an extracellular binding domain that recognizes their specific ligand. For example, the insulin receptor binds specifically to insulin and this binding initiates a series of biochemical reactions that adjust the physiological state of muscle and fat cells to elevated serum glucose. Binding of the ligand to the receptor initiates a conformational change that is transmitted through the membrane to the intracellular tyrosine kinase and the regulatory domains of the receptor. (See Figure 15.1.) The tyrosine kinase domain then catalyzes the addition of a phosphate group donated by ATP to tyrosyl residues in specific substrate proteins; in many (if not most) cases, autophosphorylation occurs as well:

Figure 15.1 Activation of a typical receptor tyrosine kinase

The second class of receptors is coupled to a family of heterotrimeric ($\alpha\beta\gamma$) GTP-binding and hydrolyzing proteins (G proteins).¹ These **G protein-coupled receptors (GPCRs)** are integral membrane proteins that also transmit extracellular signals to the cell interior. Their characteristic hallmark is the existence of seven membrane-spanning regions that enable the protein to weave its way through the cell membrane. Upon ligand binding, an interaction with G proteins is initiated and an exchange of GDP for GTP on the α -subunit ensues. The α -GTP complex then dissociates from the trimer and initiates the signal cascade. The specific results are governed by the specific α -isoform (Figure 15.2). The

effects of many of the peptide hormones, like glucagon and prolactin, are mediated through GPCRs.

Figure 15.2 Signal transduction through GPCRs

Once a “signal” is detected by the membrane receptors, it must act upon it. In order to do this, downstream biochemical pathways must be activated or inhibited. The mechanism by which this is achieved relies to a large extent on the phosphorylation/dephosphorylation of a variety of proteins. The process is often referred to colloquially as the “kinase cascade.” A typical eukaryotic cell is awash in protein kinases and phosphatases. When it was discovered in the early 1960s that glycogen metabolism was to a large extent under the control of the reversible phosphorylation/dephosphorylation of glycogen phosphorylase, it was considered to be somewhat of an oddity. As more examples were discovered, the importance of kinases and phosphatases in the control of cell physiology was recognized; in 1992, the Nobel Prize in Physiology or Medicine was awarded to Edmond Fischer and Edwin Krebs for their discoveries regarding reversible protein phosphorylation as a regulatory mechanism. Since then, the number of protein kinases has continued to grow; it now stands at roughly 518,² representing over 1.7% of all known human genes, and perhaps one-third that many phosphatases.³ It has been estimated that perhaps as many as 30% of human proteins are covalently modifiable with phosphate.⁴

The recognition that the cellular homologues of the viral oncogenes *v-src* and *v-abl* existed was followed shortly by the recognition that proteins encoded by the genes *c-src* and *c-abl*⁵ were protein tyrosine kinases.^{6,7,8,9} The significance of these findings soon became apparent when it was discovered^{10,11} that a chromosomal translocation fused most of the *c-abl* domain with the 5'-end of *BCR*¹ (a serine/threonine kinase),¹² resulting in a more active kinase that was associated with chronic myelogenous leukemia. Targeting of the affected kinase by imatinib mesylate (Gleevec[®]) has proved to be an effective therapy¹³ for this malignancy. A hint about the versatility of directing therapy toward this class of enzymes, and perhaps a hint of things to come, is a recent clinical report¹⁴ indicating that treatment with imatinib mesylate cured a 70-year-old woman with long-standing type 2 diabetes.

Mitogens, growth factors, and a variety of other stimuli (including the inflammatory cytokines) activate the **MAPK (mitogen activated protein kinase) cascade** by binding to their respective membrane receptors (Figure 15.3). A series of kinases are activated that culminate in the activation of the “terminal” MAPKs: ERK, JNK, and p38. These then move into the nucleus and activate a transcriptional program that can lead to cell division or, at the other extreme, to programmed cell death (apoptosis). While the pathway and nomenclature can often bewilder, there is some logic inherent in the cascade. Regardless of the actual stimulus, a sequential activation of kinases occurs (see Figure 15.4) that ultimately transmits information from the cell membrane to the genome, or terminal effector proteins. Activation of all members of the cascade requires phosphorylation on multiple residues by an upstream kinase. Thus, in a typical cascade, protein kinase A (PKA) is activated by ligand binding to a GPCR. Adenyl cyclase is activated and the intracellular concentration of cAMP increases followed by the activation of PKA. MAPKKK (MAPK kinase kinase; aka MEKK) is then activated by phosphorylation catalyzed by PKA. Upon activation, it phosphorylates MAPKK, and so on.

Figure 15.3 MAPK cascade

Figure 15.4 Integration of GPCR with MAPK

Proteins are not the only signal molecules available to the cell. Phosphatidylinositol-4,5 bisphosphate (PIP₂), a component of the cell membrane, also serves in this capacity. Phospholipases hydrolyze PIP₂, producing 1,2-diacylglycerol (DAG), which remains bound to the membrane, and inositol triphosphate (IP₃), which is soluble and released into the cytoplasm where it serves as another second messenger, analogous to cAMP. IP₃ interacts with intracellular receptors and stimulates the increase in intracellular Ca²⁺ by opening membrane calcium channels or releasing intracellular stores from the endoplasmic reticulum.

The final class of signal transducing receptors is represented by the **nuclear hormone receptor superfamily**. This group of highly conserved proteins resides in the cytoplasm and, upon binding to their (generally lipophilic) ligands, translocates into the nucleus. Upon

¹The BCR gene is the site of breakpoints used in the generation of the two alternative forms of the Philadelphia chromosome translocation found in chronic myeloid leukemia and acute lymphocytic leukemia. Online Mendelian Inheritance in Man, accessed (<http://www.ncbi.nlm.nih.gov/entrez/dispomim.cgi?id=151410>).

Section IV

Fundamental Physiological Processes

entering the nucleus, these proteins bind to specific regions of the genome and initiate or enhance the transcription of specific genes. Among the ligands that influence cellular activity by interacting with nuclear receptors are the hormones cortisol, estradiol (see Figure 15.5), testosterone and thyroxine, as well as the “vitamins,” retinoic acid and vitamin D₃.

Intracellular Environment: Oxidative Stress

ATP is generated in the mitochondria by the two-electron reduction of molecular oxygen to water. Electrons flow through a sequence of protein complexes in an orderly fashion. However, even under ideal conditions, electrons leak from mitochondria and are capable of reducing molecular oxygen to superoxide:^{15,16}

It has been estimated that between 1 and 2% of molecular oxygen is consumed in this manner.¹⁷ Under some conditions (like diabetes), mitochondrial dysfunction increases and the potential for even higher concentrations of superoxide exists.^{18,19}

Superoxide in and of itself is relatively innocuous but it is a portent of more serious consequences. The enzyme superoxide dismutase catalyzes the reduction of superoxide to hydrogen peroxide:

Cells have a variety of mechanisms for disposing of hydrogen peroxide, including catalase and several peroxidases, the most important of which may be glutathione (GSH) peroxidase that catalyzes the reaction:

The reaction consumes glutathione, a sulfur-containing tripeptide with a number of important cellular functions.²⁰ One of the more important is serving as a redox buffer to keep the cellular environment properly poised to ensure proper protein folding and enzymatic activity.^{21,22,23} (See Figure 15.6.) The redox state of the cell is controlled to a large (but not exclusive) extent by the GSH/GSSG couple:

$$E_h = E'_0 + 31.25 \cdot \frac{[(\text{GSSG})/(\text{GSH})^2]}{}$$

where $E'_0 \approx -264$ mV at 37° C and pH = 7.4.²⁴

Figure 15.6 Effect of redox state on cellular activity and protein folding

Reprinted from Jones (2002) Meth Enz 348:93 with permission from Elsevier.

In addition to serving as a redox buffer, glutathione is consumed as a substrate in several key reactions, all depleting cellular GSH reserves: conjugation of GSH to electrophiles^{25,26} and protein thiols;²⁷ its role in amino acid uptake²⁸ and drug export;^{29,30} and the export of GSSG³¹ as a means of maintaining E_h . If left unchecked, the cells would enter a state of oxidative stress and death would rapidly ensue (see Figure 15.1). Given the sensitivity of cells to changes in redox status, it should come as no surprise that means have evolved to keep glutathione tone in an optimum range. The reduction of GSSG is carried out by the NADPH-dependent enzyme glutathione reductase. The primary source of NADPH is the pentose phosphate cycle and inhibition of this pathway with agents such as DHEA³² reduces intracellular GSH.³³ The rate-limiting step in the *de novo* synthesis is the synthesis of γ -glutamyl cysteine, a reaction performed by a specific ligase. Reduction of GSH by the induction of GST with isothiocyanate³⁴ or by reducing the rate of GSSG reduction by depletion of NADPH³⁵ stimulates the synthesis of GSH. Increasing the E_h by stimulating differentiation increases the expression of

glutamate:cysteine ligase³⁶ in an attempt to keep GSH and E_h constant. The importance of this enzyme is also illustrated by the fact that the overexpression of the enzyme in adenovirus-transformed cells protected them from the oxidative stress induced by IL-1 β .³⁷ It is possible to increase the GSH in cells by treating with non-toxic cysteine donors like N-acetyl cysteine or L-2-oxo-thiazolidine-4-carboxylate³⁸ or flavonoids.³⁹

Redox control of the transcription factor NF κ B is the model for redox control of gene expression.⁴⁰ In an early attempt to explain often conflicting data, Dröge and his coworkers⁴¹ proposed that increased oxidative stress in the cytoplasm was necessary to activate translocation into the nucleus, but that reducing conditions were necessary in the cytoplasm. Despite skepticism regarding the specifics of this model,⁴² data continue to appear in the literature in support of the general concept. The activity of receptors or their downstream partners can be controlled by either the redox state of the cell or by covalent modification by glutathione. Although current data often appear contradictory, it is apparent that redox signaling and glutathione have key roles to play in the regulation of transcription factors and support for the hypothesis continues to appear in the literature.^{43,44,45,46,47,48,49,50}

Regulation of Metabolic Processes

All cells are confronted with the task of balancing energy production and utilization. ATP is energy currency in biological systems, so the problem becomes one of keeping the concentration of ATP at levels that are optimal for cell function. A healthy cell must maintain an ATP/ADP ratio of about 10:1.⁵¹ In the 1960s, Atkinson rationalized and quantified this concept by introducing the term “energy charge.” The enzyme adenylate kinase was a key player in the concept because, if the reaction

was at equilibrium, then

$$[\text{AMP}]/[\text{ATP}] = \{[\text{ADP}]/[\text{ATP}]\}^2.$$

Since the ratio of AMP/ATP varies as the square of the ADP/ATP ratio, it becomes a sensitive indicator of the health of the cell; small changes in the ADP/ATP ratio are accompanied by relatively large changes in the ratio of AMP/ATP. All of this might have remained an interesting curiosity had it not been for the discovery of a family of enzymes, AMPK/SNF1, that is universally distributed in all eukaryotes.^{52,53} The mammalian AMP-activated pro-

tein kinases (AMPK) that balance anabolic and catabolic pathways are based on the ratio of AMP/ATP.

Enzyme Basics

The enzyme that was later named AMPK was originally isolated by Yeh and coworkers⁵⁴ who catalyzed the 5AMP-dependent phosphorylation of acetyl-CoA carboxylase (ACC), the rate-limiting step in fatty acid biosynthesis:

Within limits, the authors were able to demonstrate that the activity of AMPK increases with an increase in the ratio of AMP/ATP. The ensuing phosphorylation of ACC inhibits the enzyme, effectively shutting off fatty acid biosynthesis. As the ratio increases, kinase activity drops and ACC activity increases. When the enzyme was finally cloned and sequenced, it was discovered to be widely distributed in the eukaryotic kingdom.^{55,56} The enzyme is heterotrimeric and each subunit has multiple isoforms that exhibit tissue-specific distribution;⁵⁷ 12 heterotrimeric combinations are possible.

AMPK is a serine/threonine kinase that is activated by phosphorylation. Although the specifics are still somewhat sketchy, it appears that at a minimum a specific threonine residue (T¹⁷²) must be phosphorylated for AMPK to exhibit enzymatic activity. The identity of the specific kinase has not yet been confirmed. (The kinase is usually referred to as AMPKK but the fact that it is named does not yet mean that it has been identified.) Recently, a probable candidate has emerged, a tumor-suppressor gene, LKB1, has been shown to phosphorylate not only AMPK but thirteen other kinases with similar structure.⁵⁸ Regulation of AMPK is complex and includes not only phosphorylation but allosteric activation by AMP, which makes it a better substrate for the upstream kinase while at the same time making it a worse substrate for phosphatases. Finally, AMPKK is allosterically activated by AMP.⁵⁹

The Role of AMPK in Muscle

It is estimated that, in humans, 70% of glucose disposal occurs in skeletal muscle (the bulk of the remainder is handled largely by the liver). The glucose transporter GLUT4 is instrumental in the uptake of glucose by muscle cells. Upon stimulation by insulin or exercise, GLUT4 is recruited to the plasma membrane and facilitates glucose uptake. Emerging evidence implicates AMPK in

GLUT4 translocation in both insulin-dependent and insulin-independent pathways. During exercise, ATP is consumed and the ratio of AMP/ATP increases leading to a stimulation of AMPK. At the same time, GLUT4 expression and activity are increased.⁶⁰ The effects are limited to the muscles affected, but systemic effects can be demonstrated by the use of 5-aminoimidazole-4-carboxamide- β -D-ribofuranoside (AICAR), an intermediate in purine biosynthesis that, upon uptake by cells, is rapidly converted into an AMP analog that stimulates AMPK. Chronic administration mimics many of the effects of exercise, increased GLUT4 expression, membrane localization and glucose transport⁶¹ as well as potentiating the effect of insulin. In animal models, AICAR has been shown to relieve some of the symptoms associated with metabolic syndrome,⁶² an observation that makes AMPK an attractive therapeutic target.

Unlike other tissues, skeletal (and cardiac) muscle possesses a single isoform of ACC, ACC-2.⁶³ Like ACC-1, it becomes inactive upon phosphorylation. Since neither skeletal nor heart muscle carries out *de novo* fatty acid synthesis, the question arose as to why they should possess ACC in the first place and why should it be under such stringent control. The hypothesis was advanced⁶⁴ that its function was to generate malonyl-CoA which could then be used to regulate fatty acid oxidation. High concentrations of malonyl-CoA are known to inhibit carnitine palmitoyl transferase-1 (CPT-1) the gatekeeper of fatty acid transport into the mitochondrion. By inhibiting CPT-1, fatty acid oxidation is effectively curtailed. Under conditions where energy demand is high, such as vigorous exercise, fatty acid oxidation should not be limited by transport into the mitochondrion, where one would expect ACC-2 activity to be minimal. AMPK activation leads to phosphorylation and inactivation of ACC-2. This hypothesis has now been confirmed under several different conditions.^{65,66,67,68,69} The most direct confirmation of the hypothesis was provided by Abu-Elheiga and coworkers,^{70,71} who demonstrated that ACC-2 knockout mice were hyperphagic and resistant to obesity, and that fatty acid oxidation was enhanced and not inhibited by insulin.

Conditions that increase AMP, or provision of an AMP surrogate, indicate that cells are operating at a deficit under these conditions; pathways that have the potential to increase energy generation are favored. Thus, in muscle cells, glucose transport is enhanced and fatty acid oxidation increased. Both are the result of

AMPK activation. As we will see below, the same principle applies to other cells of the body; while the specifics differ, the underlying principle remains the same.

The Role of AMPK in the Liver

The classic targets of AMPK in the liver are ACC and HMG-CoA reductase, the first committed step on the sterol biosynthetic pathway.⁷² Exposure of freshly isolated hepatocytes to AICAR results in the rapid (<10 minutes) inhibition of both biosynthetic enzymes.⁷³ In the liver, AMPK not only affects lipid biosynthesis but modulates glycogen metabolism. Infusion of AICAR into the portal vein of dogs at concentrations sufficient to stimulate AMPK stimulated glycogenolysis and hepatic glucose output even under conditions of hyperinsulinemic conditions.⁷⁴ The authors attributed the glycogenolytic effect of AMPK to some of its demonstrated effects as an inhibitor of glycogen synthase and a stimulator of glycogen phosphorylase, both of which are achieved by phosphorylation of the enzyme. These findings demonstrate that response of liver cells to high AMP levels can overcome the normal response of hepatocytes to insulin. The hepatic output of glucose that results from AICAR administration compares well with the stimulation of glucose uptake by muscle under the same conditions and can be rationalized as a response by the liver to reduced energy levels.

The liver is the principal organ involved in converting excess carbohydrates into fatty acids and triglycerides. This happens within minutes of exposure to elevated glucose, and is mediated in part, posttranslationally, by AMPK-activated glycolysis and lipogenesis. It has also become apparent that not only does activation of AMPK exert effects on enzyme activity through phosphorylation, but there are also marked effects on the expression of a number of glycolytic and lipogenic enzymes. Included in this list are the genes for the liver isoform of pyruvate kinase (L-PK), fatty acid synthase (FAS). It is well established that in the presence of insulin high levels of glucose stimulate the expression of genes involved in conversion of carbohydrates to lipids in the liver.^{75,76} It now appears that insulin plays an indirect role in this response merely by promoting glucose metabolism; glucose metabolites are the true effector molecules. The genes regulated in this manner, such as FAS and L-PK, are characterized by a unique DNA sequence within their promoters, referred to as the carbohydrate response element (ChRE).^{77,78} When activated

by high concentrations of glucose metabolites, a specific transcription factor^{79,80,81} binds to the promoter and transcription is initiated. Under conditions in which AMPK is activated, by AICAR^{82,83} or by genetic manipulation,⁸⁴ transcription driven by ChRE is blunted.

The Role of AMPK in Adipose Tissue

Adipose tissue is the major storage site for triglycerides. Therefore, one might expect that, under conditions in which energy charge is low and AMPK is activated, lipolysis would be stimulated in order to increase systemic levels of a readily available source of energy in the form of fatty acids. Exposure of adipocytes to β -adrenergic agents stimulates hormone-sensitive lipase (HSL) and the release of fatty acids from triglyceride stores. Activation of HSL is initiated by phosphorylation of the enzyme by protein kinase A (PKA).⁸⁵ Contrary to expectations, however, under conditions in which AMPK is activated,⁸⁶ the release of fatty acids from adipocytes is actually reduced. Phosphorylation of HSL by AMPK prevents phosphorylation by PKA. The explanation for this apparent paradox rests with the recognition that if fatty acid release from adipocytes exceeds the capacity of tissues such as muscle to utilize it, a futile cycle would ensue and the adipocytes would actually suffer an energy drain under conditions when demand for energy preservation is expected to be high (i.e., high AMP).

The Role of AMPK in the Hypothalamus

Thus far, we have been concerned with what might be called the local effects of AMPK activation. Since the early 2000s, an appreciation has been developing for the fact that AMPK may actually play a role in feeding behavior and, therefore, in the regulation of whole-body energy metabolism. Hints that this might be the case first appeared when it was discovered that two adipocyte-derived hormones, leptin⁸⁷ and adiponectin,⁸⁸ activated AMPK in muscle and liver, respectively.

It has been known for some time that leptin inhibits feeding behavior and that ghrelin, a peptide hormone synthesized in the stomach, stimulates feeding, and that both act, at least in part, via the same neuronal circuits. It has now been shown that both have direct effects on AMPK activity within the hypothalamus. Intraperitoneal injection of leptin inhibits, and ghrelin stimulates, AMPK activity. Furthermore, stimulation of

AMPK by administering AICAR directly to the hypothalamus through an in-dwelling catheter stimulated food intake.⁸⁹ Alpha-lipoic acid (α -LA) has a history of use in diabetic neuropathy; recently it has been shown to possess anti-obesity effects that appear to be the result of the suppression of hypothalamic AMPK activity.⁹⁰ The anorexic effects of α -LA were due neither to toxicity nor leptin; the latter possibility was eliminated since the effects were observed in leptin-deficient mice (*ob/ob*). AICAR administered directly to the hypothalamus reversed the effects of α -LA. Intraperitoneal injection of α -LA to rats caused a significant decrease in the phosphorylation of both AMPK and ACC within the hypothalamus. In peripheral tissues, α -LA is known to increase glucose transport and cellular ATP levels, conditions that typically inhibit AMPK activation. While the authors did not demonstrate this effect directly, they were able to show that by manipulating the energy status within the hypothalamus they inhibited AMPK.

Studies that began in yeast and progressed to mammalian cells in order to determine how energy charge was maintained have now advanced to the state where the same basic mechanism can account, at least in part, for the control of feeding behavior and body weight in mammals.

Metabolic Syndrome: A Failure to Communicate?

As discussed in other parts of this book, there is an epidemic of metabolic syndrome and type 2 diabetes affecting nearly 50 million individuals in the United States alone.⁹¹ The reasons for the “outbreak” are complex, but lack of exercise and poor diet top the list. The consequences are well known. However, from a physiological standpoint, the disease can be viewed as a general breakdown in cellular signaling mechanisms that evolved to maintain homeostasis. It is perhaps fair to say that the recognition that adipose tissue is a major source of signaling peptides—adiponectin, leptin, and inflammatory cytokines like IL-6 and TNF- α (as reviewed by Gimeno and Klamann⁹²)—has shaped a dramatic rethinking concerning the causes and therapy of the disease. It is now clear that while lowering blood glucose is necessary, it is not sufficient for managing this condition effectively.

The complexity of these signaling pathways can be gleaned from a quick glance at Figure 15.7. The diagram

represents the events that are initiated when insulin binds to its receptor on the surface of an idealized cell. The end result ranges from the familiar—translocation of the glucose transporter (GLUT4) to the cell surface to facilitate glucose uptake—to activation of members of the MAPK pathway, culminating in the initiation of transcription. Along the way, interaction with RAS, a member of the GPCR kinase family, can be seen. Clearly, when a state of insulin resistance develops, it is one of the early indicators of metabolic syndrome, with the potential for a lot of chaos.

Figure 15.7 Insulin signaling pathway

Considerable effort is being devoted to ameliorating metabolic syndrome and type 2 diabetes by modifying insulin signaling. It should come as no surprise that many of the traditional medicines that have been used for centuries to treat diabetes have recently been demonstrated to affect these very same signaling pathways.⁹³ While it is not possible to discuss all the potential combinations and permutations, two targets are currently the subject of much active research and provide the potential for significant progress in treating the current epidemic. Both are subject to modification by dietary intervention, providing some confidence that pharmaceutical agents need not be the first approach.

Peroxisome Proliferator-Activated Receptors (PPARs)

PPARs are members of the nuclear hormone superfamily and, when bound to their activating ligands, they move from the cytoplasm into the nucleus, bind to specific regions of DNA (termed peroxisome proliferator

response elements, or PPREs), and stimulate transcription. They differ from the steroid hormone receptors in that they tend to be promiscuous with regard to their ligands. Thus, molecules as seemingly different as arachidonic acid and pioglitazone (Actos[®]) are both agonists. There are three members of the family:

- PPAR α is a transcription factor that activates the transcription of genes involved in fatty acid oxidation.⁹⁴
- PPAR γ is actively involved in adipogenesis, the initiation and development of adipocytes.^{95,96}
- PPAR δ (β) has similar ligand-binding properties, but its actual role in cell physiology is still largely unknown.⁹⁷

The interest in PPARs as potential therapeutic targets derives largely from the results obtained with two classes of pharmaceutical agents. The fibrates are PPAR α agonists and have proven under appropriate circumstances to be effective lipid-lowering agents.⁹⁸ Insulin sensitivity has been shown to improve in response to intervention with glitazones, prototypical PPAR γ agonists.^{99,100} Both classes of compounds were discovered without knowing their primary targets; only later was their mode of action determined when they were found to activate the metabolism of xenobiotics.

Both classes of compound are thought to work in part by reducing circulating triglycerides. Fibrates do so by increasing the rate of disposal via stimulation of fatty acid oxidation. The PPAR γ agonists are a little more subtle. By stimulating adipogenesis, they provide a site in which triglycerides may be deposited, effectively removing them from the circulation. In fact, one of the side effects of glitazones therapy is weight gain. Their paradoxical behavior (weight gain concomitant with improved insulin sensitivity) is explained by the fact that they while they induce adipogenesis, the adipocytes stay small. It is the large adipocytes that generate most of the adipocytokines that are now being recognized as major contributors to metabolic syndrome and insulin resistance.

The range of natural products known to exhibit activity as modulators of PPAR activity is impressive.¹⁰¹ Activators range from the everyday (soy phytoestrogens) to the esoteric (ajulemic acid from *Cannabis sativa*). Obese Zucker rats maintained on a high-soy diet exhibited greatly improved glucose tolerance that could be associated with the ability to activate both PPAR γ - and

PPAR α -driven gene expression.¹⁰² Similar results were obtained with ethanolic extracts of licorice by Mae and colleagues.¹⁰³ A wide variety of prenylflavonoids derived from licorice were found to be potent activators of PPAR γ and their effects translated into decreased fasting insulin and systolic blood pressure. When one also considers that certain dietary fatty acids¹⁰⁴ exhibit similar effects, there can be little doubt of the potential benefit afforded by attention to diet.

Adiponectin

Adiponectin (adipocyte complement-related protein of 30 kDa, or ACRP30) is a peptide hormone that is secreted exclusively by adipocytes. Circulating levels in healthy adults range from about 2 to 17 $\mu\text{g/mL}$,¹⁰⁵ or nearly 0.01% of the total plasma protein. It is synthesized as 30 kDa monomer but, by virtue of a collagen-like binding domain, forms homotrimers or even higher-order structures. It is induced during adipocyte differentiation and its secretion is stimulated by insulin.¹⁰⁶ As might be expected with such a protein, it has been shown that PPAR γ agonists increase its expression and plasma concentration.¹⁰⁷ The authors evaluated troglitazone (Rezulin®) in middle-aged, slightly overweight (BMI $29.1 \pm 0.8 \text{ kg/m}^2$) subjects and found that adiponectin increased roughly two-fold. The results were duplicated in *db/db* mice, in which they were also able to demonstrate an increase in adiponectin specific mRNA. Although adiponectin is an adipocyte-specific protein, its expression and serum levels decrease with increasing obesity and/or insulin resistance.^{108,109,110,111} Adiponectin improves insulin sensitivity and exhibits anti-inflammatory activity. Low levels of circulating adiponectin are thus linked *mechanistically* to insulin resistance and type 2 diabetes, rather than just being biochemical markers of an abnormal metabolic state. It's particularly interesting that, in Rhesus monkeys prone to the development of type 2 diabetes subsequent to obesity, adiponectin declines prior to the development of diabetes,¹¹² suggesting predictive value for this serum protein.

Adiponectin regulates glucose and lipid metabolism in muscle, liver, and adipocytes. Binding to cell surface receptors in muscle cells leads to activation of AMPK¹¹³ and it has been shown recently in type 2 diabetics that activation of AMPK by adiponectin is impaired.¹¹⁴

In laboratory animals, a short-term intervention with a soy-protein diet increases the expression of adi-

ponectin.^{115,116} The durations of the experiments were too short (10 days) to result in significant weight loss, so it appears that soy protein is affecting adiponectin expression independently of body weight.

Summary

Evolution has resulted in the elaboration of sophisticated mechanisms to maintain cells (and whole organisms) in an optimal state. The systems are not foolproof. If balance is significantly disturbed, it can be difficult to return to a state of grace. The pathways utilized to maintain homeostasis may look bewildering (as in Figure 15.7), but in reality control is achieved by the application of relatively few mechanisms, highly elaborated to be sure, but fairly simple at their core.

One of these vital mechanisms is phosphorylation. The judicious use of kinases to modify enzymes and proteins by adding phosphate groups and thereby changing the activity, positively or negatively, is universally used by eukaryotes to control cell physiology. The second basic mechanism discussed above is the use of redox chemistry, particularly in the form of sulfhydryl groups (as for example in glutathione), to maintain the redox potential of cells in an optimal range.

If one steps back and tries to visualize the forest rather than the trees, the beauty and functional simplicity of the systems are remarkable.

Chapter 16

Bioenergetics and Biotransformation

Gary Darland, PhD

Introduction

Energy is the *sine qua non* of life. With the exception of green plants and some bacteria, all energy is derived by the orderly breakdown of simple organic compounds and the capture of the energy released. The major catabolic pathways for accomplishing this task are highly conserved and found in all life forms today.

All chemicals, including foods, possess intrinsic energy; if burned, heat is released and it is possible to devise an engine to transform this energy into work. In the latter half of the 19th century J. Willard Gibbs applied the first and second laws of thermodynamics and developed the concept of free energy (ΔG), a measure of the capacity of a system to perform work. Formally, the equation is:

$$\Delta G = \Delta H - T\Delta S$$

It incorporates the concepts of enthalpy (H), or heat content, and entropy (S), a tendency of a closed system to approach total disorder. According to Gibbs, “all systems change in such a way that free energy is minimized.” By convention if $\Delta G < 0$, useful energy is produced; otherwise, energy is consumed. Any chemical reaction includes the release or consumption of energy.

In order to make useful comparisons between reactions, it is necessary to have a fixed frame of reference. Hence, the term “standard free energy change” was defined as:

$$\Delta G^0 = -RT \ln K_{eq}$$

where K_{eq} is the equilibrium constant for the reaction in question, R is the gas constant ($1.987 \text{ cal mol}^{-1} \text{ K}^{-1}$), and $T = 298^\circ \text{ K}$ (25° C). In a closed system, one that is not influenced by outside factors, chemical reactions proceed toward equilibrium.

The discussion below summarizes the primary energy-producing pathways of the cell. It is not meant to describe all of the ways in which macronutrients enter into the central metabolic pathways. It is reasonable for clinicians to ask of what relevance is the material presented below to clinical medicine. Aside from an appreciation of the beauty of the biochemistry, the answer can be as varied as medicine itself.

Perhaps consideration of the role of the micronutrient coenzyme Q (CoQ) can serve as an illustration. CoQ plays a central role in oxidative phosphorylation, the major source of ATP (energy). A deficiency of CoQ results in both a decrease in energy production and an increase in reactive oxygen species. Thus, it could be hypothesized that conditions like chronic fatigue syndrome might respond favorably to supplemental CoQ, a supposition that has been borne out in a few studies.^{1,2} Furthermore, since statins inhibit the synthesis of CoQ, it is also a reasonable hypothesis that side effects of statin therapy are possible (and have, in fact, been noted).³ Whether or not the side effects are directly related to the inhibition of CoQ—and whether the addition of CoQ to statin therapies will improve outcomes—are the subjects of ongoing research. There are some interesting studies reporting benefit for combination therapy of CoQ and statins.^{4,5}

Anaerobic Catabolism of Glucose: Glycolysis

A central characteristic that distinguishes metabolic pathways from a simple chemical transformation is that the former generally involve numerous individual reactions. Since thermodynamics deals only with initial and final states, and not the path by which equilibrium is reached, the involvement of multiple reactions does not

Section IV

Fundamental Physiological Processes

affect the amount of energy available. It does, however, permit cells to capture some of the energy for use in critical activities. The compound that serves this function is adenosine triphosphate (ATP), illustrated in Figure 16.1.

Figure 16.1 The structure of adenosine triphosphate (ATP)

Glycolysis, the anaerobic conversion of glucose to two molecules of lactic acid, illustrates this concept. The formula for the chemical conversion of glucose to lactic acid is:

glucose $\rightarrow$ 2 lactate + 2 H^+ , $\Delta G^\circ = -47.4$ kcal/mol,
while the same conversion performed by the glycolytic pathway results in:

or a release of roughly eighteen fewer kcal/mol of glucose converted.¹ The missing energy was stored in the terminal phosphoester bond of the two ATP molecules.

or, alternatively:

Figure 16.2 Glycolysis or the Embden-Meyerhof-Parnas pathway

The glycolytic pathway is ancient and has persisted virtually unchanged since shortly after the origin of life.⁶ It was elucidated in the early 20th century and is often referred to as the Embden-Meyerhof-Parnas (EMP) pathway, after its discoverers. Examination of Figure 16.2 reveals two molecules of ATP are actually consumed early in the pathway in order to convert one molecule of glucose into a molecule of fructose-1,6- diphosphate:

This investment is recovered, with interest, in the two energy-producing steps in the pathway:

¹Taken from H. R. Mahler and E. H. Cordes. Biological Chemistry, 2nd Edition. Harper and Row. 1971, p497.

Since there are two molecules of triose produced for each molecule of hexose, four ATP molecules are recovered after an investment of two.

The final accounting issue deals with the disposal of reducing equivalents, in the form of NADH, that are generated by the oxidation of glyceraldehyde-3-phosphate:

In the absence of oxygen, this is achieved by reducing pyruvate to lactate:

All of the ATP produced by glycolysis involves what biochemists refer to as “substrate level phosphorylation.” The energy existing in a phosphoester bond in one molecule is preserved by transferring the phosphate group to ADP. (See Figure 16.2.)

Aerobic Oxidation of Pyruvate

The conversion of glucose to pyruvate by glycolysis generated two molecules of ATP, representing ~15 kcal/mol of energy currency for the cell. The complete oxidation of glucose to carbon dioxide and water has the potential to deliver in excess of 680 kcal/mol of energy:

Only 2% of the available energy in glucose is captured by the cell. The aerobic oxidation of pyruvate enables the cells to generate considerably more ATP.

The Pyruvate Dehydrogenase Complex: Production of Acetyl-CoA

Under aerobic conditions, pyruvate is transported by a specific carrier protein into the mitochondria and transformed to acetyl-CoA by the multicomponent pyruvate dehydrogenase complex (PDC).

This complex enzyme consists of three distinct enzymes and is dependent upon both lipoic acid (part of the structure of coenzyme A) and thiamine pyrophosphate (TPP). The conversion begins with the oxidative decarboxylation of pyruvate by the E_1 component, a reaction requiring TPP:

The product of this reaction, “active acetaldehyde,” remains bound to the enzyme for subsequent reaction with the transacetylase (E_2) component:

which generates acetyl-CoA and a reduced lipoamide moiety that remains affixed to E_2 . The final step is oxidation of the lipoamide moiety by E_3 , a reaction requiring both flavin adenine dinucleotide (FAD) and NAD^+ :

The net result of this sequence of reactions is:

The NADH generated can be used to reduce oxygen and generate ATP by oxidative phosphorylation (discussed below). In addition to an important role in biosynthesis reactions (such as lipid biosynthesis), acetyl-CoA serves as the entry point to the Krebs cycle by which the oxidation of glucose is completed.

In addition to the enzymes described above, two other complex enzymes (whose function it is to control the flow of carbon through this central step) are also important. Pyruvate dehydrogenase kinase (PDK) and pyruvate dehydrogenase phosphatase (PDP) control the activity of the PDC by catalyzing reversible phosphorylation/dephosphorylation of the E_1 subunit. When fatty acids are being rapidly oxidized, intramitochondrial levels of acetyl-CoA and/or ATP tend to be elevated. Under these conditions, PDK is activated and E_1 is phosphorylated. In the phosphorylated state E_1 is inactive and flow through PDC is blunted. Pyruvate is then used for anabolic purposes such as gluconeogenesis or amino acid biosynthesis. When the levels of ATP or acetyl-CoA decline, PDK activity decreases and PDP activity increases. The activity of pyruvate dehydrogenase is restored.^{7,8} Diet and exercise are among the key modulators of the PDC.^{9,10}

ⁱⁱ Molecular Cell Biology, 4th ed. Lodish H, Berk A, Zipursky SL, et al. New York: W. H. Freeman & Co. 2000.

Krebs Cycle

The final steps in the oxidation of pyruvate to CO_2 and water are achieved by the Krebs, or tricarboxylic acid, cycle (Figure 16.3).

Figure 16.3 The Krebs cycle

It is hard to overstate the importance of the Krebs cycle cell metabolism. Not only does it play a central role in the oxidation of pyruvate, but it also serves as a source of precursors for the macromolecules that are essential to life. The eight individual reactions that comprise the cycle include three oxidative reactions that generate NADH:

The oxidation of μ -ketoglutarate is performed by an enzyme complex similar to the pyruvate dehydrogenase complex and includes the same cofactors—TPP, lipoamide and FAD.

The oxidation of succinate to fumarate is catalyzed by the flavoprotein enzyme succinate dehydrogenase:

The cycle includes one substrate level phosphorylation:

The reaction is catalyzed by the enzyme succinyl thiokinase. Energetically GTP and ATP are identical and a transphorylation reaction readily interconverts the two:

Oxidative Phosphorylation

In addition to the complete oxidation of the carbon skeleton of pyruvate, the Krebs cycle generates six molecules of NADH and two molecules of FADH₂ per molecule of glucose. The reducing equivalents must be disposed of. Mitochondria are able to achieve this and capture the energy of their oxidation as ATP by enzyme complexes located on the inner membrane of the mitochondrion that comprise the mitochondrial electron transport assembly and ATP synthase. The assembly catalyzes a series of oxidation reduction reactions, some of which are thermodynamically competent to support ATP production via ATP synthase. Proton translocation and the development of a transmembrane proton gradient provide the necessary coupling mechanism.

As in all chemical reactions, oxidation-reduction (redox) reactions involve energy. In this particular case, the amount of free energy available is expressed by the Nernst equation:

$$\Delta G^\circ = -nF\Delta E_0$$

where n represents the number of electrons and $F = 23.06$ kcal/volt/mol. Tables of representative values for E_0 can be found in most beginning biochemistry textbooks.

For years biochemists struggled with the mechanism by which ATP was produced in the mitochondria by the electrochemical gradient generated during the oxidation of pyruvate. The breakthrough came with the development of the chemiosmotic hypothesis by Peter Mitchell in 1961.¹¹ He proposed, and it has since been repeatedly confirmed, that during the oxidation of the reduced cofactors, NADH and FADH₂, a transmembrane proton gradient is generated. As protons move down this gradient thru complex V, F_1F_0 ATPase, ATP is synthesized. A schematic of the process is illustrated in Figure 16.4.

Figure 16.4 Mitochondrial electron transport and oxidative phosphorylation

Energy from Food

Glucose is the starting point for the central metabolic pathways described above. In order to derive energy from food, it is usually necessary to break down complex polymers of simple sugars, amino acids, or acetate. The individual components of proteins, complex carbohydrates, and fats can then enter the glycolysis cycle. A wide variety of mechanisms is available to accomplish these tasks, but two are worth special consideration.

Glycogen, the principal storage form of glucose in muscle and liver, is a branched chain polysaccharide with a structure that is similar to amylopectin, a component of starch. It consists of α -1,4 and α -1,6 glycosidic linkages between individual glucose molecules. Phosphorolysis of the α -1,4 bonds by the enzyme glycogen phosphorylase generates glucose-1-phosphate: $\text{glycogen}_n + \text{P}_i \rightarrow \text{glycogen}_{n-1} + \text{glucose-1-phosphate}$. The activation of glucose by ATP is not required.ⁱⁱⁱ The interconversion of glucose-1-phosphate into glucose-6-phosphate by the enzyme phosphoglucomutase provides access to the glycolytic pathway.

Glycogen phosphorylase is a homodimeric enzyme that exists in two distinct conformational states. Under conditions where the concentration of AMP is high rela-

tive to that of ATP, the enzyme is capable of binding to glycogen and initiating the phosphorolysis of glycogen. Under normal circumstances this process is sufficient to maintain adequate glucose levels. However, under conditions of muscular exertion or stress, the activity of the enzyme can be increased. The enzyme is regulated by a reversible phosphorylation/dephosphorylation cycle. The regulation of its phosphorylation state is under the control of cAMP-dependent protein kinases and phosphatases. In the presence of epinephrine or acetylcholine, intracellular cAMP increases, thus activating glycogen phosphorylase kinase and inhibiting phosphatase. The activation leads to a rapid production of glucose-1-phosphate in the muscle, permitting accommodation of the “fight or flight” response. Uncontrolled glycogenolysis in the liver is one factor contributing to the hyperglycemic state that characterizes diabetes.¹²

Lipids and fatty acids are a major source of energy for animal cells. The oxidation of fatty acids occurs in the mitochondria. Free fatty acids are liberated from triglycerides by hydrolysis, a process catalyzed by a family of enzymes referred to as lipase. The free fatty acids are activated to their thioesters and transported into the mitochondria with the aid of carnitine palmitoyltransferase I (CPT1), carnitine-acylcarnitine translocase, and inner membrane protein CPT2.

Given the key role of carnitine in the mobilization and metabolism of fatty acids, it should come as no surprise that carnitine as its acetyl or propionyl ester has found utility in clinical situations in conditions where the efficient utilization of lipids is required.^{13,14} (See Figure 16.5.)

Figure 16.5 Fatty acid oxidation

ⁱⁱⁱ In chemistry, one never gets something for nothing. The activation of glucose actually occurred during the synthesis of glycogen and was “stored” in the glycosidic bond.

Summary

Glycolysis and the Krebs cycle are the principal pathways by which macronutrients are converted into energy. Under anaerobic conditions, glycolysis predominates, producing lactate and ATP by substrate level phosphorylation. The process is inefficient, capturing less than 5% of the energy present in a molecule of glucose. In the presence of oxygen, however, the complete oxidation of glucose to CO₂ and water is achieved, and roughly one-third of the available energy is captured in the form of ATP. The entire process is under strict control. One of the key control points is that of the pyruvate dehydrogenase complex, the step that controls the entry of pyruvate into the Krebs cycle. Control is affected by the reversible phosphorylation/dephosphorylation of the enzyme complex.

Chapter 17

Digestion and Excretion

DeAnn Liska, PhD, and Jeffrey S. Bland, PhD

Introduction

Every living system, whether cell, organ, whole body, or even a community of people, has to have two fundamental capacities: to bring in substances that provide energy and sustenance, and to remove waste. It is an inevitable consequence of human biology that being alive means waste is generated within the body. And it is also a fact of life that we are exposed to innumerable substances, both beneficial and detrimental, simply by breathing, eating a meal, walking through a garden, or lying in bed. All kinds of substances are present in food, air, blankets, carpet, walls, and everything that surrounds us. Therefore, healthy function requires that the body differentiate between the good and the bad in our environment. Moreover, it is essential that the body can identify the substances necessary to maintain health and selectively take those substances into circulation, where they can nourish the cells throughout the body, while keeping out the damaging materials. To do so, the body must have protection and defense systems in place, healthy transport and circulation functions, and optimal elimination of waste.

Since this text is aimed primarily at clinicians whose professional training includes the study of normal digestive processes, we will focus our discussion here on an overview of some of the very significant ways in which normal digestive physiology is disturbed, eventually contributing to disease and bringing patients into the practitioner's office. Further perspectives on the GI tract and digestive function can be found in Chapters 24 and 28.

Over a lifetime, a person will consume over 25 tons of food, providing the body with nutrients through the digestion and absorption process. During this process, the body must maintain protection from harmful exter-

nal organisms and toxins that accompany food. For example, in 1999 alone, over 1 billion pounds of pesticides were applied in the United States, and over 5.6 billion pounds were applied worldwide.¹ Pesticides are now a ubiquitous component of our environment and can be found within the home as well as in gardens and on grocery foods; even eating an organic diet cannot guarantee elimination of pesticides. Pesticide exposure is related to several types of cancers, including non-Hodgkin's lymphoma, leukemia, multiple myeloma, soft-tissue sarcoma, prostate, pancreas, lung, ovary, breast, testis, Hodgkin's disease, liver, kidney, rectum, brain and neurological system, stomach, and endometrial cancer.² (Further discussion of toxic exposures can be found in Chapters 13, 22, and 31.)

Conditions such as diabetes mellitus, Parkinson's disease, asthma, and hypothyroidism are also related to environmental exposures to toxic substances.^{3,4,5} Toxins such as dioxin are long lasting in the body because they are fat soluble—they accumulate and become stored in body fat. Even pharmaceutical drugs have been found at measurable levels in rivers, drinking water, and sediments, which presumably occurs primarily from the elimination of unmetabolized drug through the urine.⁶ The magnitude of these insults was discussed in a 2001 review on toxin exposure, which indicated that the expense of treating environmentally related conditions accounts for between \$57 billion and \$397 billion of the healthcare economy annually in the United States and Canada.⁷ Clearly, the ability to protect against these damaging substances must be part of a healthy digestion and absorption process.

Unfortunately, xenobiotics such as pesticides and pollutants aren't the only dangers that enter our system through the food we eat. Pathogens can also be present,

and many individuals find that they are intolerant to certain food substances. Food allergies alone, which can be immediate (e.g., IgE-mediated) or delayed (e.g., IgG-mediated), are estimated to afflict approximately 8% of children and 2% of adults worldwide.⁸ Food allergies and intolerances account for a diverse range of symptoms, from migraines and skin problems, to cardiovascular effects and gastrointestinal disorders (see Table 17.1).

Table 17.1 Symptoms and Diseases Associated with Food Allergy and Intolerance

System	Symptom/Disease
Cardiovascular	Edema, inflammation of the veins producing purpura, irregular heart rhythm, spontaneous bruising, urticaria, vasculitis
Gastrointestinal	Canker sores, celiac disease, chronic diarrhea, colic (babies), constipation, Crohn's disease, duodenal ulcers, gas, gastritis, indigestion, inflammatory bowel disease (IBD), irritable bowel syndrome (IBS), malabsorption, nausea, recurrent mouth ulcers, stomach ulcers, ulcerative colitis, vomiting
Genitourinary	Bed wetting, chronic bladder infections, frequent urination, nephritic syndrome
Immune	Serous otitis media
Mental/Emotional	Attention deficit disorder, anxiety, depression, epileptic seizures, memory loss, schizophrenia
Musculoskeletal	Joint pain, myalgias, rheumatoid arthritis
Respiratory	Asthma, chronic or allergic sinusitis, constant runny nose or congested nose, nasal polyps
Skin	Eczema; itchy skin; psoriasis; red, itchy eyes; urticaria
Miscellaneous	Migraine headaches

All of these examples have in common that the body must differentiate friend from foe—that is, the body must selectively identify those substances that are necessary for existence (nutrients, water, oxygen, phytonutrients, beneficial microbes) from those that are

either not beneficial or, even more important, those that are detrimental. After this first step of recognition, the body must then selectively absorb and transport the necessary substances, while eliminating the detrimental materials. To do this, the body has elaborate systems for digestion and absorption, protection and defense, transport and circulation, and waste elimination.

Digestion and Absorption

From a functional medicine perspective, digestive physiology is the component of nutriture that provides the substances necessary to support bioenergetics. That is, the role of the digestive process is to prepare and separate individual nutrients from the complex food matrix that enters the body. This process begins with ingestion of the proper complement of macro- and micronutrients in the food matrix. (A more detailed description of the biochemistry of this process is provided in Chapter 16.) Individual nutrient needs can vary substantially depending upon genetics, health status and history, age, gender, environmental factors, and even location of residence. In addition, the food matrix consumed by a person is influenced by cultural background, location, access to various foods, economic and political issues, sensory and health perceptions, and habits. In much of the developed world, there is greater food diversity available year-round today than at any other period in human history. Foods can be raw, minimally processed, shelf-stable, prepackaged, prepared, nutrient-dense, or nutrient-depleted. The selection of what foods to ingest determines the quality of the diet and the ultimate influence it has on physiological function.

The proper diet is only the beginning of the process, however, since once food is ingested it must then be properly digested in order for nutrients to be absorbed. Proteins are digested to amino acids, carbohydrates to monosaccharides, and fats to free fatty acids. The digestive process is influenced by the nature of the food matrix. Minimally processed whole foods are, in general, digested more slowly than highly processed foods. This slows the release of nutrients and influences the rate at which absorption of both macro- and micronutrients occurs. A diet high in sugar and added fats will result in rapid absorption of glucose and fatty acids, creating increased demand upon the hormonal nutrient regulatory systems and enzymes such as insulin, cortisol, and insulin-like growth factor.

Clinical Implications

Clinically, these observations about digestion are important because all nutrition intervention programs need to begin with diet analysis, and the intervention prescribed must be achievable by the patient. This requires that the clinician know not only what the patient is ingesting on a routine basis, but also the context in which the person is living. A diet diary or food-frequency questionnaire should be utilized as part of the routine historical information that all health practitioners obtain on their patients. Taken with patient history, this information helps to determine amount and types of protein, fat, and carbohydrate intake and allows for the evaluation of micronutrient density (i.e., vitamins and minerals), phytonutrient intake (e.g., flavonoids, polyphenols, isoflavones, glucosinolates), accessory nutrient intake (e.g., coenzyme Q10, carnitine, taurine, lipoic acid), and fiber. This information is critically important in designing a nutrition program personalized to the patient's specific needs.

Digestion initially involves the breakdown of large molecules in food into smaller units—for example, the breakdown of protein into amino acids. Adequate stomach acid is particularly important not only for digestion, but also for protecting against pathogenic organisms and food antigens.^{9,10} For example, antacid use has been shown to inhibit digestion of proteins and cause food allergy in an animal model study.¹¹ Stomach acid decreases with age, a condition called hypochlorhydria, which is related to the prevalence of atrophic gastritis in people over age 60. Hypochlorhydria is also associated with increased levels of *Helicobacter pylori* (*H. pylori*), an increase in proximal small intestine pH, small intestine bacterial overgrowth, and decreased secretion of intrinsic factor, which is necessary for adequate absorption of vitamin B12.^{12,13,14}

The presence and secretion of adequate amounts of specific digestive enzymes are essential for healthy digestion and absorption of nutrients, and lack of any of the necessary enzymes can have local and systemic effects. Exogenous pancreatic enzymes have been shown to reduce histamine secretion and clinical symptoms associated with challenge of an allergenic food in a double-blind, placebo-controlled trial.¹⁵ Pancreatic secretions may decrease with age, and are adversely affected by alcohol abuse, pancreatitis, cystic fibrosis, diabetes, gallstones, and inflammation.^{16,17} Pancreatic dysfunction necessitates oral replacement of pancreatic enzymes, as well as bicarbonate, which acts to neutralize the chyme after it leaves the stomach. Other diges-

tive dysfunctions include inadequate bile secretion, which has also been associated with increased mucosal infiltration of *H. pylori*.^{18,19}

Water-soluble nutrients are absorbed by a different mechanism than are the fat-soluble substances. Water-soluble nutrients (carbohydrates, amino acids, and the water-soluble vitamins) are absorbed in the small intestine by transport across the brush border cells through both passive and active transport systems. Fat-soluble nutrients (the fat-soluble vitamins and fatty acids) must first undergo emulsification with bile and are then taken into the lymphatic system for later association with plasma proteins. Clearly, for adequate absorption of nutrients, a healthy small intestinal mucosa is essential. It is possible to have specific defects in either the water-soluble or the fat-soluble absorptive pathways, resulting in symptoms of specific nutrient deficiency. The GI mucosal barrier, then, is the major first line of defense against unwanted toxins, antigens, and microbes that may transition intact through the digestive process.

Protection and Defense

The GI Mucosal Barrier

The GI mucosal membrane surface is the largest interface between our internal body and the external world. It covers more than 400 square meters, which is over 200-fold greater than the surface area of the skin.²⁰ The GI mucosal layer has the specific charge of allowing in only health-promoting nutrients and phytonutrients, while keeping out potentially damaging molecules and pathogenic organisms; it is the protective cell layer that provides the barrier between the inside of the body and the external world, and is responsible for nutrient absorption. The GI mucosa includes the gastric epithelial layer, which covers the stomach and protects it from damaging stomach acid. This mucosa also plays an important role in protecting the stomach from ingested toxins, drugs, alcohol, and pathogens such as infectious bacteria and viruses. The mucous gel that coats the stomach is comprised of phospholipids, secreted by gastric epithelial cells, that render the surface layer resistant to damage by stomach acid.^{21,22,23}

Two pathways exist for transport across the epithelium: intracellular (through cells, controlled by the cell membrane) and paracellular (between cells, controlled by the permeability of tight junctions, which are distributed

around the apical membranes of enterocytes).²⁴ In a normal, healthy intestine, the tight junctions constitute a barrier that provides limited access for substances from the outside (lumen) to be absorbed inside the body. They force substances to go through a cell to enter into circulation (Figure 17.1). To go through a cell, most substances require specific uptake systems, such as an active transport system, which can be regulated by the body. Some substances transition through cells passively—for example, fat-soluble substances that can easily cross the cell membrane layer (see below). Since the detoxification system is very active in the intestinal mucosa, and is attached to the membrane inside the cell, the body also has a defense mechanism against this passive uptake as long as the substance goes through the cell.

Figure 17.1 Permeability dynamics

Without the GI barrier, molecules of all types can pass into circulation without being detected; they can slip around the cells, thereby avoiding the body’s first-line protection and defense mechanisms. In a healthy intestinal tract, the intestine’s tight junctions limit the transport of large molecules (>500 Da) across the epithelium. In an unhealthy intestine, however, the tight junctions become “leaky” and these large molecules, which can include unprocessed proteins or large amino acids that have intact antigenic sites on them, can then slip into circulation. Intestinal permeability—or “leaky gut”—is the name given to the condition in which this barrier is breached and foreign antigens and other damaging substances slip around the cells and into circulation.^{25,26,27,28}

Abnormal or increased intestinal permeability is commonly seen in patients presenting with intestinal inflammation, food allergies and intolerances, and

celiac sprue. For example, a study of 200 children with cow’s milk allergy showed a significant increase in intestinal permeability (assessed by the commonly used dual sugar permeability assay) in the children with the allergy as compared to controls.²⁹ Abnormal intestinal permeability has also been documented in patients after radiation or chemotherapy treatments (probably due to the killing of proliferating cells), and is induced by stress. Poor nutrient intake or absorption, or lack of enteral nutrition (e.g., parenteral nutrition) cannot support healthy regeneration of the rapidly proliferating cells in the small intestine and, therefore, can also profoundly affect the integrity of the GI barrier function.³⁰ Endogenous toxins, such as bacterial and fungal by-products produced by resident flora, and exogenous toxins, such as incompletely digested food, food additives, alcohol, over-the-counter drugs like NSAIDs, and foreign microbes, can also negatively influence intestinal integrity (see Table 17.2).^{31,32}

In-depth discussions of GI-related processes and conditions can be found in Chapters 24 and 28.

Clinical Implications

The re-establishment of the “intelligent mucosal barrier” is achieved clinically by introducing a program that (1) removes potential offending antigens and toxic substances from the diet; (2) enhances digestive support with the use of exocrine pancreatic digestive aids (*replace*), where required; (3) *reinoculates* the intestinal tract with symbiotic bacteria (probiotics) and selective substrates for their metabolism such as fructooligosaccharides or arabinogalactans (prebiotics); and (4) helps to *repair* the GI mucosa by supplementing the diet with nutrients necessary for the promotion of mucosal healing, such as L-glutamine, zinc, pantothenic acid, and vitamin E. In functional medicine, we call this the 4R program (see Chapter 28).

Table 17.2 Some Factors Associated with Intestinal Permeability

Alcohol
Cancer radiation therapy
Corticosteroids
Excessive stress
Excessive simple sugar consumption
Fasting
Food allergies
Gastrointestinal infections
NSAIDs
Nutrient insufficiencies
Premature birth
Whole food exposure before the age of 4 months

Inhalation and the GI Tract

Most clinicians are aware of inhalant allergens and their influence on such conditions as inflammatory asthma. A functional medicine approach, however, looks for the connections among different systems: the web of interactions that may underlie a set of symptoms. As an example of this complexity, inhalant antigens have been proposed to play a role in gastroenteropathies. For example, animal studies have shown that esophageal eosinophilic inflammation occurs after intranasal allergen challenge.³³ Human studies have also suggested an interaction between the GI tract and the airways. A study in Sweden showed that adults with birch pollen allergy have increased eosinophils and cells positive for IgE in their duodenum during pollen season.³⁴

Although the role of inhaled toxicant, such as carcinogens in tobacco smoke, has been accepted as a contributor to disease, emerging data suggest active and passive tobacco smoke exposure may also contribute to disease in other ways. For example, tobacco smoke has been shown to contain endotoxin, which is a very potent proinflammatory agent, and may contribute to respiratory inflammation.³⁵ Emerging data have also linked the fine and ultra-fine particulate matter present in air pollution to cardiovascular morbidity and mortality. Therefore, the intake of these particles during aerobic exercise should be considered, especially for patients who jog or run in urban areas and are exposed to excessive car exhaust during exercise.³⁶

The Skin as a Barrier

As the external barrier, skin is under a constant barrage of insults from physical conditions, microbes, and chemicals. The skin functions much like the intestinal tract, using tight junctions as a barrier to potentially damaging environmental substances. Skin also has an extensive immune system.³⁷ Emerging data indicate the presence of antimicrobial peptides,³⁸ enabling the human epidermis to kill invading microbes. In this capacity, recognition of a pathogen by the keratinocyte triggers cytokine production that leads to elimination of the pathogen.³⁹

Although an important barrier, a review of published research indicates that the study of the skin barrier may be more difficult than understanding intestinal permeability, since there is no good model system or permeability test. Studies are being published showing that

supporting and enhancing the barrier function of the skin may have therapeutic potential. For example, a study was done with preterm infants in Bangladesh, who were known to have compromised skin barrier function that put them at high risk for serious infections.⁴⁰ In this study, daily massage with sunflower seed oil was compared to massage with a product containing lanolin, petrolatum, and mineral oil; the infants receiving the sunflower oil massages were 41% less likely to develop nosocomial infections. In another study, the oxidation of squalene by UV exposure was reported to be significantly inhibited after one application of a skin rinse with vitamin E, as compared to the rinse without vitamin E.⁴¹

Immune System Surveillance and Removal Mechanisms

Immune system functionality is discussed in great depth in numerous other places in this book (see Chapters 18, 23, and 27). The brief review below highlights the vital role the immune system plays in protection and defense through the intake, processing, and excretion of external substances.

The gut-associated lymphoid tissue (GALT).

Approximately 60% of the immune system, and more than 80% of the immunoglobulin-producing blasts and plasma cells, are located within the mucosa of the GI tract. This complex system is called the gut-associated lymphoid tissue (GALT).^{42,43} The primary purpose of the GALT is to provide the first line of defense against foreign invaders such as food antigens and pathogenic bacteria. A major difference between the GALT and the circulatory immune system is that the GALT can produce two layers of defense to a foreign pathogen or antigen: the localized secretory IgA (sIgA) response, and the systemic IgE or IgG response. Taken together, these two responses account for the production of the majority of the body's immunoglobulins.⁴⁴

The localized sIgA provides the first immunological response to antigens that are ingested; sIgA has been described as an "antiseptic paint" covering the intestinal tract. As the predominant immunoglobulin on the surface of the GI mucosa, sIgA can effectively prevent infection, neutralize viruses, and remove antigens before they cross the mucosal barrier and reach circulation so they can be excreted directly through the feces.^{45,46} Therefore, sIgA prevents these invaders from entering the system without activating the complement or inflammatory systems.⁴⁷ Adults produce three to four grams of sIgA per

day, which can also be found in saliva and colostrum.⁴⁸ A low level of total sIgA in the GI tract is associated with altered intestinal permeability and an increased uptake of food antigens, resulting in atopic symptoms.⁴⁹

Antigens and foreign substances that escape the sIgA surveillance can enter the mucosal layer, where the GALT provides the second layer of defense. In this process, which is the classic response described in most textbooks, the interaction with the antigen-specific IgE and IgG induces a systemic immune response in which antibodies are generated, cytokines are produced, and the full immune system is engaged. Along with activation of the systemic immune system, an inflammatory response often commences at the site where the antigen has invaded. This inflammatory response closes off the area, blocking the influx of more antigens. (The activation of the inflammatory cascade is a double-edged sword because the inflammation response leads to production of reactive oxygen species, which are used to destroy invading pathogens but which can also damage healthy, intact tissue.)

The GALT is also instrumental in the development of immune tolerance to harmless antigens in the diet and commensal microbes. Oral tolerance begins in the newborn with small amounts of intact food antigens, including beta-lactoglobulin, egg, peanut, and gliadin.⁵⁰ Oral tolerance is an important process in which the body becomes able to recognize food molecules and not respond to them with a full-fledged antibody-immune response. Studies with children who have food allergies have shown compromised transforming growth factor-beta and reduced numbers of the T-helper lymphocytes that produce this cytokine (i.e., Th3 cells) in the duodenal epithelium and the lamina propria.^{51,52} The oral tolerance response is also stimulated by the commensal intestinal microbes, and this relationship suggests a role of intestinal microflora in development of healthy oral tolerance response.^{53,54}

The systemic immune system. The systemic immune system is composed of the circulating lymphocytes, the B cells and T cells, which circulate through the body in search of their target antigens. Initially, lymphocytes must be activated toward a specific antigen. Antigens entering the body through mucosal surfaces activate the lymphocytes that are waiting in the mucosa-associated lymphoid tissues (MALT): intranasal and inhaled antigens activate lymphocytes in palatine tonsils and adenoids; and antigens taken in through the

GI tract are taken into specialized epithelial cells called M (microfold) cells (Figure 17.1), which then transport the antigen to Peyer's patches.⁵⁵ Activation via the Peyer's patches is the most common pathway for induction of the immune response. Immune responses to blood-borne antigens are usually initiated in the spleen, and responses to microorganisms in tissues are generated in local lymph nodes.

Induction of the immune system is quite complex, but current dogma indicates that two major pathways exist: cellular immunity that involves the Th1 pathway; and humoral immunity that involves the Th2 pathway. (See Figure 17.2.) The pathways are named after the T-helper cells involved in the pathway (e.g., Th1 and Th2); T-helper cells are differentiated from each other by the products they produce (that is, the specific cytokines they secrete when activated). In general, the Th1 pathway functions against invading organisms, where Th1 cells secrete interferon- γ and interleukin-2, and also involves macrophages and cytotoxic T cells that act in concert to kill the invading organisms. The Th2 pathway is induced in response to antigenic stimuli and leads to secretion of interleukins-4, -5, and -6 by T-helper cells, which support the function of the antibody-producing B cells (see Figure 17.3).

Much literature has indicated that these two systems balance each other: when one is overexpressed, the other is inhibited. For example, glucocorticoids selectively inhibit the Th1 pathway, and shift a person toward Th2 reactions, which may lead to higher susceptibility to allergic responses.⁵⁶ Estrogens inhibit Th1 proinflammatory cytokines and stimulate Th2 cytokines, which is suggested as the reason that autoimmune diseases that involve overexpression of Th1 (e.g., rheumatoid arthritis, multiple sclerosis) frequently remit during pregnancy but exacerbate during postpartum periods.⁵⁷ Th1 and Th2 are also differentially involved in such conditions as psoriasis and atopic dermatitis, respectively.⁵⁸ Genetics is known to play a role in the robustness of Th1 or Th2 responses, as are lifestyle and nutrition.^{59,60,61,62} In addition, early exposure to infectious organisms is also implicated. For example, the "hygiene hypothesis" has been proposed to account for the increasing prevalence of atopic diseases over the past decade. The hygiene hypothesis suggests that diminished exposure to childhood infections leads to a decreased Th1 response, which therefore may enhance the Th2 response in an individual.^{63,64}

The functioning of the immune system with respect to specific conditions will be discussed in more detail elsewhere, but important to this discussion is the understanding that many components must work together in the delicate balance of immune system function, and

the immune system forms a communications link among different tissues with respect to surveillance and defense, and includes macrophage cells, T cells, and B cells. In the brain, glial cells function much as macrophages do, removing waste and providing nutrients to neurons; they are affected by several neurodegenerative conditions.⁶⁵ Because the immune system responds to foreign agents, the interplay with the environment is crucial in its regulation and activity. In addition, several of the immune system-regulated cytokines have clinical relevance (see Figure 17.2), which may show individual responses depending on a person's genetics. It is also important to note that the Th1 and Th2 responses also appear to work together to facilitate recovery from infection, and may support each other in other important ways.⁶⁶ In addition, emerging data indicate a role for a third class of T-helper cells, the Th3 cells, which downregulate Th2 responses.⁶⁷

The Detoxification System and Defense

Drugs and toxicants have to get into the body to function and/or to produce toxic effects. By far the easiest way to evade a healthy barrier system is simply to slide through cell membranes by passive diffusion. Therefore, many drugs are designed as lipid-soluble molecules,⁶⁸ and many of the toxic substances that are found in our bodies are also lipid soluble. Small, weak acids and bases can slip into cells by riding in with water in a passive manner; however, while water-soluble (hydrophilic) molecules are taken into the water-based blood and transported to the kidneys where they can be excreted, lipid-soluble (hydrophobic) molecules cannot be directly removed via the kidneys.⁶⁹ The very nature of lipid-soluble compounds means they will be able to attach to cell membranes, which are composed of lipids, and slide through these membranes into the cell, where they can directly interact with important proteins and molecules necessary for healthy function, thus exerting damage within the cell. The primary mechanism in the body for removing lipid-soluble toxins is the detoxification system, which functions to convert lipid-soluble substances to water-soluble metabolites so they can be excreted via the urine.

After a xenobiotic is taken into the body, it first passes through the liver. Therefore, the liver is a primary site for detoxification and for the majority of detoxification enzymes, including alcohol dehydrogenase, the phase I cytochrome P450 enzymes (CYP P450), and the

phase II conjugation enzymes (e.g., glucuronidases and conjugases that attach glutathione, glycine, taurine, and sulfate). (Detailed discussions of these processes can be found in Chapters 22 and 31.) The position of the liver in this sequence accounts for the statistics showing that liver injury from drugs and xenobiotics leads to 2–5% of hospitalizations from jaundice, an estimated 15–30% of the cases of fulminant liver failure, and ~40% of the acute hepatitis cases in patients older than 50.⁷⁰

Because the detoxification enzymes show such high variability from subject to subject, the adage “one man’s meat is another man’s poison” is relevant to how individuals detoxify drugs, toxicants, and environmental compounds. That is, individuals relate to their environments in very individualized ways with respect to the detoxification system, and responses can vary dramatically such that one person can show intense symptoms at the same level of exposure that another person finds tolerable. Some of this variability is due to environment, lifestyle, and history, but the majority comes from genetics.^{71,72} Because the detoxification system is so involved in managing environmental interactions within the body, it may be no surprise that dietary components can have significant effects on the activity of detoxification enzymes.^{73,74,75}

Commensal Microflora and Defense

The beneficial symbiotic microflora that reside primarily in the large intestine have a direct impact on promoting a healthy GI tract barrier and supporting defense functions. Much research has been focused on how commensal microflora, including bifidobacteria and lactobacilli, provide beneficial effects. For example, the production of short-chain fatty acids (SCFAs) by these bacteria appears to promote growth and differentiation of intestinal mucosal cells, which results in decreased risk of colon cancer and attenuation of intestinal permeability.⁷⁶ Probiotics, which are exogenous sources of friendly bacteria, also appear to benefit patients with atopic eczema, possibly by promoting antigen degradation and healthy GI barrier function.⁷⁷ Intestinal microflora influence digestion not only through nutrient needs and the ability to digest large carbohydrates (such as fibers that escape hydrolysis in the stomach and small intestine), but also through a feedback effect on transit time. SCFAs may also protect intestinal integrity by stimulating intestinal mucosal cell turnover and intestinal mucosal blood flow.⁷⁸

Most notably, healthy microflora is required for development and support of GALT function; beneficial symbiotic bacteria also provide protection to the body by acting as antagonists toward pathogens. They use several mechanisms to provide an environment resistant to colonization by pathogens, including competitive inhibition for bacterial adhesion sites. For example, *Lactobacillus acidophilus* has been shown to inhibit adhesion of several enteric pathogens to human intestinal cells.⁷⁹ Bacterial symbiotes can also produce various antimicrobial substances, thereby inhibiting pathogens by bacteriostatic and bacteriocidal mechanisms. One class of bacteriostatic molecules is the alpha-defensins class of molecules and, to date, six alpha-defensins have been identified.⁸⁰

Transport and Circulation

Transport and circulation functions are not often considered a part of the body’s defense, but they are instrumental in supporting the body’s defense functions and providing nutrients throughout the body. Once absorbed, nutrients must be distributed to the tissues where metabolism occurs, and many nutrients have specific carrier proteins or structures that facilitate their transport. Not only does this allow the body to regulate nutrient delivery, but the specificity of transport allows a level of defense. Defects in transport proteins or specific genetic uniqueness, for example (as seen with polymorphisms of the apolipoproteins such as apo E and Lp(a)), can result in altered transport/distribution effects that alter physiological function.

The importance of healthy circulation, transport of nutrients to cells, and elimination of waste from tissue sites is shown by the mere fact that the vasculature is the first functional organ to form during embryonic development, and disruptions in its formation or function are lethal to local tissue and the whole system.⁸¹ Large artery rigidity is known to contribute to morbidity and mortality associated with the most common chronic conditions seen today, including arterial hypertension, diabetes mellitus, and heart failure. Aortic rigidity precedes the development of arterial hypertension in individuals with borderline hypertension.⁸² The microcirculation also plays an important role in defense mechanisms.

Transport of nutrients to the cells is not the end of the process. The fat-based cell membranes provide a barrier function within the body, separating the aque-

ous-based extracellular environment from the aqueous-based intracellular environment. Very small water-soluble molecules can slip into the cell passively in water, but the concentrations of these tend to be low. Therefore, specific transport processes are also required to get water-soluble nutrients across the fat-based cell membranes. Many of these nutrients are taken into cells through an active transport process. For example, glucose is taken into the cell from the blood via the GLUT2 or GLUT4 receptors. Dysfunctions in this uptake system can occur.

Maintenance of healthy cell membranes is essential and data have shown that the type of fat in the diet directly influences the fat in the cell membranes. Omega-3 fats have been shown to promote healthy function of membrane receptors by influencing the environment around the receptors. For example, in an animal feeding study, rats consuming omega-3 fatty acids in place of omega-6 fatty acids (in otherwise identical diets) showed lower serum triglycerides and an attenuated insulin-stimulated transport of glucose into adipocytes than the animals with the omega-6 fats.⁸³ Cell culture studies have shown that the amount of EPA as compared to linoleic acid influences membrane fluidity and receptor-mediated signaling through the phospholipase-C/phosphoinositol pathway.⁸⁴ A compelling series of articles has been published addressing membrane phospholipid composition and neurotransmitter function in depression and schizophrenia.^{85,86} As stated in one review: "This suggests that a tight relationship exists between essential fatty acid status and normal neurotransmitter function, and that altered PUFA levels may contribute to the abnormalities in neurotransmission seen in schizophrenia."

Because cell membranes are composed primarily of fat, and many toxicants, including most drugs, are fat soluble, many of these substances can cross the cell membrane barrier without specific transport processes. Therefore, as another layer of defense, cells have an "antiporter" system for these xenobiotics, which acts to pump molecules out of the cell. This antiporter system is called P-glycoprotein, which is a product of one of the multi-drug resistant genes (MDR1 and MDR2). This system was first described in tumor cells that became resistant to chemotherapeutic agents as a result of increased expression of this transporter. The P-glycoprotein transporter is found in many tissues, such as cells in the small intestine, liver, and kidney, and at the

blood-brain and blood-testes barriers.⁸⁷ P-glycoprotein functions to limit absorption of drugs and xenobiotics and to promote their excretion, but is also strongly influenced by concomitantly administered drugs.⁸⁸

Circulation and transport of nutrients affect the functioning of the cardiovascular system, which is heavily influenced by factors such as homocysteine^{89,90} that are influenced by nutrition. Many dietary factors are known to affect nitric oxide synthase, the enzyme responsible for generating nitric oxide (NO), which regulates vascular relaxation.⁹¹ Emerging data indicate that the oxygenation state of hemoglobin also regulates NO.⁹² Antioxidants in the diet can also affect oxidant stress, which can, in turn, alter endothelial function.⁹³

Clinical Implications

Fat-soluble substances such as steroid hormones are transported on their own binding proteins and are vulnerable to environmental influences. For example, sex hormone-binding globulin, an important transport protein for the regulation of plasma concentration of sex steroid hormones, can be influenced by many environmental factors, including smoking, oral contraceptive use, soy isoflavone intake, stress, toxic chemical exposure, and excess alcohol intake. All of these factors can influence the relative concentration of the sex hormone-binding globulin, thereby modifying the concentration and availability of specific sex hormones, such as estrogen, testosterone, or progesterone.

In the functional medicine workup, evaluation of whether a patient may have a transport or circulatory difficulty, or a cellular resistance to the substance of concern, needs to be considered. Conditions that could modify the transport or circulation of substances include dyslipidemia, altered blood pressure or vascular reactivity, regional ischemic events, the breakdown of membrane barriers of defense, increased oxidative stress and injury, or the presence of chronic inflammation. Specific tailored therapies can be integrated into the overall treatment plan that focus on improving active transport by strengthening proper membrane barrier function and proper membrane bioenergetics so that active transport can be maintained, by supporting proper vascular endothelial function, and by enhancing cellular uptake through stimulation of membrane receptor sites and mitochondrial and nuclear signaling systems.

Elimination of Waste

Metabolism of nutrients either by the host or by enteric or opportunistic microorganisms also results in the production of metabolic by-products, or waste. These need to be properly excreted to complete the nutrient

cycling process. Excretion of waste products can occur by way of solid, liquid, or gas exchange. Aerobic metabolism of glucose produces carbon dioxide and water that both need excretion. Carbon dioxide is excreted as a gas by the lungs. Water is excreted as a liquid through the kidneys, skin, and intestines, and as a vapor through the lungs and skin.

Protein metabolism results in the production of urea and sulfate, which are excreted through the kidneys. Incomplete protein metabolism results in the formation of amines such as trimethylamine, ammonia, or other middle-molecular weight nitrogenous substances that are excreted through the urine and skin. These nitrogenous compounds have strong “fishy” odors, which often characterize people with protein metabolic disorders or hepatic or GI difficulties in managing protein in the diet.

Fats are ideally metabolized and excreted as carbon dioxide, water, and phosphate (as it relates to phospholipid metabolism). Fat metabolism problems result in the excretion of fat in the stool (i.e., steatorrhea) or alterations in serum lipid levels (i.e., elevated serum cholesterol or triglycerides).

Fecal vs. Urinary Excretion

Many metabolites and dietary substances undergo further metabolic modification as they are converted to excretory products. This includes hormones, neurotransmitters, eicosanoids, vitamins, and phytochemicals, as well as xenobiotics and drugs. The principal mechanism by which these excretory products are created is through the detoxification/biotransformation pathways, although some may be secreted in kidney tubules without transformation. Most of this conversion is done in the liver, although detoxification enzymes are also present in the GI mucosa, kidneys, lung epithelial tissue, and other tissues, which can also contribute to biotransformation. Once a substance has undergone biotransformation to its conjugate, it is partitioned into either the bile for excretion in the feces or through the kidneys to be excreted in the urine. Dehydration has a serious adverse influence on detoxification and excretion due to decreased urinary output. In patients with functional impairment in excretion, copious amounts of water should be administered.

Fecal excretion also plays an important role in eliminating the remnants and cellular debris of enteric bacteria. It is estimated that there are two to nine pounds of

enteric bacteria in the human digestive tract. These organisms have their own natural life cycles and, when they die, their cell bodies must be excreted. Beyond that, enteric bacteria produce many metabolites that must be detoxified by the gastrointestinal biotransformation systems and excreted as secondary metabolites.

An example of the relationship between enteric bacteria and metabolites is the conversion of lignans and isoflavones by specific enteric flora into secondary metabolites such as equol. Equol is absorbed across the gastrointestinal lumen, has impact on modulating aspects of functional physiology, and is then excreted in the urine. Although the exposure to equol seems beneficial to the host, there are many other examples of enteric bacteria metabolism resulting in the formation of toxic compounds that must be biotransformed and excreted. In addition, certain enteric bacteria also possess enzymes such as beta-glucuronidase that can deconjugate detoxified substances (such as estrogen metabolites) in the colon and render them available for resorption. This places an additional burden on the detoxification and excretory systems.

Functionally, the excretory system can be improved through enhanced bowel transit time because that implies less contact time for absorption of toxic substances. This is clinically achieved by increasing the intake of insoluble fiber. Supplementing the diet with symbiotic microorganisms such as specific strains of lactobacilli and bifidobacteria can also enhance transit time. For example, the *L. acidophilus* NCFM® strain has been shown to decrease incidence of pediatric diarrhea, significantly decrease levels of toxic amines in the blood of dialysis patients with small intestine bacterial overgrowth (SIBO), and facilitate lactose digestion in lactose-intolerant individuals.⁹⁴

Fiber can also promote transit time and healthy excretion, as well as providing other positive benefits to a patient. The fibers classed as “prebiotics” are particularly beneficial. Prebiotics are fibers that have been shown to preferentially promote commensal GI microflora, and include fructans (such as inulin and fructooligosaccharides, or FOS), arabinogalactans, and soy oligosaccharides. Some fibers have been shown to promote short-chain fatty acid production and healthy microflora in the GI, but may not be officially designated as prebiotics. For example, rice fiber has been shown to improve bile acid excretion and decrease fecal bacterial enzyme activities associated with pathogens

and imbalanced flora, such as beta-glucuronidase, mucinase, and nitroreductase.⁹⁵

It is important to emphasize the clinical benefit of introducing a dietary detoxification program that includes more whole fruits and vegetables and fiber-rich whole grains when trying to improve excretion. There are many detoxification-focused diets that increase the intake of cruciferous vegetables (broccoli, cauliflower, Brussels sprouts, and cabbage), red and orange vegetables, and whole fruits, including apples and berries. These foods contain specific phytochemicals that have been found to enhance detoxification. Fasting is not considered an optimal approach to detoxification and the improvement of excretion due to its lack of fiber content and its tendency to cause constipation. Regular exercise also helps in maintaining proper peristaltic action and promoting proper transit time.

Summary

The theme that emerges from this discussion of digestive physiology is that the delivery of fuel to the cells and the subsequent removal of waste products produced during metabolism are much more complex than just examining the presence or absence of the substance itself. Rather, in a functional medicine evaluation, one has to determine whether there are difficulties in transport of a substance once it has been absorbed, whether it is properly distributed to the appropriate tissues through circulation, and whether, once delivered, it can be taken up by cells correctly to promote proper function. Each of these processes has been found to show great genetic variability from person to person, and we now know that there are many environmental, lifestyle, and dietary variables that influence each of these steps in the maintenance of proper cellular function.

Chapter 18

The Biology of Inflammation: A Common Pathway in Cardiovascular Diseases, Part I

Peter Libby, MD

Introductionⁱ

This primer on inflammation biology describes the mechanisms of innate and acquired immunity, and the key players in the inflammatory response, explicating and disentangling the connections between them—the better to argue the case that the entire spectrum of inflammatory diseases represents host defenses gone awry. A number of cardiovascular conditions, some exotic, but many common, involve an important component of inflammation, representing host defense mechanisms that can cause disease. Part I of this essay provides a general background to the biology of inflammation. The discussion will serve as a roadmap and glossary of inflammation that will facilitate placing this topic into the clinical context of cardiovascular diseases. Part II, a discussion of how these concepts influence atherosclerosis and myocardial infarction, can be found in Chapter 27.

Inflammation is Intertwined with the Vasculature

Physicians in ancient times recognized the importance of inflammation in pathophysiology. Inflammation has features easily recognizable at the macroscopic level and grossly apparent on physical examination. The Latin terminology handed down from Celsus in

classical times described the cardinal features of inflammation: *rubor*, *tumor*, *calor*, and *dolor*. *Rubor* (redness) arises from increased local blood flow due to vasodilatation. *Calor* (heat) also likely reflects increased regional blood flow and vasodilatation. *Dolor* (pain) results from local release of inflammatory mediators that stimulate nociceptors in local nerves. *Tumor* (swelling) reflects tissue edema and often accompanies the redness and heat at sites of inflammation. Localized increases in vascular permeability, part and parcel of the inflammatory process, contribute to the local edema manifest as swelling. Aside from pain, all of these classic signs of inflammation relate to perturbations in the vasculature. Increased blood flow, vasodilatation, and increased vascular permeability characteristically accompany sites of inflammation. Considered in this context, the general pathology of inflammation falls within the province of cardiovascular pathophysiology in its most fundamental aspects.

Although known to the ancients, knowledge about the cellular basis of inflammation required advances in microscopy and tissue analysis made in the 19th century. The commercial development of aniline dyes in the textile industry stimulated the development of synthetic organic chemistry in the 1800s. The scientific “spin-off” of this commercially driven research and development included the application of newly synthesized dyes to provide contrast of stained tissues during microscopic examination. This technological advance spurred the development of cellular pathology embodied in the work of Rudolph Virchow. Armed only with stained tissue sections and keen inductive reasoning, the cellular pathologists of the 19th century worked out

ⁱAdapted, with permission, from: Libby P. Inflammation: a common pathway in cardiovascular diseases. *Dialogues in Cardiovascular Medicine*. 2003;8(2):59-73. The original article has been divided into two parts for this book; part II can be found in Section VI: A Practical Clinical Approach, as the first piece in Chapter 27. **Acknowledgment:** Supported in part by a grant from the National Heart, Lung, and Blood Institute (HL-34636).

the involvement of leukocytes in inflammatory reactions in tissues.¹

The 19th century also witnessed the birth of experimental pathology. The investigation of inflammatory phenomena figured prominently in the early development of this science. Elie Metchnikoff, summering in Messina, Italy, observed the engulfment by the leukocytes of marine invertebrates of foreign bodies, a process he called phagocytosis.² These observations and Metchnikoff's astute interpretations led to the recognition of the role of leukocytes and host defenses against foreign invaders. As the germ theory of disease developed in the latter part of the 19th century, the concept of foreign bodies extended to microbial invaders. To this day, much of the biology of inflammation consists of exchanges of messages among various classes of leukocytes and with parenchymal cells.

The molecular nature of the messages exchanged among cells during inflammatory reactions developed largely during the 20th century. During the first two-thirds of the 20th century, much work focused on the purification and elucidation of the structures of low-molecular-weight mediators of inflammation. Molecules such as histamine, related to a simple amino acid, exemplified "autocoids" involved in inflammatory responses. Histamine can cause profound changes in vascular biology, including increased permeability of microvessels. Histamine also elicits the contraction of smooth muscle cells, manifest as vasoconstriction of some beds and bronchoconstriction in the airways. Small-molecule lipid mediators characterized during this period included the prostaglandins, the leukotrienes, the lipoxins, and platelet-activating factor (PAF). Some peptide mediators of inflammation of higher molecular weight, including bradykinin, also underwent purification and characterization.

In the latter third of the 20th century, the study of protein mediators of inflammation and immunity burgeoned. Advances in protein biochemistry, and eventually molecular biology, led to the identification of the cytokines, now considered major messengers in host defenses and inflammatory reactions. Originally considered products of "professional" inflammatory cells such as leukocytes, traditional concepts viewed "peripheral" cells, such as those of the vasculature or parenchymal cells of various organs, as responders to signals elaborated by leukocytes. More recently, we have come to appreciate that many cell types, notably including vas-

cular endothelial and smooth muscle cells, can produce as well as respond to various cytokines.³ Thus, our understanding of the complexity of the networks involved in inflammatory signaling has grown considerably as scientific knowledge has advanced.

Phagocytes: The First Line of Host Defenses

In the more than a century following Metchnikoff's definition of phagocytosis, appreciation of the importance of this process has only grown as we have filled in the cellular and molecular mechanisms. The granulocyte—or polymorphonuclear leukocyte—embodies *par excellence* the phagocyte involved in acute inflammatory reactions. In acute bacterial infections, chemotactic peptides of microbial origin such as formyl-methionyl-leucyl-phenylalanine (f-met-leu-phe) or anaphylatoxins (see below) beckoned granulocytes from the vasculature to the nidus of infection. Activated by these bacterial products and others such as endotoxin (lipopolysaccharides manufactured by certain bacteria), the polymorphonuclear leukocyte degranulates, releasing enzymes that can attack the invaders. Granulocytes also manufacture enzymes that produce molecules involved in killing microbial invaders. Various oxidases generate superoxide anion, O_2^- , an example of a bactericidal reactive oxygen species. The granulocyte also releases myeloperoxidase, an enzyme that produces hypochlorous acid (HOCl). Hypochlorous acid, more commonly known as laundry bleach, can also kill bacteria. Although bacterial products may directly initiate the recruitment of granulocytes during infection, endogenous mechanisms soon join in.

Bacterial endotoxin can stimulate the expression on the surface of vascular endothelial cells of an adhesion molecule that binds selectively to a ligand on granulocytes.⁴ E-selectin, not normally expressed by resting endothelial cells, arises rapidly on endothelial cells stimulated with bacterial lipopolysaccharide or certain cytokines. E-selectin binds to sialyl Lewis X molecules on the granulocyte surface. This interaction captures the polymorphonuclear leukocyte flowing through post-capillary venules and mediates a rolling of the granulocyte on the endothelial surface.⁵ Other members of the selectin family may serve similar roles in slowing the progress of the polymorphonuclear leukocyte through the microcirculation. Tarrying in venules due to selectin-mediated rolling, the leukocyte can then form firmer interactions by binding to members of another family of adhesion mole-

cules expressed by inflamed endothelial cells: members of the immunoglobulin (IgG) superfamily.⁶ These molecules, exemplified by intercellular adhesion molecule-1 (ICAM-1), arrest the rolling leukocyte, the next step in the recruitment process. Once adherent, the granulocyte receives chemoattractant signals from beyond the endothelial layer to trigger transmigration of the adherent leukocyte so that it can penetrate into the target tissue. The bacterial-derived chemoattractants, such as f-met-leu-phe, promote this directed migration. In addition, host cytokines such as interleukin-8 (IL-8), manufactured locally in response to bacterial products such as endotoxin, can unite with bacterially derived chemoattractants to call the polymorphonuclear leukocyte into the tissue invaded by bacteria.^{7,8} This schema of a local inflammatory stimulus (the bacteria) and recruitment of leukocytes by adherence transmigration, followed by activation of the effector mechanisms of the leukocyte as summarized above, applies not only to acute inflammation due to a bacterial infection, but serves as a general paradigm for localized inflammatory responses.

Of course, bacterial invasion sometimes spreads beyond the local tissue. Septicemia, or blood-borne infection, elicits a systemic or generalized host-defense reaction with profound cardiovascular consequences. Bacterial endotoxemia wreaks havoc with homeostasis of blood coagulation.⁹ Endotoxin induces endothelial expression of the potent procoagulant molecule tissue factor.¹⁰ It also augments production of inhibitors of fibrinolysis such as plasminogen activator inhibitor-1 (PAI-1).¹¹ Such changes can give rise to disseminated intravascular coagulation, one of the dread consequences of disseminated gram-negative infection. Circulating endotoxin leads to widespread release of cytokines, such as IL-1 and tumor necrosis factor (TNF) (see below). These cytokines can induce fever, which in turn causes tachycardia. In addition, the small molecule nitric oxide (NO), produced by endothelial cells stimulated with bacterial endotoxin as well as deriving from other inflamed cells including leukocytes, can promote vasodilatation and hypotension.¹² A hyperkinetic state ensues with low resistance and high cardiac output characteristic of septic shock. This picture, all too commonly encountered clinically, represents an extreme case on a systemic or generalized scale of the acute inflammatory response to a bacterial invader.

Not all bacterial infections play out on a scale of hours to days. Chronic microbial infections represent

an example of inflammatory responses that endure longer. While some of the cells and messengers in the *dramatis personae* of chronic inflammatory responses differ from those described above in the context of acute responses, many of the fundamental principles remain the same. Consider, for example, the classic chronic bacterial disease tuberculosis. The pathological hallmark of infection with the tubercle bacillus is a granuloma rather than an abscess populated by polymorphonuclear leukocytes. In the granuloma, the mononuclear phagocyte, rather than the polymorphonuclear leukocyte, takes center stage. Derived from blood monocytes, the tissue macrophage becomes the key effector cell in chronic inflammatory responses. The tubercle granuloma can last for years, as opposed to the abscess populated by polymorphonuclear leukocytes in a pyogenic bacterial infection. The granuloma represents the results of the interaction of the parenchymal tissue of the infected organ with the macrophages. This pathology plays out in a similar fashion in atheroma, an example of a special case of granuloma formation considered below.

As alluded to above, recruitment of monocytes to sites of chronic infection or inflammation recapitulates on a slower scale the accumulation of granulocytes to foci of acute inflammation. In the case of the monocyte, adhesion molecules of the IgG superfamily, such as vascular cell adhesion molecule-1 (VCAM-1), interact with integrin molecules on the mononuclear cell, such as very late antigen-4 (VLA-4). Once adherent to the endothelial cell, endogenous chemoattractant molecules direct the migration of the mononuclear phagocyte into the inflamed tissue. While IL-8 favors recruitment of granulocytes, members of another chemokine family, the CXC chemokines, selectively recruit monocytes. Macrophage chemoattractant protein-1 (MCP-1) represents an example of a mononuclear phagocyte chemoattractant that helps to recruit these cells to sites of formation of granuloma for other chronic inflammatory processes.

Granulocytes, the typical effector cells of acute inflammatory responses, have eponymous granules packed with preformed mediators. When recruited to sites of acute inflammation, they degranulate, rapidly produce a reactive oxygen species through the “respiratory burst,” and die, often by apoptosis.¹³ At sites of chronic inflammation, the life history of the mononuclear phagocyte differs considerably. The blood monocyte, recruited to a site of chronic inflammation,

differentiates into a macrophage. A variety of endogenous stimuli favor the transition of the blood monocyte into a tissue macrophage involved in chronic inflammatory responses. Molecules such as macrophage colony-stimulating factor (M-CSF) and activators of protein kinase-C promote monocyte differentiation. Equipped for prolonged combat rather than a short battle with acute invaders, the macrophage effector mechanisms typically outlast those of granulocytes.

Macrophages have a well-developed phagolysosome system that is well suited for combating chronic invaders. For example, the macrophage can engulf particulate matter such as the tubercle bacillus and transport the engulfed particle to the lysosome, an intracellular compartment filled with digestive enzymes. Often in concert with phagocytosis, the macrophage elaborates reactive oxygen species, including superoxide anion (O_2^-), NO, and hypochlorous acid.¹² The macrophage appears capable of producing these small-molecule effectors of host defenses on a more prolonged timescale than the granulocyte. The mononuclear phagocyte excels at producing higher-molecular-weight mediators as well. The macrophage, when activated, can produce large quantities of cytokines. In addition, the tissue macrophage produces abundant proteases involved in tissue remodeling, a property of particular importance in cardiovascular pathology (see below).^{14,15} Pus (comprised of a mixture of live, dying, and dead granulocytes) typifies abscesses at sites of acute inflammation. In granuloma, however, rather than committing suicide, macrophages may fuse, forming giant cells whose palisade of nuclei classically characterizes the tuberculous granuloma. Prolonged persistence of the phagocytic cell predominates at sites of chronic, as opposed to acute, inflammatory responses.

The Innate Immune Response

The two general pathways of inflammation described above represent two limbs of host defense mechanisms now often described as “innate immunity.” The term innate denotes instant readiness to cope with invaders, circumventing the need for an instructional period as the acquired (antigen-specific) immune response requires. The types of structures on invaders that trigger the innate immune response include molecules with shared structural features, such as gram-negative endotoxin. The structures that recognize these relatively conserved structures have been called “pattern-recognition

receptors.” Families of pattern-recognition receptors include scavenger receptors (first characterized in the context of atherosclerosis),¹⁶ and a recently characterized family of transmembrane molecules known as toll-like receptors (TLR).¹⁷

Innate immunity represents a first line of defense against invaders capable of rapid deployment. Innate immunity plays out first not only within the organism, but also earlier during phylogeny. The innate immune response represents a more primitive form of host defense present in invertebrates and independent of the more selective recognition involved in adaptive immunity, a more recent development during evolution.¹⁸ In addition to the leukocytic effector cells of acute and chronic inflammation described above, the complement system contributes importantly to innate immunity.^{19,20} The alternative pathway of complement activation recognizes common patterns (for example, de-sialylated glycoconjugates on the surface of erythrocytes). Activation of complement by the alternative pathway leads to formation of the terminal membrane attack complex that can effectively punch holes in invading microbial cells. In this way, complement can kill bacterial and other invaders and, when unleashed inappropriately, host cells as well.

Cytokines: Omnipresent Organizers of the Inflammatory Response

As noted above, for most of the 20th century, attention focused on small molecules as mediators of inflammation. Over the last quarter century, we have become acquainted with large families of protein mediators of inflammation and immunity known collectively as cytokines.²¹ These cytokines fall into many categories. Originally considered exclusively as products of leukocytes, many initially bore the name “interleukin.” As our knowledge of the biology of cytokines has increased, so has our appreciation that many cells can elaborate these multi-functional mediators. Hence, more recently recognized families of cytokines often bear other names. Many of the cytokines categorized early on derive from mononuclear phagocytes, classifying them as monokines. Others, produced by T lymphocytes, bore the name “lymphokine.” Chemoattractant cytokines fall into families known as chemokines.²² A related class of protein mediators known as colony-stimulating factors has overlapping characteristics with classical cytokines

(e.g., interleukin-3). Therefore, discussions of cytokines often include colony-stimulating factors. The following paragraphs will introduce briefly certain of the prototypical cytokines to illustrate the properties of these important mediators. Table 18.1 shows examples of cytokines important in cardiovascular pathology and often cited in the cardiovascular literature.

Table 18.1 Examples of Cytokines Involved in Cardiovascular Inflammation

Cytokine	Abbreviation(s)	Important functions
Interleukin-1	IL-1	Endogenous pyrogen, T-cell coactivator, proinflammatory activation of vascular cells
Tumor necrosis factor	TNF	As above, autocrine regulator of myocardiocytes
Gamma interferon	IFN- γ	Macrophage activator, inducer of histocompatibility antigens, prototype Th1 cytokine
Interleukin-10	IL-10	Often anti-inflammatory, prototype Th2 cytokine
Macrophage colony-stimulating factor	M-CSF	Macrophage activator and co-mitogen
Monocyte chemoattractant protein-1	MCP-1	Macrophage chemoattractant
CD40 Ligand	CD40L, CD154, gp39	As IL-1 but also activates caspase-1 and induces macrophage tissue factor expression
Interleukin - 18	IL-18	Gamma interferon induction

Interleukin-1: The Prototypical Monokine

As is typical, the protein now known as interleukin-1 (IL-1) represented a convergence of various activities found to reside in a small family of closely-related proteins after years of parallel work in various laboratories.²³ The molecular characterization of IL-1 arose from the identification, purification, and eventually the cDNA cloning of the active principle in mediating fever known as endogenous pyrogen. The example of IL-1 illustrates many features common to cytokines. Seldom produced by resting cells, many cell types produce this protein inducibly in response to inflammatory stimuli such as bacterial endotoxin. Initially synthesized as a 33000 dalton precursor, interleukin-1 β (IL-1 β), the predominant secreted form of this cytokine, requires processing to attain its full biological activity. An enzyme known as interleukin-1 β -converting enzyme, or ICE, effects this conversion.²⁴ Interestingly, ICE represented the prototype of a new family of proteinases known as caspases, so named because they are cysteinyl proteinases that cleave at aspartyl residues (asp) in their substrates. The other isoform of IL-1, known as interleukin-1 α (IL-1 α), often remains associated with the cell surface and does not require proteolytic processing for biological activity.

IL-1 binds to selective transmembrane receptors. The signaling receptor for IL-1 β feeds into the same intracellular pathway as the pattern recognition receptors, TLRs, alluded to above. IL-1 β engagement of its signaling receptor ultimately causes activation of a transcription factor known as nuclear factor-kappa B (NF κ B).²⁵ NF κ B, when activated, binds to cognate sequences in the promotor regions of the genes encoding a wide variety of inflammatory effectors. Thus, IL-1 β action unleashes a coordinate program of inflammatory mechanisms in many leukocytes and other host cells. In this way, IL-1 β acts as a master regulator of the innate immune response, evoking the elaboration of many other cytokines, including augmentation of its own gene expression.²⁶ Like many potent biological pathways, IL-1 β has an endogenous inhibitor, a structural homologue known as IL-1 receptor antagonist. This endogenous molecule competes for the signaling receptor of IL-1 β , limiting its actions. Itself induced in response to inflammatory signals, the IL-1 β receptor antagonist constitutes a negative feedback loop poised

to prevent untrammelled amplification of this potent proinflammatory pathway

Tumor Necrosis Factor-Alpha: A Death-linked Cytokine

Tumor necrosis factor- α (TNF- α), a close cousin of IL-1 β , exhibits augmented production and spectral and biological activities similar to that due to IL-1. Like IL-1 β , TNF- α has several surface receptors. The active signaling receptor, however, elicits activation not only of NF κ B, but also of the pathway that causes programmed cell death, or apoptosis.²⁷ Thus, in addition to the proinflammatory action that TNF- α has in common with IL-1 β , it links to the control of cell death.

Interleukin-6: A “Messenger” Cytokine

A prominent target gene for activation by TNF- α and IL-1 β , many peripheral cells, including vascular smooth muscle, can secrete copious quantities of interleukin-6 (IL-6) when stimulated by the primary proinflammatory cytokines IL-1 or TNF. IL-6 activates B cells and promotes their maturation, an important aspect of antibody production and acquired immunity. Of great interest in cardiovascular pathology, IL-6 serves as a link between the acute inflammatory response mediated by the primary proinflammatory cytokines and the systemic reaction to acute inflammation, known as the “acute-phase response.”^{28,29} IL-6 alters the pattern of protein synthesis by hepatocytes. After encountering IL-6, the liver shifts new protein synthesis from “house-keeping” proteins such as albumen toward production of acute-phase reactants, which serve as readily sampled systemic markers of inflammation. The acute-phase reactants may also participate in inflammatory responses involved in cardiovascular pathology. For example, C-reactive protein (CRP), a classic acute-phase reactant, has garnered considerable interest recently as a prognostic or predictive indicator of cardiovascular risk.³⁰ In addition, CRP can activate complement and thus actively participate in innate immunity. Serum amyloid-A, another prominent acute-phase reactant, may increase hundreds of times in the plasma of patients with inflammatory states. Serum amyloid-A can bind to high-density lipoprotein (HDL), impairing some of the salutary properties of this lipoprotein molecule, thus potentially increasing coronary risk prospectively.³¹ Another acute-phase reactant, fibrinogen,

directly participates in blood coagulation. In this manner, the acute-phase response may link to a thrombotic diathesis of considerable import in cardiovascular diseases. IL-6, as an instigator of the acute-phase response, can in this manner serve as an important link between inflammation and cardiovascular events.

Interferon Gamma: The Prototypical Lymphokine

Immune interferon, or interferon gamma (IFN- γ), contrasts with the aforementioned cytokines inasmuch as a much smaller gamut of cells produce this cytokine. Classically considered exclusively a product of activated T lymphocytes, even after exhaustive investigations only a few cell types have proven capable of producing IFN- γ . As might be expected of a cytokine derived from a cell type prominent in adaptive immunity, IFN- γ enhances antigen presentation by augmenting the expression of major histocompatibility complex antigens important for recognition of foreign antigens.³² However, IFN- γ also stimulates mononuclear phagocytes, among other aspects of the innate immune response. Nonetheless, the range of actions produced by IFN- γ shows considerably more selectivity than that of IL-1 or TNF, illustrating that all cytokines act promiscuously.

Macrophage Chemoattractant Protein-1: A Typical Chemoattractant Cytokine

Several families of chemokines exist. Specialists use a shorthand based on the spacing of conserved cysteine residues in the amino acid sequence of the cytokines to classify these various families. MCP-1 falls into the family of CXC cytokines, indicating that an unspecified (X) amino acid residue lies between neighboring cysteine residues.³³ Chemokines typically bind to specific membrane receptors grouped into similar families based on their ligand. The MCP-1 receptor, CXC-R2, belongs to the large family of heptahelical, or seven-membrane-spanning, G protein-coupled receptors. Thus, the signaling mechanism of chemokines does not generally overlap with those of the primary proinflammatory cytokines. As the spectrum of receptors on various classes of cells varies, so does the specificity of the targets for chemoattraction of various chemokines. MCP-1, as mentioned above, binds selectively to cells of the mononuclear family. Mice lacking the receptor for MCP-1 show impaired recruitment of mononuclear phagocytes to sites of chronic inflammation.

The Lymphocytes: Major Mediators of Acquired Immunity

Thus far, our discussion of inflammatory responses has focused on innate or “ready-made” immunity. Higher organisms have added to the repertoire of host defenses a complex surveillance and effector system based on highly variable and fine structural determinants known as acquired immunity. This name also conveys the idea that acquisition of this form of immunity requires time, rather than being prefabricated as in the case of innate immunity. The T lymphocyte orchestrates acquired immunity, which has both humoral (antibody-mediated) and cellular limbs.

Generation of the Acquired Immune Response: The Helper T Cell

A subset of T cells known as helper T cells, usually bearing the CD4 determinant, initiates most acquired immune responses by recognizing antigen via engagement of a selective cell surface receptor. The recognition of antigens by the helper T cell requires presentation on the surface of a cooperating cell, known as the antigen-presenting cell, or APC. The T-cell receptor does not recognize the foreign antigen in isolation, but requires presentation in the context of a structure on the surface of the APC, the class II major histocompatibility antigen. Each individual bears his or her own mix of these highly polymorphic molecules that serve an essential role in generating the immune response. Incidentally, histocompatibility antigens bear this name because they themselves are capable of generating an immune response to organs transplanted from different members of a species, hence the term histocompatibility antigen. The engagement of the T cell’s receptor for antigen causes the T cell to secrete IFN- γ , which raises the level of class II histocompatibility antigens on the surface of potential antigen-presenting cells, priming them to contribute to the generation of the acquired immune response. Engagement of the antigen receptor also causes the T cell to augment its production of a lymphokine known as IL-2, originally termed T cell growth factor. The T cell activated by antigen also increases its expression of the cell surface that binds IL-2. Thus, the T cell that has encountered foreign antigen in the context of its own class II molecule can undergo self-perpetuated clonal expansion, producing and responding to its own growth factor, an example of

an autocrine growth control loop. Expanding the population of antigen-specific T cells amplifies the response to a given foreign antigen—for example, to a virus.

The term “helper T cell” refers to the ability of the CD4 cell, when activated, to promote development of a full-blown immune response, both humoral and cellular. Stimulation of the humoral immune response involves the expression on the surface of the activated T cell of CD154, also known as CD40 ligand.³⁴ This surface molecule binds to a cognate receptor on the B-lymphocyte, the antigen-producing cell, causing it to mature into a plasma cell capable of secreting large quantities of antibody directed against specific antigens. The IL-2 secreted by the activated T cell serves not only in autocrine growth, but also in “paracrine growth,” stimulating the proliferation of CD8 cells, also known as killer or cytotoxic T cells, the efferent limb of the cellular immune response.

Cytolytic T Cells: Effectors of the Cellular Immune Response

Stimulated by IL-2 secreted by the activated helper T cell, CD8 cells proliferate and become activated themselves. The CD8 cell recognizes foreign antigen in the context of class I MHC (major histocompatibility complex) molecules. While helper T cells recognize antigen presented on the surface of antigen-presenting cells in the context of self-class II MHC, the cytolytic T cell recognizes antigen presented in the context of class I molecules on the surface cells infected with viruses or, in the case of transplanted organs, the foreign cell itself. Recognition of the foreign antigen causes the cytolytic T cell to secrete a molecule known as perforin, which resembles the terminal membrane attack complex component of complement, and likewise can poke holes in the membrane of the cell under attack.³⁵ In addition, digestive enzymes, such as granzyme, arise from the activated killer T cell. The cytolytic T cell, usually bearing the CD8 antigen on its surface, also can express Fas, a TNF-like molecule, on its surface. Fas engages Fas ligand on the cell under attack. Fas ligation, like TNF, causes activation of the cell-death cascade. The Fas pathway thus represents yet another mechanism by which the CD8-positive T cell can kill a cell that harbors a viral infection or otherwise presents foreign antigen.

B Cells: A Source of Antibody

As described above, the effector limb of cellular immunity requires contact between the cytolytic T cell and its target. Humoral responses mediated by antibody, soluble molecules, do not require such cell-cell contact. The B cell, in receipt of “help” from T cells and aided by the “messenger” cytokine IL-6, becomes a plasma cell specialized in secreting large amounts of antibody.

Antibody can serve several roles in host defenses. By binding to determinants on the surface of microbial invaders, antibody molecules can “fix” complement through the classical pathway, leading to lysis of the invading cell by mechanisms already discussed. Antibody coating the surface of bacteria also can engage the Fc receptors on the surface of phagocytes, targeting them for engulfment and destruction. This function of antibody, known as opsonization, was likened by the Irish playwright George Bernard Shaw to putting butter on a slice of bread before eating it.³⁶ Antibody can also neutralize invaders such as viruses simply by binding them tightly and preventing their access to target cells.

Clinical Implications of Host Defenses Gone Awry

We have now outlined a series of host defense mechanisms ranging from primitive to highly developed and specific, all focused on defending the organism from invading pathogens and foreign bodies. These defense mechanisms each serve important roles in health and homeostasis. Individuals with congenital or acquired deficiencies in any of these major pathways of host defenses exhibit heightened susceptibility to different types of disease. As impaired antibody responses predispose to pyogenic bacterial diseases, consider the case of the increased incidence of pneumococcal disease in splenectomized patients. Individuals with impaired cellular immunity have difficulty eliminating viruses and intracellular bacteria, as in the case of the acquired immune deficiency syndrome (AIDS). Individuals with mutations that impair their ability to make superoxide anion show susceptibility to pyogenic infections, particularly *Staphylococcus aureus*.

Unfortunately, these powerful host defense mechanisms can cause disease when expressed inappropriately or in excess. The entire spectrum of inflammatory diseases represents host defenses gone awry. The humoral and cellular immune responses, appropriately directed

against foreign invaders, become pathological when turned against self, as in the case of the autoimmune diseases. Many autoimmune diseases cause vasculitis, placing them within the spectrum of cardiovascular diseases. Acute allograft rejection and the chronic vasculopathy often seen in transplanted organs represent another undesired consequence of the otherwise salutary host-immune response. In some cases, microbial invaders may elicit an immune response that cross-reacts with an endogenous host structure. Such antigenic mimicry may account for the association of rheumatic heart disease with streptococcal infections. Recent evidence inculcates antigenic mimicry between *Chlamydia pneumoniae* and a determinant of cardiac myosin as a mechanism of autoimmune cardiomyopathy. Cholesterol emboli may activate complement, provoking an inflammatory response with often dramatic clinical consequences.

Table 18.2 lists a number of cardiovascular conditions, some exotic but many common, that involve an important component of inflammation, representing host defense mechanisms that nonetheless can cause disease. In Part II of this essay (Chapter 27), we will consider examples of some common cardiovascular diseases that specifically illustrate this principle.

Table 18.2 Examples of Cardiovascular Diseases Involving Inflammation

Disease	Example of Inflammatory Process in Pathogenesis
Atherosclerosis	Fibroproliferation in response to macrophage-derived mediators
Unstable angina pectoris	Inflammation characterized by elevated C-reactive protein without infarction
Atheroma disruption	Macrophage-induced collagenolysis, T-cell inhibition of collagen synthesis
Vascular thrombosis	Condition favored by acute-phase reactants fibrinogen and plasminogen inhibitor
Myocardial infarction	Phagocyte ingestion of necrotic cells and subsequent tissue repair
Myocarditis	Leukocyte infiltration and cytokine activation of cardiocytes and endothelium
Abdominal aortic aneurysm	Prominent inflammation of the adventitia as well as intima-media
Cholesterol emboli syndrome	Complement activation
Cardiovascular complications of lupus erythematosus, scleroderma, rheumatoid arthritis, etc.	Vasculitis
Rheumatic heart disease	Pancarditis
Transplantation rejection	Killer T-cell-mediated myocardiocytolysis
Allograft vasculopathy	CD4-mediated fibroproliferative response to foreign antigens
"No-reflow"	Leukocyte sludging due to activated endothelium
Restenosis post-arterial intervention	Activation of vascular cells and leukocyte recruitment provoked by injury
Infective endocarditis	Complement activation by immune complexes contributes to complications

Female Hormones: The Dance of the Hormones, Part I
Bethany Hays, MD

Introduction

The health of the human organism is determined by its flexibility in responding to the environment, and by the balance between the breakdown and use of functional and structural chemicals and their replacement. This essential process is called metabolism. Response to the environment is determined primarily by 1) information obtained through the senses and mediated by the brain and hypothalamus (the adrenal side), and 2) information obtained from food or other environmental exposures and mediated by the immune system and the pancreas and liver (the insulin side). The research literature is replete with interesting examples of the interconnectedness of these functions.^{1,2,3,4,5,6,7,8,9}

Biologic function can be broadly conceptualized into reactions of approach or avoidance:

- Negative sensory information from the environment (fear, for example) leads to an avoidance reaction that involves withdrawal, contraction, and shutting down of growth and reproduction. It is mediated by the adrenal (stress adaptive) hormones, adrenaline, and cortisol. Adrenaline is primarily activating, for fight or flight; cortisol is primarily suppressive (e.g., of the immune system, of the brain as in depression, of growth as in osteoporosis).
- Positive environmental sensory information (e.g., attraction) allows for growth and reproduction and is represented by the hormone insulin, which allows

for growth and storage of energy. Insulin interacts with a number of trophic hormones (including estrogen, testosterone, DHEA, and thyroid) that balance adrenaline and cortisol in different ways. Insulin is triggered both by environmental signals (e.g., the presence of food in the GI tract) and by internal signals of glucose status.

The major hormones (adrenaline and cortisol) appear to have a critical role in maintaining life and balancing the metabolism but, by themselves, would not provide the flexibility in response to the environment that has characterized the human species. The minor hormones provide a much higher degree of flexibility. Once we have a better understanding of how these hormones “dance” with each other to balance metabolism and respond to a changing environment, we can design treatment strategies that are consistent with the body’s attempt to create longevity and avoid some of the missteps previously made with regard to hormone replacement.¹⁰

An Evolving Model of Health Care

In medicine we have traditionally diagnosed (or named) a disease and then used that diagnosis to determine a treatment that is standardized to cover the majority of people presenting with that disease. This orientation may be partly responsible for current concerns about iatrogenic morbidity and mortality.^{11,12,13,14}

The functional medicine model inverts this paradigm, placing the patient's genetic and environmental individuality as the fulcrum around which healthcare evaluation and treatment are organized. This systems biology approach allows for consideration of common mechanisms of disease across multiple systems, the importance of interactions within and between complex systems, and the role of individually variable responses. This approach supports increased personalization and precision in a patient's evaluation and care through the integration of modern genomics, proteomics, and metabolomics.

In a review article in *The New England Journal of Medicine*,¹⁵ Wylie Burke, MD, PhD, points out a number of ways in which medicine today is being transformed by the understanding of genomics and proteomics.

- Diseases are being reclassified through genomic understanding. For example, in the past, Duchenne's muscular dystrophy, Becker's muscular dystrophy, and x-linked dilated cardiomyopathy were considered distinct clinical entities, but are now being grouped as related dystrophinopathies.
- The complexity of gene-gene and gene-environment effects on disease is beginning to be appreciated at a new and deeper level. He discusses, as an example, the effect on cystic fibrosis patients of *Pseudomonas aeruginosa* interacting with the gene for mannose-binding lectin, a protein that functions in innate immune responses.
- Dr. Burke concludes: "The study of gene mutations has provided a new model of pathophysiology in which the molecular causes of disease are illuminated by genetics. Evidence is now emerging of the complex interactions between genes and between genes and the environment in the causation of many diseases, and the study of these interactions represents the next important step in genomic research."

Balance and imbalance—core concepts in functional medicine—are not precise terms. We study biochemical and physiological pathways in order to determine the mechanisms that contribute to the functionality of different organ systems. When those mechanisms do not function properly, biologic processes and pathways become dysfunctional—imbalanced. As knowledge of molecular function unfolds, it is increasingly apparent that pleiotropic effects are plentiful and, therefore, that

the common pathways leading to disease have many varied routes of expression—biochemical individuality plays a very significant role.

Hormonal balance adds yet another layer of complexity to the understanding of physiologic function and malfunction. Major hormonal pathways affect basic function and survival; the minor hormones, as noted above, provide the flexibility that underlies the unique adaptivity and creativity of humans. The interactions among hormones that respond to the basic approach/avoidance decisions of the organism help bring the complex functioning of the human body into better focus.

In order to apply the concept of genomics to the diseases primarily affected by hormonal imbalances, we first need to follow these hormone molecules through their "life cycles" to describe both balance and imbalance. We will then explore how they behave and interact to affect common conditions of hormone imbalance.

The "Life Cycle" of Estrogen

Estradiol, the primary functioning estrogen, is produced primarily in the ovarian theca cell from androgenic molecules produced in the granulosa cell during the reproductive lifetime of the ovary. After menopause, estradiol is formed in small amounts in the ovary but in larger amounts in the periphery. It is produced by aromatization of testosterone by CYP 19(arom) in the ovary and other tissues,¹⁶ or by 17 hydroxylation by EDH 17 B2 (17 β -hydroxysteroid dehydrogenase type 2) of estrone in the periphery. The presence of estrogen precursors and the presence and activity of these two enzymes determine the amount of estradiol in the cell and subsequently in the circulation. Relatively small amounts (nanograms) of estrogen compared to larger amounts (micrograms) of other steroid hormones have powerful effects, so the regulation and metabolism of estrogen is potentially much more important than other adrenal or ovarian hormones. Although the main contributor to the circulating levels of estrogen prior to menopause is the ovary, after menopause a number of sites produce estrogen,¹⁷ which can have significant local effect even if their contribution to the serum levels is small. A number of pathological tissues appear to have the ability to upregulate the production of estrogens, thereby increasing the local presence of estrogen as well.¹⁸ The two other primary forms of estrogen are

estrone and estriol. Estradiol and estrone are inter-convertible while estriol is largely a downstream metabolite and is naturally present in significant amounts only during pregnancy. The biologic potency of these estrogen forms is variable not only inherently, but also in different tissues.

Sex Hormone Binding Globulin (SHBG)

When estradiol is released into the bloodstream, it binds loosely with SHBG, which is produced in the liver. The amount of SHBG is a major determinant of the amount of free estrogen and testosterone (which also binds to SHBG), and can therefore be a major determinant in the availability of these steroids and their effects on target tissues. Polymorphisms of the gene producing SHBG have been identified; they can significantly affect the amount of circulating estradiol.¹⁹ SHBG production in the liver also responds to the amount of estrogen and testosterone circulating through the liver, with higher levels of estrogen and lower levels of testosterone increasing the production.

Estrogen Receptors

Estrogens and estrogen-like molecules function via transcription-regulating nuclear proteins called receptors. In the case of estrogen, the receptors are activated by the ligand (estrogen), forming dimers.²⁰ The estrogen receptor is now known to exist in at least two forms. The second estrogen receptor, designated “ β ,” has been shown to interact in some cells with the original estrogen receptor (now designated “ α ”) to form heterodimers. Thus, homodimers of alpha or beta receptors, heterodimers (one each of alpha and beta), and their ligands (estrogens and estrogen-like chemicals, those containing a phenolated A ring) eventually find their seat on the estrogen response elements (ERs) of the DNA, after interacting with heat shock proteins in the cytoplasm and regulatory proteins in the nucleus. It is thought that the different homodimers or the heterodimers, or perhaps cytoplasmic co-regulating proteins determine which ERs will be triggered in a given tissue.²¹ Certain tissues contain higher numbers of α or β receptors. Breast, endometrium, and ovarian stroma are α -receptor-rich tissues, whereas brain, bone, intestinal mucosa endothelium, and prostate are β -receptor-rich tissues.²² Thus, an estrogen receptor alpha homodimer found in breast or endometrium will initiate cell divi-

sion, whereas an estrogen receptor beta homodimer in bone may inhibit osteoclastic cell activity.

In this way an estrogenic chemical can act as a stimulant or agonist in one tissue and as a depressant or antagonist in another. In the classic estrogen-sensitive tissues, breast and endometrium, DNA transcription of ERs codes for activities primarily related to cell division. Therefore, estrogen is a trophic or growth-producing hormone in these tissues. In other tissues such as bone, liver, endothelium, skin, and brain, alpha and beta receptor homodimers and heterodimers can have either an agonist or antagonist effect, allowing estrogen to act as either a growth stimulant or a suppressor of growth.

There are many chemical ligands to these estrogen receptors (called selective estrogen receptor modulators or SERMs) that occur in both natural and pharmaceutical forms. They may function through different interactions with the alpha- and beta-receptors forming different homo- and heterodimers. The ultimate effect in a given cell is the integration of the number and ratio of homo- and heterodimers formed, as well as the affinity of the estrogen or estrogen-like chemical for the α - or β -receptor. For instance, estrone has a higher affinity for the ER- α . This would suggest that it would be more active in breast, endometrium, and ovary, where it would have cell growth-stimulating effects (less desirable in menopause and postmenopause), and less active in the ER- β containing tissues like brain, bone, and endothelium. These latter organs (brain, bone, and endothelium) are often the targets of menopausal hormone replacement and would require much higher doses of estrone to have the desired effect. This understanding provides part of a rationale for administering estradiol as a replacement hormone rather than CEE (conjugated equine estrogens), estrone, or estrone-containing combinations.

The type and number of estrogen receptors are induced by the presence of estrogen²³ and certain estrogen-like molecules such as tamoxifen,²⁴ and are down-regulated by progesterone via the progesterone receptor. Thus, in tissues such as the endometrium, estrogen receptors are seen in high numbers in the follicular (estrogen) phase of the menstrual cycle and are low or absent in the late luteal phase after progesterone receptors appear. In other tissues, such as breast, progesterone receptors are expressed throughout the menstrual cycle, potentially functioning to suppress estrogen receptors and suggesting that the two tissues may respond differently to progesterone stimulation. They

may also respond differently in the postmenopausal state than in the premenopausal state. Clinical and epidemiological data support this hypothesis.^{25,26,27,28,29,30}

For many years it was thought that estrogen only functioned through the estrogen receptor, one of a family of nuclear receptors that activate estrogen response elements on DNA. More recent research shows that the transcription of many genes is modulated by estrogen. Microarray studies showed that estrogen affects hundreds of genes in diverse cell lines and tissues. (Nearly four hundred human genes are listed in the ERGD—the Estrogen Responsive Genes Database.³¹) The gene expression profiles change in various developmental stages and disease states. In fact, a gene's responses to estrogen are dependent on many factors, including the available subtype of ER, the co-regulators, the estrogen exposure time, and the amount of estrogen. It is now known however, that estrogen has non-genomic actions on cells as well. These estrogen responses are thought to be mediated through cell membrane receptors because their rapid effects could not occur if mediated by the slower process of gene transcription.³² Examples are the effect of estrogen on NO (nitric oxide) production, and certain functions of estrogen in the brain and pancreatic insulin cells.

Estrogen Metabolism and Phase I Detoxification

Once the estrogen molecule has engaged with the cell, it must be inactivated and excreted in order for the feedback mechanisms that control its action to function normally. In other words, for a hormone to “dance” with other hormones, it must have a flexible response pattern—i.e., be able to increase and decrease rapidly. If functioning estrogens build up in the system, the delicate ebb and flow of hormones is impaired; the resulting imbalance then affects monthly cycling, pregnancy, and lactation. Following menopause, the dance of hormones continues, but to different ends—prolonging life and supporting structural, cardiac, and neurological function. Healthy hormonal balance post menopause still requires that the levels of hormone be tightly regulated, with rapid and effective disposal of used and unnecessary estrogens.

The estrogen molecule is disposed of by the same cytochrome P450 enzyme system that is used to eliminate drugs, toxins from the environment, and biologically active or unwanted food substances. This, in combination with the very small number of estrogen

molecules needed to have full estrogenization, suggests that the body views estrogen as a potentially dangerous toxin, unlike DHEA or progesterone. Emerging research is beginning to explore which estrogenic compounds and metabolites actually create the greatest risk.^{33,34}

Estrogen has three major phase I detoxification fates: CYP 1A1 primarily converts estrogens to 2-OH estrogens; CYP 1B1 primarily converts estrogen to 4-OH estrogens; and enzymes of the CYP 2C family and 3A4³⁵ convert estrogen to 16-OH estrogens.^{36,37,38,39} These three oxidized molecules have the same dangerous potential as other phase I detoxification by-products since they are reactive or “sticky” molecules. They must therefore be rapidly detoxified using a number of phase II pathways. Because of the large number of P450 SNPs (single nucleotide polymorphisms), there is great variation in the human population. The resultant diversity of intermediate metabolic end products and the proportions among 2-, 4-, and 16-OH estrogens have been shown to have potential in predicting the risk of estrogen-related diseases such as breast, uterine, and prostate cancer.^{40,41,42,43,44}

Some of these SNPs are potentially modified by the environment. The activity of CYP 1A1, for instance, can be upregulated by the glucosinolates (such as indol-3-carbinol) in *Brassica* vegetables.⁴⁵ This upregulation increases the precursor for a powerful anti-estrogen, 2-methoxyestrone.⁴⁶ Conversely, the activity of CYP 1B1 is responsible for the production of 4-OH estrogens, which can be rapidly converted to DNA-damaging quinones.⁴⁷ CYP 1B1 can be up- and downregulated by a number of drugs, by lifestyle factors such as avoidance of polycyclic aromatic hydrocarbons,⁴⁸ and by herbs (ginseng, an inhibitor⁴⁹). CYP 2C and CYP 3A4 convert estrogen to 16-OH estrogen, considered to be a stronger estrogen than estradiol. The integrated effects of the biotransformation of estrogens by these P450 enzymes can be followed by assaying for 2-OH, 4-OH, and 16-OH estrogens.

Estrogen and Phase II Detoxification

Each of these phase I products must be further detoxified by phase II reactions using molecules such as methyl groups, sulfate groups, or glucuronides. The resulting phase II products are then water soluble, non-reacting, and do not have the hormonal effect of their parent molecules. As water-soluble molecules, they can be excreted in bile (primarily) or in the urine.

Sulfation: the circulating pool of estrogen. Sulfated-estrogen hormones act as another pool of estro-

gens; removal of the sulfate molecule by sulfotransferase (SULT) enzymes (also called EST or estrogen sulfotransferase)⁵⁰ activates estrogen. Remember that very small amounts of estrogen appear to have large effects and that estrogen is viewed by the body as a toxin. Free estradiol is kept in the ng/dL range as compared with the much higher amounts of testosterone, DHEA, and progesterone. The large pool of available SHBG-bound estrogens suggests, however, that need for estrogen can increase and decrease rapidly. Sulfation is a potentially important modulator of estrogen effect.

Methylation. Methylation capability is important in several ways relevant to women's health and is intimately tied to estrogen metabolism in the phase II detoxification of estrogens. Perhaps the most important effect of methylation in estrogen metabolism is the production of 2-methoxyestrone in the liver. 2-methoxyestrogens appear to provide protection from other more dangerous estrogen metabolites (e.g., 4- and 16-OH estrogens)⁵¹ and are being studied as therapeutic interventions for breast cancer. Methylation adequacy can be evaluated by testing for serum homocysteine and serum or urinary methylmalonic acid. Corrective action, using appropriate doses of specific B vitamins, can be assessed by the results of these tests.

Glucuronidation. Glucuronidation of estrogens occurs through the action of UDP-glucuronosyltransferase (UGT).⁵² Once the molecule is glucuronidated, it passes into the gut through the bile. In the presence of imbalanced bacteria producing excessive β -glucuronidase, the glucuronide molecule is stripped off and the estrogen reabsorbed; this process is called enterohepatic recirculation. This repeated circulation of estrogen through the liver may be a potent stimulation for production in the liver of estrogen-induced proteins such as SHBG and clotting factors. Symbiotic bacteria and adequate fiber, as well as D-glucarate, will improve glucuronidation and excretion of estrogens.⁵³

The "Life Cycle" of Progesterone

Progesterone is a 21-carbon steroid and an early precursor molecule in the adrenal and ovarian steroid cascades. As such, it can be converted into estrogen, cortisol, aldosterone, and testosterone in different tissues. In physiological doses this multi-pathway metabolism seems to protect the patient from overexpression of any one end product and contributes to the low side-

effect profile of progesterone. Progesterone is produced in the adrenals in small amounts throughout life, in large amounts in the ovary following ovulation and formation of the corpus luteum, and in massive amounts by the placenta during pregnancy.

Progesterone has numerous functions, including downregulation of the estrogen receptor, inhibition of estrogen transcription activation at the DNA level, and effects on cellular adhesion, on local estrogen metabolism (such as the induction of enzymes converting E2→E1), and on sulfation.

Progesterone has been shown to stimulate cell cycle turnover in a way additive to estrogen in normal breast tissue. In a study by Soderqvist⁵⁴ of normal breast tissue (biopsy of normal volunteers without any evidence of disease or pathology) in women with hormonally proven ovulation, some women had enhanced response to progesterone and some had a paradoxical decrease in mitotic activity. The authors allude to the possibility of regional differences in response as well as mechanisms that may affect the relative risk (RR) of cancer stimulation in these women. Pike, in a review of estrogen/progestogen effects on breast cancer incidence, notes that cancer cells and pre-cancerous cells may respond differently to a particular hormonal milieu.⁵⁵ Therefore it is simplistic to say that progesterone either prevents or encourages breast cancers.

Hans Selye in the 1940s discovered that progesterone and some of its metabolites have profound anesthetic properties. These effects are thought to be primarily due to alpha 3,5-dihydroprogesterone's (allopregnanolone) actions on the GABA receptor in the brain.^{56,57,58,59} These effects are so rapid (minutes) that it is unlikely they are mediated via progesterone receptor transcriptional activity. Rather, they act at a site close to or identical to that of barbiturate action. Metabolism of these brain-active chemical metabolites occurs primarily in the liver. Therefore, when progesterone is administered orally, especially in high doses, significant CNS effect can be expected in some patients.

Oral routes of administration of bioidentical progesterone have a rapid intrahepatic metabolism and short serum half-life, complicating the pharmacodynamics of treating with progesterone.⁶⁰ Transdermal preparations have been shown in most studies to attain inadequate levels to create luteal-phase effects, and levels of hormone in the serum vary depending upon the preparation used.⁶¹ Apparently because of selective secretion in

saliva, much higher levels can be obtained in the saliva when progesterone is given transdermally rather than orally. Transdermal progesterone can deposit in the subcutaneous fat, and this can be a problem for premenopausal women who need both high luteal-phase levels to create the secretory changes in the endometrium and the rapid decline in hormone level leading to breakdown of the endometrial lining and menstruation. Transvaginal progesterone, on the other hand, has been shown to have a “first pass” effect in the uterus, perhaps explaining the apparent protection of the endometrial lining from overgrowth despite low serum levels of progesterone.⁶²

These issues make the decision about progesterone therapy complex. Like estrogen, some of the metabolites of progesterone are more potent in certain tissues than the parent hormone. Progesterone is bound in the circulation primarily by albumin and, therefore, testosterone and estrogen levels do not determine the amount of free progesterone available to distant tissues, as they do for each other through their effect on SHBG.

Progesterone Receptors

Progesterone functions through nuclear receptors that trigger DNA transcription in a manner similar to estrogen's interaction with estrogen nuclear receptors. Like estrogen, progesterone functions differently in different tissues. In the endometrium, progesterone induces secretory activity and apoptosis, leading to breakdown of the endometrium upon withdrawal. In the breast, progesterone has been shown in *in vitro* cellular experiments to induce cell cycling followed by growth inhibition and cellular differentiation.^{63,64}

The “Life Cycle” of Testosterone

Testosterone is a 19-carbon steroid formed by hydroxylation of androstenedione in the testes, the ovaries, or the adrenal glands. Testosterone is the *life-force hormone*. In both men and women it is a primary source of libido and it is associated with aggressive behavior. Although males and females start life with low levels of both estrogen and testosterone, at puberty they differentiate so that women have more estrogen and men have more testosterone. Androgens such as DHEA, androstenedione, and testosterone decline slowly over time, in both men and women.^{65,66} After menopause, estrogen levels in women fall significantly,

while testosterone levels continue their slow decline with age, leaving women relatively testosterone dominant after menopause. Men's testosterone levels also fall, eventually leaving them relatively more estrogen dominant and, in fact, with higher estrogen levels than women of the same age after mid-life, creating what some have suggested is a kind of androgynous de-differentiation of the sexes in old age.⁶⁷

Testosterone is secreted in men and women in a diurnal pattern with peak output in the early morning. In women, however, testosterone is also secreted in “surges” around the time of ovulation (related to the midcycle increase in production of both estrogen and testosterone) and just before the menses (due to increased production of androstenedione from the corpus luteum⁶⁸), correlating well with women's reported increased interest in initiating sex and fantasizing at these times. These differences should be taken into account when prescribing hormone replacement with an intention to increase libido.

Where do Postmenopausal Hormones Come From?

Based on use of dexamethasone suppression, ACTH, and HCG stimulation to separate out the adrenal from ovarian contributions to circulating hormone levels, it is thought that most of the estrogen in plasma post menopause comes from adrenal precursors that are aromatized in extra-ovarian locations. Progesterone and 17-OH progesterone appear to have an almost exclusively adrenal origin following menopause. In fact, the ovaries and the adrenals should be considered together in most situations, as estrogen feedback may actually occur through the effect of estrogen on hypothalamic CRF-producing cells.⁶⁹ DHEA is primarily adrenal in origin, but the fact that even lower levels are seen in oophorectomized women suggests a small but significant ovarian contribution. Testosterone, DHT, and androstenedione appear to be produced in both adrenals and in the postmenopausal ovary.⁷⁰

The Pathway from Hormonal Balance to Imbalance

As more detailed understanding of hormonal function emerges, the importance of genetic uniqueness and complex interactions between hormones and between

the hormonal system and the environment becomes evident. The delicate balance among these hormones may tip into imbalance in any number of ways. However, the approach described by the functional medicine web will allow the clinician to dissect these complexities and formulate appropriate therapeutic approaches.

Immune System Modulation of Hormonal Balance

The intimate interconnections between the immune system and the endocrine system have led some to call the immune system the migratory or “portable” endocrine system.⁷¹ It seems appropriate that the hormones intimately associated with reproduction in women would integrate with the immune system, enhancing allograft tolerance required for full fetal gestation to occur during a pregnancy. Postpartum, the complex interaction between the mother’s immune system and her child’s during breastfeeding protects mother and child from infection.

The effect of estrogen on the immune system is likely involved in the modulation of inflammation-based diseases such as cardiovascular disease, osteoporosis, and Alzheimer’s, which increase with the drop in estrogen seen in the postmenopause period.

“During reproductive years females tend to have a more vigorous immune response: higher immunoglobulin concentrations, stronger primary and secondary responses, increased resistance to the induction of immunological tolerance and a greater ability to reject tumors and homografts.”⁷² Changes in resistance to infection, immune response, hormone levels and genetics may affect a variety of diseases in women. Levels of estrogen before and after menopause and levels of estradiol and progesterone during pregnancy appear to affect autoimmune diseases. For instance, the augmented Th1 response during the reproductive years may explain the increased incidence but decreased severity of autoimmune diseases such as MS in women. However, hormonal changes coincident with pregnancy modulate improvement in the Th1-associated autoimmune diseases, when the Th1 and Th2 systems alternate dominance and become more “cooperative.”⁷³ Due to the biphasic response of the immune system to estrogen, women during their reproductive years are more likely to mount a Th1 response to an infection or antigen, except during pregnancy.⁷⁴ This may explain the feeling of many women that their symptoms and signs associated with Th2 disorders began with a pregnancy.

A 2004 review reported that “the Th1/Th2 balance may affect the susceptibility to or the course of infections as well as autoimmune and atopic/allergic diseases.”⁷⁵

Thus, pregnancy appears to represent a unique situation for the immune system, switching from a Th1-dominant environment to an often Th2-dominant environment. Although it has been almost universally held that pregnancy is a “high estrogen state,” it is in fact a time when ovarian production of hormones is suppressed and placental production of estrogens, primarily estradiol, and progesterone is high. Estradiol may block the effects of estradiol on the mother’s immune system, just as it blocks the negative effects of estrogen for the fetus. Progesterone has been shown to stimulate the Th2 system, which is responsible for activating B-cells and downregulating Th1. However, recent analyses of this situation have suggested that the Th1/Th2 story may be an oversimplification, and further research is needed.⁷⁶

The Crosstalk of Other Hormones

Estrogen receptors are phosphoproteins; this means their function can be altered by changes in phosphorylation initiated by protein kinases. Substances such as growth factors activate the kinases and can therefore initiate transcription of ER-responsive genes without the presence of estrogens.⁷⁷ This “crosstalk” has been shown to take place *in vitro* between estrogen signaling pathways and dopamine, epidermal growth factor, transforming growth factor- α , insulin or IGF-1, and cyclic AMP.⁷⁸ Progesterone has been shown to upregulate this crosstalk.⁷⁹ This research suggests possibilities for the stimulation of ER-negative breast cancer cells and a mechanism for the increased incidence of breast cancer seen in the Women’s Health Initiative and other studies in women on progestogens. It also suggests one possible mechanism for the increased incidence of breast cancer in women with insulin resistance and diabetes and provides some logic to the recommendation to avoid milk products (a high source of IGF-1) in cases of breast cancer.⁸⁰

Progesterone vs. Progestins

Considerable differences exist between isomolecular *progesterone* and synthetic *progestins*. In the U.S., because most therapeutic regimens include progestins, studies in the literature must be carefully scrutinized to determine

whether the *progestogen* (the term used to describe both) is (isomolecular) progesterone or a synthetic progestin.

Progesterone also plays a role in the metabolism of estrogens. Increased progesterone increases sulfatase activity, which increases free estrogen levels. Artificial progestins do not all have similar effects. Norethisterone has no effect on sulfatase activity and 19-nor-progestins such as NETA decrease sulfatase.⁸¹ Progesterone decreases conversion of E1→E2 via 17-hydroxysteroid dehydrogenase (HSD) but does not affect aromatase activity.

Although man-made progestins clearly have a progesterone-like effect on the endometrium, are better absorbed by mouth, and have a longer half-life (with good clinical correlates such as the reversal of the incidence of estrogen-induced cancers of the endometrium virtually to the level of the placebo⁸²), newer information suggests that the previous assumption that they also have the same beneficial profile in breast, blood vessels, and brain was probably a mistake. From the work of Clarkson et al.⁸³ in cynomolgus monkeys, and supported by data from the PEPI trial (one of the few randomized studies in which isomolecular progesterone was compared to progestins), we know that medroxyprogesterone acetate (MPA) markedly attenuates the beneficial effects of estrogens on blood vessel-dilating effects, as well as the accumulation of collagen in diet-induced atherosclerotic plaques. They also showed that MPA increased insulin resistance. In this setting, therefore, progestins would be expected to increase the risk of coronary events and breast cancer risk seen in insulin resistance. It is not known how natural progesterone or cycling of progesterone will compare.

Progesterone has been hypothesized to be both a preventive and a priming factor in breast cancer progression. Progesterone induces apoptosis and cell differentiation, but it also promotes a switch (cross-talk) from growth driven by steroid hormones to growth driven by peptide growth factors. These two conflicting actions on the breast cell might be projected to produce two different populations. For one, progesterone would be preventive; for the other, it might induce breast cancer. It is likely that pre- and postmenopausal women represent these two populations.

It is difficult if not impossible to mimic the ovarian production of progesterone therapeutically. Because of the difficulties of formulating a well-absorbed bioidentical hormone (until the development of micronized progesterone), oral progestins were substituted for

progesterone in most of the studies done on hormone replacement, including the largest RCT, the Women's Health Initiative. As stated before, a great deal of confusion exists in the literature because progestins have often been substituted in research studies for progesterone, on the assumption that they would function the same, without clarification of the substitution. So, bio-identical progesterone is often credited with producing symptoms and risks that actually are only seen with artificial progestins. Artificial progestins have numerous side effects (mood alterations, headaches, breast tenderness, and bloating⁸⁴) not seen as often with bioidentical progesterone, and they fail to provide some of the downstream metabolites of progesterone such as the brain active steroid allopregnanolone, a known GABA receptor agonist.⁸⁵ How to formulate a clear therapeutic plan in the face of this often contradictory information is addressed in Chapter 32.

Sex Hormone Binding Globulin and Testosterone

Decreased SHBG levels are often seen in cases of hirsutism, acne vulgaris, and polycystic ovary syndrome, due to relative increases in testosterone. SHBG levels may be modestly reduced in hypothyroidism, acromegaly, Cushing's disease, obesity, and hyperprolactinemia. Growth hormone decreases SHBG. Increased SHBG is seen in hyperthyroidism, cirrhosis of the liver, estrogen dominance or low progesterone, and during pregnancy and hormone therapy. Much of the interaction between hormones is mediated by these binding globulins; therefore, therapies that affect SHBG levels should be undertaken with caution if the release or binding of free estrogen or testosterone is not an intended outcome. SHBG levels can also be used as a marker for the total amount of estrogen and testosterone traversing the liver (high levels suggest estrogen dominance and low levels suggest an increased testosterone-to-estrogen ratio). SHBG levels can also help in the estimation of the total estrogen burden when testosterone levels are normal.

"There are no agreed upon definitions of androgen deficiency in women, nor is there a clear-cut parameter, such as free testosterone level, with an accepted limit below which biochemical testosterone deficiency can be diagnosed," according to Dr. Susan Davis of Victoria, Australia.⁸⁶ According to some, the effect of testosterone in women is primarily mediated by its ability to lower SHBG, thereby increasing the levels of free estrogen. Since levels of testosterone have a positive correlation

with breast cancer,^{87,88} careful consideration of the benefits of the therapy is prudent before prescribing testosterone as a first line approach when women complain of decreased libido.

Low levels of testosterone should be considered in women who have undergone surgical menopause or loss of ovarian function secondary to radiation or chemotherapy, autoimmune destruction of the ovary, and in women on birth control pills, as they suppress both estrogen and testosterone from the ovary and LH from the pituitary, which reduces the stimulus for ovarian stromal production of testosterone.⁸⁹ In any event, testosterone is unlikely to have much effect on libido without “priming” by estrogen, which often solves the problem by itself.

Clearly, in some postmenopausal women on HRT the addition of testosterone has an improved effect over estrogen alone.⁹⁰ The most important role of testosterone in normal hormone function post menopause may well be its effect on relative estrogen levels. The lower levels but higher ratios of testosterone to estrogen in postmenopausal women decrease SHBG, making estrogen more available and thereby keeping the low levels of estrogens more clinically functional for longer in tissues. Glucocorticoids, growth hormone, and insulin also lower SHBG, increasing available estrogen as well as testosterone. Conversely, hormones that raise SHBG (such as thyroxine and oral estrogens) may decrease available testosterone and should be evaluated as part of the complex interrelationship of hormones before simply adding exogenous testosterone.

Testosterone is also metabolized to estrogen in peripheral tissues through the aromatase enzyme pathways in skin, bone, and brain, making estrogen available to these tissues locally without raising blood levels of estrogen. This may be particularly important in the case of bone metabolism, where testosterone may not only stimulate osteoblastic bone building but increase the estrogen inhibition of osteoclastic reabsorption.

Detoxification and Biotransformation Interactions

Sulfation of estrogens and other steroid hormones provides a second pool of circulating estrogens, making them available to tissues with sulfatase capability. Patients with inadequate dietary sulfate and those with sulfation defects may have smaller circulating levels of estrogen with higher levels of free estradiol. Supplying

sulfate groups as NaSO₄ by oral supplementation may improve estrogen metabolism for these individuals.

Tissues with high levels of sulfatase may have elevated estrogen effects in the presence of normal blood levels of estrogen. It has been demonstrated that various progestins (promegestone, nomegestrol acetate, medrogestone, dydrogesterone, norelgestromin), tibolone and its metabolites, as well as other steroidal (e.g., sulfamates) and non-steroidal compounds, are potent sulfatase inhibitors. In other studies, it has been shown that medrogestone, nomegestrol acetate, promegestone or tibolone can stimulate the sulfotransferase activity for the local production of estrogen sulfates, leading to significant reduction in free estrogens. The integrated effect, as postulated, would lower estrogen stimulation. This has led to the concept of selective estrogen enzyme modulators (SEEMs) of the intracrine production of estrogens in breast cancer cells⁹¹ and may explain the beneficial effect of using high-dose progestins in breast cancer.

Methylation capability is critical to catechol metabolism of dopamine, epinephrine, and norepinephrine and therefore may have effects on the incidence of depression, the interaction of estrogen and adrenaline, and the incidence of hot flashes mediated by norepinephrine in the hypothalamus. It is also clearly related to dopamine-mediated diseases such as Parkinson's.

Environmental and Nutritional Modulation of Hormonal Balance

A large body of evidence is accumulating that examines the role of xenobiotics on hormonal function through a variety of mechanisms. These substances have a phenolic A ring, similar to estradiol, that is able to interact with the ligand-binding site of the estrogen receptor.⁹² To date, identified effects include alteration in the cytochrome P450 family of detoxification and biotransformation enzymes, agonist or antagonist effect to native hormones via receptor mechanisms, altered transcription of nuclear receptors through protease-mediated degradation, inhibitors of histone deacetylase activity, and altered DNA methylation.^{93,94,95,96} Direct, non-receptor-mediated inhibition of estrogen sulfotransferases by xenobiotics has also been described.⁹⁷

Nutritional deficiencies from inadequate intake or depletions induced by excess oxidative stress also constitute an important pathway for imbalances to develop.

For instance, zinc deficiency, which is one of the most pervasive nutrient deficiencies in industrialized societies, may have significant impact on steroid hormone function since the steroid nuclear receptors are zinc finger proteins that require zinc binding for proper function.⁹⁸ An example of induced depletion is that of B12 by xenobiotic epoxides; protection from this depletion may be provided by adequate glutathione stores.⁹⁹

In Chapter 32, we will look at specific clinical correlates, emphasizing the web of interconnectedness in the dance of hormones and the challenges of clinical decision making based on multiple dynamically interacting variables.

Hormones and Breast Cancer

Estrogen and Breast Cancer

There has been ongoing debate between the advocates and opponents of postmenopausal hormone replacement because of the effects of estrogen and, more recently, progestogens on breast cancer incidence and cause.¹⁰⁰ It is difficult to determine how much of the literature is unbiased and how much is influenced by the “stakeholders.” The pharmaceutical industry appears to hold the purse strings on much of medical research, both epidemiologic and basic science.^{101,102}

It has been said that the fact that endometrial cancer has a dose-response relationship to estrogen, whereas the dose-response relationship between estrogen and breast cancer does not appear to be as clear, suggests that the effect of estrogen on breast cancer is not a direct causal relationship.¹⁰³ However, the presence of estrogen clearly increases the incidence of breast cancer, and there may be a time-related effect with long exposures enhancing the risk.^{104,105} According to the Women’s Health Initiative, the relative risk of cancer in women taking at least one form of hormone therapy (Prempro®) is 1.29, a non-statistically significant increase in the WHI, as the confidence interval (CI) included 1. However, this number is very close to a number of other studies, some of which did show statistical significance.^{106,107} Furthermore, the rate of intralobular cancer has increased while the rate of intraductal cancer has remained stable from 1974 to 1998. Intralobular cancer is more associated with combination HRT, even though it has a more favorable outcome, because a majority of the tumors are estrogen sensitive.¹⁰⁸

Various genes of high and low penetrance are associated with increased or decreased incidence of breast cancer.¹⁰⁹

- High-penetrance/low-frequency genes, such as BRCA1, BRCA 2, p53, PTEN, and LKB1, confer a high risk of breast cancer but do not make up the majority of cases of cancer in women since they are low frequency in the population, making up less than 10% of breast cancers.
- Low-penetrance/high-frequency genes, such as those coding for the CYP enzymes involved in both production and metabolism of estrogen, are less potent, increasing an individual woman’s risk of cancer only slightly; however, they are probably involved in the majority of cancers.¹¹⁰
 1. 4-OH estrogens have been shown to create DNA-damaging quinones, and they may be a significant breast cancer risk factor in women bearing an upregulated polymorphism of the CYP 1B1 enzyme (research results have been mixed).^{111,112,113,114} The increased risk of breast cancer caused by estrogens is likely to be mediated through the stimulation of cell cycle turnover of DNA-damaged cells. Thus, estrogen can increase 4-OH metabolite damage to DNA, but the primary contribution to breast cancer is the increase in the growth, immortalization, and failure of apoptosis of breast cancer cells.
 2. CYP 1A1 can be upregulated by environmental toxins and result in a modest increase in some women.¹¹⁵
 3. One polymorphism of 2D6 (poor metabolizers) has been associated with an increased risk of breast cancer.¹¹⁶
 4. Polymorphisms for CYP 19 (aromatase) have been shown in some cases to increase risk.¹¹⁷
- Phase II detoxification is also important genetically. The following genes for phase II conjugation have significant effect on hormone function:
 1. Glutathione transferase polymorphisms coding for major detoxification and antioxidation pathways are associated with increased breast cancer risk.^{118,119,120}
 2. Polymorphisms for methylation (MTHFR and COMT) have been discussed elsewhere and are also associated with increased risk.^{121,122}

3. Polymorphisms of sulfotransferase (SULT 1A1) have also been implicated in increased risk of bioactivation of both estrogen metabolites and xenobiotics.^{123,124}
4. 17OH steroid dehydrogenase and upregulation of aromatase are also implicated.
- DNA repair genes such as XRCC1 399Q increase risk in African American women. Other XRCC variants are also associated with risk.¹²⁵
- Genes associated with ER and PR receptors can affect breast cancer risk.^{126,127}
- Polymorphisms for heat shock proteins (HSP70) and cytokines (TNF- α) may also confer risk.¹²⁸

Progesterone and Breast Cancer

It was long held that because progestins protected the endometrium they must also protect the breast. Studies of cell division, however, showed a very different pattern of response in the breast as compared to the endometrium, with increased cell division during the luteal phase in breast tissue. The Women's Health Initiative (WHI) findings initially showed a statistically non-significant increase in breast cancer (RR 1.29; CI 1.0-1.59) that was not seen in the subsequent study of women on estrogens alone, where the RR was .71 (CI 0.59-1.01). This research is often used to suggest that progestins increase the risk of breast cancer and therefore should not be used postmenopausally when the uterus is not present. Interpretations of this apparent difference between progestin-treated and non-treated women do not take into account the possibility of different levels of estrogen in these two groups.

The recent publication of the WHI,¹²⁹ with its subpopulation of women who (because of prior hysterectomy) were not given progestins, suggests a considerable difference in the incidence of breast cancer between these two groups. It should be remembered, however, that estrogen levels between these two groups were not measured and were possibly different. Half of women who undergo hysterectomy have also had bilateral oophorectomy, and would therefore be expected to have lower levels of both estrogen and testosterone.¹³⁰ Estrogen levels were not measured in either arm of the WHI.¹³¹

Because of the conflicting information regarding the culpability of progesterone or progestins in the causation of breast cancer, it *should not* be used therapeutically in a cavalier fashion. It is likely, however, that progesterone has a protective effect in premenopausal

women as the cyclic production of progesterone from the corpus luteum also induces differentiation and apoptosis, thereby maintaining the positive effects of estrogens (the maintenance of type III lobules which are less cancer prone) on the amount of at-risk tissue.¹³² In postmenopausal women progesterone may have very different effects, especially when applied in high doses.¹³³

Insulin and Glucose Metabolism and Breast Cancer

Finally, another piece of the puzzle falls into place when we begin to consider the interrelationship of women's hormones with insulin and glucose metabolism. Women's hormones affect the ability of women to find and store energy (glucose) for pregnancy. In an environment of excess calories, particularly of low quality, this ability turns lethal. High glycemic-index foods increase insulin requirements, ultimately leading to insulin resistance and elevated insulin levels. Hyperinsulinemia has been shown to be a marker of increased risk of breast cancer.¹³⁴ Further supporting the interrelationship between ovarian/adrenal steroids and carbohydrate metabolism is the finding that progesterone primes the breast cell for "cross-talk" with so-called secondary hormonal factors such as the peptide growth factors.¹³⁵ Insulin, EGF, and IGF-1 may be among these growth factors.

Progestins and, to a lesser extent, progesterone induce insulin receptors, one of the protein kinase cell surface receptors that are mitogenic. While this may improve the functioning of insulin, it may also increase the mitogenic stimulation of insulin. Progestogens are also thought to increase insulin resistance, however. Progestogens also downregulate IGF-1 receptors via induction of IGF-2.¹³⁶ This may be important in the evolution of estrogen receptor-negative tumors.¹³⁷

Obesity in the premenopausal woman often indicates insulin resistance, which can lead to anovulation and polycystic ovary syndrome (PCOS).^{138,139,140} Concomitantly, there is a higher ovarian production of estrogen, making the relative contribution of fat estrogens unimportant, but lower levels of progesterone, decreasing breast cell cross-talk with IGF and insulin. In the postmenopausal period, however, the obese woman has significantly more estrogen from fat production than the non-obese woman and, in addition, has insulin resistance, increasing the production of peptide

growth factors. These findings and this model of hormone fluctuations may help explain why premenopausal obesity is associated with decreased risk of breast cancer, whereas postmenopausal obesity is linked with a higher risk of breast cancer. When progestins are added in the postmenopausal woman, an even higher risk of breast cancer is the result. However, contradicting this theory is the finding that CEE and MPA increase the risk of breast cancer only in women who are not obese.^{141,142} These relationships are complex and subgroup analysis in some of the large randomized studies will have to be done before these interrelationships are clear.

Cortisol and breast cancer. The clinical supposition that women under more stress are at greater risk for cancer has been borne out by research that shows an association between abnormal adrenal function and breast cancer. Sephton et al. found that survival was diminished in women who had flattening of the diurnal rhythm of cortisol production.¹⁴³ Therefore, attention to adrenal stress is important in the outcomes of patients with breast cancer.

Table 19.1 provides a summary of breast cancer risk factors, along with an estimation of the magnitude of risk for each one, reprinted with permission from a 2005 review of the evidence.

Hormones and Heart Disease

Estrogen and NO Production

Estrogen has been shown to rapidly increase production of NO by the endothelial cell in an estrogen receptor-mediated action that is not arbitrated by the intranuclear receptor.¹⁴⁴ Because of its rapid effects, it has been suggested that placing an estrogen patch at the first sign of a heart attack or stroke might be a life-saving therapy for women. However, the induction in the liver of clotting factors might complicate the course of vessel occlusion unless prompt anti-coagulation was undertaken simultaneously and perhaps unless the genetics of the individual for clotting functions was known. In any event, this is not considered standard of care for women suffering symptoms of heart attack or stroke, although it holds some potential for the future. Administering estrogen to males was counterproductive in the same setting. There are other beneficial effects of estrogen on the initiation and progression of cardiovascular disease. Estrogen is known to have beneficial

effects on LDL and HDL cholesterol but negative effects on triglycerides. Vascular responsiveness to estrogen appears to diminish after 10–12 years post menopause, as estrogen levels decline, and it is not clear whether it can be restored.¹⁴⁵ This effect of estrogen on NO and vasomotor stability has direct implication for hot flashes, sublingual estrogen having been shown to rapidly stabilize the vascular response to a hot flash,¹⁴⁶ and may be related to the disappearance of hot flashes after around age 60 in most women.

There is also evidence that estradiol decreases angiotensin II-induced free radical production and that it acts to upregulate manganese superoxide dismutase (SOD) and extracellular SOD in monocytes.¹⁴⁷

Postmenopausal hormone replacement, especially via oral administration, has been shown by the Women's Health Initiative to have profoundly negative effects on the incidence of clotting, PE, heart attack and stroke.¹⁴⁸ These effects appear to be largely mediated through upregulation of the liver's production of clotting factors especially in the subset of genetically susceptible populations. Final conclusions about the cardiovascular net relative risks and benefits of estrogen in the postmenopausal woman remain to be elucidated.

The Brain and Estrogen: Depression, Anxiety, and Hot Flashes

Brain symptoms and preservation of brain function are the two most important aspects of estrogen therapy faced by the discerning practitioner. The brain symptoms that most often lead a woman to consult her practitioner and cause the practitioner to consider hormone therapy are hot flashes and depression. Hot flashes, a brain symptom caused by dysregulation of the hypothalamic temperature control mechanism, are the most troublesome symptoms of mid-life women and the ones most likely, along with the insomnia that often accompanies them, to lead women to abandon their fears of breast cancer and choose to take hormone therapy. Hot flashes are also linked to depression in postmenopausal women.¹⁴⁹

Table 19.1 Summary of Breast Cancer Risk Factors

Breast Cancer Risk Factors		Magnitude of Risk
Well-confirmed factors	Increasing age	++
	Geographical region (USA and western countries)	++
	Family history of breast cancer	++
	Mutations in BRCA1 and BRCA2 genes	++
	Mutations in other high-penetrance genes (p53, ATM, NBS1, LKB1)	++
	Ionizing radiation exposure (in childhood)	++
	History of benign breast disease	++
	Late age of menopause (>54)	++
	Early age menarche (<12)	++
	Nulliparity and older age at first birth	++
	High mammographic breast density	++
	Hormonal replacement therapy	+
	Oral contraceptives, recent use	+
	Obesity in postmenopausal women	+
	Tall stature	+
	Alcohol consumption (~1 drink/day)	+
Probable factors	High insulin-like growth factor I (IGF-I) levels	++
	High prolactin levels	+
	High saturated fat and well-done meat intake	+
	Polymorphisms in low-penetrance genes	+
	High socioeconomic status	+
Factors that Decrease Breast Cancer Risk		
Well-confirmed factors	Geographical region (Asia and Africa)	--
	Early age of first full-term pregnancy	--
	Higher parity	--
	Breast feeding (longer duration)	--
	Obesity in premenopausal women	-
	Fruit and vegetables consumption	-
	Physical activity	-
	Chemopreventive agents	-
Probable factors	Non-steroidal anti-inflammatory drugs	-
	Polymorphisms in low-penetrance genes	-
++ (moderate to high increase in risk)		-- (moderate to high decrease in risk)
+ (low to moderate increase in risk)		- (low to moderate decrease in risk)

Hot Flashes

Hot flashes are associated with the dysregulation of the hypothalamic temperature regulatory system in the brain. The astute woman having hot flashes will notice that just before the hot flash begins she experiences either a sensation that it is warm or that she has had an

increase in adrenaline with associated rapid heartbeat, anxiety, etc. It then seems as if the temperature regulatory mechanism, which normally adjusts the body's internal temperature, has gone wild. Instead of making a minor adjustment, the temperature-rheostat seems to have only two settings: on and off. A flush is followed

by sweating, increased pulse, and other disturbing symptoms such as chest tightness, anxiety, and finally coldness. These symptoms are all similar to the symptoms of overproduction of adrenaline. Although the hypothalamic temperature control mechanism appears to be *noradrenaline* regulated, the interrelationship between these two neuropeptides and the relationship of high-adrenaline or high-catecholamine states with women who struggle with hot flashes cannot be ignored. A third hormone also comes into play here: thyroid is known to be involved in temperature regulation. The “high-adrenaline” lifestyle of the average American woman may explain why other cultures appear to suffer less with hot flashes. Estrogen and adrenaline counterbalance each other in the brain, both being brain “activators.” Estrogen increases alpha adrenergic receptor density in the hypothalamus¹⁵⁰ and decreases it in the cortex. It decreases the seizure threshold¹⁵¹ and increases serotonin availability.¹⁵² Estrogen increases anxiety when an imbalance with the anxiolytic properties of progesterone occurs. Therefore, estrogen and catecholamines interact in the brain and estrogen levels may be one of the balancing mechanisms when catecholamine levels are tonically elevated.¹⁵³

There is also recent evidence suggesting a direct role of hypoglycemia as the triggering event in hot flashes. Through an experimental “glucose clamp technique” study, it was demonstrated that a drop in glucose triggered a cascade mediated through norepinephrine that resulted in the compensatory hot flush. Estrogen is necessary for mRNA transcription of the glucose transport protein into the brain and loss of estrogen results in relative neuroglucopenia.¹⁵⁴ This raises important and practical considerations for the management of menopausal vasomotor symptoms through modulation of glucose control. It has also been suggested that the hot flash is a protective counter-regulatory mechanism in the central nervous system and that those women who do not mount a significant vasomotor response have a greater degree of cognitive impairment in the absence of estrogen.¹⁵⁵

SSRIs in the treatment of hot flashes. Currently, because of the published WHI findings, many women and their doctors are resisting hormonal treatment of hot flashes. Hlatky showed that after a few years only a subset of women continues to have difficulty with hot flashes and, significantly, these are the same women

who have trouble with depression.¹⁵⁶ One SSRI (venlafaxine at a dosage of 75–150 mg per day¹⁵⁷) reduced hot flashes 60–70%. This SSRI is both a serotonin and a norepinephrine reuptake inhibitor. Other SSRIs that have shown some effectiveness with reduction of hot flashes are paroxetine 12.5–25 mg,¹⁵⁸ and citalopram 20–60 mg and fluoxetine 20 mg/day.^{159,160} Gabapentin 900 mg/day has also shown some effect.¹⁶¹ All SSRIs and SNRIs may have sexual side effects.¹⁶²

Adrenaline and Anxiety

Adrenaline increases anxiety, increases temperature, and can cause downregulation of the triiodothyronine receptor. When adrenaline is continuously elevated, the body tries to balance these actions by lowering estrogen and thyroid. Estrogen lowering may leave the menopausal woman with very low levels of estrogen and, through estrogen’s effect on thyroid-binding globulin, thyroid. There is evidence from the WHI and the HERS trials that women who appear to continue to struggle with hot flashes are also the women who will benefit from hormone therapy for other brain symptoms such as depression/anxiety.¹⁶³

Depression

The World Health Organization has declared depression to be the number one illness affecting women’s health overall, affecting 9–12% of women worldwide. Gender differences in the incidence of depression (twice as frequent in women¹⁶⁴) and the fact that this discrepancy begins at menarche and dissipates somewhat at menopause implicates estrogen (or progesterone) in its causation. Adrenaline primarily contributes to anxiety and hot flashes; cortisol is associated with depression. Progesterone balances estrogen and has anxiolytic effects but, because of its close association with cortisol, can cause increased depression.¹⁶⁵

Emotional lability, anxiety, and depression timed with the premenstrual phase of a woman’s cycle are perhaps the most troublesome among the symptoms collectively known as premenstrual syndrome, or PMS. This complex of symptoms affects approximately 75% of the female population,¹⁶⁶ and is severe enough in up to 20% of women to require treatment.¹⁶⁷ In addition, “[t]hree to eight percent of women of reproductive age meet strict criteria for premenstrual dysphoric disorder (PMDD).”^{168,169}

It has been recognized by many authors that these symptoms occur primarily during times of changing hormones: menarche, pregnancy and postpartum, premenstrually, and in perimenopause.¹⁷⁰ It makes sense that during these changes in hormone levels and balance there would be more challenges to the system's flexibility, and a less flexible system would suffer the consequences of imbalances that create symptoms. In situations where estrogen or progesterone is adapting to other hormones that are out of balance, women appear to be vulnerable to increased symptomatology. Because of the interaction of the neurotransmitters, the hypothalamic/pituitary hormones, and the nervous and immune systems, sorting out the individual woman's needs during these times of change can be daunting.

Cortisol, which is stimulated by the high-adrenaline lifestyle and stress,¹⁷¹ is strongly associated with many types of depression.^{172,173} Since there is a predominance of the pattern of high adrenaline → high cortisol → high insulin in our culture, one can often see the pattern of high adrenaline → anxiety → high cortisol → anxious depression → depression. As the toxic upregulation of the adrenals continues, the ability to sustain adrenaline levels fails, often leading to caffeine abuse as a potent blocker of adrenaline metabolism. The dominance of cortisol leads to increasing problems with abdominal obesity, sleep disturbances, and depression. As cortisol dominance takes over and the ability to secrete adequate adrenaline declines, depression becomes the primary symptom and anxiety abates. As cortisol raises blood sugar, inducing the context for insulin resistance, weight begins to distribute throughout the body. Since this mechanism for producing insulin resistance is so ubiquitous, the apple body type, though often thought simply to be a symptom of insulin resistance, frequently is in fact a symptom of insulin resistance that is initially triggered by elevated cortisol.¹⁷⁴

Estrogen becomes involved in this scenario in a number of ways. Elevated adrenaline may be balanced by depressed production of estradiol within the ovary. This is probably mediated by the effects of cortisol, which decreases estrogen effect centrally as well as peripherally. This may lead to infertility even in the presence of normal blood levels of estrogen maintained by the numerous pools to support estrogen availability. The integrated effect on the delicate balance that exists within the ovarian tissues may disturb ovulation. When estrogen is given exogenously, especially in the presence of a proges-

tin that does not have anxiolytic effects (such as birth control pills), anxiety may be severe.¹⁷⁵ In a brain that is only marginally balanced, the surges of estrogen and progesterone in the luteal phase of the cycle may create the anxiety and irritability known as PMS. During this time of higher production of both estrogen and progesterone, it is likely that the imbalances between estrogen and progesterone are more pronounced. Postmenopausally, high adrenaline levels can depress an already low estrogen level below the level needed to maintain bone density and brain synaptic functions, making hormone replacement a seductive approach unless the practitioner realizes that the real pathology is the elevated adrenaline. When estrogen is added, adrenaline and cortisol may actually decrease to some extent, thus creating a balance in the over-activated brain. This can be helpful in the short term, but the ultimate goal should be to lower adrenaline and cortisol and remove excess exogenous estrogen from the picture.

Thyroid Interactions

Meanwhile, the thyroid gland reactively attempts to balance the effects of elevated adrenaline. Adrenaline is a cardiac irritant, as is thyroid.^{176,177} When adrenaline is chronically elevated, the feedback mechanisms of the body attempt to counteract the negative effects on cardiac irritability by lowering T_4 . This can lead to modest elevations in TSH with symptoms of hypothyroidism. Many clinicians have instigated treatment for "sub-acute or sub-clinical hypothyroidism" in this clinical context. When thyroid hormone is added in this situation, it is not unusual to see the patient "intolerant" of doses which the truly hypothyroid patient tolerates easily. The clinical approach is often to continue thyroid replacement but at a lower dose, building to larger doses slowly.

However, the complexity of the problem worsens in this clinical context. If the excess-adrenaline state is not addressed and the patient's metabolism is additionally required to accommodate the increase in thyroid hormone levels, further compromises in the dance of hormones occur. Rigidity, which is characteristic of aging, rather than the flexibility of a more youthful and adaptive system, eventuates.

Adrenaline also inhibits the function of T_3 at the receptor level. This may explain the symptomatology of the perimenopausal woman who has problems with hot flashes but in the intervals between her "surges" feels cold. A more appropriate management of hot flashes

would be to address high adrenaline (avoid hypoglycemia stimuli, perform stress-reduction activities, moderate exercise, and improve sleep hygiene). To moderate temperature fluctuations, patients can wear layered clothing and instigate nasal breathing with onset of the hot flash. Moderation in the swings in estrogen can be achieved by supporting estrogen (and lowering adrenaline) through metabolic interventions (e.g., isoflavones, avoidance of xenoestrogens, improvement in biotransformation and excretion of hormones), all of which have shown some efficacy in treating hot flashes, although the evidence is very mixed.^{178,179,180,181,182}

Depression, Anxiety and Hormone Therapy

Treatment of depression, which can be life threatening, is a more urgent issue and may require temporary or permanent hormone therapy. It appears that 80% of the female menopausal population will do better in the long run without prescribing estrogen. Another 20% appear to require estrogen for prevention of depression. These may be women who have undergone oophorectomy, who have autoimmune destruction of the ovary, or who have physiologic depression of estrogen production in the context of elevated adrenaline. While estrogen therapy is still the most effective treatment of hot flashes, it is not always helpful for depression and may exacerbate anxiety (as discussed above). However, when hormone levels are measured and found to be low, patients should be evaluated (and treated, if necessary) for symptoms of elevated adrenaline. If hormone levels appear to be low due to inadequate function of the ovary after menopause, replacement is in order. The goal should be physiologic replacement to the level of normal menopausal women: 15–25 ng/dL.

At this level, it may not be necessary to replace progesterone, provided that the woman is making adequate progesterone from the adrenals and does not have excessive estrogen metabolites or xenoestrogen exposure. In the absence of adequate adrenal progesterone, this imbalance should be corrected as well with bioidentical progesterone. Since progesterone is rapidly converted in the liver to allopregnanolone, a brain-active GABA receptor agonist, oral administration may only be appropriate for patients with increased need for anxiolysis. Otherwise, symptoms of grogginess or even worsened depression may occur. It should be remembered that transdermal absorption is variable and vaginal and buccal absorption can be quite high, so finding

the right dose and route of administration of progesterone can be difficult.^{183,184}

In premenopausal women with depression, hormone therapy will more likely be aimed at balancing estrogen/progesterone levels by decreasing estrogen over-activity by improving metabolism, biotransformation, and excretion of estrogen, and by raising progesterone, thereby dampening swings in the levels of these hormones. In postpartum women, levels may need to be elevated by replacement and in perimenopausal women, also characterized by oscillating levels of these key hormones, the first intervention includes steps toward balancing metabolism.

In both pre- and postmenopausal women, it is also important to address the overactivity of the hypothalamic-pituitary axis (HPA) system, which can become unresponsive to the normal downregulation feedback of cortisol. Cortisol levels are increased when circadian rhythms are interrupted, especially sleep disturbance. Depression frequently accompanies dysfunctional sleep patterns.¹⁸⁵ Dexamethasone suppression testing is abnormal in this clinical context. This has been shown in animals to be lifelong and may be programmed *in utero*. It appears that a stressed mother programs her fetus to come into a stressful environment and the fetal brain develops with increased numbers of CRF (corticotropin-releasing factor) producing cells reflected in increased levels of CRF in the cerebral spinal fluid. Cortisol also fails to turn off the CRF production in the amygdala, increasing fear and anxiety responses.¹⁸⁶ These individuals have a lifelong struggle with overactivity of the HPA and may respond to stress-reducing techniques such as meditation, HeartMath, mindfulness-based stress reduction, yoga, energy medicine, or other therapies that teach patients to modify the input to their HPA axis and thus lower cortisol and adrenaline. Furthermore, strategies to reduce adrenaline will also decrease both anxiety and the stimulus to cortisol production.

Hormones and Autoimmune Disease

It seems probable from the increased incidence of autoimmune disease in women that hormones (or hormonal balance) play a part in the alterations of the immune system that are involved in a number of autoimmune diseases. Estrogen appears to push the

immune system in the direction of the proinflammatory Th1 pathways, except in pregnancy.

Because pregnancy is actually a high-estriol/high-progesterone state, estriol, functionally a weak estrogen, may actually act as a selective estrogen receptor modulator (SERM) and progesterone clearly has anti-estrogen properties. The changes in the phase II detoxification pathways associated with pregnancy have a profound effect on estrogen balance, on the ratio of 2- to 16-OH estrogen metabolites, and on individual tissues producing and metabolizing their own estrogens (such as breast, synovium, and brain). 16-OH metabolites go up in SLE and RA patients and go down in pregnancy.¹⁸⁷ The decrease in TNF- α during pregnancy increases apoptosis of activated immune cells (as does vitamin D). Estrogen is also thought to decrease TNF- α during pregnancy contributing, it is thought, to the improvement in MS during pregnancy. However, the full complexity of the mechanism underlying the immune response changes in pregnancy has not been worked out.

Mechanisms that initiate autoimmune disease and those that sustain it may be different. Some studies suggest that the timing of oral contraceptives is important in the later incidence of RA.¹⁸⁸ One model of autoimmune disease that seems to fit the available information and a functional medicine understanding of the interwoven web of functional interactions is as follows: Epitopes of triggering factors from the environment encounter the immune system and interact with the antigen-presenting system of the immune cells, especially in persons whose HLA systems are vulnerable. Estrogen and estriol appear to have a function in the presentation of antigens. Progesterone and androgens appear to be involved in apoptosis of activated immune cells; estrogen, contrarily, may be involved in sustaining the inflammatory activity of the activated T cells. The presence of adequate amounts of DHEA (suggesting the ability of the adrenals to produce appropriate amounts of cortisol) is necessary to quench the immune “fires.” When adrenal stress or fatigue is present, this system fails, allowing amplification of the inflammatory pathways.

At this point, the presence of an estrogen-dominant environment further complicates the immune system’s attempts to shut down the reactive furnace. Possible mediators of this process include xenoestrogens, genetic predisposing factors that increase inflammatory estrogen metabolites (such as the 16-OH or 4-OH), increased

aromatase enzyme, and inflammatory cytokines such as IL-6, TNF- α , and IL-1 β .¹⁸⁹ IL-6 inhibits ovulation by interfering with the LH pulse generator and IL-1 β increases FSH and LH, further stimulating estrogen production from the ovary. Inflammatory prostaglandins induced by the proinflammatory cytokines such as PGE2 then increase aromatase, adding to the estrogen fueling of the process and creating a feed-forward inflammatory catastrophe.

RA exemplifies this cascade effect, leading to a disease of upregulated Th1. RA worsens with pathological increases in estrogen, except during pregnancy (explanation for this anomaly has been presented above). RA worsens at menopause.¹⁹⁰ This is also true of MS.¹⁹¹ During pregnancy, estriol and progesterone may function to inhibit presentation of antigens to Th1 cells, and increase apoptosis of activated immune cells, respectively.

Systemic lupus erythematosus (SLE), a disease of upregulated Th2, is variable in its response to pregnancy, sometimes getting better but often getting much worse. In SLE, high estrogen increases Th2 activity, whereas the decrease in estrogen at menopause is usually associated with improvement in SLE symptoms.^{192,193}

In some autoimmune diseases, estrogen is thought to have a biphasic effect, and there may turn out to be a bell-shaped curve with regard to the effect of estrogen on the immune system—i.e., too much or too little estrogen may be equally detrimental to the normal functioning of the immune system. In any event, it would appear that the relationship of estrogen to diseases of autoimmunity is complex and not fully worked out at this point. Statements such as the one that follows demonstrate the difficulty in interpreting information when it is not made clear whether the estrogen levels are normal prior to therapy and whether the hormone is given with the intention of achieving physiologic levels. As Salem¹⁹⁴ pointed out:

The immune basis for these phenomena is poorly understood. Based on a distinctive profile of cytokine production, data accumulated thus far have revealed modulator effects for estrogen on the Th1-type and Th2-type cells, which represent two polarized forms of the effector specific immune response. Recent evidence indicates that estrogens inhibit the production of Th1 proinflammatory cytokines, such as IL-12, TNF-alpha and IFN-gamma, whereas they stimulate the production of Th2 anti-inflammatory cytokines, such as IL-10, IL-4, and TGF-beta. This can explain why estrogen suppresses and potentiates Th1- and Th2-mediated diseases,

respectively. We hypothesize that exacerbation or suppression of inflammatory diseases by estrogen is mediated by skewing Th1-type to Th2-type response. This view represents a novel mechanism for the modulator effect of estrogen on certain inflammatory diseases that can lead to beneficial or detrimental impacts depending on the type of immune response involved. Such a concept is valuable when considering the application of combination therapies that include estrogen.

Hormones and Specific Gynecological Syndromes

Endometriosis

Endometriosis occurs in up to 20% of asymptomatic women and in higher percentages of women with infertility. Historically, there have been two main theories for the initiation of endometriosis: the retrograde menstruation theory postulates that menstrual fluid carrying live endometrial cells flows retrograde out the tubes and implants on the peritoneum;¹⁹⁵ and the coelomic metaplasia theory suggests that transformation of totipotent cells occurs in the coelomic epithelium of the peritoneum.¹⁹⁶ It is possible that a combination of these is true. It has been suggested that retrograde menstruation supplies nutrients or stimulators of the endometriosis process without being the source of the endometrioid cells. This might explain why hysterectomy dramatically improves the disease for most women, although some are still found to develop endometriosis after tubal ligation or hysterectomy.

It appears that early endometriosis is regulated by different chemistry than late/established endometriosis. In early endometriosis, high levels of inflammatory cytokines, lymphocytes and macrophages are found in the peritoneal fluid, implicating inflammation or the immune system in the initiation of the disease. If the coelomic metaplasia theory is correct, a logical next question would be: what initiates the cellular transformation of the totipotent cells? Since the immune system has cells that produce the cytokines that can have an effect on DNA, and 60% of the immune system surrounds the gastrointestinal tract (which is in close approximation to the tissue affected by endometriosis), the gastrointestinal tract may also be a good place to look for an “upstream” approach to endometriosis.¹⁹⁷

Recent studies have begun to dissect the mechanisms of cell transformation from totipotent cells and/or failure to remove cyclic ectopic endometrial cells in the

peritoneal cavity. It has been demonstrated that IL-1 is overproduced in the peritoneal fluid and peritoneal-derived macrophages of endometriosis patients, and that this overproduction stimulates the synthesis and secretion of migration inhibitory factor (MIF) through a NFκB mechanism.¹⁹⁸ Upregulation of macrophage-stimulating protein (MSP) and its receptor (RON) have also been demonstrated by microarray mRNA transcription studies.¹⁹⁹ MSP has a dual role in preventing apoptosis and in promoting cell scatter facilitating invasion, both potentially important mechanisms in establishment and persistence of endometriosis implants. Other direct studies have also shown resistance to apoptosis in endometrial cells.^{200,201}

Matrix metalloproteinase enzymes (MMPs) and their complementary tissue inhibitor metalloproteinases (TIMPs) also have altered patterns in endometriosis. The metalloproteinase system has been shown to play a key role in normal endometrial remodeling and ultimately in tissue disruption leading to menstruation.^{202,203} Additionally, some xenobiotics have been shown to interfere with MMP function, possibly by interfering with the usual progesterone suppression of the MMP production.²⁰⁴

Finally, others have suggested a prominent role of oxidative stress with activated peritoneal macrophages generating increased amounts of lipid peroxides and lipid peroxide degradation products, which promote a sterile inflammatory reaction.²⁰⁵

These findings suggest a strong immune/inflammatory component of endometriosis, as well as several potential underlying mechanisms affecting the increased risk noted in women with other family members with endometriosis. Additionally, the xenobiotic effect on these underlying mechanisms may suggest a contribution to the increasing incidence of endometriosis over the past few decades. It is likely that endometriosis is the final common pathway of a variety of possible mechanisms and represents a good example of the pleiotropic concept of many chronic processes, where multiple mechanisms converge to present as a common clinical disease.

If endometriosis is a benign transformation of the coelomic totipotent cells, it is logical to ask if there is a malignant form of this disease. In fact there are three cell types induced in this type of tumor of the peritoneum (including the peritoneum reflecting over the ovary). These are the three cell types of the female genital tract: the serous (tubal), endometrial (endometrium),

and mucinous (cervical) cells. Benign forms of proliferation of each of these are known as endosalpingiosis, endometriosis, and pseudomyxoma peritonei, respectively. The malignant forms of these cell types are called epithelial cancers of the ovary. Understanding ovarian epithelial cancer in this way explains why we have so much trouble diagnosing ovarian cancers before they have “metastasized.” In fact, they start out in multiple sites in the peritoneum and only appear to be ovarian because the largest bulk of tumor will be found in the ovary, where growth-inducing hormones such as estrogen are found. While malignant transformation of endometriosis has been seen, it is likely that the benign and malignant forms of this peritoneal disease are no more related than the benign and malignant transformation of other cell types. Further support for the connection of the gut and malignant peritoneal disease is the common finding of an association of gastrointestinal symptoms with ovarian cancer²⁰⁶ and the little known association of milk (one of the most reactive foods) and ovarian cancer.²⁰⁷

As is true in a number of transformed tissues (breast cancer cells, fibroids), aromatase enzyme is found in high levels in endometriosis.²⁰⁸ This would suggest that early endometriosis is transformed into late, hormonally stimulated endometriosis by the upregulation of aromatase. There is an accompanying increase in prostaglandin E2 as well, probably induced by the inflammation of the early upregulated proinflammatory cytokines.

Fibroids

Fibroids represent another abnormal cell type that seems to have the capability of upregulating estrogen in the local environment. Fibroids have a commonly seen but not reliable relationship with endometriosis.²⁰⁹ The transformation of the myometrial cell by some stimulus seems to occur in families, suggesting either a genetic or common environmental initiator. Interestingly, reports are beginning to appear that also point to the ability of certain xenobiotics to upregulate estrogen receptor transcription and expression of estrogen responsive genes in myomas.²¹⁰ The reported association with endometriosis and the increased familial association of fibroids may represent a common environmental pathway or may represent an increased genetic susceptibility to xenobiotics. Once the myometrial cell is transformed, the same therapies that seem to improve dis-

eases of estrogen sensitivity apply to the treatment for regression of fibroids.

Osteoporosis

One of the statistically significant findings of the Women's Health Initiative was the decrease in bone fractures seen in the women on hormones.^{211,212} There has been a question, however, of how much estrogen is needed to produce improvement in bone strength. In a recent report by Ettinger et al.,²¹³ very low dose (.0014 mg) transdermal estradiol has been shown to increase bone mineral density in older women (average age 66). Ettinger points out that earlier studies showing little improvement in women with lower doses of hormone were done in surgically menopausal younger women. It would be expected that it would take a higher dose of hormone to produce normal levels of hormone in these women, as estradiol levels decline with age.

Osteoporosis is clearly an immune-associated disease. The presence of TNF- α producing T cells is essential for priming the estrogen-deficient bone environment to influence bone metabolism. In a study from the research group of Pacifici et al.,²¹⁴ it has been shown that the increased activation of TNF- α producing T cell in the ovariectomized mice is due to increased INF-gamma levels, resulting from ovariectomy-induced enhanced secretion of IL-12 and IL-18 by macrophages.²¹⁵ Therefore, the association of osteoporosis and menopause may actually be an association of changes in the immune system that are affected by changing levels of estrogen.

Summary

The research underlying the various functions of hormones, the causes and effects of dysfunction, and the influences of genetics, age, life stage, lifestyle, and environment on all the various factors is still a work in progress. Some of what has been written here may be superseded by new information by the time this book is published. However, there are some themes we can rely on for evaluating the fundamental clinical imbalances that are related to women's hormones:

- Caution is always warranted in prescribing drugs that will alter function, because the unforeseen effects, downstream, upstream, or sidestream, may be critically important.

- Each woman must be evaluated as an individual, for her particular situation may not reflect the “average” picture often described in the research.
- Effects of lifestyle and environment are powerful—stress, diet, exogenous toxins, and the possibility of nutrient insufficiencies or deficiencies (from diverse causes) should be fully evaluated.
- All hormonal effects occur *in relation* to other hormones in the body. Looking at a single hormone in isolation is usually unwise.
- The relationship of hormonal imbalance to other key aspects of the matrix—particularly immune balance and inflammation and gastrointestinal balance—must be considered. Interventions may begin at one of these other points if the preponderance of clinical evidence points that way.

Male Hormones

Daniel Cosgrove, MD

Introduction

The products of the testis have been recognized as essential to male virility and male physical characteristics since ancient times. Over 95% of circulating testosterone is made in the Leydig cells in the testis. Yet Leydig cells make up less than 10% of testicular volume. Among the seminiferous tubules are intertubular spaces with lymphatics, blood vessels, and Leydig cells. The Leydig cells receive signals and secrete testosterone. These regulatory signals include paracrine factors (e.g., cytokines, including IL-1, IL-6), corticotropin-releasing hormone (CRH), IGF-1, and various peptides and steroid hormones.

Historically, androgens have been thought to have two principal effects: *androgenic* and *anabolic* effects. *Androgenic* includes the growth, development, and maintenance of the male reproductive tract. Testosterone is required for male sexual differentiation in the fetus and in the adolescent. It is required to maintain adult male sex characteristics, and spermatogenesis. *Anabolic* effects include stimulation of somatic growth, i.e., increased muscle and bone density.

Recently, the broader and more complex role of androgens has been recognized, but is still far from fully understood. Androgens play an important role in immune function, in the development and maintenance

of muscle and bone, and in erythropoiesis, i.e., bone marrow-making red blood cells.^{216,217,218} Testosterone can affect cardiovascular disease and emotional well-being.^{219,220} Low serum testosterone levels correlate with depression and accelerated arteriosclerosis, among other disease states, but to what extent lack of testosterone plays a causative role, or is itself a manifestation of a greater imbalance, is not clear.

Synthesis

Testosterones, and all mammalian hormones, are synthesized from cholesterol through a series of enzymatic steps requiring P450 and other reactions (see Figure 19.1). Pregnenolone, 17-alpha-hydroxypregnenolone, progesterone, DHEA, and androstenedione or androstenediol are some of the possible synthetic steps.

Although 95% of men's testosterone is made in the testis, the adrenal glands secrete DHEA and androstenedione, which are potential precursors to testosterone.ⁱ The most important (rate-limiting) step in “steroidogenesis” is the delivery of cholesterol into the P450 complex in the mitochondria. This is regulated by the StAR protein.ⁱⁱ

GnRH (gonadotrophin-releasing hormone) is produced in neurons in the anterior hypothalamus, adjacent to the pituitary in the brain. GnRH is secreted in pulses, which causes the pituitary to secrete luteinizing hormone (LH), also in pulses. GnRH activates LH secretion by both direct receptor protein mechanisms as well

ⁱThe testis secretes virtually all of these precursor hormones, but their concentration in the spermatic vein is proportionately the same as their concentration inside the testis. Winters [Winters, “Androgens in Health and Disease,” 2003, pg.13] has written, “One idea is these precursor steroids are secreted as unnecessary byproducts in the transformation of pregnenolone to testosterone, because none is known to have a physiological function in males” (emphasis added). This statement reflects the perception among many medical scientists that describing specific roles for these hormones, other than precursors, is speculative. There are conflicting reports and conclusions about the independent role of each of these potential precursors, especially pregnenolone and DHEA, but in recent years it has become more accepted to acknowledge that there is a complex relationship between stress and various sex steroids. Although the testicular secretion of these hormones is relatively minor, there is no doubt that DHEA circulates in the bloodstream at a concentration roughly 1000 times greater than testosterone. DHEA is often measured in mg/mL, whereas testosterone is usually measured in ng/mL. DHEA is discussed later in this chapter.

ⁱⁱMutations of StAR can cause an uncommon type of congenital adrenal hyperplasia, the lipoid type (LCAH). Instead of the usual virilization in most CAH, because precursors to cortisol are shifted to androgens, there is complete loss of adrenal and gonadal steroid production because the cholesterol cannot get into the mitochondria.

as by increasing transcription. LH pulses then stimulate testosterone production in the Leydig cells of the testis. LH affects testes in a similar manner to the GnRH effect on the pituitary: it has immediate effects (4 hours) and delayed effects (about 72 hours) and these are thought to be a result of direct activation of cAMP, and then via upregulated genes, respectively.²²¹

Figure 19.1 Synthesis of the male sex hormones in Leydig cells of the testis

Note: P450ssc, 3β-DH, and P450c17 are the same enzymes as those needed for adrenal steroid hormone synthesis. 17,20-desmolase is the same as 17,20-lyase of adrenal hormone synthesis. Feedback and Modulation of Testosterone Production

Although testosterone therapy is gaining in acceptance, the concept once promoted as an anti-aging approach—that simply measuring and restoring testosterone blood levels is adequate justification for treatment—was terribly oversimplified. There are web-like complex interactions of many organs and signaling pathways with many factors affecting testosterone production, in addition to LH. Every few years, medical scientists revise their conception of the role of androgens, as understanding of their complexity improves.

A few facts to consider about testosterone production:

- Testosterone, in a sense, regulates its own production by its negative feedback inhibition of LH secretion; testosterone feedback inhibition also occurs via GnRH.^{222,223,224,225} Testosterone has an effect on LH within a few hours, but also downregulates GnRH gene expression.
- Testosterone receptors and estradiol (ER-alpha) receptors are on Leydig cells and each has two specific pathways to decrease production of testosterone.^{226,227,228}
- Estradiol is very important in negative feedback to decrease LH. Several studies suggest estradiol may be required.^{229,230,231,232} Estradiol plays an important role in several functions in normal men. It is created almost entirely from aromatization of testosterone.
- T₃ directly stimulates Leydig cell hormone production in mice, partly by increasing StAR expression.²³³
- Men with prolactin (PRL) producing pituitary microadenomas have low plasma testosterone levels because pulsatile LH secretion is suppressed.²³⁴
- Growth hormone (GH), secreted by the pituitary, has been reported to play some role in testosterone production, but it is probably minimal. GH increases IGF-1, and there are IGF-1 receptors on Leydig cells. Testosterone levels are generally normal in men with GH deficiency²³⁵ but men treated with GH for several months increased their plasma testosterone levels somewhat.²³⁶
- Corticotropin-releasing hormone (CRH), best known for its role in stimulating ACTH production from the pituitary, is secreted by Leydig cells and acts through high-affinity receptors on Leydig cell membranes to negatively regulate LH action by inhibiting its effect on cAMP-related androgen synthesis.²³⁷ This could partially explain the mechanism of testosterone deficiency in stress.
- Corticosterone reduces LH-stimulated processes in rat Leydig cells²³⁸ and may contribute to testosterone deficiency in stress.
- FSH was once thought to influence testosterone production but it appears to have a negligible effect.²³⁹

Effects of Androgens

Brain and Cognitive Effects

Several CNS functions are regulated by testosterone (T), including fetal sexual development and differentiation of

the brain, and gonadotrophin secretion. Behavior and cognition are also modulated by T. Many of the effects of T are mediated through the androgen receptor (AR) which is widely but selectively distributed throughout the brain.²⁴⁰ Some of these effects are termed “activational” effects, and their mechanism is complex and poorly understood. Castrated rats fail to demonstrate normal sexual behavior, but the behavior is restored by T replacement.²⁴¹ Mice with age-related decreases in plasma T show a progressive impairment of spatial learning and memory related to T levels, which can be reversed with T supplementation.²⁴²

DHT (dihydrotestosterone) binds the AR much more tightly than T,²⁴³ and DHT seems to also play a role in the brain.^{244,245} DHT, unlike T, cannot be converted to estrogen. Estrogen, converted from T by aromatase, binds both alpha and beta estrogen receptors (ER) in the brain. Fink²⁴⁶ demonstrated that both estrogen and testosterone, but not DHT, increase serotonin in parts of rat brains via specific mechanisms. Shughrue later raised the issue of the clinical importance of this relationship:

The estrogen induction of SERT mRNA ... together with the correlation between sensitivity of ... serotonin neurons to estrogen ... provides a potential topochemical handle with which to investigate testosterone/estrogen regulation of SERT (serotonin transporter) gene expression. These findings are discussed in relation to the possible role of interactions between sex steroids and serotonin mechanisms in mood disorders, schizophrenia and Alzheimer's disease.²⁴⁷

While the animal studies and *in vitro* studies help clarify the mechanisms, many behavioral studies with humans demonstrate the effects. There have been many studies examining the relationship between androgen levels and cognitive performance, but these have produced inconsistent results.²⁴⁸ In general, literature reviews and functional MRI studies suggest that men and women use different parts of the brain to process certain cognitive tasks, and these brain differences are differentiated in the fetus under the influence of hormones. In addition, the activational effects of hormones modulate the neural pathways for adults.

Cherrier and Craft²⁴⁹ discuss fascinating differences in cognitive function and recruitment of various parts of the brain, relative to endogenous androgens.

Men, on average, tend to use a Euclidean (distance) or cardinal direction (N,S,E,W) approach to spatial navigation, whereas women on average tend to use landmark references [A previous study] found that when young men and women were required to learn a route on a tabletop map, men were able to learn the

route in fewer trials, but women remembered more of the landmarks located along the route.²⁵⁰

Studies with exogenous androgens have inconsistent results, but general themes do appear. There is a clear pattern in those studies of humans with relatively low androgens at baseline (e.g., elderly or hypogonadal men) showing improvements in test scores of spatial ability and other beneficial, but selective, improvements in cognitive function.^{251,252,253} One reason for apparent inconsistent results is that treating normal males with androgens has not been as dramatically effective at improving cognitive scores as studies that use hypogonadal men, or female-to-male transsexuals taking testosterone.

Muscle and Body-Building Effects

As mentioned in the introduction, androgens have been thought to have two principal effects: *androgenic* and *anabolic* effects. Recreational bodybuilders and athletes discovered that certain derivatives of testosterone had greater anabolic than androgenic activity, and these became known as anabolic steroids.^{254,255} In the decades of the 1970s and 1980s there was considerable polarization of views about the anabolic effects of androgens. In general, the academic view was that supraphysiological doses of testosterone do not further increase muscle mass or improve muscle strength, and that anabolic and androgenic activity cannot be dissociated; they are described by the same dose-response relationship, and are mediated through the androgen receptor (AR).

Recent studies have now established that, in fact, androgenic steroids, especially when “stacked” (adding multiple steroids simultaneously), definitely increase fat-free mass, muscle size, and strength,²⁵⁶ and the anabolic effects persist in a linear dose-response relationship²⁵⁷ over a wide range of concentrations. The androgenic effects use the AR, but involve recruitment of tissue-specific coactivators and corepressors. The mechanisms are not entirely clear since ARs in most tissues are either saturated or downregulated at physiologic testosterone concentrations.^{258,259,260}

Although the potential for abuse by young athletes is considerable, the application of androgenic steroids can be helpful in various medical conditions with muscle wasting and bone loss. These include autoimmune disorders, especially in patients who have received chronic glucocorticoids,^{261,262} but also HIV-infected men, patients with end-stage renal disease, ALS, and

others. Many studies have demonstrated great variability in individual responses to androgens; the mechanisms are not understood.^{263,264}

Bone Effects

The skeleton is a metabolically active organ, constantly undergoing remodeling under the dual control of metabolic and structural needs, and modulated by both estrogen and testosterone. Men lose bone mass with age, and hypogonadism is one cause of male osteoporosis. Low T levels are a risk factor for minimal trauma hip fracture.²⁶⁵ In young men with acquired hypogonadism, T replacement increases bone density.²⁶⁶ The bone-building effects of T seem to be due both to T itself, as well as to its conversion to estrogen.²⁶⁷

Cardiovascular Disease

There are reports of cardiovascular events in young male bodybuilders using high doses of anabolic-androgenic steroids (AAS).²⁶⁸ Pathological data from men abusing exotic AASs should not be extrapolated to the legitimate therapeutic use of androgens, or to androgen physiology,²⁶⁹ although a 2004 study reported adverse (and long-lasting) effects on apolipoproteins and lipoprotein(a) from self-administered AAS.²⁷⁰

Low endogenous testosterone is a component of the metabolic syndrome, characterized by obesity, glucose intolerance, hypertension, hypertriglyceridemia, low HDL cholesterol, a procoagulatory state, and an anti-fibrinolytic state. (Many discussions of metabolic syndrome can be found in this book; refer to the index for cross-references.) Body weight, leptin, and insulin levels decrease with testosterone treatment in hypogonadal men.^{271,272,273} In general, providing exogenous T to eugonadal men lowers HDL cholesterol, but treatment of hypogonadal men does not lower HDL.^{274,275}

An elevated serum level of lipoprotein(a) is an independent risk factor for heart disease. It is inherited, but not rare. Lifestyle changes such as diet and exercise have little effect upon Lp(a) serum levels. Supplementation with exogenous T in both hypogonadal and eugonadal men lowered serum Lp(a) by over 30%.²⁷⁶

Both fibrinogen and plasminogen activator inhibitor-1 (PAI-1) serum levels correlate with increased heart disease risk. Higher doses of T given to healthy men led to a sustained decrease of fibrinogen by 20% and decreased PAI-1 levels.²⁷⁷ In general, these effects are

most pronounced with higher doses in normal men and minimally significant in the usual replacement doses for hypogonadal men.

Perception and Androgens

Changes in testosterone in patients undergoing psychological stress. The brain itself affects GnRH, which is produced within neurons, as described above. Neurons have the obvious influence of external stimuli: vision, hearing, and perception in general. Stress results in decreased serum testosterone levels. Bernton²⁷⁸ demonstrated in 1995 that Special Forces military training resulted in low testosterone. More recently, Gomez-Merino²⁷⁹ reported that the immune and hormonal systems were affected by a five-day military course following three weeks of combat training. She concluded:

The impaired secretion of dehydroepiandrosterone sulfate (DHEA-S) and prolactin, two immunomodulatory hormones, was thought to be a response to the chronic stressors. Lowered testosterone reflects a general decrease in steroid synthesis as a consequence of the physical and psychological strain.ⁱⁱⁱ

The biochemical mechanism(s) by which “psychological strain” leads to decreased GnRH in the hypothalamus are unclear. It could be due to changes in the pulsing, or downregulated genes, as described above.

Several authors writing about sailing, especially sailing alone for long periods, describe decreased beard growth rate that returns about two days prior to arrival onshore and encountering women. Mike Golding, a well-known, world-class sailor, has written about it.

An intriguing but little known feature of sailing singlehanded non-stop around the world is that due to the amount of time they spend alone at sea the amount of testosterone male skippers produce drops to a very low level. Aside from beard growth lack of testosterone in men can affect the pitch of the voice, temper as well as a host of more complex side issues ... “You certainly don’t need to shave as much when you are out here because your beard slows down,” says Golding. “And it probably changes your demeanour a little.

ⁱⁱⁱ Although most anterior pituitary hormones, including growth hormone (GH), adrenocorticotrophic hormone (ACTH), luteinizing hormone (LH), and thyroid stimulating hormone (TSH), are stimulated by hypothalamic releasing factors, the secretion of prolactin (PRL) is under inhibitory hypothalamic control. Dopamine is the predominant PRL inhibitory factor and disruption of hypothalamic dopaminergic pathways or alteration of dopamine synthesis leads to hypersecretion of PRL. Increased PRL is associated with lower testosterone, but in this clinical study, PRL levels also decreased.

You are less prone to getting angry. It doesn't mean you are not upset, but you don't get angry."²⁸⁰

Testosterone and depression. Studies that have examined changes in testosterone in depressed men have yielded mixed results, but these differences may relate to variability in the populations studied (age; healthy or ill), different assays, and timing of the measures. Small studies that compare age-matched controls are subject to the considerable variability among normal males. Levitt and Joffe²⁸¹ found no difference in total and free testosterone, estradiol, and cortisol in 12 depressed males and age-related controls. Margolese²⁸² reviewed the literature in 2002 and found several studies reporting significant between-group differences in total testosterone levels.

Barrett-Connor²⁸³ studied endogenous androgen levels in 856 men 50–89 years old, as well as the prevalence of depression measured with the Beck Depression Inventory (BDI). Bioavailable testosterone decreased with age, confirming two earlier studies^{284,285} and BDI scores increased with age, confirming other reports of increasing prevalence of depression in older men.^{286,287} However, in addition, the BDI score was significantly and inversely associated with bioavailable testosterone, independent of age, weight change, and physical activity.

Correlating *endogenous* low serum testosterone levels with depression does not necessarily mean that testosterone *supplementation* improves mood in hypogonadal men. However, Wang demonstrated that testosterone replacement does improve mood in hypogonadal men in an early small trial²⁸⁸ and then confirmed it with more recent studies.^{289,290}

Supraphysiological doses of testosterone treatment in eugonadal healthy men led to statistically significant increased "anger hostility scores" in a small study performed by O'Connor in England.²⁹¹ O'Connor contends that these increased scores were still well within the normal range, and that there was no increase in aggressive *behavior*.

Hypogonadism and Fertility

Testosterone has been discussed in fertility clinics for decades, but only recently has its role in anti-aging therapies become more mainstream. Fertility literature describes decreased testicular function manifested by decreased libido, decrease in ejaculate volume, infertility, and change in beard and body hair growth. Individuals with sperm counts between 10 and 20 million/mL

are classified as having mild oligospermia.²⁹² Pregnancies in this group frequently occur, and therefore these individuals are classified as subfertile rather than infertile. Males with sperm counts below 5 million/mL have severe oligospermia. Such individuals, as well as azoospermic males, require an endocrine evaluation. FSH, LH, thyroid-stimulating hormone (TSH), prolactin, testosterone, and estradiol levels are typically obtained. FSH and LH values in excess of 40 mIU/mL indicate primary testicular failure, which is refractory to treatment. Donor sperm or adoption is usually then recommended to these couples. When FSH, LH, and testosterone levels are all low, this indicates a hypothalamic-pituitary disorder, and a brain MRI is indicated.²⁹³

Traditionally, it has been thought that low levels of testosterone might impair sexual desire but not necessarily sexual functioning. "Administration of testosterone may increase libido but generally will not restore impaired sexual function."²⁹⁴ The discrepancy here may be that the author was referring to supplementation of eugonadal men presenting with complaints of sexual dysfunction. Wang²⁹⁵ reported significant increases in sexual desire, enjoyment, percent full erection, and satisfaction with erections ($p < 0.001$ for all) in comparing testosterone gel supplementation to placebo in her study of 150 hypogonadal men; the effects remained from six months until the end of the treatment period. Shippen has claimed virtual resolution of erectile dysfunction in about 80% of his patients.²⁹⁶ My own clinical experience with hundreds of men is that testosterone improves sexual function in hypogonadal men, but rarely is an adequate remedy alone; eugonadal men do not show the same response.

Testosterone and its Derivates

Dihydrotestosterone

There are two important androgens. Testosterone (T) is converted to dihydrotestosterone (DHT) by the enzyme 5-alpha-reductase. DHT blood levels are about one tenth of T levels, but the potency of DHT in bioassays is at least twice that of T. Its activity at the local tissue level may be more important. In these respects, its function is analogous to the T_3 thyroid hormone.

DHT is *required* for prostate differentiation (fetal development) and function. Inhibitors of this enzyme are used therapeutically to diminish the development of

benign prostate hypertrophy (BPH).²⁹⁷ In fact, there is evidence that all men gradually develop BPH and even prostate cancer if they live long enough, and that treating with inhibitors of the 5-alpha-reductase enzyme such as finasteride (Proscar®) delays the development of BPH and ameliorates some of its symptoms.²⁹⁸ Saw palmetto is a popular herb available without a prescription. It has proved effective in treating symptoms of BPH.^{299,300} Its primary function appears to be inhibiting the 5-alpha-reductase enzyme.

Men treated with these enzyme inhibitors do not experience muscle loss. And men with congenital absence of the enzyme have normal muscle development at puberty (although they would lack masculinization of external genitalia). It appears then that DHT is not necessary for the androgenic effect of testosterone upon muscle, so therapeutic anabolic androgens that cannot be converted to DHT are under investigation for use in patients with muscle wasting (e.g., those with HIV or ALS).

Hypogonadal men treated with testosterone cream or patches should apply the patch away from the scrotum or upper inner thigh. Apparently, 5-alpha-reductase enzyme concentrations are greater under the skin near the groin than elsewhere, and application near the scrotum leads to disproportionately higher serum levels of DHT.

DHT definitely contributes to libido and sexual arousal. Aggressive lowering of DHT, even without decreasing T, has the potential adverse effect of decreasing libido and sexual arousal.

The Role of Estrogen

Estrogen plays several crucial roles in men. Recently, the discovery of a few men lacking aromatase or estrogen receptors has led to a greater understanding of the role of estrogen. Certain theoretically predictable clinical features in these men have been described, including osteopenia, increased bone turnover, hyperinsulinemia, glucose intolerance, and abnormal lipid profiles.^{301,302,303,304} Estrogen appears to increase the risk for BPH.³⁰⁵

As mentioned earlier in this chapter, estrogen has an important role in modulating brain function. Androgen and estrogen receptors are found in the brain, and aromatase locally in the brain appears to be important. In mice, aromatization of testosterone to estrogen within the developing brain activates the estrogen receptors

and is necessary for normal sexual differentiation of the hypothalamic nuclei. As noted above, estrogen also appears to play a key role in negative feedback within the HPA axis by inhibiting LH secretion.

In 1998, Eugene Shippen³⁰⁶ wrote a book for laymen that reflects many ideas currently held by clinicians practicing hormone therapies. He devoted an entire chapter (without references) to the role of estrogen. He suggested that aromatization of testosterone is increased with aging; with liver dysfunction, especially within the P450 system; with zinc deficiency; with excessive alcohol consumption; and with obesity. Therefore, in those patients with elevated estradiol/testosterone ratios combined with low testosterone, administering more testosterone only creates further excessive aromatization, and further increases the estradiol/testosterone ratio. Although this principle may be important in some patients, unfortunately this has led to the potentially inappropriate practice of prescribing aromatase inhibitors routinely with testosterone prescriptions.

What has been demonstrated or refuted about Shippen's claims since the publication of his book? Obesity has long been known to be associated with increased estradiol, and estrogens are synthesized in fat cells. Wang's recent study using transdermal testosterone in 163 hypogonadal men reported progressively increasing serum estradiol levels from 6 to 24 months of treatment to "the upper limit of the male reference range."³⁰⁷ This was in contrast to T, DHT, LH, FSH, and SHBG serum levels, which all appeared to stabilize and become level within six months.

There has been the suggestion that zinc supplementation may decrease the risk of prostate cancer.³⁰⁸ There is some evidence that zinc deficiency impairs testosterone synthesis³⁰⁹ and several animal and bench studies suggest that zinc modulates testosterone,³¹⁰ but clinical studies are few, and at least one recent publication warns against the potentially toxic or pro-carcinogenic practice of "high dose" supplementation of zinc for prostate health.³¹¹ Zinc is a normal component of seminal fluid, and severe zinc deficiency has been associated with infertility, but, otherwise, mild zinc deficiency in the Western diet is not an established cause of accelerated aromatization of testosterone to estrogen.

Acute ethanol ingestion lowers serum testosterone levels and raises LH levels, suggesting a primary effect on the testes.³¹² Chronic alcoholism is associated with hepatic cirrhosis and elevated estradiol and gynecomastia.³¹³

Alcohol use in moderation has not been demonstrated to be a significant cause of altered estradiol/testosterone ratios. In the Tromsø study,³¹⁴ measuring hormone levels in over 1,500 patients, there was no difference between alcohol users and non-users, and no dose-response effect among users.

DHEA

The adrenal gland's production of DHEA (dehydroepiandrosterone) peaks at about age 20. Thereafter, blood concentrations of DHEA decline steadily throughout adulthood in both sexes, typically dropping to 15–20% of youthful levels in old age. This decline has led researchers to search for an association among blood levels of DHEA, signs of aging, and diseases associated with aging. Unlike testosterone, which is available only by prescription, DHEA is widely available as a supplement. The popularity of DHEA arose from a number of reports in the popular press of a study conducted by Morales et al.³¹⁵ that characterized DHEA as similar to the mythical fountain of youth. For three decades, there have been inconsistent reports about the various risks and benefits of DHEA supplementation, leaving many prudent clinicians wondering whether the hype had overshadowed good science.

Recently, there has been a tremendous outpouring of medical literature documenting many clinical benefits of DHEA, especially its anti-diabetes and anti-atherosclerosis effects,^{316,317,318,319} yet clarifying its minimal or absent utility for body-building in younger men, despite ubiquitous claims on supplement-selling websites.

Although one reads repeated comments that DHEA's actions are because it converts to androgens, there is increasing evidence that DHEA has independent sites of action.³²⁰ Moreover, DHEA has virtually no conversion to androgens in the bloodstream in men, and very little in women.

DHEA and cardiovascular disease. In 1986, Barrett-O'Connor³²¹ reported that *endogenous* DHEA serum levels correlated with decreasing mortality, especially age-related cardiovascular mortality. Higher endogenous levels of DHEA could have been a result of less stress or more exercise; one could not conclude that supplementing exogenous DHEA conferred benefit. Other studies failed to confirm these findings.³²²

More recently, Kawano demonstrated that DHEA supplementation (25 mg/day) in hypercholesterolemic middle-aged men (not selected for initial low serum

DHEA-S) improved vascular endothelial function, measured by brachial flow index.³²³ Other benefits in these same patients included improved insulin sensitivity and decreased plasminogen activator inhibitor type 1 (PAI-1) concentration. PAI-1 and decreased insulin sensitivity are well-known independent risk factors for atherosclerosis. DHEA administration has reduced atherosclerotic plaque in animal studies.^{324,325}

In a recent human clinical study, DHEA improved insulin sensitivity and decreased abdominal fat in both elderly men and women, leading Villareal³²⁶ to conclude DHEA has promise as therapy for metabolic syndrome. The beneficial effect of DHEA on endothelium is apparently independent of androgen receptors. A membrane-bound, G protein-coupled receptor for DHEA has been identified in bovine vascular endothelial cells, which could be one potential mechanism.³²⁷

DHEA's role in mood and cognitive function.

Compagnone reported in 1998 that DHEA increased dendrite growth in mice, and had other beneficial neurological functions independent of its role as a "precursor."³²⁸ It has immediate neurotransmitter-related functions, and is not limited to its presumed traditional role as a steroid binding a cell nucleus. More recently, Suzuki and Svendsen demonstrated that DHEA is involved in the maintenance and division of human neural stem cells.³²⁹ This led to attempts at using it in clinical treatment of Alzheimer's disease, which were not successful.³³⁰ Clinically, several studies have associated low DHEA levels with depression or decreased mood.

DHEA is not an androgen. Recently DHEA has been the subject of debate in that, unlike many androgen steroids (e.g., androstenedione), it was specifically exempted from the list of controlled substances in the Anabolic Steroid Control Act of 2004, which became law in early 2005. The legislation specifically reads:

The term "anabolic steroid" means any drug or hormonal substance, chemically and pharmacologically related to testosterone (other than estrogens, progestins, corticosteroids, and dehydroepiandrosterone).³³¹

This exemption has generated justifiable debate, due in part to the mixed reports in the medical literature about the androgenic effects of DHEA, or its ability to easily convert to more potent androgens following administration. Both DHEA and DHEA-S *can* be converted in *peripheral* tissues to androstenedione, testosterone, and dihydrotestosterone, and both are aromatized to estrogens.³³² DHEA is a chemical precursor to tes-

tosterone within cells (as is cholesterol), but several studies have confirmed that DHEA supplementation does not increase serum testosterone levels in men, but does to some extent in women.^{333,334}

In general, muscle building and improved athletic performance are not an effect of DHEA. Nawata has written in *Hormone Research*, “Although DHEA and DHEA-S have *few intrinsic androgenic actions*, they have recently attracted widespread attention due to their beneficial anti-aging effects” (emphasis added).³³⁵

Virtually all testosterone is made from the testes, but DHEA found in the bloodstream is secreted by the adrenal glands. DHEA circulates at over 1,000 times the concentration of testosterone, yet DHEA does not simply convert to testosterone in the bloodstream in men, or castration would not lower testosterone. On the other hand, given even a minor conversion pathway from DHEA to testosterone, one might expect that adding DHEA exogenously might create higher androgen levels, given the high serum concentration of DHEA relative to testosterone. At least one investigator has found evidence of increased androstenedione and DHT in subjects given relatively high doses (100–250 mg) of oral DHEA.³³⁶ Minor improvements in strength were found in elderly men supplementing with 100 mg of DHEA.³³⁷

The Approach to the Patient

The remainder of this discussion is drawn from knowledge gained not only from familiarity with the medical literature (as referenced previously) but also from my own experiences in developing therapeutic and prevention-oriented strategies for patients. Opinions expressed are mine.

Men with *acquired* hypogonadism (after trauma, for example) experience several well-established changes: alterations in body composition with decreased muscle mass and increased fat mass, decreased muscle strength, decreased bone mass (i.e., bone demineralization, which defines “osteoporosis” when it becomes severe), impaired red cell production, decreased libido, and erectile dysfunction. Psychological symptoms include depression, anxiety, insomnia, memory impairment, and reduced cognitive function.

Testosterone levels decrease with aging, so that 25–50% of men over 65 have levels that are more than two standard deviations below the norms for young adult men. Aging men, as a group, experience the signs and

symptoms listed above for hypogonadism in young men. This epidemiological *association* does not demonstrate *causation*; one could imagine that both the lower serum levels of testosterone and these symptoms are all simply “part of the aging process.” Nevertheless, as reviewed earlier in this chapter, recent studies have shown that all of the symptoms and signs listed above have been shown to improve with testosterone therapy.

Defining which older men are “androgen deficient” and merit therapy, or have decreased testosterone as a normal consequence of aging, is influenced in part by philosophy, and there is no consensus. Part of the problem is that there is no biochemical measure of androgen activity, which can vary with different target tissues. In addition, there is no single *clinical* measure of androgen effects, and different measures (libido, muscle mass, bone density) respond differently to a given dose of testosterone. Therefore, treating individual men should be based upon the identification of specific impaired androgen-dependent functions, combined with low T levels. Successful testosterone treatment in the individual patient is measured by specific clinical improvements, such as increased strength and muscle mass in a frail man with initially low T serum levels.

The decision to treat with testosterone is complicated by the fact that many psychological and/or physiological processes affect all of the signs and symptoms of hypogonadism, and could be solely the cause. For example, an obese sedentary man with poor nutrition presented with sarcopenia (i.e., decreased muscle mass), muscle weakness, increased body fat, insulin resistance, metabolic syndrome, osteopenia, and impaired cognitive function and decreased libido. An older man with these symptoms would be likely to have low serum testosterone that is partly predictable because of age alone. All of these changes have been demonstrated to improve with testosterone, yet *all* of these changes could also be a consequence of fitness and nutrition issues, and all could be improved with changes in fitness and nutrition, without using hormones (see Chapters 13, 26, and 29).

In addition to clinical manifestations of hypogonadism resulting from other causes, low serum testosterone can itself be a result of several medical conditions, including diabetes mellitus, liver disease, hemochromatosis, and obesity, especially with increased abdominal fat. Lower T levels have been associated with several medications, including ketoconazole, cimetidine, and

Section V

Fundamental Clinical Imbalances

glucocorticoids. Smoking and chronic alcohol use lower T levels.

These confounding issues may be difficult to differentiate (and multiple issues may be contributing factors). Heavy alcohol use is independently associated with bone demineralization, and it would also be expected to influence body composition, nutrition, erectile function, and mood. In addition, excessive alcohol effects testicular production of testosterone. Obviously, restoring T levels without addressing alcoholism would fail to address the fundamental cause of the imbalance.

However, in both an alcoholic and the sedentary obese man with poor nutrition, testosterone could, in combination with lifestyle changes, accelerate the improvement in all of the parameters measured.

Ideally, one would like to know what imbalances in male hormones look like clinically and how to assess them (key indicators), as well as where they come from (genetics, diet, nutrition, environmental toxins, stress, etc.). In reality, this will not be possible with the vast majority of patients, because of the enormous overlap of causes and indicators. Frequently, as the clinician begins to understand the patient as a whole person in the setting of his or her life, not simply as a series of parameters and measures to be adjusted, the most important issues may not be hormones or even nutrition, per se. In the example above, the obese sedentary man's wife died two years ago after 40 years of marriage in which she cooked and was the center of social relationships. This led to a change to a diet of fast food and processed food high in refined sugars and low in protein and phytonutrients. The subsequent depressed mood as well as social relationship changes led to decreased physical activity. His poor nutrition was compounded by new-onset "stress eating," and the resulting weight gain and energy loss led to even less physical activity. The combination of these factors accelerated his osteoarthritis of the knees, which further impaired his ability to walk to the store and get adequate groceries. My point here is that hormones, like all of these parameters, can be both cause and effect. A thorough history, physical exam, and laboratory screening will help to pinpoint a more accurate and comprehensive assessment.

There may be debate about the relative importance of lifestyle interventions such as improving nutrition and fitness, decreasing stress, or improving relationships. However, it is safe to say that without addressing a number of fundamental changes, no specific targeted

therapy will be adequate for this individual. On the other hand, we could agree that addressing the root cause for the patient example above means getting him into new social interaction and helping him derive meaning in his life apart from his now-deceased wife, but *solely* addressing *that* issue is unlikely to be as effective as a combined approach. Testosterone could still play a role in accelerating improvement in several of the parameters that would be followed in this individual.

Testosterone Therapy

It is illegal to prescribe androgens for sports performance or cosmetic muscle enhancement. The prudent clinician will document the diagnosis of hypogonadism, and list those symptoms and signs that support the diagnosis. Since it has been claimed that hormones cause cancer, and testosterone causes prostate cancer, careful monitoring for cancer is crucial.

Options for testosterone therapy. Testosterone is currently not available orally except as modified compounds that are hepatotoxic. Injections have been used for decades, but the inconvenience of injections, the marked swings of serum levels with peaks and troughs, and the tissue damage with potential fibrosis from repeated injections for years, make this choice inferior to topicals for most patients. Topical application is now available in a patch, and most recently as a gel (AndroGel®). One of the first patches was recommended as a scrotal patch. Any application of testosterone near the groin usually results in unwanted higher DHT levels, apparently due to an increased concentration of the 5-alpha-reductase enzyme subcutaneously near the groin. Patches are recommended for application on the upper torso, but there have been problems with tape, either in lack of adhesion or skin sensitivity. Patches are also limited for titration of the dose. The gel is increasingly the preferred delivery system, but AndroGel is expensive. Compounding pharmacies have been adding testosterone to creams for decades. I have been prescribing testosterone in creams for many years, but now that AndroGel is on the market, if the patient's insurance will reimburse for it, and he is comfortable with the diagnosis of hypogonadism for his medical and life insurance companies, the gel becomes the best choice. The inexpensive creams have the advantage of simply adding DHEA if needed. A typical prescription is testosterone 50 mg and DHEA 25 mg per gram of cream;

apply one gram twice daily. Many men prefer to take a single dose, so the concentration is doubled and the cream is applied once daily, either in the morning or evening. Most men apply it in the morning.

Assessing the patient after initiating therapy. The patient should return in two weeks for a review of potential adverse effects (especially aggression) and perceived benefits, such as libido, desire to exercise, or any change in fatigue and energy. Laboratory tests can be obtained at two weeks, just to be certain the dose is not much too low or too high, but a recheck in 6–12 months will allow more accurate clinical and laboratory evaluation. At that time, clinical changes should be evident. Subjective changes in mood, well-being, libido, and erectile function should have stabilized and no longer be subject to placebo effect (as they might be immediately following the start of therapy). Body composition, weight, changes in exercise program, and muscle strength should be measured. For patients with low bone density, DEXA or CT repeat measures should wait for at least one year.

Lab measures. Virtually all published studies of testosterone use serum levels. Saliva testing for testosterone has its advocates but it has not been accepted widely.

It is important to document the last dose. If the patient takes the cream twice daily, he should withhold his morning dose and have the blood drawn in the morning, about 12 hours after the last dose. If he takes only one dose every 24 hours, be sure to consistently check a level at the same time, and be aware that comparing T levels from blood drawn 24, 12, or sometimes 1 hour after cream application can cause big changes in the serum level.

I recommend ordering baseline serum total and free testosterone, DHT, estradiol and DHEA-S, PSA, hemoglobin, and iron (optimally as the panel with iron and transferrin saturation) as a baseline prior to therapy. The four hormones can be remeasured 2–6 weeks later. Optimally, they should also be checked six months later (when PSA and hemoglobin should also be rechecked), and then annually thereafter. It is reasonable for the cost-sensitive patient to not remeasure all four hormones every time. Many men see their hemoglobin creep up from 15 g to nearly 20 g. At 17 g, I encourage them to give blood. The formal prescription for removing a unit is rarely necessary. Testosterone therapy is not a contraindication for most blood banks. If the patient has a strong hematopoietic response to testosterone, a unit of blood may have to be given twice annually. This

may have a risk of iron deficiency but, in practice, most men have iron levels beyond what they need. Since iron is a potent oxidant, lowering the iron level through blood donation is an added benefit.

DHEA. A common mistake is ordering DHEA rather than DHEA-S, the sulfated form. DHEA-S shows more stable blood levels. Not all patients need DHEA therapy with testosterone, but some patients appear to get even lower levels of DHEA after therapy, presumably due to a feedback mechanism, and do well with both prescribed.

Estradiol measures before and after therapy can indicate how much conversion is occurring from T to estradiol, which is in part an indication of the activity of an individual patient's aromatase enzyme. Estradiol serum level of 50 pg/mL with a total testosterone of 500 ng/dL, i.e., about 10% (which is really 1% converting both measures to the same units) is fine. Prescribing anastrozole (Arimidex), which blocks this enzyme activity thus decreasing the estrogen/testosterone ratio, is very rarely necessary. Athletes using high-dose androgens for bulking up may need it, but it should not be necessary for most men with hypogonadism. Low levels of estrogen may affect neurons and bone, and may lead to loss of teeth. Rarely, there are patients with gynecomastia and/or an elevated estradiol level for whom lowering the testosterone dose may decrease its benefit. In my experience, lowering the testosterone usually works, and does not bring into the equation other potential adverse effects of another medication.

DHT is typically about 10% of T; both are often measured in ng/dL. To repeat a theme, the individual variation in conversion of T to DHT, apparently a function of 5-alpha-reductase activity, is enormous. In a few patients, DHT rises dramatically and disproportionately to T. First, ensure the patient is not applying it near the groin. I recommend these patients avoid any application from waist to knees, just to be certain. Having excluded an issue of application of cream or gel, these patients, and perhaps any patient at risk of benign prostatic hypertrophy (BPH), could use saw palmetto or finasteride. Saw palmetto is available without prescription. I recommend it to nearly all men over 50 since lower DHT has been associated with decreased progression of BPH. Finasteride is sold in 1 mg doses (Propecia® and others) to decrease men's hair loss from the scalp, and in 5 mg doses (Proscar and others) for BPH symptoms. Often half of the 5 mg pill works well to keep DHT levels at 10% or less of total T.

PSA should not rise as a result of testosterone therapy. Typically PSA fluctuates perhaps 0.2 ng/mL, but an increase of about that amount in six months merits a repeat test and close scrutiny. Be cautious about comparing PSA results from different labs or different techniques of measure. I measure PSA at least every six months for those patients taking any hormone therapy. For patients with PSA levels greater than 2.5, I measure free PSA (which includes total PSA in the report). Higher PSA levels suggest increased risk of prostate cancer, but *lower* free PSA levels also suggest increased risk. Free PSA is usually measured with the Beckman method, whereas total PSA screening is performed with another method that may have a different total PSA value.

Testosterone measures and lab methodology. The process for measuring hormones differs among labs and often various choices are available at one lab. Testosterone levels are now available measured by “LC/MS/MS,” which means liquid chromatography followed by mass spectroscopy, and then again run through mass spectroscopy. This is the gold standard. Results may be a little lower than those obtained from the traditional Centaur machine. The greatest variations come with measuring free or bioavailable T. T is nearly all bound to SHBG, and more loosely bound to albumin. Long discussions center around “bioavailable T” vs. “free T” since some T that is not totally unbound (usually with albumin) still has activity. SHBG tends to increase in men with age, but there is great variability among individuals. The lab report with “bioavailable T” often lists free T, albumin, and SHBG all as one report. Free and bioavailable are *calculated* values, and often not correct. Only a few years ago, it was discovered that SHBG has two binding sites, not one, so the calculations were wrong. In addition, genetic variations in SHBG allow for tight or loose binding of T, which results in less or more free T, but calculated values cannot take these variations into account.

The best measure of free T is with equilibrium dialysis, so that a membrane permeable to T but not to larger proteins is placed for 18 hours, and then the free T on the other side is quantified. This technique is the gold standard. The report often simply has total and free T measures listed. Beware of labs that measure free T using ammonium sulfate to precipitate out all the proteins. This methodology should be abandoned due to great fluctuations in results.

Following total testosterone only may be better than once thought. It is not subject to the tremendous variation associated with methodologies for free T. In addition, total testosterone may better reflect overall body stores.

Estradiol in men requires a sensitive, accurate measure for these low concentrations. Be sure the lab is not using the inexpensive ELISA kits for estrogen, which are not sufficiently accurate.

Philosophical Considerations

Some modern clinicians might forbid Michelangelo to paint the Sistine Chapel. The fumes from the paint and the prolonged awkward positions on the scaffolding, as well as anxiety about the work itself and arguments with patrons and assistants, would all take a toll on his health. The best physicians, however, would not forbid the work, but would help him achieve his goals with greater safety and preservation of function. Strategies might include getting a pad on the scaffolding, improving ventilation, some stretching exercises, and breathing exercises before arguments with church officials. The value of his work—to Michelangelo, not to others—and the overall cost (to him) of that work, can only be estimated after a good history and careful assessment. And only then can one make recommendations appropriate to the individual.

This little fable is meant to point out that the philosophy and belief system of the doctor influence decisions made on behalf of the patient. In terms of using hormone therapy to offset adverse effects of aging, some clinicians may believe there is a special intrinsic value in remaining natural over “artificial” and “allowing nature to take its course.” Such physicians may rarely prescribe androgens. However, women and men both have diminished physical functions and greater vulnerability to injury and illness following their prime reproductive years. On average, a man loses 75% of his testosterone, and 40% of his lean muscle mass with age. Age-related frailty includes lack of balance and strength, leading to greater vulnerability and increasing risk of hip and vertebral fractures with resulting posture change (kyphosis) and lack of height. In addition, aging men as a group have less joy and more depression. An aging man with low testosterone can expect, as a result of taking testosterone, greater overall drive, including a greater desire to exercise, greater bone density, greater

muscle mass and strength, improved mood, and less susceptibility to depression.

For the first time in history, life after age 60 might fairly routinely last another 30–40 years. With less frailty, thoroughly screened for cancer and heart disease, the older man now has a unique opportunity to change roles, to continue to be highly productive, and to remain physically and sexually active. Certainly, the benefits of taking testosterone must be weighed against the risks of therapy, but the risks associated with doing nothing must also be taken into consideration. Ultimately, the physician must serve the patient, helping him (with reasonable safety) to achieve his personal goals or refer him to another practitioner.

The Epidemic of Insulin Insensitivity

Dan Lukaczer, ND

Introduction

When thinking about patients from the perspective of fundamental clinical imbalances, insulin balance is a critical piece of the puzzle. In most tissues, adequate insulin secretion is necessary for proper glucose disposal and management.³³⁸ The binding of insulin to its receptor in the cell membrane is the first step of a metabolic cascade leading to cellular glucose uptake. When insulin does not bind properly or efficiently, however, the ensuing dysfunction leads to a series of complex effects on various tissues that result in a host of metabolic abnormalities. Insulin insensitivity may be the single most important underlying metabolic dysfunction related to chronic disease. For that reason, you will find it addressed a number of times in this book, from different perspectives.

The term insulin resistance refers to a reduced sensitivity of the cell to the action of insulin. Insulin resistance or insensitivity results when normal insulin action is impaired and the cell does not “hear” the message of the insulin signaling molecule. To overcome this impairment, and to maintain glucose homeostasis, the pancreas will attempt to secrete larger and larger amounts of insulin.³³⁹ There is great interindividual variation in the ability of insulin to mediate glucose disposal. Studies have shown that insulin sensitivity can vary up to 10-fold in non-diabetics.³⁴⁰ Without this compensatory hyperinsulinemia, individuals who are

insulin resistant develop glucose intolerance and diabetes. However, if the pancreas can continue to secrete large amounts of insulin, the individual then continues to maintain near-normal glucose homeostasis.

Insulin resistance and the resultant hyperinsulinemia are surprisingly common, and may be seen in as many as 25% of a normal non-diabetic population;³⁴¹ most individuals who develop insulin resistance maintain normal to near-normal glucose control. It is estimated that 60 to 70 million Americans fall into this category. However, up to 25% of these individuals will go on to develop type 2 diabetes.

Insulin Resistance and Chronic Disease

Not all individuals who are insulin resistant ultimately develop diabetes. However, those who do not are still at increased risk for a variety of other age-related diseases³⁴² that include coronary heart disease (CHD), stroke, polycystic ovary syndrome (PCOS), colon and breast cancer, and cognitive decline. The insulin resistance syndrome (IRS), also referred to as syndrome X or metabolic syndrome, refers to a cluster of signs and symptoms that includes: varying degrees of impaired glucose tolerance, depressed HDL cholesterol, elevated triglycerides, elevated blood pressure, and truncal adiposity. The underlying pathophysiology of the syndrome involves insulin resistance and consequent hyperinsulinemia.

As abdominal fat is increased, insulin sensitivity decreases, production of inflammatory cytokines increases, and the relative risk of heart disease, dementia, and cognitive decline all increase. Recent publications have demonstrated the relationship among lifestyle, adipocyte activity, inflammation, and chronic disease incidence.^{343,344}

Diabetes

There are an estimated 16 million type 2 diabetics in the U.S. and the overwhelming majority carry the underlying pathophysiology of insulin resistance.³⁴⁵ The relative severity of insulin resistance *and* impairment of pancreatic beta cell function determines the severity of hyperinsulinemia and when *or if* hyperglycemia occurs. Normally, insulin has a suppressive effect on circulating free fatty acids (FFAs). When the insulin secretory response declines, circulating FFA levels become elevated. FFAs, in turn, stimulate hepatic glu-

glucose production. Without the normal insulin inhibitory signal, hyperglycemia occurs as the liver continues to secrete normal amounts of glucose into a greatly expanded plasma glucose pool.³⁴⁵ With increasing hyperglycemia there is a further reduction in beta cell function (possibly as a result of glucotoxicity) and a further fall in insulin.

Type 2 diabetes mellitus affects 90%–95% of people with diabetes and most often appears after age 40. However, it can no longer be considered an adult-onset disease, as it is now found commonly in obese teenagers.³⁴⁷ The diagnosis of type 2 diabetes, impaired glucose tolerance, and impaired fasting glucose is based on both the World Health Organization³⁴⁸ and the American Diabetes Association (ADA)³⁴⁹ guidelines. (For an extended discussion, see Chapter 37.) According to these criteria, type 2 diabetes can be diagnosed either by an oral glucose tolerance test (2-hour post-75-gram load) with a value of 200 mg/dL or greater, or by a fasting glucose concentration of 126 mg/dL or greater. In addition, there are intermediate categories of glucose tolerance. Impaired glucose tolerance is diagnosed by a 2-hour post-load oral glucose tolerance test of 140 mg/dL or greater but less than 200 mg/dL, and impaired fasting glucose is diagnosed by a fasting glucose of between 100 and 125 mg/dL. Both individuals with impaired glucose tolerance (IGT) and those with impaired fasting glucose (IFT) are at high risk of developing diabetes. From the ADA position statement:

Recently, IFG and IGT have been officially termed “pre-diabetes.” Both categories, IFG and IGT, are risk factors for future diabetes and cardiovascular disease (CVD) On the basis of expert opinion, screening should be considered by health care providers at 3-year intervals beginning at age 45 years, particularly in those with BMI ≥ 25 kg/m². Testing should be considered at a younger age or be carried out more frequently in individuals who are overweight (BMI ≥ 25 kg/m² ^{iv}) and have additional risk factors.³⁵⁰

This excellent ADA 2005 article provides an in-depth look at a very complex subject.

Coronary Heart Disease

Those individuals who maintain a compensatory hyperinsulinemia in the face of insulin insensitivity do so at great biological cost. A primary consequence is

increased risk for CHD. Metabolic syndrome is associated with CHD through three mechanisms:

1. Elevated insulin directly stimulates lipogenesis in arterial tissue and enhances the growth and proliferation of arterial smooth muscle cells, contributing to arteriosclerosis.^{351,352}
2. Insulin resistance and hyperinsulinemia decrease fibrinolysis by stimulating plasminogen activator inhibitor 1 (PAI-1), which is associated with an increased risk for coronary thrombosis. PAI-1 is higher in patients with CHD and is related to insulin resistance and insulin-mediated glucose disposal.^{353,354}
3. Hyperinsulinemia leads to increased hepatic production of triglycerides (TG) and inhibition of high-density lipoproteins (HDL). Elevated TG and depressed HDL are important risk factors for CHD.^{355,356,357}

This strong relationship between insulin, TG, and HDL apparently results from insulin's influence on the cholesteryl ester transfer protein, which promotes the movement of cholesteryl ester from HDL to very low-density lipoproteins (VLDL).³⁵⁸ The higher the TG levels, the greater the losses of cholesteryl ester from HDL and the lower the plasma HDL concentration. Additionally, Apo A1, which is the major protein associated with HDL and independently associated with reduced risk of coronary heart disease, is catabolized in a high-insulin state, further degrading HDL.

Risk of Cognitive Decline

When the balance of inflammatory mediators is shifted through altered gene expression patterns, the central set points of our physiology are being influenced—the so-called homeodynamic set points, which have to do with alterations in the neuroendocrine-immune system. This is one “super system,” with parts interrelated through receptor physiology and signaling mechanisms that transfer information molecules throughout the body and modify its function. The endocrine system is changed; the immune system is changed; and the nervous system is changed, as a consequence of the shift toward inflammation. “[T]here is accumulating evidence suggesting that inflammation is the bridging link between atherosclerosis and the metabolic syndrome.”³⁵⁹ That is why the metabolic syndrome results in a greater risk for cognitive decline

^{iv} May not be correct for all ethnic groups.

through the adverse impact of inflammatory mediators on neuronal function.³⁶⁰

Hypertension and Stroke

Insulin resistance may also play a key role in hypertension. As many as 50% of the hypertensive population may be insulin resistant.³⁶¹ The sodium hypothesis of hypertension attributes increased peripheral vascular resistance to elevated *intracellular* sodium concentrations. Based on cross-cultural comparisons, this was thought to be mainly due to increased dietary intake of sodium in salt-sensitive individuals. Intracultural studies suggest, however, that dietary salt may account for only a minor segment of increased blood pressure in the hypertensive population.³⁶² It has been proposed that a larger segment of essential hypertension is caused by enhanced renal sodium reabsorption in the distal tubule promoted by hyperinsulinemia.³⁶³ Hyperinsulinemia may also play a role by altering internal sodium and potassium distribution in a direction that is associated with increased peripheral vascular resistance.³⁶⁴ Insulin appears to work through other mechanisms as well to increase sympathetic nervous system activity and thus peripheral resistance.³⁶⁵ This relationship between insulin and blood pressure is further supported by studies that show blood pressure drops when the insulin dose is decreased in obese hypertensive patients with type 2 diabetes.³⁶⁶ Additionally, blood pressure increases when insulin treatment is initiated in diabetic patients.³⁶⁷

Polycystic Ovary Syndrome (PCOS)

Insulin resistance appears to have a critical relationship to androgen hormonal modulation. Research over the past 10 years has linked insulin resistance and hyperinsulinemia with PCOS, a disorder affecting an estimated 6% of women of reproductive age and the most common cause of female infertility in the United States.³⁶⁸ Hirsutism and acne are also common consequences of this disorder. Studies have shown that high circulating insulin may stimulate ovarian cytochrome P450c17 α and 17,20 lyase enzymes in predisposed women, resulting in elevations in serum testosterone and free unbound testosterone, both seen in PCOS.

Insulin influences the androgenic state directly by affecting the metabolism of ovarian androgens, and indirectly by regulating circulating levels of sex hor-

mone binding globulin (SHBG). Insulin has been shown to lower the production of SHBG.³⁶⁹ SHBG binds to testosterone and estrogens, making them biologically unavailable. Lowered SHBG therefore indirectly increases the delivery of testosterone to tissues as increased amounts of testosterone are unbound and bioavailable.³⁷⁰ Studies indicate that improving insulin sensitivity and decreasing circulating insulin beneficially affects women with PCOS.^{371,372}

Cancer

An area of increasing research interest is the relationship of insulin resistance to cancer. One hypothesis has postulated a link between colorectal cancer, insulin resistance, and hyperinsulinemia.^{373,374} While the epidemiological data are not completely consistent, the two largest prospective studies to date do support a modest correlation between colorectal cancer risk and diabetes.^{375,376} Additional support for a promoting effect of insulin on colorectal carcinogenesis has been found in animal models, thereby providing direct evidence for a possible cause-and-effect relationship between hyperinsulinemia and colorectal cancer.^{377,378}

Even more recently, speculation has centered on the link between hyperinsulinemia and breast cancer.³⁷⁹ It has been known for some time that exposure of breast tissue to estrogens increases the risk of breast cancer. It is well established that only the fraction of estrogens unbound to SHBG are biologically available to receptors on target cells. As mentioned earlier, insulin inhibits the formation of SHBG. While SHBG binds to both testosterone and estrogen, it binds preferentially to testosterone; therefore, decreased levels of SHBG will result preferentially in increased levels of free unbound estrogen.³⁸⁰ In support of this concept, some epidemiological studies have shown that high plasma levels of unbound estrogen are associated with increased risk of breast cancer, at least among postmenopausal women.^{381,382,383,384}

Summary

Insulin resistance syndrome represents one of the most important imbalances in clinical care today. It is a multifactorial health condition that has become increasingly common in industrialized societies. It affects, by conservative estimates, a quarter of the U.S. population. It initially manifests as impairments in

insulin sensitivity that cause a cascade of biochemical changes resulting in increasing risk for a host of chronic degenerative diseases. Coronary heart disease, hypertension, polycystic ovary syndrome, cognitive decline, and type 2 diabetes appear to be directly related to this metabolic imbalance. Certain cancers may also be causally related. The economic costs of treating these end-stage disorders are enormous. Recognition and early treatment are, therefore, essential. Treatment of the underlying biochemical defect, loss of insulin sensitivity, and resistance to glucose disposal is of central importance. While genetic inheritance may determine propensity to the disorder, modifiable factors such as weight, exercise, smoking, diet, and nutrition play a critical role. A comprehensive strategy of lifestyle and dietary modifications along with nutrient supplementation is an important step in clinical management of this fundamental clinical imbalance.

Chapter 20

Neurological Imbalances

Catherine Willner, MD

Introduction

It is important to understand some of the ways in which the nervous system is different from other organ systems in the body—and the extent to which its failure to function can be a devastating consequence both to the individual and to society. The cells and tissues of the human nervous system share many features in common with all other cellular structures in the body. In this sense, all principles of functional medicine can be applied in situations where the predominant problem faced by a clinician seems to be one that is neurological. In fact, it would be the most appropriate application of the principles of functional medicine to optimize functioning *before* a specific disease related to genomic or environmental risk can be identified. However, getting to that ideal requires understanding the nervous system in terms of the unique biochemistry, physiology, and pathology that sometimes set it apart from other systems. These issues deserve special attention.

Functional medicine approaches the nervous system as one part of a web of interconnectedness of all bodily systems and functions and assesses how to optimize processes that permit healthy functioning of the whole organism. Functional neurology considers this web as it impacts the ability of the nervous system to perform optimally in all of its functions. It is sometimes a struggle to make the leap between traditional neurology and these paradigms, but it is also a very exciting challenge. We will look briefly at certain aspects of traditional neurological assessment, explore some unique characteristics of the nervous system, and then discuss the application of this knowledge to functional neurology.

Traditional Neurological Assessment

Neurologists are taught very precisely to label in space (anatomy), function (physiology and pathology), and time (pathophysiology of acute, subacute, and chronic), and to consider genetics and the environment (though we are traditionally taught little in terms of how to impact the latter two elements). Often, those disorders that we recognize as being impacted by environmental influences are considered as irreversible or too delayed to alter when they result from certain toxic exposures or severe deficiencies. There are, of course, exceptions, such as disorders associated with B12 deficiencies, or metabolic changes that occur with acute or chronic alcohol exposure, or the cognitive and other neurological changes associated with altered thyroid status. We are taught that these can be at least partially reversed by treatment if they are recognized early, and their recognition is a core aspect in traditional neurological training. However, in many circumstances, by the time these disorders have actually resulted in diagnosable conditions involving the nervous system, the damage is quite severe. Traditional neurology is only beginning to respect the more subtle aspects of metabolic dysfunction and to apply methods to assess or prevent early failure in the system (e.g., the use of folate to prevent neural tube defects).

Assessment of the temporal sequence of pathophysiological events is often useful in diagnostic considerations. Acute events, particularly those that occur suddenly such as stroke, migraine or seizure, are different than the subacute (infection, demyelinating disorders like multiple sclerosis) or chronic progressive disorders that involve cognition and memory (dementias), movement, or other bodily functions. Those are usually considered the system disorders: parkinsonism,

cerebellar disorders, autonomic failure, peripheral neuropathies, and various combinations (multisystem diseases or atrophy). Disorders that cause progressive loss of the functions of the nervous system have been traditionally labeled *neurodegenerative*. Some of these chronically progressive disorders are listed in Table 20.1.

Table 20.1 Traditional Neurodegenerative Disorders

Dementias (Alzheimer's, Pick's, Lewy body disorders)
Idiopathic Parkinson's disease
Parkinson plus syndromes (dementia, the most frequent)
Cerebellar degeneration (olivopontocerebellar atrophy)
Shy-Drager syndrome (autonomic failure)
Progressive supranuclear palsy
Motor neuron disorders (e.g., ALS)
Hereditary peripheral neuropathies

Because we are living longer as a population, and because our population as a whole is aging, many people are surviving much longer with these diagnoses, although the impact on the patient's quality of life and the economic burden on society are both significant. However, it is important to take into consideration that other disorders, not specifically considered neurodegenerative, also are costly to manage. For example, the toll in terms of work attendance, activities of daily living, and pain caused by migraine alone is quite high.¹ The availability of progressively more expensive pharmaceuticals to treat this disorder has not solved the underlying problem, although it brings symptom relief to many.² As with almost every other traditionally labeled "neurological disease" or disorder, *prevention* of stroke, migraine, epilepsy, multiple sclerosis, peripheral neuropathy, the dementias, and the degenerative system disorders should be as important as management.

Function and Structure: The Nervous System

Probably the most important task performed by the nervous system in a general sense is communication, which permits coordination of adaptive responses both within the brain and throughout the entire organism. This permits, for example, *awareness* (perception) of both internal and external environments and *performance* in those environments. Rapid adjustment or fine tuning of both awareness and performance is a function of the unique features of that communication system. Though such processes are present in most other organ

systems, the nervous system is unique because of the rapidity with which it can alter function, and also because of the greater distances from the origins of many signals. It is also unique because it permits awareness of and interaction with the environment (consciousness, memory, cognition). This system of communication requires electrical potentials as well as chemical interactions from neurotransmitters or substances more traditionally considered hormonal. And, the nervous system allows us to perceive and to react both at a conscious level and with autonomic activity, where conscious awareness is not required.

There are certain features of the nervous system that warrant consideration in this discussion:

- The nervous system has *unique energy requirements* that include fairly consistent access to oxygen and to glucose, though other carbon-based fuels can be accommodated. It is a demanding metabolic environment with high energy requirements partly because of the generalized need to maintain electrochemical gradients to allow generation of action potentials appropriately and to allow receptors to function normally. Mitochondrial function, as the source of this energy, is key to optimization of function.
- The method of communication at synapses by neurotransmitters and receptors requires continuous recycling of both the chemicals and their receptors. This requires a normally functioning genome as well as access to substrate to make the enzymes, the neurotransmitters, and the receptors.
- Maintenance of the membrane structure system is critical to normal performance of neurons and the surrounding complex cellular system of glial cells. Discussion of their complex functions is beyond our scope, but one of their major functions is to provide insulation by forming myelin, which permits electrical activity to travel appropriately to the correct destination at speeds in the range of 100 m/s.
- As a result of that need for insulation, both in the brain and at a distance, through the fiber tracts and the peripheral nervous system, the concentration of lipid is unique and high, both as cell membrane components and in the myelin, which insulates axons (the processes sent out by cells to accomplish this communication). The relatively high content of polyunsaturated fatty acid (PUFA) places the

brain at significant risk for lipid peroxidation secondary to free radical damage.

- It is also important to remember that the neurons are, for the most part, postmitotic tissues. Though potential for regeneration (especially in the periphery) and plasticity of surviving neurons is one of the strong points of the system, the limited ability of the nervous system to regenerate or replace damaged cells does have serious consequences.
- Certain regions of the brain, specifically the substantia nigra and the striatum, have very high concentrations of iron, which also increases the risk of peroxidation.
- Finally, the nervous system is relatively segregated from the rest of the body—from the bloodstream in particular by the blood-brain and blood-nerve barriers.³ This segregation necessitates a separate source for immunological protection and defense, mostly provided in the CNS by the glial cells. When the system fails, the consequences can be devastating. (Neuroimmunology is a very complicated and fascinating subject. The gut, with its unique role of interaction with the external environment, has similar types of barriers and unique defenses and many of the same principles of functional medicine can be applied. See *The Gut-Liver Axis* in Chapter 31).

A short summary of the features discussed above is presented in Table 20.2. Now, let's consider some of the consequences of these features and how functional neurology might approach the task of enhancing or protecting these functions, particularly in situations where the nervous system might be vulnerable. Our specific focus will be on the consequences of oxidative dependence—free radical damage, neurotoxicity, and apoptosis (cell death).

Table 20.2 The Nervous System—Unique Features

High energy requirements, mitochondrial dependence
High metabolic turnover, excitatory transmitters
Post-mitotic state
High lipid content (specialized membranes, PUFA)
Transmembrane electrochemical gradient
Region-specific mineral concentration (Fe)
Sequestration (BBB/BNB/myelin)

Neurological Vulnerability: Oxidative Dependence and Free Radical Stress

The nervous system, with its high metabolic requirements, uses about 20% of the oxygen provided from ventilation. Oxygen and oxygen species are used in the body for several different functions, including their role in the respiratory chain for energy production, as ATP is manufactured by alteration of carbon bonds to form water and carbon dioxide. Oxidation also plays a role in defense against destruction or damage caused by foreign substances and free radical attack.

Free radical formation is a necessary and essential function of these systems; however, when the system is not balanced, that function fails. There are elaborate mechanisms of protection from free radical damage for the brain and body:⁴ enzymes such as SOD (superoxide dismutase—requiring Zn, Cu, Mn), glutathione peroxidase (requiring Se), and catalase (requiring Fe); dietary antioxidants (Vitamins C and E, among others); and endogenous antioxidants (coenzyme Q10, carnitine, lipoic acid).

There are risks in this setting that are both genetic and environmental. In both acute and chronic disorders, there is evidence that both energy metabolism deficits and glutamate-mediated excitatory transmitter dysfunction may be causative and integral to damage by reactive oxygen and nitrogen species.⁵

The Basics of Oxidative Stress and Neuronal Function

The respiratory chain provides the mechanisms for production of energy through the formation of high-energy phosphate bonds. (The basics of bioenergetics are discussed in Chapter 16.) The system is a complex one, involving membranes, enzymes, cofactors, substrates, and the cellular organelles called mitochondria, which are maternally inherited and contain their own DNA (mtDNA is discussed further in Chapter 21). Getting down to absolute basics, the neurons, like every other cell in the body, utilize carbon-based atoms and oxygen to produce energy for the production of enzymes, neurotransmitters, and structural components of the cell (such as complex receptors). One of the most important functions of this system is the maintenance of an electrochemical gradient or membrane potential, which is unique for cell systems that can generate an “action potential” or other electrical charge. The action potential

is the basis for the rapid communication capacity of the nervous system. As mentioned above, the necessity to provide insulation or sequestration for the electrical charge is supported by the formation of myelin, which is a complicated lipid structure produced by glial cells in the central nervous system and by Schwann cells in the periphery. These supporting cells (including the glia) perform many other protective functions as well by processing or storing many of the neurotransmitters in the system when they are not acting as receptors.

Energy is required to accomplish all of these tasks. When the mitochondria fail to produce adequate energy, the result will be suboptimal function at many levels in the cells within the system in general.⁶ However, in addition to the impact that might be caused by inadequate energy availability for normal functioning, there is also the risk posed by the process of extracting such energy. The work of producing energy via the mitochondria has a price that includes generating free radicals and other products that have to be handled by the system. Free radicals are dangerous to many targets, especially the mitochondrial DNA and lipid-laden membranes (which are especially available in the nervous system). If not appropriately managed, free radicals cause oxidative stress, a topic that is discussed in greater depth in Chapters 21 and 30. A list of common targets for free radical damage is presented in Table 20.3.

Table 20.3 Free Radical Targets

Lipid cell membranes
Cell receptor complexes
Enzymes
Structural proteins (neurofilaments)
DNA
Mitochondrial buffering*
Viruses, bacteria*
*Normal functions

The generally recognized diseases associated with mitochondrial disorders, which were traditionally referred to as mitochondrial encephalomyopathies, are now more commonly called mitochondrial cytopathies⁷ to emphasize the multisystem nature of the dysfunction. The most common of these are summarized in Table 20.4. There are disorders now known to be associated with defects in each of the five complexes classically described within the mitochondria.⁸ Though most

of the proteins and subunits of the mitochondria are actually encoded by nuclear DNA, there are 13 critical polypeptide subunits of the electron transport complexes that are formed by mitochondrial DNA.⁹ The actual mitochondrial dysfunction can be anything from a specific point mutation in mitochondrial DNA to large-scale deletions or duplications. The inheritance is variable from maternal, both dominant and recessive, to acquired or sporadic mutations. Many changes in function that occur with aging are thought to be related to the consequences of oxidative stress or various toxic insults, to which the mitochondria seem to be particularly predisposed because of their relative absence of DNA-repairing enzymes.¹⁰

Table 20.4 Mitochondria-related Disorders

Kearns-Sayre syndrome (ophthalmoplegia, retinal pigmentation, conduction block, dementia)
LHON (Leber’s hereditary optic neuropathy; subacute blindness in young adults)
MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes)
MERRF (myoclonic epilepsy, ragged red fibers)
CPEO (chronic progressive external ophthalmoplegia)
Pearson’s syndrome (sideroblastic anemia, pancreatic dysfunction, death in infancy)
NARP (neuropathy, ataxia, retinitis pigmentosa syndrome)
Maternally inherited myopathy with cardiomyopathy (spares the CNS)

The heterogeneity of these disorders is related to the specific dysfunction, but the major organ systems involved are those that are most dependent on oxidative metabolism: the brain and muscle (skeletal and heart) are the most frequently affected, though other tissues like the kidney and liver are also clearly at risk. The abnormality most often discussed in the skeletal muscle is the development of mitochondrial proliferation with abnormal morphology (which, along with patchy atrophy, gives the appearance of “ragged red” fibers on trichrome staining). Interestingly, these changes are not seen frequently with nuclear DNA changes, but are quite common with disorders produced by abnormalities of the mitochondrial DNA.

Glutamate Excitotoxicity and Cell Dysfunction

Glutamate, probably the most abundant free amino acid in the central nervous system, is the main excita-

tory amino acid (EAA) neurotransmitter in the CNS.¹¹ Though the majority of glutamate is actually housed within the neuronal storage vesicles, there are high quantities in the extracellular space. The other major excitatory substance is aspartate. Analogous to the double-edged sword of mitochondrial respiratory chain free radical production, these EAA neurotransmitters are critical to the brain's plasticity of function. However, in excess, they are toxic to neurons. There are two major receptor types for glutamate, ionotropic and metabotropic. Ionotropic receptors are grouped into two major subtypes: NMDA (N-methyl-D-aspartate) and non-NMDA receptors (the AMPA/kainate receptor). The metabotropic receptor is coupled to cyclic GMP and modulates production of intracellular messengers, which also influence the ionotropic glutamate receptors. Under normal circumstances, when adequate energy and cell function permit the electrochemical gradient to maintain a normal membrane potential, the NMDA receptor is blocked by magnesium. Loss of the gradient results in loss of the magnesium ion blocking the NMDA receptor, which, when activated by glutamate, results in influx of calcium into the neuron. Under normal circumstances, this reaction is self-limiting. In models of neurotoxicity, there is an escalating cascade of damage leading to cell death.¹²

This same scenario of excitatory neurotoxicity is postulated in the mechanisms of ischemic and hypoxic damage as seen with stroke or hemorrhage. In this setting, rather than a clear-cut loss of energy and change in gradient potential altering the receptor for glutamate, it is suspected that there might actually be increases in the amount of glutamate because of failure of the surround to modulate the substance.¹³ The consequence is overactivation of the receptor due to excess amounts of glutamate, then ultimately cell failure. Both sodium and calcium are increased intracellularly in this setting.

Exogenous glutamate receptor agonists are known to produce neurotoxicity. One of the best understood models comes from clinical insights about lathyrism,¹ characterized especially by spastic paralysis of the hind or lower limbs. Lathyrism results from an AMPA glutamate receptor agonist found in the foods known to be associated

with this condition; it produces a clinical syndrome similar to or mimicking ALS, predominantly with upper motor neuron changes.

Once the receptor cell is activated, glutamate is normally recycled by active transport back into glial cells or it is to some extent sequestered in neurons.¹⁴ Its elevation extracellularly can cause continued reactivation of both NMDA and non-NMDA receptors, thereby allowing increased levels of calcium to enter the neuron. Calcium is normally buffered by intracellular buffering proteins such as calbindin or parvalbumin. However, when the buffering capacity is exceeded, the excess calcium ions may catalyze the activity of specific destructive enzymes that are not normally activated. These include xanthine oxidase, nitric oxide synthase, and phospholipase, all of which produce free radicals, including reactive oxygen and nitrogen species.¹⁵

Sustained elevation of calcium in particular is thought to initiate toxic consequences, including activation of catabolic enzymes such as proteases, phospholipases, and endonucleases that damage enzymes, membranes, and DNA.¹⁶ These can be rapidly lethal. High intracellular calcium also leads to uncoupling of the mitochondrial reactions, resulting in further production of free radicals as well as energy failure. Other activations include initiation of protein kinase and lipid kinase cascades, which include, for example, activation of calcium calmodulin kinase (CaMK) and other kinases that modify the function of ion channels, including the NMDA and AMPA/kainate receptors.¹⁷ High intracellular calcium leads to formation of free radicals by several other mechanisms as well, including calcium-dependent activation of phospholipase A2, which liberates arachidonic acid, leading to further free radical production and lipid peroxidation.

Glutamate Excitotoxicity and Free Radical Production: The Feed-Forward Loop

During normal cell function, stimulation of the NMDA receptors leads to activation of nitric oxide synthase (NOS). The release of nitric oxide that occurs as L-arginine is oxidized to citrulline by NOS is a short-lived reaction and self-limiting under normal circumstances.¹⁸ Nitric oxide is a potent vasodilator and a free radical species itself, but is not thought to cause severe damage in normal physiology. As with other reactions, its normal role in metabolism is necessary for health. Once increased excitotoxicity leads to calcium-altered

¹The grass pea, *Lathyrus sativus*, ... [has] a high content of β -N-oxalyl-L-alpha, β diaminopropionic acid (ODAP), the compound considered to incite the condition known as "lathyrism," an irreversible paralysis, if the seeds are consumed in excessive amounts From <http://www.hort.purdue.edu/newcrop/proceedings1993/V2-256.html#Grasspea>.

enzyme systems and free radical generation, there is damage of all the cell components mentioned above. Superoxide (O_2^-), produced by xanthine oxidase, reacts with nitric oxide (NO), produced by NO synthase, to form peroxynitrite ($ONOO^-$), one of the most potent reactive nitrogen species; it causes nitration of intracellular proteins containing tyrosine.¹⁹ These changes result in further damage to structural and enzyme proteins and increase the demand on the mitochondria, which further upregulate in response, but cannot adequately counter the production of their own free radicals, resulting in even more damage. Peroxynitrite is also indicted in other reactions within neurons,²⁰ including DNA deamination, strand breaks, mutations, and damage to the mitochondrial Complexes I and II and to mitochondrial aconitase. Ultimately, cell death occurs as a result of multiple system failures.

Because of the significant toxicity posed by peroxynitrite, research is being conducted concerning the role of the nitric oxide and NOS systems in the neurodegenerative disorders and their potential for manipulation to prevent this cascade of damage.²¹ There are a number of disease models where induction of NOS is suspected as a trigger in the progression of pathology. Indications have been seen in the experimental model of multiple sclerosis (EAE, experimental autoimmune encephalomyelitis) and are widely demonstrated in models of cerebral ischemia for stroke. Aminoguanidine, an inhibitor of NOS, was used in the EAE model and resulted in a dose-dependent reduction of disease expression.²² Using the MPTP model (discussed in Chapter 21), researchers have shown that pretreatment with an inhibitor of NOS (7-nitrosindazole) prevented development of parkinsonism and typical cognitive changes seen in baboons exposed to MPTP.²³ Application of NOS synthase inhibitors also provided protection in cortical neuron cell cultures against the toxic effects of beta-amyloid, which is the altered protein structure known to be associated with the plaques of Alzheimer's disease.^{24,25} It is also known that exposure of rat microglial cells in culture to beta-amyloid results in the release of nitric oxide, especially in conditions of inflammatory upregulation.²⁶ Arginine analogs have been used to interfere with this NOS pathway; however, most of the substances studied are potent vasoconstrictors that interfere with normal function, making clinical application elusive.²⁷

Similar problems have been encountered in attempts to identify pharmacological substances that block the NMDA receptors. Some of the newer anticonvulsant-type medications have some degree of NMDA-blocking activity. Although in theory this might be protective in many settings, including acute brain injury, ischemia, or surgical stress, when direct application of NMDA inhibitors has been attempted, significant problems with memory, learning, and overall functioning have resulted.²⁸

Summary

Certain unique attributes of the nervous system, in combination with the complexities of mitochondrial function and the generation of free radical species as part of normal metabolic function, lead to the recognition of a delicate balance that must be fostered to permit healthy human functioning. These insights also offer the opportunity to apply scientific principles to the optimization of CNS systems in an effort to minimize genetic and environmental risks that can result in myriad neurological disorders, from migraine to stroke to MS to parkinsonism and dementia.

Chapter 21

Oxidation-reduction Imbalances

Catherine Willner, MD

Introduction

In Chapter 20, we learned about the importance of energy to the nervous system, and we discussed its vulnerability to injury as a result of the oxidative stress that accompanies energy production. Now, we will examine in greater depth the structure, function, and genetics of the mitochondria—the energy producers of the body—and their role in certain nervous system pathologies.

The tiny cellular organelles called mitochondria are present in almost all cells, with predominance in highly metabolically active cells such as skeletal and cardiac muscle and the nervous system. The relationship between mitochondria and the cells in which they reside is a unique interdependence and has much to teach about the important principles of energy and oxidative stress and their importance in functional medicine. In this past century, the theory that mitochondria were originally bacteria that formed a symbiotic union with early prokaryotic cells has generally come to be accepted, though there were historically many alternative hypotheses as to their origin.^{1,2} Among several factors arguing for their origin as “oxygen-metabolizing” early bacteria are the many features they share with unicellular organisms, including morphology, consisting of two membranes and invaginations called cristae, with shapes typical of bacteria. Weighing in as perhaps the strongest argument for bacterial origin is the fact that they contain their own genetic material. For a very detailed and fascinating review of this history, as well as the current scientific status of mitochondrial functions across species, the work by Scheffler is an excellent resource.³

Mitochondrial Functions

Biochemical processes that occur within mitochondria are outlined in Table 21.1. The best known of these processes is oxidative phosphorylation, accomplished by the membrane-based respiratory chain, which consists of five subunits and requires a number of transporters and complex molecules. (Chapter 16 on Bioenergetics contains Figure 16.4, which depicts this mechanism.) This complex oxidizing electron transport chain is the primary source of the high-energy phosphate substrate ATP, but it is important to remember that many other functions also take place there. The citric acid cycle, amino acid biosynthesis (and, most prominently in liver tissue, the urea cycle), and fatty acid oxidation all make substrate available for oxidation within mitochondria. Additionally, calcium regulation or buffering and a series of control mechanisms for the process of programmed cellular demise (apoptosis) are also in the domain of mitochondrial control. These are biochemical processes that, in general, regulate energy metabolism and prepare for the oxidation of carbon-based structures to provide energy for other cellular functions. In an efficiently functioning mitochondrion, the downstream products of this process are ATP, carbon dioxide, and water. The presence of mechanisms impacting the ability to induce apoptosis makes sense because energy and calcium metabolism must be closely monitored to maintain normal cellular function, especially in the cells that have high energy demands. Mitochondrial function and the ability to support normal cellular functions, especially in highly demanding neuromuscular tissues, not only change with age but are at risk from environmental, intrinsic, and genetic injuries and insults. These functions are worthy of discussion as they relate to the unique genetics and structure of mitochondria because

understanding the physiology creates the potential for modifying pathology.

Calcium metabolism and cytoplasmic sequestration
Apoptosis

Mitochondrial Genetics

Mitochondria contain their own DNA (mtDNA) and in humans mtDNA is responsible for forming some necessary substrates for energy production. A large number of the components necessary for this process actually are formed from messages contained in nuclear DNA, especially Complex II, which is associated with succinate dehydrogenase. Many other genes that might be required for a bacterium to function independently have been relocated to or subsumed by nuclear DNA. Mitochondria have lost the ability to translate proteins as efficiently as their independently surviving counterparts. Mitochondrial DNA in the human is double stranded and circular, consisting of 16,569 base pairs;⁴ it contains approximately 37 genes in comparison to the thousands of genes present in bacterial DNA. For the most part, the functions that remain the responsibility of mtDNA are associated with oxidative phosphorylation. The mitochondrial genes encode for 13 polypeptides involved in that process, as well as ribosomal RNA and transfer RNA.

Mitochondria and mtDNA are primarily maternally inherited. (There have been exceptions reported, with clinical disorders such as myopathy originating from paternally inherited mtDNA.⁵) Clinical manifestations of mitochondrial dysfunction, discussed below, are highly variable and will be expressed in both females and males, but it is predominantly the females who pass on the mitochondrial and mtDNA mutations to their progeny. There is potential for some paternal contribution to mitochondrial (dys)function because of nuclear genetics, but mtDNA is involved in producing essential components of oxidative phosphorylation and evidence has mounted during the past century that mtDNA mutations produce many of the clinical disorders related to mitochondrial dysfunction.

The expression of these disorders is complex, not only because of the interaction of mitochondrial and nuclear genetics, but also because of how mitochondria reproduce within different cell lines and tissues. The number of mitochondria within any given cell varies on the basis of energy requirements for different tissues. In the context of athletic training or increased energy demands within a specific tissue, the number of mitochondria can increase, which requires replication of the mitochondria completely unrelated to cellular division. Additionally, there is more than one mtDNA in the typical mitochondrion, which permits variable expression of mutations during replication. The co-existence of normal mtDNA alongside mtDNA with mutations, whether spontaneous or inherited, is known as heteroplasmy. In a normal person, a completely normal mtDNA genome is present in all the mitochondria (homoplasmy). In an individual carrying mutations, there will be some normal and some mutated mtDNA within the mitochondria. These interesting features of mitochondrial genetics and their interactions with different cellular components account for variations on the expression of dysfunction in different tissues, in different family members from the same mother, and in changes that occur over time. For a more in-depth discussion of these interesting phenomena, excellent reviews are available.^{6,7}

Mitochondrial Structure

The content of the phospholipid bilayer is composed of two membranes, an important factor in mitochondrial function. Like all membranes, the mitochondrial membranes function better when fluidity is optimized. The inner membrane is especially unusual because of the relatively high content of protein complexes forming the respiratory chain. Cardiolipin (diphosphatidylglycerol) is thought to be unique to this inner membrane; it is highly concentrated at these sites and appears to be involved in proper functioning of the respiratory chain, where oxidative phosphorylation occurs. As mentioned above, the respiratory chain is composed of five subunits named Complex I–V. Four of the five are predominantly produced by coordinated actions of nuclear and mtDNA-generated polypeptides. Complex II is formed uniquely from nuclear transcription products. Two of its four subunits are associated with the enzyme succinate dehydrogenase, which is one of the enzymes involved in the

citric acid cycle. Therefore, there is a mechanism for the respiratory chain to monitor CoA utilization and reducing equivalents (NAD and FAD) in the organelle. These substrates, nicotinamide adenine dinucleotide and flavin adenine dinucleotide, are derived from B vitamins (niacin and riboflavin). Cytochrome c and other heme-based molecules are integral to the function of the respiratory chain and are produced within the mitochondria.

Another very important structural and functional component is the ubiquinone family, specifically coenzyme Q10. Because this sterol-like structure is formed within the body using the same acetylation pathway as cholesterol, its formation can be disrupted by statin drugs, which block an early step in the metabolic pathway of its production (HMG CoA reductase). Though there may be some element of selectivity of enzymes for substrates leading to this pathway, enabling statins to impact cholesterol synthesis more dramatically, this is incompletely documented. For more detailed analysis of these processes and other functions accomplished in and by mitochondria, a number of interesting reviews can be consulted.^{8,9,10,11,12}

Mitochondropathies

Disorders of mitochondrial function cross many medical disciplines simply because of the presence of mitochondria in metabolically active tissues. Though there are clearly clinical manifestations isolated to single tissues, the disorders typically attributed to mitochondrial dysfunction involve several tissues. They are intriguing because of the complex issues related to maternal inheritance in the mtDNA, tissue heterogeneity and heteroplasmy, as well as the autosomal genomics relevant to nuclear DNA. The highly energy-dependent nature of the neuromuscular system, however, naturally leads to a prominent position for these tissues in the pathophysiology of mitochondrial disorders. Many have been named or classified by the systems involved or the symptoms associated, although, as the complex genetics of mitochondria have been elucidated, there has been an effort to associate specific disorders with specific alterations in either mitochondrial or Mendelian nuclear genetics, or both. In addition to genetic explanations for failure of energy metabolism, there are also disorders associated with mitochondrial failure caused by other factors, including those associated with use of certain antibiotics that damage

mitochondria^{13,14} or pathological conditions such as stroke, where mitochondrial function can be altered to the point that apoptosis is triggered despite initial cellular survival following anoxic insult. There are also genetic mutations that damage other mitochondrial functions besides ATP production, including disorders of mineral storage, calcium homeostasis, and multiple cellular processes that can lead to apoptosis.

The earliest description of mitochondrial disorders associated with alterations in mitochondrial DNA was a report in the late 1980s of a mitochondrial myopathy associated with a specific large genetic deletion.¹⁵ Leber's hereditary optic neuropathy (LHON) within one specific family was then identified to be associated with a point mutation.¹⁶ LHON is clinically associated with rather sudden onset of blindness from optic atrophy, most often seen in males.

The more common syndromes associated with mtDNA defects, though all quite rare, have been named historically by their symptom complexes. MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes) typically presents during childhood with a clinical presentation that includes episodes of vomiting, headaches with migrainous features, and vascular events similar to stroke episodes (although imaging does not typically show lesions concordant with normal "vascular" strokes). The presence of lesions typical of scarring beyond vascular territories has made an argument for these being metabolically induced areas of tissue damage.¹⁷ Over time, there is progressive loss of function. As information about the genetics of mitochondria has been uncovered, the MELAS syndrome, like other disorders, has been found to be associated with many different mutations in mtDNA.¹⁸

MERRF (myoclonus, epilepsy, ragged red fibers) is characterized by those clinical features, including the myopathy associated with the pathological hallmark of ragged red muscle cells on biopsy. Ataxia and cognitive decline to the point of dementia are typical, as is damage to other energy-dependent tissues, such as hearing and peripheral nerves. A list of the more common syndromes with neurological features is presented in Table 21.2.

A very intriguing case presentation of a patient with myopathy developing in adulthood emphasizes the variability associated with mitochondrial division and replication. The pathology, associated with ragged red fibers and Complex IV-deficient fibers, increased over a 12-year period of study.¹⁹ Progenitor muscle satellite

cells capable of regenerating muscle tissue showed no, or only very low levels of, mutated mtDNA, leading to an intervention that seemed to reverse the presentation by stimulating these progenitor cells.²⁰ In tissues that do have the ability to regenerate, albeit slowly, this represents an exciting potential for possible treatment of these frequently devastating disorders. Though beyond the scope of this discussion, the treatments directed at these disorders have been rather disappointing, including use of antioxidants and nutrients to support mitochondrial structure and function.

Table 21.2 Mitochondriopathies (the more common syndromes)

MELAS (mitochondrial encephalomyopathy, lactic acidosis, stroke-like episodes)
MERRF (myoclonic epilepsy with ragged red fibers)
LHON (Leber's hereditary optic neuropathy)
KSS (Kearns-Sayre syndrome)
CPEO (chronic progressive external ophthalmoplegia)
PS (Pearson syndrome)
NARP (neuropathy, ataxia, retinitis pigmentosa)
MILS (maternally inherited Leigh syndrome)
AID (aminoglycoside-induced deafness)

The autosomal inheritance related to mitochondrial dysfunction is more complex simply because of the volume of functions served by nuclear DNA products and because there can be overlap of disorders of both genomes, which further complicates the clinical picture. Leigh syndrome, a disorder of infancy and childhood involving psychomotor delay, a variety of cognitive changes, and seizures, can be inherited as a recessive, x-linked or maternal disorder. Because of the large number of mitochondria and their dependence on energy, the tissues most involved include the nervous system and cardiac and skeletal muscle. The liver, kidney, and pancreas can also be involved in many of these syndromes. Exercise intolerance, frank myopathies with muscular weakness and wasting, arrhythmias, and a variety of neurological symptoms are common in these conditions. Leukoencephalopathy (white matter lesions by MRI) is fairly typical. Evaluating for dysfunction in these tissues is the starting point in the assessment of these patients, but formal neurological evaluation is very useful to delineate the nervous system features that occur so frequently. Liver and renal function should

also be assessed, as well as lactate levels, which can be elevated at rest. Not all patients will present with such laboratory changes. Limited exercise can sometimes reveal early and significant elevation of lactate levels. When suspected, cellular DNA can be analyzed, including in the white blood cells. As discussed above, because Complex II is not under the control of mtDNA, a normal or elevated level of succinate dehydrogenase can be diagnostic of a mitochondrial DNA disorder in the context where the activity of other complexes is reduced.

There are genetic disorders of other types of mitochondrial function in addition to those associated directly with energy production, such as iron transport and storage. An x-linked sideroblastic anemia related to iron export has been identified and so have defects of iron storage in certain presentations of Friedrich's ataxia. A mutation recognized to be related to a deficiency of thymidine phosphorylase, leading to accumulation of thymidine, may prove to be amenable to treatment.²¹ Finally, genetic and environmental disorders associated with reduced coenzyme Q10 have been identified. They do respond to replacement therapy in the absence of other significant genetic pathologies but the clinical response has not been uniform in all disorders.²²

These disorders of mitochondrial function can be inherited maternally or develop sporadically from spontaneous mutations and must, to some extent, exhibit heteroplasmy (with some normal "wild-type" mitochondria) to permit survival. As techniques capable of quantifying mtDNA damage, especially deletions, have become available, there has been mounting evidence that progressive mitochondrial dysfunction is associated with aging and is highly variable between different tissue types and individuals.²³ Cells with high rates of turnover tend to exhibit less mtDNA damage, while cells with slower turnover, such as muscles and the nervous system, show progressive increase in the frequency of mtDNA deletions.

Oxidative Stress

Mitochondria provide high-energy substrates at a cost. The process of oxidative phosphorylation, though an efficient pathway for the production of ATP, is also a major source of free radicals, which have the potential to damage cellular components, including any and all structures that can be oxidized. Phospholipid membranes, DNA, enzymes, and other proteins are most

vulnerable to this type of damage. It is estimated that 1-2% of oxygen utilized in normal mitochondria ultimately forms free radicals such as superoxide, hydrogen peroxide, and hydroxyl radicals, which obviously puts the mitochondrial membranes, cardiolipin, and mtDNA at high risk for oxidation. Though there are elaborate buffering systems in place, both at the level of the mitochondria and within the cellular matrix, these protective processes can be overwhelmed. Free radical oxygen and nitrogen processes, generated as part of normal metabolism, can also intermix to produce peroxynitrite, a particularly volatile substance with great potential for lethal damage to cellular components.

There are other sites at risk for oxidative stress in cells that utilize oxygen, including the cytochrome P450 system, peroxisomes, and cytosolic oxidases. These subcellular components have their own systems of protection, which can also be overwhelmed. As methods for assessing oxidative damage to various structures have become more available, we have learned that such damage is present in many chronic diseases, especially in those that involve neurological tissues. Because a normal membrane potential is required for propagating action potentials and for normal receptor function in neurons, the importance of healthy membranes with adequate ATP is paramount to normal neurological function. Consider, for example, the physiology of excitotoxicity mediated by the excitatory transmitters, glutamate and aspartate, which act at the NMDA (N-methyl-D-aspartate) receptor. This receptor complex allows calcium to enter the cell, which is a normal physiological mediator of numerous cellular processes. However, when the system malfunctions, the consequence of abnormal activation of these receptors is called excitotoxicity, and it can contribute to pathology and ultimately cellular demise in many different clinical settings. An excellent review of this important topic was done by Waxman and Lynch in 2005.²⁴

Neurodegenerative Disorders

The hallmark of the neurodegenerative disorders is progressive loss of specific populations of neurons. Because neurons are so energy dependent and mitochondria do have a significant role in programmed cellular demise, specifically the process of apoptosis, mitochondrial dysfunction has come to be associated with such disorders.²⁵ Though some of the neurodegen-

erative disorders are indeed associated with known genetic risks, more commonly the pathophysiology identified at autopsy (and in animal models of these disorders) involves free radicals, oxidative stress, and altered calcium metabolism—that is, environmental rather than genetic common denominators. As we now understand the mitochondrial pathologies, both genetically and mechanistically, we see that in disorders where mitochondrial dysfunction is a primary pathological manifestation, progressive neuronal loss is often a part of the process. This awareness has made the role of mitochondria in other neurodegenerative disorders a reasonable hypothesis.

One of the manifestations of LHON, involving primarily mtDNA (maternal) inheritance of a disorder of Complex I of the respiratory chain, includes involvement of the basal ganglia and clinical manifestations of dystonia, as well as extrapyramidal features typical of parkinsonism that is responsive to dopamine therapy.^{26,27} Similar mutations involving a familial multisystem degeneration, also associated with parkinsonian features, was shown to be associated with mtDNA mutations.²⁸ However, when looking at larger populations of patients with Parkinson's and/or Alzheimer's disease, though there were some members of these groups that had specific mtDNA mutations, there have not been any specific mutations or sets of mutations that are consistent across the groups.²⁹

Further evidence of the role of mitochondrial dysfunction in neurodegenerative disorders includes syndromes presenting in infants and children. Leigh syndrome, which occurs typically in very young patients who are normal during very early development, shows widespread subcortical degeneration involving multiple brain structures. The pathology includes demyelination, gliosis, and vascular proliferation and is associated with either mtDNA maternal inheritance or autosomally mediated mitochondrial dysfunction. Several different types of presentations have been identified.^{30,31}

Friedreich's ataxia (FRDA) is an autosomal recessive disorder presenting typically in early adulthood with clinical features of progressive limb and gait ataxia, loss of deep tendon reflexes with axonal sensory neuropathy, and pyramidal (long tract) signs. It is the most common of the hereditary ataxias. The FRDA gene has been identified and is known to code for a specific protein, called frataxin. This protein is present in significant amounts

in the cerebellum and spinal cord. In the presence of the abnormal genetic response, it is not produced in adequate amounts, leading to problems with mitochondrial function due to iron accumulation. This negatively impacts the activities of respiratory chain Complexes I, II, and III and the matrix enzyme aconitase. The result is mitochondrial failure, but also increased free radical oxidation because of the presence of excess free iron (which further damages enzymes).³² Interestingly, the widely prevalent antioxidant enzyme superoxide dismutase fails to reverse this iron-based free radical damage in cell cultures, but there has been evidence of improved cellular function in cultures using other antioxidants, such as idebenone.³³

Other examples of genetic dysfunction associated with mitochondrial mutations that lead to progressive neurological disorders include at least some of the hereditary spastic paraplegias.³⁴ The autosomally recessive Wilson's disease is clinically associated with liver failure, psychiatric disease, dystonia, and rigidity similar to Parkinson's symptoms. Dysfunction in a copper transport ATP-ase, one of which localizes to mitochondria, is characteristic of this condition. There have also been Complex I enzyme defects identified in the liver mitochondria of patients with this disorder.³⁵

Parkinson's Disease

A closer look at Parkinson's disease was made possible when a rather sudden clinical onset in certain patients was correlated with use of an illegal analog of a narcotic, injectable meperidine, called MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine).³⁶ This ultimately led to animal models of drug-induced Parkinson's disease. Numerous publications about the pathology observed in these patients revealed that MPTP is neurotoxic to dopaminergic neurons by way of a reaction through the active metabolite, called MPP⁺ (1-methyl-4-phenylpyridinium), which is formed by action of monoamine oxidase in glial cells. MPP⁺ enters neurons via a dopamine reuptake pathway and is identified in mitochondria, where it interferes with the activity of Complex I, leading to compromised oxidative phosphorylation and increasing the risk of oxidative damage significantly.³⁷ Compromise of Complex I activity has also been identified in other cells in patients with Parkinson's disease, including platelets.³⁸ Genetic markers for nuclear dysfunction related to Complex I have been identified.³⁹ There is also evidence for mtDNA contribu-

tions in certain cases.⁴⁰ However, when a larger series of Parkinson's patients was evaluated, there was no obvious concordance in these findings for consistent mtDNA mutations.⁴¹

What seems to be clear is that genetic mutations in Complex I activity impact some patients with later-onset Parkinson's disease. A small study using very high doses of coenzyme Q10 and vitamin E did demonstrate benefit sufficient to delay treatment with L-dopa.⁴² The lead author contends that larger studies are necessary before recommending use of this approach, but the study did demonstrate a dose-related effect; the best outcome used the highest dose of coenzyme Q10, comparing 300, 600 and 1200 mg over the course of 18 months. Criticisms have been levied about these early data because patients quickly reported improvement in activities of daily living, but one could argue that this would be expected if energy metabolism were improved. The extent to which this approach is neuroprotective is presently being debated and larger trials are anticipated.⁴³

Part of the controversy surrounding any delineation of neuroprotective effects of antioxidants and other molecules presumed to be involved in neurotoxicity stems from the data surrounding the large clinical trials investigating the pathophysiology elucidated by the MPTP data.⁴⁴ Inhibitors of monoamine oxidase B (MAO-B), including selegiline, rasagiline, and others, have been assessed for their ability to block conversion of MPTP to MPP⁺ (an oxidative reaction), as well as for their ability to block oxidative metabolism of dopamine, because of early studies in primates in the MPTP model.⁴⁵ A number of studies directed at modifying the pathology identified with MPTP have been published, leading ultimately to the large controlled trial within the Parkinson study group. The most notable of these is the DATATOP trial looking at treatment with vitamin E in the form of α -tocopherol and l-deprenyl (selegiline).⁴⁶ This large double-blind, placebo-controlled study showed no isolated benefit of vitamin E, but did confirm prior findings of delayed onset of disability using the presumed MAO-B inhibitor selegiline. Eventually, a possible dopaminergic, and hence symptomatic, effect of this agent was suspected, which clouded the interpretation. More recently, the impact of these drugs has been thought to be neuroprotective through mechanisms that block apoptosis.⁴⁷ Rasagiline has been shown to exert a number of anti-apoptotic effects.⁴⁸ In studies looking at this drug, using a design to reduce the confounding contribution of

symptomatic improvement, there are early indications that it is neuroprotective.⁴⁹

Dopaminergic cellular demise in Parkinson's disease is associated with several well-delineated mechanisms, as discussed above. These include the presence of mitochondrial dysfunction, oxidative stress, and proinflammatory cytokines suggestive of chronic inflammation; this is a neurotoxic and probably excitotoxic effect, leading ultimately to apoptosis.⁵⁰ Abnormalities in the processing of proteins in the cell, related to the ubiquitin-proteasome system, which may explain the presence of Lewy bodies in certain patients, have also been elucidated.^{51,52} Environmental factors are now discussed frequently as contributing to the pathology because of findings in twin studies.⁵³ What seems to make most sense is that vulnerability in the function of dopaminergic neurons, which are susceptible to toxicity from compounds that could mimic the effect of MPTP, contributes to progressive cellular degeneration and mitochondrial dysfunction. This is not a well-documented primary problem in all cases, especially in those where Complex I likely plays a significant role. Efforts at identifying appropriate neuroprotective strategies include limiting the exposure to L-dopa, optimizing antioxidant therapies, and supporting mitochondrial function with the goal of reducing cellular death by apoptosis. These are now the focus of intense debate and research. Pending further research, the relative safety of higher doses of coenzyme Q10 and the use of tolerable agents that can target the MAO-B or, more likely, the propargylamine inhibitors, are the most appropriate first course of therapy. Of course, keeping the patient away from all potential neurotoxins is also vital.

Episodic Neurological Disorders

Altered energy metabolism and mitochondrial processes also participate in several other neurological syndromes, including the episodic disorders, such as migraine. A 1995 review hypothesized a possible relationship between migraine and magnesium concentrations in the brain.⁵⁴ Other episodic disorders, including seizures, have been reviewed in terms of the possible contribution of mitochondrial dysfunction and the consequences of oxidative stress leading to progressive damage.⁵⁵ Because of the paramount importance of energy for maintaining cellular function, the electrochemical gradient, and appropriate structure of the lipid bilayer within the nervous system, a role for

mitochondrial dysfunction would be logical in episodic disorders such as migraines, seizures, and stroke.

Summary

Neuromuscular tissues are predominantly post-mitotic, energy-dependent tissues. As such, they are highly dependent on normal mitochondrial function. Under normal circumstances, the process of oxidative phosphorylation generates free radicals as part of the production of ATP, and these dangerous byproducts are typically managed by a system of antioxidant protection within the mitochondrion as well as within the cell. When mitochondrial function is interrupted or dysfunctional, this free radical stress escalates. Dysfunction of energy metabolism results in dysregulation of calcium within the cell, sometimes directly by changes in the NMDA receptor via mechanisms of excitotoxicity, and sometimes by other pathways. This process, which is normally buffered by mitochondria, further contributes to cellular dysfunction, escalating to produce more oxidative damage and failure of mitochondrial function. At some point, mechanisms of apoptosis, mostly governed by mitochondria, lead to cell death. These mechanisms, in addition to others associated with cellular dysfunction (like chronic inflammation), seem to be a common denominator for many neurological disorders. In virtually all neurodegenerative conditions, there are some similarities with the changes discussed above in Parkinson's disease, including those with known genetic contributions such as Huntington's disease, and the motor neuron disorders such as ALS (amyotrophic lateral sclerosis). The contributions of these various physiological processes are being assessed with the hope that these disorders can eventually be treated effectively. The ability to alter cellular dysfunction, and hence survival, is the goal of all neuroprotective strategies, and optimizing energy production without the ravages of excess oxidative stress is a laudable goal. Unfortunately, approaches for modifying these various parameters, including use of antioxidants and substrates to optimize mitochondrial function, have produced mixed results in published studies.

Chapter 22

Detoxification and Biotransformational Imbalances

DeAnn Liska, PhD, Michael Lyon, MD, David S. Jones, MD

The Detoxification Systems—Introduction

The concept that toxins accumulate in the body and are the cause of various health problems has long been a fundamental tenet of traditional healthcare systems around the world. For centuries, societies have valued therapies that have promoted the idea of cleansing and detoxifying. From the simple water fast used since antiquity to the sometimes elaborate detoxifying regimes of spas, including saunas, enemas, hydrotherapy treatments, and dietary modifications, detoxification as a therapeutic goal has long been pursued (see Table 22.1 for common terms used in reference to detoxification).

In the early 21st century, as society has increasingly been exposed to toxic compounds in the air, water, and food, it has become apparent that an individual's ability to detoxify substances to which he or she is exposed, both exogenously (xenobiotics) and endogenously (products of metabolism), is of critical importance to overall health. Many of the xenobiotics to which we are exposed show little relationship to previously encountered compounds or metabolites, and yet healthy bodies are often capable of managing these environmental exposures through complex systems of detoxification enzymes.

Public acknowledgement regarding the extent of environmental exposure to xenobiotics is at an all-time high. For example, the EPA estimates that in 1994 alone, over 2.2 billion pounds of toxic chemicals were released into the environment in the United States.¹ EPA estimates for 2002 have grown to 4.7 billion pounds.² Moreover, it is likely that at least 25% of the United States population suffers to some extent from heavy metal poisoning.

Table 22.1 Common Terms Used in Reference to Detoxification

Term	Definition
Toxicology	The science that deals with reversible and irreversible noxious or harmful effects of (chemical) substances on living organisms.
Biochemical toxicology	A field of toxicology focusing on the biochemical mechanisms that underlie dysfunction or toxicity (i.e., molecular toxicology).
Xenobiotics	Chemicals or molecules that are foreign to the biologic system, originating externally (e.g., toxic substances in the environment, phytochemicals, drugs).
Detoxification	Any process of decreasing the negative impact of xenobiotics (toxic substances and nontoxins) on bodily functions. The process of detoxification involves biotransformation of endogenous and exogenous molecules into excretable metabolites. The term <i>detoxication</i> is often used to refer specifically to the intracellular biotransformation process.
Induction	Initiation of transcription of a gene leading to upregulation of a particular biochemical pathway. See also <i>upregulation</i> .
Upregulation	The increased activity (following induction) of a particular biochemical pathway resulting in an increased concentration of the product(s) of that pathway.

Discovery of the Detoxification Reactions

The hypothesis that xenobiotics consumed by animals, including man, are transformed to water-soluble substances and excreted through the urine was first put forth in the late 18th century. For more than 100 years after the initial observation, research into the identification of various metabolites continued, and many conjugation reactions were identified.

In his landmark 1947 monograph, *Detoxification Mechanisms*, Roger Williams brought together many observations and defined the field of detoxification. Williams described how these non-reactive compounds could be biotransformed in two phases: functionalization, which uses oxygen to form a reactive site, and conjugation, which adds a water-soluble group to this reactive site.⁴ The original terms (functionalization and conjugation) describing these two steps eventually became known as phase I and phase II detoxification, respectively. The result is the biotransformation of a lipophilic compound into a water-soluble compound that can be discharged in urine. Therefore, detoxification is not one reaction, but rather a process that involves multiple reactions and multiple players.

“The term ‘cytochrome P450’ first appeared in the literature in 1962. It was a microsomal membrane-bound hemoprotein without known physiological functions at that time and was characterized by a unique 450-nm optical absorption peak of its carbon monoxide-bound form”⁵ (A remembrance of the early work on cytochrome P450s by one of its prominent researchers was published in 2003.⁶) A high concentration of this cytochrome P450 enzyme was soon found to be localized in the liver, and researchers discovered that it was responsible for converting lipophilic (fat-loving) toxins into biotransformed intermediates that were more water soluble (the phase I process).

Later research revealed that these biotransformed intermediates undergo further biotransformation in the liver by a second series of enzymes called conjugases (the phase II process). A good review of the history of these discoveries was written by Smith and Williams in 1970.⁷ The conjugases are enzymes that attach molecules such as glucuronic acid, sulfate, glutathione, glycine, taurine, or methyl groups to the biotransformed intermediates. As this research continued into the 1980s and 1990s, investigators discovered a surprising number of phase I cytochrome P450s and phase II conjugases.

For example, we are now aware that endogenously-produced hormones and other signaling molecules are not only detoxified by these enzymes, allowing for elimination, but also are metabolized into other signaling molecules, allowing for more variation in the activities of these important substances.

Scientists and clinicians still face a considerable challenge in understanding detoxification. The question of how the body can handle such a range of compounds it has never seen before has led to much work aimed at exploring the protein structure and regulation of various enzymes involved in detoxification.^{8,9} We now know that a battery of enzymes, each with broad specificity, is available for managing the work of detoxification: there are “at least 57 human P450s (termed isoforms) which are all encoded by separate genes ... and most cytochrome P450 genes are subject to genetic polymorphism.”¹⁰ And, “Nearly fifteen P450s are involved in the metabolism of drugs and other xenobiotics chemicals”¹¹ The whole field is very complex and rapidly evolving.

A Broader Definition of Detoxification

The complex systems of the detoxification enzymes generally function adequately to minimize potential damage from xenobiotics. However, dysfunction may occur when these systems are overloaded or imbalanced. Some studies have suggested an association between the ability of the body to adequately transform toxic xenobiotics and metabolites, and the etiology of various puzzling disease entities, such as chronic fatigue syndrome, fibromyalgia, and multiple chemical sensitivities.¹² Research has also begun to validate the hypothesis that chronic neurologic symptoms, such as those seen in Parkinson’s disease, may result from impairment of detoxification ability.^{13,14,15} A link between compromised detoxification ability and certain types of cancer has been reported, although the research is still evolving.^{16,17,18} Xenobiotics implicated in cancer causation include polyaromatic hydrocarbons (often abbreviated as PAH) and asbestos. It has been suggested that many cases of cancer are due to compromised ability to adequately detoxify xenobiotics, a condition that may result from a genetic tendency toward lower detoxification activity, insufficient nutrient support for detoxification, and/or excessive intake of xenobiotics or environmental carcinogens.^{19,20} These accumulated data suggest that an individual’s ability to

remove toxins from the body may play a role in the etiology or exacerbation of a range of chronic conditions and diseases.²¹ We still say “may” for all these putative interconnections, because we really do not know for certain. Research is emerging all the time that casts doubt on earlier findings and opens new avenues for future investigations.¹ Linking detoxification to a specific disease in a research study is nearly impossible with today’s tools, since the detoxification enzyme system is so complex and individualized, and is involved in supporting so many functions in the body. As in countless other areas of medicine, however, clinicians must still make decisions for their patients in the light of the best information available.

New functional assessment tools are now available to significantly enhance our understanding of biochemical differences between individuals. These tools allow clinicians to quantitatively analyze the body’s ability to adequately detoxify the compounds to which it is exposed. Moreover, as our understanding of the underlying biochemical mechanisms involved in the regulation and nutritional support of the detoxification systems continues to deepen, the connections to disease are becoming clearer, and clinicians are gaining a better understanding of how to develop a therapeutic detoxification program.

Biotransformation

The conversion (biotransformation²²) of toxic substances into non-toxic metabolites (and their subsequent excretion) takes place primarily at two major sites, although many systems are ultimately involved. The majority of detoxification occurs in the liver and secondarily in the intestinal mucosal wall. Some also occurs in other tissues, but to a lesser extent. As mentioned previously, the phase I and phase II processes biochemically transform toxic substances into progressively more

water-soluble, and therefore excretable, substances through a series of chemical reactions (Figure 22.1).

Bioinactivation vs. Bioactivation

Biotransformation leads to changes in a molecule, increasing its water solubility and, in most cases, hastening its excretion. Many biotransformation reactions may also be considered bioinactivation or detoxification reactions. Bioinactivation generally means a decrease in the intensity of the toxic effect of a molecule because its presence is more transient and the toxic nature of the molecule is often reduced.

However, biotransformation reactions may also result in products that are more toxic than the parent compound. Such reactions are referred to as bioactivation reactions. Bioactivation reactions are more likely to occur in phase I of the biotransformation system. Let’s look at an example of how this happens:

- The introduction of a polar moiety, which accompanies phase I reactions, is intended to prepare the molecule for conjugation reactions (phase II). However, this intermediate state is often more reactive than the original molecule, and it may interact with components of biological systems (e.g., proteins or DNA). For example, the organophosphate pesticide parathion is transformed into paraoxon by a phase I oxidation reaction. The resulting molecule is several times more potent a neurotoxin than its parent molecule.
- In a subsequent reaction, paraoxon can be hydrolyzed, as a result of which, the toxic effect on its target enzyme acetylcholinesterase is lost.
- Thus, the first biotransformation reaction, the oxidation to paraoxon, results in bioactivation, while the second reaction, the hydrolysis, results in bioinactivation.

Exposure

All organisms are exposed constantly and unavoidably to exogenous xenobiotics, as well as to the by-products of metabolism, which can also be toxic. Fat solubility (lipophilicity) enables these substances to be absorbed and it also makes elimination of many xenobiotics a major challenge. Elimination of xenobiotics is most often determined by their conversion (biotransformation) to water-soluble chemicals by enzymes in the liver and other tissues that facilitate their elimination.

¹Most of the research available on these topics is epidemiological, animal research, or bench science, so our knowledge of real effects in real people is still very limited. Animal research has been emphasized because animal models of drug research are accepted as evidence of human effects. However, a 2004 review article by MacDonald in *Toxicological Sciences* (v. 82:3-8) is replete with examples of highly significant differences between animal and human metabolism of drugs, particularly for “false positives”: “Positive findings in long-term rodent studies do not necessarily predict human hazard.” Guengerich observed in a 2003 review (*Molecular Interventions*, v. 3(4):194-204) that “The relevance of P450 modulation to cancer risk has not been easy to establish in humans ...” He reports that early research linking lung and prostate cancers, for example, to P450 alterations has not been reproducible.

Figure 22.1 Liver detoxification pathways and supportive nutrients

Those highly lipophilic xenobiotics tend to readily penetrate lipid cell membranes and accumulate in fatty tissues. This is particularly true for lipophilic xenobiotics that are resistant to biotransformation (e.g., PCBs, DDT). Figure 22.2 demonstrates the process and sequencing of absorption, biotransformation, and excretion.

Phase I Reactions

Phase I detoxification is generally the first enzymatic defense against foreign compounds. In phase I, oxidation, reduction, and/or hydrolysis reactions are used to either expose or add a functional group, usu-

ally a hydroxyl (-OH), a carboxyl (-COOH), or an amino (-NH₂) group (see Figure 22.3). The structure of the molecule determines which of these reactions takes place. Phase I reactions are responsible for beginning the transformation process of detoxifying xenobiotics such as petrochemical hydrocarbons, many medications, and some endogenous substances (including steroid hormones and other end products of metabolism that would also be toxic if allowed to accumulate). In most cases, this biotransformation allows the phase I compound to undergo phase II conjugation reactions. In some cases, the compound may be eliminated directly after the phase I reaction.²³

Figure 22.2 Absorption, biotransformation, excretion

The phase I system is actually a group of many isoenzymes (several hundred variations have been identified) that have affinities for different substrates. Although several types of phase I detoxification enzymes exist, the most common are the cytochrome P450 superfamily of mixed function oxidases.²⁴ P450s are responsible for metabolism of most xenobiotics²⁵ and have an extremely broad range of substrate specificities. The mammalian P450 enzymes are found predominantly in the endoplasmic reticulum and mitochondria in most cells.^{26,27} The greatest abundance is in the liver; however, significant cytochrome P450 activity occurs in the gut wall, kidneys, lungs, and even the brain. Many forms of P450 enzymes have been isolated and their DNA sequences determined, providing evidence that these P450 enzymes are distinct gene products.²⁸ They are “involved in the metabolic oxidation, peroxidation, and reduction of many endogenous and exogenous compounds including xenobiotics, steroids, bile acids, fatty acids, eicosanoids, environmental pollutants, and carcinogens” and have been linked to the “development of numerous diseases and disorders

including cancer and cardiovascular and endocrine dysfunction ...”²⁹

Type of Reaction	Substrate	Metabolite(s)
A. Oxidations		
<i>I. Mixed-function oxidase-dependent reactions</i>		
aromatic hydroxylation		
aliphatic hydroxylation	$R - CH_3$	$R - CH_2OH$
epoxidation		
N-hydroxylation		
O-dealkylation	$R - O - CH_3$	$ROH + CH_2O$
N-dealkylation	$R - NHCH_3$	$R - NH_2 + CH_2O$
S-dealkylation	$R - S - CH_3$	$R - SH + CH_2O$
deamination	$R - CH_2 - CH_3$ NH_2	$R - C(=O) - CH_3 + NH_3$
S-oxidation	$R - S - R'$	$R - S(=O) - R'$
dechlorination	CCl_4	$[CCl_3^*] \rightarrow CHCl_3$
oxidative desulfuration		
<i>II. Amine oxidation</i>		
<i>III. Dehydrogenation</i>		
	$R - CH_2 - NH_2$	$R - CHO + NH_3$
	$CH_3 - CH_2 - OH$	$CH_3CHO \quad CH_3COOH$
B. Reductions		
azoreduction	$R - N=N - R'$	$R - NH_2 + R' - NH_2$
nitroreduction	$R - NO_2$	$R - NH_2$
carbonyl reduction	$R - C(=O) - R'$	$R - CH(OH) - R'$
C. Hydrolyses		
esters	$R - C(=O) - O - R'$	$R - C(=O) - OH + R' - OH$
amides	$R - CONH_2$	$R - COOH + NH_3$

Figure 22.3 Overview of possible types of phase I biotransformation reactions

The cytochrome P450 enzymes use oxygen and cofactor NADH (reduced nicotinamide adenine dinucleotide, which is the active form of niacin) to add a reactive hydroxyl radical. As a consequence of this step in detoxification, reactive molecules (which may be more toxic than the parent molecule) are produced. If these reactive molecules are not further metabolized by phase II conjugation, they may cause damage to proteins, RNA, and DNA within the cell. Several studies have shown evidence of associations between induced phase I cytochrome P450 activities and/or decreased phase II activities and an increased risk of diseases such as cancer³⁰ and Parkinson's disease.^{31,32}

Although phase I activities detoxify both endogenous and exogenous molecules, most information on them has been derived from studies of drug metabolism. (Understanding and assessing the metabolism of endogenous molecules is a more difficult research pursuit.) Thanks to the rapid progress of technology, ongoing data

Section V

Fundamental Clinical Imbalances

collection is helping to elucidate the specific roles of many of these P450s in drug metabolism. Since environmental xenobiotics are detoxified by the same enzymes as drugs, there may be much we can learn from this research about where we might detect the effects of environmental xenobiotics on detoxification. Figure 22.4 shows the predominant interactions of drugs with nine P450 enzymes; these percentages represent the number of interactions of the substances with the enzymes, from data collected as of June 2001.³³ (This figure represents only a very small subset of the data published; the report is 365 pages long and identifies substrates, inducers, inhibitors, reactions, and other information for an amazing number of drugs and drug types.)

Figure 22.4 Percentages of cytochrome P450s involved in drug interactions

Phase II Reactions

The major phase II detoxification activities in humans include:

- Glucuronide conjugation (proceeds via enzymatic reactions in which active glucuronic acid is used)
- Sulfate conjugation (proceeds via enzymatic reactions in which active sulfate is used)
- Glutathione conjugation or mercapturic acid formation (an enzymatic process resulting from the conjugation of reactive intermediates with glutathione; the conjugated product is then converted into mercapturic acid and excreted)

- Amino acid conjugation
- Acetylation
- Methylation

In most cases, phase II reactions decrease the biological activity and subsequent toxicity of the parent molecule. Biotransformed molecules are combined with endogenous hydrophilic compounds, creating substances with sufficient hydrophilic character to allow rapid excretion. These “conjugation reactions” can occur with a variety of substances, and involve cofactors derived from the organism’s metabolism (e.g., glucuronic acid, sulfate, glycine, or glutathione—see Table 22.2). In phase II conjugation, the biotransformed metabolic intermediate is conjugated with a polar group provided by one of these cofactors, which is attached to the active site that was added (most often as an -OH) or unmasked during the phase I reactions.

Clinical Implications of Biotransformation

Cytochrome P450 enzymes oxidize the xenobiotic entity and transform it into a reactive electrophile ready for conjugation with the polar cofactor during phase II of the detoxification process. Because the biotransformed xenobiotics most often are more reactive than their parent molecules, this process plays a significant role in establishing or increasing the toxic nature of a xenobiotic. This reactive biotransformed intermediate may exert toxic effects within the liver (or systemically, if it escapes from the hepatocyte) if not immediately transformed further by one of the several conjugating enzymes (phase II detoxification). These effects may include one or more of the following reactions:

1. Covalent binding of the reactive metabolite to:

- Proteins (e.g., cross linking of structural proteins; change in conformation of receptors, membrane pumps, enzyme carrier proteins, or peptide hormones).
- Lipids (e.g., cell membrane phospholipid binds to reactive intermediate forming lipid-soluble xenobiotic and initiating lipid peroxidation).
- Nucleic acids (e.g., irreversible binding to DNA, initiating carcinogenesis).

Table 22.2 Major Phase II Detoxification Activities in Humans

Reaction	Enzyme	Localization ^a	Substrates
H ₂ O	Epoxide hydrolase	Microsomes	Epoxides Cytosol
Glutathione	Glutathione transferases	Microsomes	Electrophiles
Glucuronic acid (UDPGA) ^b	Glucuronyl transferases	Microsomes	Phenols, thiols, amines Carboxylic acids
Sulfuric acid	Sulfotransferase	Cytosol	Phenols, thiols, amines (PAPS) ^b
Methyl group (SAM) ^b	N- and O-methyl transferases	Cytosol Microsomes	Phenols, amines
Acetic acid (Acetyl-CoA) ^b	N-acetyl transferases	Cytosol	Amines
Amino acids (Acetyl-CoA, taurine, glycine)	Amino acid transferases	Microsomes	Carboxylic acids

^a Microsome refers to membrane-associated activities, but these activities may be localized to the cellular membrane or to internal membranes; cytosol refers to soluble activities present in the cytosolic portion of the cell.

^b Abbreviations in parentheses are co-substrates: UDPGA = uridine-3,5'-diphosphoglucuronic acid; PAPS = 3'-phosphoadenosine 5'-phosphosulfate; SAM = S-adenosylmethionine; CoA = coenzyme A.

2. Creating (or increasing) oxidative stress:

- Cytochrome P450 enzymes are oxidases which, in the process of xenobiotic biotransformation, generate reactive oxygen species (superoxide, peroxide, or hydroxyl radicals) in excess of the normal flux of reactive oxygen species generated by mitochondrial respiratory activity.
- Xenobiotics, once biotransformed, are reactive electrophiles which are quenched by cellular antioxidant defenses (superoxide dismutase, catalase, glutathione peroxidase). This excess demand for antioxidant activity can lead to depletion of cellular antioxidant defenses, thus increasing oxidative stress.

Phase I detoxification requires little nutritional support to be fully active. In fact, during fasting or starvation, phase I activity may increase substantially while circulating xenobiotics are freed from both adipose and lean tissue, resulting in a significant increase in toxic stress. Therefore, traditional approaches to fasting or detoxification involving minimal nutritional support for an extended period of time may have negative clinical consequences in chronically ill patients. For excre-

tion of xenobiotics to be effective, phase I activity requires antioxidant support and phase II activity requires specific nutritional support.

Importance of Balancing Phase I and Phase II Detoxification

Proper functioning of both phases is essential because the reactive intermediate metabolites produced during phase I may be more harmful or toxic than the original substance. The two phases must be functioning in balance to successfully complete the detoxification process. The amounts and types of steroids, fatty acids, and other endogenous molecules involved in cellular communication can also be greatly influenced by altered or compromised detoxification status of an individual. Therefore, the balance of activities between the phase I and phase II processes is of fundamental importance in detoxification and, as shown in Figure 22.1, less tissue damage from oxidant stress and free radical generation occurs when these reactive intermediates are promptly and efficiently acted upon by a phase II reaction. If phase II reactions are inhibited in some way, or if phase I has been upregulated without a concomitant

increase in phase II, the optimal balance may be compromised (imbalanced detoxification). Furthermore, the phase II reactions require cofactors that are consumed during the process and must be replenished through dietary sources and energy in the form of ATP.³⁴

The Role of the Intestine in Detoxification

Most literature on detoxification refers to liver enzymes and to the liver as the site of the majority of detoxification activity for both endogenous and exogenous compounds. However, the gastrointestinal lining is the first point of contact for the majority of xenobiotics. Over the course of a lifetime, the gastrointestinal tract processes more than 25 tons of food, which represents the largest load of antigens and xenobiotics confronting the human body.³⁵ Furthermore, because most drugs are consumed orally, the gastrointestinal tract is also the body's first contact with many drugs. It is not surprising, then, that the gastrointestinal tract has developed a complex set of physical and biochemical systems to manage this load of exogenous compounds. Several factors influence how much of a chemical ends up in the systemic circulation, thus requiring detoxification by the liver.

The gastrointestinal tract initially provides a physical barrier to exogenous components, but it also influences detoxification in several other ways.^{36,37} (An extended discussion of this subject can be found in Chapter 31.) Gut microflora can produce compounds that either induce or inhibit detoxification activities. Pathogenic bacteria can produce toxins that enter the circulation and increase toxic load (more information about toxic load can be found further along in this chapter). Moreover, in a process called enterohepatic recirculation, the gut microflora also has the ability to remove some of the conjugation moieties. Once moieties such as glucuronyl side chains are removed, the xenobiotic may revert to its original form and re-enter the circulation, leading to an increased toxic load.

Detoxification enzymes such as CYP3A4 and the antiporter activities (Figure 22.5) have been found in high concentrations at the tip of villi in the intestine.^{38,39} Adequate first-pass metabolism of xenobiotics by the gastrointestinal tract requires integrity of the gut mucosa. Compromised barrier function of the mucosa will more easily allow xenobiotics to transit into circulation without an opportunity for detoxification. Support

for healthy gut mucosa is instrumental in decreasing toxic load.

Figure 22.5 Phase III metabolism: The antiporter

Recently, antiporter activity (p-glycoprotein or multidrug resistance) was re-defined as the phase III detoxification system in some literature, although the term has not caught on with everyone in the scientific field.⁴⁰ Antiporter activity is an important factor in the first-pass metabolism of pharmaceuticals and other xenobiotics. The antiporter process is an energy-dependent efflux pump that pumps xenobiotics out of a cell, thereby decreasing the intracellular concentration of such substances.⁴¹ Since many of the detoxification enzymes are located at or near the cell membrane barrier, if a xenobiotic is not metabolized the first time it is taken into a cell, the process of pumping it out of the cell and back into the intestinal lumen and then taking it into the cell again (a recirculation process) affords the cell another opportunity to metabolize the substance before it gets too far within the cytosol, where it can do damage. Antiporter activity in the intestine appears to be co-regulated with the intestinal phase I CYP3A4 enzyme, providing further support for its role in detoxification.

Two genes encoding antiporter activity have been described: multidrug resistance gene 1 (MDR1) and multidrug resistance gene 2 (MDR2). The MDR1 gene product is responsible for drug resistance of many cancer cells and is normally found in epithelial cells in liver, kidney, pancreas, small and large intestine, brain, and testes. MDR2 activity is expressed primarily in the liver and may play a role similar to that of intestinal MDR1 for liver detoxification enzymes; however, its function is

currently undefined. One downside to the antiporters has been the observation that they are sometimes overexpressed in cancer cells, allowing those cells a protection against chemotherapy. For this reason, clinical trials are underway to evaluate the use of inhibitors of antiporter activity in cancer cells to enhance the activity of chemotherapeutic agents in resistant cancers.^{42,43,44} A third, similar gene has also been described (MDR3), but its role in detoxification has not been elucidated.^{45,46}

Regulation of Detoxification Activities

Detoxification systems help manage exposure to exogenous compounds, and a number of factors influence the activity of the enzymes involved in this process. Specific detoxification pathways may be induced or inhibited, depending on the presence of various dietary or xenobiotic compounds, the age and sex of the individual, lifestyle habits such as smoking, and genetics. Furthermore, disease can also influence activity of the enzymes. In some disease states, detoxification activities appear to be induced or upregulated, but in other conditions these activities may be inhibited from acting or not produced at high levels.

Factors influencing detoxification:

- Diet and lifestyle
- Environment (xenobiotic exposure)
- Genetic polymorphisms
- Age and gender
- Disease
- Medications (competitive inhibition)

Induction Activities

Several situations can cause induction of phase I and phase II enzyme activities. When the body is faced with a high xenobiotic load, the phase I and/or phase II enzymes involved in detoxifying the compound(s) can be induced, leading to a greater amount of enzyme and a faster rate of detoxification. Inducers can upregulate selectively, affecting only one enzyme or one phase of detoxification, or broadly, affecting multiple activities.⁴⁷

For example, polycyclic hydrocarbons from cigarette smoke and aryl amines from charbroiled meats result in dramatic induction of the CYP1A1 and CYP1A2 enzymes. This leads to a substantial increase in phase I activity, with little or no induction of phase II enzymes.^{48,49,50} Also, taking phenobarbital for epi-

lepsy can eventually lead to chronic induction of phase I. Induction of some phase I activities without co-induction of phase II may lead to an uncoupling of the phase I and phase II balance and, therefore, a higher level of reactive intermediates that can cause damage to DNA, RNA, and proteins.

Many compounds in the flavonoid family (found in fruits and vegetables) are capable of inducing multiple phase II activities. For example, ellagic acid in red grape skin has been shown to induce several of the phase II enzymes while decreasing phase I activity.^{51,52} Cruciferous vegetables (the Brassica family, such as cabbage, bok choy, broccoli, and Brussels sprouts), garlic oil, rosemary, and soy all contain compounds that can induce several phase II enzyme activities.^{53,54,55,56} Commonly, the glutathione S-transferase and glucuronyl transferases are co-induced by these multifunctional inducers. In general, this increase in phase II supports better detoxification in an individual and helps promote and maintain a healthy balance between phase I and phase II activities. This enhancement of phase II activity has been proposed to explain, at least in part, the ability of fruits and vegetables to protect against many cancers.^{57,58,59,60}

Inhibition Activities

Both phase I and phase II enzyme activities can also be inhibited. Inhibition can occur by competition between two or more compounds for the same detoxifying enzyme. Increased toxic load can lead to inhibition of a number of compounds by simply overwhelming the systems and competing for multiple detoxification enzyme activities—a process called competitive inhibition. Some compounds selectively inhibit only one detoxifying activity, such as quinidine, which competitively inhibits CYP2D6 activity. Cimetidine is an example of a compound that can bind directly to the heme iron of the cytochrome P450 reactive site to inhibit phase I metabolism. Much has been written about grapefruit juice, which contains high amounts of the flavonoid naringenin, and its ability to inhibit first-pass metabolism of many drugs that are detoxified through the CYP3A4 enzyme-antiporter system in the intestine.^{61,62} Table 22.3 lists some pharmaceutical inhibitors of phase I cytochrome P450 enzymes; a more complete list of inhibitors and inducers of P450 enzymes can be found in the Appendix.

Table 22.3 Some Pharmaceutical Inhibitors of Phase I Cytochrome P450 Enzymes

Pharmaceutical	P450 Enzyme Inhibited
H2-Receptor Blockers Cimetidine	All Cytochrome P450s
Antiarrhythmics Quinidine Propafenone	CYP2D6 CYP2D6
Antibiotics Erythromycin Clarithromycin Troleandomycin Fluoroquinolones	CYP3A4 CYP3A4 CYP3A4 CYP1A2
Antidepressants Nefazodone Fluoxetine Norfluoxetine Paroxetine Sertraline	CYP3A4 CYP2D6, CYP2C19, CYP3A4 CYP2D6, CYP1A2 CYP2D6 CYP2D6
Antifungals Itraconazole Fluconazole Ketoconazole	CYP3A4 CYP3A4 CYP3A4

A common mechanism of inhibition for some of the phase II enzymes is depletion of necessary cofactors. In humans, sulfation is particularly susceptible to inhibition due to compromised cofactor status. The serum sulfate concentration is a balance between (1) absorption of inorganic sulfate and its production from cysteine, and (2) elimination of sulfate by urinary excretion and sulfation of low molecular weight substrates. In humans, the serum sulfate level varies dramatically over 24 hours, and is decreased in individuals who are fasting or ingesting high levels of substances that are metabolized by sulfation (such as acetaminophen). Humans excrete approximately 20 to 25 millimoles of sulfate in 24 hours; therefore, sulfate reserves must be maintained through dietary intake of sulfur-containing amino acids or inorganic sulfate, both of which have been shown to support increased serum sulfate levels.⁶³

Detoxifying Enzymes and Genetic Polymorphism

A significant amount of data has now accumulated demonstrating that widespread genetic polymorphisms for the expression of cytochrome P450 enzymes exist within the human species.^{64,65} Population studies have shown great variations in individual metabolizing ability for all detoxification pathways, including both cytochrome P450 systems and conjugating pathways.^{66,67} A well-described polymorphism in this category is a low activity form of CYP2D6, an enzyme that is an important metabolizer of many narrow-spectrum drugs, including antiarrhythmics, antidepressants, and antipsychotics. Individuals with this polymorphism comprise 5–10% of Caucasian populations and are referred to as poor metabolizers (PMs). This impairment may affect the metabolism of more than 25 therapeutic drugs and a wide range of xenobiotics, to different degrees within different individuals.⁶⁸ Because each of us has two alleles (two genes encoding a specific gene), it is possible to have one gene that encodes the wild type (average activity) and another one with a SNP that encodes lower activity. Individuals who receive two versions of the gene encoding a slower CYP2D6 activity have a severely limited ability to metabolize xenobiotics that require this enzyme.⁶⁹ Research has suggested that adverse side effects occurring from drugs that need CYP2D6 activity for elimination may be reduced by decreasing dosages in those individuals who are slow metabolizers of CYP2D6.⁷⁰

On the other end of the spectrum are individuals described as extensive metabolizers (EMs). Such individuals require a higher dose of certain drugs to achieve therapeutic effects and may have a more robust capability to handle certain environmental toxins. Although apparently less common than PMs, EMs have been identified for CYP2D6. Heritable polymorphisms are also known for several conjugating enzymes (phase II detoxification) that are extensively involved in the metabolism of exogenous chemicals.⁷¹ For example, genetic polymorphisms of the glutathione-S-transferase (phase II, glutathione conjugation) enzyme family are known to occur,⁷² and are regarded as a significant factor conferring susceptibility to environmental toxins. The role of these genotypic variants in the development of functional illnesses such as chronic fatigue syndrome or fibromyalgia may be significant, but the subject has not been well studied.

Distinguishing phenotypic variability from polymorphic genetic variability adds to the complexity of understanding human individuality. "Genotypic variability is easy to identify by means of polymerase chain reaction-based or DNA chip-based methods, whereas phenotypic variability requires direct measurement of enzyme activities in liver, or, indirectly, measurement of the rate of metabolism of a given compound *in vivo*. There is a great deal of phenotypic variability in human beings, only a minor part being attributable to gene polymorphisms."^{73,74}

Metallothioneins and Genetic Polymorphism

One of the most important detoxification systems in all species, from bacteria to humans, depends upon the production of a family of at least four different proteins known as metallothioneins (MTs). MTs are highly unusual proteins composed of about 30% cysteine. They are responsible for storage, transfer, and detoxification of intracellular metal ions.⁷⁵ The primary role of MTs in the absence of toxic metals is the transport and short-term storage of zinc and copper. However, the importance of MTs in protection against and elimination of toxic metals is also well described. MTs are known to efficiently bind several toxic metals (particularly cadmium and mercury) and act as a transporter of the toxic metal to the liver or kidneys where glutathione conjugation and subsequent excretion of the toxic metal may then take place. Because MTs form high-affinity complexes with several metals, they may prevent toxic metals from reacting with other biomolecules or acting as free radical catalysts, thus attenuating their toxicity.⁷⁶

There is a wide variation in the concentration of MTs between species. Humans, for example, have about ten times the concentration of MTs in their organs as do rats or mice. Additionally, genotypic polymorphisms for expression of certain MTs within a species have been demonstrated. Mutant mice and rat models have been identified with complete absence of the genes for one out of four MT isoforms. In these MT-deficient animals, susceptibility to the toxic effects of heavy metals is increased by 60- to 100-fold. In contrast to this, it has been shown in animal models that resistance to heavy metal toxicity may be conferred in mutants possessing multiple copies of MT genes in their chromosomes. These animals may be capable of more prolific upregulation of MT production.⁷⁷

Genetic polymorphisms for MT expression also exist in humans.⁷⁸ Human cancer cell lines are known to be highly polymorphic in their ability to express MT genes. This is a primary reason that cancer patients vary in their resistance to metal cancer chemotherapeutic drugs.⁷⁹ Some laboratories have begun to offer test panels to assess MT function. These assays may provide clinically significant means to screen an individual's susceptibility to metal intoxication. Importantly, gene expression for MT production is highly inducible (e.g., through zinc supplementation, fasting, and exercise).^{80,81,82,83} Because of this, working with factors that induce optimal production of MTs may be important during a heavy metal detoxification regimen.

The emerging field of toxicogenomics will undoubtedly revolutionize medicine and pharmacology on several fronts.⁸⁴ Assessing a patient's genetic susceptibility to environmental toxins or adverse drug reactions will enable clinicians to tailor their interventions and will likely lead to more effective treatments for patients with a variety of complex disorders.

Age, Gender, and Disease Influences

Several other factors also influence expression and the resultant activity of many detoxification enzymes. For example, similar to many other proteins, detoxification activities are under strict developmental control. The phase I CYP3A enzymes and the phase II enzymes catalyzing glucuronidation, sulfation, and glutathione conjugation are present in the human fetus. At birth, these enzymes are capable of catalyzing most biotransformation reactions, but the rate of these reactions is generally slower than in adults. Within the first two weeks of life, phase I and phase II detoxification systems become more fully expressed.⁸⁵ However, as the body ages, the phase I and II detoxification pathways decline in efficiency and effectiveness, likely contributing to many of the health effects associated with aging.^{86,87}

Gender also affects the type, amount, and activity of various detoxification enzymes. The CYP3A family of detoxification enzymes is particularly sensitive to hormones. The CYP3A4 enzyme appears to be regulated, at least in part, by progesterone or the ratio of progesterone to estrogen. For example, premenopausal women generally show 30% to 40% more CYP3A4 activity than men or postmenopausal women.⁸⁸ Pregnant women also appear to have increased levels of CYP3A activity as well. CYP3A4 is the major phase I

detoxification pathway for the anti-epileptic agents phenobarbital and phenytoin. Researchers have suggested this hormone regulation of CYP3A explains why many women require a higher dose of antiepileptic medications during their pregnancy.⁸⁹

Disease and health status of the individual also affect detoxification activities. Because the majority of detoxification occurs in the liver, it is not surprising that impairment of normal liver function due to alcoholic disease, fatty liver disease, biliary cirrhosis, and hepatocarcinomas can lead to lower detoxification activity in general. The phase I and phase II enzyme activities are localized differently within a cell. Phase I activities are associated with membrane, but the majority of phase II activity occurs in the cytosol (fluid component of the cytoplasm). Different types of phase I and phase II activities may be localized differently in the organ systems as well, which is the case in the liver. This compartmentalization means that a disease that influences one region of the liver may affect some activities more than others. Moreover, influences on cell membrane integrity (for example, from dietary lipids or oxidation of membrane lipids) could influence phase I activity more than phase II. Therefore, the amount of decrease in detoxification activity resulting from disease or loss of integrity of the tissue may vary from one isozyme to another.

Some conditions can actually increase or induce detoxification system function. The phase I activity of CYP2E1 is a good example of this. CYP2E1 catalyzes oxidation of ethyl alcohol to acetaldehyde, and also detoxifies many of the small carbon-chain molecules, including ketone bodies, that result from gluconeogenesis and the breakdown of fatty acids. CYP2E1 is increased in insulin-dependent diabetes, in morbidly obese individuals, and, conversely, during starvation.^{90,91} The reason CYP2E1 is induced in morbidly obese individuals and during starvation is not fully understood; however, it may have to do with the role CYP2E1 plays in metabolism of products from gluconeogenesis and energy metabolism and may influence how these pathways become imbalanced during altered metabolism. The full range of changes in other detoxification systems in response to health status is not fully understood.

Induction of various P450 isoenzymes can be detrimental when carcinogens are not capable of causing genetic damage until they undergo activation to a reactive (electrophilic) intermediate.⁹² For example, it has

been shown that the risk for hepatic carcinoma is associated with the degree or activity of a particular isoenzyme of the cytochrome P450 system.⁹³ Another example is seen in individuals with a high inducibility phenotype for phase I CYP1A1. These individuals appear to have a higher risk for cancer, regardless of exposure to smoking or other known carcinogens.⁹⁴ As many cancers can be related to environmental exposure or dietary intake, it is apparent that individual detoxification ability can be an important factor in their development.⁹⁵

Effects of Medications

The consequences of defective drug metabolizing enzymes and pathways in a patient are varied:

- Inefficient elimination of an active drug or toxic substance may cause a functional overdose.
- Inefficient activation or increased elimination of a drug may result in a lack of efficacy.
- Symptoms of toxicity, with idiosyncracies unrelated to the substance, may appear.
- Exacerbation of symptoms in chronic conditions may occur.
- Association with an apparently spontaneous disease has been noted.⁹⁶

Various medications such as SSRIs, macrolide antibiotics, and H2 blockers (e.g., cimetidine) may inhibit one or more of the phase I enzyme systems (Table 22.3).⁹⁷ When this occurs, endogenous and exogenous toxicants may remain in the body untransformed, thus causing toxic reactions. In 1998, using a meta-analysis procedure, researchers from the University of Toronto reported that fatal adverse drug events from correctly prescribed medications are much more common than previously identified and may be between the fourth and sixth leading cause of death in hospitals in the United States.⁹⁸ These researchers attempted to exclude adverse events associated with errors in drug administration, drug abuse, and accidental poisoning. The authors of the study suggest that these adverse drug events may result from factors such as age, gender, and multiple drug exposure. Unfortunately, no data exist to correlate adverse drug events with detoxification profiles. However, accumulated data suggest that individuals with inhibited or compromised detoxification pathways would be more susceptible to adverse drug events.⁹⁹ There is considerable discussion in the research literature of ways to integrate into clinical prac-

tice genotyping for the purposes of enhancing drug safety and maximizing drug efficacy.¹⁰⁰ Gene expression profiling for anticancer drugs,^{101,102} antidepressants and antipsychotics,¹⁰³ and many others is now available in research settings; the challenge will be to bring the technology—and the expert interpretation of the data—into the clinical setting.

Functional Assessment of Phase I and II Detoxification and Toxic Load

The detoxification system in humans is extensive, highly complex, and under myriad regulatory mechanisms. Until recently, science has had difficulty calculating and objectively analyzing the individual response to toxic compounds. In any large population exposed to the same low levels of carcinogens, some individuals will develop cancer while others will not. The variability that one finds here and in other diseases appears to be associated, in part, with the individual's ability to detoxify various pro-carcinogens and other xenobiotics. Therefore, it is not only the level of the toxin in the environment, but also the total amount of toxin in the individual—and his or her response to that load—that is significant.

Toxic Loadⁱⁱ

Understanding how xenobiotics affect human health is germane to the concept of *total load*. Total load describes the total of all exposures and influences that bear on human physiology. Since these factors often determine the efficiency of the body's detoxification system, nutrient status and organ reserve, they are central to any question of how xenobiotics affect humans. The concept of total load suggests that the totality of factors can seriously affect an individual's system of metabolic management.

For many years, efforts to understand how xenobiotics affect human health focused on determining whether or not a substance produced cancer in laboratory animals. Once studies confirmed this finding for animals, researchers applied these studies to humans. While these efforts provided much insight into detoxification, metabolism, and cell biology, in many ways they now detract from more pertinent questions, such

as: What is the capacity of xenobiotics to alter the *function* of biological systems, and how does this contribute to illness? According to the latter perspective, cancer, as an end-stage manifestation of chemical exposure, seems to be only a second-order issue, since so many physiological events precede its development.

In the early 1990s, two seminal volumes published by the National Academy of Sciences raised concerns about the *functional* changes induced by exposure to low levels of xenobiotics. These volumes, *Environmental Neurotoxicology*¹⁰⁴ and *Biologic Markers in Immunotoxicology*,¹⁰⁵ highlight two important issues—functional changes result from low-level chemical exposure, and their effects can multiply when an individual is exposed to more than one agent.

An animal study about the lethal dose of lead and mercury dramatically illustrates this latter point—the multiplicity of toxic effects. In this study, scientists administered LD1 of mercury *combined* with the LD1 of lead to animals. (LD1 is the acute dose leading to death of 1% of a test population. LD50 refers to the dose that produces a fatal response in 50% of the animals and is a typical measure used in toxicology.) Remarkably, the LD1 of mercury + LD1 of lead resulted in LD100, or 100% mortality, within five days.¹⁰⁶ This study demonstrated a profound difference in outcome between low-toxicity substances administered in combination and low-toxicity substances administered alone.

Given the ubiquitous nature of chemicals in the environment, it is likely that *single* exposure is more the exception than the rule. It is also likely that, despite considerable research, we actually know very little about the true effects of chemicals on human function, because so little research is done on chemical synergy. More important, considering the little we know about factors that influence physiologic function and their synergistic effect on chemical function, determining the effect of chemicals on human function is extremely difficult.

However, working within the concept of total load, it is clear that assessing both the sources of foreign substances and the patient's ability to deal with and process those foreign substances is central to the question of how toxicants and xenobiotics differentially affect humans. Rea^{107,108} has succinctly outlined the following factors that influence the total load phenomenon:

- Xenobiotics (insecticides, herbicides, drugs, solvents, metals, etc.)

ⁱⁱ Excerpted from *Clinical Nutrition: A Functional Approach* (2nd Ed). Institute for Functional Medicine, Gig Harbor, WA: 2004.

- Infections (streptococcus, pseudomonas, parasites, etc.)
- Toxins (aflatoxin, fusarium, penicillium toxins, ergot toxins, etc.)
- Biological inhalants (molds, algae, pollens, foods, etc.)
- Physical phenomena (electromagnetic fields, ionizing radiation)
- Lifestyle (drinking, smoking, etc.)
- Mechanical problems (biomechanical dysfunction, such as nasal, intestinal, or other obstruction)
- Hormonal aberration (DHEA, cortisol, estrogen, progesterone, testosterone, etc.)
- Psychosocial factors (stress, coping skills, belief systems, psychological trauma)

While nutritional status is not a direct part of the total load, the factors noted above are widespread and influenced by nutritional status. Rea, who has followed more than 20,000 patients with chemical sensitivity, reported laboratory evidence that nutrient abnormalities are widespread among these patients. He noted that nutrient supplementation was central to restoring physiologic balance; however, reducing total load was also essential to patient recovery. His findings suggest that total load *and* nutrient metabolism are inseparable components of any program designed to manage the physiological alteration associated with chemicals.

Challenge Testing

In assessing an individual's detoxification ability, one evaluates the functional capacity of his or her detoxification systems. The complexity of those systems (and the biochemical uniqueness of each individual) suggests that a single test or type of assay to fully assess detoxification status may not be possible. For some enzyme activities, such as CYP2D6, which is primarily influenced by genetics, determination of slow or fast metabolism is possible with one gene analysis. However, to understand the detoxification profile of a particular individual at a moment in time, other approaches are necessary.

Measuring functional capacity and performance of an organ system or biochemical pathway is not new. Exercise EKG and the oral glucose tolerance tests are two common challenge tests in which functional capacity and, therefore, organ reserve are appraised. A challenge test differs substantially from the more commonly used

clinical assessments, such as the liver tests found in most serology panels.

The standard liver tests SGOT, GGPT, and SGPT measure liver pathology—not liver metabolic function.¹⁰⁹ Elevation of these enzymes in the serum occurs as a consequence of hepatocyte damage. Because the majority of detoxification occurs in the liver, a clinician may make the assumption that elevated liver enzymes may also mean compromised detoxification ability. However, because the different detoxification activities are compartmentalized and detoxification occurs in other tissues as well, establishing a definitive link between elevated liver markers and altered detoxification is not always possible; altered detoxification can be demonstrated without any changes in these liver enzyme markers and, conversely, these markers may be altered and some detoxification functions may be performing adequately.

Challenge tests measure the detoxifying ability of an individual when challenged with a test substance. These tests allow assessment of the metabolic capacity of the detoxification systems, and thus provide a functional view of an individual's ability to adequately deal with his or her environment.

To evaluate the various metabolic pathways of detoxification discussed above, probe substances (see Table 22.4), whose detoxification pathways are well established, are ingested. Their metabolites are measured in the urine, blood, or saliva. This type of test takes into account the myriad factors influencing detoxification capacity, and remains the standard today.^{110,111,112,113}

Probe substances. Many environmental toxins, such as those in polyaromatic hydrocarbons used as pesticides, several carcinogens in cigarette smoke, and the polyaromatic amines found in charbroiled beef, are detoxified by CYP1A2 activity. Genetics, nutrition, medications, and environmental factors (including alcohol, heavy metals, and smoking) can all influence the inducibility of this enzyme system.^{114,115,116,117,118,119,120}

Research over the past 20 years has shown that the caffeine challenge test is a useful, non-invasive way to assess CYP1A2 detoxification activity.¹²¹ Elevation or depression of the rate of caffeine clearance suggests upregulation or downregulation, respectively, of the phase I system. For this challenge test, a defined amount of caffeine is ingested, after which two to three saliva samples are obtained at specified times. Caffeine is almost completely absorbed by the intestine, and its

rate of clearance is measured in saliva.^{122,123} Dietary elimination of caffeine-containing foods and medications should be instituted 24 hours before the test.

Table 22.4 Examples of *in vivo* Probes for Drug Metabolizing Enzymes

Enzyme	Probe Drug(s)
CYP1A2	Caffeine
CYP2C9	Tolbutamide
CYP2C19	Mephenytoin, Proguanil
CYP2D6	Sparteine, Dextromethorphan, Debrisoquine
CYP2E1	Chlorzoxazone
CYP3A4	Erythromycin (breath test), Midazolam, 6 β -Hydroxycortisol
N-acetyl transferase	Sulphadimidine, Isoniazid, Caffeine
Glucuronyl transferase	Oxazepam, Acetaminophen
Sulfation	Acetaminophen
Glycination	Benzoic acid, Salicylate

As previously mentioned, phase II reactions involve a number of distinct conjugating substances. The most important appear to be amino acid conjugation, glutathione conjugation, glucuronidation, and sulfation. Acetaminophen has been used as a probe substance to assess glucuronidation and sulfation. Acetaminophen is primarily metabolized directly through the phase II sulfation and glucuronidation pathways to form urinary acetaminophen sulfate and acetaminophen glucuronide, respectively.¹²⁴ (Figure 22.6 depicts acetaminophen detoxification in humans.) If these pathways are inhibited or compromised due to depleted cofactor status, the acetaminophen is metabolized through an alternate pathway requiring a phase I biotransformation followed by conjugation with glutathione and conversion to acetaminophen mercapturate. The biotransformed intermediate, N-acetyl-p-benzoquinoneimine (NAPQI), is a highly hepatotoxic substance and, if not rapidly cleared by glutathione conjugation, can result in severe toxicity.¹²⁵ The standard emergency treatment

for acetaminophen overdose is to use high levels of N-acetylcysteine to detoxify NAPQI.

The major metabolites from the detoxification of acetaminophen are acetaminophen glucuronide and acetaminophen sulfate. Acetaminophen mercapturate is a minor metabolite and N-acetyl-p-benzoquinoneimine (NAPQI) is a hepatotoxic intermediate that may accumulate if Phase I activity is induced and/or Phase II glutathione conjugation pathway is unable to further metabolize NAPQI to the mercapturate for excretion.

Figure 22.6 The detoxification of acetaminophen in humans

The major metabolites from the detoxification of acetaminophen are acetaminophen glucuronide and acetaminophen sulfate. Acetaminophen mercapturate is a minor metabolite and N-acetyl-p-benzoquinoneimine (NAPQI) is a hepatotoxic intermediate that may accumulate if phase I activity is induced and/or the phase II glutathione conjugation pathway is unable to further metabolize NAPQI to the mercapturate for excretion.

Several amino acids are used as conjugation moieties for amino acid conjugation, including glycine, taurine, arginine, and ornithine. The glycine conjugation pathway appears to be a major amino acid conjugation pathway in humans and, therefore, can be a means of evaluating amino acid conjugation activity. The glycine conjugation pathway can be assessed using either aspirin or sodium benzoate as probe substances. Aspirin is readily degraded into salicylic acid, which is eventually

conjugated and metabolized through glycine conjugation and glucuronidation to form salicyluric acid (the major metabolite) and salicyl glucuronides (minor metabolites), respectively (Figure 22.7).¹²⁶ Alternatively, in individuals with salicylate sensitivities, the common food preservative sodium benzoate can be used to assess phase II glycine conjugation.¹²⁷ Either way, the metabolites are then measured in the urine.

The major metabolite from detoxification of aspirin is the glycine conjugate salicyluric acid.
Salicyl phenolic glucuronide and salicyl acyl glucuronide are minor metabolites.

Figure 22.7 The detoxification of aspirin in humans

These probe markers serve as useful, well-researched challenge substances for functional evaluation of four important phase II detoxification pathways.¹²⁸ As with the caffeine challenge, foods and medications containing aspirin, acetaminophen, and sodium benzoate are eliminated 24 hours prior to challenge tests utilizing those substances. Using a combination of probe substances to measure sulfation, glucuronidation, glycination, and activation of phase I activity, a clinician is provided with an assessment of an individual's detoxifi-

cation capacity that offers insight into the unique response and possible sensitivity the patient may display to his or her environment.

For most toxins in need of detoxification, multiple pathways are involved. Under optimal conditions, there is a particular affinity of a xenobiotic for a particular pathway. The body may compensate for an underdeveloped, or bottlenecked, pathway. Alternative pathways may be less desirable because of incomplete detoxification or accumulation of toxic intermediates, as described above. Not only are the sufficiencies of the various individual pathways important, but the relative balance of phase I and phase II detoxification is critical, as it determines the longevity of the biotransformed intermediates.

Testing for the Presence of Toxic Elements

Testing for the presence of the most common toxic elements, mercury (Hg), lead (Pb), arsenic (As), cadmium (Cd), aluminum (Al), and nickel (Ni), can be an integral part of the overall assessment.¹²⁹ These toxic elements are largely undetected by standard laboratory analyses. Furthermore, toxic symptoms may occur due to low-level but chronic exposure.¹³⁰ In addition to subtle (but cumulative) metabolic toxicity, these heavy metals may impair other detoxification pathways so that negative effects of xenobiotics are intensified. For example, antimony exposure depletes hepatic glutathione in rat models, resulting in impaired phase II glutathione conjugation activity, which affects the ability of the body to detoxify other toxic compounds that require conjugation with glutathione.¹³¹

Elemental analysis of hair and provocative urine testing (e.g., DMSA oral) provide the most reliable measures of the presence of toxic metals.¹³² Serum testing can also be valuable for lead, mercury, aluminum, and cadmium, as well as other toxic metals. Identification and removal of toxic elements such as these may result in a positive clinical outcome for patients experiencing fatigue and cognitive disorders. Excretion of the elements can be monitored in urine.

A Clinical Perspective on Detoxification

Several decades of extensive research into detoxification of xenobiotics has resulted in an evolution of our clinical understanding of detoxification.^{133,134} Chapter 31 presents a discussion of the clinical approach to improving detoxification. Before approaching the ques-

tion of intervention, however, a solid understanding of the metabolic systems involved in detoxification—and the common influences upon them—is vital. Although the research is far from mature, there are many indicators that clinicians should be aware of.

Substances that induce or upregulate phase I, such as alcohol, smoking, coffee, and certain medications, can have a deleterious effect upon the balance of phase I to phase II activity, because the phase II pathways may be unable to keep up with the increased demand. The result would be an increase in activated intermediates and free radicals, which can react with and damage proteins, RNA, and DNA, further promoting a cycle of imbalanced detoxification in the individual.

The phase II conjugation enzyme systems are dependent on the presence of adequate amounts of cofactors and conjugation moieties, such as glutathione, sulfate, and glycine. Therefore, nutritional insufficiency of these cofactors could be deleterious to adequate balance between phase I and phase II activity. Moreover, the phase II activities are highly dependent on the presence of adequate energy in the form of ATP to carry out the conjugation reactions, so depletion of ATP reserves can also influence the balance of phase I to phase II activities.

Clinical Presentation

There are a number of common warning signs indicating that toxicity may be a factor for patients:

- A history of increasing sensitivity to exogenous exposures (toxic xenobiotics)
- Abundant use of medications
- Significant use of potentially toxic chemicals in the home or work environment
- Sensitivity to odors
- Musculoskeletal symptoms (similar to fibromyalgia)
- Cognitive dysfunction
- Unilateral paresthesia
- Autonomic dysfunction and recurrent patterns of edema
- Worsening of symptoms after anesthesia or pregnancy
- Paradoxical responses or sensitivity to medications or supplements¹³⁵

Several specific clinical examples are summarized below.

Gilbert's syndrome. Gilbert's syndrome (GS), thought to be a condition with little morbidity, is a

genetically-induced, nutritionally-exacerbated metabolic disorder that affects the way bilirubin is processed by the liver, causing jaundice. GS is caused by an alteration of activity in one of the glucuronyl transferase enzymes that catalyzes the phase II conjugation step of glucuronidation.¹³⁶ A study published in 1992 suggested that GS can predispose people to bioactivation and potential toxicity of drugs for which glucuronidation constitutes a major, alternate pathway of elimination.¹³⁷ Unfortunately, other than one study of zinc sulfate in 2002,¹³⁸ a recent PubMed search on Gilbert's syndrome brings up no significant recent follow-up on those early findings. Further research would be highly desirable, especially since there are at least 10 versions of glucuronyl transferase, and it is not known what effect each has on the other.

Chronic fatigue syndrome. Research reported in the mid-1990s on the etiology of chronic fatigue syndrome (CFS) suggested that there might be a relationship between impairment of detoxification pathways and symptomatology, partly as a result of toxic exposure.^{139,140} Correction of these imbalances and deficiencies has been of significant benefit to some patients.¹⁴¹ A clinical trial published in 1995 used a food elimination diet and nutritional modulation to support detoxifying pathways; significant improvement in subjective symptomatology as well as phase I and II activities was reported.¹⁴² Unfortunately, the research base on this issue is still sparse and unconvincing; interest in the investigation of toxicity as a cause and improved detoxification as a therapeutic response appears to have waned of late. Both the etiology of the condition and the nature of effective treatments are as yet unclear. Many researchers have hypothesized that multiple causes may require that treatment approaches be adapted to the various sub-group characteristics, once they can be clearly defined.^{143,144,145}

Encephalopathy and pancreatitis. These two conditions provide examples of how xenobiotics can influence the clinical picture. Exposure to various solvents is correlated with development of chronic toxic encephalopathy, which may present as diverse neuropsychiatric disorders. A genetic defect in one of the glutathione transferase enzymes (and therefore GSH-conjugation deficiencies) results in lowered detoxification capacity and greater likelihood of encephalopathy.^{146,147} Idiopathic pancreatitis can be associated with upregulation of the cytochrome P450 enzymes in many patients.

Patient histories often include exposure to diesel fumes, paint solvents, and trichloroethylene. This type of xenobiotic exposure also seems to accentuate the susceptibility to ethanol-related pancreatitis.¹⁴⁸

Chronic degenerative diseases. Detoxification has clinical implications for chronic degenerative diseases as well. Research on the etiology of Parkinson's disease has shown defects in the ability of patients to adequately metabolize sulfur-containing xenobiotics.¹⁴⁹ This altered detoxification may then render susceptible individuals at higher risk for neurotoxicity when exposed to sulfur-containing compounds.¹⁵⁰ The combination of genetic susceptibility, reduced detoxification capacity, and increased exposure to neurotoxins creates an increased risk of damage that may lead to clinical disease over the course of time. Connections to Alzheimer's, Parkinson's, and other motor neuron diseases have also been made.^{151,152} Genetic makeup is certainly a major factor, but strong support for nutritional and environmental factors is vital.¹⁵³ Research has supported the relationship between compromised detoxification ability, lupus erythematosus, and rheumatoid arthritis.¹⁵⁴

Detoxification and hormone-related conditions. It is clear that the modern abundance of chemicals in our environment results in the eventual exposure of nearly everyone to toxic compounds via water, air, and food. Many xenobiotics that show toxic effects are lipophilic. These substances can accumulate in the body and are found stored in the highest concentrations in reproductive, liver, and adipose tissues. For example, human seminal fluid may contain compounds such as pentachlorophenol, hexachlorobenzene, DDT metabolites, and PCBs. Adipose tissue also can contain PCBs, DDT metabolites, and chlordane.¹⁵⁵ In one study of hexachlorobenzene content in adipose tissue, it was shown that the median levels actually increased by 50% over levels determined five years previously.

The functional changes resulting from these xenobiotic accumulations can be profound. The compounds naphthalene, anthracene, and biphenyl have strong affinities for glucocorticoid and androgen receptors after being acted upon by hepatic conjugation reactions.¹⁵⁶ Combinations of xenobiotics may have effects on hormonal activity far beyond the sum of their individual activities.¹⁵⁷

Since various drugs or chemicals may have an inhibitory or stimulatory effect on detoxification capacity, detoxification of other molecules through the same

pathway(s) may be slowed down or speeded up, as in the case of cigarette smoking inducing certain phase I P450 isoenzymes. These same enzymes are involved in the detoxification of estrogen. As a consequence, it has been noted that serum estrogen levels are lower in women who smoke. This fact may in part explain the increased incidence of osteoporosis and menopausal symptoms in women smokers as compared to non-smokers.¹⁵⁸

Supporting the Detoxification Systems

Chapter 31 will provide more guidance on the clinical approach to detoxification. In general, a program that supports healthy detoxification processes should do the following:

- Remove foods and beverages that are likely to contain toxins, food allergens, or antigenic challenge. (Antigens, as well as other endogenously produced and exogenous agents, increase the total xenobiotic load that must be handled by the detoxification pathways or other systems.)
- Eliminate or reduce ongoing toxic exposures in home and/or workplace.
- Meet basic daily nutritional needs, including adequate, high-biological-value protein content.
- Possibly provide increased amounts of the nutrients that function as cofactors for, or are otherwise required in, the enzymatic steps that occur in the biotransformation of toxic substances.
- Provide adequate hydration with clean water to promote elimination of biotransformed molecules.
- Consider interventions such as sauna or chelation, when specifically indicated, to reduce toxic load.

Nutrients critical to effective detoxification include:

- Efficient sulfation reactions require (among other things) vitamin A, adequate protein in the diet, and adequate sources of dietary sulfur (sulfur-containing amino acids, and foods such as garlic and onions).
- Glucuronidation reactions require magnesium and may be inhibited by smoking, fasting, and possibly high fructose intake. As this is a membrane-bound enzyme system, the integrity of the lipid bilayer is important for efficient glucuronidation.
- Glutathione reactions are some of the most crucial in the deactivation of xenobiotics. Synthesis of the glutathione cofactor requires adequate vitamins B6 and B12, magnesium, and folate. Glutathione transferases may be inhibited by a number of

dietary constituents, including alcohol and plant phenols, or induced by Brassica family compounds.

- Amino acid conjugation may be enhanced by administration of the cofactor amino acids (e.g., glycine or taurine).

Table 22.5 provides a list of plant compounds that influence detoxification.

Needs for additional nutrients or enhanced amounts of cofactors may be assessed by laboratory analyses such as determination of the amount of a nutrient or metabolite, assay of an activity dependent on the nutrient,

and/or challenge testing. Individuals with increased phase-I-to-phase-II ratios and/or low urinary or serum sulfate may require nutritional antioxidant support as well as enhanced conjugating nutrient support. Glycine, taurine, and sulfhydryl donors (e.g., glutathione, N-acetylcysteine, methionine, cystine, and cysteine) should be considered in planning a detoxification regime for those individuals. In the absence of testing availability, certain circumstances discovered through the history and physical exam may also serve as general indicators of an individual's nutritional insufficiencies.

Table 22.5 Plant-derived Compounds that Influence Detoxification

Flavonoids	The flavonoid class of plant compounds contains a wide range of biologically active components. Examples include naringenin, which is found in grapefruit and inhibits the activity of CYP1A2 and CYP3A4. Naringenin is a very powerful inhibitor; a single glass of grapefruit juice has been shown to contain enough inhibitory activity to decrease up to 30% of CYP3A4 activity for 12–24 hours. ^a Pharmaceutical companies have promoted the use of this inhibitory activity to enhance the availability and clinical activity of some drugs. Unfortunately, this activity may also increase the toxicity of other compounds that are metabolized by these cytochrome P450 enzymes. Rutin and quercetin have been shown to act synergistically with ascorbic acid and tocopherol, and protect against oxidation injury induced by glutathione deficiency. ^{b,c} Rutin and its aglycone, quercetin, are flavonoids found in tea, onions, and some citrus foods that also inhibit cytochrome P450 activity. ^d Conversely, the flavonoids tangeretin and nobilutin, found in orange juice, have been shown to induce CYP3A4. ^e <i>Rosmarinus officinalis</i> (rosemary) contains the flavonoids carnosol, carnosic acid, rosmanol, and ursolic acid, which possess high antioxidant activity. These polyphenols have been shown to scavenge inflammation-induced nitric oxide and peroxynitrite radicals. ^f Carnosol and carnosic acid stimulate the phase II detoxification enzymes glutathione-S-transferase and quinone reductase, and suppress DNA damage from xenobiotics. ^g
Monoterpenoids	Monoterpenoids such as d-limonene are derived from citrus foods, in particular lemon, and have a number of interesting effects on the detoxification systems. In animal models, limonene increases levels of CYP2C; however, it inhibits the activity of CYP2E1. ^h These monoterpenoids induce the phase II detoxification glutathione and glucuronidation activities, which may account for their ability to improve resistance to glutathione depletion by chronic acetaminophen administration and inhibit tumorigenesis in animal models. ^{i,j}
Curcumin	Curcumin is the yellow pigment and an active component in the spice turmeric (<i>Curcuma longa</i>). Curcumin has a wide range of biological activities that include acting as a potent antioxidant, antiinflammatory agent, and anti-mutagen. ^{k,l} Curcumin has also been shown to induce glutathione production and glutathione-S-transferase activity, and may inhibit some cytochrome P450 activities. ^{m,n}
Forskolin	As many xenobiotics are stored in the adipose tissue, enhancement of lipolysis during a detoxification regimen can be of significant benefit. This natural product, derived from <i>Coleus forskohlii</i> , may be useful in increasing the cAMP levels, which can indirectly assist (via adenylyclase) with lipolysis. ^{o,p}
Indole-3-carbinol	Indole-3-carbinol is found in the Brassica family of vegetables (cabbage, Brussels sprouts, broccoli). Metabolites of indole-3-carbinol are readily formed after its ingestion, and they inhibit the activity of the CYP1A1 and CYP1A2 isoforms in humans. ^q Indole-3-carbinol metabolites also have the capacity to enhance the phase II glutathione pathways, thereby providing a means to clear xenobiotics more efficiently. ^r

Summary

We are inevitably exposed to higher levels of xenobiotics in food, water, and air; many of us also bear an increased endogenous toxic load from faulty digestion, poor dietary habits, and metabolism of many medications (competitive inhibition). Thus, our individual detoxification profiles may be highly relevant to our risk of disease and dysfunction. Research is opening up an extremely important field of inquiry into the identification and proper counseling of individuals with various genetic susceptibilities or inadequacies that may require dietary, environmental, or supplemental modification to accommodate their biochemical individuality.

Studies of detoxification function show that the enzymes that control the various phase I and phase II processes vary significantly from person to person, even in healthy people.^{159,160} There are numerous pharmacogenetic variants affecting detoxification disposition that are manifested only upon drug or environmental challenge. This new understanding of detoxification brings us to a greater appreciation of Roger Williams's mid-20th century work and his popularization of the term and concept of "biochemical individuality."¹⁶¹ Differences in detoxification capacities based upon individual genetic predispositions, environmental exposures, and nutritional insufficiencies can have a profound effect upon susceptibility to a wide variety of diseases (and upon our ability to respond to interventions, whether pharmaceutical, nutritional, or botanical). Xenobiotics may act as immunotoxic agents, suggesting a biochemical connection between the immune, nervous, and hepatic detoxification systems.¹⁶² A very intriguing question is how many of the diseases we now consider idiopathic—of unknown origin—might be linked to

atypical detoxification reactions? Disordered detoxification may have wide-ranging impact upon hepatic, renal, cardiovascular, neurological, endocrine, and immune system function. It certainly feels safe to say that the complicated interrelationships involved in exposure to various substances, genetically determined detoxification pathways, alteration of the pathways by foods, drugs, and chemicals, and sensitivity of tissues to secondary metabolites from toxic substances, play an under-recognized role in contributing to the development and perpetuation of many health problems.

Identifying slow, fast, or otherwise imbalanced individual detoxification pathways can be extremely important. Laboratory assessment of detoxification gives the health professional more precise and definitive tools for assessment, a better understanding of an individual's unique metabolic detoxification capacity, and the opportunity to tailor nutritional support and environmental factors to reduce symptoms associated with metabolic toxicity.

Nobel Laureate (Physiology or Medicine), 1937

Introduction

The Inflammatory Response

One of the most enduring clinical observations made by the physicians of antiquity was that the human body responds to trauma or infection in a predictable manner, a phenomenon called inflammation. Written descriptions of this phenomenon date as far back as the Ebers papyrus (1550 BC), but the first concise, empirical definition has been attributed to Cornelius Celsus, circa 30–40 AD, who described its cardinal signs as redness and swelling with heat and pain (*rubor et tumor cum calore et dolore*). Galen of Pergamum (ca. 129–199 AD) later added a fifth sign: disturbed function (*et functio laesa*). Two centuries later, it was proposed that excessive secretion (*fluor*), should also be added to this group.¹

Whether the stimulus is a laceration, a burn, or an inhaled speck of pollen by a person with atopic syndrome, a remarkably similar combination of signs is elicited. These similarities imply that only a limited number of physiological pathways are required to produce this pattern, but superficial appearances can be deceptive. It is true that there is considerable overlap in effector mechanisms, but the machinery that runs those effector mechanisms is extremely complex. In fact, we cannot fully comprehend how this machinery works—much less how to gracefully manipulate it—without

first making some significant revisions in the scientific paradigm used to interpret its actions.

Even though it lacks an identifiable single conductor, inflammation is nevertheless a highly orchestrated event that utilizes an intricate reciprocity between the innate and acquired/adaptive branches of the immune system.² It relies on the basic process of signal transduction to convert information that specialized molecular sensors perceive as constituting foreignness, danger, or damage into a series of enzymatically catalyzed biochemical cascades.³ In turn, the downstream metabolites unleashed by these cascades activate the transcription of messenger proteins that are then dispatched to inform and instruct the larger cellular community of the host regarding the nature of the impending threat. What follows is a veritable symphony of intercellular dialogue, consisting of the enlistment and coordination of an integrated network of cell types whose mission is to defend their host and repair the damage caused by intrusions from pathogenic microbes or toxic biologic substances resulting from thermal, electromagnetic, mechanical, or chemical injury.^{4,5,6}

Immune Imbalance, Inflammation, and Chronic Disease

It has become increasingly evident that the process described by Celsus is a sword with two very sharp edges. The immune system's ability to mount an adequate inflammatory response is critical to survival—its absence is tantamount to a death sentence. When the immune system operates in a balanced fashion, the process is self-limited and largely beneficial. But the dysfunction that results from a wide variety of systemic imbalances can lead to a loss of regulatory control, in which case the process becomes perpetual and destructive to the host.⁷ The most obvious examples of this

outcome can be found in chronic inflammatory disorders such as rheumatoid arthritis, inflammatory bowel disease, and eczema, or the granulomatous response to tuberculosis and other intracellular infections.

As it turns out, however, these conditions are only the tip of the iceberg and the consequences of imbalanced immune function are much more pervasive than previously appreciated.^{8,9} Inflammation is now understood to be a central aspect of the pathophysiology of a wide range of conditions from obesity,¹⁰ diabetes mellitus,¹¹ atherosclerosis,^{12,13} and hypertension, to Alzheimer's and Parkinson's diseases, cancer,^{14,15} depression,^{16,17,18,19} and autism. Support is increasingly growing for the contention that *all* chronic illness has a significant inflammatory component. Even the frailty associated with biological aging (and perhaps aging itself) appears to result from the cumulative effects of inflammation.^{20,21,22}

All of this tells us that the physiology of inflammation is not a locally isolated phenomenon, but instead is a process that is closely intertwined with the overall health of the individual.^{23,24,25} Consequently, the revelations that emerge from investigating how these mechanisms operate under normal and abnormal conditions are proving to have profound implications for every branch of medicine. Before we can adequately and intelligently assume the task of safely and effectively influencing the course of chronic inflammatory disorders, it is essential for us to fully understand the underlying mechanisms at work. Since the tenor of the interaction between immune cells and foreign substances determines whether the outcome will be quiescent tolerance or the initiation of an inflammatory cascade,²⁶ it is critical that we understand what influences this interaction on a structural and biochemical level. It has become increasingly clear to researchers in the life sciences that structure and function are inextricably interrelated. Consequently, we must have a working knowledge of the normal molecular biology of inflammatory triggers, effector cells, and their mediators before we can truly understand how this process goes awry.

The Cellular and Molecular Biology of Immunity and Inflammation

Knowing how specific three-dimensional structures interact with immune and other effector cells to activate the inflammatory response, and how various medi-

ators act on a molecular level to amplify or dampen that response, will help us find precise ways to modify the body's reactions when interventions are needed. Such interventions could involve prevention, modulation, or augmentation of immune function; whatever the strategy, the overriding principle—according to the tenets of functional medicine—is to achieve a positive outcome without causing additional harm in the process. To better appreciate the critical role that triggers and mediators play in this process, it is essential to understand the overall context in which the immune system operates.

Innate and Acquired Immunity: Development and Function

The primary roles of a healthy, balanced immune system are:

1. identify potentially infectious or injurious substances (e.g., necrotic cellular debris),
2. distinguish self-antigens (i.e., nonthreatening) from nonself-antigens (i.e., threatening),
3. assess the potential level of threat posed by infectious, toxic or nonself-antigens,
4. mount a response that is appropriate to the level of threat, and
5. repair any damage that ensues from adversarial encounters.

The primary responsibility for identifying infectious or injurious substances is assigned to the innate arm of the immune system.^{27,28} For this reason, the sentinel agents of innate immunity, including macrophages, dendritic cells, and related antigen-presenting cells (APCs), are widely distributed throughout mucosal surfaces, connective tissues, and organs.²⁹ Natural killer cells, which constitute between 5 and 15% of peripheral circulating lymphocytes, are also involved in innate immunity.^{30,31,32}

Rather than identifying every possible antigen, APCs express cell surface receptors for patterns unique to microorganisms, allowing for rapid identification of pathogens without the need for prior exposure to them. APCs are typically activated and are able to initiate an inflammatory response within minutes to a few hours after injury.³³ An important skill possessed by dendritic cells is their ability to migrate (under the influence of chemokines, TNF- α , IL-1 β and other inflammatory cytokines) from epithelial and mucosal surfaces to draining lymph nodes or to far-flung sys-

temic sites, which gives them access to increasingly large venues for broadcasting warning messages about locally generated infractions.^{34,35}

In contrast, the tasks of the acquired/adaptive arm are to provide an expandable army of clones that can (1) amplify the cascade initiated by activated APCs, and/or (2) functionally recognize pathogens missed by the innate system.³⁶ Accomplishing the second task relies on an exquisite sensitivity for distinguishing between self- and nonself-antigens. This requires a high level of refinement and training, enabling the lymphocytes to become efficient but extremely obedient killing machines. Without this training, they could attack their host (which is exactly what happens in autoimmune disorders). The early phases of training are under control of the thymus. This training has been referred to as “self-referential,” in that it exclusively relies on *internal* cues for preparing the lymphocytes to recognize a potentially vast array of *external* cues that it may encounter throughout the life of the host. Lymphocytes that fail in their early training and react to self-antigens are rapidly eliminated.

The later phases of training involve “mentoring” by APCs and regulatory lymphocytes. Exposure to a pathogen allows APCs to capture it and subsequently process and display its peptide fragments in the MHC II (major histocompatibility complex) sites on their surface membranes. Contact with these MHC-peptide complexes on mature dendritic cells acts to prime lymphocytes so that they will be able to recognize the pathogen during subsequent exposure. Because of its reliance on clonal expansion, the acquired immune system may take days or even weeks before its reaction to infectious and other nonself triggers becomes apparent. Rejection of a transplanted organ or delayed hypersensitivity reactions are typical examples, while IgE-mediated, type I allergic reactions are an obvious exception to this generalization.³⁷

Innate immunity and chronic inflammation. For many years it was thought that the innate system was mostly involved in the *acute* inflammatory response, and that the primary mediator of *chronic* inflammation was the acquired immune system (i.e., B and T lymphocytes). However, new evidence indicates that an overstimulated or dysfunctional innate system—acting in conjunction with affected vascular and connective tissues—plays at least as prominent a role in instigating and perpetuating chronic conditions.^{38,39,40} For example, dendritic cells can function both as initiators *and* active

modulators of the immune response by ongoing induction of lymphocytes.⁴¹ Although increased numbers of activated B and T lymphocytes are typically found wherever there is chronic inflammation (e.g., the synovitis associated with rheumatoid arthritis or the persistent dermatitis with eczema), both cell types are under the *direct control* of dendritic cells.⁴²

Dendritic cells can also actively participate in the ongoing tolerization of T lymphocytes against self-antigens. This suggests that the loss of tolerance that appears in autoimmunity or transplant rejection, or the increased tolerance that occurs with cancer, could—paradoxically—both be manifestations of dysregulation by dendritic cells.^{43,44,45} Recognizing this has led to renewed interest in the specific pathways involved in the activation, maturation, and subsequent deactivation of dendritic cells and other APCs.

Molecular Triggers of the Immune Response and their Receptors

As previously noted, one of the primary triggers for the innate immunologic reaction is a group of specific microscopic structures. These structures have been termed pathogen-associated molecular patterns (PAMPs). PAMPs are highly conserved, “generic” motifs that are abundant in many different microorganisms, including viruses, bacteria, and fungi. Since they are *not* normally found in vertebrates, their presence serves as a major warning signal to APCs and phagocytes. PAMPs include bacterial lipopolysaccharides (LPS, aka endotoxin) from gram-negative cell walls; teichoic and lipoteichoic acids (LTA) predominantly from gram-positive bacteria; flagellin, pilin, and N-formyl-methionine found in bacterial proteins; peptidoglycan, mannans, glucans, glycolipids, and zymosan from fungal cell walls; double-stranded RNA from viruses; unmethylated cytosine-guanine dinucleotide sequences (CpG DNA) found in bacterial and viral genomes.

APCs and other innate immune cells recognize PAMPs through a variety of transmembrane and intracellular glycoprotein receptors. While these receptors can identify over 1,000 different structures, they have no capacity for recognizing self-associated antigens. In other words, they are incapable of reacting to host tissues. There are two main classes of pattern-recognition receptors, signaling and endocytic. In addition, a series of soluble pattern-recognition receptors circulate in the bloodstream, where they function as opsonins that can

bind to microbes, initiating the complement cascade and phagocytosis.⁴⁶

Toll-like receptors (TLRs) are the primary signaling pattern-recognition receptors.^{47,48} At least nine different TLRs have been identified. Typically appearing in pairs, different cell types express different TLR combinations, translating into varying abilities of an APC to respond to a particular bacteria, virus, fungus, etc. A significant feature of the TLR system is its presence in all multicellular organisms, indicating the ancient and fundamental role it has played throughout evolution. (In contrast, specific antigen recognition by antibodies—acquired/adaptive immunity—occurred much later in the course of evolution and is only found in vertebrate species.) TLRs are members of the larger superfamily of interleukin-1 receptors, with which they share the same intracellular subunit and many of the same downstream signaling molecules.^{49,50,51,52,53}

Intracellular Signaling Pathways and their Gene Products

These highly specialized pathogen sensors transduce the warning signals conveyed by foreign macromolecules into a flurry of activity by intracellular protein kinases and related enzymes that employ phosphorylation and similar catalytic processes to turn on a network of intracellular biochemical pathways.^{54,55,56,57} In most cases, this leads to the activation in the cytosol of nuclear factor-kappa B (NFκB) by uncoupling it from I-kappa B inhibitor proteins, which are subsequently degraded.⁵⁸ This allows the translocation of NFκB to the nucleus, where it binds to specific gene promoter regions on DNA, resulting in the increased transcription and translation of proinflammatory cytokines, type II inducible cyclooxygenases, inducible nitric oxide synthases, various adhesion molecules (VCAM, ICAM, etc.), and metalloproteinases.^{59,60,61}

Interestingly, even though activation of the NFκB family of transcription factors is a constant feature of this process, ligand binding to different pairs of TLRs results in the synthesis of different types and mixtures of cytokines. For example, TLRs that bind to viral components (e.g., TLR-3 and TLR-8) lead to increased production of interferons.⁶² Zymosan from fungal cell walls will bind to a different combination of TLRs (TLR-2/TLR-6) than bacterial endotoxins (TLR-4/TLR-4).⁶³ Both lead to increased production of proinflammatory cytokines, including IL-2, TNF-α and IL-8, but the specific

profile will be slightly different depending on the initial trigger. Since NFκB is upregulated in all these situations, this indicates the collateral involvement of a large network of additional receptors, transcription factors and co-regulatory molecules that determine the specific gene promoter regions to which NFκBs are able to bind. For example, endotoxin's effects are also mediated through LPS binding protein and CD14, both of which collaborate with TLR4 to stimulate the synthesis of proinflammatory cytokines.⁶⁴ Similarly, the effects of fungal beta-glucans are also mediated through binding to dectin-1, a recently identified transmembrane lectin APC receptor that collaboratively promotes the activation of TLR2 signaling.⁶⁵

Additional Innate Receptors: Endocytic Receptors, Scavenger Receptors, and RAGEs

In addition to signaling pattern-recognition receptors, endocytic receptors also play a critical role in the innate inflammatory response. Located on the surface of macrophages and other phagocytes, these multiligand receptors facilitate the binding, engulfment and degradation of pathogens and cellular debris. The predominant members of this class include a superfamily of macrophage scavenger receptors and receptors for advanced glycosylation end products (RAGEs). Macrophage scavenger receptors, like toll-like receptors, are also glycoproteins that bind to many of the same PAMPS, including endotoxin from gram-negative and lipoteichoic acid from gram-positive bacteria. However, they also “scavenge” negatively-charged endogenous substances that have been chemically altered or modified, such as oxidized LDL, HDL, and other lipids, glyco-oxidized adducts (i.e., advanced glycosylation end products), and amyloid E-protein.⁶⁶ RAGEs differ from scavenger receptors in that they bind exclusively to endogenously generated molecules, including AGEs, amyloid fibrils, and prion-derived peptides.⁶⁷

Like TLRs, scavenger receptors and RAGEs utilize activated NFκB as the central conduit for increasing transcription and translation of proinflammatory cytokines and enzymes. The normal role of signaling and endocytic scavenger receptors is to assist with host defense, cell adhesion, and removal of debris from systemic circulation. However, considering that they are activated by many of the same triggers associated with *chronic* inflammation, it is not surprising to find that genetic variants, resulting in an upregulation of their

expression, have been linked to a seemingly disparate group of conditions, including atherosclerosis, Alzheimer's disease, and cancer (e.g., prostate).^{68,69} This is consistent with the converse observation—for example, polymorphisms in toll-like receptor 4 that *downregulate* its response to LPS are associated with decreased production of proinflammatory cytokines and an increased risk of contracting severe bacterial infections, but a *decreased risk* of developing atherosclerosis.⁷⁰ Similarly, a person with increased expression of macrophage scavenger receptors and RAGEs would be more vulnerable to the inflammatory effects of a diet high in free radicals, oxidized fat, and refined carbohydrates.⁷¹

NFκB-mediated Gene Activation: Final Common Pathway for Inflammatory Responses

In summary, the innate immune system depends heavily on signals provided by all of these receptors to determine the need for possible defensive action. Consequently, this signal transduction network and its downstream cascades of enzymatic activation are increasingly being recognized as a major crossroads that links inflammatory triggers with the effector cells and mediators that achieve their effects.⁷² Directly in the center of this crossroads is the NFκB protein family, which appears to be upregulated in almost every acute *and* chronic inflammatory disorder, whether it is appendicitis, pancreatitis, periodontitis, tuberculosis, cancer, diabetes, inflammatory bowel disease, rheumatoid arthritis, neurodegenerative disease, COPD, osteolytic bone disease, or muscular dystrophy.^{73,74,75,76,77,78,79}

NFκB proteins can be activated by a variety of physiologic and nonphysiologic stimuli, including exposure of cells to PAMPs,⁸⁰ reactive oxygen species (particularly oxidized lipids),⁸¹ reactive nitrogen species, glycated proteins,⁸² homocysteine, gliadin, arsenic, lead, iron or nickel, polycyclic aromatic hydrocarbons,⁸³ polychlorinated biphenyls (PCBs), cigarette smoke,⁸⁴ TNF-α, IL-1, IL-18, interferon and other inflammatory cytokines, activated B and T lymphocytes, adenosine, bradykinin,⁸⁵ angiotensin II, ionizing radiation, mechanical lung ventilation, and even simple mechanical stretching of muscle fibers.⁸⁶ Although the acute activation of NFκB plays a central role in both innate and acquired defenses against infection, it can become constitutively activated with chronic oxidative stress or with aging (in which case, constitutive expression does not just appear in hematopoietic cells, but in a wide range of tis-

ues).^{87,88,89} Although this constitutive activation would appear to be invariably detrimental, the discovery that it can also occur in healthy lymphoid tissue raises the possibility that low-level gene promotion by NFκB may exert a beneficial influence in maintaining immunologic homeostasis.⁹⁰

The issue of NFκB's beneficial effects is extremely significant in light of current efforts to synthesize pharmaceutical agents to inactivate NFκB.^{91,92,93} Glucocorticoids are the best known example of such agents.⁹⁴ One of the main therapeutic effects of glucocorticoids is to increase the intracellular synthesis of I-kappa B, which binds to and inhibits NFκB.⁹⁵ The potent anti-inflammatory effects of glucocorticoids are well known, as are their side effects. A designer pharmaceutical agent that is even more effective than glucocorticoids at inhibiting NFκB would be predicted to have even more negative consequences. In contrast, a large number of naturally occurring phytochemicals derived from foods and botanical medicines have been found to downregulate NFκB without completely inhibiting it. These substances include alpha-lipoic acid,⁹⁶ vitamin C, vitamin E, N-acetylcysteine,⁹⁷ cat's claw extract,⁹⁸ silymarin from milk thistle, flavonoids from citrus,⁹⁹ resveratrol from purple grape skin,^{100,101} curcumin from turmeric,^{102,103} green and black tea polyphenols,¹⁰⁴ ginkgolides from Ginkgo biloba, parthenolide from feverfew,¹⁰⁵ boswellic acid from *Boswellia serrata*,¹⁰⁶ and baicalin from Chinese skullcap.¹⁰⁷ Even *simple caloric restriction* (which reduces oxidative stress), can reduce NFκB activation. Considering that many of these foods or herbs have been safely consumed for long periods of time—in some cases over a thousand years—without reports of significant adverse effects, exploring their therapeutic potential as immunomodulators should be an extremely high priority for immunologists, pharmacologists, and *clinicians*.)

Depending on the type of cell involved, reactive oxygen species, heavy metals, and other toxins can activate numerous other transcription factors besides NFκB, such as AP-1, a collective term for a group of dimeric proteins with varying subunits (e.g., Jun, Fos, or Activating Transcription Factor) found in endothelial cells that regulate many of the same genes as NFκB, including cytokines, chemokines, matrix metalloproteinases, adhesion molecules, and inducible nitric oxide synthase. Also expressed in endothelial cells are hypoxia-inducible transcription factors (HIF-1, HIF-1β, and HIF-2), which strongly influence transcription of numerous proinflammatory vascular genes.¹⁰⁸

The Role of Danger Signals in Immune Activation

It is important to point out that simple exposure to PAMPs is often insufficient for activating an immune response. This is especially important with regard to commensal bacteria in the intestines. Most of these bacteria possess macromolecules that are theoretically capable of binding numerous receptors on antigen-presenting cells. Although many of these potential triggers are masked by secretory IgA or mucin glycoproteins, a significant level of interaction with dendritic cells and macrophages still occurs on a regular basis.¹⁰⁹ However, in healthy individuals, the inflammatory response to these bacteria is kept under control and tolerance is the rule.^{110,111} What accounts for this ongoing truce between immune cells and their mortal enemies that allows a lifetime of relatively quiet cohabitation?

Inhibition of toll-like receptor signaling by intracellular proteins like interleukin-1 receptor-associated kinase-M (IRAK-M) and regulatory effects of suppressor lymphocytes and their associated cytokines (e.g., TGF- β , IL-4 and IL-10) clearly play a role in keeping the peace and maintaining homeostasis in the innate system.^{112,113,114,115,116} Intestinal macrophages—the largest such reservoir in the body—have been found to display profound inflammatory anergy without limitations in their phagocytic or bacteriocidal activity.¹¹⁷ This appears to result from downregulation of their ability to produce proinflammatory cytokines by TGF- β and other non-specific suppressor factors, all of which may be induced by exposure to high concentrations of soluble dietary antigens.

Even though tolerance is the norm, the state of calm is relatively fragile and can easily be disrupted, a situation that most likely occurs on a frequent and regular basis.^{118,119,120} While most of those disruptions are not clinically evident, they can manifest as transient autoimmune phenomena sometimes associated with bacterial and viral infections, such as rashes and arthralgias. A breach in tolerance can also lead to persistent post-infection problems like rheumatic valvular disease, post-streptococcal glomerulonephritis, or immune-mediated behavioral problems like tics and obsessive-compulsive disorder associated with PANDAS syndrome (Pediatric Autoimmune Neuropsychiatric Disorders associated with Streptococcal Infections).¹²¹

It may be that the source of disruption leading to activation or intolerance is not just a stranger, but a stranger combined with molecular indications of threat:

“stranger plus danger.” A theory championed by the immunologists Charles Janeway and Polly Matzinger (among others) is that when the message of foreignness transmitted by PAMPs is accompanied by specific danger signals, the result is robust activation of APCs.^{122,123} Without the presence of these additional signals, innate immune cells might be less likely to respond to a potential inflammatory trigger.¹²⁴ To use an analogy, consider a street cop in a rough neighborhood, who has become inured to the minor thefts of petty criminals. However, he doesn’t hesitate to swing into action when alerted by alarms from a bank being robbed.

Sources of danger signals. Injured or dying cells—a sequela of trauma, postischemic reperfusion, or accelerated apoptosis—release a wide variety of substances that might communicate danger messages.^{125,126} Crystalline uric acid (monosodium urate), a degradation product of DNA and RNA, is a strong candidate to be one of the principal endogenous danger signals. Well known for its role in the excruciatingly painful inflammation of acute gouty arthritis, uric acid has been shown to stimulate the maturation of dendritic cells and enhance their ability to present foreign antigens to T lymphocytes.¹²⁷ Mammalian DNA is immunologically “cloaked” by methyl groups, but *undermethylated* DNA (found in systemic lupus erythematosus and other autoimmune disorders) is also thought to act as a danger signal in certain contexts.¹²⁸ Other candidates for communicating danger are heat shock proteins (HSPs), pluripotential molecular chaperones that are elaborated by cells subjected to a wide variety of physical and emotional stressors.¹²⁹ Among many other actions, HSPs have been found to stimulate the maturation of dendritic cells and also to initiate an acute inflammatory response by binding directly to toll-like receptors.¹³⁰

Individuals who are less physically fit tend to be less adept at producing HSPs; as a consequence, their immune systems are less effective at mounting an appropriate inflammatory response to bacterial or viral invasion. This may offer a partial explanation for why people who exercise more are often more resistant to infection. Another implication of these findings is that the biochemical events set in motion by non-pathogenic stressors—such as severe or persistent emotional turmoil—could result in the loss of tolerance to normal intestinal flora, thus paving the way for inflammatory bowel disease or possibly even atherosclerosis.¹³¹

Loss of Tolerance, Th1/Th2 Imbalance, and the Role of Normal Gut Flora

Despite the growing body of data illuminating the phenomenon, it is clear that much remains to be understood about oral tolerance. Of equal importance to the factors that can disrupt the peace and lead to a loss of tolerance are those that can help to restore and maintain it. The latter is a concept that is just starting to be exploited through the use of probiotic bacteria, which have been shown to enhance the tolerizing effects of suppressor T cells, but undoubtedly work through numerous other mechanisms as well.^{132,133} Certain species of lactobacilli have even been shown to produce IL-10, which exerts similar immunomodulatory and anti-inflammatory effects as regulatory lymphocytes. Research on the tolerizing effects of very low doses of specific orally administered antigens such as type II collagen (in rheumatoid arthritis) and myelin basic protein (in multiple sclerosis) has also been promising, although there are many unknowns about the most effective dosage and length of administration required to achieve a clinical effect.¹³⁴

An emerging body of literature postulates that one reason for the rising tide of atopic syndrome, inflammatory bowel disease, and autoimmune disease (e.g., type 1 diabetes, multiple sclerosis) in modern societies is the lack of exposure to tolerizing amounts of antigens in the first year of life.^{135,136,137,138,139} Numerous studies show that children who are raised on farms, have multiple siblings, spend time in day-care centers, or live with cats or dogs in the first 6 to 12 months of life are less likely to develop allergies than children from relatively sterile urban environments.¹⁴⁰ In contrast, offspring of mothers who took antibiotics during pregnancy are more likely to be atopic.¹⁴¹ The “hygiene hypothesis” suggests that an infant’s immature immune system requires a certain level of inoculation by dietary antigens to become fully competent.^{142,143} In this case, competence is defined as the balanced expression of cell-mediated immunity, driven by Th1 cytokines (INF- γ , IL-2, and IL-12), with that of humoral immunity, driven by Th2 cytokines (IL-4, 5, 6, and 10). Since Th1 cytokines exert counter-regulatory effects on Th2 lymphocytes and vice versa, it is critical that both subsets are equally active (or equally suppressed) to achieve balanced immune functioning.^{144,145,146,147}

Under normal circumstances, the neonatal immune system is somewhat biased towards Th2 dominance. After birth, the intestinal flora develops in conjunction with growth factors present in colostrum and breast milk.^{148,149} Exposing the gut to small amounts of antigens from helminths or “friendly” microbes, including saprophytic mycobacteria and lactobacilli, results in interactions between the normal flora, dendritic cells, and macrophages in the gastrointestinal-associated lymphoid tract.^{150,151,152,153,154,155} This serves to program and mature the APCs, which induce CD4+CD25+ regulatory lymphocytes (Tr1 and Th3 cells) to secrete IL-10, TGF- β and other regulatory cytokines; they, in turn, exert a modulatory effect on both Th1 and Th2 lymphocytes along with enhanced production of secretory IgA.^{156,157} The net effect of activating regulatory lymphocytes is suppressed immune responses to ingested antigens.^{158,159,160,161} In the absence of such regulatory programming, a subset of children with polymorphisms in innate receptors such as TLR2 or NOD2 have a higher risk of developing atopic syndrome or inflammatory bowel disease. Interestingly, even though regulatory lymphocytes appear to be activated by specific antigens, they *respond* in a “generic” non-antigen specific manner—a phenomenon referred to as bystander suppression.

The obvious question is whether Th1/Th2 imbalances or similar dysregulated immune function can be prevented *in utero* or during the neonatal period. While no one is recommending feeding dirt to children, administration of probiotic bacteria to both pregnant women and neonates decreased the incidence of atopic syndrome in several clinical trials.^{162,163} The apparent success of this approach has led to increased interest in the possibility that restoring immune tolerance in the gut could also reverse disorders of immune dysregulation, such as inflammatory bowel disease, autoimmune arthritis, or asthma, even after they have become firmly established.^{164,165,166} In addition to the use of specific strains of probiotic bacteria, trials are also underway with the use of helminth-derived antigens. While some of the findings are mixed and many questions remain about the specifics of this strategy, early results do suggest sufficient beneficial effects to warrant further study.

Acquired/Adaptive Immune Responses and Inflammation

As previously discussed, repeated exposure to specific pathogens or other antigens can also activate the acquired, antigen-specific immune response primarily mediated by B and T lymphocytes. This type of response is familiar as the etiology of the Gell and Coombs schema of hypersensitivity reactions, including type I IgE-mediated immediate allergic reactions; type II antibody-/complement-mediated cytotoxic reactions; type III immune complex-/complement-mediated reactions; and type IV cell-mediated (T-cell, macrophage) delayed reactions.¹⁶⁷ Each category of unbalanced or excessive immune responses is associated with a specific group of inflammatory disorders, such as atopic syndrome and anaphylaxis (type I), hemolytic transfusion reactions (type II), serum sickness and connective tissue disorders with associated vasculitis, synovitis, endocarditis, and glomerulonephritis (type III), and contact dermatitis or thyroiditis (type IV).¹⁶⁸

Although innate responses are usually distinguished by their immediacy of onset relative to the acquired response—type I reactions excepted—their ultimate manifestations often share many overlapping features with acquired responses and can have almost identical signs and symptoms. For example, the dermatitis caused by exposing a sensitized individual to the Rhus antigen from a poison ivy plant can appear very similar to a localized sunburn. Even though the specific constellation of physiologic and biochemical pathways that are activated may vary considerably depending on the specific type of injury, the portal of entry and the region or system of the body that is affected, the overall process maintains a recognizable thematic consistency. This unifying theme is the restoration of health and homeostasis by defending tissues against invasion by pathogens and repairing the damage incurred by that invasion.

Endogenous Inflammatory Mediators and their Physiologic Effects

Since it is designed to defend and repair the body against pathogens and trauma, the inflammatory response could accurately be defined as *a process with a purpose*. Whether initiated by the release of debris from injured or necrotic cells, the activation of macrophages and monocytes by PAMPs, AGEs or oxidized LDL, or the exposure to environmental or autologous antigens, a set

of common pathways will be invoked, leading ultimately to the increased production of proinflammatory cytokines. As key players in this process, these messenger molecules transmit alarm signals that activate numerous cell types, including additional leukocytes, platelets, local endothelial cells, and fibroblasts. Activation of phospholipase A2 in membranes of leukocytes and platelets liberates arachidonic acid, which then undergoes rapid enzymatic conversion into prostaglandins, thromboxanes, and leukotrienes.^{169,170} Mast cells, basophils, and other leukocytes degranulate, releasing histamine and proteolytic enzymes. Activated endothelial cells release pro-coagulant factors. The complement cascade is activated and bradykinin is liberated from high molecular-weight kininogen.

The net effect of all these events is hypersensitization of sensory nerve fibers to noxious stimuli, an increase in local vascular perfusion, hyperpermeability of post-capillary venules, an increase in coagulability, smooth muscle relaxation (vasodilatation) or contraction (bronchoconstriction), and mobilization of additional leukocytes. Once mobilized by chemokines, leukocytes become sticky and attach to endothelial adhesion molecules (VCAM-1, etc.) on the vascular wall, roll (under the influence of selectins), become superadherent (under the influence of ICAM-1), and extravasate into the injured area. Activated platelets release thromboxanes, become sticky, clump together and adhere to rough surfaces of the extracellular matrix exposed by injury to the endothelium.

As noted previously, these complex and diverse physiologic shifts are united by common goals. Increased blood flow allows the rapid removal of debris and pathogens. Increased capillary permeability permits the migration of leukocytes to the site of injury. Shifting fluids into the extravascular compartment results in dilution of toxins and pathogens. Increased coagulation causes the formation of microthrombi, which assist in walling off the injured area. Complement split products bind to pathogens, thereby increasing their susceptibility to phagocytosis (i.e., opsonization). Pain activates a withdrawal reflex, preventing additional trauma. Increased temperature has an antiseptic effect.

The acute-phase response: systemic effects of local inflammation. In addition to the local consequences of an inflammatory reaction, there are additional systemic effects known as the acute-phase response. As previously discussed, activation of TLRs

on tissue macrophages and other leukocytes by pathogens results in increased production of IL-6, IL-1- β and TNF- α . These proinflammatory cytokines then travel via the systemic circulation to the liver, where they induce synthesis of a group of proteins called acute-phase reactants.¹⁷¹ Increased levels of glucocorticoids work synergistically with IL-6 and IL-1- β to further stimulate hepatic protein synthesis. During an acute inflammatory response, collective production of these proteins is dramatically elevated, and can range up to 45 grams per day.¹⁷²

There is an initial, rapid increase in C-reactive protein (from 100 to 1000 fold in 24-48 hours) and mannan-binding protein (MBP), both of which function as soluble pattern-recognition receptors, adding further to the body's ability to recognize PAMP structures on foreign invaders. C-reactive protein acts as an opsonin by binding to phospholipids in microbial membranes. This increases phagocytosis along with activation of the classic complement cascade. Similarly MBP participates in opsonization by binding to mannose found in bacterial and fungal cell walls. There is also a rapid increase in serum amyloid A, which influences leukocyte adhesion, migration, proliferation, and aggregation.¹⁷³

Over time, these rapidly released proteins are joined by a slower increase in hepatic production of proteins involved in coagulation (fibrinogen, prothrombin, plasminogen-activator inhibitor-1), transport proteins (ferritin, ceruloplasmin, and haptoglobin), hepcidin, anti-proteolytic proteins (α -1-antitrypsin, α -2-macroglobulin), complement (CH50, CH100), and complement components (C3 and C4). Elevations in the erythrocyte sedimentation rate, a commonly used clinical marker for the presence of an acute-phase response, are primarily a reflection of elevated plasma fibrinogen, and tend to change relatively slowly. In contrast, C-reactive protein levels can change rapidly and tend to be a much more precise marker of the overall degree of inflammation.¹⁷⁴

The liver's need for the raw materials to synthesize these proteins contributes to an overall state of catabolism, exemplified by the diversion from plasma of amino acids that are normally used for skeletal muscle. The endocrine system in turn, releases a host of hormones that induce catabolism and gluconeogenesis, including adrenocorticotrophic hormone, cortisol, catecholamines, growth hormone, insulin, glucagons, and thyroxine. In addition to myalgias, muscle wasting, and cachexia, other systemic consequences of this acute-

phase response include anorexia, lethargy, dysthymia, anemia (inhibition of erythropoietin), leukocytosis, thrombocytosis, hypoalbuminemia, hyperglycemia, hyperlipidemia (primarily hypertriglyceridemia), increased plasma glutathione, increased inducible nitric oxide synthase, hypercupremia, hypozincemia, and hypoferrremia. Activation of toll-like receptors and/or systemic elevations of pyrogenic cytokines (primarily IL-6 but also IL-1- β and TNF- α) raise prostaglandin E2 in the hypothalamic thermal control center, which responds by increasing body temperature.¹⁷⁵ It has been of great clinical interest to recognize that surgical trauma creates a scenario identical to this acute-phase reaction (with all of its attendant morbidity), and that the intensity of the response corresponds to the extent of the trauma. Strenuous exercise and childbirth can also produce mild acute-phase reactions.

Counter-regulatory Control Mechanisms

Although the intrinsic goal of this process is to restore homeostasis by fighting off infection and repairing tissue, it is obvious that the acute-phase reaction can quickly become detrimental if it continues unabated. As with oral tolerance, the immune system provides numerous checks and balances to keep the acute-phase response from getting out of control. One of the most extensive anti-inflammatory counter-regulatory mechanisms is mediated by two peroxisome proliferator-activated receptors, PPAR α and PPAR γ . These nuclear receptor transcription factors were first discovered as ligands for lipid- and glucose-regulating pharmaceutical agents—PPAR α for fibrates, and PPAR γ for thiazolidinediones—and were therefore thought to primarily be involved in control of metabolism. It was then determined that fatty acids and eicosanoids were natural PPAR ligands; for example, leukotriene B4 (LTB4) activates PPAR α , while prostaglandin J2 binds to PPAR γ . When these mediators are released during the inflammatory cascade, they bind to and activate effector cells, but also bind to PPARs, which then negatively interfere with NF κ B-driven production of multiple inflammatory gene products. Research now shows that increased activity of PPARs can lower overall oxidative stress and reduce the inflammation found with asthma, cardiovascular disease, and cancer.^{176,177,178,179,180,181,182,183,184}

(As with NF κ B, significant efforts are being made to find potent pharmaceutical agents that stimulate PPAR

activity; however, as evidenced by the severe hepatotoxicity exhibited by some of these agents, such an approach is fraught with difficulties. Part of the problem may be that the effects of activating PPARs are not exclusively anti-inflammatory—in certain contexts, they can exert inflammatory effects as well. However, for reasons that are not completely understood, dietary essential fatty acids, including fish oil (EPA/DHA)¹⁸⁵ and 9,11 isomers of conjugated linoleic acid (CLA) have also been found to activate PPARs without any associated toxicity.

DHEA, an endogenous androgenic steroid that is widely used as a dietary supplement, has been shown to upregulate PPAR α without evidence of hepatotoxicity in normal therapeutic doses, which may explain some of DHEA's purported "anti-aging" effects. Similarly, diindolylmethane, a glucosinolate derivative from cruciferous vegetables, appears to be a specific ligand for PPAR γ , and may exert influence on lipid and glucose metabolism.)

Other critical counter-regulatory control points involve:

1. downregulation of TLR activation by IRAK-M;^{186,187}
2. modulation of cytokine activity, by increased production of lipoxins,^{188,189,190} resolvins, transforming growth factor-beta, and/or other anti-inflammatory cytokines (IL-4, IL-10);¹⁹¹
3. neutralizing effects of circulating cytokine receptors (e.g., IL-1 receptor antagonist, soluble TNF- α receptor); and
4. dampening of the intracellular signaling pathways induced by eicosanoids or cytokines (e.g., inhibition of phospholipase A2 by uteroglobin and other endogenous mediators).¹⁹²

Obviously, the scales that hold inflammatory mediators in one tray and anti-inflammatory mediators in the other must be extremely precise in their measurements.¹⁹³ All it takes is a slight tip in the balance and the entire system can become disrupted—hence the great care that must be taken when one attempts to manipulate this system with pharmaceutical agents.

Loss of Regulatory Control: A Maladaptive State Resulting in Chronic Inflammation

While the overall trend is similar, different people who have the same illness (or undergo similar degrees of trauma) can experience wide variations in their production of acute-phase reactants. This indicates that each component of the inflammatory response is subject to

individual regulatory control, which is a reflection of the interplay between genetic predisposition and environmental influences. It follows then that one of the predominant factors in determining the overall health of an individual is whether the person's immune system is operating in a fundamentally balanced or imbalanced fashion.¹⁹⁴ When the immune system is acting in a balanced and appropriate way, the vast majority of inflammatory reactions to ongoing insults do not create significant or noticeable perturbations in a person's overall state of health. These reactions are adaptive in the sense that they are part of a self-regulating cybernetic loop.¹⁹⁵ In other words, they are in a continuous state of readjustment based on feedback about current conditions in the internal and external environment.¹⁹⁶

Inflammatory reactions become problematic when they are (1) extreme, as in the case of sepsis, disseminated intravascular coagulation, anaphylaxis, and anaphylactic shock; (2) progressively destructive, as in the deleterious sequelae of reperfusion after myocardial or neural ischemia, certain chemical injuries, sunburn, or frostbite; or (3) persistent or recurrent, as in the case of allergy or autoimmune disease. In these scenarios, the largely beneficial response to acute injury transforms into a detrimental pattern that injures the very same tissues that it was designed to heal. Simply put, the damage caused by an inflammatory response to injury can sometimes be equivalent to—or greater than—than the original injury.

Many chronic inflammatory diseases are characterized by elevated levels of C-reactive protein,¹⁹⁷ INF- γ , IL-1, IL-6,¹⁹⁸ and TNF- α , i.e., the very same mediators expressed during the acute-phase reaction.^{199,200,201} Although the elevations may not be as high as they are in the acute phase, they are distinct and reproducible. It's as if the acute-phase reaction has been dampened, but never adequately extinguished. Instead of an inferno, a better analogy would be a slow, smoldering fire with intermittent eruptions. A wealth of evidence has now accumulated showing this is the case for a wide range of conditions, including asthma, eczema, osteoarthritis, rheumatoid arthritis, systemic lupus erythematosus, thyroiditis, neurodegenerative disorders, diabetes mellitus, and cardiovascular disease.^{202,203,204,205,206,207}

In the examples given above, the pattern of reaction may not serve any overtly useful purpose at all. Consequently, this situation can be described as maladaptive. No longer part of a carefully orchestrated cybernetic

feedback system, the pattern operates without the self-regulating constraints that normally prevent it from being harmful. This shift from a balanced state of dynamic immunologic activity that is oriented toward maintaining homeostasis, to a state of chronic imbalance, can be likened to a planned, controlled burn in a dry forest that leaps past strategically placed barriers and becomes an expanding conflagration. A particularly deleterious aspect of a maladaptive inflammatory reaction is that it can become stuck in a recursive, “feed-forward” cycle, independent of the triggers that initially set it in motion. In addition to intracellular protein kinase-based cascades, a host of extracellular cascades can also be activated, including complement, kininogen-bradykinin, and coagulation (fibrinogen), all of which serve to amplify the inflammatory response.

Anaphylaxis, self-amplifying cascades, and the butterfly effect. Anaphylaxis is perhaps the most dramatic example of how remarkably efficient this self-amplification process can be. Initial exposure to antigenic epitopes present in hymenoptera venom, certain foods, latex, drugs, etc., leads to activation of T-helper 2 lymphocytes, which utilize IL-4 and related cytokines to transform B lymphocytes into plasma cells that secrete IgE antibodies specific to the epitope. These IgE antibodies bind to Fc receptors on the surface of mast cells found in the respiratory mucosa, gastric mucosa, skin, and connective tissue.²⁰⁸

In susceptible (e.g., atopic) individuals, re-exposure from ingestion or inhalation of the epitope results in binding to ligand recognition sites on the IgE antibodies. When two or more IgE antibodies are bound, this cross-linking aggregation activates membrane-linked G proteins, which in turn activate tyrosine kinases. This initiates a cascade of phosphorylation reactions involving numerous intracellular proteins, resulting in increased intracellular levels of cGMP, an influx of Ca⁺⁺ into the cell, and—within minutes of the initial exposure—subsequent degranulation, which liberates an array of vasoactive and smooth muscle-constricting mediators including histamine, heparin, TNF- α , and adenosine, followed by *de novo* synthesis of additional proinflammatory cytokines, prostaglandins, and leukotrienes.²⁰⁹ Once released into the extracellular environment, these mediators then activate additional mast cells through “non-antigenic” pathways, a process of recruitment that allows a local phenomenon to rapidly escalate until it involves multiple organ systems.²¹⁰

As mentioned earlier in this discussion, the linear cause-and-effect paradigm that has long dominated conventional medicine does not fully encompass the complex network of physiologic reactions that occur in situations like anaphylaxis, sepsis, or disseminated intravascular coagulation, or the mechanisms by which streptococcal pharyngitis leads to rheumatic valvular disease. A linear model would liken anaphylaxis to a “domino effect,” in which an initial trigger sets into motion a series of sequential events. But this model falls short in its ability to predict when the reaction will occur and what the speed of onset and severity—the overall trend—will be once it develops. For example, it is well known that anaphylaxis is not a dose-response phenomenon: the relative severity of anaphylactic reactions is independent of the amount of antigen involved. In some situations, extremely minute quantities of antigen (e.g., a sudden whiff of peanuts from the package opened by a passenger in the next row on an airplane) are sufficient to activate a fatal response within minutes.

But why does a person have different reactions to the same food at different times? And why does the reaction self-attenuate in some situations but not others? A more sophisticated explanatory model might approach these questions by exploring in great detail every aspect of the initial conditions in which the reaction was triggered. In other words, seemingly peripheral information such as the person’s mood, the temperature of the room, or the time of day when the reaction occurred might be given equal weight to the level of antigenic exposure. This emphasis on having a thorough knowledge about the context in which a problem developed is based on a concept called the “butterfly effect,” which describes the tendency of a complex system to be highly sensitive to initial conditions.

Inflammation: a complex response to simple phenomena. Complex systems like the human body are prone to acting in unpredictable ways. The butterfly effect suggests that—in the right context—a butterfly flapping its wings could set off a series of events that result in a tornado in some other part of the world. In other words, when the right force is applied at the right time to a susceptible object, this tiny shift in initial conditions leads to a disturbance in the overall balance of the system that results in a series of interconnected, self-amplifying, exponentially expanding reactions that become dramatically more powerful and on a much larger scale than the original shift in energy.

This concept is the essence of chaos theory, and it provides a potential framework that can encompass all of the complex physiological pathways described in this chapter, without pretending to fully comprehend the specific ways in which these pathways work in every conceivable situation.^{211,212,213,214,215} As will be discussed later, the scientific paradigm represented by chaos theory is not limited to the study of inflammation and immune disorders, but applies to the entire discipline of functional medicine. The important point here is that a minuscule disruptive event can be sufficient to create a severe or chronic inflammatory condition.²¹⁶ But it is also true that a relatively minor intervention—if carefully conceived—can sometimes create a positive perturbation that leads to a restoration of balance. For example, simply taking a probiotic supplement can cause major changes in the gut flora, resulting in a series of physiologic events that ultimately decreases the person's systemic allergic symptoms.

Returning to the example at hand, after considering how destructive mast cell degranulation can be—not just in the case of anaphylaxis but also because of its major role in a wide range of immunologic reactions—it is tempting to perceive this entire system as nothing more than a dangerous remnant from a less hygienic past. Perhaps IgE and the weapons it unleashes were useful when humans were under continuous assault by helminths and other parasitic infections, but it's hard to believe that they are necessary in the age of modernity. Or are they? Again, it's important to point out that the inflammatory process has a purpose: to maintain the overall health of the individual. In fact, several studies have shown that mast cells play a critical role in the innate immune response against bacterial infection. They also help modulate Th1 delayed hypersensitivity reactions. And, considering the diverse range of cytokine receptors they display, and their ubiquity in the body, it is likely that they interact with other cell types in essential ways that we do not yet understand. The ultimate conclusion is that no single aspect of the inflammatory process—no single cell type, no individual eicosanoid, cytokine, adhesion molecule, or transcription factor—is inherently bad. This concept strongly challenges interventions derived from a monocular perspective focusing on the elimination of individual mediators without recognition of the potential for “collateral” damage in such a process.

The Drug-Disease Model of Inflammation: History and Current Issues

Clearly, determining the myriad exogenous and endogenous factors involved in catalyzing and perpetuating the transformation from acute to chronic inflammation is one of the most pressing issues in medicine today. The answers to the questions about what factors allow the inflammatory process to get out of control and stay out of control, and what interventions are the most effective, safest, and most easily implemented to prevent and treat chronic inflammation, have major ramifications for every branch of medicine, from pathology to public health policy. One of the defining features of functional medicine is the unique perspective it provides for exploring these issues. By reviewing how the disease-centered model came to dominate the diagnosis and treatment of chronic inflammatory disorders, we can analyze the shortcomings inherent in that approach, and clinicians can achieve a better understanding of how the functional medicine perspective differs and what it has to offer.

Value Systems and the Goals of Scientific Research

Consider the implications of the following statement: “Many of the key enzymes and proteins in the arachidonic acid signaling cascade were identified, and rational drug design is in progress to interact with these targets.”²¹⁷ Implicit in the quotation is an intimate reciprocity long shared by the disciplines of immunology and pharmacology (and, by implication, the pharmaceutical industry).²¹⁸ For example, an immunologist might start the discovery process by investigating specific inflammatory mediators (e.g., leukotrienes), then explore upstream to find the biochemical pathways involved in their production (metabolic conversion from arachidonic acid precursors), followed by the enzymes that catalyze the rate-limiting, regulatory steps in those pathways (e.g., 5'-lipo-oxygenase). This information is shared with pharmacologists, who then develop synthetic agents that inhibit the activity of those regulatory enzymes (e.g., zileuton, a 5'-lipo-oxygenase inhibitor) or block the receptors activated by the mediators (e.g., montelukast). Reports regarding the clinical effects of those drugs then serve as feedback for further refining the immunologists' understanding of how exogenous and endogenous factors modify the inflammatory cascade. In turn, this information is used to develop anti-

inflammatory agents with a higher degree of specificity for their targets, with the expectation that this specificity will translate into improved efficacy.

An alternate version of this process might begin with identification of a plant extract or synthetic drug that appears to have anti-inflammatory or immunomodulatory properties. Working downstream, pharmacologists attempt to elucidate the mechanisms by which the extract or drug exerts its effects. Eventually, this leads to a greater understanding of which endogenous mediators are being affected, what specific pathways are involved, and what factors influence the activity of those pathways. The ultimate goal of this process is to develop a patentable substance that can be extracted and isolated from the plant or synthesized in the laboratory.

Contrast the strategies described above to the following goals:

- identify anti-inflammatory substances in commonly eaten foods or inexpensive, readily obtainable supplements and herbs;
- disseminate that information widely so that it can be used to improve the overall health of the population; and
- search for common dietary and environmental triggers that are contributing to our epidemic of inflammatory disease and then use that information to shape public policy.

Unfortunately, achieving these latter goals requires heavily funded research and education initiatives. Because natural products, dietary interventions, and lifestyle changes do not involve patentable drugs, they don't attract the same kind of support that pharmaceutical research does. The challenge is to find ways to achieve these goals, to ease the burden of chronic disease on our population, and thereby to help ease the cost burden of health care as it is practiced today.

NSAIDs and the Development of the Pharmaceutical Industry

The development of nonsteroidal anti-inflammatory drugs (NSAIDs) can serve as a model for how the pharmaceutical industry originated in, but then moved away from, access to therapeutic natural products. The narrative stretches back approximately 2500 years to the time of Hippocrates of Cos (460–377 BC). Even as he was attempting to understand the mechanisms behind the various diseases of his day (many of which

later turned out to be immune system disorders), Hippocrates engaged in empirical medicine by prescribing an extract made from a popular folk remedy of his day to alleviate pain (*dolor*) and fever (*calor*) in his patients. One of the main ingredients in this extract was willow bark (*Salix alba*), an herb that had already been used for over a thousand years. In the 1820s, after another two millennia of popular use, a glycoside called salicin was isolated from the bark. In 1839, Karl Löwig mixed salicin with hydrochloric acid (similar to the gastric environment) and produced salicylic acid. Later identified in many other plants, salicylates were determined to be the active constituent responsible for the herb's anti-inflammatory properties. Salicylic acid quickly came into widespread use as a panacea for a wide range of illnesses.

In 1853, the French chemist Charles Gerhardt was able to synthesize a crude version of acetyl-salicylic acid (ASA) by adding an acetyl group to salicylic acid. Several years later, Carl Kraut managed to refine the process and produce a pure form of ASA. However, the clinical significance of this compound was not appreciated until 1897, when Arthur Eichengrün, a chemist with the German dye production company Friedrich Bayer, instructed his colleague, Felix Hoffman, to repeat Gerhardt's acetylation experiments with the hope that a pure version of ASA might provide a more tolerable alternative to salicylic acid. Eichengrün then tried the drug on himself, after which he conducted clinical trials that showed it caused much less gastric discomfort and nausea than its precursor. In 1899, he subsequently renamed this drug aspirin, to denote an acetylated form of salicylic acid obtained from *Spiraea*, the former Latin genus for meadowsweet, which—like willow bark—is a rich source of the parent compound. (Unfortunately, when the Nazis came into power, Eichengrün—a Jew—was sent to a concentration camp, and the credit for discovering aspirin went to the “Aryan” Hoffman and his superior, Heinrich Dreser. However, the true story eventually emerged and Eichengrün's role was reinstated.)^{219,220}

Aspirin achieved distinction as the first major synthetic drug ever sold in tablet form—an event which spawned the modern pharmaceutical era. Aggressively marketed around the world, aspirin quickly became extremely popular and has continued to be one of the most successful synthetic medicines in history: over 100 billion aspirin tablets are now taken each year all over the planet.²²¹ Salicylates in willow bark, meadowsweet,

and numerous other plants were eventually found to work by inhibiting cyclooxygenase (originally called prostaglandin H2 synthase), the rate-limiting enzyme involved in the conversion of arachidonic acid into proinflammatory prostaglandins and thromboxanes.²²²

Indomethacin, one of aspirin's first commercially viable successors, was synthesized in 1963. Although it was a very potent drug, its usefulness was limited by significant GI toxicity. In 1969, after 15 years of evaluating a host of potential competitors through an extensive trial and error process, ibuprofen was introduced as an effective and well-tolerated aspirin alternative. In 1971, not long after ibuprofen's release, Dr. John Vane discovered that the mode of action of aspirin, ibuprofen, and indomethacin was to block the production of *prostaglandins*: short-lived, locally-acting chemical mediators (also called autocooids) that are now known to be present in all inflamed tissue.²²³ He later determined that the specific enzyme blocked by all of these drugs was cyclooxygenase—a feat for which he shared the Nobel Prize in 1982 and was knighted in 1984. The desire to find ever-safer and more potent alternatives led to a detailed study of structure-function relationships between cyclooxygenase, salicylates, and ibuprofen. Out of this research emerged a plethora of related cyclooxygenase inhibitors that came to be referred to as NSAIDs.

Within a few short years, NSAIDs became the treatment of choice for many manifestations of the inflammatory response, particularly fever and pain. They also became, and remain, the standard of care for treating inflammatory arthritides and many types of nociceptive pain (i.e., pain caused by injury to tissues). In addition, some of them have been shown to play a role in preventive medicine. Because of its antiplatelet properties, low-dose aspirin has proved to be particularly effective at preventing myocardial infarctions and other thrombotic disease. More recently, it has been shown to help prevent neoplasms of the colon and breast.

Despite these advantages, NSAIDs also have significant limitations. They have no discernible impact on many inflammatory manifestations, including allergic reactions, urticaria, asthma, and atopic syndromes. In fact, NSAIDs are frequently implicated in allergic drug reactions. They are minimally effective for neuropathic pain, fasciitis, or tendonitis (even though they are often prescribed for these problems). They also commonly produce side effects, including gastrointestinal hemorrhage, edema, and renal damage. Less appreciated by

mainstream practitioners—despite extensive documentation in the medical literature—is the fact that NSAIDs can increase small intestine permeability and create a chronic inflammatory enteropathy. By accelerating the translocation of macromolecules and pathogenic microbes from the GI tract into the systemic circulation, NSAIDs inadvertently increase the total antigenic load. This, in turn, leads to the increased formation of antigen-antibody complexes that can initiate inflammatory reactions, either in the bloodstream or after their deposition in connective tissues or basement membranes.

Concerns about the limitations of NSAIDs resulted in a push for safer and more effective alternatives. Laboratory research in the 1980s and early 1990s at Washington University, St. Louis, conducted by Needleman, Siebert, Fu and Masferrer, and at the University of Rochester, led by Donald Young and his colleagues, led to the discovery that there were two isoforms of cyclooxygenase with distinctly different functions. According to the model developed by these researchers, COX-1 is a ubiquitous, constitutively expressed intracellular enzyme located in the endoplasmic reticulum that plays a primary “housekeeping” role in maintaining healthy gastric mucosa and renal blood flow. It is the only COX isoform expressed in platelets, where it catalyzes production of precursors to thromboxane A2, a potent proaggregatory agent.²²⁴

COX-2 shares a 60% sequence homology with COX-1. Under normal conditions it is barely detectable. However, after exposure to certain inflammatory triggers—including trauma, free radicals, cytokines, growth factors, and endotoxins from pathogenic microbes—it is rapidly induced, appearing in the endoplasmic reticulum and nuclear membrane of macrophages, synoviocytes, and many other cells.²²⁵ An important distinction is that COX-2 expression is readily blocked by glucocorticoids, which generally do not affect COX-1 activity.

The working model postulated that COX-1 is a “good” enzyme and that COX-2 is primarily—perhaps exclusively—responsible for producing the mediators responsible for pain and inflammation. Since both isoforms catalyze the same biochemical reactions and produce the same end products, the presumption is that the difference in their biologic effects results from the site of action and the level of mediators produced—i.e., COX-1 produces a constant but low level of prostanooids, in contrast to COX-2, which, after induction, produces much higher levels.²²⁶

Since drugs like aspirin and ibuprofen nonselectively inhibit both COX-1 and COX-2, it is axiomatic that their anti-inflammatory properties are accompanied by the undesirable side effects previously mentioned, including gastric ulceration and renal toxicity. Young and Needleman's model implied that an ideal anti-inflammatory drug could bypass these effects, provided that it specifically inhibited COX-2 when used at normal therapeutic doses. This concept was utilized to synthesize celecoxib, the first of the selective COX-2 inhibitors, which was introduced to the market in 1998. Celecoxib was followed soon after in 1999 by rofecoxib and later by valdecoxib. Bolstered by the initial positive results of the CLASS and VIGOR trials, and heavily promoted as safe and effective alternatives to nonselective NSAIDs, within a few years of their release these agents became some of the top-selling drugs in the world, each generating \$2.5–3 billion in annual sales.

The popularity of COX-2 inhibitors provided more evidence for the successful strategies used to market them than evidence of their clinical effectiveness. The reality was that they never lived up to their promise. Serious questions have been raised about the hypothesis that prostanoids involved in inflammation are exclusively produced by COX-2, and that COX-1 is exclusively responsible for producing the prostanoids that protect renal function and the gastric mucosa. In point of fact, COX-1 has been found to be inducible in certain inflammatory states and COX-2 appears to participate in several beneficial housekeeping roles throughout the body, especially in the CNS and the renal cortex, where its constitutive expression is widespread.²²⁷

A major concern has been that, even though COX-2 inhibitors are 10–20 times more expensive than nonselective NSAIDs, they have never been found to be any better at relieving pain or inflammation. Furthermore, when used in higher doses or for long periods of time, they can still cause GI injury, and are associated with an increased risk of myocardial infarction and other thrombotic events.²²⁸ (The mechanism for this effect is not fully understood, but is most likely related to the preferential blockade of prostacyclin production by endothelial COX-2, without the concomitant inhibition of thromboxane by COX-1. This leads to a relative increase in thromboxane activity compared to prostacyclin—the exact opposite of the effect that is achieved by low-dose aspirin.^{229,230}) It was no surprise to many informed observers when, in September 2004, Merck

and Company suddenly withdrew rofecoxib from the world market after a clinical trial testing its potential to prevent recurrence of colonic polyps showed a significant increase in heart attacks and strokes in study participants after 18 months of use.

Linear Thinking, Magic Bullets, and Limitations of the Disease-Specific Paradigm

This story about a fundamental pathophysiologic process and the evolution of a class of drugs used to modify that process reveals how a conglomeration of personalities, empirical knowledge, scientific discoveries, and economic incentives all mesh together to create a consensus based on what appears to be a logically derived, evidence-based standard of care that may, in reality, turn out to be deeply flawed. The rapid rise and fall in popularity of COX-2 inhibitors and the ongoing, aggressive search for similar pharmaceutical agents show how easy it is for a kind of mass delusion to develop, both within the medical community and among the general public. It illustrates the limitations inherent in the conventional paradigm, which continues to focus on overly simplistic solutions for complex problems—solutions that, unfortunately, continue to be disproportionately influenced by the profit motive.²³¹

The ongoing wish to discover therapeutic “magic bullets” is a direct consequence of thinking about disease as a linear process. (A line with branches, perhaps, but still a line.) It presupposes that the best way to control a pathologic process is to figure out which physiologic pathways have become dysfunctional, identify the most influential steps in those pathways, and then control, shut down or eliminate those steps. In most cases, this control is achieved with potent synthetic pharmaceutical agents. A consequence of this way of thinking is that every disease tends to get paired with the specific drug used to treat it. In some cases the pairing is very useful, but in others it is misleading or even counterproductive. It *might* be useful to consider type 1 diabetes mellitus a primary insulin deficiency, even though its pathophysiology is more complex than that. (Consider that, before the discovery of insulin, salicylates were commonly used as a relatively successful treatment for hyperglycemia.) However, despite being cast in the same mold as type 1, type 2 diabetes mellitus is not simply a matter of insulin deficiency. Similarly, rheumatoid arthritis is no more a methotrexate deficiency than eczema is a corticosteroid deficiency,

even though such relationships are frequently implied in the medical literature.

This model is based on a Newtonian view of the world in which diseases are classified as discrete, self-contained entities for which the *differences* between each disease are more important than the similarities. For example, it would be extremely unlikely for a conventional practitioner to consider the similarities between seemingly disparate diseases like rheumatoid arthritis, ulcerative colitis, and multiple sclerosis, even though all three conditions could be seen as different manifestations of the chronic inflammatory response. Studies showing that people with psoriasis are predisposed to the metabolic syndrome might appear anomalous until one considers that the chronic inflammation associated with psoriasis can exacerbate insulin resistance.

Even though parallels may exist, each disease is thought to develop and progress on its own linear pathway of cause and effect. This perspective is exemplified by the ascendance of specialty (and subspecialty) medicine, where physicians work with one bodily system (or perhaps one organ or even one disease), as though each disease could somehow be extracted from the surrounding ocean of physiological processes in which it formed. According to this model, an individual is born with a set of genes that determine the risk of developing a specific disease. Although that risk can be modified by environmental factors, the person's genetic predisposition plays the dominant role. Once the genes have been fully expressed and a disease has developed, the pathological process cannot be reversed, only controlled.

The War Against Inflammation: Negative Consequences of Treating Symptoms Instead of Correcting Underlying Dysfunction

In metaphoric terms, inflammatory diseases are viewed as a kind of war that needs to be fought with the most powerful weapons available. The most desired outcome is to win that war by shutting off the inflammatory process as quickly as possible. Since the end justifies the means, one should be prepared to accept a certain degree of collateral damage. In this case, collateral damage translates into side effects from the treatment being administered. So long as the side effects are not immediately debilitating (based on the practitioner's assessment, not the patient's), they should be considered a necessary evil in the fight against disease.

For example, disease-modifying, anti-rheumatic drugs (DMARDs) such as methotrexate or leflunomide are being recommended increasingly early in the course of rheumatoid arthritis, even in cases of relatively mild severity. The effectiveness of these drugs for providing relief of inflammatory signs and symptoms is heavily emphasized to justify their use as first-line therapies. However, another fact that receives much less attention is that both of these drugs have a very narrow therapeutic window because of their severe toxicity. Among other things, they are potent immunosuppressive agents associated with a significantly increased risk of developing malignant neoplasms.

Similarly, monoclonal antibodies against various cytokines, such as TNF- α and its receptors, are increasingly being used as a therapeutic target for rheumatoid arthritis and other autoimmune disorders. The dramatic clinical successes associated with these drugs obscures three important facts: (1) cytokines are multifunctional—they are not inherently good or bad; (2) cytokines rarely act alone—they act in concert, as integral parts of a large, complex signaling network; (3) different combinations of cytokines can have very different effects, depending on the specific receptor cells they are activating. Understanding this leads to the conclusion that any attempt to block a single aberrant message without changing the imbalanced system that created it in the first place will inevitably lead to untoward long-term consequences.

For example, infliximab, a TNF- α blocker used to treat RA, Crohn's disease, and psoriasis, increases the risk of developing tuberculosis, sepsis, and pneumonia, indicating that TNF- α is a critical part of the host defense against certain pathogens.^{232,233} Similarly, natalizumab is a monoclonal antibody that binds to and inhibits α -4- β -1 integrin, an adhesion molecule that is expressed by activated lymphocytes and monocytes. Blocking this adhesion molecule prevents the migration of leukocytes across the blood-brain barrier—a process that is thought to be an essential step in the inflammatory demyelination found in multiple sclerosis. Although the drug initially showed great promise in decreasing the number of relapses and new lesions in people with MS, it had to be given intravenously once a month and was extraordinarily expensive. However, soon after its introduction to the market, it was voluntarily withdrawn by the manufacturer and further clinical trials were stopped following reports of three

confirmed cases (including one fatality) of progressive multifocal leukoencephalopathy that developed in patients after taking the drug.²³⁴ These problems clearly illustrate the potentially dire consequences that can result from isolated approaches to interfering with the inflammatory cascade that do not consider the impact of the intervention on the entire system.²³⁵

Interventions for Chronic Endothelial Inflammation: Statins vs. Diet and Lifestyle Changes

Another current example of thinking inside the box is the use of statin drugs to prevent cardiovascular disease. For many years, it has been assumed that the primary therapeutic action of statins results from their ability to lower serum cholesterol by competitively inhibiting the 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase enzyme responsible for catalyzing the reduction of HMG-CoA into CoA and mevalonate, a cholesterol precursor. However, there is an increasingly large body of evidence that the lipid-lowering properties of statins are actually secondary to their anti-inflammatory effects, which appear to be at least partially achieved through the downregulation of NFκB. Statins are now being increasingly repositioned as anti-inflammatory drugs with the potential to treat cancer, multiple sclerosis, or Alzheimer's disease.^{236,237}

This begs the obvious question: if cardiovascular disease is primarily a chronic inflammatory disorder^{238,239} (see Chapters 18 and 27, for a focused discussion of the inflammatory basis of CVD), why do we continue to utilize a class of expensive prescription drugs based on a concept of pathophysiology that is flawed and outdated? From a public health standpoint, wouldn't it be more cost effective (not to mention logical) to investigate the benefits of carefully designed diets that are rich in phytochemicals with known anti-inflammatory effects, and lower in inflammatory triggers such as *trans* fatty acids and refined carbohydrates?^{240,241,242} The benefits of such an approach would appear to be illustrated by numerous studies showing that a Mediterranean diet can decrease mortality to a much greater extent than statins, and at a fraction of the cost.^{243,244} However, despite these major challenges to their title as the standard of care for prevention of cardiovascular disease, statins continue to be prescribed to larger and larger percentages of the population, thus discounting the value of diet and nutrition. (The many benefits of

diet and nutrition as therapeutic strategies for both prevention and management of chronic disease are thoroughly explored in Chapter 26.)

Compartmentalized Thinking and the Suppression of Innovation

One of the biggest problems that emerges from this kind of compartmentalized thinking is that it stifles innovation and discourages the use of interventions that require stepping out of the box to get a broad overview.²⁴⁵ Dr. David Horrobin, a pioneer in the use of dietary essential fatty acids as biological response modifiers for psychiatric disorders and chronic inflammatory diseases, addressed this issue in an elegant essay titled, "The Philosophical Basis of Peer Review and the Suppression of Innovation."²⁴⁶ In his article, Horrobin described the potentially detrimental effects of the peer review process, which can become so focused on maintaining acceptable standards of research methodology that it loses sight of the larger goal of medicine, which is to find, in his words, "improved ways of curing, relieving, and comforting patients." In another editorial, Horrobin says that our current system of research inhibits progress and discourages research into the potential benefits of natural substances:

No drug that does not have the support of a substantial company is likely to be funded. No drug can attract such corporate support unless it is fully patent protected. In this climate, there can be few trials of nutrients or biochemical intermediates, of novel uses for old drugs, and of natural products, which were all major sources of past therapeutic success. We have taken drug discovery procedures from patient-orientated clinicians and handed them over to large bureaucracies who will work only with patent-protected products that give an adequate financial return. No wonder that real progress is so slow.²⁴⁷

An open and prepared mind is needed to recognize valuable information that may not fit neatly into any of the prevailing ideas in health care today. It is, in part, the goal of this book to prepare the way for new thinking.

Cookbook Medicine: Behaviorism, Practice Guidelines, and Diagnosis-based Protocols

Several decades ago, similar issues about the most effective strategies for solving problems were confronted in the field of cognitive psychology. For many years a "stimulus-response" model was thought to be the basic unit of behavior. The stimulus-response unit assumes

that similar stimuli will elicit similar behavioral responses. Despite its popularity, this model proved to have many limitations in predicting how humans might react to various situations. In 1960, Miller, Galanter and Pribram challenged the paradigm by proposing an alternate unit called the TOTE model (Test-Operate-Test-Exit).²⁴⁸ The obvious flexibility and widespread applicability of the TOTE unit led to its adoption as a fundamental concept in information-processing theory. Instead of organizing around fixed *response patterns*, the TOTE model emphasizes the importance of having a fixed *goal* as the desired outcome. A range of different behaviors can be employed as a “test” to see if they achieve the goal. If they do not, the behavior is immediately “exited” (without applying a value judgment) and another attempt is instituted, repeating the process until the goal is ultimately achieved. In essence, the stimulus-response model is organized around a fixed methodology, which implies a variable outcome, in contrast to the TOTE model, which maintains a fixed goal, but allows a variable range of behaviors to achieve that goal.

The stimulus-response unit has many parallels with the protocol model that has increasingly come to dominate clinical care. In the protocol model, the “stimulus” is a diagnosis, which is linked to a set of algorithms or “behaviors” that are recommended interventions based on a standard of care called practice guidelines. These practice guidelines are derived from an expert consensus regarding current evidence. In reality, they represent a fixed methodology (often pejoratively referred to as a “cookbook” approach) to a given stimulus. The problem with such an approach is self-evident: if every individual with a problem is treated the same way, then the outcomes are likely to be highly variable. For example, if every individual with a blood pressure of 140/90 is treated with a thiazide diuretic—per current practice guidelines—some will improve, some will have no response at all, others will have allergic reactions, others will develop severe hypokalemia, and a few will have idiosyncratic reactions that cannot be explained by the known mechanism of action of the drug.

Patient-centered Functional Medicine: Teleology Replaces Dogma

The patient-centered approach espoused by functional medicine is very different from the protocol model. The validity of clinical protocols based on a pre-

determined, generalized standard of care is not a given. Instead, the assumption is that each patient is an individual who may require a unique set of interventions for solving the problem(s) at hand. If the goal of solving the problem is paramount, then the practitioner does not have to be bound to a specific methodology. In other words, functional medicine emphasizes teleology over dogma. Rather than pursuing increasingly regimented and standardized treatments for specific diseases, functional medicine clinicians seek to identify the underlying patterns and processes that led to the development of disease or dysfunction in the first place. This model gives the practitioner much more leeway in designing interventions that are tailored for a specific patient. It also makes a considerable demand on the practitioner to stay current with emerging knowledge in many fields: biochemistry and physiology, genetics and genomics, behavioral change and environmental medicine, to name some of the most important ones. Interventions based on improving function can draw on an expanded database that includes information from diverse sources—bench science *and* clinical research, drugs *and* diet, nutritional supplements *and* botanical medicines. Suddenly, the therapeutic armamentarium is much larger and much more flexible.

The functional medicine matrix provides a tool for information gathering and clustering that can help to sift and sort the larger volume of data that comes to the clinician's attention in this model. (See the final section of the book, *Putting It All Together*, for a discussion on using the matrix.) Potential imbalances in various bodily systems and environmental inputs are identified and used to construct a web-like map that illustrates a person's overall condition and helps to pinpoint general areas where interventions may be most needed and most widely effective. A rich and colorful picture of a person's life emerges. The matrix tool makes it abundantly clear that it is, indeed, more important to know what kind of person has a disease than what kind of disease a person has (to paraphrase William Osler). Gathering information in this manner allows the practitioner to maintain an open mind about what is happening in the life of the patient, and a high degree of flexibility about how to work with any conditions that may be present. The assumption is that one can always reach for a deeper understanding of how an individual's health has gone awry—there will always be other questions to ask.

While it is respectful of the full range of therapeutic options and possibilities, functional medicine is not complementary and alternative medicine (CAM)—a very broad field containing numerous systems, disciplines, and modalities with specialized and often quite distinct beliefs and practices. Rather, functional medicine creates a shared arena, based in Western medical science, that is available to conventional and CAM practitioners alike. Clinicians take from functional medicine concepts and approaches that can be applied within their scope of practice, whatever it may be. Functional medicine includes diagnostic techniques and interventions that are science based at minimum and evidence based whenever possible; many of those practices have been validated in clinical trials, and others are extrapolated from current research findings about the potential underlying mechanisms involved in a particular disease process. Functional medicine does not eschew a conventional understanding of the pathological basis of disease, since the clinical utility of these concepts—especially for treatment of acute conditions—is undeniable. In fact, as illustrated by the discussion of basic concepts of inflammation, a thorough understanding of pathophysiology is a prerequisite to mastery of this material. However, it is understood that the lack of placebo-controlled, double-blind studies to support an intervention does not constitute a *prima facie* rationale for automatically discounting that intervention if the underlying science is strong. (See Chapters 5 and 6 for a full discussion of how functional medicine uses science and the research base.)

Functional Medicine Applied to Immune Imbalances

An example will help illustrate these concepts. Rather than immediately reaching for the prescription pad for patients with hypertension, a functional medicine practitioner will ask an array of questions geared toward identifying any underlying imbalances that might be contributing to the person's elevated blood pressure. The informed practitioner will be particularly cognizant of current research that strongly suggests hypertension is actually a chronic inflammatory disorder, for which oxidative stress is one of the primary triggers. Consequently, very important questions include:

- What kind of diet does the person have? Particularly, what is the intake of refined carbohydrates, and is there exposure to rancid fats?
- What kind of exercise does the patient engage in? For how long and how often?
- Has there been any exposure to heavy metals, pesticides, or other environmental toxins that might be an ongoing source of oxidative stress?²⁴⁹
- What is the intake of antioxidants and essential fatty acids (that might have a mitigating effect on the disorder)?^{250,251,252,253}
- What about electrolytes and trace elements, especially magnesium?
- Are there any unresolved stresses in the person's life that might be causing hypothalamic-pituitary-adrenal imbalances that, in turn, could be adversely affecting the renin-angiotensin system, which could be upregulating NFκB-mediated transcription of inflammatory mediators?^{254,255,256,257}
- What coping strategies are utilized?
- How well does the patient sleep at night?
- Are there any symptoms suggestive of sleep apnea?

Similarly, a patient might present with an initial complaint of recurrent, painful, and swollen joints in the hands, knees, and/or feet, accompanied by redness and warmth. The traditional medical model would steer a practitioner to order a blood test for rheumatoid factor and start the person on an NSAID. What then should the practitioner do if the NSAID is ineffective and/or the blood test comes back negative? The conventional choice would most likely involve switching to a more potent pharmaceutical agent and expanding the array of immunological tests performed in search of an alternate diagnosis to rheumatoid arthritis—in other words, looking for another box in which to place the person.

A functional medicine practitioner, on the other hand, will likely seek more detailed information about the person's lifestyle and dietary habits. An extensive history would be taken to look for any stressful events (both emotional and physical) that might have occurred before the symptoms first appeared.²⁵⁸ Potential exposures to environmental toxins would be explored.²⁵⁹ A review of systems would be performed with particular attention paid to issues such as gastrointestinal symptoms or reactions to food.^{260,261,262} The search for previous medical problems might extend even as far back as infancy with questions regarding the presence of colic, frequent ear infections, heavy use of antibiotics, or NSAIDs.

Functional Medicine's Origins in Systems Biology, Complexity Theory, and Cybernetics

In contrast to a mechanistic, Newtonian model, this kind of approach is modeled on current theories about systems biology, quantum mechanics, and non-linear dynamics (also called chaos or complexity theory).^{263,264,265,266,267,268} According to Hiroaki Kitano, in his article, "Systems Biology: A Brief Overview,"

System-level understanding, the approach advocated in systems biology, requires a shift in our notion of "what to look for" in biology. While an understanding of genes and proteins continues to be important, the focus is on understanding a system's structure and dynamics. Because a system is not just an assembly of genes and proteins, its properties cannot be fully understood merely by drawing diagrams of their interconnections.²⁶⁹

After closely examining the constellation of physiologic events involved in inflammation (both acute and chronic), one cannot help but agree with Maimonides' adage that there is much more that we don't know than what we do know about the way this process with a purpose works—about how all the different parts and pathways manage to interact in an effective manner. Despite its extreme degree of complexity, it does follow recognizable and predictable trends.²⁷⁰ One of those trends is the tendency for the situation to recur if the underlying conditions that set it off in the first place are still present. This suggests the ultimate futility of chasing down one enzyme or inflammatory mediator at a time to extinguish an aberrant inflammatory response. One is reminded of the hydra, a mythological beast from Argolis with many heads from which it spewed a deadly venom. When one head was severed, it would simply grow another one.

By examining the concatenation of events involved in inflammation, one can conclude that not just the immune system, but the entire human organism is a complex adaptive system, composed of multiple interacting and self-regulating cybernetic loops.^{271,272,273} The neurologic, endocrine, and immune systems each have their internal feedback loops, and these dynamically interact with all the other systems. Dr. Albert Szent-Györgyi, the noted Hungarian biochemist who first isolated ascorbic acid and flavonoids, postulated that living systems possess a kind of organizing force called *syntropy*, that acts as a counterbalance to the disintegrative force called entropy. Somewhat controversial at the

time, his concept of syntropy now appears to be a prescient forerunner of complexity theory.

When humans develop a disease, it is not random occurrence, but rather a behavioral pattern that emerges as a result of an underlying imbalance in one or more of these systems. It is a fallacy to think of a disease as an object that can be placed in a container. The measles virus can be placed in a test tube, but the infectious disease we call measles cannot. Measles is not a thing; it is a behavioral process, the result of a complex interaction between a person's immunologic genotype and his or her external and internal environments. Unfortunately, by nominalizing disease processes, our current system of medical nomenclature ends up limiting our concepts—and therefore our choices—about the most effective way to approach those processes. It is much more difficult to find a single, effective, safe cure for a disease than it is to look for ways to modify the disease process.

Functional medicine draws from complexity theory by focusing on the recognition of repeating patterns that might be influencing the person's condition. These patterns are more accurately described as an interconnecting web rather than a series of crisscrossing lines. In the same way a tree branches out into complex, but repeating "holographic" patterns called fractals, an inflammatory disorder can also be expressed in repeating patterns that may appear random on initial evaluation, but with closer examination can be found to possess a consistent internal coherence.^{274,275} The most useful strategy in such a situation is to analyze the overall trend of the pattern—in which direction is it headed? Is it slowing down, stabilizing, or accelerating? What external or internal factors could be responsible for this trend? And, most important, what can be done to influence the trend without causing major disruptions in the person's physiology?

Supporting Homeostasis/Homeodynamics and Self-healing

Similar to Szent-Györgyi's notion of syntropy, an American physiologist, Walter Cannon, PhD, recognized in the 1930s that the human body possesses a certain "wisdom" that continuously returns it to a state of internal equilibrium. He called this state "homeostasis," from the Greek words meaning "to remain the same." Homeostasis is achieved by a series of behavioral adjustments based on information about the body's internal and external environments. As described in Chapter 9,

we propose using the more accurate term “homeodynamics,” to indicate that most bodily processes actually fluctuate continually within a certain viable range in order to respond to environmental influences. This process of information feedback was termed “cybernetics” by Dr. Norbert Weiner, the mathematician/philosopher. Homeodynamics coupled with cybernetics provides a rational, scientific underpinning for the notion that each patient possesses an inherent ability for self-healing, for returning to a state of healthy balance.^{276,277,278} Placing a stronger emphasis on the patient’s role in the healing process creates a partnership between patient and practitioner. In this model, the practitioner’s role is both healer and educator, helping patients make appropriate decisions regarding their goals for emotional, mental, and physical health—and identifying appropriate means for achieving them.

Modifying Processes Rather than Curing Diseases

Consider the example of celiac disease, also called gluten enteropathy. According to the linear disease model, it results from a genetic intolerance to low molecular-weight lectins (gliadins) found in wheat, barley, and rye. Exposure to these proteins results in chronic inflammation of the small intestine villi, leading to malabsorption, often accompanied by diarrhea, malaise, and weight loss. Additional complications can include anemia, osteoporosis, and gastrointestinal lymphoma. Theoretically, all one needs to do is eliminate gluten and the condition will eventually resolve.

This information is accurate, but it is not an adequate description of the phenomenon. It does not explain the high degree of phenotypic variability of the condition for which many people can be asymptomatic, despite regular ingestion of gluten-containing foods.²⁷⁹ A significant percentage of people who have the MHC class II “celiac genes” (i.e., HLA DQ2 and HLA DQ8) won’t develop the disorder, and not everyone with the disorder can be found to have the genes. It also does not fully address the wide range of extraintestinal inflammatory manifestations associated with gluten-sensitivity, including dermatitis herpetiformis, thyroiditis, type 1 diabetes, and neurologic dysfunction such as cerebellar ataxia. When these conditions are associated with celiac disease, they are referred to as manifestations of an autoimmune process, which clearly involves more than a simple inflammatory reaction to gluten.^{280,281,282}

A closer look at the pathophysiology reveals that the condition we call celiac disease results from a complex interaction between not one but several HLA and non-HLA genes, in combination with dietary gluten and other environmental factors that are not yet fully understood. One of those “environmental factors” may be the microbial ecology in the person’s intestines. A person with a healthy balance of normal flora relative to pathogens may be less susceptible to developing overt reactions to gluten. Or, it could be that a person who is exposed to a lot of environmental toxins or has a high baseline level of oxidative stress may be more prone to becoming symptomatic or developing autoimmune manifestations.²⁸³ These are hypotheses that are well worth investigating.

By thinking of this problem as a disorder *process* rather than a *disease*, the possibilities for working with it begin to expand beyond a simple elimination of gluten. For example, a practitioner of functional medicine might recommend that a person with celiac disease go beyond simple elimination of gluten and undergo a bowel restoration program designed to remove potential pathogens, replace deficient digestive enzymes, repair inflamed intestinal mucosa, and reinoculate the microflora with probiotics.²⁸⁴ (This is the 4R program, described fully in Chapter 28.) In addition, a program might be instituted for modifying the inflammatory process. Omega-3 fatty acids,^{285,286} antioxidants,²⁸⁷ and anti-inflammatory phytochemicals such as bioflavonoids could be used.

As mentioned in the earlier discussion on oral tolerance, this kind of intervention was illustrated by several studies conducted in Finland in which children with intractable eczema were given a course of probiotic bacteria (*Lactobacillus GG*). The children who received the probiotics showed a significant improvement in their skin condition.²⁸⁸ Why would a product designed to improve bowel health be considered a therapeutic intervention for a skin disorder? Now that we have explored the complex underlying patterns of inflammatory and immune imbalance, we can perceive the body as an interconnecting web of cybernetic loops, wherein it is perfectly logical to think of the gastrointestinal tract as a potential trigger or mediator (or modulator) for inflammatory reactions that could appear anywhere else in the body.

Summary

Acute inflammation is the body's normal physiologic response to injury or invasion by pathogens. Chronic inflammation is a maladaptive immunologic process responsible for a wide variety of seemingly disparate diseases. A close examination of the molecular biology of inflammation reveals an extraordinarily complex process that utilizes signal transduction networks linked to a series of intricately regulated enzymatic cascades and intercellular messenger molecules that is best understood through the lens of complexity theory and non-linear dynamics. Inflammatory diseases result from imbalances in this network and are not isolated phenomena that can be separated from the context in which they developed.

The butterfly effect tells us that the same trigger can have vastly different results depending on the context in which that trigger appears. Similarly, the same intervention can have vastly different effects depending on the individual who receives that intervention. Consequently, the problem of excessive or chronic inflammation is not adequately addressed by isolating individual inflammatory autacoids and using potent pharmacologic agents to inhibit the production or actions of those substances. Instead, a wider lens is needed to view the entire landscape of an individual's life.

Within that landscape can be recognized the following: (1) antecedents such as genetic polymorphisms and epigenetic factors that could increase the person's predisposition to immunologic dysregulation and imbalances, (2) acute or recurrent exogenous triggers resulting from a person's lifestyle or environmental exposures that might be responsible for activating an inappropriate inflammatory response, and (3) endogenous mediators that are being overexpressed in response to those triggers. The ongoing presence of these triggers and mediators fuels the fire and perpetuates the pathology of inflammatory disease.

The functional medicine practitioner's role is to become a conductor of the client's metabolic symphony, someone who relies on the individual's inherent syntropic ability to help restore homeodynamic balance. The most direct and practical ways to accomplish this are:

1. help the client to make dietary and lifestyle changes that will reduce exposure to harmful inflammatory triggers, and

2. employ a rational mixture of antioxidants, biological response modifiers, or/and other therapeutic nutrients and supplements (including enzymes, prebiotics, and probiotics) to assist the person's immune system in moving back toward balance.

Chapter 24

Digestive, Absorptive, and Microbiological Imbalances

Thomas Sult, MD

Introduction

Imbalances in the gastrointestinal system are vital to understand and detect, as visits for GI distress of one kind or another account for a very significant number of healthcare visits.¹ Further along in the book (see Chapter 28), we will explore the functional medicine approach to clinical care for these disorders. Here, we want to review and analyze the role that each element of the GI system plays in achieving health, so that we can understand where imbalances arise and how they manifest in the patient. We'll begin with a brief review of the basic structures and functions involved in digestion and absorption.

Structures of the Digestive System

The digestive or alimentary tract starts at the mouth and ends at the anus. It is composed primarily of the tubular structures: the mouth, esophagus, stomach, three parts of the small intestine (duodenum, jejunum, ileum), and four parts of the large intestine (cecum, ascending, transverse and descending colon). With the ancillary organs included (salivary glands, liver, gall bladder, and pancreas), the digestive system is formed. While not considered integral parts of the digestive system structures, the nervous, endocrine, and immune systems have considerable input to and receive output from that system.

As we will see, there are many opportunities for missteps and malfunctions in this complex, multi-stage process. Although space precludes an exhaustive discussion of all the activities involved in digestion, we will discuss some of the most clinically pertinent areas of interest.

The Brain

It may seem odd to list the brain as being one of the structures involved in the digestive process, but we learned long ago from Pavlov and his dogs that the brain can start the digestive process.

The “Second Brain”

Michael Gershon, MD, in his book, *The Second Brain*, writes, “We now know that there is a brain in the bowel, however inappropriate that concept might seem to be. The ugly gut is more intellectual than the heart and may have a greater capacity for feeling.” This second brain is the enteric nervous system (ENS). While the brain “exerts considerable neuroregulatory influence,” reports Gershon, it is often trumped by the ENS.² Chapter 28 contains a detailed discussion of the ENS by Dr. Gershon.

The Mouth

Mastication, or chewing, is the process of cutting, grinding, and mixing the food bolus with saliva. Saliva is a complex mix of lubricants, enzymes, and antimicrobials. An under-recognized and very important function of the saliva is the antimicrobial component. Saliva contains several anti-infective agents including thiocyanate, lactoferrin, secretory IgA (sIgA), and lysozyme. These agents help prevent infective agents from hitchhiking with the food bolus into the lower GI tract, thus preventing infection and dysbiosis. Salivary sIgA is the primary immunoglobulin of the mucosal immune system; its levels are improved by pleasant emotions.³ Interestingly, overtraining in athletes will lower sIgA, resulting in upper respiratory infection (URI).⁴ It appears that this effect can be muted with the use of acupuncture.⁵ In the elderly, moderate exercise has been shown to improve

sIgA, possibly reducing the age-associated lowered resistance to URI.⁶ Pathogen-specific sIgA has been reported in response to bacteria and fungal species.^{7,8}

Connecting the mouth to the stomach is the esophagus. Dysmotility disorders of the esophagus are common. The origin of these phenomena is not known, but evidence exists to suggest that ENS autoimmunity is partly responsible; however, controversy still exists.⁹

The Stomach

The stomach holds food in storage and further mixes the food bolus with HCl and gastric digestive enzymes. These enzymes continue the process of digestion that was begun in the mouth. Proteins are broken down into peptides. Lipids are broken down into free fatty acids. This prepares the food bolus, or chyme, for delivery to the small intestine.

The stomach produces HCl in the parietal cells via an ATP-dependent process. (This is the site of action of the proton pump inhibitors or PPIs.) This acid environment favors the unfolding, or denaturation, of proteins to facilitate enzymatic breakdown. Pepsinogen is converted to pepsin and many microorganisms are destroyed by the low pH.

These processes are under both neural and hormonal control. The primary central nervous system (CNS) influence on gastric secretion and motility is the vagus nerve. The primary hormonal influence is gastrin. The vagus nerve is the dominant CNS input, but is still a minority influence on the GI system. The ENS has inputs to the GI system that are orders of magnitude larger.¹⁰

Gastrin is produced in the antrum of the stomach in G cells. Its secretion is stimulated by the presence of protein in the gastric lumen. It is inhibited by a pH lower than 3. Gastrin stimulates gastric motility and the release of gastric acid and pepsinogen. It also plays a role in the proliferation of gastric mucosal cells, especially the acid-secreting cells. One is left to wonder what the long-term implications of chronic acid suppression might be on the total number of acid-secreting cells and gastric motility.

The Small Intestine

The stomach, which is both adapted to and secretes acid, differs substantially from the duodenum, which is adapted to a neutral pH environment. The chyme that is deposited into the duodenum from the stomach has a very low pH that must be neutralized. A sophisticated

feedback system exists to perform this function. Within the duodenum is a set of sensing cells that communicate with the hormonal system, the nervous system, and the ENS.¹¹ When acid is sensed within the duodenum, S cells release secretin. Secretin then stimulates the pancreas to release bicarbonate. Secretin also slows gastric emptying until the pH is in a neutral range. At that point, secretin is no longer released and the stomach begins to empty again. In this way, the rise and fall of pH in the duodenum regulates the ebb and flow of chyme from the stomach into the duodenum.

I-enteroendocrine cells of the duodenum and jejunum secrete cholecystokinin. This hormone, released in response to protein and fat, is responsible for the flow of pancreatic enzymes and gallbladder contraction.^{12,13} Excessive cholecystokinin can stimulate hypertrophy and hyperplasia of the pancreas.¹⁴ The regulation of pH, motility, and enzyme secretion is likely too complicated for a simple hormone system. A complex network of nerves and ganglia exists to provide control and feedback for duodenal, hepatic, and pancreatic function. In fact, the distal stomach seems to be involved in these neuro loops as well. They function in concert with, and independently from, the CNS. In addition, they appear to be able to override the effects of the CNS in many circumstances.^{15,16,17,18}

It now appears that the endocrine release serves as a backup system to the ENS, which is the primary minute-to-minute control system.¹⁹ In addition, it appears that most of the neurotransmitters recovered in blood are derived from the ENS rather than the central nervous system. Not surprisingly, common side effects of many neuro/psychoactive drugs, including antidepressants, are GI related^{20,21} and may even have therapeutic GI effects.²²

Small intestine motility. The motility of the gut involves a complex and highly organized set of events. Each segment of the gut shows coordinated and independent activity that propels the chyme from the duodenum to the large intestine, and mixes the chyme with the digestive “juices” within the gut lumen. The “slow” waves of the small intestine range from 10–12 cycles per minute at the proximal (duodenal) end to 6–9 cycles per minute at the ileum. It is highly likely that this activity is coordinated by the ENS.^{23,24,25,26} This control is likely related to functional heterogeneity in the myenteric plexus that corresponds to the anatomical heterogeneity of the gut.²⁷ In part, this is accomplished

via Hox genes and their regulation by intercellular signals. This pathway organizes the gut structure by utilizing cell autonomous programs, directed by transcription factors, allowing cells of the embryonic gut to affect the developmental fate of their neighbor cells. Both temporal and spatial expressions of relevant genes are orchestrated in this way. The result is the establishment of major structural components of the gut such as sphincters and muscle layers.²⁸ It is likely that differences in enzyme and transporter protein distribution are similarly regulated.

It is now recognized that many disorders of motility are in reality an inflammatory process of the ENS. A partial list of such disorders includes: paraneoplastic, infectious and achalasia disorders; congenital hypertrophic pyloric stenosis; chronic intestinal pseudo-obstruction; Hirschsprung's disease and chronic idiopathic constipation; neurological disorders; and probably irritable bowel syndrome. Several causes have been identified, including viral antigen expression in the enteric neural environment, molecular mimicry (onconeural antigens), and the role exerted by cellular and humoral autoimmunity.²⁹ Inflammatory bowel disease (IBD) and infection are associated with disordered smooth muscle and secretory function. Inflammation-induced changes of the ENS have been reported in IBS and chronic infectious colitis, and are responsible for the dysmotility of these conditions.³⁰ Gall bladder function is a complex and coordinated event, with implications for motility. Cholesterol has a direct inhibitory effect on gall bladder smooth muscle cell membrane causing impaired contraction. Inflammation within the gall bladder wall has a similar effect.³¹

The Large Intestine

From the terminal ileum, the chyme moves through the ileocecal valve and into the large intestine. This segment of the gut has two primary responsibilities: fermentation (ascending colon) and absorption (descending colon). Gut organisms in the ascending colon act on carbohydrate fractions (resistant starch) left in the chyme. They produce short-chain fatty acids that are used as fuel for the enterocyte. A fraction of the short-chain fatty acids is absorbed by diffusion, transported via the portal vein, and utilized by other tissues for energy. While the importance of short-chain fatty acids to humans is not yet fully mapped out, it may be that absorption of these fatty acids accounts for some of the

cardiac and anti-cancer benefits of fiber.³² Consumption of fibers may influence changes in the microflora of the gut. These changes may mediate immune interactions in several ways. First, the bacteria may influence immunity through direct contact with immune cells. Second, the production of short-chain fatty acids may play a role. And third, enhanced mucin production may alter immunity.³³ The primary functions of the descending colon are the absorption of water and electrolytes, and the formation of the stool.

The Guardian of the Interior

There are two routes of entry into the body from the intestines. The first is the portal system. Blood from the splanchnic arteries is enriched with nutrients at the small intestine. It then collects in the portal vein and is delivered to the liver. This is the major entry for water-soluble nutrients, such as amino acids, short-chain fatty acids, and water-soluble vitamins. The second route is via the lymph system: the nutrients (or other substances) collect at the basolateral membrane and move into the lymph channels, entering the blood circulation at the thoracic duct. This mechanism bypasses the liver, its first pass effect, and therefore its detoxification ability. The lymph is the primary entry method for lipid-soluble substances.

About 70% of lymph tissue in the body is associated with the gut, which is logical since the gut is the major portal of entry to the body. Antigens that have survived acidification, enzymatic breakdown, and microbial defenses are examined by the gut-associated lymphoid tissue (GALT). Development of the GALT is dependent upon intestinal microbes. The development of the GALT is not, however, an antigen-specific process. Various types of intestinal microbes under certain types of stress conditions guide GALT development,³⁴ thus blurring even further the line between the bacteria and the human, and lending more support to the notion of the "undiscovered organ" (see Chapter 28 for more discussion on gut flora and GALT).

The GALT is comprised of a network of uniquely arranged B cells, T cells, and phagocytes, which sample the luminal antigens. This activity takes place at specialized epithelia which are called follicle-associated epithelia (FAE). These FAE coordinate responses between the immune cells and other mucosal barrier components. The primary "sampling" cell is the M cell. Recently, non-Peyer's patches-associated M cells, termed villous

M cells, have been discovered. These villous M cells are able to process antigens from a variety of bacteria and mount an antigen-specific immune response. This seems to be an independent component of mucosal immune integrity.³⁵ The GALT is composed of organ-specific, tissue-homing T cells. These T cells are induced in mesenteric or Peyer's lymph nodes but not in peripheral lymph nodes. The GALT dendritic cells gain their ability to confer gut-homing capacity on the T cells from the intestinal mucosal microenvironment. Additionally, these same dendritic cells seem to be involved in immunogenic vs. tolerogenic responses and Th1 vs. Th2 subpopulation selection.³⁶ At least in part, chemokines are responsible for lymphocyte trafficking within the GALT. They also play a role in intestinal segmental specialization and lymphocyte subset selective localization. The result is direction and differentiation of intestinal effector and memory lymphocytes within the GALT, along with homeostatic and inflammatory localization of lymphocytes to the intestines.³⁷

Antigens not recognized as beneficial will be processed by the GALT. Through constant vigilance, the GALT differentiates food and commensal bacterial antigens from pathogenic antigens. The mucosal barrier microenvironment heavily influences the immune response that results from antigen interaction.³⁸ Generally, the GALT will inhibit the development of allergy and autoimmunity. The GALT reaction to enteric antigens is to induce both mucosal and systemic immunity. It has been shown that oral antigens from bacterial lysates may reduce the frequency and seriousness of diarrhea, mucosal infection, and diverticulitis. This is accomplished by increasing IgA and cytokines at the mucosal and luminal level.³⁹ But the response to food or pathogenic antigens starts out the same. It is the microenvironment that determines whether the final response will be tolerogenic or immunogenic. Food antigens, when presented with an adjuvant, will induce an immunogenic response. More disconcerting is that a chronic intestinal infection or inflammation may in itself be an adjuvant.⁴⁰ This may lead to multiple food allergies or sensitivities. Whether it is the adjuvant nature of chronic inflammation or some other mechanism that results in auto-antibodies to mucin in ulcerative colitis (UC) is unclear. In any event, once present, they serve to differentiate UC from Crohn's disease. Additionally, they perpetuate chronic mucosal inflammation in UC.⁴¹ The pathogenesis of UC is related to a

disturbance in immune regulatory T cells. A serum factor from a UC patient was shown to be interleukin-7, which has been shown to induce T cell proliferation in the thymus.⁴²

Nutritional elements have been shown to enhance the function of the GALT. A combination of arginine, n-3 fatty acids, and nucleotides was able to significantly reduce sepsis and multi-organ failure in trauma patients. One paper suggested that "Immunonutrition [as a] ... strategy available to clinicians caring for trauma patients ... should be strongly considered" ⁴³ At least in parenterally fed mice, glutamine supplementation may improve GALT volume and function. Arginine may improve CD4 cell percentages but not volume of the GALT.⁴⁴ Recent studies have shed some light on these issues. Specific nutrients may be able to enhance enteral blood flow in a site-specific manner. In rats, an immune-enhanced enteral diet, enriched with arginine, fish oil, and RNA fragments, was able to increase blood flow to the ileum. Because the GALT is located primarily in the terminal jejunum and ileum, this may affect GALT activity.⁴⁵

Unfortunately some pathogens have developed strategies to take advantage of these GALT features and are able to penetrate the defenses.⁴⁶ Translocation is the process of a large molecule moving through a biologic barrier. This is also known as leaky gut.⁴⁷ In the presence of a leaky gut, translocation may result in allergy, autoimmunity, or high levels of inflammatory immune complexes delivered to the liver, resulting in detoxification pathway stress. This process has been linked to arthritic conditions. Some of these symptoms and diseases are related to immune interactions between gut luminal microbes and HLA tissue types.^{48,49,50} Alternatively, this leakiness may overwhelm the liver detoxification systems and allow the escape of toxic substances into the systemic circulation, resulting in distant effects such as encephalitis.⁵¹

Digestion and Absorption

Digestion is largely an intraluminal, extracellular process. Primary functions of the digestive system are:

- Breakdown of complex foods and absorption of nutrients (monosaccharides, monoacylglycerols, fatty acids, amino acids, vitamins, minerals, water, and phytonutrients).

- Barrier to keep out unwanted substances and organisms (bacteria and toxins).
- Site for specialized cells that produce mucus, fluids, digestive enzymes, intrinsic factor, peptide hormones, and other “neurotransmitters.”
- Production of other cells that have sensing functions.
- Communication of information about the environment to the endocrine and immune systems.

The control of pancreatic and gall bladder function by the ENS and hormonal system has been described above. The structural aspects of the small intestine also contribute to digestion and absorption. Due to the circular folds of the mucosa, the villi and the microvilli, the area of the cylindrical intestine, is increased about 600 times to a total area of 200 square meters. This provides for greater concentrations of epithelial-derived enzymes and greater surface area for absorption.⁵²

Absorption occurs by four general mechanisms:

- The first mechanism is passive diffusion, which is the primary absorption route for water, short-chain fatty acids, and gases such as H₂ and CO₂. Passive diffusion can be bi-directional, moving down the concentration gradient in an energy-independent manner.
- The second mechanism is mediated transport, both passive and active, involving specific carrier or transport proteins at the cell membrane. Frequently, the transport protein on the luminal or brush border membrane (BBM) side of the enterocyte differs from the transport protein on the basolateral membrane (BLM) side of the enterocyte.⁵³ The simplest mediated transport is facilitated diffusion. The transport protein can be regulated, but the transport is down an established electrochemical gradient. The active mediated transport mechanisms involve energy expenditure. They may involve uniport pumping of one item, symport pumping of two items in the same direction, or antiport exchange of items in and out of the cell. These systems may use primary or secondary energies to accomplish the task. An example of primary energy use is the Na/K ATPase pump. This system pumps Na out of and K into cells at the expense of ATP, where 1 mol of ATP pumps 3 mol of Na and 2 mol of K (an antiport). In the secondary energy utilization system, an established electrochemical gradient is used to power the

system. An example of this is the SGLT1 transporter. In this system, glucose is transported against its concentration gradient by co-transporting Na out of the cell with its concentration gradient (a symport).⁵⁴ By using the “stored” energy from the Na/K ATPase pump, the cell can concentrate glucose without the use of additional ATP. Single nucleotide polymorphisms (SNPs) at the level of the transport protein gene, or proteomic problems with regulation of these sites may lead to various diseases.⁵⁵ Additionally, SNPs and proteomic or other problems with the brush border enzymes or their regulation may involve defects in enzyme synthesis, alterations in intracellular transport, and catalytically altered apoenzyme.⁵⁶

- A third mechanism of absorption is pinocytosis. This is a receptor-mediated process. It is the general route of absorption for intact proteins and other large molecules. Smaller molecules may “hitchhike” with these larger molecules in the solution of the involutioned vacuole. Pinocytosis is subject to all of the genomic, proteomic and metabolomic processes, and is affected by SNPs and errors of receptor-mediated processes.
- The last route of absorption is paracellular, involving the absorption of substances between the enterocytes at the “tight junctions.” It is normal for water to be absorbed in this way, and electrolytes go with the water via “solvent drag.” Epithelial cells possess the capacity to alter the permeability of the tight junction. This process is controlled by cytoplasm factors.⁵⁷ It now appears that the cytoskeleton is in direct communication with the tight junction and helps to control its function.⁵⁸ Unfortunately, it is possible that a loss of integrity of the tight junctions, through inflammation or infection, will allow the absorption of substances in an unregulated manner. These substances, when present at the basolateral membrane, may be immunogenic, create a toxic burden, or both.

Increased permeability has been observed in several disorders and may be both an effect and a mediator of disease. One study reported the sensitivity of intestinal permeability for prediction of relapse in Crohn’s disease at 81%.⁵⁹ Bowel disorders with increased permeability include inflammatory bowel disease, Crohn’s disease, food allergy, and celiac disease. Systemic diseases with

increased permeability include inflammatory joint disease, rheumatoid arthritis, ankylosing spondylitis, Reiter's syndrome, chronic dermatological conditions, schizophrenia, and allergic disorders.^{60,61}

The small intestine is able to respond to environmental changes with significant alterations in brush border enzymes and enterocyte transporter and receptor proteins. When hibernating hamsters were examined, these proteins were optimized to deal with the extremes of hibernation vs. feeding in an energy-efficient manner.⁶² When rats are challenged with various dietary compositions, the expression of villous enzymes, transporters, and receptor proteins changes rapidly to optimize utilization of the foods available.⁶³ The distribution of enzymes and transporter and receptor proteins is not random.⁶⁴ The small intestine is a regionally task-specific organ, with longitudinal controls in place to ensure correct mixing and digestion of chyme. If a significant bolus of undigested food reaches the ileum, the "ileal brake" will stop the progression of food until adequate breakdown has occurred (another function of the ENS). The expression of transporter and receptor proteins is also region specific.

The enterohepatic circulation of bile acids is an example of such a process. Bile is produced in the liver and stored in the gall bladder. With proper stimulation, it is released into the duodenum to aid in digestion. While it is reabsorbed by passive diffusion throughout the entire length of the intestine, there are receptor-mediated transport mechanisms found only in the distal ileum.^{65,66} This ensures an ample supply of bile acids throughout the colon during digestion. This system is very efficient and results in the loss of only about 1% of the bile to the feces. Liver organ reserve may be taxed by any situation that increases transit time in excess of bile salt reabsorption. The average liver synthesis of bile acids is 0.5 grams per day, yet some 50 grams flow through the gut each day. Essentially, the same 4 grams of bile acids are recirculated through the gut some 12 times per day. If the gut were to lose a larger percentage of bile to the fecal mass, the digestion of fats would be impaired. The major excretory pathway of cholesterol out of the body is via the 1% of unrecirculated bile. Bile acid sequestrant medication, used to lower cholesterol, may contribute to liver stress and poor digestion of fats due to excess bile acid loss to the fecal mass.

Organisms of the Gut

Within the gut is a population of about 400 different microbial species; however, 30 to 40 species account for about 99% of the intestinal load. The absolute numbers of these microorganisms is vast; they outnumber our own human cells by at least an order of magnitude.^{67,68} It is estimated that the total weight of these microbes is two to nine pounds, placing this among the body's largest "organs." These microbes have several functions and seem to be truly symbiotic and mutualistic. At least one species has the ability to bind to specific receptors on the enterocyte.⁶⁹ It is interesting that the population of genetic subgroups, within a species of bacteria, varies with its position within the colon. This suggests significant sub-specialization by sites within the gut.⁷⁰ This population of microbes may be termed the "undiscovered organ."⁷¹

The traditional view of these microorganisms is that they are single living and not cooperative; however, recent advances in microbiology tell us that they are cooperative, not only within a species but among various species.^{72,73} They also exhibit complex life cycles.⁷⁴ They live in single cell or planktonic forms and colonial forms known as biofilms. Biofilms are highly ordered, often multi-species films exhibiting cooperation and specialization within the film.⁷⁵ They exhibit complex structures that are achieved by poorly understood mechanisms that appear to involve bacteriophage-induced cell death. These bacteriophages appear to live within the bacterial genome as prophages. Some evidence suggests these phages are controlled in a manner that creates reproducible three-dimensional structures including microcolonies, channels, and matrix.⁷⁶ The structure is protective and forms nutrient flow channels.

The expressed genetic heterogeneity of two forms of the same species is often significant.⁷⁷ The interactions of various microorganisms is dependent on their planktonic vs. biofilm states. In one example, when *Candida* is in its filamentous form, *Pseudomonas* was able to attach, therefore forming a dense biofilm, and killing the *Candida*. When *Candida* was in its yeast form, no binding, biofilm, or kill occurred.⁷⁸ The expression of certain genes, or lack thereof, has been reported to be involved in both virulence and drug resistance.^{79,80,81} The biofilm was originally thought to be a simple diffusion barrier to antibiotics.⁸² It is now clear that specific components of the biofilm interact with antibiotics in a

neutralizing way.⁸³ These interactions are not mediated by beta-lactamase. Pathogenic microbes have been shown to preferentially increase the thickness of their biofilm matrix layer when exposed to antibiotics.⁸⁴ Biofilm formation is now recognized as the major reason for resistance to pathogenic and opportunistic bacterial and fungal strains.⁸⁵

While not confirmed, it is likely that the probiotic species within the gut live in a mix of individual planktonic forms and complex multispecies biofilms, which are thought to play a key role in the protective functions of probiotics. Probiotic species that are able to produce biofilms have been studied.^{86,87,88} The mechanism of biofilm formation involves breaks in the peptidoglycan cell wall through an autolysin mechanism, resulting in colony formation and biofilm production.⁸⁹ In addition to forming biofilms, probiotic species seem to inhibit the formation of invasive biofilms. *Lactobacillus* demonstrates a significant ability to inhibit biofilms of undesirable species.⁹⁰

Several other naturally occurring biofilm inhibitors are now recognized. They seem to work by inhibiting a set of “quorum sensing” signaling molecules.⁹¹ Several components of the innate immune system, including lactoferrin, are able to prevent biofilm formation.⁹² Lactoferrin is active against a broad spectrum of bacteria, fungi, and protozoa. The effects are both direct cidal activity, due to its binding to specific receptors, and iron binding and sequestration.⁹³ Specific fractions of human milk have anti-biofilm activity that works by blocking microorganism lectins that are active in biofilm formation.⁹⁴ Cellulase has been used as a biofilm inhibitor. Investigators believe it may be effectively used in combination with other agents to treat biofilm contamination of medical devices.⁹⁵ Several extracts from marine algae have been shown to significantly inhibit several species of biofilm forming organisms.⁹⁶ Salicylates are also potent inhibitors of biofilm formation.⁹⁷ Other prostaglandin inhibitors have shown promise as biofilm inhibitors. Several NSAIDs were able to inhibit biofilm formation in *C. albicans*, with aspirin showing the greatest effect. It is well known that prostaglandins are produced in *C. albicans* and they play a key role in colony formation. Now it seems prostaglandins play an important role in fungal biofilm formation.⁹⁸

It has been pointed out that nature has been doing “biological warfare” for millennia.⁹⁹ The more rapidly evolving probiotic species may be better adapted to

fighting off invading species than our own more slowly changing immune systems. Components of probiotic biofilm have significant anti-infective, anti-adherent qualities, and possibly anti-tumor activity. The morphogenetic autoregulatory substance farnesol inhibits biofilm formation in *C. albicans*. In the case of the anti-tumor activity, at least one component appears to be a conserved transduction pathway, the same farnesol pathway. Inhibition of this pathway induced apoptosis in epidermoid cancers with reduction of ras oncogene expression and lowered PPAR activity.¹⁰⁰

Clinical Implications of GI Imbalance

Probiotics

Both prevention and management of some human diseases may be addressed with the use of probiotic bacteria. Preliminary findings of several recent human trials suggest probiotics may help both gastrointestinal and systemic conditions.¹⁰¹ When this protective probiotic biofilm is disrupted by any number of perturbing factors, it may be replaced with a dysbiotic set of organisms that create their own biofilm. Because biofilms often exhibit unique forms of antibiotic resistance, it is often difficult to eradicate these invading species.^{102,103} This construct of biofilm formation lends new insight into a complex problem and suggests new ways of intervening, including the use of biofilm inhibitors or probiotics capable of defeating the biofilms of the dysbiotic species. Perhaps both these interventions will be coupled with antimicrobial and prebiotic techniques.

With the complexity of the microorganism interactions and the high order of both microorganism-to-microorganism, as well as microorganism-to-human symbiosis, what else are these probiotics able to do? They have a large number of functions:

- They produce cytochrome P450-like enzymes and help with detoxification.
- The presence of increased numbers of P450-like enzymes from bacterial origin may induce the expression of liver P450 enzymes.¹⁰⁴ How might bacteria communicate with the human liver to induce genetic expression of P450? It appears that conserved communication pathways are common to both prokaryotes and eukaryotes. Signal molecules from prokaryotes are able to affect pathways within the eukaryotes, even in complex

organisms.¹⁰⁵ The discovery of these conserved pathways may explain a great deal of the symbiotic nature of these relationships.

- Probiotics have also been shown to produce some B vitamins and vitamin K.
- They aid in digestion, enhance absorption of nutrients, combat diarrhea, and interact with immune system components to improve resistance.^{106,107}
- Additionally, probiotics exert antimutagenic, anti-tumor, and immunomodulation effects. Probiotics have shown antitumor activity in several transplantable tumors in mice.¹⁰⁸
- They may also modulate the leakiness of the gut.¹⁰⁹ This could help practitioners with the task of treating inflammatory ENS neuropathies.

The Gut-Brain Axis

The distinction between pure inflammation and ENS interaction is blurring. The gut contains the greatest concentration of immune tissue in the body. These immune cells are intertwined with the greatest concentration of nerves outside of the CNS. Both the immune cells and the nerves seem to be in intimate communication with the mucosal epithelia via a large array of signaling molecules. These interactions control both physiologic and pathophysiologic features of gut function.^{110,111} It is now known that bi-directional ENS and CNS communication is commonplace, occurring via neuronal, immunological, and endocrinological pathways. This has been termed the brain-gut axis. Disturbances of immune, endocrine, CNS, or ENS inputs can have significant bi-directional consequences. The same neurotransmitters influence gastrointestinal, endocrine, immune, behavioral, and emotional function.¹¹² While psychological stress has been shown to induce relapse of established intestinal disease, new evidence suggests that psychological stress can induce intestinal inflammation in a previously healthy host.¹¹³ These new findings suggest that, for instance, a component of depression may be in the gut, and a component of IBS may be in the head.

Inflammatory Enteric Neuropathy

It may be that serum anti-ENS antibodies to detect the early stages of inflammatory degenerative enteric neuropathy may be helpful.¹¹⁴ ENS inflammatory neuropathy exhibits dense infiltrates of inflammatory immune cells. These inflammatory reactions are located

at the neural microenvironment. It appears that symptoms of inflammatory ENS neuritis may develop acutely or indolently. An example of the acute form may be the development of IBS after an acute illness, while the indolent form may be the slow, progressive development of paraneoplastic syndromes.¹¹⁵ Degenerative and genetic mechanisms also play a critical role in ENS pathology underlying gut dysmotility. It is highly likely that the same or similar neurotoxic events that occur in the CNS are at work in the ENS. This has been demonstrated for glutamate. Excessive stimulation by glutamate has resulted in both acute and delayed cell death by both necrosis and apoptosis. This may be an important mechanism of gut damage from anoxia, ischemia, and excitotoxins present in food.¹¹⁶

Controlling the Inflammatory Environment

Control of the inflammatory environment plays a critical role in GI health. While exhaustive lists of inflammatory mediators and excitotoxins have been developed, simpler strategies for the management of inflammation may be available. Control of leakiness of the gut and antigen presentation at the lamina propria within the gut may help balance T-helper cell population distribution and thus control inflammation.¹¹⁷ Additionally, control of leakiness of the gut wall may reduce inappropriate gut luminal content/immune interactions, thus reducing immune-mediated inflammation, both locally and at a distance.¹¹⁸ Clinically, if we are able to improve gut leakiness and improve T-helper cell populations to a more tolerogenic form, this may lead to improved inflammatory mediators within the gut. This may be accomplished by using oligo-antigenic diets, anti-inflammatory agents, and factors that improve microbial balance.

Chapter 25

Structural Imbalances

Alex Vasquez, DC, ND

Introduction

When discussing the “structural” aspect of the functional medicine matrix, we commonly think of the musculoskeletal system; this is appropriate since the majority of the body is comprised of the bones, muscles, and interconnecting joints that form our limbs, torso, neck, and craniomandibular complex. Structural considerations are also relevant for several nonmusculoskeletal conditions. In some patients, aspects of their “structural imbalances” or “structural dysfunction” may be readily apparent and obviously relevant to their primary health concern. In other patients, structural imbalance may be more subtle and/or less obviously relevant to their clinical situation. It is important to distinguish subtle from unimportant; many structural imbalances and dysfunctions may go undetected, or may be categorized as “not relevant,” if they lie outside the practitioner’s awareness or scope of training and specialty. Examples of these important subtleties and breaches of structural integrity include the slight increases in intestinal permeability associated with eczema, inflammatory bowel disease, and several types of arthritis,¹ and the proprioceptive defects and subtle aberrations of joint motion that may contribute to chronic back and neck pain and predispose to recurrent injury and therapeutic recalcitrance.^{2,3}

The more we know about micro- and macrophysiology, the more we are challenged when attempting to draw clear boundaries between organ systems and biochemical vs. nutritional vs. structural vs. neurologic processes. It is increasingly clear that all musculoskeletal conditions involve numerous overlaps with other elements of the matrix. The best way to convey the interconnectedness of the structural aspect of the matrix with these other elements is simply to discuss and give examples of each with an appreciation of the bi-directional

linkage whereby one aspect affects the other. The sections that follow provide a brief review of those aspects of the matrix that most strongly affect and are affected by structural imbalances. A graphic representation of these interconnections is provided in Figure 25.1. (In a sense, this whole book provides the underlying evidence for these multifaceted and multidirectional interconnections, but Chapter 10 addresses the issue directly.)

Figure 25.1 Interconnectedness of structural aspects of the matrix with other elements

Environmental Inputs

Our use of the phrase “environmental inputs” implies our appreciation of the roles of diet, nutrition, exercise, and trauma in human health and disease. We should add the importance of sun exposure as an environmental factor with relevance for a wide range of clinical problems, since insufficient sun exposure generally leads to a deficiency of vitamin D, which can exacerbate inflammation,⁴ musculoskeletal pain,^{5,6} and increase the risk of inflammatory diseases such as rheumatoid arthritis.⁷ (To compensate in part for lack of sun exposure,

administration of vitamin D in doses of 4,000 IU per day for adults can reduce inflammation, alleviate musculoskeletal pain, and ameliorate a wide range of health problems.⁸) Other environmental and lifestyle factors, such as repetitive overuse, can promote tissue inflammation and trauma to articular tissues, thus accelerating joint degeneration by inducing chondrocyte senescence via oxidative mechanisms.⁹ As an intangible environmental input, exposure to psychoemotional stressors is consistently associated with an increased propensity toward allergic and inflammatory diseases.¹⁰

The American/Western style of eating (commonly referred to as SAD, for the standard American diet) is characterized by foods with an excess of linoleic and arachidonic acids, an overabundance of foods with high glycemic loads and indices, and a deficiency of phytonutrients. Since arachidonic and linoleic acids and high-sugar foods are proinflammatory, the American diet can be described as inherently proinflammatory and thus contributory to the scourge of painful musculoskeletal conditions that plagues Westerners.¹¹ Therefore, treatment programs for patients with inflammatory disorders must include advice for a health-promoting, anti-inflammatory diet in order to shift the balance of their physiology away from inflammation and catabolism and toward homeostasis and anabolism.¹²

Moderate regular exercise, increasingly less common in our over-stressed and over-scheduled times, stimulates the release from muscle tissue of cytokines (“myokines”) that produce a net anti-inflammatory effect.¹³ Exercise also helps to maintain a coordinated neuromuscular system and avoid or correct the underlying proprioceptive defects that contribute to chronic musculoskeletal pain, particularly in the low back, knees, and ankles.¹⁴ As an external therapeutic intervention, spinal manipulation can also be placed in this category of environmental inputs; it is noteworthy that spinal manipulation has also been shown to benefit non-musculoskeletal systems, particularly pulmonary and gastrointestinal.¹⁵ Environmental inputs can help shift the balance toward—or away from—a localized or systemic inflammatory response. In summary, the environment can be therapeutically manipulated to reduce the prevalence and severity of painful inflammatory musculoskeletal disorders.

Gastrointestinal Status

On a microscopic level, the integrity of the intestinal mucosa deserves attention, since increased intestinal permeability can promote macromolecule absorption, which can lead to immune complex deposition and systemic immune dysfunction that can exacerbate musculoskeletal inflammation.¹⁶ In this way, the status of the gut influences the status of the musculoskeletal system, and the converse is also true. From a therapeutic standpoint, some patients note a subjective improvement in gastrointestinal function following chiropractic-type spinal manipulation,¹⁷ and this exemplifies how the status of the musculoskeletal system can influence the status of the GI system. It is increasingly clear that the gut shares a bi-directional linkage with the nervous system, and therefore the nervous system, via the musculoskeletal system, can be used as a modulator of gastrointestinal function. A full discussion of these issues from the clinical perspective can be found in Chapter 28, including a detailed discussion of the enteric nervous system (the gut-brain connection).

Mind, Spirit, Emotions, and Community

Musculoskeletal pain and inflammation can cause at least three types of secondary depression. First, inflammatory mediators released from degenerative tissues and systemic inflammation have psychoactive effects that can contribute to fatigue, somnolence, anxiety, depression, dementia, and psychosis.^{18,19} Second, patients with acute or chronic musculoskeletal disorders are, of course, frequently in pain and are commonly less able to pursue hobbies and activities that would otherwise give them pleasure. Third, decreased mobility can contribute to a reduction in social contact, and the sense of social isolation that results can lead to mental and emotional distress.²⁰ In these ways, musculoskeletal dysfunction can adversely affect mental and social health.

Treatments aimed at improving musculoskeletal health can have positive emotional, mental, and social benefits. Exercise helps alleviate depression, and group exercises can provide a valuable source of social contact, which may further alleviate depression and promote social health.²¹ High-dose vitamin D supplementation corrects the vitamin D deficiency that is common in patients with musculoskeletal pain,²² provides an important anti-inflammatory benefit,²³ and alleviates

musculoskeletal pain.²⁴ Other effects of vitamin D repletion include lessening the severity of depression²⁵ and enhancing mood, sociability, and overall sense of well-being.²⁶ The proteolytic enzyme bromelain provides anti-inflammatory benefits, helps to alleviate the pain of osteoarthritis, and enhances an overall sense of well-being.²⁷ Full-body soft tissue massage and myofascial manipulation can help to alleviate depression and insomnia, enhance mood, and lessen the severity of premenstrual syndrome for women.²⁸ Similarly, EPA and DHA from fish oil can ease joint pain and inflammation while also providing an antidepressant benefit.²⁹ Meditative relaxation appears capable of reducing inflammatory responses by neurogenic mechanisms,³⁰ and it is reasonable for orthopedic patients to regularly practice meditation and relaxation techniques.

Immune and Inflammatory Imbalances

The muscles and joints that comprise the bulk of the structural aspect of the matrix are commonly affected by inflammatory and immune imbalances. Musculoskeletal rheumatic diseases such as rheumatoid arthritis and the enteropathic spondyloarthropathies clearly exemplify the effects of a dysregulated immune system upon the structures of the peripheral joints and spine, respectively. In patients with inflammatory musculo-skeletal disorders, emphasis should be placed first on normalizing and then on optimizing immune function by addressing the underlying factors that have synergized to affect immunodysregulation and create or intensify autoimmunity. Suppressing immune response with immunosuppressants such as prednisone, anti-inflammatory drugs such as NSAIDs (which promote joint destruction and chondrolysis^{31,32}), or selective COX-2-inhibiting drugs (which consistently elevate the risk of cardiovascular death^{33,34,35}) should not be the first treatment approach. Rather, addressing the underlying causes of proinflammatory imbalance is a more reasonable clinical approach for immune-mediated pain and inflammation than simply suppressing the inflammatory consequences that result. Many (and perhaps most) diseases categorized under “immune and inflammatory imbalance” will have a propensity to affect the structural/musculoskeletal systems, since inflammatory conditions generally exacerbate joint inflammation and degeneration.

Hormones and Neurotransmitters

Endocrine disturbances can contribute to immune dysfunction, which can then contribute to a systemic inflammatory response that leads to structural imbalances in the gastrointestinal tract and musculoskeletal system. Absolute or relative excesses of estrogen and insufficiencies of testosterone, cortisol, and DHEA are common in patients with inflammatory/rheumatic disorders.^{36,37,38,39,40} Detection and correction of thyroid autoimmunity may alleviate inflammatory musculoskeletal disorders, such as adhesive capsulitis.⁴¹ As an endocrine disease, diabetes mellitus can contribute to carpal tunnel syndrome and adhesive capsulitis, and the elaboration of proinflammatory mediators from adipose tissue (adipokines) underscores the importance of weight optimization as part of the treatment for patients with inflammatory disorders.⁴² Massage therapy has been shown to have “neuroendocrine” effects by raising levels of dopamine and serotonin and by alleviating depression, anxiety, and insomnia.⁴³ Any discussion of the effects of the nervous system on the musculoskeletal system must emphasize the importance of neurogenic inflammation as a major contributor to joint inflammation and cartilage degeneration. Indeed, sensory nerves exacerbate local tissue catabolism via the direct release of inflammatory and degeneration-inducing signals, including cytokines and prostaglandins.⁴⁴ Thus the neuroendocrine and musculoskeletal systems can affect each other in a bi-directional manner, and this interaction allows for the establishment of a feed-forward cycle wherein trauma-induced tissue injury results in immunogenic inflammation and associated pain, the latter of which then triggers neurogenic inflammation, which then amplifies the ongoing immunogenic inflammation.

Detoxification

The link connecting musculoskeletal pain with impaired detoxification has not been fully characterized. However, detoxification programs are empirically beneficial for relieving aches and pains and many other specific and nonspecific complaints.⁴⁵ Many dietary, lifestyle, and interventional modalities can facilitate the removal of endogenous and exogenously acquired toxicants and can therefore be thought of as promoting detoxification of these substances; many of these same modalities are beneficial for patients suffering from musculoskeletal

pain and inflammation. Health-promoting vegetarian diets have been shown to alleviate the pain and inflammation of rheumatoid arthritis,⁴⁶ and such diets can also promote urinary alkalinization,⁴⁷ which enhances the excretion of toxic xenobiotics and poisons.⁴⁸ Moderate exercise can help alleviate the pain of and disability caused by conditions such as fibromyalgia and osteoarthritis,⁴⁹ and exercise promotes the lymphatic flow and lipolysis that are generally considered essential for the mobilization of fat-stored xenobiotics. Detoxification programs are discussed in greater detail elsewhere in this text (see Chapters 22 and 31).

Oxidative Stress and Energy Production

Inflammatory musculoskeletal disorders are commonly associated with increased oxidative stress,⁵⁰ which can impair mitochondrial function, leading to expedited chondrocyte senescence and an overall reduced synthesis of the proteoglycans that form cartilage.^{51,52} This supports the rationale for using dietary and supplemental antioxidant therapy in the treatment and prevention of degenerative or symptomatic musculoskeletal conditions. More specifically, nutrients that support mitochondrial function may be of value in reducing oxidative stress resulting from impaired energy metabolism.⁵³ An excellent example of this concept and its clinical application is the use of niacinamide in the treatment of osteoarthritis; niacinamide is known to support mitochondrial function, and it is safe and effective in the treatment of osteoarthritis.⁵⁴

Structural Interconnections

Subtle structural dysfunction can lead to clinical conditions of sufficient severity that intervention is warranted. In addition to deficits in proprioceptive function that contribute to low-back and lower-extremity pain and injury,^{55,56} subtle restrictions in or excesses of joint mobility, particularly of the spinal column, may lead to chronic pain. Clinically, the technique of motion palpation is a validated method of joint assessment and can be used to quantify and qualify subtle abnormalities in axial and peripheral joint function.^{57,58} Restrictions in motion can be ameliorated with manual manipulative therapy,⁵⁹ and excesses in motion can be addressed by therapeutic exercise and ergonomic modifications.⁶⁰ This approach is particularly relevant for patients with, for example,

chronic back and neck pain wherein deficits in proprioception and imbalances in muscle strength and tension can be alleviated with a multicomponent intervention that includes spinal manipulation, proprioceptive retraining, targeted muscle strengthening, and post-isometric stretching.⁶¹ Intra-articular adhesions and entrapment of synovial folds and intra-articular menisci are anatomical contributors to localized pain that call for a physical rather than pharmacologic intervention, and these can be alleviated with manipulative therapy,⁶² although some cases of entrapped synovial folds may be treated surgically.⁶³

Summary

Several important considerations are relevant to the prevention or alleviation of musculoskeletal pain, the most common reason for considering the structural aspect of the matrix. Frequently overlooked causes of musculoskeletal pain and/or overt or subclinical inflammation include vitamin D deficiency, consumption of a proinflammatory diet, lack of exercise, excess adipose tissue and resultant elaboration of adipokines, proprioceptive deficits, subtle joint dysfunction (including intraarticular adhesions), and entrapment of intraarticular menisci and synovial folds. All of these are correctable with nonpharmacologic and nonsurgical means; addressing them successfully will help improve the patient's overall health and reduce the impact of these problems on other aspects of the functional medicine matrix. (See Chapter 29 for further discussion of clinical approaches to structural imbalances.)

A Practical Clinical Approach

Chapter 26

Clinical Approaches to Environmental Inputs

- ▶ *Diet and Nutrition*
- ▶ *Micronutrient Insufficiency Leads to DNA and Mitochondrial Damage*

Diet and Nutrition
Mark Hyman, MD

Introduction

Functional medicine is neither a new healthcare discipline nor a new subspecialty of medicine; it does not fundamentally alter our current understanding of the biomedical sciences. Rather, it applies what we have learned from the scientific literature—and from clinical medicine—through a different model, interpreting the findings in the context of both genetics and environment, and looking at functionality from the deepest levels of physiology and biochemistry to the most obvious psychosocial influences on health.

Guided by the organizing framework or *matrix* of functional medicine, clinicians are empowered to offer effective solutions for difficult and complex clinical problems. Space travel was not based on belief or superstition, but on physics. The first man to venture into space did so based on scientific theory, and he did so successfully, using established scientific principles, despite the fact that it had never been done before. Analogously, medicine, as we know it, is poised at the edge of a new frontier. Scientific inquiry has taken us deep into the realm of biology, and new principles and concepts have emerged. These new principles and concepts will set the stage and provide the tools for navigating *inner space*, where the complex interplay of genes, molecules, and environment promotes health and creates disease. While we await future research to unify and weave together diverse strands of scientific discovery and undoubtedly shed new light on this matrix, the

weight of current evidence already provides a roadmap and some extremely useful tools.

The matrix of functional medicine (discussed in Chapter 34) is an evolving prism or lens for understanding medicine, but we must not confuse the lens with the object of perception. The profound complexity of biologic systems, and their interplay with the environment, is far too vast to be encompassed by any one theory. However, the matrix—the principles, the environmental inputs, the fundamental physiological processes and the core clinical imbalances—is a remarkably robust model for addressing the epidemic of chronic degenerative diseases, the myriad chronic syndromes, and the environmental, lifestyle, and immune disorders that are the plagues of the 21st century. By applying these principles to the everyday problems that affect our patients, we enter uncharted territory with respectful caution, an attitude of open inquiry, free of dogma, and ready for discovery.

Understanding the intersection of diet and disease, and the role of nutrition in both the creation and amelioration of disease, is both practical and instructive. It is practical because nutrition is the single most powerful clinical tool in preventing and treating disease. It is instructive because food (along with oxygen) is the key substrate for life and influences every biologic process and every core clinical imbalance. The duality of nutritional influences on health is striking. On one hand, our current diet is the principal agent of chronic degenerative disease in our time. On the other hand, when

the current science of clinical nutrition is applied artfully, it has the power to prevent, reverse, and even cure many of our chronic diseases.

Dietary Influences on Health: Creating Imbalance or Balance

A one-size-fits-all approach to nutritional advice has proved problematic. Likewise, popular interest in nutrition and the vast market for dietary “cure-alls” and “quick fixes” has led to a confusing, often contradictory, array of “expert” advice. Even in the clinical setting, practical application of nutrition must take into account diversity of nutritional needs across the genetic and chronological spectrum, food preferences of individuals from different cultural backgrounds, the complex psychological aspects of food, and the lack of effective tools for matching dietary recommendations to the individual. Despite those limitations, there are some basic nutritional principles upon which most scientists and nutritional experts agree. There are also a number of therapeutic nutritional strategies that can be applied widely and successfully in the treatment of chronic disease. Understanding the role of nutrition in creating *and* correcting the core clinical imbalances is essential for knowing how to influence the basic biologic functions of health and disease.

Food plays a dual role—it can help and it can harm. A standard American diet (SAD) contributes to degenerative and immune disorders. It is a diet rich in refined sugars such as high fructose corn syrup, saturated fat, and *trans*-fatty acids, and low in fiber, legumes, nuts, fruits and vegetables, essential fatty acids, essential nutrients, and phytonutrients. The pH of our modern diet is low (acidic), and the sodium:potassium ratio is very high. This dietary pattern has been very clearly and strongly linked to chronic disease. Conversely, a diet that is better adapted to our evolutionary needs can ameliorate dysfunction and improve health. A healthful diet is primarily plant based; rich in fruits, vegetables, nuts, seeds, and legumes; high in fiber, essential fatty acids and nutrients; and low in saturated fat, *trans* fats, refined sugars, and carbohydrates. It should have an alkaline pH and a low sodium-to-potassium ratio.¹

Frankly, we could stop right there. Changing dietary patterns in the manner just described would go a long way toward reversing our epidemic of chronic disease. However, most of us live in the real world, where our patients are seldom able to so completely alter their

dietary habits. Most of our patients already have many of the dysfunctions and diseases of contemporary life, and we must treat them with all the skill at our command. Therefore, we will take this opportunity to delve deeply into clinically relevant issues surrounding food and nutrients, so that we can equip ourselves with knowledge and practical clinical approaches for managing our patients (and ourselves) more effectively.

Genetic and Evolutionary Influences on Dietary Choices

Food and its components (including macronutrients, micronutrients, phytonutrients, food additives, and contaminants) can act directly or indirectly to affect gene expression and consequently influence health and disease. This is the new field of *nutrigenomics*. Food, then, must be recognized to contain *information* as well as energy. Nutrients impact cell signaling and other informational processes. Critical aspects include the influence of nutrients on second messenger balances (cGMP:cAMP); their role in information processing; regulation of growth factors; production of cytokines; and apoptosis, particularly in relation to cancer.

Individual genetic predispositions will often dictate unique dietary requirements. Although foundational principles can be applied to nearly all individuals, refinement of dietary inputs is necessary to accommodate specific individual needs (influenced not only by genes, but also by environment and age). Two of the clearest examples of the links between genetics and diet in the cause and cure of disease are celiac disease and metabolic syndrome. Both have a genetic connection; both are strongly linked to multiple dysfunctions and diseases across organ systems; and both can produce a vast array of presenting complaints.

Gluten. Numerous immune and inflammatory disorders occur as a result of exposure to gliadin, a unique protein found in wheat and other grains. Up to 30% of Northern Europeans carry the HLA DQ8 or DQ2 gene and 1% express the syndrome of celiac disease.² Wheat protein is a relatively new food in European populations and may explain the development of an immune response in reaction to gluten in the diet. Avoidance of gluten alleviates the symptoms and frequently reverses the immune dysregulation, systemic inflammation, and autoimmunity associated with its ingestion. In addition to a direct upregulation of the inflammatory response, gluten may trigger a cascade of other imbal-

ances leading to increased oxidative stress, thyroid dysfunction, infertility, and menstrual disorders. Further, it has been shown to initiate the formation of neuroactive peptides or gluten exorphins,³ which affect cognitive function and contribute to morbidity in the autistic spectrum disorders.

Metabolic syndrome. The effects of a shift away from our evolutionary diet are dramatically manifested in the transition from a wild, omega-3 fatty acid-rich diet, abundant in vitamins, minerals, phytonutrients (from whole foods), and fiber to a diet high in processed foods, refined sugars and flours, and nearly absent of phytonutrients, vitamins, and minerals. Current research suggests that this shift in our dietary pattern has led to the current pandemic of obesity, metabolic syndrome, and diabetes,^{4,5} as well as to associated imbalances in nearly every core physiologic system, contributing to cardiovascular disease, cancer, and dementia. Today's modern diet not only lacks many essential components of healthful nutrition, required by our genetic and evolutionary development, but it also contains substances never before ingested by humans, notably high fructose corn syrup and *trans*-fatty acids. Both of these common substances further enhance the tendency toward insulin resistance and a cascade of hormonal dysfunctions (including pancreatic, thyroid, adrenal, and sex steroid imbalances) that, in turn, lead to increased inflammation, oxidative stress, hepatic congestion, impaired detoxification, and structural imbalances of the cell membranes—a daunting litany and one that will be echoed throughout this chapter as we examine our subject from many different perspectives. The good news, however, is that shifting from a processed and refined diet to a whole-foods, plant-based diet, devoid of refined sugars and carbohydrates, *trans*-fatty acids, and processed foods, directly influences and reverses the cascade of hormonal dysregulation central to the metabolic syndrome. Additionally, such dietary patterns have been shown to reduce oxidative stress and inflammation, while improving detoxification and membrane structural integrity.

Clinical Nutrition: A Young Science

Nutrition is a young science, poised to provide answers to aid practicing physicians in preventing, controlling, and treating the exploding global burden of chronic disease. The view of nutrition as simply a source of energy or calories to prevent malnutrition, and micronutrients to prevent deficiency diseases, is being sup-

planted by a new conception of nutrition in health and disease. Macro- and micronutrients and other non-nutritive substances in food are integral to understanding the causes, prevention, and treatment of disease. Nutrients are the fundamental substrates for our physiology and biochemistry; they are both etiologic factors and corrective tools. Translating basic science, epidemiological research, and small randomized trials into practical nutritional policy and advice remains challenging. However, when the data are viewed collectively, an important set of guiding concepts emerges that help us organize our interpretation and clinical utilization of the data.

While on a foundational level, the first law of thermodynamics holds, further investigation has revealed the “calories-in, calories-out” model of energy balance to be overly simplistic. Nutrients play a key role in bioenergetics beyond calorie content. A deeper understanding of bioenergetics illustrates that caloric content of food is only part of the story. Macronutrient composition of the diet asserts influence on thermoregulation, with variable effects on obesity, challenging the simple calorie-counting approach. In addition, the upregulated metabolism of detoxification and toxic overload creates significant energy costs.

The functional medicine practitioner's core questions. While the concept of fundamental clinical imbalances is a useful navigational tool for assessing and treating common clinical problems, it is, at best, an approximate description of a very complex biologic system—the human organism. An input or intervention designed to affect one organ or function may subsequently affect the entire interrelated and interdependent system—the whole human being. The practitioner must be skilled at interpreting the complex array of symptoms, tests results, and responses to treatment. While such complexity presents a challenge to the clinician, it is important to keep in mind that the essence of functional medicine is contained within two very simple questions: What harms us? What makes us thrive?

These key questions facilitate thinking about every clinical problem and provide access to the whole functional medicine matrix. They underlie the principles, the environmental inputs, the fundamental physiologic processes, and the core clinical imbalances. These two questions can be applied to every inquiry, for every illness, and for the promotion and creation of optimal health. And they are of paramount interest when considering clinical nutrition.

Exploring the first question, what harms or disturbs a person, may identify problems such as poor diet, chronic stress, toxic exposures, allergies, and/or infections. Delving into this question requires careful historical inquiry, focused testing, and environmental assessments, all of which we will explore as our discussion proceeds. The second question—what is currently missing and ultimately necessary for the full and vital expression of life—concerns food, water, air, vitamins, minerals, conditionally essential nutrients, light, sleep, rest, rhythm, and love.

The amount and particular balance of these “ingredients” differs for each individual. Wherever there is an imbalance, it is the result of something creating harm, or of some essential life-sustaining ingredient that is missing. In this context, understanding both what is present and what is missing in your patient’s diet must be understood. (To borrow a turn of phrase from Kenneth Pelletier, PhD, “food as slayer and food as healer” are both likely roles.) Keeping these concepts in mind will help the practitioner filter new data and understand the context of this emerging research and information in the field of nutrition.

An exhaustive review of nutrition and its effects on health and disease is beyond the scope of the chapter. However, by using the model of chronic disease to illustrate the role nutrition plays in disease causation and in each of the fundamental processes that underlie our physiological, biochemical, and genomic functioning, we can glimpse the potential of nutritional intervention to influence the global burden of chronic disease. Fortunately, even before we begin our journey, we can summarize (see Table 26.1) the most important general nutritional advice that clinicians can give to their patients. If we do nothing more than guide patients in these directions, we will have accomplished a great deal.

The Global Burden of Chronic Disease:
The Role of Diet and Lifestyle

Chronic disease has replaced infectious and acute illnesses as the leading cause of death in the world, both in developed and developing countries.⁶ In 2002, the leading chronic diseases, including heart disease (17 million), cancer (7 million), chronic lung diseases (4 million), and diabetes (1 million), caused 29 million deaths worldwide. These ailments are almost entirely attributable to lifestyle risk factors such as poor diet, sedentary lifestyle, tobacco,

and alcohol use. The misperception that these diseases affect primarily developed and affluent societies has led to a misappropriation of resources, which fails to deal with the exponential growth of chronic lifestyle- and diet-related disease. The major global health policy makers and agencies do not allocate appropriate resources to prevention of lifestyle problems because they have yet to fully acknowledge the extent of the problem, or perhaps because perceived or real economic concerns govern their actions. Heads of state, health ministries, the World Health Organization, academic and research institutions, non-governmental organizations, private donors, the World Bank, and the United Nations allocate only a fraction of their resources to chronic disease prevention, despite a rich evidence base for the role of lifestyle and diet in the prevention of the major chronic diseases. An examination of the nutritional literature and direct comparison to other efforts at prevention (pharmacologic) is needed to highlight the powerful, cost-effective, and critical role nutrition plays in causation, prevention, and treatment of chronic disease.

Table 26.1 General Nutritional Advice

Eat More of:	Eat Less (or None) of:	Beneficial Dietary Habits
• Anti-inflammatory foods • Detoxifying foods • Fiber • Food you love that makes you feel nourished • High-quality, healthy protein • Omega-3 fats • Real, organic food • Vegetables and fruit • Nuts and seeds • Legumes • Whole grains	• High fructose corn syrup • High glycemic-index foods • High glycemic-load meals • <i>Trans</i> or hydrogenated fats	• Eat breakfast • Eat protein and fat with every meal (especially breakfast) • Eat something every 3–4 hours • Finish last meal at least 2–3 hours before bedtime • Improve pH balance through intake of alkaline (plant-based) foods • Lower the dietary sodium: potassium ratio • Take a multi-vitamin and other nutrients as needed

Diet, Lifestyle, and Chronic Disease—the Emerging Research

An emerging body of literature provides a firm foundation for practice and public policy in nutritional and lifestyle interventions for chronic disease.⁷ A single nutrient, food, or lifestyle habit when studied as an isolated intervention—while helpful—may not show significant effect but, when assessed collectively, the power of lifestyle over pharmacologic approaches for primary and secondary prevention is clear. Adherence to healthful lifestyle practices in an elderly population (specifically, a Mediterranean diet pattern, moderate physical activity, non-smoking status, and moderate alcohol consumption) was associated with nearly a 70% reduction in all-cause and cause-specific mortality.⁸ Other observational studies⁹ showed similar data including an 83% reduction in coronary artery disease,¹⁰ 91% reduction in diabetes in women,¹¹ and a 71% reduction in colon cancer in men.¹² While more difficult in design and execution, a few randomized trials have confirmed the effectiveness of diet and lifestyle in disease prevention. The Lyon Diet Heart Study¹³ showed a 79% reduction in heart disease in patients with established heart disease after a few years of following a Mediterranean diet. The PREMIER group used an intervention of increased activity, weight loss, and Dietary Approaches to Stop Hypertension (DASH), which reduced blood pressure over six months.¹⁴ In a secondary prevention trial, an integrated lifestyle approach of a plant-based diet, exercise, smoking cessation, and stress reduction demonstrated a 50% reduction in cardiac events.¹⁵ A large systematic review of all pharmacologic and dietary interventions on total and cardiovascular mortality analyzed 97 studies with 137,140 patients in the intervention groups and 138,976 in the control groups. The largest reductions in all-cause and cardiovascular mortality resulted from fish oil, followed by statins.¹⁶

Long-term assessment of outcomes in dietary trials is difficult; determining the precise effects of *trans* fat intake, carbohydrate quantity and quality, and alcohol consumption on chronic disease burden can be particularly challenging. Yet randomized trials of a healthful lifestyle can be (and already have been) used to assess shorter-term effects on clinical outcomes, biochemical markers of risk, and intermediate endpoints. Where these are not possible, a careful analysis of basic science research, along with available clinical and epidemiolog-

ical research, should be used to help form a picture of the overall role of dietary influences on disease. A randomized trial comparing a Mediterranean diet (whole grains, vegetables, fruits, nuts, olive oil, fish) vs. a control group following a “cardiac healthy” diet primarily focused on achieving less than 30% fat, exemplified the importance of intermediate markers of disease. Even after controlling for weight loss and physical activity, the authors found that inflammatory markers, insulin resistance, and endothelial function improved in the treatment group.¹⁷

The evidence is already undeniable that healthful dietary patterns such as those we have been discussing are associated with a decrease in chronic disease burden and all-cause mortality. The harmful effects of *trans* and certain saturated fats, refined carbohydrates, and other food additives or toxins are also well supported in the medical literature. The effects of diet can be viewed through their impact on processes such as gene expression, cell-signaling and informational systems, and bioenergetics. Our understanding of the many complex effects of these processes is being expanded continuously as the research base evolves. For the clinician, the concepts of nutritional imbalances, inflammation, oxidative stress, hormone imbalance, digestive function, impaired detoxification, mitochondrial function, and energy balance serve to focus our analysis of the dietary influences on health, and provide a context and method for interpreting and integrating new data into the practice of functional medicine.

Dietary Influences on Cardiovascular Disease: A Unified Theory of Causation

Cardiovascular disease (CVD) is a recurring theme in this book; it serves as a measure of our chronic disease burden (see the *Introduction* section) and as a primary example of the inflammation model of disease (Chapters 18 and 27). It is a central condition in the detailed functional medicine case study that wraps up our *Putting It All Together* section (Chapter 37). Here, we will discuss the profound causative influence of diet and nutrients on CVD. This thematic emphasis seems appropriate, because CVD is the leading killer in the United States today.

The effects of diet on health can be viewed in two ways:

- First, understanding the effects of diet on conditions such as cardiovascular disease can provide a more effective approach to assessment and therapy. This view also helps to illustrate the limitations of our current disease classification system, which does little to provide a unifying concept for the underlying dysfunctional biochemistry and physiology in any particular condition.
- Second, the effects of diet on each of the core clinical imbalances of the functional medicine matrix can provide a unique and novel prism through which to see both the common underlying causes and also many new therapeutic opportunities for chronic diseases that cross many organ systems.

Cardiovascular disease, both because of its high prevalence and its intimate connection to diet, is the model used here to describe the relation between particular foods and clinical imbalances. The effect of diet as both etiologic agent and therapeutic agent will then be explored. There are many gateways to using the functional medicine matrix in clinical practice. The old classification of disease should not be discarded, but rather seen within the context of a patient-centered, function-oriented model. Functional medicine provides a useful meta-framework for interpretation of the relevant data leading to new and unique understanding and treatments.

Historically, cardiovascular disease has been described as predominately an arterial pathology, with focus placed on the health and disease of the vascular tree, and the treatment on opening or bypassing the arterial blockage. However, the origins of cardiovascular disease are now seen predominantly as nutritional, neuroendocrine, oxidative, and inflammatory. The development and rupture of plaque in the arterial wall are processes related to a cascade of events that occurs over decades; these processes are primarily endocrine and immune in nature. The hallmarks of cardiovascular disease (hypertension, coagulopathy, and endothelial dysfunction) are secondary to upstream inputs controlled, in the main, by diet. The diet directly influences insulin sensitivity, oxidative stress, inflammation, lipid status, methylation, cardiocyte cellular energetics, membrane stability, and electrophysiologic dysfunction; these are the root functions

that are imbalanced in all chronic degenerative diseases and cardiovascular disease in particular.

CVD and Diet: The Evidence for Causation and Reversal

Willett and Hu, in “Optimal Diets for the Prevention of Coronary Disease,”¹⁸ reviewed the extensive literature of the last two decades on the dietary influences on cardiovascular disease. They looked at dietary fats, carbohydrates, micronutrients, and phytonutrients. Their conclusions were summarized in three practical strategies:

1. substitute non-hydrogenated unsaturated fats for saturated and *trans* fats,
2. increase the consumption of omega-3 fatty acids from fish, fish oil supplements, or plant sources, and
3. consume a diet high in fruit, vegetables, nuts, and whole grains and low in refined grain products.

Further, they predicted that such a diet, together with regular physical activity, avoidance of smoking, and maintenance of a healthy body weight can prevent the majority of cardiovascular diseases in Western populations.

While these conclusions are relatively simple, the science behind them is complex. Both observational and interventional studies confirm links between diet and insulin resistance. Primary genetic lipid disorders are rare and the majority of cardiovascular disease in our society is linked to metabolic syndrome, which is propagated by a diet high in refined sugar, carbohydrates, and saturated and *trans* fats, and low in fiber and phytonutrients. This leads to insulin resistance at the membrane level, hyperinsulinemia, impairment of fatty acid oxidation, upregulation of inflammatory cytokines such as interleukin-6 (IL-6) and tumor necrosis factor- α (TNF- α), coagulopathy, reduction in adiponectin, and endocrine dysfunction in adrenal, thyroid, and sex steroid hormones. In a prospective study of 181 consecutive patients presenting to the emergency room with myocardial infarction, two-thirds had either undiagnosed diabetes or impaired glucose tolerance after a 2-hour glucose tolerance test.¹⁹ In a cross-sectional study of 234 men, a direct correlation was seen between the glycemic milieu and cardiovascular risk, even in those with normal glucose tolerance. Likewise, even within the current definition of normal glucose tolerance, the

degree of stenosis on the angiogram was shown to be directly related to the level of glucose and insulin after a glucose load.²⁰ A high glycemic-index and glycemic-load diet is clearly associated with atherothrombotic risk.^{21,22} *Trans*-fatty acids have well-documented, specific atherogenic, inflammatory, and pro-thrombotic effects.^{23,24} Though diet is the predominant influence on the key processes of glucose metabolism, lipid balance, inflammation, methylation, and oxidative stress, any trigger that affects these functions can lead to cardiovascular disease (see Figure 26.1). Examples of other important influences include infections, environmental toxins, stress, smoking, and allergens.

Figure 26.1 Influence of diet on risk of coronary heart disease

Diet is both the agent of dysfunction and the agent of healing in cardiovascular disease. With the exception of smoking and lack of exercise, nearly all the modifiable risk factors for coronary heart disease in the INTERHEART²⁵ study of 52 countries (a case-control study with 15,152 cases and 14,820 controls) were caused by and remediable through diet, including abnormal lipids, hypertension, diabetes, and abdominal obesity. Many clinical trials have demonstrated the benefits of diet in improving either clear endpoints such as myocardial infarction and death, or intermediate endpoints such as lipid levels, inflammatory markers, oxidative stress, and glucose metabolism.

Eating the right fats is key to prevention and treatment of coronary artery disease. Dietary n-6 and n-3 fatty acid balance plays a critical role in cardiovascular

health.²⁶ Linoleic acid downregulates LDL-C production and enhances its clearance. Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) improve vascular endothelial function, lower blood pressure and triglycerides, improve insulin sensitivity, activate PPARs, stabilize cardiac membranes (thus reducing cardiac arrhythmias),²⁷ and reduce inflammation and platelet sensitivity. A Mediterranean-style, low glycemic-load diet²⁸ (whole grains, fruits, vegetables, nuts, higher fiber foods, olive oil, and a lower ratio of n-6 to n-3 fatty acids) improved endothelial function and vascular inflammatory markers in patients with metabolic syndrome. After two years' adherence to the diet, there was global improvement in the endothelial function score, as a measure of blood pressure and platelet aggregation response to L-arginine; lipid and glucose parameters; insulin sensitivity; and circulating levels of high-sensitivity C-reactive protein (hs-CRP) and interleukin-6 (IL-6), -7 (IL-7), and -18 (IL-18). A lipid-lowering dietary portfolio of soy, almonds, plant sterols, and viscous fiber was equivalent to a low-fat diet plus a statin (lovasatin) in lowering lipids, and was *more* effective in lowering C-reactive protein and homocysteine.²⁹ A dietary and lifestyle intervention in women with android obesity demonstrated reductions in markers of inflammation, oxidative stress, and platelet aggregation, which can be indicators of insulin resistance.³⁰

The DASH and PREMIER³¹ trials clearly established the beneficial effects of a plant-based diet on reduction in cardiac risk factors. Consumption of a diet high in fruits and vegetables, whole grains, fish, poultry, and low-fat dairy products had a significant inverse association with the risk of cardiovascular disease.³² Conversely, eating a diet high in red and processed meats, refined grains, high-fat dairy products, sweets, and desserts had a significant positive association with coronary artery disease (CAD).³³ Ornish's 10% fat atherosclerosis-reversal diet may have been effective more for its plant-based, fiber-, vitamin-, mineral- and phytonutrient-rich food, than because of any absolute effect from reduction of fat. The total fat content of the diet is less important than the type of fat; risks increase with higher levels of saturated and *trans* fats and decrease with high levels of omega-3 and monounsaturated fats.³⁴ Increasing dietary protein from plant foods (soy, nuts, legumes, and seeds) and low-fat animal sources may have additional beneficial effects on the reduction of cardiovascular risk.³⁵ Homocysteine and impaired methylation have been

linked to cardiovascular disease,³⁶ and plant-based diets rich in whole grains, fruits, and vegetables reduce homocysteine and its adverse effects. Not only does the composition of the diet affect cardiac risk factors, the timing and frequency of meals is also important.³⁷ The specific ideal amounts or ratios of protein, fat and carbohydrate are not entirely clear, nor are they crucial to health, so long as the basic concepts of a healthful diet outlined above are maintained. The effects of this diet are multiple and support the normalization of function and restoration of balance. This dietary pattern improves insulin sensitivity, reduces inflammation and oxidative stress, lowers homocysteine, LDL-C and triglycerides, raises HDL-C, improves endothelial function, lowers blood pressure, is anti-coagulant, anti-arrhythmic, and improves mitochondrial function and cardiocyte energetics. Cardiovascular disease is perhaps the clearest example where diet is both the cause and the cure. It reminds us of Hippocrates' ancient admonition, *"Leave your potions in the chemist's crucible if you can heal your patient with food."*

Practical Dietary Guidelines for the Reduction of Cardiovascular Disease

- Replace saturated and *trans* fats with monounsaturated and polyunsaturated fats.
- Increase intake of omega-3 fatty acids from fish or plant sources.
- Increase intake of fruits, vegetables, whole grains, legumes, nuts and seeds.
- Increase intake of fiber.
- Reduce glycemic load of diet by reducing or eliminating refined sugars and flours.
- Eat regular meals and snacks.
- Eat real, unprocessed food low in added sodium.
- Use low-fat animal products in moderation (low-fat dairy and poultry).

The Role of Diet-Gene Interactions in Health and Disease

Nutrigenomics

Having established the incontrovertible link between diet and disease, using CVD as the example, let's return to the link between diet and genetic expression in general. The genomic era in medicine will mark a turning point in our understanding of the etiology and treatment of disease. The human genome consists of approximately

30,000 genes, which in turn contain approximately 5 million single-nucleotide polymorphisms (SNPs). Over 1,000 human disease genes have been identified, 97% of which cause monogenic diseases. Unfortunately, the illnesses that plague humans in the 21st century are not monogenic diseases. The chronic illnesses that cause the most significant mortality and morbidity in the world, including cardiovascular disease, diabetes, obesity, cancer, and neurodegenerative diseases, are polygenic and result from the complex interaction between multiple genes and multiple environmental factors. The most important factor, one that influences gene expression multiple times every day, is our diet.

Nutrigenomics is an integrative field of science where the questions of nature and nurture may finally be elucidated. It is in the intersection of the environment with the genome where nutrigenomics provides key insights into the variations in disease patterns within a population. Such insights allow us to understand how common dietary chemicals affect the equilibrium between health and disease through their influence on the structure or function of an individual genome. Kaput³⁸ proposes five tenets for this field of genomic research:

1. Common dietary chemicals act on the human genome, either directly or indirectly, to alter gene expression or structure.
2. Under certain circumstances and in some individuals, diet can be a serious risk factor for a number of diseases.
3. Some diet-regulated genes (and their normal, common variants) are likely to play a role in the onset, incidence, progression, and/or severity of chronic diseases.
4. The degree to which diet influences the balance between healthy and disease states may depend on an individual's genetic makeup.
5. Dietary intervention should be based on knowledge of nutritional requirement, nutritional status, and genotype.

Regulation of Post-translational Gene Expression

Multiple mechanisms exist through which diet influences gene function, or expression, and structure. These include direct effects on gene expression, transcription and translation and post-translational influence on gene products, epigenetic effects, and DNA repair. Indirect effects include selective alteration of

gene expression through transcription factor systems that regulate the activation of sets of genes under different environmental conditions. Some nutrients can bind to or activate specific transcription factors, while other nutrients affect redox balance to indirectly affect transcription factor activity.

Key examples can illustrate the clinical utility of understanding these SNPs and the role of nutrients in gene expression. Vitamins act as powerful regulators of post-translational gene expression through their actions as coenzymes in many common diseases (for example, the effects of folate on methylenetetrahydrofolate reductase or MTHFR). Dietary fat and carbohydrate can regulate expression of the LDL phenotype (effects of *trans*-fatty acids and insulin resistance on LDL particle size). Dietary fat and antioxidants regulate inflammation through their effect on a class of nuclear receptors involved in gene transcription (for example, the effects of omega-3 fatty acids, *trans* fat, and antioxidants on the family of nuclear receptors called peroxisome proliferator-activated receptors, or PPARs).

Bruce Ames, in a landmark paper on nutrients and gene expression, stated that “the molecular basis of disease arising from as many as one-third of the mutations in a gene is an *increased* Michaelis constant, or K_m (decreased binding affinity) of an enzyme for the vitamin-derived coenzyme or substrate, which in turn lowers the rate of the reaction.”³⁹ The implication is that many diseases arising from SNPs may be treated through the intake of high doses of substrates (nutrients) for particular reactions in order to accommodate for variant enzymes. He describes over 50 diseases where high-dose vitamin therapy can reduce the incidence of disease from variant enzymes. (This chapter concludes with a contribution from Dr. Ames discussing the potential genotoxicity of micronutrient insufficiency.)

An abundance of research surrounds the methylenetetrahydrofolate 677C→T (MTHFR) polymorphism. The variant enzyme results in a smaller pool of 5-methyltetrahydrofolate and an accumulation of homocysteine, which has been associated with an elevated risk of cardiovascular disease. A higher frequency of the 677C→T polymorphism has been associated with cardiovascular disease, neural tube defects, Down syndrome, migraines, diabetic nephropathy, congenital cardiac malformations, dementia, male infertility, cervical dysplasia⁴⁰ and other conditions. Paradoxically, in colon cancer, the

677C→T (MTHFR) polymorphism reduces colon cancer risk, but only in the presence of adequate folate.⁴¹

Another common polymorphism, ALDH2 or mitochondrial aldehyde dehydrogenase (NAD^+), has been associated with intolerance to alcohol and an increased risk of vasospastic angina, dementia, and oral, esophageal, and stomach cancer.⁴² The enzyme catalyzes the NAD-dependent oxidation of ethanol. The Glu487-to-lysine variant has a 150-fold increase in the K_m for its NAD cofactor. This leads to high blood acetaldehyde levels in alcohol consumption and in the absence of adequate niacin, and increases the risk for carcinogenesis and neurotoxicity. Multiple genes may interact to increase risk. In the presence of the ALDH2 variant and the Apo E 4 variant allele, the age of Alzheimer's onset is significantly reduced. Long-term niacin use may have the potential to reduce this risk. This underscores the importance of multiple polymorphisms of low penetrance combining in any one individual to affect risk. It is the interplay with the environment (diet, exercise, stress, environmental toxins) that affects the outcome in the individual. Most polymorphisms have a relative risk for the related disease of < 2. Therefore, an integrated approach using nutrition, exercise,⁴³ and stress management tools is more likely to optimize gene expression and reduce the risk of chronic disease.

A major challenge in nutrigenomics-focused research on human disease prevention is that randomized trials are often not easy or feasible due to practical or ethical considerations. Combining gene analysis of polymorphisms with observational studies can help strengthen causal connections between dietary factors and disease prevention.⁴⁴ For example, higher urinary levels of isothiocyanates from cruciferous vegetables have been associated with lower risks of lung cancer. The strongest risk reduction was found in those with polymorphisms for glutathione S-transferase genes that delayed the elimination of the isothiocyanates, perhaps increasing their benefit.⁴⁵

Diet and the Fundamental Physiological Processes: Enhancing Optimal Function and Reducing Disease

Human life, particularly, in health and disease, is the result of countless independent forces impinging simultaneously on the total organism and setting in motion a multitude of inter-related responses.

—René Dubos

An exhaustive review of the dietary influences on human biology would require a separate volume entirely, but much of the background and scientific support for this approach to patient care has been outlined earlier in this textbook. We will now examine some specific instances where food creates imbalance and where a change in diet can promote healing. The fundamental role of food in health and disease can be appreciated, and a context for its application in diagnosis and therapy can be understood through the exploration of examples within each of the core physiologic dysfunctions of the functional medicine matrix. Each subsequent section will end with clinical suggestions for assessment and therapy. These recommendations are not exhaustive, but rather demonstrative of an approach to translating the science into clinical practice.

A common theme will appear—that very similar interventions will address the causes and become the treatment for most of the chronic diseases of the 21st century. Modifications, adjustments, inclusions, and exclusions will always be required, depending on the genetics, history, and stage of dysfunction of your patient, but the basic principles of a diet that supports health will be the same: an organic, whole-foods diet, rich in a variety of fruits and vegetables, fiber, whole grains, legumes, nuts and seeds, lean animal protein, and monounsaturated and omega-3 fatty acids; and low in processed foods, sugar, high fructose corn syrup, *trans*-fatty acids, caffeine, and alcohol. (Clinicians cannot ignore the need for exercise and stress management, of course, but those are covered elsewhere in the book.) Even when delineation of “ideal” percentages of macronutrients or micronutrient doses for an individual patient is not possible, following the guiding principles of providing the basic nutritional substrates for optimal function will yield remarkable clinical results. Controversies do exist about the specific components of a healthy diet (for example, whether soy is helpful or harmful, or whether all saturated fats are harmful).

However, the science of nutrition and nutrigenomics provides a firm foundation upon which to create improved clinical outcomes in chronic disease.

Functional Medicine and Nutrition: A Natural Partnership

The principles, processes, and imbalances of functional medicine are best understood as didactic tools that help clinicians better explain the mystery of biology and human function using a lens that is more refined and developed, but nonetheless only an approximation of reality. The web-like physiology and biochemistry of the human being is complex and densely interconnected. Any input, harmful or helpful, enters the system and creates a multitude of interrelated responses. A single input, such as gluten, in a susceptible individual can trigger damage to the intestinal mucosa, impairing nutrient absorption and creating B12, mineral, and vitamin D deficiencies, in addition to upregulating the gut-associated lymphoid tissue (GALT) and activating a systemic immune response that can, in turn, lead to oxidative stress and imbalances in thyroid and sex hormones. Inflammation may in turn affect nuclear PPARs through TNF- α , increasing insulin resistance, impairing fatty acid oxidation, and leading to changes in body composition. What an extraordinary outcome from the ingestion of a single component of some very common foods!

This is only one example of what occurs repeatedly in living systems, where there is an infinite array of macroscopic and microscopic, physical and meta-physical inputs, both beneficial and harmful. Humility in the face of the vast mystery of human life and function must be our guide.

We cannot fully master the practice of medicine and healing, but we can be guided by three simple principles that make the challenge less daunting:

1. One input (environmental or genetic) may cause many diseases, and one disease may be caused by many inputs.
 2. Always consider the two key questions of functional medicine: What harms this patient? What makes this patient thrive?
 3. The science behind functional medicine can be difficult to understand, but it can also be relatively simple to practice.
-

The functional medicine matrix provides a way to sift and sort data obtained from the medical literature, the patient history, and the biochemical and physiologic assessments of laboratory work and physical examination. It is a framework that helps to organize our thinking and our approach to patients. It is a fundamentally new and refreshing way of providing innovative and effective solutions for what ails our patients in the 21st century.

The Matrix: Dietary Influences on Hormonal Balance

The influence of diet on hormone balance is vast and includes the differential effects of specific types of carbohydrates and fats, amino acids, fiber and gut flora, as well as micronutrient effects on hormone synthesis, receptor function, metabolism, and detoxification. Anti-nutrients—harmful foods and non-nutritive substances in our food supply, including xenobiotics, exogenous hormones, and antibiotics—have powerful effects on hormone function. The most striking and useful clinical examples of dietary influences on hormonal balance will be reviewed, including effects on the master hormones (insulin, cortisol, and adrenalin), on thyroid function, and on sex hormone balance. We will also review the ways in which diet can create imbalance or restore optimal function. Specific diagnostic and therapeutic strategies will be presented.

The master hormones. Hormonal signals act both as a symphony of endocrine signals governing diverse functions throughout the organism, and as a hierarchical system where dysfunction in the “governing” hormones leads to dysfunction throughout the system. The key governing hormones regulated by dietary inputs, which interact in an immediate and direct feedback system, are insulin, cortisol, and adrenalin. These, in turn, influence sex steroid hormones, thyroid hormones, growth hormone, and others. (See Sidebar for common symptoms of HPA axis dysfunction.)

Perhaps the most visible intersection of diet and hormones is the influence of diet on glucose metabolism in the metabolic syndrome. To review briefly what has been thoroughly discussed elsewhere in this book, in the context of genetic predisposition or in the face of overwhelming exposure to refined carbohydrates (180 pounds of sugar consumed per person per year in the United States), a chronic state of hyperinsulinemia, hypercortisolemia, and hyperadrenalism is induced, with

its cascade of adverse biologic effects. A high glycemic-load diet increases central adiposity, elevates triglycerides and LDL-C, and reduces HDL-C. It also upregulates inflammatory cytokines such as IL-6 and TNF- α , increases advanced glycation end products and oxidative stress, and elevates PAI-1 and fibrinogen. Other problems include non-alcoholic steatohepatitis and impaired detoxification; PCOS in various presentations (including anovulation, infertility and hirsutism); endothelial dysfunction leading to cardiovascular disease; dementia and cancer (including hormonal cancers); and other chronic morbidities resulting from obesity. Dietary factors⁴⁶ other than high glycemic-load carbohydrates that contribute to the epidemic of metabolic syndrome include lack of dietary fiber, essential fatty acid deficiency, caffeine, excess saturated and *trans*-fatty acids, protein insufficiency,⁴⁷ micronutrient deficiencies (vitamin E, biotin, the B vitamins, zinc, bioflavonoids, alpha-lipoic acid, arginine, carnitine, and inositol), and deficiency of antioxidants.⁴⁸ High glycemic-load diets not only increase insulin resistance but shift the hypothalamic-pituitary-adrenal (HPA) axis toward sympathetic overactivity, with increases in cortisol, ACTH, and norepinephrine, and decreased heart rate variability.^{49,50} Table 26.2 provides some therapeutic strategies for managing insulin resistance, and Table 26.3 provides a list of laboratory tests for assessing indicators of the condition.

Symptoms of Adrenal and HPA Axis Dysfunction

• Cravings for salt and/or sweets	• Low blood pressure
• Dark circles under the eyes	• Mental foginess or trouble concentrating
• Dizziness upon standing	• Need to start the day with caffeine
• Fatigue	• Non-restorative sleep
• Feeling stressed	• Panic attacks or being easily startled
• Feeling tired but wired	• Poor tolerance for alcohol, caffeine, and other drugs
• Feeling weak and shaky	• Sleep problems—difficulty either falling asleep or staying asleep
• Frequent infections (catching cold easily)	• Sweaty palms and feet when nervous
• Headaches	• Water retention
• Heart palpitations	• Weak muscles
• Hypoglycemia	
• Impaired ability to tolerate exercise	

Table 26.2 Therapeutic Strategies: Insulin Resistance

Dietary Recommendations		Nutrient Supplementation	Lifestyle Changes
To Minimize the Causes of IR	To Improve Insulin Sensitivity		
Eliminate refined flours and sugars	Increase fiber to 50 g/day	Increase levels of magnesium, chromium, vanadium, vitamin E, biotin, B complex	Engage in regular stress management practices such as yoga, deep breathing, meditation, guided imagery, etc.
Eliminate sodas and sweetened drinks	Use predominantly soluble fiber**	Take a high-potency multi-vitamin/mineral daily	
Eliminate artificial sweeteners*	Reduce the glycemic load of meals	Alpha-lipoic acid, 200 mg, twice a day	Engage in regular exercise: cardiovascular exercise for 30–45 minutes, 5–6 days/week; and strength training 10–30 minutes, 3 days/week.
Eliminate junk food and processed foods	Eat beans or legumes daily	Supplement EFAs: EPA, DHA (fish oil), ALA (flaxseed or oil), GLA (borage or evening primrose oil)	
Eliminate <i>trans</i> or hydrogenated fats	Have protein and fat with every meal or snack	Ginseng may help regulate insulin, blood sugar, and adrenal function	Eat smaller, more frequent meals (3 meals and 2–3 snacks). Eat no later than 2–3 hours before bedtime.
Limit alcohol to 3 drinks per week	Have lean protein for breakfast	Arginine may improve insulin resistance	
Limit caffeine	Eat omega-3 fats daily Have 2 tbsp ground flaxseed daily Reduce saturated fat from animal foods (meat, poultry, dairy)	Other herbal or nutritional supplements may be helpful: green tea, fenugreek, cinnamon, <i>Gymnema sylvestre</i> , bitter melon, and garlic	

*Artificial sweeteners can trigger insulin response from brain signals and can fuel cravings for sweets.
**Soluble fiber slows sugar absorption from the gut, and is found in legumes, nuts, seeds, whole grains, vegetables, and fruit.

Other secondary hormones and neuropeptides⁵¹ are influenced by dietary macronutrient quality and balance, stress, and physical activity, all of which also influence appetite and energy balance. There exists an intricate and dynamic cross talk between the gut endocrine system (ghrelin, peptide YY, cholecystokinin (CCK), proglucagon products), the adipocytokines, adipo-hormones (leptin, adiponectin, resistin), and the hypothalamic neuropeptides (neuropeptide Y (NPY), α melanocyte stimulating hormone (α MSH), agouti-

related protein (AgRP), cocaine and amphetamine-regulated transcript (CART), orexin). In summary, these cell-signaling molecules act either directly or indirectly to inhibit or stimulate food intake, and in turn are influenced by meal composition, food quantity, and timing.
Influences on hormonal signaling from food go beyond their caloric aspects. A low glycemic-load diet over two years with a 10% weight loss caused less reduction in resting energy expenditure or metabolic rate than a low-fat diet with an identical 10% weight

loss, as well as greater reductions in insulin resistance, serum triglycerides, C-reactive protein, blood pressure, and self-reported hunger. This demonstrates that changes in dietary composition can affect the physiologic adaptations that defend body weight.⁵² Regular meal frequency (5–6 small meals a day) results in lower total energy intake, greater post-prandial thermogenesis, and lower fasting total and LDL cholesterol and postprandial insulin profiles.⁵³

Table 26.3 Laboratory Testing for Insulin Resistance Indicators

Test to be Performed	Results to be Concerned About
75 g glucose tolerance test with insulin levels	FBS > 90; fasting insulin > 8; 2-hour BS > 140; 2-hour insulin > 40
Ferritin	> 200
Fibrinogen	> 350
High-sensitivity C-reactive protein	> 1.0
Homocysteine	> 8.0
Liver function tests	Elevated AST, ALT, GGT
Low serum magnesium	< 2.0
NMR lipid profile (assessment of lipid particle size)	Small LDL and HDL particles and large VLDL particles
Total cholesterol, HDL-C, LDL-C, triglycerides	HDL levels < 50 for men, < 60 for women; triglycerides > 100; triglyceride/HDL ratio > 5
Uric acid	> 7.0

The sex hormones. Sex hormones are influenced by diet in many ways. One prime example is estrogen, and conditions related to estrogen/progesterone imbalance, including hormonal cancers, endometriosis, premenstrual syndrome, uterine fibroid tumors, fibrocystic breasts, cervical dysplasia, and infertility. Improving hormonal balance can be accomplished by nutritional and lifestyle interventions such as increasing fiber, reducing fat, increasing intake of phytoestrogens, weight loss, and exercise. Certain nutrients and phytonutrients may

enhance specific pathways of estrogen metabolism and detoxification (e.g., isoflavones, essential fatty acids, indole-3-carbinol, B vitamins, magnesium, limonene, and antioxidants). While diet can lead to suppression of hormones in diseases like anorexia nervosa, the focus here will be on modulation of excess endogenous and exogenous estrogens through diet. Table 26.4 provides a summary of symptoms, risk factors, and therapeutic strategies for hormonal imbalance in women.

Symptoms and Signs of Insulin Resistance

- Sugar cravings
- Hypoglycemia (night sweats, irritability, palpitations, dizziness, fatigue relieved by eating)
- Post-prandial fatigue after carbohydrate meals
- Chronic fungal infections
- Fatigue
- Central obesity (waist-to-hip ratio > 0.8 in women and 0.9 in men)
- Polycystic ovary syndrome or infertility
- Hypertension
- Family history of diabetes, hypoglycemia, or alcoholism

These interventions affect many of the underlying physiological causes for hormonal imbalance, primarily the following:

- Diet can modulate estrogen synthesis, receptor activity, and detoxification and metabolism of estrogens. Briefly, estrogen is detoxified and metabolized predominantly through phase I (hydroxylation) and phase II (methylation and glucuronidation). Hydroxylation produces either 2-hydroxyestrone (2-OH), 4-OH or 16 α -OH. 2-OH is a weak estrogen and may have anti-cancer properties. 16 α -OH and 4-OH metabolites have estrogenic and carcinogenic properties. Methylation renders the metabolites more inert, and glucuronidation is the major excretory pathway. All these detoxification pathways are influenced by diet. [A comprehensive review of women's hormones can be found in Chapter 19 (Part I) and Chapter 32 (Part II).]
- Dietary causes of hormonal imbalance include excess energy intake and obesity, leading to increased conversion of androgens to estrogen by aromatase.
- Hyperinsulinemia increases ovarian testosterone production and reduces sex hormone binding globulin (SHBG), increasing free estrogen levels.

Table 26.4 Hormone Imbalance in Women: Symptoms, Risk Factors, and Therapeutic Strategies

Common Symptoms	Risk Factors	Therapeutic Strategies		
		Dietary Recommendations	Nutrient Supplementation	Lifestyle Changes
Premenstrual Syndrome: • Backache, joint or muscle pain • Depression • Edema, swelling, puffiness, or water retention • Feeling bloated • Feeling unable to cope with ordinary demands • Headaches • Monthly weight fluctuation • Mood swings • Premenstrual food cravings (sugar or salt) • Tender, enlarged breasts • Irregular cycles, heavy bleeding, light bleeding • Infertility • Premenstrual migraines • Breast cysts or lumps or fibrocystic breasts • Uterine fibroids	• Use of birth control pill or other hormones • Family history of breast, ovarian or uterine cancer • Exposure to pesticides (food, water, air) • Obesity	Eliminate or reduce: • Alcohol consumption at no more than 3 glasses a week • Artificial sweeteners • Dairy products • Processed foods • Refined sugars and carbohydrates • Saturated/<i>trans</i> fats • Xenobiotics, antibiotics and hormones in food	• Antioxidants and phytonutrients (vitamin E, resveratrol, curcumin, NAC, green tea, selenium, etc.) • Calcium, magnesium and vitamin D • Indole-3-carbinol • Methylation cofactors (folate, B6, B12) • Multivitamin/mineral • Omega-3 fatty acids • Probiotics	• Regular exercise • Stress management • Weight reduction
Perimenopause or Menopause: • Bloating or weight gain around the middle, facial hair • Dry skin, hair and vagina • Hot flashes • Insomnia • Joint pains • Loss of libido or sex drive • Mood swings or depression or anxiety • Night sweats • Palpitations • Trouble with memory or concentration		Increase or emphasize: • 1–2 cups/day of cruciferous vegetables (broccoli, collards, kale, etc.) • Fiber, up to 25–50 g/day; include legumes, whole grains, vegetables, nuts, seed, fruits • Filtered water (reverse osmosis) to eliminate xenoestrogens • Garlic for sulfur and to help with detoxification • Intake of omega-3 fatty acids (wild salmon, sardines, herring, flaxseed) • Organic foods to minimize intake of xenoestrogens, hormones, and antibiotics • Phytoestrogen consumption (soy, flax)		
		*Follow guidelines for balancing glucose metabolism (Table 26.2).		

- High-fat diets promote C-16 α hydroxylation over C-2 hydroxylation.
- Antioxidant-deficient diets may promote the oxidation of catechol estrogens (2-OH and 4-OH) yielding toxic reactive molecules called quinones.
- Alcohol interferes with estrogen detoxification, increasing estradiol levels and the risk of breast cancer.⁵⁴
- Environmental toxins are a significant source of exogenous estrogen exposure (xenoestrogens), many of which find their way into our food supply through pesticides and herbicides. Hormones used in commercial livestock and milk production also increase exposure to environmental estrogens.⁵⁵ Even antibiotics found in the food supply may be associated with increased breast cancer risk by altering gut flora involved in enterohepatic circulation of estrogens.⁵⁶

Fortunately, diet can also promote normalization of estrogen metabolism through diverse mechanisms:

- Dietary fiber and lignins (found in flaxseed, the bran layer of grains, beans, and seeds) reduce the enterohepatic circulation of estrogen by binding unconjugated estrogens and enhancing fecal excretion. They also increase serum levels of SHBG and improve the balance of intestinal flora, reducing intestinal β glucuronidase and deconjugation of estrogens.
- Reducing glycemic load can diminish adverse effects on sex hormones.
- Essential fatty acids (EFAs) increase C-2 hydroxylation and decrease C-16 α hydroxylation in breast cancer cells.
- Probiotics found in food (yogurt and fermented products) and in supplements may help normalize estrogen metabolism by reducing β glucuronidase, producing bacteria, and promoting the formation of anti-carcinogenic enterolactones from lignins.
- Indole-3-carbinol, a compound found in cruciferous vegetables such as broccoli, Brussels sprouts and cabbage, increases the protective 2-OH estrogens. Clinically, it may help in the prevention and treatment of estrogen-related cancers and has been shown to reverse cervical dysplasia.
- Phytonutrients, often mislabelled phytohormones, modulate hormonal response through multiple mechanisms, including competitive inhibition at

the receptor sites, increasing plasma SHBG levels, decreasing aromatase activity, and shifting estrogen metabolism from the C-16 α to the C-2 pathway. The main dietary sources are isoflavones from soy,¹ kudzu root, legumes, and clover, and lignans from flaxseeds, other seed oils, whole grains, legumes and vegetables.

- Other beneficial phytonutrients include curcumin, which can increase hepatic glutathione, and glutathione-S-transferase, hence facilitating the detoxification of quinones from the oxidation of catechol estrogens. Antioxidants in food and supplements may also help reduce the oxidation of catechol estrogens into quinones.
- Multiple plant compounds may inhibit or modulate NF κ B: soy isoflavones have been shown to have anti-tumor and health-promoting effects⁵⁷ that may be a function of their effects on NF κ B. NF κ B is a critical gene transcription factor, the activation of which induces the expression of IL-6. Interleukin 6 (IL-6) is an inflammatory cytokine controlled in part by hormonal feedback mechanisms. Excess IL-6 production stimulates tumorigenesis (breast, prostate, colon, lung, and ovary) and accelerates aging in general.

Other dietary factors promote hormonal balance, including methylation cofactors, folate, pyridoxine, and cobalamin. Elevated intracellular levels of B6 decrease gene transcription responses when estrogen binds to the estrogen receptor. Methylation cofactors are also critical in DNA synthesis, repair, and methylation.

Testing hormonal function is a complicated subject, and is discussed in depth by Dr. Bethany Hays in her contributions to this book (Chapters 19 and 32). In terms of basic assessment approaches, the following are useful laboratory tests:

- 24-hour urine for estrogen metabolism
- 2:16 α OH estrogen ratios
- FSH, LH, estradiol, progesterone, free testosterone, SHBG
- Homocysteine

¹Basic science and clinical data on soy are varied, yet both epidemiological and experimental data in animals and humans, with historically consumed levels of isoflavones, demonstrate protective effects through modification of estrogen receptor activity, increases in SHBG, and lower rates of hormone-dependent cancers. Soy isoflavones may help to restore balance by integrating hormonal ligand activities and by interfering with signaling cascades.

- TSH, free T₄, free T₃, thyroid peroxidase antibodies
- SNPs involved in hormone metabolism and detoxification, such as MTHFR, CYP 1B1, COMT, and GSTM1

The Matrix: Dietary Influences on Oxidative Stress, Mitochondrial Function, and Energy Metabolism

Oxidative stress, with its resultant mitochondrial injury, is a vital common pathway in the pathophysiology of disease. Thousands of peer-reviewed papers delineate the role of oxidative stress in nearly every disease, acute and chronic. Exhaustive epidemiologic evidence suggests that dietary antioxidants are protective against most of the age-related diseases, including cardiovascular diseases, neurodegenerative diseases, cancers, and inflammatory disorders. Interventional studies of antioxidants in the prevention of disease are mixed,⁵⁸ often because of design flaws and confounding factors. Regardless of the current controversies surrounding antioxidant supplementation, recognizing clinical and laboratory manifestations of oxidative

stress and mitochondrial dysfunction is essential. Specific dietary and nutraceutical interventions can reduce oxidative stress and enhance mitochondrial function and bioenergetics (see Tables 26.5, 26.6 and 26.7 for detailed information on common symptoms, associated conditions, and dietary, nutritional supplementation, and lifestyle/environment recommendations). Oxidation and reduction (redox) are basic biochemical reactions that exist throughout nature. In humans, this process is controlled through the exogenous and endogenous exposure or production of oxidants and antioxidants. Redox balance is intimately involved in the control of cell signaling and gene transcription, apoptosis, and aging in each cell and for the total organism. Dietary, environmental, and even psychological factors influence redox status. The biology of aging (and hence all age-related degenerative disease) is intimately connected to uncontrolled oxidation, mitochondrial injury, DNA mutations, and cell death. Oxidants cause damage to biomolecules, including DNA, organelles, cell membranes, lipids, and proteins.

Table 26.5 Oxidative Stress and Mitochondrial Dysfunction: Symptoms, Associated Conditions, and Contributing Factors

Common Symptoms of Oxidative Stress	Common Conditions Associated with Oxidative Stress	Consequences of Free Radical Attack	Dietary Sources of Oxidative Stress and Mitochondrial Injury
• Allergies • Anxiety • Depression • Digestive problems • Dizziness • Fatigue • Headaches • Hypoglycemia • Irritability • Lowered resistance to infection • Muscle and joint pains • Muscle weakness • Poor mental function and cognition	• ALS • Alzheimer’s disease • Asthma • Cancer • Cardiovascular disease • Chronic fatigue syndrome • Diabetes • Fibromyalgia • Iron overload (or hemochromatosis) • Multiple chemical sensitivity • Multiple sclerosis • Occupational exposures • Osteoarthritis • Parkinson’s disease • Rheumatoid arthritis	• Breaking apart and clumping together of proteins • Breaking off proteins from cell membranes, destroying the integrity of the cell • Changes in immune function • Damage and disruption of organelles and the nuclear membrane • Damage to DNA and mutations • Fusion of proteins and fats in cell membranes causing damage to cell communication • Inactivation of enzymes • Increased permeability of cell membrane	• Charbroiled foods and polycyclic aromatic hydrocarbons • Excess sugar/glucose • Excess alcohol that can lead to an increase in cytokines • Exposure to petrochemicals and heavy metals in the diet • Overeating; excess caloric intake • Processed and nutrient-poor foods in the diet • Rancid fats from the diet • Under-nutrition and nutritional deficiencies

Table 26.6 Oxidative Stress: Therapeutic and Protective Strategies

Lifestyle and Environment Changes	Nutritional Supplementation	Botanical Antioxidants
- Minimize environmental toxin exposures - Minimize ionizing radiation (ultra-violet, x-rays, radon) - Reduce exposure to tobacco smoke (first- or secondhand) - Reduce air pollutants with HEPA or ULPA filters (carbon monoxide and nitrogen dioxide) - Avoid excessive or insufficient exercise - Improve inadequate sleep/wake rhythms/cycles - Treat chronic infections - Reduce internal sources of oxidative stress, i.e., gut ecology imbalances - Improve liver and gut detoxification - Reduce exposure to fungal toxins from environmental and internal molds and fungi - Reduce stress; cortisol and stress both increase inflammation - Deep breathing to increase oxygenation of tissues and cells	- Mixed carotenoids including beta- and alpha-carotene, lutein, lycopene, and zeaxanthin - Mixed tocopherols 400 to 800 IU/day—including d-alpha-, gamma- and delta-tocopherols - Proanthocyanidins 50–100 mg/day - Selenium 100–200 mcg/day - Vitamin A 5,000 to 10,000 IU/day - Vitamin B complex - Vitamin C 500–2000 mg/day - Vitamin D 400 IU to 1200 IU/day - Zinc 15–75 mg/day	Botanical antioxidant pigments: - Carotenoids (lycopene, beta-, alpha-, and gamma-carotene, lutein, astaxanthin, zeaxanthin, phytoene, phytofluene) in orange and yellow vegetables - Green tea polyphenols - Anthocyanidins (berries, grapes) - Quercetin (fruit and vegetable rind) - Curcuminoids (turmeric) <i>Trans-resveratrol</i> (phytoalexin from grapes) Herbal antioxidants: - Ashwagandha (<i>Withania somnifera</i>), ancient Ayurvedic adaptogen - Blueberry and bilberry (<i>Vaccinium myrtillus</i>) - Chocolate (<i>Theobroma cacao</i>) - Cranberry (<i>Vaccinium macrocarpon</i>) - Garlic (<i>Allium sativum</i>) - Ginger (<i>Zingiber officinales</i>) - Ginkgo (<i>Ginkgo biloba</i>) - Grape seed (<i>Vitis vinifera</i>) - Green tea (<i>Camellia sinensis</i>) - Hawthorne (<i>Crataegus oxyacantha</i>) - Horse chestnut (<i>Aesculus hippocastanum</i>) - Milk thistle (<i>Silybum marianum</i>) - Purple grape (<i>Vitis labrusca</i>) - Rosemary (<i>Rosmarinus officinalis</i>) - Spinach - Turmeric (<i>Curcuma longa</i>)

The single most important factor regulating the redox balance is diet. Reactive oxygen species (ROS) are generated in the mitochondria as a by-product of the conversion of calories and oxygen into the body's usable energy source—ATP or adenosine triphosphate. Our cells contain 100,000 trillion mitochondria. They consume 90% of our oxygen intake. Forty percent of each cardiocyte is filled by mitochondria. Fatigue is a central component of most diseases, a phenomenon directly related to oxidative stress and mitochondriopathy. Endogenous antioxidant mechanisms such as SOD,

catalases, and GSHPx are dependent on essential dietary nutrients as cofactors (Zn, Cu, Mn, vitamin C, and Se). Exogenous antioxidants (dietary antioxidants, polyphenols, phytonutrients, and conditionally essential nutrients) protect DNA, molecules, mitochondria, and cells from excess oxidative damage. Endogenous oxidant production is directly tied to caloric intake—hence, the reduction in age-promoting cell signaling and gene transcription found in caloric restriction.⁵⁹ (Caloric restriction is the only clearly established method to enhance longevity in animal models.)

Table 26.7 Supplements to Enhance Mitochondrial Function

Basic Mitochondrial Support	Enhanced Mitochondrial Support
• Amino acids: arginine, aspartic acid, cysteine • B complex vitamins • Biotin 1000–2000 mcg/day • Calcium 800–1200 mg/day • Magnesium 400–600 mg/day • Pantothenic acid 50–500 mg/day • Riboflavin 10–100 mg/day • Thiamine 10–100 mg/day • Zinc 20–50 mg/day	• Acetyl-L-Carnitine 500 to 4000 mg/day • Alpha-lipoic acid 100 to 600 mg/day • Coenzyme Q10, 50 to 1200 mg/day • Creatine 2–4 g/day • N-acetylcysteine (or NAC) 500 to 2000 mg/day • NADH 5 to 20 mg/day • Reduced glutathione 300 to 600 mg/day

A nutrient-poor, calorie-rich, high glycemic-load, antioxidant-deficient, refined diet (generally, the standard American diet, or SAD) increases ROS and all of their downstream biologic effects. Exogenous food additives, petrochemicals, heavy metals, and iron excess or deficiency also increase oxidative stress. Dietary factors (or any factors) that increase inflammation (*trans* and saturated fats, deficiencies of essential fatty acids, high glycemic load, lack of fiber, etc.) also increase oxidative stress through cell-signaling pathways involving NFκB and other key transcription factors.⁶⁰

In susceptible individuals, dietary antigens (gluten, dairy, eggs, etc.) trigger imbalances in Th1 and Th2 cytokines, thus increasing oxidative stress. Cell membrane and mitochondrial membrane function, critical in cell signaling and signal transduction, is determined in part by the quality of membrane fatty acids. Fluid monounsaturated and polyunsaturated (omega-3) fatty acids support normal membrane function and help to balance the inflammatory prostaglandin cascade. ROS can also trigger cell signals that increase inflammation through regulation of gene transcription factors such as NFκB, and modulation of the PPAR family of nuclear receptors leading to a feed-forward cycle of inflammation, oxidative stress, mitochondrial injury, and accelerated disease processes and aging.

Dietary interventions to reduce oxidative stress and mitochondrial damage must take into consideration the way in which the redox system functions. By design, it is dependent on multiple antioxidants from the diet, endogenous antioxidants and their cofactors, as well as relatively higher levels of dietary phytonutrients such as polyphenols. Each antioxidant becomes oxidized in the process of reducing ROS. In turn, it is reduced down the chain, thereby preventing uncontrolled oxidative stress reactions. This occurs in every cell and tissue and is dependent on an adequate supply of the basic dietary antioxidants such as vitamin C, the tocopherols, carotenoids, and the proper substrates for synthesis and recycling of glutathione (glutamine, glycine, cysteine, selenium, and phytonutrients) and lipoic acid. Glutathione is the final common pathway for the reduction of oxidants, and also plays a critical role in detoxification. Glutathione is depleted and oxidative stress increased in most chronic disease.⁶¹

It must be remembered, however, that reduction *and* oxidation together are involved in cell signaling. Quenching all ROS is not the objective. Creating redox balance is central to the prevention and treatment of disease, however difficult to clinically assess or measure. Diagnosing oxidative stress and acquired mitochondrial dysfunction is both difficult and important as a target for therapy. (Table 26.8 contains a list of tests that can be used to detect problems in these areas.) Further, it is difficult to determine whether oxidative stress is the cause or consequence of age-related disease.⁶² Indeed, it is both, and modulation of redox status through dietary macronutrients, micronutrients, and phytonutrients is an important clinical therapeutic tool.

Dietary strategies to balance redox status must begin by increasing intake of a variety of antioxidant-rich foods,⁶³ as well as foods that provide phytonutrients such as flavonoids and polyphenols (found in teas, red wine, cocoa).^{64,65} The concept of a “metabolic tune-up” was introduced by Bruce Ames, PhD. This important strategy focuses on the use of supplements to optimize function by reducing DNA damage and mitochondrial oxidative decay, and improving the K_m of enzymes by providing higher doses of the corresponding micronutrient co-enzyme.⁶⁶ While evidence in large controlled human clinical trials is limited, the intelligent use of nutraceuticals in modulating redox status and optimizing function is safe and can be clinically effective.

Table 26.8 Testing for Oxidative Stress and Mitochondrial Dysfunction

Testing for Oxidative Stress	Testing for Mitochondrial Dysfunction
• 4-hydroxy-2(E)-nonenal (4-HNE) • Antioxidant enzyme assays of superoxide dismutase (SOD), glutathione peroxidase (GSHPx), and catalase • Assessment of iron overload: transferrin saturation, ferritin, serum iron and total iron binding capacity • Assessment of antioxidants (blood levels) can occasionally be helpful (e.g., vitamin A, vitamin E, CoQ10, and beta-carotene) • F2-isoprostanes • Lipid peroxides (TBARS) in urine or serum • Malondialdehyde (MDA) • Myeloperoxidase • Serum lactoferrin • Urinary 8-hydroxy-2-deoxyguanosine (8-OH-2DG) • Urinary hydroxyl markers, including catechol and 2,3-dihydroxybenzoate measured after an aspirin and acetaminophen challenge • Whole blood or intracellular glutathione and reduced glutathione	• Cardio metabolic stress testing: VO2max • Muscle biopsy (rarely) • Organic acids

The Matrix: Dietary Influences on Detoxification

Diet and detoxification intersect in two important ways. Diet is a source of many environmental and natural toxins. Diet also is the source of amino acids, fiber, nutrients, and phytonutrients critical for facilitating elimination of both metabolic and environmental toxins through phase I and phase II detoxification, as well as through gastrointestinal and renal excretion. Diet interacts with many phase I and phase II genes regulat-

ing detoxification and can be used as an aid in coping with the increased burden of environmental and dietary toxins. A number of degenerative and chronic diseases have been linked to toxic overload, or impaired detoxification; these include the neurodegenerative diseases, cancers, chronic fatigue, fibromyalgia, and endocrine, autoimmune, and inflammatory disorders. (Analysis of these topics and the evidence behind them can be found in Chapters 22 and 31.)

The major sources of food toxins include the petrochemical residues in our food and water from certain farming practices, mercury from industrial waste (often found in predatory fish), lead in our water supply, advanced glycation end products from food preparation, polycyclic aromatic hydrocarbons from char-broiled meats, *trans* fat, and naturally occurring plant toxins such as aflatoxins. Minimizing the exposure to these toxin sources is important; however, the most important role for diet is providing the substrates and cofactors for optimal detoxification through cellular, hepatic, gastrointestinal, and renal mechanisms.

With the advent of four million synthetic compounds, heavy metals, and the metabolic/digestive waste from the planet's billions of people (not to mention the commercially raised livestock), our innate detoxification-coping capacities have been exceeded. All humans in the 21st century store chemical toxins, and about 25% store heavy metals in our tissues. Managing this toxic burden is metabolically expensive, and requires adequate nutrients and cofactors that support detoxification pathways. The major categories of toxins are chemical toxins, heavy metals, microbial compounds (from bacteria, yeast, or other organisms), and the breakdown products of normal protein metabolism. The heavy metals most implicated in disease are lead, mercury, cadmium, arsenic, nickel, and aluminum. The chemical toxins include toxic chemicals and volatile organic compounds (VOCs), solvents (cleaning materials, formaldehyde, toluene, benzene), drugs, alcohol, pesticides, herbicides, and food additives. Bacteria and yeast in the gut produce waste products, metabolic products, and cellular debris that can interfere with many body functions and lead to increased inflammation and autoimmune diseases. These include endotoxins, toxic amines, toxic derivatives of bile, and various carcinogenic substances such as putrescine and cadaverine. Last, the body must rid itself of the by-products of normal protein metabolism, including urea and ammonia.

The detoxification system is comprised of the skin, liver, kidneys, intestines, and lungs. It relies on the right balance of macronutrients, fiber, micronutrients, and phytochemicals to be effective. For example, methylation cofactors are essential for phase II detoxification. Adequate protein nutrition is required to supply the amino acids used in phase II reactions such as glutathione and glycine conjugation and sulfation. Phytochemicals (including, for example, the glucosinolates in cruciferous vegetables and the catechins in green tea) increase the activity of glutathione-S-transferases. Teas may have other benefits such as binding metals in the diet.⁶⁷ Polyphenols⁶⁸ (flavonoids in berries and other plant foods with deeply colored pigments) enhance the expression of γ glutamylcysteine synthetase, increasing intracellular glutathione concentration, which is depleted in many chronic diseases. Catechol-O-methyltransferase (COMT) and cytochrome enzymes, including 1B1, detoxify toxic estrogen metabolites. These enzymes can be facilitated through dietary intervention with methylation cofactors and indole-3-carbinol from cruciferous vegetables. These gene-environment interactions influence the risks of cancer, osteoporosis, cardiovascular disease, neurodegenerative disease, depression, and more.⁶⁹

The functional capacity to metabolize and excrete toxins varies from person to person and determines the rate and amount of toxin accumulation. The total load—all the exposures and influences that tax an individual's physiology—need to be considered when trying to create optimal health. Even low-level toxins have a profound effect on cells, biological systems, and their proper functioning, so efforts at limiting exposure are important, and maximizing the effectiveness of our detoxification capacity and elimination organs is critical. The clinical approach to detoxification must be individualized, based on biochemical and genetic variations from patient to patient (as well as differences in their environmental exposures). However, there are some basic principles that encourage mobilization of toxins, maximize their excretion, and minimize their redistribution in other sites in the body. It is important to ensure these aspects of healthy detoxification are working well together. They depend on the right food, exercise, adequate sweating, vitamins, minerals, accessory (or conditionally essential) nutrients, hyperthermic or heat treatments like saunas or steam baths, stress management, and occasionally heavy metal chelation treatments with medications like DMSA for removal of accumulated mercury, arsenic, and lead.

The translation of the science of detoxification into clinical practices is not mature; however, the application of that science to common health problems can be a remarkably effective tool for the clinician. (Please refer to Chapter 31 on Detoxification and Biotransformation for a more comprehensive discussion of these and additional relevant issues.) Assessment of exposures, testing endogenous detoxification capacity, identifying a patient's detoxification-related SNPs, and performing provocation tests for heavy metals are all useful evaluation approaches. Table 26.9 contains a list of tests by which toxic load and detoxification capacity can be assessed, and the suggestions provided in Table 26.10 can help to correct impaired detoxification systems, maximize endogenous detoxification capacity, and safely eliminate stored toxins. Treatment choices need to be individualized for each patient, depending on symptoms, genetic predispositions, environmental exposures, functional capacity, dietary habits, concomitant illnesses, and medications.

Table 26.9 Assessing Toxic Burden and Detoxification Capacity

- Detoxification SNPs can be evaluated: phase I (CYP 1A1, 1B1, etc.) and phase II (COMT, NAT, GSTM1, GSTP1, etc.).
- Detoxification challenge tests can assess functionality (provocations with caffeine, aspirin, acetaminophen).
- Detoxification enzymes can be measured:
 - Reduced glutathione
 - Glutathione peroxidase
 - SOD (superoxide dismutase)
- Heavy metal toxicity can be assessed:
 - RBC or whole blood
 - Hair analysis
 - Chelation challenge with DMSA
- Chemical antibodies to various toxins and metals can occasionally be useful.
- Organophosphates can be identified through a 24-hour urine collection.
- Organochlorine residues can be identified through a fat biopsy. This is used mostly for research purposes, but certain labs process clinical specimens.
- Urinary d-glucarate can be used to assess exposure to industrial toxins or xenobiotics.
- Urinary organic acids—specific compounds can be measured:
 - Sulfates
 - Pyroglutamate
 - Orotate
- Urinary porphyrins, by-products of damaged hemoglobin, can be clues to damage done by chemical or heavy metal toxins.
- Urinary trimellitic anhydrides (TMA) can be used to assess exposure to volatile organic compounds (VOCs).

Table 26.10 Detoxification Strategies: Dietary, Environmental, and Lifestyle Approaches

Avoiding and Removing Toxins	Dietary Support for Detoxification	Nutritional Supplementation
• Avoid excess exposure to environmental petrochemicals (garden chemicals, dry cleaning, car exhaust, secondhand smoke) • Clean and monitor heating systems for release of carbon monoxide, the most common cause of death by poisoning in America • Drink filtered water (reverse osmosis or carbon filter) • Enhance lymphatic flow with regular exercise, yoga, or lymphatic massage • Facilitate excretory functions: 1–2 bowel movements a day; 6–8 glasses of water a day; sweat regularly and profusely with exercise and the use of steam baths or saunas • HEPA/ULPA filters and ionizers to reduce dust, molds, volatile organic compounds, and other sources of indoor air pollution • House plants • Minimize EMR (electromagnetic radiation) and ionizing radiation • Organic food and animal products to avoid petrochemical pesticides, herbicides, fumigants, hormones, and antibiotics • Reduce heavy metal exposure (predatory and river fish, water, lead paint, thimerosal-containing products, etc.) • Reduce or eliminate the use of toxic household and personal care products (aluminum-containing underarm deodorant, antacids, and pots and pans) • Remove allergens from the diet and the environment • Treat gut infections and imbalanced gut ecology—often a source of endotoxins	• Bioflavonoids in grapes, berries, and citrus fruits • Burdock root for liver detoxification and increasing the production of urine and sweat • Celery increases urine flow • Chlorophyll in dark green leafy vegetables and in wheat grass • Cilantro can help remove heavy metals • Cruciferous vegetables (cabbage, broccoli, collards, kale, Brussels sprouts) 1 cup daily • Curcuminoids (turmeric and curry) • Dandelion greens help liver detoxification, improve the flow of bile, and increase urine flow • Foods that contain the monoterpene limonene (citrus peel, caraway, and dill weed oil) can boost glucuronidation used for hormones and many medications • Fresh vegetable juices (carrots, celery, cilantro, beets, parsley, ginger) • Garlic (a few cloves a day) • Green tea boosts liver detoxification (increases GST enzymes) • High-quality, sulfur-containing proteins (found in eggs, whey protein, garlic, onions) • Increase fiber intake through use of beans, whole grains, vegetables, fruits, nuts and seeds • Pycnogenol in grape seeds is a powerful antioxidant that can protect against toxic by-products of detoxification • Rosemary has carnosol, a potent booster of detoxification enzymes • Try decaffeinated green tea in the morning • Try herbal detoxification teas containing a mixture of burdock root, dandelion root, ginger root, licorice root, sarsaparilla root, cardamom seed, cinnamon bark, and other herbs	• Alpha-lipoic acid 100–600 mg/day • Amino acids (taurine 500 mg 2x/day, glycine 500 mg 2x/day) • B-complex vitamins • Bioflavonoids • Carnitine 1000–3000 mg/day in divided doses • Daily high-potency multivitamin/mineral formula • Essential fatty acids to facilitate glucuronidation • Extra-buffered vitamin C with mineral ascorbates in powder, capsule, or tablets during periods of increased detoxification • Milk thistle (silymarin) 70 to 210 mg/day • Mixed carotenoids 15,000 to 25,000 U/day • Molybdenum 50 to 200 mcg/day • N-acetylcysteine 500 to 1000 mg/day • Probiotics to help normalize gut flora and reduce endotoxins • Selenium 200 mcg/day • Zinc 30 to 50 mg/day

The Matrix: Dietary Influences on Inflammation

Inflammation and immune dysfunction are both cause and manifestation of core physiologic disturbances that are intimately associated with accelerated aging and chronic disease. The inflammatory response cuts across all organ systems and medical specialties, and wears many different guises. For that reason, the subject is addressed frequently in this book, from a number of different perspectives. For in-depth discussions of the underlying physiology, as well as the assessment and management of the inflammatory process, see Chapters 18, 23, and 27. In this chapter, we draw many of those threads together to examine the role of diet as an underlying common influence on the inflammatory process.

Inflammation can function both as a systemic trigger for, and as a mediator in, all the major degenerative diseases, including cardiovascular disease, neurodegenerative disease, and the increasingly prevalent allergic and autoimmune disorders. Diet and exercise are the two major modulators of the inflammatory response. Other inflammatory triggers include infections, gut dysbiosis, toxins, stress, environmental allergens, and trauma. Cytokines (interferon, interleukins, tumor necrosis factor, etc.) and eicosanoids (prostaglandins, prostacyclins, leukotrienes, thromboxanes) are the messenger molecules of the immune system. They upregulate or down-regulate inflammation, depending on the needs of the organism. A maladaptive shift toward inflammation occurs in the face of specific inputs (high glycemic-load diet, intake of food allergens, inflammatory fats) and in the absence of other inputs (omega-3 fatty acids, exercise, etc.).

While inflammation has many causes, two factors stand out in our 21st century epidemic of chronic disease:

- first, the increase in inflammatory response secondary to a high glycemic-load diet, and the resultant metabolic syndrome;
- second, and closely related, is our sedentary lifestyle.

A host of other autoimmune, allergic, and inflammatory disorders are related to diet in two major ways: genetic or acquired food sensitivities or allergies, and macronutrient, micronutrient, and phytonutrient modulation of the inflammatory response.

Chronic, age-related degenerative diseases.

Inflammation is central to all of the degenerative diseases that represent the leading causes of death in the

21st century. Elevations of inflammatory markers such as C-reactive protein and IL-6 have been found to increase all-cause mortality,⁷⁰ cardiovascular and neurodegenerative diseases, many cancers, macular degeneration, diabetes, and hypertension. Identifying all the proximal triggers of inflammation in patients is important. Often, dietary factors are the most significant modulators of inflammation. A high glycemic-load diet,⁷¹ metabolic syndrome,⁷² and a sedentary lifestyle are responsible for the majority of inflammation and degenerative disease. Additional dietary factors that contribute to inflammation include saturated and *trans*-fatty acids,⁷³ caffeine,⁷⁴ alcohol in excess,⁷⁵ deficiency of antioxidants, micronutrient deficiencies, and a low-fiber diet (which adversely affects gut flora and increases exposure to metabolic and environmental toxins). Pharmacologic modulators of inflammation have been proposed, including aspirin, non-steroidal anti-inflammatories (NSAIDs), and non-traditional anti-inflammatories such as statins, thiazolidinediones, and fibrates. However, a comprehensive lifestyle approach—including the modulation of diet by reduction in saturated⁷⁶ and *trans* fats and glycemic load; use of multivitamins,⁷⁷ supplemental antioxidants⁷⁸ (key cell-signaling factors in gene transcription of inflammatory mediators), omega-3 fatty acids,⁷⁹ fiber,⁸⁰ and probiotics,⁸¹ and the addition of regular exercise⁸²—can collectively reduce systemic inflammatory mediators to a greater degree than pharmacologic interventions. Interventions that reduce inflammation reduce overall morbidity and mortality across the disease spectrum.

Testing for indicators of inflammation. A general assessment of inflammation is provided by C-reactive protein and sedimentation rate. Since those will not localize the source of inflammation, other approaches are used to further clarify the clinical picture; these include testing for celiac disease (discussed below) and antibody testing for both autoimmune conditions (thyroid, anti-thyroglobulin, anti-nuclear, and other antibodies) and chronic infections (including polymerase chain reaction, or PCR, testing and assessment of yeast overgrowth and fungal organisms). Stool and vaginal cultures can be done, as well as urinary organic acids for yeast metabolites (which are all inhibitors of metabolic function). Indicators of gut inflammation can be assessed through urinary organic acids and stool analysis (dysbiosis), hydrogen breath testing (small bowel bacterial overgrowth), and lactulose-mannitol challenge (intestinal permeability).

Food allergy, GALT, and immunity: Relationships to chronic disease. In addition to the factors discussed above, two other diet-inflammation relationships have important clinical relevance: food sensitivities of various types, and the role of diet in gut microecology and GALT activation.

Food allergy is not a single disease, nor is it caused by one pathophysiologic disturbance. Food allergy (or sensitivity) can be defined as an adverse immunological or hypersensitivity response to food. This response may be antibody or cell mediated. There are also many food reactions that are not immunologically mediated, including food intolerances (e.g., lactose) and food sensitivities (e.g., preservatives, additives, MSG, sweeteners such as aspartame, sulfites, etc.). Classic food allergy⁸³ has been recognized as IgE dependent and is acute in onset (urticaria, asthma, or anaphylaxis); food sensitivities tend to be either IgE associated and delayed in onset (atopic dermatitis) or cell mediated and both delayed and chronic (celiac disease).

Some recognition has been given to the role of IgG-mediated immune response and chronic disease,⁸⁴ but the research has been sparse and inconclusive, due to the pleomorphic nature of individual responses to foods. Using elimination/provocation diets and, to some degree, IgG food antibody testing,⁸⁵ clinicians have identified inflammatory triggers responsible for a wide array of chronic symptoms not mediated by the classic IgE food allergy pathway. Conditions responsive to elimination diets include: headaches, IBS, fatigue, autoimmune disorders, chronic sinusitis, arthritis, inflammatory skin disorders, fibromyalgia, and CFIDS. While these disorders are often multifactorial, persistent immune activation of the GALT by foods can be a perpetuating factor. Food sensitivities or chronic GALT activation can be primary or secondary, cell-mediated responses, antibody-mediated responses, or both. However, in most cases, some precipitating event disturbs the gut mucosal integrity, leading to GALT activation that is then mediated by genes, food proteins, and microbial antigens. This initiates either a Th2 allergic response or a Th1 autoimmune response. Systemic inflammation then ensues, along with a wide host of common and often difficult-to-treat ailments. Elimination diet is one of the most powerful and underutilized tools available to the clinician for addressing chronic symptoms. (Elimination diet as a clinical tool is discussed in Chapter 35.)

Oral tolerance to common food antigens is impaired when the gut mucosal barrier is disturbed. This barrier must achieve a fine balance among very different and vitally important functions: fending off microbial antigens from gut flora, mounting a rapid response to pathogens, allowing assimilation of innocuous food antigens, and facilitating (or suppressing) inflammatory responses. Changes in diet to promote normalization of gut flora and to reestablish normal gut mucosal barrier integrity are critical in addressing the morbidity of chronic allergic and inflammatory diseases. Because health and disease function in a web-like manner, discerning cause or effect in any particular disease may be difficult (or even irrelevant). An approach that removes offending agents and restores balance within the core systems will yield remarkable clinical results. Food allergy or sensitivity may be the cause or the result of disturbed gut mucosal integrity. To resolve the clinical problem at hand, attention must be paid to both removing the offending allergens (forever, in the case of a genetically programmed immune response such as in celiac disease, or temporarily, in the case of an acquired IgG food sensitivity because of an intestinal insult), *and* restoring normal gut microecology and mucosal integrity.

Gluten—a pervasive influence. The relationship between gluten and chronic disease represents a classic food-disease connection. Unfortunately, the variable nature of clinical response to this single food antigen can obscure the diagnosis. Genetic susceptibility to gluten is found in up to 30% of those of European descent, yet in only 1% of the population is the disease fully expressed. There appears to be a graded response to gluten from mild to life threatening. The list of conditions associated with celiac disease is long.⁸⁶ (See Table 26.11.)

Screening for celiac disease is important in the face of *any* inflammatory, autoimmune, or chronic disease. Typical screening is done for IgA and IgG antigliadin antibodies and IgA antiendomysial antibodies; tissue transglutaminase (tTG) antibodies can be tested for in questionable cases. Total IgA should always be measured to rule out IgA deficiency. If IgA deficiency is present, tTG IgG can be helpful. These tests lack 100% sensitivity (or specificity). Intestinal biopsy for villous atrophy is the gold standard,⁸⁷ but lesions can be patchy and there is evidence that clinical symptoms and non-local manifestations can be independent of mucosal pathology. Occasionally useful is testing for HLA DQ2 and HLA DQ8 genotypes (which are present in 95% of celiac

Section VI

A Practical Clinical Approach

cases), especially in the face of IgA deficiency.⁸⁸ Stool testing for local IgA anti-gliadin antibodies or tTG can be confirmatory in suspicious cases where serum IgA or IgG and tTG are negative. A 12-week trial of elimination/provocation is, however, the most useful diagnostic approach.

The intersection of inflammation and clinical disease, and the opportunities for disease management, are, perhaps, the most fruitful, effective, and satisfying areas of functional medicine. The increasing prevalence of two

major clinical problems—chronic degenerative diseases, and chronic inflammatory and immune diseases—are both intimately tied to diet and lifestyle, and those tools promise the greatest clinical effect when applied intelligently. Tables 26.12 and 26.13 summarize some of the most common conditions associated with inflammation and the major causes of inflammation, and they provide suggestions for nutrient supplementation, botanical anti-inflammatory agents, and lifestyle changes.

Table 26.11 Clinical Presentations of Celiac Sprue

Common Features	Less Common Features	Associated Conditions	Complications
Adults • Iron-deficiency anemia • Diarrhea Children • Diarrhea • Failure to thrive • Abdominal distention	General • Short stature • Delayed puberty Gastrointestinal • Recurrent aphthous stomatitis • Recurrent abdominal pain • Steatorrhea Extraintestinal • Folate-deficiency anemia • Osteopenia or osteoporosis • Dental-enamel hypoplasia • Vitamin K deficiency • Hypertransaminasemia • Thrombocytosis (hyposplenism) • Arthralgia or arthropathy • Polyneuropathy • Ataxia • Epilepsy (with or without cerebral calcification) • Infertility • Recurrent abortions • Anxiety and depression • Follicular keratosis • Alopecia	Definite associations • Dermatitis herpetiformis • IgA deficiency • Type 1 diabetes • Autoimmune thyroid disease • Sjögren's syndrome • Microscopic colitis • Rheumatoid arthritis • Down syndrome • IgA nephropathy Possible associations • Congenital heart disease • Recurrent pericarditis • Sarcoidosis • Cystic fibrosis • Fibrosing alveolitis • Lung cavities • Pulmonary hemosiderosis • Inflammatory bowel disease • Autoimmune hepatitis • Primary biliary cirrhosis • Addison's disease • Systemic lupus erythematosus • Vasculitis • Polymyositis • Myasthenia gravis • Schizophrenia	• Refractory sprue • Enteropathy-associated T-cell lymphoma • Carcinoma of the oropharynx, esophagus, and small bowel • Ulcerative jejunoileitis • Collagenous sprue

Information from Farrell RJ, Kelly CP. Celiac sprue. *N Engl J Med*. 2002;346:180-88.

Table 26.12 Inflammation: Major Causes and Associated Conditions

Common Conditions Associated with Inflammation	Major Causes of Inflammation
• Allergies • Asthma • Attention deficit disorder (ADD) • Autism • Autoimmune diseases (lupus, rheumatoid arthritis, autoimmune thyroiditis) • Cancer • Cardiovascular disease • Chronic fatigue syndrome (CFS) • Cystitis • Dementia • Dermatitis (eczema, psoriasis, acne) • Diabetes • Emphysema and bronchitis • Fibromyalgia • Glomerulonephritis • Inflammatory bowel diseases (IBD) • Inflammatory liver disease (hepatitis from alcohol, sugar, viruses) • Irritable bowel syndrome (IBS) • Neurodegenerative disease (Alzheimer's, Parkinson's, MS, ALS) • Obesity • Osteoarthritis • Prostatitis • Reflux (GERD) • Sinusitis	• Allergens – Environmental allergens (dust, animal dander, pollens, etc.) – Common food allergens and sensitivities: - Citrus - Corn and corn products - Dairy products—milk, cheese, yogurt - Gluten grains—wheat, barley, oats, rye, spelt, kamut - Yeast - Eggs • Dysglycemia and insulin resistance (the major dietary causes of inflammation) • Environmental allergy (pollens, dust, molds, animals) • External (exogenous) toxins – Synthetic compounds (air pollution, water pollution, food additives, pesticides) – Prescription drugs, drugs of abuse, cosmetics, household chemicals – Naturally occurring compounds (microbial toxins, mycotoxins) – Plant toxins – Heavy metals (e.g., lead, mercury, arsenic, cadmium) • Infection—acute or chronic • Internal (endogenous) toxins, gut-derived: – Ammonia – Nitrites – Amines such as cadaverine and putrescine • Lack of blood flow • Malnutrition • Nutrient deficiencies (e.g., omega-3 fatty acids, zinc, vitamin C, folate) • Oxidative stress • Physical injury or trauma • Psychological stress

Table 26.13 Managing Inflammation: Dietary Suggestions, Anti-inflammatory Phytonutrients, and Lifestyle Recommendations

Dietary and Nutrient Suggestions	Anti-Inflammatory Phytonutrients	Lifestyle Recommendations
• Elimination Diet for assessment (to identify inflammatory triggers) and treatment (to relieve the inflammatory burden)* • Balanced B complex • Essential fatty acids (flax, fish, and evening primrose oil) • Mixed carotenoids 15,000–25,000 IU/day • Multimineral supplement • Vitamin A 5000 to 10,000 IU/day • Vitamin C 500 to 2000 mg/day • Vitamin E mixed tocopherols 400 to 800 IU/day	Bioflavonoids • <i>Ginkgo biloba</i> • Pycnogenol or grape seed extract • Quercetin • Rutin Immune tonic herbs • Astragalus • Garlic • Licorice • Siberian ginseng (<i>Eleutherococcus senticosus</i>) Immune tonic mushrooms • Hakumokuji (<i>Tremella fuciformis</i>) • Kawaratake (<i>Coriolus versicolor</i>) • Maitake (<i>Grifola frondosa</i>) • Reishi (<i>Ganoderma lucidum</i>) • Shitake (<i>Lentinula edodes</i>) • Tochukaso (<i>Cordyceps sinensis</i>) Other anti-inflammatory and immune-boosting herbs and compounds • Aloe vera • Boswellia (<i>Boswellia serrata</i>) • Capsaicin • Enzymes (bromelain and other proteolytic enzymes) • Ginger (<i>Zingiber officinale</i>) • Glucosamine and chondroitin sulfate • Green tea (<i>Camellia sinensis</i>) • Immune-active whey proteins with immunoglobulins and natural antibody complexes • Niacinamide • Probiotics • Turmeric (<i>Curcuma longa</i>)	• Correct insulin resistance—see recommendations in Table 26.2 • Exercise • Reduce obesity • Relaxation, meditation, laughter: experiment and explore – Autogenic training – Breathing techniques – Chakra therapy (group laughing session) – Guided imagery – Hypnosis – Journaling – Laughter—what makes you laugh? – Meditation – Mindfulness – Prayer – Psychotherapy – Relaxation techniques – Support groups – Yoga

*Please see the Appendix for a comprehensive elimination diet protocol.

The Matrix: Dietary Influences on Digestive Function

The health of the gut determines what nutrients are absorbed and therefore it is directly linked to the health of the total organism. It is often said that we are what we eat, but it is more accurate to say we are what we absorb. Chronic intestinal inflammation may lead to nutrient malabsorption and the resultant effects of chronic micronutrient deficiencies. Regardless of the illness, the role of gut health is critical. Gut imbalances can create, or fuel, an upregulated immune system, and nutritional imbalances from improper absorption can adversely affect the entire organism. This makes the gut a primary target for clinical intervention in the treatment of disease and the creation of health.

Intestinal health can be defined as the optimal digestion, absorption, and assimilation of food in the context of a balanced microecology, and an intact intestinal barrier function. These processes are continuously influenced by dietary and environmental inputs. The well-recognized inflammatory disorders—asthma, allergic rhinitis, inflammatory bowel disease, arthritis, and autoimmune diseases—and the recently recognized inflammatory disorders—cardiovascular disease, diabetes, obesity, neurodegenerative disease, and cancer—can often be traced back to the gut. When a clinician thinks “inflammation,” the next thought must be “the gut.”

Causes of gut dysfunction. Over 100 million Americans have digestive disorders. There are more than 200 over-the-counter (OTC) remedies for digestive disorders, many of which—most unfortunately—can create additional digestive problems. Visits for intestinal disorders are among the most common to primary care physicians. Rampant intestinal ill health is *not* a normal condition of human beings. It is the result of major changes in our evolutionary diet and the effect on the balance of the intestinal ecosystem. Cordain and colleagues, in “Origins and Evolution of the Western Diet: Health Implications for the 21st Century,”⁸⁹ outline the data that connect changes in our food patterns since the agricultural revolution to the diseases of today. The collision of our ancient genome with a modern diet is a significant causal factor in modern diseases. Cordain claims that seven fundamental nutritional characteristics of our diet have changed, and that these explain the dramatic rise in chronic and degenerative diseases:

1. glycemic load,
2. fatty acid composition,
3. macronutrient composition,
4. micronutrient density,
5. acid-base balance,
6. sodium-potassium ratio, and
7. fiber content.

Among many other adverse influences on health, these changes have affected the gut by changing the microenvironment of the intestinal tract. Problems can arise from inadequate stomach acid, poor digestive enzyme function, inadequate nutrient absorption, destruction of healthy bacteria, overgrowth of abnormal bacteria or yeasts, fermentation of starches, and disturbed signals to the enteric nervous system⁹⁰ of the gut, secondary to stress, various toxins, and antigens. Recent research has connected gut problems to symptoms and diseases far outside the gut: allergies, asthma, eczema, arthritis, headaches, autism, fibromyalgia, chronic fatigue and more.

The intestine is an “intelligent” organ. In addition to its role in digestion, absorption, and assimilation of nutrients, it interacts directly with the environment and protects the host from external threats through the microflora, the mucosal intestinal barrier, and the local immune system.⁹¹ It is a complex ecosystem, much like the rainforest; if its balance is disturbed, its problems can create a ripple effect throughout the entire system. The forces that disturb the equilibrium are rampant: poor diet, food allergens, toxic food components, viruses, bacteria, parasites, overgrowth of yeast, use of medications (especially antibiotics, anti-inflammatories, and acid blocking drugs), various illnesses, and stress.

Investigating gut dysfunction. We must ask some key questions to understand why the gut may be malfunctioning; the answers will help the clinician design a program to correct underlying dysfunctions:

- Are digestive enzymes and acid production adequate to break food down to its component parts and make the food particles small enough for absorption?
- Is the gut mucosal barrier working properly, selectively absorbing the right things (amino acids, sugars, fats, vitamins, and minerals, etc.), and keeping out the harmful things (undigested food particles, microbial particles, or toxins)?

- Does the microflora have the right kind and amount of good healthy bacteria, located in the right places along the digestive tract?
- Are the components of the microflora in proper balance, without undue competition from potentially harmful bacteria, yeasts, and parasites?
- Is the microflora getting the right kind and amount of fiber (both insoluble and soluble) and nutrients to stay healthy and flourishing?
- Are problems in the gut causing stress on the liver and immune system because toxins or allergens are being absorbed through a leaky gut or disturbed intestinal barrier?

The process of answering these questions will identify the starting point(s) to help the patient restore intestinal health and treat the host of disorders that manifest as direct intestinal symptoms or symptoms from more distant sites.

Therapeutic options for digestive imbalances. The term “functional foods” has entered the nutritional and popular lexicon to indicate a food that “is shown to beneficially affect one or more target functions in the body beyond adequate nutritional effects in a way that is relevant to either the state of well-being and health, or to a reduction in disease incidence.”⁹² This paradigm—that there are foods *and* nutrients that impair gut function and others that enhance it—is a useful lever to impact chronic health complaints that exist across multiple organ systems.

A number of these foods and nutrients have been studied and found to repair and heal the intestinal mucosal barrier, improve microflora balance, and modulate the proinflammatory state of the GALT.^{93,94} Important examples include:

- Glutamine improves gut and systemic immune function, especially in patients in prolonged states of parenteral nutrition; helps heal GI mucosa after damage from radiation or chemotherapy; and reduces episodes of bacterial translocation and clinical sepsis.
- Arginine is a precursor for nitric oxide, and has demonstrated benefits in inflammatory bowel diseases, as well as intestinal diseases resulting from trauma, critical illness, or cancer.
- Zinc leads to improvements in children with GI diseases; prevents childhood mortality; and corrects deficiencies linked to anorexia, hypogeusia, poor

growth, alopecia, delayed sexual maturation, skin diseases, and severe diarrhea.

- Vitamin A plays an important role in epithelial cell integrity, immune function, and retinal function. Deficiencies are implicated in the risk of diarrhea, respiratory infections, impaired gut function, and death in children.
- Probiotics enhance mucosal immune defense, protect against microbial translocation and colonization, and improve inflammatory bowel disease and atopic disease.
- Prebiotics (fermentable starches such as inulin and fructose oligosaccharides) have many potential health benefits, such as improved bowel function, increased mineral absorption, and lowered risk of colon cancer, though human studies are limited.
- Gamma linolenic acid leads to progressive improvement in rheumatoid arthritis with long-term use; suppresses human T-cell proliferation, tumor growth, and metastasis; normalizes nerve conduction and sciatic endoneurial blood flow; and suppresses oxidative damage associated with diabetes (when administered with vitamin C).

Clinically, functional medicine finds some of its most powerful applications with inflammatory diseases mediated by gut dysfunction and improved by repairing gut function. Applying basic principles of functional medicine such as the 4R program (see Chapter 28 for an in-depth presentation of this gut repair approach) can correct many conditions related to food allergy and gut dysbiosis (often synergistically related). While many types of interventions to restore gut balance may be necessary—including elimination of food allergens and heavy metals, use of herbs, medications, enzymes, probiotics, essential fatty acids, amino acids and various nutrients, and the addition of stress management and exercise to the patient’s lifestyle—improving diet is critical. By restoring our dietary patterns to correct the adverse evolutionary shifts discussed above, many of the dietary causes of gut dysfunction and related illnesses can be corrected.

A number of clinical tools can be extremely useful in improving gut function. While more clinical research is needed, these interventions are based on the most fundamental principle of functional medicine: remove what harms and provide what heals. The details may be different from person to person, but the concept will

guide diagnosis and therapy. This is an area of medicine where some clinical applications that are logical extensions of the underlying science have outpaced the clinical research literature; fortunately, the positive clinical outcomes from this approach warrant its application where conventional approaches routinely fail.

Elimination diet. One of the most powerful tools for identification of problems and for beginning a GI repair program is the elimination diet (discussed more fully in Chapter 35). This is typically a trial of an oligo-antigenic diet (elimination of a number of the most common dietary triggers, to reduce intake to those foods least likely to cause or mediate any ongoing inflammatory reaction). A well-structured elimination diet, besides getting rid of possible triggers of inflammation and immune irritation, offers the patient the opportunity to experience a much healthier approach to eating. It is usually a mostly plant-based diet that includes organic and unprocessed foods that are high in vitamins, minerals, antioxidants, anti-inflammatory phytochemicals, fiber, and essential fatty acids and that excludes saturated and *trans* fats, sugar, empty calories, and the 4,000 food additives, hormones, antibiotics, and xenobiotics (foreign toxic chemicals) that are everyday fare for most Americans. Many common ailments will resolve with a brief (2–6 week) elimination diet. Even in those patients without particular symptoms or obvious allergies, an elimination diet can give the immune system a rest and allow for deeper healing and repair throughout the body.

Other dietary approaches to improving digestive function include replacing hydrochloric acid and digestive enzymes, where needed; increasing fiber; adding both probiotics and prebiotics; treating infections and dysbiosis; using nutrients that help heal the gut; and changing lifestyle and eating habits. Interestingly, *how* we eat can be just as important as *what* we eat. If we are stressed, or eat in a hurry, or eat too much at the wrong time of day, our “gut brain” gets confused. This “second brain” (as the gut is often called) turns on signals that make us gain weight, and that impair digestion and absorption of nutrients, relax gut muscles that prevent reflux (the lower esophageal sphincter), and tighten muscles that should relax to let the food pass from the stomach (the pylorus), increasing reflux. By following a few simple guidelines, digestion can improve significantly and patients can even lose weight. Table 26.14 provides suggestions for increasing fiber and making

dietary and lifestyle changes; Table 26.15 presents information on the use of probiotics and prebiotics; Table 26.16 addresses yeast infections; Table 26.17 addresses parasitic infections; Table 26.18 addresses bacterial infections; and Table 26.19 provides information on gut-healing nutrients.

Restoring the integrity of the digestive ecosystem can be fairly straightforward for many patients, but steps should be taken in the proper sequence and therapeutic strategies should be initiated and evaluated systematically. The following are useful guidelines in planning your patient's gut healing program:

- **Day 1:** Start the elimination diet first; have the patient follow it one or two weeks to assess the effect on digestive function. It may be continued for four weeks or longer, depending on the response.
- **Day 3:** Start digestive enzymes and a trial of hydrochloric acid (HCl) *if appropriate* (see symptoms) after two days on the elimination diet.
- **Day 7:** Start probiotics to reintroduce healthy bacteria back into the digestive system.
- **Day 14:** Attempt to identify the source of dysbiosis—yeast overgrowth, small bowel bacterial overgrowth, parasites, *H. pylori*, etc. (through testing or further analysis of symptom patterns and history). Testing prior to initiating a program may be indicated in some patients, although often an elimination diet is effective in identifying the problems and further testing is not needed.
- If indicated by findings in the previous step, initiate non-prescription or prescription medications for identified sources of infection at least two weeks before beginning the next step.
- **Day 28** (or later, depending on whether any medications have been introduced): Start the “repair phase” of gut healing by adding healing nutrients, essential fatty acids, and any other components that you have determined are necessary for restoration of the integrity of the gut lining. Continue on this phase for at least two months. Use probiotics for at least three months and consider a long-term reduced maintenance dose.

Table 26.14 Therapeutic Strategies for Healing the Gut: Changing Dietary and Lifestyle Habits

Suggestions for Increasing Fiber	Dietary and Lifestyle Changes
• 2 tbsp/day of ground flaxseed. Use a coffee grinder just for the flaxseed. Grind 1/2 cup at a time and keep tightly sealed in a glass jar in the fridge or freezer. Sprinkle on salads and on grain or vegetable dishes, or mix in a little unsweetened applesauce. • Beans (all forms of legumes) are the highest sources of dietary fiber. • Increase vegetable intake—with few calories, high levels of antioxidants, and protective phytochemicals, these are excellent fiber sources. • Use whole grains such as brown rice or quinoa. • Include a few servings of low glycemic-index fruits to the diet daily (berries are the highest in fiber and other protective phytochemicals). • Include a handful of nuts each day: almonds, walnuts, pecans, or hazelnuts. • Consider a good fiber supplement containing soluble and insoluble fibers and no sweeteners or additives, if necessary. • Start slowly. Switching abruptly to a high-fiber diet can cause gas and bloating. Increase the total amount gradually, up to 50 g/day.	• Chew each mouthful 25 to 50 times, or at least try! This releases EGF (epithelial growth factor), needed for repair and healing of the digestive lining. • Eat slowly and do not do anything else while eating. Remember, it takes 20 minutes for the brain to get the message that the stomach is full. • Take pleasure in meals; take time to enjoy eating with friends or family; create simple mealtime rituals such as a blessing or soothing environment. • Pick beautiful and attractive foods that please all the senses. • Eat regularly, at least every 3–5 hours. Studies have shown that people overeat if they are extremely hungry. Hypoglycemia can cause swings in blood sugar and carbohydrate cravings. • Mix it up—try to avoid mono-meals. Have a variety of fruits and vegetables, protein-rich foods, whole grains, and small amounts of healthy oils and fats in each meal. • Never eat standing up. • Stop eating three hours before bedtime. Late-evening eating can increase reflux and promote weight gain. • Breathe! Activate the parasympathetic “gut brain” by taking 5 deep breaths before eating—5 seconds in and 5 seconds out for 5 breaths. • Get a water filter (reverse osmosis is the best) to avoid intake of pathogenic microbes. Portable carbon filters in water bottles are available for those on the move. • Wash all fruits and vegetables thoroughly and peel all fruits and vegetables that are not going to be thoroughly cooked. • Wash hands after being outside, and always before and after handling food. • Wash hands after handling raw food and soak utensils and cutting boards if they were used for slicing raw fish, meat, or poultry to reduce exposure to salmonella. Stress Reduction Dealing with stress is critical to repairing the digestive system. The connections between the brain and the gut are powerful. The enteric nervous system or the “gut brain” has more neurotransmitters than the brain. These chemical messengers play a critical role in proper GI function, or malfunction. Tools such as meditation, yoga, or other relaxation therapies can retrain the “automatic” nervous system and overcome the dangers of excessive stress, and its effect on our digestion and feeding behavior.

Table 26.15 Using Probiotics and Prebiotics

Role of Healthy Flora	Probiotics	Prebiotics
- The microflora of the human adult consists of >100,000 billion bacteria and >400 different species. - The microflora synthesizes vitamins and nutrients (biotin, B12, folic acid, pantothenic acid, pyridoxine, riboflavin, vitamin K, butyric acid and amino acids). - These microbes produce short-chain fatty acids (SCFAs), the substrate fuel for intestinal epithelial cells. - They improve digestion and absorption of nutrients by producing digestive enzymes. - The microflora metabolizes environmental and internal toxins; for example, they convert mercury into less toxic forms. - They prevent other microbes from colonizing the gut (which is what happens with traveler's diarrhea), and they can metabolize bacterial toxins. - They make it difficult for potential invaders by competing for nutrients. - They stimulate immune function by increasing antibody production (including producing natural antibiotics to kill pathogenic microbes), and by producing anti-cancer compounds like n-butyrate. - The microflora converts food phytochemicals into protective compounds (e.g., flaxseed lignans are converted into enterolactones that have anti-cancer properties). - Charbroiled foods containing polycyclic aromatic hydrocarbons, and aflatoxin (the toxic mold on peanuts) can be neutralized by the microflora.	Therapeutically, probiotics have been found useful in diarrhea, in controlling asthma, allergies and eczema, and in reducing leaky gut and inflammatory molecules (cytokines). Supplementing pregnant women and then their infants for six months with a <i>Lactobacillus</i> GG resulted in a 50% reduction in asthma, eczema, and allergy in the children at 2 years of age.* Start a 6- to 12-week course of a probiotic to restore normal symbiosis or ecological balance: - Take 5–10 billion organisms a day on an empty stomach in divided doses (twice a day). Preparations include freeze-dried bacteria packaged in powders, tablet, or capsule form. - In treatment of more severe GI dysfunction, daily doses of 50 billion or more organisms have been used. - Look for reputable, refrigerated brands of mixed flora including <i>Lactobacillus acidophilus</i>, <i>Lactobacillus rhamnosus</i> or GG, and <i>Bifidobacterium bifidum</i>. - Some products contain no live flora because they are very susceptible to damage from heat, processing, or improper storage. - Some strains do not colonize the gut well. - Try some strains backed by research such as <i>Lactobacillus</i> GG (Culturelle®), and the DDS-1 strain of <i>Lactobacillus acidophilus</i>. * Kalliomaki, M. Probiotics in primary prevention of atopic disease: a randomized placebo-controlled trial. <i>Lancet</i>. 2001;357:1076-79.	In addition to supplementing with healthy bacteria (probiotics), studies have shown that providing good food for the flora can improve outcomes. The food for probiotics is called prebiotics and includes mostly nondigestible plant components that are used by the flora for nourishment. Some common foods that fill these criteria include fructose-containing oligosaccharides, which occur naturally in a variety of plants such as onion, asparagus, burdock root, Jerusalem artichoke, chicory, and banana.** Or consider supplements of fructose-containing oligosaccharides such as inulin or chicory root. ** Roberfroid MB. Prebiotics: preferential substrates for specific germs? <i>Am J Clin Nutr</i>. 2001;73(2 Suppl):406S-9S.

Table 26.16 Identifying and Treating GI Yeast Infections

Predisposing Factors and Associated Conditions	Symptoms of Yeast Infection	Therapeutic Strategies
Predisposing factors: • Altered bowel flora • Decreased digestive secretions • Dietary factors including a high-sugar, high-fat, low-fiber diet • Impaired immunity • Impaired liver function • Nutrient deficiency • Prolonged antibiotic use • Psychological stress Past history: • Chronic antibiotic use for infections or acne • Chronic vaginal yeast infections • Oral birth control pills • Oral steroid hormones Demographics: • Female • Age 15–50 years Associated conditions: • Eczema • Irritable bowel syndrome • Psoriasis • Sensitivity to foods, chemicals, or other allergens	General symptoms: • Craving for foods rich in carbohydrates or yeast • Chronic fatigue • Loss of energy • General malaise • Decreased libido Gastrointestinal symptoms: • Thrush • Bloating and gas • Intestinal cramps • Rectal itching • Altered bowel function Genitourinary symptoms: • Vaginal yeast infections • Frequent bladder infections • Interstitial cystitis Hormonal symptoms: • Menstrual irregularities, pain, bleeding, etc. • Premenstrual syndrome • Thyroid dysfunction Nervous system symptoms: • Depression • Irritability • Inability to concentrate Immune symptoms: • Allergies • Chemical sensitivities • Suppressed immune function	• Deal with predisposing factors (such as chronic use of antibiotics, steroids, hormones—stop unless absolutely medically necessary). • Trial of yeast-control diet: elimination of refined carbohydrates, sugar, and fermented foods. • Test for yeast overgrowth. • Nonprescription antifungals include oregano, garlic, citrus seed extract, berberine, tannins, undecylenate, <i>Isatis tinctoria</i>, and caprylic acid. • Antifungal prescription medications include nystatin, fluconazole, itraconazole, and terbinafine. • Immunotherapy • Identify potential environmental toxic fungi (stachybotrys, strains of aspergillus, chaetomium, and penicillium). • Utilize the 4R Program (Chapter 28) and institute stress reduction and stress management practices (addressed in previous tables in this chapter).

Adapted from the *Textbook of Natural Medicine*, Pizzorno and Murray, Churchill Livingstone, 1999.

Table 26.17 Identifying and Treating GI Parasitic Infections

Signs and Symptoms of Parasitic Infections	Common Parasites	Therapeutic Strategies
• Abdominal pain and cramps • Constipation • Diarrhea • Excessive flatulence • Fatigue • Fever • Food allergy • Foul-smelling stools • Gastritis • Greasy stools • Headaches • Hives • Increased intestinal permeability • Indigestion • Irritable bowel syndrome and irregular bowel movements • Low back pain • Low levels of secretory IgA • Malabsorption • Poor appetite • Weight loss	• <i>Giardia lamblia</i>* • <i>Entamoeba coli</i> and <i>Endolimax nana</i> • <i>Blastocystis hominis</i> • <i>Entamoeba histolytica</i>* • <i>Cryptosporidium</i> species* • <i>Dientamoeba fragilis</i> • <i>Entamoeba hartmani</i> *Bold-faced parasites are considered more dangerous, but other minor parasites can often be the cause of symptoms.	General approaches: • Drink filtered water. • Wash and/or peel fruits and vegetables, especially if eaten raw, or consider soaking them in a dilute hydrogen peroxide solution of 1 teaspoon of 3% hydrogen peroxide and 2 quarts of water, then rinse with filtered water. • Avoid salad bars and street vendors. • Wash hands carefully with soap and water before eating and after coming in from outdoors, especially if working in the garden or dirt. • If eating out, eat only freshly prepared foods, not things that have been sitting out for a while or microwaved. • Wash sponges in the dishwasher daily. • Thoroughly wash all cutting boards and kitchen surfaces after use. Non-prescription approaches: • Take digestive enzymes for a few months—parasites often cause malabsorption and maldigestion. • Avoid vitamins during treatment because vitamins help the parasites flourish. • Herbal therapies include <i>Artemisia annua</i>, oregano, and berberine-containing plants (<i>Hydrastis canadensis</i>, <i>Berberis vulgaris</i>, <i>Berberis aquifolium</i>, and <i>Coptis chinensis</i>). Prescription medications: • Humatin (paromomycin) in adult doses of 250 mg 3x/day for 14 days and Bactrim® DS or Septra® DS (trimethoprim and sulfamethoxazole) every 12 hours for 14 days. • Yodoxin (iodoquinol) 650 mg 3x/day for 14 days. Yodoxin is antifungal as well as being anti-parasitic. • Flagyl® (metronidazole) 500 mg 3x/day for 10 days with meals.

Table 26.18 Identifying and Treating GI Bacterial Infections

Small Bowel Overgrowth	<i>Helicobacter Pylori</i>
The upper portion of the intestine is generally sterile. Small bowel overgrowth of bacteria or other organisms can lead to irritable bowel syndrome, food allergies, inflammatory diseases and autonomic dysfunction.* Symptoms can be similar to low stomach acid and ineffective digestive enzymes (indigestion, bloating, and fullness after eating), but can also include signs associated with yeast overgrowth, nausea, diarrhea, arthritis, and autoimmune diseases. Testing - Hydrogen breath testing for small bowel bacterial overgrowth - Organic acids: indican, D-lactate Treatment Repair the digestive system: - Follow general guidelines for improving gut function (see previous tables). - Avoid easily fermentable foods, including sugars, starches, and soluble fiber (until the problem is corrected). - No wheat or sucrose; no lactose (milk sugar). - Additional restrictions depend on symptoms and response and may include: no gluten grains, no cereal grains, no potatoes, no fruit, juices and honey, no legumes; cook all vegetables. Non-prescription preparations: - Oregano, citrus seed extract, isatis, or berberine compounds. - Special spices for the gut include garlic, onions, turmeric, ginger, cinnamon, sage, rosemary, oregano, and thyme. All these can be added to the diet to support healthy digestive functioning. Prescription medications: Occasionally prescription medication may be needed. Some of the useful compounds include: - Rifaximin 200–400 mg 3/day** (non-absorbed antibiotic) - Metronidazole 250 mg 3x/ day for 7 days (for anaerobes or bacteria that don't like oxygen, like <i>Bacteroides</i> or <i>Clostridia</i> species) - Tetracycline 500 mg 2x/day for 7 days (also for anaerobes) - Ciprofloxacin 500 mg 2/day for 3 days (for aerobes) - Bismuth (as in Pepto-Bismol®) - Antifungal preparations (as above)	The role of this bacterium as the cause of stomach ulcers has been clarified. It is found in 90–100% of people with duodenal ulcers, 70% of people with gastric ulcers, and in about 50% of people over the age of 50. It may be associated with stomach cancer, inflammation throughout the body, and possibly with heart disease. It is often acquired in childhood and can be the cause of life-long gastritis or stomach inflammation. For many patients, it is also implicated in reflux and heartburn, although studies have been inconclusive. Genetic and nutritional differences among individuals can affect whether or not <i>H. pylori</i> causes gut symptoms or cancer. For those with elevated C-reactive protein, chronic digestive symptoms, or a family history of gastric cancer, treatment is advisable. Currently, most physicians treat only documented ulcers, possibly overlooking many people who could benefit from treatment. Low stomach acid predisposes to the growth of <i>H. pylori</i>, as do low antioxidant defense systems. Low levels of vitamin C and E in gastric fluids promote the growth of <i>H. pylori</i>. Testing - Breath testing - CLO test or intestinal biopsy <i>H. pylori</i> antibodies - Stool antigen test Treatment Non-prescription preparations: - Bismuth subcitrate 240 mg 2x/day before meals for 2 weeks. It can cause a temporary harmless blackening of the tongue and stool. - DGL or deglycyrrhizinated licorice can help eradicate the organism and relieve symptoms. - Myrrh gum resin Prescription medications: - Amoxicillin 1 g 2x/day, Clarithromycin 500 mg 2x/day, omeprazole 20 mg 2x/day for 10 days - Prevpac® (lansoprazole-amoxicillin-clarithromycin combination) one 2x/day for 14 days - Helidac® (bismuth-metronidazole-tetracycline combination) one 4x/day with meals for 2 weeks - Tritec® (ranitidine bismuth citrate) 400mg 2x/day for 28 days

Table 26.19 Testing for Gut Function; Gut-Healing Nutrients

Testing for Gut Function	Gut-Healing Nutrients
Comprehensive digestive stool analysis Hydrogen breath testing for small bowel overgrowth Intestinal permeability (lactulose-mannitol challenge) Organic acid urine testing for dysbiosis Parasitology analysis Complete blood count: This common test can give many clues to underlying infection. It shows the different types of white blood cells and their responses to different organisms. Useful indicators include the following: - Anemia with an elevated mean corpuscular volume (MCV) can be sign of B12 or folate deficiency. B12 is absorbed in the small intestine, and if there is chronic inflammation, bacterial overgrowth, or a parasite, it is often poorly absorbed, resulting in an elevated MCV. Anything over 95 may indicate B12 malabsorption or folate deficiency. Anemia with a low MCV may indicate iron deficiency from intestinal blood loss or malabsorption as found in celiac disease. - A low neutrophil and high lymphocyte count can be a sign of chronic yeast or viral infections. A low total white blood cell count can also be a sign of stress to the immune system. - Eosinophils are elevated in parasitic infections or from exposure to allergens. Further testing for parasites or allergies should follow. Homocysteine and methylmalonic acid—these can help pick up B12 or folate deficiency secondary to malabsorption or inadequate intake. 25-OH vitamin D is an important fat-soluble vitamin that is deficient in malabsorption states.	Specialized gut support products and nutrients are often necessary for gut healing and repair. These are the final tools for correcting digestive problems, healing a leaky gut, and reducing relapse or recurrence of digestive and immune problems. These should be taken for 1-3 months, depending on the severity of symptoms and response to treatment. These compounds needed for gut repair can be divided into four main categories: Gut food: Glutamine 1,000–10,000 mg a day. This is a nonessential amino acid that is the preferred fuel for the lining of the small intestine and can greatly facilitate healing. It can be taken for one to two months. It generally comes in powder form and is often combined with other compounds that facilitate gut repair. Nutrients and antioxidants: - Zinc 20–50 mg - Vitamin A 5000–10,000 IU/day - Vitamin B5 pantothenic acid 100–500 mg/day - Vitamin E 400 to 800 IU/day in the form of mixed tocopherols These can be taken separately, or as part of a good high-potency multivitamin. Essential fats and oils: - GLA (gamma-linolenic acid) 2-6 g/day - Gamma-oryzanol (rice bran or rice bran oil) 100 mg three times a day - Omega-3 fatty acids 3 to 6 g a day of EPA/DHA Anti-inflammatories and gut detoxifiers: - N-acetylcysteine 500 mg twice a day - Reduced glutathione 300 mg twice a day - Quercetin 500 mg twice a day and other bioflavonoids These potent anti-inflammatories and detoxifiers are key to restoring balance in the gut lining by protecting it from oxidant damage and helping with detoxification within the gut.

Not following all of these steps, and/or not following them in order, can lead to more digestive upset in the short term, and may not allow full healing, even if the patient feels better initially. This approach is designed to move systematically through a gut repair program and to prevent relapse.

Dietary Influences on Sarcopenia

Sarcopenia,⁹⁵ or “poverty of the flesh,” is the term we use to describe the decline in muscle mass and

strength seen in “healthy aging.” Sarcopenia differs from wasting (an involuntary weight loss due to inadequate caloric intake), or cachexia (general physical wasting and malnutrition usually associated with chronic disease), or a cytokine-driven loss of lean body mass with the maintenance of weight. Conventionally, sarcopenia is perceived as a loss of muscle solely related to decreased activity, common in the aging population, and it is associated with a progressive increase in dysfunction and disability. The economic

costs of sarcopenia have been estimated to be between \$11.8 and \$26.2 billion per year, or approximately 1.5% of total health care expenditures.⁹⁶

While physical activity and strength training are central to reversing sarcopenia and its related dysfunction (see the Exercise sections of Chapters 13 and 29), nutritional, hormonal, immune, and metabolic factors play a large role as well, so it is a good example of a condition that involves multiple areas of the functional medicine matrix. Understanding these relationships opens the door to interventions other than increased activity that correct underlying causes of sarcopenia.

The dynamics of the aging muscle are regulated by factors influenced by dietary intake—insulin resistance, oxidative stress, inflammation, protein nutrition, sex hormone balance, and mitochondrial function. Any input that influences these metabolic and hormonal factors will have an effect on sarcopenia. Old concepts of decreased protein synthesis in aging have been challenged. Older men were found to have higher rates of protein synthesis than younger men, dispelling the notion that sarcopenia is due to inadequate basal or fasting protein synthesis.⁹⁷ Therefore, other factors that shift the balance from anabolism to catabolism must be considered.

Protein intake, digestion, absorption, assimilation, and utilization (and hence muscle protein synthesis) are affected by the amount and quality of protein intake, as well as by age. One-third of women and men over 60 years of age eat less than 0.8 g/kg of protein per day (the RDA) and approximately 15% eat less than 75% of the RDA for protein. Factors that influence protein digestion and absorption include hypochlorhydria,⁹⁸ use of acid-blocking medications, zinc deficiency, food allergies, celiac disease, and dysbiosis. Supplementation with essential amino acids may enhance protein synthesis in healthy elderly adults. However, consumption of these amino acids, along with non-essential amino acids and carbohydrates (as frequently found in protein drinks), impairs the anabolic response of muscle proteins to the positive effects of amino acids.⁹⁹ Ensuring adequate digestion, protein intake, and availability of essential amino acids is important for maintaining normal muscle mass with aging.

Sarcopenia is related to a reduction in anabolic stimuli (physical activity, CNS activity, reductions in

estrogens, androgens, growth hormone, and insulin sensitivity) and an increase in catabolic stimuli (subclinical inflammation and oxidative stress).¹⁰⁰ Hormonal changes with age are affected by diet and environment, and include decreases in estrogen, testosterone, and growth hormone. Estrogen and testosterone are anabolic, and they inhibit catabolic cytokines (including IL-1 and IL-6). Insulin inhibits protein breakdown. Insulin resistance, which increases with age, high glycemic-load diets, visceral fat mass, and inactivity, impairs the protective effect of insulin. Inflammation has also been linked to catabolism and sarcopenia through increases in IL-6, IL-1, and TNF- α in healthy aging adults. This may be mediated through direct catabolic effects, anorexia of aging triggered by inflammation, inducing insulin resistance or lowering growth hormone and insulin-like growth factor-1 concentrations, and increasing apoptosis.¹⁰¹ Oxidative stress contributes to sarcopenia through damage to cellular components, including DNA, proteins, lipids, cell membranes, and the sarcoplasmic reticulum.¹⁰²

Interventions that improve protein intake and digestion, reduce insulin resistance, inflammation and oxidative stress, and improve hormonal balance can reduce age-related sarcopenia and loss of function, particularly when combined with physical activity and stress management.¹⁰³ The web-like nature of our physiology is clearly evident in the pathophysiology of sarcopenia. This understanding can be used to design a comprehensive approach to normalize function. Each patient should, of course, have a personalized assessment and plan, but the following suggestions indicate some dietary and lifestyle strategies for preventing and reversing sarcopenia:

- Ensure adequate protein intake (0.8 gm/kg to 1.2 gm/kg depending on activity level).
- Consider essential amino acid supplementation without non-essential amino acids or carbohydrates.
- Improve insulin sensitivity.
- Reduce inflammation.
- Reduce oxidative stress.
- Improve hormonal balance.
- Initiate resistance and aerobic conditioning.
- Initiate stress management to mitigate the catabolic effects of chronic cortisol exposure.

The Risks in our Food Supply

Harmful Foods: Dietary Components as a Causative Factor in Disease

A number of foods and non-nutritive substances in our diet adversely affect our health and need to be reduced or eliminated. Some have well-documented risks, such as *trans* fatty acids, while others pose potential risks. Other components of our diet have also been shown to cause (or have the potential to cause) harm, including refined polyunsaturated oils, fake fats (Olestra, Simplese®), refined sugars, high fructose corn syrup, refined carbohydrates, artificial sweeteners, food toxins, and genetically engineered foods.

Trans-fatty acids (*trans* fat). In many controlled metabolic studies, *trans*-fatty acids¹⁰⁴ (found in stick margarine, vegetable shortening, commercially baked goods, deep-fried foods, fast foods, and many restaurant foods) raise LDL-C and lower HDL-C compared to *cis*-fatty acids,¹⁰⁵ and raise the total cholesterol-to-HDL ratio (TC/HDL) twice as much as saturated fat. *Trans* fat also increases plasma lipoprotein(a) and triglycerides, and impairs endothelial function by inhibiting the enzyme delta-6-desaturase, which may adversely affect essential fatty acid metabolism and prostaglandin balance. High intakes of *trans* fat can promote insulin resistance and increase the risk of type 2 diabetes.¹⁰⁶ *Trans*-fatty acids may also increase the risk of colon and breast cancer,^{107,108} allergic diseases in children,¹⁰⁹ and neurodegenerative diseases.¹¹⁰ *Trans*-fatty acids adversely affect plasma markers of inflammation in healthy men including elevations in C-reactive protein, interleukin-6, tumor necrosis factor-alpha, and E-selectin.^{111,112} Elimination of *trans*-fatty acids from our diet may help to reduce the incidence of cardiovascular disease, neurodegenerative diseases, obesity, diabetes, cancers, and inflammatory disorders.

Fake fats. Olestra and Simplese may have adverse health effects by reducing availability of fat-soluble vitamins, including serum retinol, 25-hydroxyvitamin D, alpha-tocopherol, phyloquinone, and carotenoid concentrations,¹¹³ in addition to the risk of stool incontinence.

High fructose corn syrup. High fructose corn syrup (HFCS) consumption increased >1,000% (0.292kg/person/year to 33.4kg/person/year) from 1970 to 1990 and now represents >40% of caloric sweeteners added to

foods and beverages.¹¹⁴ The introduction of HFCS into the food supply is associated with the beginning of the obesity epidemic. While other factors for this epidemic (including reduced levels of physical activity, increased portion sizes, eating outside the home and at fast-food restaurants) certainly play a very important role, changes in the types of foods eaten, and the overall “toxic food environment,”¹¹⁵ including the effect of HFCS in soft drinks and other sweetened beverages, merit serious consideration as an etiologic factor in the obesity epidemic.

The digestion, absorption, and metabolism of fructose differ in significant ways from glucose. Fructose is absorbed through a nonsodium-dependent process and enters the cell in an insulin-independent manner. In high doses, it becomes an unregulated source of carbon precursors (acetyl-CoA) for hepatic lipogenesis, specifically triacylglycerol (triglyceride) synthesis. This is associated with reductions in HDL and increases in the more atherogenic LDL-B particles. It is important to note that reductions in LDL-C with high-carbohydrate diets are often associated with conversion from LDL-A to LDL-B, and that change is associated with increased cardiovascular risk. Increased consumption of HFCS may be a cause of increasing dyslipidemias that may be better treated by reducing HFCS than by statin therapy.

Fructose does not stimulate insulin secretion or the consequent increase in leptin, which serves as a counter-regulatory afferent signal for reductions in appetite. While glucose is transported into the brain, affecting neuroregulatory appetite signals, fructose is not. Ghrelin, a gastric peptide that stimulates appetite, is not reduced with fructose consumption. Fructose may also decrease adiponectin levels, the adipocyte peptide. Adiponectin improves insulin sensitivity independent of obesity. Thus, the normal regulatory mechanisms associated with carbohydrate (as well as fat or protein) consumption do not function optimally in a diet high in HFCS, leading to increased appetite, energy intake, and weight gain. This effect is seen predominately in liquid vs. solid foods. Fructose consumption is associated with insulin resistance, increased energy intake, impaired metabolism, weight gain, dyslipidemias, and hypertension.¹¹⁶ Though more research is needed to further clarify the metabolic and endocrine effects of fructose consumption, sufficient data exist on the adverse consequences of fructose on body weight, adiposity, and the metabolic indexes associated with insulin resistance to recommend dramatic reductions of HFCS in our food supply. (It is important to

note that the quantities of fructose consumed in fruit are significantly lower than in sweetened beverages, and the metabolic effects of fructose in fruit are modified by increased intake of fiber, micronutrients, phytonutrients, and antioxidants.)

Refined carbohydrates and sugars. Foods with a high glycemic index (GI) or glycemic load (GL) lead to obesity,¹¹⁷ heart disease,¹¹⁸ diabetes, cognitive impairment,¹¹⁹ dementia, and cancer (colon, breast, prostate, pancreas).¹²⁰ Insulin resistance or metabolic syndrome affects 80 million Americans.^{ii,121} In 1997, the average American “consumed a record average 154 pounds of caloric sweeteners. That amounted to more than two-fifths of a pound—or 53 teaspoonfuls—of added sugars per person per day”¹²² This is a sharp contrast to the estimated 20 teaspoons *per year* eaten by our genetically similar Paleolithic ancestors. This pattern of eating carries with it multiple adverse effects, including weight gain, increased caloric consumption, increased hunger, decrease in the efficiency of energy utilization,¹²³ and adverse effects on the mesolimbic dopaminergic system, which links sugar consumption and drug addiction through stimulation of similar neural reward pathways.¹²⁴ These foods also increase catecholamines, cortisol, inflammatory markers such as C-reactive protein, interleukin-6 and tumor necrosis factor- α , and markers of coagulopathy such as PAI-1 and fibrinogen. High GI foods or GL meals lead to hyperinsulinemia, elevated triglycerides, low HDL, hypertension, elevated waist-to-hip ratio or visceral obesity, decreased adiponectin, autonomic dysfunction, non-alcoholic steatohepatitis, hyperuricemia, and hormonal disorders such as polycystic ovary syndrome in women and infertility and low testosterone in men, as well as mood swings, anxiety, depression, and fatigue.

Unfortunately, despite this litany of adverse effects, refined carbohydrates and sugars are ever present in our diet. White bread, sugar, pasta, white rice, and white potatoes are quickly absorbed starches with a high glycemic index.¹²⁵ Consumption of these foods has increased dramatically since the introduction of the food pyramid that advises us to eat 6–11 servings of rice, bread, cereal,

and pasta a day. Soft drinks or sugar-sweetened beverages and alcohol in excess contribute to the problem as well. Care should be taken in reading food labels to identify sugar in other guises, such as high-fructose corn syrup, sucrose, glucose, maltose, dextrose, lactose, fructose, corn syrup, or white grape juice concentrate. Sugar is sugar by any other name; this includes honey, barley malt, maple sugar, sucanat, natural cane sugar, or dehydrated cane juice. Food processors do not have to state if there is added sugar in their products. They are required only to list the total grams of sugar. It is best to avoid or reduce hidden sugars in all foods, including (but not limited to) ketchup, salad dressings, luncheon meats, canned fruits, bread, peanut butter, crackers, soups, sausage, yogurt, relish, cheese dips, chewing gum, and breakfast cereals, and to choose foods with a low glycemic index or meals with a low glycemic load.¹²⁶

Harmful Non-Nutritive Food Additives: Intentional and Unintentional

Artificial sweeteners. Aspartame (NutraSweet®),¹²⁷ neotame, acesulfame potassium, saccharin, sucralose, and dihydrochalcones are consumed by two-thirds of adults and are significant components of our diets. Questions remain about their safety, including both short- and long-term risks. The manufacturers of these products largely publish the safety data;ⁱⁱⁱ and post-market surveillance and monitoring are limited. Aspartame, an excitotoxin,¹²⁸ provides an example of the potential problems of non-nutritive sweeteners in our diet. Some studies suggest adverse effects,^{129,130,131} including toxicity from methanol and formaldehyde¹³² derived from the amino acids in aspartame. Methanol, a toxic alcohol, is present in small quantities in aspartame; however, when heated (in a soda can on a hot day, or in a hot truck during transport, for example) more methanol is created, leading to the possibility of more serious toxic effects. Other effects include stimulation of hunger through the cephalic phase insulin response; a number of studies have shown that aspartame ingestion may actually lead to increased food/calorie intake.^{133,134} Animal and human studies show that aspartame may disrupt brain chemistry¹³⁵ and induce neurophysiological changes that might increase seizure risk,¹³⁶ depres-

ⁱⁱ Estimates range from 47 million to over 100 million, depending on the criteria used. Recent data suggest that even those who do not meet the current criteria for glucose intolerance (2-hour sugar >140mg/dl) have a graded increase for cardiovascular risk and angiographic lesions. It is likely that over 90% of the 65% of Americans who are overweight (figure from U.S. population data) have some degree of insulin resistance, making the prevalence much greater.

ⁱⁱⁱ Of 166 studies, 74 had at least partial industry-related funding and 92 were independently funded. While 100% of industry-funded studies conclude aspartame is safe, 92% of independently funded research identified aspartame as a potential cause of adverse effects.

sion,¹³⁷ and headaches.^{138,139} While conclusions have yet to be reached with regard to the specific outcomes in humans or safe dosage effects, the existing evidence warrants vigilance. Until better data on long-term risks of non-nutritive sweeteners are available, physicians should caution their patients about the use of such substances, in light of the conflicting safety data.

Sorbitol, malitol, and xylitol are common non-absorbed sugar alcohol sweeteners found in food; they can be responsible for increased intestinal gas production, bloating, and abdominal pain.

Intentional food additives. The FDA has approved the use of almost 4,000 food additives. Most of these are studied as single agents in animal models to determine risk, but it is humans who consume them, in large quantities and in multiple combinations that have never been studied. A 1985 study reported that the average American consumes 13–15 grams of these per day—nearly three teaspoons full or about five pounds of additives a year. The main types of food additives include coloring agents, antioxidants, emulsifiers, stabilizers, stimulants, flavorings, preservatives, and artificial sweeteners. Specific additives that can cause symptoms include tartrazine (FD&C yellow #5), sulfites, nitrates and nitrites, BHT, BHA, and aspartame.

Tartrazine is banned in Sweden because of adverse reactions, including hives, asthma, eczema, and other allergic conditions. This is a common coloring in foods and many drugs, including some antihistamines, antibiotics, steroids, and sedatives. Sulfites are common in wine and dried fruits, and are sprayed on fresh foods such as salad bars and shrimp; they often cause allergic reactions, including hives, asthma, and even death. Detoxification of sulfites is impaired with molybdenum deficiency. Nitrates and nitrites are known gastric carcinogens. BHT (butylated hydroxytoluene) and BHA (butylated hydroxyanisole) are the most common antioxidants in prepared and packaged foods; they can cause hives.

MSG, a common flavor enhancer found in many commercially prepared foods, is responsible for the “Chinese restaurant syndrome,” and can cause other symptoms and reactions, including headaches, trouble thinking, memory loss, and fainting spells. This additive is especially dangerous, as it often lurks covertly.

Petrochemical pesticides, herbicides, fumigants, hormones, and antibiotics. The Environmental Protection Agency (EPA) has been monitoring human expo-

sure to toxic environmental chemicals since 1972, when they began the National Human Adipose Tissue Survey (NHATS). This endeavor involves the analysis of levels of various toxins in fat tissues from cadavers and elective surgeries (ever wonder what happens to fat removed during liposuction?). In 1982, five of the most toxic chemicals were found in 100% of samples: OCDD (a dioxin), styrene, 1,4-dichlorobenzene, xylene, and ethylphenol. Nine additional chemicals were found in 91–98% of samples, including benzene, toluene, ethylbenzene, DDE (a breakdown product of DDT, banned in the U.S. since 1972), three dioxins, and one furan. Polychlorinated biphenyls (PCBs) were found in 83% of the population. A Michigan study found DDT in over 70% of four year olds, probably received through breast milk. In the context of our global economy, it's possible to eat food that was picked a day before in Guatemala, Indonesia, or Asia, where the use of pesticides is much less regulated. Many of these chemicals are stored in fat tissue, making animal products concentrated sources. One hundred percent of beef, as well as 93% of processed cheese, hot dogs, bologna, turkey, and ice cream are all contaminated with DDT. Children fed an organic diet have significantly lower pesticide levels in urine samples than children fed a conventional diet.¹⁴⁰

Beyond chemicals, other potential hazards in foods include hormones and resistant microorganisms, or bacteria. Dairy products contain various growth hormones (BGH) and residues of synthetic estrogens, such as diethylstilbestrol (DES), used to stimulate growth. Antibiotic-resistant bacteria that originated from animal sources have been isolated in humans. We now have trans-species (chicken to human) resistance of bacteria. “The Union of Concerned Scientists recently estimated that, each year, 24.6 million lb (11.2 million kg) of antimicrobials are given to animals for non-therapeutic purposes and 2 million lb (900,000 kg) are given for therapy; in contrast, 3 million lb (1.3 million kg) are given to humans.”¹⁴¹

The potential health risks of these substances include problems with immunity, such as decreased resistance to infection and increased autoimmunity, toxin-associated cancers, neurologic damage and neurodegenerative diseases such as Parkinson's disease,^{142,143} and hormonal disruptions such as infertility and thyroid disorders.^{144,145}

Mercury. Predatory fish (swordfish, shark, tile fish, king fish, tuna) consumption is a significant source of

mercury exposure in our diet and has been associated with toxic effects on the immune, nervous, cardiovascular, renal, gastrointestinal, and dermatologic systems.¹⁴⁶ Mechanisms of toxicity include damage to DNA, RNA, mitochondria, enzymes, immunopathology, and autoimmunity. Mercury can act as a metabolic uncoupler, hapten or immune-sensitizing small molecule, and enzyme inhibitor by binding irreversibly to the sulfhydryl-containing proteins. Avoidance of mercury-containing fish is an important way to reduce risk. The Environmental Protection Agency (EPA) has established guidelines for safe fish consumption; these are provided on their website.¹⁴⁷

Genetically engineered foods. The scientific literature documenting the benefits and risks of genetically modified (GM) foods is replete with opinion and weak on science.¹⁴⁸ There are many claims for potential benefits and few published studies about potential risks. Unfortunately, there are no clear conclusions on harm or benefit.

Proposed benefits include: improvement in fruit and vegetable shelf life and organoleptic quality; improved nutritional quality and health benefits in foods; improved protein and carbohydrate content of foods; improved fat quality; improved quality and quantity of meat, milk and livestock; the use of GM livestock to grow organs for transplant into humans; increased crop yields; improvement in agriculture through breeding insect-, pest-, disease-, and weather-resistant and herbicide-tolerant crops; use of GM plants as bio-factories to yield raw materials for industrial uses; use of GM organisms in drug manufacture, in recycling and/or removal of toxic industrial wastes.

Controversies and risks proposed include: alteration in nutritional quality of foods, potential toxicity, possible antibiotic resistance from GM crops, potential allergenicity and carcinogenicity from consuming GM foods, environmental pollution, unintentional gene transfer to wild plants, possible creation of new viruses and toxins, limited access to seeds due to patenting of GM food plants, threat to crop genetic diversity, and religious, cultural and ethical concerns.¹⁴⁹ Unfortunately, financial and political interests cloud open scientific inquiry, and fear of harm interferes with honest evaluation of potential benefits. Prudence suggests caution until further, and more long-term, studies are completed to evaluate the risks to human health. We can hope that a significant portion of those studies will be funded by a completely disinterested source.

In addition to guidelines provided throughout this chapter, the following suggestions can help all of us minimize the risks in our food supply:

1. Eliminate *trans* fats.
2. Eliminate artificial sweeteners and HFCS.
3. Eat organic plant and animal foods to minimize risk of ingesting petrochemicals, hormones, and antibiotics.
4. Eliminate large predatory fish such as tuna, swordfish, tile fish, and shark (see EPA fish advisory for mercury content of food to reduce intake of mercury).
5. Minimize intake of GMO or genetically modified foods until further data clarify the safety profile.

We can also become more aware of preserving the healing components of food through proper storage and preparation. Nutrients are highest in fresh, local, and organic foods. Food handling may damage nutrients through excessive exposure to heat, light, air and water. For example, essential oils are damaged by high heat and exposure to light; nuts and seeds oxidize if left at room temperature. Phytonutrients are delicate and may need special preparation to maximize their healing potential. Microwaving foods increases the advanced glycation end products (AGEs), thereby increasing oxidative stress and inflammation when microwaved foods are consumed. Here are a few guidelines for maintaining maximum healing properties of foods:

- Choose fresh, whole, unprocessed foods.
- Choose foods that are organic and locally grown when possible.
- Include a wide diversity of colorful plant foods to maximize the intake of phytonutrients, vitamins, and minerals.
- Avoid high-heat preparation of fruits and vegetables and overcooking.
- Do not microwave food.
- Store food in airtight, dark containers to reduce oxidation.
- Keep oils and oil-containing foods (nuts and seeds) in dark, airtight containers in cool or cold storage to prevent oxidation.

Summary

Diet and Nutrition in the Clinical Setting: The Clinician's Role

The clinician provides treatment. The skilled therapeutic use of diet and nutrition, while powerful, can be a challenging tool to apply in the management of disease. Despite the fact that specific dietary programs or interventions may not have been thoroughly studied, a collective view of the current body of literature provides a rich and solid foundation for dietary recommendations that address the underlying causes of disease and restore normal physiologic functions. When analyzed from an evolutionary perspective, diet can be understood, not just as a source of energy, but also as *the* central way in which our genes interact with our environment. Part of the clinician's job is to communicate this clearly to patients, along with basic knowledge about the risks in our common dietary patterns and in our food supply.

The known and unknown components in our diet influence, in a moment-to-moment way, the biologic mediators and cellular communication that determine health or disease. Understanding this unique quality of food gives the practitioner a sharp tool with which to attack chronic disease. Food, and the amino acids, fatty acids, carbohydrates, fibers, vitamins, minerals, and phytonutrients contained within it, directly influence hormone and neurotransmitter functioning, including the HPA axis, insulin, adrenal, thyroid, and sex hormones; redox status and mitochondrial bioenergetics; inflammatory and immune mediators; detoxification enzyme functions, digestive function and gut ecology; as well as cell membrane status, sarcopenia, and structural health. In short, diet provides the clinician with an effective point of access to the entire functional medicine matrix.

Understanding these processes gives the practitioner a new way to assess and treat common clinical problems. The process of finding the "right diet" for an individual patient can be daunting; however, a careful medical and family history, physical examination, and focused testing can help clarify a patient's unique needs. Those needs may also change over the course of the patient's life, or the course of an illness. What might agree with them at one moment, might not at another, and then might again later. This is the art of applied nutritional science.

The clinician educates. Most people accept that too many calories, or too much fat, or too much sugar is bad for them, and they are aware that reducing their intake of those foods may prevent obesity and cancer. However, the deeper relationship between food and health and disease is still a surprise to many patients. The role of the clinician is to delineate for the patient the ways in which diet creates imbalance, and can also be used to create balance, reverse dysfunction, and restore health. Clinicians can use food to resolve many of their patients' difficult chronic conditions. From a practical perspective, the most powerful and pervasive therapeutic tools a clinician has are diet and nutrition. These have a greater effect in the prevention and treatment of chronic disease than any medication or therapy, except perhaps exercise.

The clinician helps patients change behavior. The prevailing belief is that patients want easy answers and are unwilling to change dietary or lifestyle habits. My assertion is that we, as clinicians, have too often abdicated the role of mentor in helping patients change. (A vital piece of the puzzle is provided in Chapter 36, where information is presented on one very successful method of helping patients to change unhealthy behaviors.) Patients are often willing to change or adjust their diet if they are given the right information and are taught to choose and prepare healing foods and to understand how to balance their metabolism through food. If both patients and practitioners are empowered with the belief that changing dietary habits can help to resolve their symptoms and create good health, then change becomes simpler. Admonishing the patient to lose weight and exercise, without translating that advice into practical information adapted to the patient's environment, resources, and psychological readiness, is not helpful and is often strikingly unsuccessful. Clinicians may need to "reinvent" their clinical practices to become more effective at achieving these goals. The anachronistic model of an eight-minute office visit is neither effective, nor cost-effective, in helping patients to change. New models must be explored, including group-delivered care, group-delivered education, nutritionist referrals, cooking classes, collective guided experiences with elimination or detoxification diets, and networking with community resources for exercise and stress management. The days of therapeutic nihilism in nutritional therapy have come to a close. A new opportunity is available to use

nutritional science and its clinical application to empower patients, enhance clinical outcomes, reduce costs, and transform our healthcare system.

Micronutrient Insufficiency Leads to DNA and Mitochondrial Damage

Bruce N. Ames, PhD^{iv}

Introduction

An optimum intake of micronutrients and metabolites, which varies with age and genetic constitution, would tune-up metabolism and contribute to a marked increase in health, particularly for the poor, young, obese, and elderly, at little cost. The focus for this tune-up would be in three areas:

- Preventing DNA damage. Deficiency of vitamins B12, folic acid, B6, C or E, or iron or zinc appears to mimic radiation in damaging DNA by causing single- and double-strand breaks, oxidative lesions or both. Half of the population may be deficient in at least one of these micronutrients.

- Preventing other problems associated with common micronutrient deficiencies of, for example, iron, zinc or biotin, which can cause mitochondrial decay with oxidant leakage leading to accelerated aging, DNA damage, and neural decay.
- Repairing mitochondrial oxidative decay, which is a major contributor to aging and increased mutagenic oxidants. This decay can be ameliorated by feeding old rats the normal mitochondrial metabolites acetylcarnitine and lipoic acid at high levels.

Intake of the 40 essential micronutrients (vitamins, minerals, and other biochemicals that humans require) is commonly thought to be adequate. Classic deficiency diseases such as scurvy, beriberi, and pernicious anemia are rare. The evidence suggests, however, that much chronic metabolic damage occurs between the level that causes acute micronutrient deficiency disease and the recommended dietary allowances (RDAs). In addition, the prevention of more subtle metabolic damage may not be addressed by current RDAs. When one input in the metabolic network is inadequate, repercussions are felt on a large number of systems and can lead to degenerative deficiency disease. This may, for example, result in an increase in DNA damage (and cancer), or neuron decay (and cognitive dysfunction) or mitochondrial decay (and accelerated aging and degenerative diseases). The optimum amount of folic acid or zinc that is truly “required” is the amount that maximizes a healthy lifespan; that amount is likely to be higher than the amount needed to prevent acute deficiency disease. The requirements of the elderly for vitamins and metabolites are likely to be different from those of the young, but this issue has not been seriously examined. An optimal intake of micronutrients and metabolites also varies with genetic constitution. A tune-up of micronutrient metabolism should give a marked increase in health at little cost. It is a distortion of priorities for much of the world’s population to have an inadequate intake of a vitamin or mineral, at great cost to individual health and to the economy, when a year’s supply of a daily multivitamin/mineral pill as insurance against deficiencies costs less than a few packs of cigarettes. The poor, and the obese, in general, eat the worst diets and have the most to gain from multivitamin/mineral supplementation and improvement in diet.

This paper has been adapted in part from Ames, BN. A role for supplements in optimizing health: the metabolic tune-up. Arch Biochem Biophys. 2004;423:227-34.

The Calorie-Rich, Micronutrient-Poor Diet

For most of human evolution, calorie shortage was likely to have limited population growth, and as food was mostly calorie-poor and unprocessed, micronutrients may have been fairly adequate. The advent of agriculture changed that, and diets became less varied. The introduction of the potato to Europe from South America in the late 1500s markedly increased the European population over the next few centuries, as the cultivation of potatoes spread and as cultivars were selected that thrived in each climate. "In 1845 close to 40% of the population of Ireland lived chiefly on potatoes. The emergence of the 'potato people' occurred against the background of the quadrupling of the population after 1700" ¹⁵⁰ Rice was clearly the main factor enabling high population density in Asia. The introduction of the sweet potato from the New World to New Guinea also was associated with a marked increase in the population. ^{151,152} Now carbohydrate and fat calories come with few micronutrients and are remarkably inexpensive, soft drinks with a high content of sugar are consumed instead of water, and the U.S. and other countries have an obesity epidemic associated with micronutrient malnutrition. ¹⁵³

Why Micronutrients?

Although optimal nutrition will benefit many degenerative diseases, and although optimal nutrition clearly involves more than micronutrients (e.g., fiber), there are important reasons for focusing on micronutrients and health, particularly DNA damage and mitochondrial damage: ^{154,155}

- More than 20 years of effort to improve the American diet have not been notably successful, particularly for the poor, although the effort should continue. A parallel approach that focuses on micronutrient malnutrition is overdue and might be more successful, because it should be easier to convince people to take a multivitamin/mineral pill as insurance against ill health than to change their diet appreciably.
- A multivitamin/mineral pill is inexpensive, recognized as safe, and supplies the range of vitamins and minerals that a person requires, although not the essential omega-3 fatty acids. Inadequate intakes of omega-3 fatty acids are widespread and are important for brain function. ¹⁵⁶ Fish oil supple-

ments with these essential fatty acids are available and inexpensive. Inadequate fiber intakes, both soluble and insoluble, are widespread. ¹⁵⁷ Fiber supplementation is also inexpensive.

Fortification of food is another approach that is useful, e.g., the recent U.S. folate fortification. However, fortification of food does not allow for differences between individuals. For example, menstruating women need more iron than men or older women, who may be getting too much. That is why two types of vitamin pills are marketed: one with iron and one without. With more knowledge, it seems likely that a variety of multivitamin pills will be developed reflecting more specific knowledge about needs that vary with age, sex, genetics, etc.

DNA Damage from Vitamin and Mineral Deficiencies

DNA damage, which is a cause of cancer (although not the only one), is recognized as deleterious and can be assayed easily and relatively inexpensively in human white cells during intervention studies, in contrast to cancer. Our strategy in the laboratory has been to use a variety of human cell lines in culture, to cause growth limitation by deficiency of a particular micronutrient and then to measure DNA damage by a variety of assays, followed by human intervention studies. We are also developing improved assays for measuring DNA damage in humans. Deficiency of vitamins B12, folic acid, B6, niacin, C or E, and iron or zinc appears to mimic radiation in damaging DNA by causing single- and double-strand breaks, oxidative lesions, or both. Half of the population may be deficient in at least one of these micronutrients. ^{158,159} Micronutrient deficiency may contribute to some of the increased cancer in the quarter of the population that eats the fewest fruits and vegetables (five to nine portions a day is advised), when compared to the quarter with the highest intake. Eighty percent of American children and adolescents and 68% of adults do not eat five portions a day. ¹⁶⁰ A major source of some vitamins such as folate is fruits and vegetables. Low folate intake has been associated with several types of cancer (see below). Heart disease is also associated with low fruit and vegetable intake and some of this effect appears due to micronutrient content. ¹⁶¹

Folate

Folate deficiency causes disruption of DNA synthesis, repair, and methylation, which leads to chromosome breaks due to massive incorporation of uracil in human DNA.¹⁶² Subsequent single-strand breaks in DNA form during base-excision repair; two nearby single-strand breaks on opposite strands cause the chromosome to break. The level of folate at which we see high uracil and breaks was, before the recent flour supplementation, the level that 25% of the U.S. population and close to 50% of poor urban minorities experienced due to poor diets.

Our current understanding of folate deficiency and its relationship to cancer illustrates the importance of considering the findings of all types of research—epidemiological, molecular, clinical, and interventional—when investigating the link between diet and cancer. There is much epidemiological evidence indicating that low folate intake increases the risk of many types of cancer.¹⁶³ As shown in Table 26.20, reduced folate intake has been associated with a higher risk of colon cancer,^{164,165} and long-term use of a folate-containing supplement has been shown to lower the risk of colon cancer by 75%.¹⁶⁶ There is also some evidence that low folate intake increases the risk of breast cancer,^{167,168} pancreatic cancer in smokers,^{169,170} and gastric, ovarian, and oesophageal cancers.^{171,172}

In vitro studies have shown that folic-acid deficiency causes a dose-dependent increase in uracil incorporation into human lymphocyte DNA.¹⁷³ Folate administration reduces both DNA uracil incorporation and the occurrence of chromosome breaks in human cells.¹⁷⁴ *Ex vivo* experiments have shown that all the markers of chromosome damage in human lymphocytes are minimized at folic-acid concentrations that are higher than the RDA.^{175,176,177} Folate supplementation above the RDA has also been shown to reduce chromosome breakage in humans.^{178,179} In other studies, chromosome breaks have been linked to cancer.¹⁸⁰

A clue to the folate-cancer connection was the discovery of a polymorphism (C677T) in the gene that encodes methylene-THF reductase (MTHFR)—the enzyme that reduces methylene-tetrahydrofolate (CH₂=THF) to methyl-THF. This polymorphism decreases the activity of MTHFR, which increases the methylene-THF pool at the expense of the methyl-THF pool, resulting in decreased incorporation of uracil into DNA and a decreased num-

ber of chromosome breaks. It is a common polymorphism in populations of people who live in northern regions of the world, with 5–25% of individuals being homozygous for this polymorphism and up to 50% being heterozygous.

Several studies have shown a two- to four-fold lower risk of colon cancer in individuals who are homozygous for the 677T allele of methylene-THF reductase (MTHFR-TT), compared with individuals who are homozygous for the C677 allele and have a high folate intake.^{181,182,183,184,185,186,187} At low folate levels, however, the MTHFR-TT genotype does not seem to be protective and might even be a risk factor. Other studies show an increased risk for developing adenomatous polyps among individuals with the MTHFR-TT genotype.^{188,189,190} Adult acute lymphocytic leukemia (ALL)¹⁹¹ and childhood ALL¹⁹² have also been inversely associated with the MTHFR-TT genotype, indicating that folate deficiency might promote ALL. (See Table 26.20.)

Unfortunately, the MTHFR-TT genotype is not all good news. As the lower level of MTHFR decreases the methyl-THF pool, it increases serum levels of homocysteine—a risk factor for endothelial cell damage and cardiovascular disease.¹⁹³ Individuals who are homozygous for this allele have a two-fold increase in plasma homocysteine levels.

Low dietary intake of folate, B12, or B6 has been associated with a higher risk for developing cervical squamous epithelial lesions in a case-control study.¹⁹⁴ In contrast to studies mentioned above, individuals with the MTHFR-TT genotype also had a higher incidence of cervical cancer. The authors suggest this is due to a lack of inhibitory methylation—that results from a decreased methyl-THF pool—of human papillomavirus (HPV), which is a significant cause of cervical cancer.¹⁹⁵

Why is this polymorphism so frequent in populations in northern Europe? Although it is credible that these populations were, historically, chronically folate deficient because of their diet, cancer and heart disease come too late in life to select for individuals with a lower risk. The MTHFR-TT genotype might be selected for based on its ability to reduce uracil incorporation into sperm DNA, which consequently results in less DNA damage in offspring.^{196,197} Levels of nonmethyl-THFs are positively associated with sperm count and density.¹⁹⁸ Folate levels are therefore also important for male reproductive function, and further support the

Table 26.20 Evidence for Folate, B6, and B12 Deficiency and Cancer Risk

Type of Cancer	Comments	References
Colorectal cancer, adenomas	Lower intake of folate was associated with higher risk of colon cancer; long-term use of folate supplement lowers the risk of colon cancer by 75%. No association was seen between folate, B6, and B12 and risk of colorectal hyperplastic polyps.	165, 166, 316 *See below.
Breast cancer	Strong inverse association was seen between folate intake and risk of breast cancer among women who drink alcohol, which interferes with folate absorption. No association was seen between folate and B6 and breast cancer.	167, 168 214
Pancreatic cancer	Risk of pancreatic cancer in smokers was inversely associated with dietary folate.	169, 170
Oesophageal and gastric cancers	Folate and vitamin B6 were inversely associated, and vitamin B12 was positively associated, with these cancers in a case-control study.	172
Acute lymphoblastic leukemia—children	Acute lymphoblastic leukemia (ALL) was inversely associated with the variant MTHFR genotypes, indicating a role for folate in the development of ALL.	192
Acute lymphocytic leukemia—adults	A significant reduction in risk of ALL was found in those with the MTHFR 677TT genotype, indicating that folate deficiency might be a risk factor.	187
Cervical cancer	Risk of invasive cervical cancer was elevated for women with higher serum homocysteine. Dietary intakes of folate, B6, and B12 were inversely related to the risk of developing cervical dysplasia. No statistically significant association between folate, B12, and cervical cancer was found.	217 194 213
Prostate cancer	Lower intake of B6 was associated with prostate cancer.	215
Lung cancer	Lower intake of B6 (higher B6 serum level) was associated with lung cancer.	216
Ovarian cancer	Low dietary folate intake was associated with ovarian cancer, especially among woman who consumed alcohol (2 drinks/day).	171

*Ulrich CM, Kampman E, Bigler J, et al. Lack of association between the C677T MTHFR polymorphism and colorectal hyperplastic polyps. *Cancer Epidemiology, Biomarkers and Prevention*. 2000;9:427-433.

concept that folate deficiency can cause DNA damage. Germ-line damage to the sperm has also been linked to childhood cancers.¹⁹⁹ Further studies are required to determine if ALL is higher in children whose fathers have a poor diet.²⁰⁰

Vitamins B12 and B6

Vitamin B12 deficiency would be expected to cause chromosome breaks by the same uracil-misincorporation mechanism that is found with folate deficiency.²⁰¹ Both B12 and methyl-THF are required for the methylation of homocysteine to methionine. If cells are defi-

cient in either folate or B12, homocysteine accumulates. When B12 is deficient, tetrahydrofolate is trapped as methyl-THF, reducing the methylene-THF pool, which is required for methylation of deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP). B12 deficiency, like folate deficiency, therefore causes uracil to accumulate in DNA (author's unpublished observations). In a study of healthy elderly men²⁰² and young adults, increased chromosome breakage was associated with low dietary intake of either B12 or folate, or with elevated levels of homocysteine.^{203,204,205} B12 supplementation above the RDA was necessary to minimize chromosome breakage.^{206,207}

Vitamin B6 deficiency would also be expected to result in uracil misincorporation. B6 deficiency causes a decrease in the enzyme activity of serine hydroxymethyl transferase, which supplies the methylene group for methylene-THF.²⁰⁸ Several studies have shown that, in individuals with the MTHFR-TT genotype, vitamin B6 intake is associated with protection against colon cancer and/or adenomas.^{209,210,211}

Recent epidemiological studies have indicated an association between B6 or B12 deficiency and cancer prevention, but results are mixed.^{212,213,214} In one case-control study of diet and cancer, vitamin B6 deficiency was associated with prostate cancer.²¹⁵ A significantly lower risk of lung cancer was found in men with higher serum B6 levels.²¹⁶ Compared to men with the lowest vitamin B6 concentrations, men in the highest quintile had about one-half the risk of lung cancer. No associations were made between B12, folate, or homocysteine and lung cancer. Serum homocysteine levels were found to predict the risk of developing invasive cervical cancer in a large case-control study.²¹⁷

Oxidation, Micronutrients, and Cancer Risk

Oxidants are mutagens and are produced as by-products of normal mitochondrial energy production.²¹⁸ Radiation is a known oxidative mutagen. Antioxidant micronutrients, such as vitamins C and E, might function as anti-mutagens and anti-carcinogens.^{219,220} The evidence that supplementation with these vitamins lowers cancer risk is inconclusive.

Both experimental and epidemiological data indicate that vitamin C protects against stomach cancer.^{221,222,223} This is a plausible conclusion, as oxidative damage from inflammation caused by *Helicobacter pylori* infection is a risk factor for stomach cancer.²²⁴ Fruit and vegetable intake—the main dietary source of vitamin C—is also inversely associated with stomach cancer. Mayne and colleagues have also reported an inverse association between vitamin C and oesophageal adenocarcinoma.²²⁵ Many other studies, however, have reported no effect of vitamin C on cancer risk. A thorough review of intervention studies showed both positive²²⁶ and negative²²⁷ studies, and so the evidence is inconclusive.²²⁸ There are several reasons why a positive effect might not have been observed. The blood cell saturation of vitamin C occurs at about 100 mg/day in humans.²²⁹ Evidence indicates that this level minimizes DNA damage.^{230,231,232,233} Perhaps the differing results

from various studies were caused by differences in whether vitamin C reached tissue saturation levels in the population that was studied. If only a small proportion of the population had inadequate tissue saturation by vitamin C intake, a real effect would be missed. Other factors that might explain the difference in results include failure to adequately assess vitamin C intake, failure to assess whether people were using vitamin supplements or failure to take into account the effect of modifiers such as body-mass index or smoking (which decreases plasma vitamin C levels).²³⁴

Many studies have investigated the effects of vitamin C supplementation in humans using biomarkers of oxidative damage to DNA, lipids (lipid oxidation releases mutagenic aldehydes), and protein.^{235,236,237,238,239} For example, intervention studies with antioxidant supplements (100 mg per day of vitamin C, 28 mg per day of vitamin E, and 25 mg per day of β -carotene) were found to decrease DNA strand breaks in lymphocytes, as measured by the comet assay.²⁴⁰ Subsequent studies showed β -carotene by itself was ineffective at reducing the number of DNA breaks,²⁴¹ but that vitamin C was effective alone.²⁴²

Studies in rats have shown that spontaneous oxidative damage occurs at a rate of about 66,000 DNA adducts per diploid cell^{243,244} and, unlike uracil misincorporation, is likely to occur with equal frequency on both strands. Repair of oxidative adducts by glycosylase results in transient single-strand breaks in DNA. Increased oxidative damage is therefore associated with low vitamin C intake.²⁴⁵ Individuals who are deficient in both folate and antioxidant intake would have higher levels of both oxidative damage and uracil incorporation in their DNA, and be expected to have a high level of double-strand DNA breakage. Radiation (an oxidative mutagen) and folate deficiency have been shown to act synergistically in causing chromosome breakage in tissue-culture cells.²⁴⁶

Smoking is another producer of oxidative stress. A smoker needs to consume 40% more vitamin C than a non-smoker in order to maintain a comparable blood-plasma level of vitamin C.²⁴⁷ Several studies have examined the associations between paternal smoking, vitamin C intake, oxidative damage to sperm DNA, and childhood cancer in the offspring. Smoking depletes vitamin C, which is required to protect DNA in sperm against oxidative damage.^{248,249,250} Smokers, or men with low ascorbate intake, have lower seminal-plasma ascor-

bic-acid levels and higher levels of oxidative DNA damage in their sperm than either nonsmokers or men with adequate ascorbate intake.^{251,252}

Unfortunately, there have been few studies that have rigorously examined the effect of paternal vitamin C level by itself on cancer in offspring. Nevertheless, there is evidence that children with fathers who smoke have an increased rate of childhood cancer.^{253,254,255,256} An epidemiological study from China makes a particularly strong case that ALL, lymphoma, and brain cancer are each increased three- to four-fold in children of male smokers.²⁵⁷ The associations were strongest in men with the highest number of pack years of smoking. It seems likely, given the available evidence, that the cancer risk to offspring of male smokers would be higher when dietary antioxidant intake is low.

Inadequate Heme Synthesis Causes Mitochondrial Decay and Oxidative DNA Damage

Heme biosynthesis is predominantly in the mitochondria. Interfering with heme synthesis causes specific loss of heme-a, a component of complex IV, with consequent release of oxidants.^{258,259} Iron deficiency (25% of menstruating women in the U.S. ingest < 50% of the RDA) also causes release of oxidants and mitochondrial decay,²⁶⁰ presumably through lack of heme-a.²⁶¹ The poor tend to have the lowest levels and intake.^{262,263} Biotin deficiency, which is quite common in the population^{264,265} also causes defective mitochondrial complex IV and oxidant leakage (Atamna et al., in preparation). There is evidence that deficiency of copper,^{266,267} a component of complex IV, or pantothenate²⁶⁸ (Atamna et al., in preparation) leads to a decrease in complex IV. Zinc deficiency causes marked release of oxidants with marked oxidative damage to DNA,^{269,270} due to the inactivation of δ -aminolevulinate dehydratase, an enzyme of heme biosynthesis containing eight zinc atoms (Atamna et al., in preparation). Zinc deficiency is associated with cancer in both humans and rodent models.²⁷¹ Zinc intake inadequacy (10% of people in the U.S. ingest < 50% of the RDA) in human cells in culture causes oxidative DNA damage, inactivation of tumor suppressor protein, p53 (a zinc protein) and inactivation of oxidative DNA repair; these effects can multiply to cause severe genetic damage.^{272,273} The consequences of these various deficiencies are likely to be accelerated aging, neural decay, and cancer.^{274,275}

Common micronutrient deficiencies are likely to damage DNA by the same mechanism as radiation and many chemicals, and appear to be orders of magnitude more important.^{276,277,278} The need to set micronutrient requirements to minimize DNA damage has been reviewed by Fenech.²⁷⁹ We have compared radiation with folate deficiency to try to put risks in perspective.²⁸⁰ The poor and others at risk are not served if huge resources are put into minor hypothetical risks²⁸¹ and major risks are not addressed.

Dark Skin, Vitamin D, and Calcium Deficiency

The hormone vitamin D is formed in the skin with the aid of ultraviolet (UV) light from sunlight; however, too much exposure to UV light is dangerous. Humans who originate from northern areas with little UV radiation have light skin to maximize their exposure to UV rays, whereas people from southern areas have dark skin to minimize their UV light exposure. Northern populations in the U.S. are exposed to insufficient sunlight and individuals are often chronically vitamin-D deficient unless they drink vitamin D-fortified milk or take a supplement. Dark-skinned people who don't drink fortified milk and who live in northern cities, such as Boston, Detroit, Cleveland, Chicago, and Seattle, are the people most at risk unless they take a supplement. "Although both dark- and light-skinned individuals can produce vitamin D in response to UV light, this response is much more limited in dark-skinned individuals. The 25-hydroxyvitamin D, or 25(OH)D, levels in African-Americans and Hispanics are, therefore, lower than Caucasians in the U.S."²⁸² In a study in Boston, 80% of African-Americans and 60% of Hispanics were vitamin D deficient²⁸³ (and M. F. Holick, personal communication). Vitamin D is necessary for calcium mobilization for bone formation, and brittle bones are a consequence of vitamin D deficiency. In addition, there is an inverse relationship between vitamin D intake or levels and several types of cancer, primarily colorectal cancer and colorectal adenomas; there is also evidence for a connection with prostate cancer.^{284,285,286,287,288} A higher intake of calcium has been shown to lower risk for colorectal adenoma recurrence.²⁸⁹ A plausible mechanism by which vitamin D deficiency could increase cancer is the known inhibitory effect of vitamin D metabolites on cell proliferation, an essential component of carcinogenesis.²⁹⁰ African-Americans have

almost double the prostate cancer rate of whites and also have lower levels of the vitamin D metabolite 25(OH)D in their blood.²⁹¹ Recent epidemiological studies suggest that much of the increased cancer rate in African-Americans is due to vitamin D deficiency.²⁹²

Dark-skinned people such as African-Americans and some Hispanics tend not to drink milk as adults, because of lactose intolerance. Europeans and other northern people domesticated cows thousands of years ago and developed the ability as adults to metabolize lactose, which is a major sugar in cow's milk. Most of the rest of the world cannot use lactose as adults and therefore show lactose intolerance when they drink cow's milk and tend to avoid it; 70% of African-Americans, 53% of Mexican-Americans and 90% of Asians are lactose intolerant compared to 15% of northern Europeans and their descendants. As African-Americans and Hispanics also tend not to take vitamin supplements, these individuals are all the more likely to be calcium and vitamin D deficient.²⁹³ Most nutrient deficiencies also correlate well with poverty and low education. However, in some cases, such as vitamin D or calcium, it is clear that genetics is an important contributor. African-Americans have lower calcium, magnesium, potassium, and folate intakes than whites.²⁹⁴ The vitamin D/calcium story illustrates why understanding genetics is important in some cases to develop appropriate interventions for the populations and individuals at risk.

Multivitamins in Humans

Evidence is accumulating that a multivitamin/mineral supplement is good insurance, and would markedly improve health (e.g., heart disease, cancer, immune function, and cataracts), particularly for the poor, the young, the obese, and the elderly.^{295,296,297,298,299,300,301,302,303,304,305,306,307} The caveat is, of course, that too much of many of the minerals (e.g., iron, zinc, copper, selenium) and some of the vitamins (e.g., vitamin A, β -carotene) are toxic, though taking a multivitamin/mineral as insurance is not of concern. Mae West's dictum about sex, "Too much of a good thing is wonderful," doesn't apply to micronutrients. Advice to take a multivitamin should always be coupled with advice to eat a good diet, as we also need fiber, omega-3 fatty acids, and other ingredients in a balanced diet.³⁰⁸ It is also good to keep in mind Mark Twain's caution: "The main distinguishing characteristic between man and the lower animals is the desire to take pills."

Delaying the Mitochondrial Decay of Aging

Oxidative mitochondrial decay is a major contributor to aging.^{309,310,311,312,313} We are making progress in reversing some of this decay in old rats by feeding them the normal mitochondrial metabolites acetylcarnitine (ALC) and R-lipoic acid (LA) at high levels. The principle behind this effect appears to be that, with age, increased oxidative damage to protein causes a deformation of the structure of key enzymes with a consequent lessening of affinity (K_m) for the enzyme substrate.³¹⁴ The effect of age on decreasing the binding affinity of carnitine acyltransferase for ALC or acetyl CoA can be mimicked by reacting it with malondialdehyde (a lipid-peroxidation product that increases with age). Feeding the substrate ALC with LA, a mitochondrial antioxidant, restores the velocity of the reaction (K_m) for ALC transferase and mitochondrial function.³¹⁵ LA is an effective inducer of phase II antioxidant enzymes, including glutathione synthesis, as well as being a potent antioxidant.^{316,317,318}

In old rats (vs. young rats), mitochondrial membrane potential, cardiolipin level, respiratory control ratio, and cellular O₂ uptake are lower; oxidants/O₂, neuron RNA oxidation, and mutagenic aldehydes from lipid peroxidation are higher.^{319,320,321,322,323,324,325,326,327} Ambulatory activity and cognition decline with age.^{328,329} Feeding old rats ALC with LA for a few weeks restores mitochondrial function; lowers oxidants, neuron RNA oxidation and mutagenic aldehydes; and increases rat ambulatory activity and cognition (as assayed with the Skinner box and Morris water maze).^{v,330,331,332} ALC and LA are also effective in improving the aging rat heart.³³³ A recent meta-analysis of 21 double-blind clinical trials of acetylcarnitine in the treatment of mild cognitive impairment and mild Alzheimer's disease showed a modest efficacy vs. placebo.³³⁴ A meta-analysis of four clinical trials of lipoic acid for treatment of neuropathic deficits in diabetes showed significant efficacy vs. placebo.³³⁵ One should keep in mind, however, that a micronutrient-poor diet, as pointed out above, accelerates mitochondrial decay.

^vDr. Ames is one of the founders of Juvenon (www.juvenon.com), a company that has licensed the University of California patent on acetylcarnitine + lipoic acid for rejuvenating old mitochondria (Ames and T. Hagen, inventors), sells acetylcarnitine + lipoic acid supplements, and does clinical trials on them. Ames's founder's stock was put in a nonprofit foundation at the founding in 1999. He is the director of Juvenon's Scientific Advisory Board, but has no stock in the company and has not taken, and will not take, any reimbursement from the company.

Public Health

A metabolic tune-up via micronutrient supplementation is likely to have great health benefits, particularly for those with inadequate diets, such as many of the poor, young, obese, and elderly, who are most vulnerable to micronutrient insufficiency. Unfortunately, these needs are not being addressed adequately by the medical community. The issues discussed here highlight the need to educate the public about the crucial importance of optimal nutrition and the potential health benefits of a simple and affordable daily multivitamin/multi-mineral supplement. Tuning up metabolism to maximize the human health span will require scientists, clinicians, and educators to abandon the outdated paradigm of seeing micronutrients as merely preventing deficiency disease, and explore more meaningful ways to prevent chronic disease and achieve optimal health through better nutrition. It is becoming clear that unbalanced diets will be the major contributor to ill health in the population, with smoking following close behind.

The Biology of Inflammation: A Common Pathway in Cardiovascular Diseases, Part II
Peter Libby, MD

Introduction¹

Recognition that inflammatory pathways play a central role in circulatory pathophysiology furnishes a new dimension to understanding even the most familiar and clinically compelling cardiovascular diseases, notably atherosclerosis and acute myocardial infarction, both of which are discussed in detail. In addition, these inflammatory aspects of cardiovascular diseases may provide, in some cases, new therapeutic opportunities to forestall the development or the consequences of various cardiovascular conditions. Seemingly far afield at the outset, contemporary inflammation biology has concrete clinical ramifications for the practitioner. Learning to redirect inappropriate inflammatory responses may help us to improve patient outcomes in years to come. This essay will illustrate how inflammatory pathways contribute to two common and clinically compelling cardiovascular diseases. The first example, atherosclerosis, affects the blood vessels. The second, acute myocardial infarction, affects the heart itself.

¹Adapted, with permission, from: Libby P. Inflammation: a common pathway in cardiovascular diseases. *Dialogues in Cardiovascular Medicine*. 2003;8(2):59-73. The original article has been divided into two parts for this book; part I can be found in Section IV: Fundamental Physiological Processes, as Chapter 18. **Acknowledgement:** Supported in part by a grant from the National Heart, Lung, and Blood Institute (HL-34636).

Atherosclerosis: A Chronic Cardiovascular Inflammatory Disease

In the past, most considered atherosclerosis a type of lipid storage disease caused by excessive cholesterol accumulating in arteries in bland pools of extracellular lipid. Recent work, however, has heightened interest in inflammatory aspects of atherosclerosis, not only at a fundamental level, but also in relation to the clinic. Actually, atherosclerosis involves inflammation at all stages, ranging from the earliest steps in atheroma formation, straight through to the ultimate clinical complications of this common affliction.

Inflammation and the Initiation of Atherosclerosis

The first steps in atherogenesis recapitulate host defenses against microbial pathogens, as explicated in Part I of this discussion (see Chapter 18). However, in this caricature of a normal host defense pathway, lipids appear to play an important role as a trigger. Lipoproteins enter the arterial intima, where they can undergo modification by oxidation, creating oxidized forms of lipids that can incite inflammation.¹ Another type of modification of lipoproteins arises by chemical condensation with glucose residues and subsequent chemical reactions that yield advanced glycation end products (AGEs).² Hyperglycemia such as that encountered in diabetics accelerates formation of AGEs. AGE-modified

proteins can also stimulate inflammation. Recent evidence has renewed interest in the possibility that infectious agents themselves may participate in atherogenesis.³ Viral or bacterial pathogens may trigger the localized inflammatory response inculcated in the initiation of atherosclerosis. Modified lipids, glycated proteins, and infectious agents and their products alike can elicit the expression of proinflammatory cytokines from cells resident in the arterial wall, including endothelium and vascular smooth muscle cells.⁴ The proinflammatory cytokines thus produced can elicit on the endothelial surface the expression of adhesion molecules, such as VCAM-1, specialized in the recruitment of mononuclear cells. VCAM-1 binds just the sub-classes of leukocytes found in early atheroma, monocyte/macrophages, and T lymphocytes. Experiments in animals with defective VCAM-1 molecules show reduced atherosclerosis in response to hypercholesterolemia, supporting a role for this adhesion molecule in lesion formation.⁵

Once adherent, the mononuclear cell enters the artery wall in response to chemoattractant stimuli. In the case of tissue microbial invasion, postcapillary venules typically serve as the portal for entry of the leukocyte into the affected tissue. In the case of atherosclerosis, the artery wall itself being the site of the inflammatory response, the chemoattractants such as MCP-1 cause the leukocyte to enter the arterial intima. Once resident within the intimal layer, the monocyte undergoes differentiation into a macrophage. In the context of atherogenesis, the macrophage takes on a special phenotype, the lipid-laden foam cell. Engorgement with lipid cannot occur by binding of LDL particles to the classic LDL-receptor. Cholesterol loading rapidly reduces the expression of the LDL-receptor. This autoregulation mechanism prevents foam cell formation. In atheroma, macrophages express a variety of “scavenger receptors” that evade this regulatory step, continue to be expressed despite cellular lipid accumulation, and permit foam cell formation by facilitating entry of modified lipoprotein particles into the phagocyte.⁶ While resting monocytes express only low levels of scavenger receptors, after exposure to certain inflammatory mediators found in atheroma, such as M-CSF, macrophages express higher levels of these receptors that facilitate foam cell formation.⁷ Mutations in various scavenger receptors limit evolution of fatty lesions in hypercholesterolemic mice.^{8,9} Leukocyte adhesion, chemoattraction, and activation thus occur within the

nascent atheroma, replicating the steps in a typical inflammatory response. The foam cell-rich fatty streak represents the first stage of atheroma formation.

Inflammation and Evolution of Atheromatous Plaque

If inflammatory stimulation persists, fatty streaks can progress to more complicated forms of atherosclerosis, such as the fibro-fatty plaque. Fibrogenesis results from elaboration by arterial smooth muscle cells of extracellular matrix macromolecules, including collagens, elastin, and various proteoglycan molecules. Smooth muscle cells in the plaque arise from precursors resident in the intima in humans. Lesional smooth muscle cells may also arise by migration of medial smooth muscle cells into the intima, across the demarcating internal elastic lamina. In some types of arterial pathology, bone marrow-derived precursors may also give rise to smooth muscle cells involved in fibrous lesion formation.¹⁰ A variety of peptide growth factors can stimulate smooth muscle migration and proliferation, as well as regulate their biosynthesis of extracellular matrix macromolecules that form the fibrous part of complex atherosclerotic plaques. Protein mediators that stimulate smooth muscle migration and division include platelet-derived growth factor and basic fibroblast growth factor (bFGF).¹¹ Although named growth factors, in practical terms, these proteins could just as well be called cytokines, as no strict difference separates these two categories of biological mediators.

Cytokines such as IL-1 or TNF can augment the production of growth factors such as PDGF or bFGF by smooth muscle cells, providing a direct link between inflammation and the control of growth of vascular smooth muscle cells. PDGF *in vivo* probably promotes smooth muscle migration to a greater extent than proliferation. PDGF can also augment collagen production by vascular smooth muscle cells, consistent with its role in lesion evolution.

Atherosclerotic lesions also contain considerable numbers of T lymphocytes.¹² These T cells bear markers of activation. Atherosclerotic lesions contain IFN- γ , a typical product of activated T cells. Smooth muscle cells and macrophages in human lesions also express class II histocompatibility antigens, an indicator of stimulation by IFN- γ . The reader can surmise from the foregoing summary of the cellular immune response that the atherosclerotic lesion thus contains all of the cells involved

in acquired immunity. Antigens found in atherosclerotic plaques, such as modified lipoproteins and heat shock proteins (produced by cells in the atherosclerotic lesion), can act as antigens, stimulating an ongoing cellular immune response in the atheroma. In addition to innate immunity (activated macrophages) and the afferent limb of cellular immunity mediated by helper T cells, cell death mediated by Fas ligation and/or cytolytic T cells may also contribute to apoptosis of smooth muscle cells and macrophages, now clearly demonstrated in advanced human atherosclerotic lesions.¹³ In illustrating the basic biology of chronic immune responses, this essay invoked the example of the granuloma engendered by infection with the tubercle bacillus. In many ways, the atheroma resembles a specialized form of granuloma—noncaseating, but with a lipid core. Many of the cellular biology and pathophysiological responses in the atheroma resemble those in the infectious granuloma. In addition, many of the molecular mediators, the cytokines and growth factors, participate in both processes. Thus, the atheroma, far from being a bland accumulation of lipids, rather resembles a smoldering chronic inflammatory response, another example of host defenses gone awry.

Inflammation and the Acute Complications of Atherosclerosis

Atheromata seldom cause acute clinical manifestations because of their obstructive, space-occupying properties. Such substantial stenoses may cause stable angina pectoris, but most acute coronary syndromes result from thrombosis-complicating plaques. In fact, many acute coronary syndromes result not from highly stenotic lesions, but from lesions that may cause lesser degrees of stenosis. Clinical data supporting this view have emerged from angiograms performed following lysis of the culprit clot by thrombolytic therapy. A substantial minority of lesions that precipitate acute myocardial infarction produces stenoses of less than 50% once the occlusive thrombus has undergone lysis. Serial angiographic studies have also shown that the culprit lesion of acute myocardial infarction often showed modest degrees of stenosis on antecedent angiograms. Other serial angiographic studies have shown that a substantial number of human atherosclerotic plaques in coronary arteries evolve rapidly and discontinuously, rather than slowly and smoothly in time.

We now recognize that most thrombotic complications of atherosclerosis that cause acute events result from the physical disruption in the atherosclerotic plaque. One form of disruption, superficial erosion, may involve concomitant inflammation, although opinions on this point differ. However, all observers agree that a fracture of the fibrous cap, the most common cause of fatal acute myocardial infarction in humans, arises at sites of heightened inflammatory responses.^{14,15} Analysis of 20 culprit lesions of fatal acute myocardial infarctions showed that T lymphocytes and macrophages predominated at sites of clinical plaque rupture, causing fatal thrombi. Smooth muscle cells and macrophages in these zones of fatal plaque disruption showed expression of the class II histocompatibility antigen HLA-DR. This result supports a role for activated T cells and macrophages in clinically significant plaque disruption. Interruption in collagen synthesis by smooth muscle cells caused by the T cell product IFN- γ (the inducer of class II histocompatibility molecules) may account for weakness and fragility of the plaque's fibrous cap at places of rupture. Autopsy studies have shown that the presence of T lymphocytes correlates inversely with indices of the synthesis of fibrillar forms of collagen, the extracellular matrix macromolecule that lends strength to the plaque's fibrous cap.

Weakening the fibrous cap results not only from decreased collagen synthesis, but from augmented collagen degradation as well. Activated macrophages secrete several types of proteinases that can attack the extracellular matrix molecules responsible for the integrity of the plaque's fibrous cap. Macrophages exposed to inflammatory cytokines step up their production of collagenases of the matrix metalloproteinase (MMP) family and lysosomal enzymes capable of dissolving arterial extracellular matrix macromolecules. These findings provide a firm foundation for involvement of inflammation in weakening of the plaque's fibrous cap and plaque disruption and thrombosis.

Once the fibrous cap fails, blood coagulation factors undergo activation by contact with tissue factor expressed by macrophages in the plaque's lipid core.¹⁶ The expression of the tissue factor gene requires activation by inflammatory mediators. As discussed in the context of gram-negative sepsis, bacterial lipopolysaccharide can induce tissue factor expression in human monocyte/macrophages. T cells, found adjacent to macrophages in fatally disrupted human atherosclerotic

plaques, can activate tissue factor expression on macrophages by producing CD154 (CD40 ligand).¹⁷ Once again, pathways first unraveled in the context of cellular immune responses appear to participate importantly in aspects of atherogenesis, this time regulating the thrombogenicity of the plaque's lipid core.

Atherosclerosis and Inflammation: Therapeutic Implications

The foregoing discussion has illustrated the pivotal role of inflammation in all phases of atherosclerosis, lesion initiation, progression, and complication. This central role of inflammation and immunity in atherogenesis suggests that anti-inflammatory therapies might have a role in the management of this ubiquitous disease. Indeed, we have advanced the notion that lipid-lowering therapy exerts its benefit in atherosclerosis in part by acting as a specific anti-inflammatory intervention directed at the relevant instigation stimulus in this disease. Experimental studies have validated the concept that lipid lowering causes inflammation associated with atherosclerosis to subside.¹⁸ Human observations have shown decreases in inflammatory markers such as CRP with lipid lowering. While much of this benefit probably accrues due to lipid lowering itself, some of the pharmacologic agents used in lipid management may have direct effects independent of their hypolipidemic actions. For example, statins may possess so-called “pleiotropic” effects. By interfering with intracellular signaling pathways, statins may interrupt certain inflammatory pathways. However, many *in vitro* studies of pleiotropic actions of statins employ concentrations not likely achievable under clinical circumstances. Other classes of agents used to manage atherosclerotic risk factors, including the fibric acid derivatives and thiazolidinediones (such as the insulin-sensitizing “glitazone” drugs), may have direct anti-inflammatory effects mediated by binding to nuclear receptors known as peroxisome proliferator-activated receptors (PPARs).¹⁹ Once again, although based on substantial *in vitro* evidence, the clinical relevance of these nonlipid-dependent effects of PPAR agonists remains speculative at a clinical level.

Acute Myocardial Infarction: An Inflammatory Cardiac Disease

The previous section discussed how inflammation can set the stage for acute coronary syndromes in concluding myocardial infarction. However, myocardial infarction itself unleashes an inflammatory response at the level of the ventricular myocardium. Tissue injury can stimulate the innate immune response. Tissue necrosis elicits recruitment of the leukocyte emblematic of the acute inflammatory response, the granulocyte. The inflammatory response mediated by granulocytes in infarcting myocardium may actually extend the injury. These specific granules of neutrophils contain a form of collagenase (MMP-8) that can cleave interstitial collagen in the myocardium, favoring expansion of the infarct zone, the first step in myocardial remodeling. Such infarct expansion correlates with worsened clinical outcome. The reactive oxygen species released by the activated neutrophil can heighten local tissue injury in the infarcting myocardium. In addition, endothelial damage following on neutrophil activation can contribute to the “no-reflow” phenomenon and microvascular dysfunction that currently represents an obstacle to reperfusion therapies. Strategies that limit neutrophil accumulation following coronary ligation can alleviate some of the consequences of reperfusion injury.

Within days after acute myocardial infarction, the acute inflammatory response gives way to a more chronic reaction. Macrophages supplant polymorphonuclear leukocytes as the principal inflammatory cell type. The macrophages also contribute to tissue remodeling. Production of interstitial collagenases and other proteolytic enzymes can accentuate tissue remodeling initiated by granulocyte-derived proteinases. Administration of inhibitors of matrix metalloproteinases can limit left ventricular remodeling following experimental coronary ligation. Targeted disruption of the gene encoding MMP-9 can likewise limit infarct expansion.

The macrophage in the infarct can phagocytize dead cardiac myocytes and their debris. The macrophage also releases fibrogenic mediators that elicit tissue repair. Granulation tissue, comprised of stromal cells proliferating in response to protein growth factors migrating into the infarcted zone in response to these mediators, leads to scar formation replacing zones of coagulation necrosis of cardiac myocytes.

Angiogenesis also characterizes granulation tissue, replacing infarcted myocardium. Inflammatory mediators released by leukocytes infiltrating the infarcted zone may promote the production of angiogenic peptides such as acidic fibroblast growth factor (aFGF), bFGF, and vascular endothelial growth factor (VEGF). Thus, the “mopping up” operation affected by the chronic inflammatory cells may also promote collateral growth as part of the normal reparative mechanism in the aftermath of an acute myocardial infarction.

The tissue injury of acute myocardial infarction elicits an acute-phase response. CRP and serum amyloid-A levels in peripheral blood in the throes of an acute coronary event correlate with prognosis. Thus, the degree of the inflammatory response mounted in response to an ischemic insult to the myocardium can have considerable clinical consequence.

The exposure to immune cells of antigens usually contained within cells due to acute ischemic injury can elicit immune responses as well. Antimyosin antibodies can instigate autoimmune myocarditis in experimental models. The postpericardiotomy syndrome (Dressler’s) may represent an autoimmune response engendered by myocardial injury. The above examples illustrate how inflammatory responses participate in many aspects of acute myocardial infarction and its clinical complications.

Summary

The general pathway of inflammation plays out in most cardiovascular diseases of clinical import. The recognition of the role of inflammatory processes in cardiovascular diseases furnishes a new dimension to the understanding of their pathophysiology; it also provides us with a model for understanding the inflammatory and innate immunity responses in other conditions. The inflammatory aspects of cardiovascular diseases may provide, in some cases, new therapeutic opportunities to forestall the development or the consequences of various cardiovascular conditions (see, for example, the discussion on essential fatty acids that concludes this chapter). Contemporary inflammation biology has concrete clinical ramifications for the practitioner. Learning to redirect inappropriate inflammatory responses may help us to improve patient outcomes in years to come.

Inflammation and Autoimmunity: A Functional Medicine Approach

Alex Vasquez, DC, ND

Introduction

Numerous diseases and clinical entities can be categorized under the headings of “allergy,” “autoimmune diseases,” and “inflammatory imbalances,” and these conditions can range from mild allergies such as seasonal rhinitis to acute inflammatory emergencies such as vision-threatening temporal arteritis or neuropsychiatric lupus. Whether we call these conditions “allergic” or “autoimmune” is somewhat irrelevant; what is more important is recognizing that these conditions represent mild or severe forms of *immune system dysfunction*, wherein the immune system has begun over-responding to normally benign immunogens, whether environmental or endogenous. From this perspective, we can approach the evaluation and treatment of immune dysfunction patients with a unique set of questions. After determining the nature of the immune dysfunction, its severity, and target immunogen(s)—and once we have ruled out or appropriately managed acute emergencies—we can ask: *What factors have contributed to the genesis and perpetuation of the immune dysfunction?* Rather than merely suppressing the manifestations of ongoing immune dysfunction with the use, for example, of corticosteroids and antihistamines, *what interventions are appropriate to help normalize/optimize immune function?* Beginning the clinical assessment and therapeutic intervention with these questions leads us in a much different direction than does the prescription pad and consideration of which dose of which drug to administer.²⁰

Very much like the nervous system and the gastrointestinal tract, the immune system represents an interface between a complex, ever-changing external environment and an internal system that is striving to maintain homeostasis and defend its boundaries from potentially harmful foreign substances. Influences from within and without may alter the status of this immunologic interface and result in dysfunction to which we then affix various labels: allergic, inflammatory, or autoimmune. Restoration of health may be attained by pursuing higher levels of concordance between the internal and external milieus, such as better matching of environmental conditions and nutritional intake to

basic physiological needs.²¹ Previous conceptualizations of allergic and rheumatic disorders failed to appreciate the interconnectedness of various body systems and thus relied on pharmacologic interventions to suppress manifestations of underlying dysfunction. Treating all allergic disorders with “antihistamine” monotherapy and treating rheumatic disorders with immunosuppressants are two common examples of standard approaches that mask but do not normalize underlying immune dysfunction. In order to integrate new data and intervene more effectively, we must appreciate the complex interconnectedness of body systems and their relationship to the external environment. In functional medicine, we work to remediate dysfunction whenever possible, rather than relying on pharmacologic symptom suppression.

Multiple Manifestations of Immune and Inflammatory Imbalance

As discussed in other sections of this book, inflammation is a complex process with numerous complications and implications, the final details of which have yet to be elucidated. The section of this chapter on essential fatty acids (EFAs) examines many of the common underlying processes that link a number of disparate conditions that all have an inflammatory cause or mediator. Here, we will consider this topic from a number of points on the functional medicine matrix, because complex patients with inflammation and immune problems may present with widely varying clinical pictures.

Where do we begin? When faced with complex patients who seem to be “hypersensitive to everything”—including common foods and their own body tissues—we are faced with a daunting task. We have all seen patients in clinical practice who have some evidence of multiple food allergies along with evidence of autoimmunity, most commonly thyroiditis. Other patients may present with inflammatory neuropathy or atopy, along with a history of environmental exposure (e.g., mold or mercury), particularly following a series of stressful life events. With patients such as these, there is generally no single “right” place to begin; rather, the treatment plan must be multifaceted to address numerous aspects contributing to immune dysregulation. With the necessity of a multifaceted approach in mind, we begin with a detailed history to

listen for which areas are a high priority. In any group of patients with the same diagnostic label (e.g., multiple sclerosis or rheumatoid arthritis), the etiologies of their *individual* diseases might be quite different. By starting with an appreciation of the major influences in mind, we can better listen to our patients and therefore intervene more accurately. However, before the patient interview begins, we must already have an appreciation of the factors that can adversely affect immune regulation, so that we can ask appropriate questions during the interview.

What factors influence immune function and, when adversely altered, might predispose to immune dysfunction? What are the history, signs, and symptoms of each? What are the appropriate methods of assessment and intervention? How might these factors interact synergistically, such that a few minor perturbations might result in disastrous health consequences? An attempt to articulate answers to these questions is provided below; emphasis is placed on the areas considered most relevant for this discussion in general, though considerations beyond this list may be relevant for individual patients.

Psychoemotional Influences

That emotional and mental forms of stress can influence immune function is well established in the research literature and in our practical life experiences. We’ve all seen and experienced the sequential onset of infectious illness following acute or chronic stress. A few pertinent examples will serve to make the point:

- Military cadets in intensive training characterized by acute mental stress, sleep deprivation, and physical exertion show a greatly increased susceptibility to infectious disease, particularly cellulitis and pneumonia.²²
- Mental-emotional factors can also play a role in the development of allergy. In a prospective case-control study, children exposed to the stress of international relocation were more likely to develop atopic sensitization.²³
- Stress may promote the development and exacerbation of inflammatory bowel diseases by effecting reductions in protective mucus and secretory IgA and by increasing mucosal permeability; the subsequent reduction in mucosal defense increases antigen absorption, promotes sensitization to sub-threshold exposure to immunogens, and results in clinical relapse.²⁴ Loss of sIgA leaves the respira-

tory, gastrointestinal, and genitourinary tracts less defended and more vulnerable to microbial colonization and antigen absorption.

- Mild emotional stress appears to increase bacterial and yeast adherence to mucosal surfaces, potentially leading to overgrowth, infection, and clinical manifestations associated with *Helicobacter pylori*, *Candida albicans*, *Escherichia coli*, *Haemophilus influenzae*, and others. The primary mechanism appears to be the stress-induced increase in salivary adhesion molecule sulfo-Lewis-a, which links microbes to mucosal glycoprotein MUC5B.²⁵
- Mental-emotional stress commonly leads to sleep disturbance and insomnia, both of which exacerbate the body's inherent inflammatory tendency, as evidenced by increases in the inflammatory marker CRP in sleep-disturbed patients.²⁶

Conversely, relaxing, pleasant experiences appear to reduce inflammatory responses, promote normalization of neuroendocrine status, and allow humoral and cellular elements of the immune system to function competently. Music therapy has been shown to increase salivary secretory IgA, decrease plasma cortisol, decrease symptoms in patients with bronchial asthma, and reduce latex-induced wheal in patients with latex sensitization.²⁷ In a controlled clinical trial with 50 human subjects, stress reduction was shown to reduce experimental neurogenic inflammation.²⁸

In sum, a shift in the balance of emotional experience away from relaxation and toward stress appears to increase susceptibility to allergy, infection, and neurogenic inflammatory responses. Clinically, we see that many immune-mediated disorders are exacerbated by stressful events, and that some patients must adopt a less stressful lifestyle if healing of their ailment is to be attained. Optimization of the patient's psychoemotional environment, frequent implementation of stress-reduction and meditative techniques, and the establishment and preservation of restorative sleep are important to shift the inherent tendency of the body away from inflammation and in the direction of health and homeostasis.

Endocrinologic Influences

Several hormones have immune-modulating effects and show characteristic patterns of imbalance in patients with inflammatory and atopic disease. Clinically, we

observe that many patients with immune dysfunction have relatively lower levels of cortisol, dehydroepiandrosterone (DHEA), and testosterone, and more rarely, "subclinical" deficiencies of progesterone may be seen. Relative elevations in estradiol and/or exposure to estrogen-like compounds (xenoestrogens) are also common among patients with autoimmune disorders. Proof of principle is found in clinical trials and case reports demonstrating successful treatment of various allergic and autoimmune disorders when patients are treated with hormones such as testosterone, DHEA, and cortisol. Cortisol is a well-known immunoregulatory hormone, and it becomes immunosuppressive when administered or produced in supraphysiologic amounts or as a potentiated analog such as prednisone. Given that cortisol is immunoregulatory, and that chronic mental-emotional stress suppresses endogenous cortisol production,²⁹ a possible mechanism by which mental-emotional stress leads to the exacerbation of immune dysfunction is immediately apparent. Low endogenous production of cortisol appears to exacerbate many inflammatory, allergic, and autoimmune disorders, and administration of bioidentical cortisol in physiologic doses can lead to clinical improvement.^{30,31}

DHEA levels are low in patients with systemic lupus erythematosus and the inflammatory bowel diseases (Crohn's disease and ulcerative colitis³²); DHEA administration can lead to clinical improvement.^{33,34} Compared to disease-free control groups, men with rheumatic/autoimmune diseases show lower levels of testosterone³⁵ and higher levels of estradiol,³⁶ thus leading to a significant reduction in the testosterone/estradiol ratio; reversal of this trend is clinically desirable. A clinical trial involving postmenopausal women with rheumatoid arthritis showed that androgen administration led to significant subjective and objective improvements.³⁷ The clinical significance of progesterone's role in immune function is much less clear, particularly since paradoxical responses to progesterone are seen in certain patient groups.³⁸ Hormonal assessment and appropriate intervention are valuable considerations in patients with allergic and rheumatic diseases.

Environmental and Xenobiotic Influences

Environmental contributions to autoimmune and inflammatory disorders deserve high priority in the evaluation and treatment of all patients with rheumatic diseases, which, again, are manifestations of immune

dysfunction. The major considerations under the heading of “environment” include diet, nutrition, ultraviolet and ionizing radiation, exogenous microbial products (i.e., inhaled mycotoxins and bioaerosols), and xenobiotics such as mercury, herbicides, pesticides, and the plethora of industrial, military, and petrochemical toxicants.³⁹

- “Food allergies” (within which, for ease of discussion, we include intolerances and sensitivities as well as classic allergies) can precipitate a wide range of inflammatory disorders, including arthritis and inflammatory bowel disease.⁴⁰ In particular, sensitivity to wheat gluten can trigger lupus,^{41,42} thyroid autoimmunity,^{43,44} and several other autoimmune endocrinopathies.⁴⁵ Given that food allergies can damage the mucosa of the small intestine and thus promote macromolecular absorption, these reactions can also promote the development of additional food allergies via enhancement of antigen absorption, which promotes immune sensitization.
- Mercury is a type-1 sensitizing agent associated with autoimmune diseases⁴⁶ such as multiple sclerosis⁴⁷ and with atopic disease such as eczema.⁴⁸ Occupational exposure to the insecticide DDT is associated with reductions in serum IgG (suggesting immune suppression), as well as increases in serum antinuclear antibodies (suggesting immune dysregulation).⁴⁹ Indeed, the paradox of immunosuppression and concomitant autoimmunity is the classic manifestation of xenobiotic-induced immunotoxicity.
- Chronic exposure to mold from water-damaged buildings can induce neuronal autoimmunity and systemic inflammation, resulting in a clinical picture that may be labeled “multiple sclerosis” or “idiopathic peripheral neuropathy.”⁵⁰
- Vitamin D insufficiency is epidemic in the United States and is extremely prevalent (> 90%) among patients with chronic musculoskeletal pain;⁵¹ this condition induces a systemic inflammatory response and causes skeletal pain by promoting the development of an unmineralized collagen matrix which hydrates, swells, and compresses sensory nerves in the periosteum. Insufficient sun exposure—whether from indoor living, sunscreen use, or nonequatorial latitudes—can result in a vitamin D deficiency that is easily correctible with oral supplementation in the range of 4,000 IU per day for adults.⁵²

Thus, when evaluating patients with inflammatory, allergic, and autoimmune disorders, attention must be given to the environment in which the patient exists—including xenobiotic and dietary exposures, as well as the sufficiency or insufficiency of sun exposure and vitamin D intake.

Gastrointestinal and Mucosal Influences: Occult Infections

As discussed in depth in Chapter 28, impaired digestion and increased mucosal permeability can alter the intestinal milieu and promote macromolecule absorption, and these alterations may precipitate systemic inflammatory imbalance. More specifically, intestinal colonization with either pathogenic or immunogenic microbes such as yeast, gram-negative bacteria, protozoa, and amoebas may provoke an immune response that cross-reacts with human body tissues, inducing a systemic inflammatory disease.⁵³ Additional details are abundant in the research literature, strongly implicating altered bowel microflora, “dysbiosis,” as the genesis for many chronic health problems.⁵⁴

While most of this research is specifically relevant for the gastrointestinal tract, the mucosal surfaces of the nasopharynx, sinuses, lower respiratory tract, and the genitourinary mucosa must be considered, along with the patient’s domestic, occupational, and recreational environments as sources of microbe-induced immune dysfunction. More recently, occult dental infections have become recognized as a source of proinflammatory immunogenic stimulation that contributes to a wide range of chronic health problems.^{55,56,57,58} Regardless of their origin—whether endogenous (i.e., mucosal or dental) or exogenous (e.g., mold bioaerosols from water-damaged buildings)—many microbial products are clearly capable of initiating clinical disease and immune dysfunction in humans.⁵⁹

In situations where further investigation is indicated, most practitioners begin searching for occult infections by assessing the gastrointestinal tract with comprehensive stool and parasitology analysis performed by a specialty laboratory (three stool samples from three days, analyzed separately). Abnormal microbes are then eliminated and health-promoting microbes are replaced with probiotics (see the 4R program discussion in Chapter 28). Empiric antimicrobial therapy against bacteria, amoebas, protozoas, and yeast may be implemented if test results are negative and

clinical suspicion of occult infection or gastrointestinal colonization remains high. Thereafter, consideration of and assessment for occult dental infections by dental specialists (“biologic dentists”), occult infections in the respiratory and genitourinary tracts, and toxic microbial exposures from the patient’s occupational, residential, and recreational environments can be pursued. Mucosal integrity of the small intestine can be assessed easily and accurately with the lactulose-mannitol assay.

Nutritional Influences

While it is true that consumption of foods to which a person is reactive can precipitate and exacerbate a wide range of inflammatory disorders, it is also true that certain foods and cultural styles of eating can either promote or retard the development of inflammatory and autoimmune disorders. The standard American diet, commonly referred to as SAD, is inherently proinflammatory due to its excess of sugars and arachidonic acid and its insufficiency of omega-3 fatty acids and phytonutrients.⁶⁰ *In vitro* evidence shows that corn oil, a rich source of the omega-6 fatty acid linoleic acid, induces an inflammatory response in hepatic Kupffer cells and an upregulation in inflammatory gene transcription that is consistent with data in humans linking vegetable oil consumption with inflammatory and malignant diseases.⁶¹ Supplied in high amounts in dairy products, beef, pork, and other foods of land-animal origin, arachidonic acid is the precursor to the proinflammatory prostaglandins and leukotrienes that participate in the genesis and progression of essentially all inflammatory conditions; diets low in arachidonate tend to have a relative anti-inflammatory effect.

Consumption of meals with a high glycemic load and foods with a high glycemic index induces an inflammatory response demonstrated by elevations in C-reactive protein and other markers of inflammation. Whole, natural foods such as fruits, vegetables, nuts, seeds, and berries are generally rich sources of phytonutrients that have antioxidant and anti-inflammatory properties.⁶² Certain dietary components, such as vitamin D, green tea, rosemary, grape seed extract, resveratrol, selenium, and zinc, are also inhibitors of the NFκB proinflammatory cascade.

Modern diets are characteristically deficient in omega-3 fatty acids, and thus most of our patients are likewise deficient in these fatty acids that have anti-inflammatory benefits mediated by inhibiting proin-

flammatory prostaglandin production, increasing production of anti-inflammatory prostaglandins, and modulating genetic expression.⁶³ Harmonization of human physiology with a nutritional environment of whole natural foods, abundant exercise, and sufficient vitamin D is an important goal in the promotion of health and alleviation of disease.⁶⁴ Within the framework of a health-promoting diet, customization will be necessary for patients who are allergic to otherwise “healthy foods” such as citrus fruits and shellfish.

Neurogenic Influences

Neurogenic inflammation may play a major role in many allergic and autoimmune/inflammatory disorders, yet the importance of addressing the nervous system in the treatment of inflammatory conditions seems to be underappreciated by many healthcare practitioners. Neurogenic inflammation, the release of proinflammatory mediators by sensory terminals of the peripheral nervous system,⁶⁵ appears to play a role in diverse allergic and rheumatic diseases, including asthma⁶⁶ and rheumatoid arthritis.⁶⁷ Since neurogenic inflammation can be inhibited by interference with nociceptive input transmitted via afferent C fibers, and since intense mechanoreceptor stimulation by spinal manipulation interferes with nociceptive input transmitted via afferent C fibers,⁶⁸ it appears possible that spinal manipulation could help produce a neurogenically mediated anti-inflammatory benefit. Similarly, the overall benefits and anti-inflammatory effects of relaxation and stress reduction are partly mediated by reductions in neurogenically mediated inflammation.⁶⁹

Additional evidence reviewed by Meggs⁷⁰ shows that neurogenic inflammation is a contributing factor in several common clinical entities, including migraine, rhinitis, and the multiple chemical sensitivity syndromes. The phenomenon of “neurogenic switching” as described by Meggs⁷¹ is the mechanism by which sensory input, chemical exposure, or tissue damage in “location A” can be transmitted neurologically to produce pain, inflammation, and tissue degeneration in “location B,” and the occurrence of this phenomenon has been demonstrated *in vivo*.⁷² Indeed, neurogenic inflammation and its transmission to distant sites may be a significant factor in many inflammatory disorders encountered in clinical practice, and its amelioration via mechanoreceptor stimulation and stress-reduction techniques is worthy of consideration and additional research.

Therapeutic Interventions and Alternatives to NSAIDs

In late 2004 and early 2005, we witnessed the end of what can be referred to as the “cyclooxygenase paradigm” of inflammation. The specific targeting of the inflammation-induced cyclooxygenase-2 isoenzyme (COX-2) by selective pharmaceutical drugs rose and fell, leaving behind a legacy of human tragedy, exorbitant expenses, and suggestions of collusion between the pharmaceutical industry and the U.S. FDA, both of which failed to protect the public from medications that were well established as hazardous soon after their release onto the healthcare market.^{73,74,75} By demonizing and targeting COX-2, the pharmaceutical industry overlooked the beneficial roles of one of this enzyme’s major products—prostacyclin, which reduces both blood pressure and platelet aggregation. The widespread cardiovascular catastrophe that ensued due to the chronic administration of these COX-2 inhibitors injured at least 160,000 patients and killed an estimated 26,000–55,000 patients.⁷⁶ Previous to the introduction of COX-2 inhibitors, it was estimated that nonsteroidal anti-inflammatory drugs killed at least 16,500 arthritis patients per year.⁷⁷ Likewise, many surgical treatments for musculoskeletal pain carry excess risk and insufficient efficacy. For example, Bernstein and Quach⁷⁸ concluded in their 2003 review, “Arthroscopy for degenerative conditions of the knee is among the most commonly employed orthopedic procedures, but its effectiveness (like the effectiveness of many surgical operations) has never been proven in prospective trials.”

For all these reasons, it seems vital that clinicians consider alternatives to some of these conventional interventions. Safe and effective natural interventions for the treatment of musculoskeletal pain are well substantiated in the biomedical research literature and have been recently reviewed elsewhere.^{79,80,81,82} Manipulative, nutritional, and botanical interventions are briefly outlined in the sections that follow.

Manual Therapies

Spinal manipulation. Naturopathic, chiropractic, and osteopathic physicians receive training in manually applied manipulative therapies, the best known of which is spinal manipulation. The conclusion that chiropractic management of low-back pain is superior to pharmaceutical and surgical management in terms of

greater safety, greater effectiveness, and reduced cost has been consistently documented for more than a decade.⁸³ In a randomized trial involving 741 patients, Meade et al.⁸⁴ reported, “Chiropractic treatment was more effective than hospital outpatient management, mainly for patients with chronic or severe back pain. ... Secondary outcome measures also showed that chiropractic was more beneficial.” A three-year follow-up study by these same authors⁸⁵ in 1995 showed, “At three years the results confirm the findings of an earlier report that when chiropractic or hospital therapists treat patients with low-back pain as they would in day-to-day practice those treated by chiropractic derive more benefit and long term satisfaction than those treated by hospitals.” In 2004, Legorreta et al.⁸⁶ reported that the availability of chiropractic care was associated with significant cost savings among 700,000 patients with chiropractic coverage, compared to 1 million patients whose insurance coverage was limited to medical treatments. A literature review by Dabbs and Lauretti⁸⁷ found that spinal manipulation is safer than the use of NSAIDs in the treatment of neck pain. Contrasting the rates of manipulation-associated cerebrovascular accidents to the adverse outcomes of pharmaceutical and surgical treatments for spinal pain, Rosner⁸⁸ noted, “These rates are 400 times lower than the death rates observed from gastrointestinal bleeding due to the use of nonsteroidal anti-inflammatory drugs and 700 times lower than the overall mortality rate for spinal surgery.” Similarly, in his review of the literature comparing the safety of chiropractic manipulation in patients with low-back pain associated with lumbar disc herniation, Oliphant⁸⁹ stated that, “The apparent safety of spinal manipulation, especially when compared with other [medically] accepted treatments for [lumbar disk herniation], should stimulate its use in the conservative treatment plan of [lumbar disk herniation].”

Mechanisms of action of spinal manipulation include the following:

1. releasing entrapped intra-articular menisci and synovial folds;
2. acutely reducing intradiscal pressure, thus promoting replacement of decentralized disc material;
3. stretching of deep periarticular muscles to break the cycle of chronic autonomous muscle contraction by lengthening the muscles and thereby releasing excessive actin-myosin binding;

4. promoting restoration of proper kinesthesia and proprioception;
5. promoting relaxation of paraspinal muscles by stretching facet joint capsules;
6. promoting relaxation of paraspinal muscles via “postactivation depression,” which is the temporary depletion of contractile neurotransmitters;
7. temporarily elevating plasma beta-endorphin;
8. temporarily enhancing phagocytic ability of neutrophils and monocytes; and
9. activation of the diffuse descending pain inhibitory system located in the periaqueductal gray matter.

While this list of mechanisms of action is certainly not complete, for purposes of this section it is sufficient to point out that joint manipulation in general and spinal manipulation in particular have objective mechanistic effects that correlate with their clinical benefits. Additional details are provided in numerous published reviews,⁹⁰ textbooks, and the unsurpassed treatise by Leach.⁹¹ When evaluated by the parameters of safety, effectiveness, and cost effectiveness, spinal manipulation is clearly a valuable and rational primary therapy for the treatment of spine-related pain and inflammation, such as neck pain and low-back pain. Clinicians should provide timely referral for manipulative therapy for their patients with spinal pain, if those skills are not within their own repertoire.

Other manual therapies and physiotherapeutic interventions. There is a growing body of research on massage, hydrotherapy, and other physiotherapies for the effective treatment of pain and inflammation associated with aging⁹² or overexertion,⁹³ or caused by physical injuries such as frozen shoulder^{94,95} and by diseases such as rheumatoid arthritis,⁹⁶ osteoarthritis,⁹⁷ and asthma.⁹⁸ Massage can also be safe and effective in the treatment of low-back pain.⁹⁹ Regardless of the approach recommended, a referral to a skilled practitioner is vital.

Nutritional Supplementation

Glucosamine and chondroitin sulfate. Articular cartilage is produced endogenously from nutrients that are biochemically transformed into glucosamine and chondroitin—the “building blocks” from which cartilage is built. Oral supplementation with glucosamine and chondroitin is intended to enhance cartilage anabolism and counteract the cartilage catabolism seen in inflammatory and degenerative processes.¹⁰⁰ Clinical

trials with glucosamine and chondroitin sulfates have shown consistently positive results with osteoarthritis of the hands, hips, knees, temporomandibular joint, and low back. For example, in a three-year, placebo-controlled clinical trial, glucosamine sulfate was superior to placebo for pain reduction and preservation of joint space in patients with knee osteoarthritis.¹⁰¹ The adult dose of glucosamine sulfate is generally 1,500–2,000 mg per day in divided doses, and the dose of chondroitin sulfate is approximately 1,000 mg daily. Both treatments are safe for multi-year use. Rare adverse effects include allergy and nonpathologic gastrointestinal upset. Clinical benefit is generally significant following 4–6 weeks of treatment, and is maintained for the duration of treatment. Glucosamine does not adversely affect glucose metabolism or insulin resistance in diabetics.

Niacinamide. More than 50 years ago, pioneering clinical studies by Kaufman¹⁰² showed that niacinamide was effective in the treatment of osteoarthritis. Confirmation of these results was recently provided in a double-blind, placebo-controlled study documenting that niacinamide therapy improved joint mobility, reduced objective inflammation as assessed by ESR, reduced the impact of the arthritis on the activities of daily living, and allowed a reduction in medication use.¹⁰³ Inhibition of joint-destroying nitric oxide appears to be an important mechanism of action in the antirheumatic effect of niacinamide; however, the nutrient may also provide an antiarthritic benefit via enhancement of mitochondrial function and reversal of aging phenotypes that characterize chondrocyte senescence. The standard dose of niacinamide for the treatment of joint pain is 500 mg given orally six times per day. Hepatic dysfunction is rare when daily doses are kept below 3,000 mg per day, yet Gaby¹⁰⁴ recommends measurement of liver enzymes after three months of treatment and yearly thereafter.

Proteolytic enzymes. Enzyme preparations containing pancreatin, bromelain, papain, amylase, lipase, trypsin, and alpha-chymotrypsin are well absorbed into systemic circulation following oral administration and provide numerous health benefits, particularly in the treatment of conditions associated with inflammation or infection (cellulitis, diabetic ulcers, sinusitis, and bronchitis).¹⁰⁵ For example, in a double-blind, placebo-controlled trial with 59 patients, Taub¹⁰⁶ documented that oral administration of bromelain significantly

promoted the resolution of congestion, inflammation, and edema in patients with acute and chronic refractory sinusitis; no adverse effects were noted. Reporting from the Tulane University Health Service Center, Trickett¹⁰⁷ reported that a papain-containing preparation benefited 40 patients with various injuries (e.g., contusions, sprains, lacerations, strains, fracture, surgical repair, and muscle tears); no adverse effects were seen. In a recent open trial of patients with knee pain, Walker et al.¹⁰⁸ found a dose-dependent reduction in pain and disability, as well as a significant improvement in psychological well-being in patients consuming bromelain orally. Although administration of single enzymes may be appropriate for clinical use, enzyme therapy is generally delivered in the form of polyezyme preparations containing pancreatin, bromelain, papain, amylase, lipase, trypsin, and alpha-chymotrypsin. Tablets are administered between meals to preserve enzymatic action and enhance absorption.

Botanical Anti-inflammatories

Devil's claw (*Harpagophytum procumbens*). Supported by centuries of use and numerous clinical trials, *Harpagophytum* is a moderately effective botanical analgesic suitable for clinical utilization. Clinical trials showing that *Harpagophytum* does not alter eicosanoid metabolism in humans suggests that this botanical works centrally or peripherally on the nervous system, and a recent experimental study shows that components of *Harpagophytum* have an antinociceptive effect in the spinal cord.¹⁰⁹ In a recent meta-analysis of 12 clinical trials, *Harpagophytum* was found to be clinically valuable and with adverse effects comparable to placebo.¹¹⁰ In patients with osteoarthritis of the hip and knee, *Harpagophytum* is just as effective yet safer and better tolerated than the drug diacerein. In a study involving 183 patients with low-back pain, *Harpagophytum* was found to be safe and moderately effective in patients with "severe and unbearable pain" and radiating pain with neurologic deficit.¹¹¹ Most recently, *Harpagophytum* was studied in a head-to-head clinical trial with the notorious selective COX-2 inhibitor Vioxx® (rofecoxib); the data indicate that *Harpagophytum* was safer and at least as effective.¹¹² About 8% of patients may experience diarrhea or other mild gastrointestinal effects, and fewer patients may experience dizziness; *Harpagophytum* may potentiate anticoagulants. Treatment should be continued for at least four

weeks, and many patients will continue to improve after eight weeks from the initiation of treatment.¹¹³ Products are generally standardized for the content of harpagosides, with a target dose of at least 30 and preferably up to 60 mg harpagosides per day. Chrubasik¹¹⁴ noted that while *Harpagophytum* appears to be safe and moderately effective for the treatment of musculoskeletal pain, different proprietary products show significant variances in potency and clinical effectiveness. Overall, the data suggest that *Harpagophytum* is better than placebo and at least as good as commonly-used NSAIDs,¹¹⁵ suggesting that *Harpagophytum* should be clinically preferred over NSAIDs due to the lower cost and greater safety.

Cat's claw (*Uncaria spp*). Like many other botanicals, *Uncaria* species, including *Uncaria tomentosa* and *Uncaria guianensis*, have been used for centuries, and modern research is providing proof of safety and efficacy. *Uncaria* demonstrates multifunctional anti-inflammatory benefits by reducing inflammation mediated by NFκB, TNF-α, COX-2, and PGE-2. Thirty patients with osteoarthritis of the knees benefited from highly concentrated, freeze-dried aqueous extraction of *Uncaria guianensis* dosed at one capsule of 100 mg daily; reduction in pain was approximately 36% at four weeks.¹¹⁶ A year-long study of patients with active rheumatoid arthritis (RA) treated with sulfasalazine or hydroxychloroquine showed "relative safety and modest benefit" of *Uncaria tomentosa* (UT).¹¹⁷ No major adverse effects have been noted; however, headache and dizziness are more common in patients receiving *Uncaria* than in patients in placebo groups. Based on its historical use as a contraceptive, this herb should not be used during pregnancy or by women desiring to conceive. Commercially prepared products contain between 250 and 500 mg per dose and are standardized to 3.0% alkaloids and 15% total polyphenols and administered 1–3 times per day. Other studies with *Uncaria tomentosa* have shown enhancement of post-vaccination immunity and enhancement of DNA repair in humans.

Willow bark (*Salix spp*). Actions of willow bark are manifold, including antioxidative, anticytokine, along with cyclooxygenase- and lipoxygenase-inhibiting effects. In a double-blind, placebo-controlled clinical trial in 210 patients with moderate/severe low-back pain (20% of patients had positive straight-leg raising test), extract of willow bark showed a dose-dependent analge-

sic effect, with benefits beginning in the first week of treatment.¹¹⁸ In a head-to-head study of 228 patients comparing willow bark (standardized for 240 mg salicin) with Vioxx® (rofecoxib), treatments were equally effective yet willow bark was safer and 40% less expensive.¹¹⁹ The daily dose ranges from 120 to 240 mg of salicin, and products should include other components of the whole plant for enhanced efficacy. Except for rare allergy, no adverse effects are known. Use during pregnancy and with anti-coagulant medication is discouraged.

Boswellia (*Boswellia serrata*). Boswellia shows anti-inflammatory action via inhibition of 5-lipoxygenase with no effect on cyclooxygenase. A recent clinical study showed that Boswellia was able to reduce pain and swelling while increasing joint flexion and walking distance in patients with osteoarthritis of the knees.¹²⁰ While reports from clinical trials published in English are relatively rare, a recent abstract from the German medical research¹²¹ stated, “In clinical trials promising results were observed in patients with rheumatoid arthritis, chronic colitis, ulcerative colitis, Crohn’s disease, bronchial asthma and peritumoral brain edemas.” Minor gastrointestinal upset has been reported, but otherwise this botanical is very well tolerated. Products are generally standardized to contain 37.5–65% boswellic acids, which are currently considered the active constituents with clinical benefit. The target dose is approximately 150 mg of boswellic acids thrice daily; dose and number of capsules/tablets will vary depending upon the concentration found in differing products.

Ginger (*Zingiber officinale*). Ginger is a well-known spice and food with a long history of consumption and use as an anti-inflammatory and antinausea agent. Components of ginger inhibit 5-lipoxygenase as well as cyclooxygenase. With its dual action in the reduction of inflammation-promoting prostaglandins and leukotrienes, as well as its ability to inhibit nitric oxide production, ginger has been shown to safely reduce the pain and disability associated with osteoarthritis, rheumatoid arthritis, muscle aches, osteoarthritis of the knees, and migraine headaches. Doses up to 1 g of ginger per day have been safely used during pregnancy to reduce nausea and vomiting¹²² and hyperemesis gravidarum.¹²³ Doses for the treatment of rheumatic conditions have ranged from 1 g (one-half teaspoon) of powdered ginger up to 50 g per day of fresh or lightly cooked root. The volatile principles of ginger often create a warm or burning sensation in the stomach that is

mild and reducible with food consumption, and research suggests that ginger has a protective benefit against gastric ulceration. No significant adverse effects due to ginger are known; the presence of cholecystitis or the use of Coumadin/warfarin are relative contraindications due to ginger’s mild cholagogic and anticoagulant actions, respectively.

Summary

The data surveyed in this section will provide most clinicians with an expanded perspective on the causes of and available treatments for clinical entities characterized by pain, inflammation, and immune dysregulation. While alternatives to NSAIDs were reviewed, their use as first-line therapy for pain and inflammation is of secondary importance to the larger and more comprehensive goal of attaining overall health improvement and a reduction in any systemic inflammatory tendency initiated and perpetuated by occult infections, food allergies, hormonal aberrations, hypovitaminosis D, xenobiotic exposure, and a proinflammatory dietary pattern.

Clinicians implementing the clinical approach outlined here can conceptualize the strategy as containing two specific arms that can be implemented simultaneously for optimal clinical improvement. First, the patient’s overall health and environmental status must be evaluated and optimized to the greatest extent possible (common sense may lead us to question the use of anti-inflammatory drugs while the patient continues to consume a proinflammatory diet, for example). Second, while both patient and doctor are engaged in characterizing and optimizing the patient’s overall health—e.g., searching for and eliminating occult infections and treating nutritional deficiencies (such as vitamin D) and nutritional excesses (such as iron overload¹²⁴)—specific nutritional and botanical anti-inflammatory and analgesic interventions can be employed to effect a more rapid resolution of swelling, discomfort, and tissue injury. This dual approach to restoring overall health and reducing symptoms is gratifying for both the doctor and the patient. A comprehensive approach, inclusive of the nutritional and botanical therapies described herein, can be supported by peer-reviewed research in the biomedical literature and is safe and cost-effective.¹²⁵

Essential Fatty Acids

Robert H. Lerman MD, PhD

Introduction

Essential fatty acids (EFAs) are of critical importance for two basic reasons. First, they are essential constituents of all cell membranes and thus are determinants of membrane stability, receptor action, membrane-bound enzyme activity, hormone binding, cell fluidity, signal transduction, and ion channel function.¹²⁶ Second, they are precursors of eicosanoids, second-messenger mediators involved in inflammation. It is the latter aspect that will be emphasized in this chapter. Evidence will be presented indicating the role of fatty acids and their derivative compounds in several inflammatory disorders, including cardiovascular disease, inflammatory bowel disease, rheumatoid arthritis, bronchial asthma, psoriasis, and renal disease.

Whereas acute inflammatory reactions are usually protective and part of the normal innate immune response, uncontrolled chronic inflammatory processes are detrimental^{127,128} and lead to disease. The functional medicine use of EFAs in these conditions is an important therapeutic tool; understanding the common pathophysiology involved in inflammation allows the functional medicine practitioner to manage seemingly disparate disorders in a consistent fashion. While the emphasis will be placed on fatty acids as precursors to eicosanoids, the value of these essential constituents via their membrane functions should not be overlooked. Nevertheless, it is important to understand that whereas supplementation with essential fats to suppress inflammation is of great value, such management should not be construed as definitive. Always, the clinician must search for and, when possible, determine and correct the underlying cause(s) of dysfunction in order to produce sustained reversal of illness.

Definitions and Pathways

PUFAs, Eicosanoids, Prostanoids, Isoprostanes, and Resolvins

Polyunsaturated fatty acids (PUFAs) include the essential fatty acids (EFAs) and their derivatives, collectively referred to as “essential fats” to emphasize the fact that many of these PUFAs are critical to life.¹²⁹ Linoleic

acid (LA; 18:2 ω 6) and α -linolenic acid (ALA; 18:3 ω 3) are the EFAs, the precursors of the ω 6 and ω 3 fatty acid families, respectively. EFA derivatives include compounds with 20 or more carbon atoms and 3 to 6 double bonds. Eicosanoids (from *eicosa* meaning “20” in Greek) are local-acting, hormone-like lipid mediators with brief half-lives, produced by oxidation of the 20-carbon ω 6 fatty acids, AA (AA; 20:4 ω 6) and di-homo-gamma-linolenic acid (DGLA; 20:3 ω 6), as well as by the 20-carbon ω 3 fatty acid, eicosapentaenoic acid (EPA; 20:5 ω 3). These fatty acids are acquired only by ingestion of essential fats from foods or supplements. (Figure 27.1 shows the arachidonic acid cascade.)

Figure 27.1 Arachidonic acid (AA) cascade

There are three main enzymatic pathways for synthesis of eicosanoids.¹³⁰ Some compounds are also formed non-enzymatically. Among the enzymatic pathways, cyclooxygenase (COX), also known as prostaglandin synthase, generates endoperoxides, which are converted into prostanoids: prostaglandins (PGs), thromboxanes (TXs), and prostacyclins (PGIs). The lipoxygenase (LOX) pathway leads to production of hydroperoxyeicosatetraenoic acids (HPETEs) and lipoxins. The so-called “third pathway” has drawn less attention and is mediated by cytochrome P450 enzymes to form a number of hydroxy fatty acids, HETEs, and epoxy acids. The main eicosanoids are the PGs, LTs (leukotrienes), and TXs. Most cells synthesize eicosanoids but the type of compound depends upon the particular cell. Platelets produce TXA₂, a potent platelet aggregator and vasoconstrictor, from AA, and TXA₃, a weaker platelet aggregator, from EPA. Endothelial cells produce PGI₂, a potent vasodilator and platelet aggregation inhibitor,

from AA, and PGI₃ with lesser vasodilatory and aggregation inhibitory effects, from EPA. Leukocytes produce LTB₄, a powerful chemotactic, vasoconstrictive, vascular permeability, and neutrophil aggregation factor, from AA, and LTB₅, with very weak chemotactic and vasoconstrictor activities, from EPA.¹³¹

Free radical-catalyzed peroxidation of AA leads to the formation of isoprostanes by the non-enzymatic pathway. Most of these eicosanoids are either biologically active or are converted into metabolites that have biological activities. F₂-isoprostanes are potent vasoconstrictors. Measurement of F₂-isoprostanes is one of the most reliable approaches for assessing oxidative stress status *in vivo*.¹³² Neuroprostanes are similar compounds formed from free radical-mediated oxidation of DHA, which is highly enriched in neurons. F₄-neuroprostanes appear valuable as a marker of oxidative stress in the brain in neurodegenerative diseases.¹³³ Isoprostanes are mediators of hypertension (HTN) and tissue ischemia.

Recently, resolvins, docosatrienes, and neuroprotectins have been identified in spontaneously resolving inflammatory exudates.¹³⁴ In initial studies, animals had been treated with aspirin, and the compounds isolated from the resolving exudates were termed aspirin-triggered resolvins. Subsequent studies indicated that these oxygenated products were also generated from EPA and DHA without aspirin. They possess potent anti-inflammatory, pro-resolving, protective, and immunoregulatory properties. They dampen inflammation and neutrophil-mediated injury and are considered self-protective mediators. Of note, DHA has been shown to be a substrate for human COX-2 in the formation of this class of compounds.¹³⁵ Expect to hear much more about them in the future.¹³⁶

Eicosanoid Precursors

AA is the principal eicosanoid precursor, as the membranes of most cells contain substantially more AA than other eicosanoid precursors.¹³⁷ It is the precursor of proinflammatory and pro-aggregatory eicosanoids; EPA is the precursor of eicosanoids with antagonistic effects. (Figure 27.2 shows dietary influences on the EFA pathways.) DGLA is the precursor of 1-series eicosanoids with principally inflammatory modulating effects. DGLA may be converted to AA via the enzyme delta-5 desaturase (D5D), an enzyme that generally has low activity in humans. Thus, most AA is of dietary origin; its primary source in the U.S. diet is from animal prod-

ucts. DGLA comes mainly from dietary LA and requires conversion to gamma-linolenic acid (GLA) by delta 6-desaturase (D6D), an enzyme whose activity may be impaired by a number of factors,¹³⁸ such as starvation, a very low-protein diet, high alcohol intake, smoking, stress-related hormones (corticosteroids and catecholamines), and intake of excessive saturated fat and/or *trans* fatty acids, as well as aging in males, ionizing radiation, some viral infections, atopic eczema, and type 1 diabetes. Vegetable and marine oils potentially suppress both D6D and D5D, with effects of fish oils being greater.¹³⁹ A calorie-restricted intake may increase D6D activity three-fold and a very high-protein diet activates it.¹⁴⁰ When D6D is inhibited, bypassing that metabolic step by providing GLA from evening primrose oil or borage oil will allow substrate for DGLA with ultimate series-1 eicosanoid formation.

Enzymes and Inhibitors

Phospholipase A₂ (PLA₂) activation is responsible for the initial mobilization of AA from membrane phospholipids.¹⁴¹ PLA₂ is located at the cell membrane and may be inhibited by drugs such as cortisone, and by natural agents such as licorice, vitamin E, and quercetin.¹⁴² Two separate isoforms of COX, COX-1 and COX-2, catalyze the same reactions. COX-1 is a constitutive enzyme and its activity doesn't change much once the cell is mature. COX-2 is highly inducible in response to inflammatory stimuli¹⁴³ and is highly expressed in inflamed tissues. It is believed that eicosanoids produced by COX-1 activity are essential for physiological functions, while those produced by COX-2 lead to various pathological changes in body tissues. COX-2 is upregulated by cytokines, mitogens, and endotoxins and produces PGs involved in inflammatory processes. Non-steroidal anti-inflammatory drugs (NSAIDs) such as aspirin, indomethacin, and ibuprofen are non-selective COX inhibitors, inhibiting both COX-1 and COX-2 activities.^{144,145,146} COX-1 derived eicosanoids are required for the protection of gastrointestinal mucosa, maintenance of renal function, and control of hemostasis. COX enzymes may be inhibited not only by medications but also by many natural agents including ginger,¹⁴⁷ turmeric (*Curcuma longa*),¹⁴⁸ melatonin,¹⁴⁹ green tea,¹⁵⁰ quercetin,¹⁵¹ and cayenne.¹⁵² Certain natural products (including hops fractions) act upstream, possibly at the level of NFκB, to reduce the production of COX-2.¹⁵³ 5-LOX is modulated by the EPA/AA ratio and inhibited by drugs such as colchicine,¹⁵⁴ as well as by

Figure 27.2 Dietary sources and the AA cascade

natural agents such as vitamin E,¹⁵⁵ onion (quercetin),¹⁵⁶ cloves (eugenol),¹⁵⁷ turmeric (curcumin),¹⁵⁸ resveratrol,¹⁵⁹ garlic (*Allium sativa*),¹⁶⁰ and *Boswellia serrata*.¹⁶¹

Recently, selective COX-2 inhibitors have come under fire, as they were found to increase myocardial infarction and stroke risk.¹⁶² The proposed mechanism for this increased risk is as follows. Non-selective COX inhibitors, but not selective COX-2 inhibitors, significantly inhibit TXA₂-dependent platelet aggregation.¹⁶³ Unopposed COX-2 inhibition reduces biosynthesis of prostacyclins, which are vasodilators and potent systemic inhibitors of platelet aggregation in healthy humans. In addition, inhibition of PGI₂ and PGE₂ in the kidney leads to sodium and water retention, thus elevating blood pressure.¹⁶⁴

Anti-inflammatory Effects of Dietary Omega-3 Fatty Acids

The first evidence of the importance of $\omega 3$ s in inflammatory conditions arose from epidemiologic observations of the Inuit, indicating a low incidence of coronary heart disease, inflammatory bowel disease, asthma, and severe psoriasis. These people traditionally

got their fat almost exclusively from marine mammals (primarily whale and seal meat) and fish. ALA suppresses the metabolic products of LA, a mechanism by which even the essential $\omega 3$ fatty acid (in flaxseed oil) has an anti-inflammatory effect. A more powerful anti-inflammatory effect is obtained by providing EPA (as in fish oil). As the conversion of ALA to EPA is slow and limited,¹⁶⁵ provision of EPA provides a more rapid and effective benefit in inflammatory conditions. Diets enriched with fish oil-derived fatty acids consistently raise plasma and membrane EPA levels.¹⁶⁶ EPA inhibits conversion of DGLA to AA and displaces AA in membrane phospholipids, thus decreasing AA availability for inflammatory eicosanoid formation. Omega-3 fatty acids have greater affinity for COX and LOX than $\omega 6$ s. EPA also exerts anti-inflammatory effects by inhibiting the 5-LOX pathway in neutrophils and monocytes and inhibiting the LTB₄-mediated function of neutrophils.¹⁶⁷

Not only do $\omega 3$ fatty acids reduce inflammation via the eicosanoid pathways, but they also suppress cytokines, the first messenger molecules. Flaxseed oil given over four weeks reduced TNF- α and mononuclear cell IL1- β production by 30%. Fish oil proved more effective

over the same time period, reducing mononuclear cell TNF- α and IL1- β by 74% and 80%, respectively.¹⁶⁸

Fish oils are also PPAR γ agonists, similar to the thiazolidinedione class of drugs used in diabetes management.¹⁶⁹ Thiazolidinediones have anti-inflammatory effects.¹⁷⁰ As diabetes and metabolic syndrome are associated with inflammation, this activity of fish oils may also serve to dampen inflammation in genetically predisposed people. The interaction with genetic predisposition should not be forgotten, as the sensitivity to anti-inflammatory effects of fatty acids is influenced by individual genotypic characteristics.¹⁷¹

Despite the growing evidence of their importance, data are accumulating that as a nation we are consuming insufficient quantities of ω 3 fatty acids.¹⁷²

Anti-inflammatory Effects of GLA Alone and in Combination with EPA

Not only is DGLA the precursor to the 1-series eicosanoids with inflammatory modulating properties, but it is also the precursor to other molecules—15-hydroxyeicosatrienoic acid (15HETrE) and 15-OH-DGLA—that block synthesis of AA products via inhibition of 5-LOX and 12-LOX.^{173,174} Neutrophils from subjects supplemented with GLA produce less of the inflammatory mediator LTB₄. In view of these effects, dietary supplements of GLA have been used to reduce the inflammatory response. Concern has been raised that GLA may increase AA in serum and lead to a proinflammatory response. By combining EPA with GLA (3.0 g/d of GLA and EPA over three weeks), proinflammatory AA metabolite synthesis was reduced, and potentially harmful increases in serum AA were not induced, while serum levels of EPA were significantly increased.¹⁷⁵ Pischon et al. found that ω 6 fatty acids do not inhibit the anti-inflammatory effects of ω 3 fatty acids and that the combination of both types of fatty acids may be associated with the lowest levels of inflammation.¹⁷⁶

Although more data are needed, the combination of GLA and EPA appears to be a reasonable approach in inflammatory conditions.

Effects of Fish Oils in Inflammatory Conditions

Rheumatoid arthritis. In rheumatoid arthritis (RA), joints are destroyed by abnormal multiplication of synoviocytes. COX-2 is induced in the synoviocytes and cartilage with release of PGE₂, PGF₂, PGI₂ and TXA₂

from the synoviocyte.¹⁷⁷ PGE₂ is involved in joint destruction by stimulating bone resorption. TXA₂ upregulates TNF- α and IL1- β synthesis. These cytokines, in turn, upregulate release of factors implicated in irreversible joint damage in RA, such as collagenase and stromelysin.¹⁷⁸ As described previously, fish oil inhibits TXA₂, thus inhibiting TNF- α and IL1- β synthesis, and thereby reducing destructive enzymes such as collagenase. In addition to the effects of fish oils on inflammation, as noted earlier, this mechanism provides an additional rationale for fish oil supplementation in patients with RA. There have been at least 13 randomized controlled trials in RA, using 2.6–7.1 g/d for 12–52 weeks, with improvement reported in all these studies.¹⁷⁹ The clinician and patient should be aware that these effects are generally delayed for 2–3 months. EPA + DHA, 90 mg/kg/day (3:2 ratio), is associated with a shorter period to response than 45 mg/kg/d. Thus, it is prudent to load initially with the higher dose, but use a lower dose for maintenance.¹⁸⁰

Diet, as mentioned previously, is the major source of AA. Accordingly, Adam et al.¹⁸¹ investigated the effects of a combination of fish oils with a diet low in AA. RA subjects were placed on either a Western diet (WD) with meat or meat products more than twice a week or an “anti-inflammatory diet” (AID) low in AA. Subjects were given menhaden oil (30 mg/kg) or corn oil, in a crossover design with 3-month treatments and a 2-month washout period. With AID during placebo treatment, there was a 14% decrease in the number of tender and swollen joints. The addition of fish oil led to a further reduction in number of tender (28% vs. 11%) and swollen (34% vs. 22%) joints in AID compared to WD groups. The authors concluded that “a diet low in AA ameliorates clinical signs of inflammation in patients with RA and augments the beneficial effect of fish oil supplementation.”

Measurement of the fatty acid profile in RA may be helpful. Cleland et al.¹⁸² reported that a peripheral blood mononuclear cell (PBMC) EPA $\geq$ 1.5% of total fatty acids is associated with suppression of TNF- α and IL-1 β . This equates to a plasma phospholipid EPA $\geq$ 3.2%, an indicator of effective EPA fortification. The use of fish oil with pharmacologic management in RA has led to reduced NSAID use and dose reduction in potentially toxic medications. In RA patients not on medication, the PGI₂ level (assessed by measurement of urinary 2,3-dinor-6-keto-PGF_{1 α}) was approximately eight times

higher than in a medicated group using NSAIDs, steroids, and disease-modifying antirheumatic drugs (DMARDs), and the TX/PGL₂ ratio was lower.¹⁸³ While not proven, fish oil could offset this TXA₂/PGL₂ imbalance from COX-2 inhibitors and potentially reduce cardiovascular disease risk.

There is moderate support for GLA in RA for reduction of pain, tender joint count, and stiffness.¹⁸⁴ GLA (2.8 g/d of GLA as FFA) was also used alone in a study of 56 active RA patients over six months and was well tolerated and effective.¹⁸⁵ The dosages of fish oil and GLA are important. Anti-inflammatory effects have not been demonstrated at 1.0 g/d EPA+DHA. No significant change from baseline in tender joint count was found with 1.4 g EPA + 0.211 g DHA + 0.5 g GLA over four months in a double-blind, placebo-controlled trial.¹⁸⁶

Inflammatory bowel disease. EFA supplementation in the management of patients with inflammatory bowel disease (IBD) is indicated to offset the effects of fat malabsorption, poor intake, and increased catabolism leading to EFA insufficiency or deficiency. We have documented evidence of plasma fatty acid abnormalities in 47 patients with chronic intestinal disorders, mostly Crohn's disease, compared with 56 controls.¹⁸⁷ On the whole, these patients exhibited indices of EFA status between those of patients with severe whole-body EFA deficiency and those of healthy subjects. More than 25% of the patients had biochemical evidence of EFA deficiency by at least one criterion. EFA supplementation is indicated not only to correct fatty acid insufficiency but also to provide anti-inflammatory support.¹⁸⁸ Fish oil use for immunomodulation is based on the hypothesis that IBD is due to an abnormal immunological response to altered antigen exposure, either viral or bacterial, involving T and B cells, cytokines, and complement, resulting in chronic, self-perpetuating inflammation. Early in the pathogenesis of IBD, multi-focal gastrointestinal infarctions may occur, suggesting a role for platelets and TXA₂. Thus, the rationale for the use of fish oil includes its effects on reducing TXA₂ production, with resultant inhibition of IL-1 β and TNF- α production, as well as its effects on reducing LTB₄, and possibly its function as a free radical scavenger.¹⁸⁹

There have been at least three double-blind studies in Crohn's disease using 2.7–5.1 g/d fish oil for periods of 12–52 weeks. In one study where the lowest dose was given, there was no benefit. In two studies, there were significant decreases in relapses.¹⁹⁰ The best form of

fatty acids for maximal therapeutic effect is not clear. Evidence suggests that an enterically coated free fatty acid (FFA) form of ω 3s is preferable. Absorption studies of the triglyceride vs. ester vs. FFA forms indicated absorptions of 60%, 20%, and 95%, respectively. In addition, a study utilizing enterically-coated FFA capsules in patients with Crohn's disease, in remission, found that an enteric-coated fish-oil preparation containing 1.8 g EPA and 0.9 g DHA was effective in reducing the rate of relapse.¹⁹¹ Fifty-nine percent of subjects in the fish oil group were still in remission after one year, vs. 26% in the placebo group.¹⁹²

In seal oil, the ω 3 fatty acids, EPA, docosapentaenoic acid (DPA; 22:5 ω 3), and DHA, are preferentially in the sn-1 or sn-3 positions on triglycerides, whereas in fish oil, EPA or DHA are preferentially in the sn-2 position. Fatty acids in the sn-2 position are not easily hydrolyzed in the intestine and are absorbed mainly as monoglycerides. However, fatty acids in the sn-1 and sn-3 positions are absorbed directly into the mucosa. DPA is the most potent inhibitor of platelet TXA₂ formation and platelet aggregation.¹⁹³ Seal oil providing 5.4 g/d EPA+DPA+DHA was instilled into the duodenum over 10 days in 10 IBD patients, nine with associated joint pain. Joint pain index, disease activity, and serum cholesterol decreased.¹⁹⁴ In a subsequent study, seal oil was compared with soy oil (10 mL three times daily over 10 days) via a nasoduodenal feeding tube in 19 patients with IBD. Follow-up of this short-term duodenal administration of ω 3-rich seal oil over six months indicated significant, prolonged beneficial effects in IBD-related joint pain. The soy oil, on the other hand, led to a tendency to exacerbation.¹⁹⁵

In ulcerative colitis patients, four double-blind studies have been reported using 1.8–5.4 g/d EPA+DHA for 12–52 weeks. One at the lowest dose had no benefit, one resulted in significant decrease in corticosteroids, and two led to benefit (histology, disease activity, decreased steroids). Also, two open studies reported benefit. The dose of fish oil is important, as indicated by the double-blind, placebo-controlled trial of Middleton et al.,¹⁹⁶ who provided 1.6 g GLA + 270 mg EPA + 45 mg DHA or placebo to 63 patients over 12 months. No differences were noted in sigmoidoscopic grades and relapse rates were similar (placebo 38%, EFAs 55%).

Renal disease. IgA nephropathy is an immune complex-mediated glomerulonephritis. It is the most common primary glomerulonephritis worldwide and leads

to end-stage renal failure in 20–40% of patients. It is characterized by mesangial cell proliferation, matrix expansion, and IgA deposition in mesangial regions of the kidney. There is no definitive treatment for this condition. Omega-3 PUFAs, corticosteroids, and angiotensin-converting enzyme (ACE) inhibitors are under investigation. By mechanisms previously described above, fish oils exert anti-inflammatory effects in this condition. Other possible mechanisms for benefits in this condition include blood pressure lowering, reduction in serum lipids, and decreased vascular resistance. In addition, studies using an animal model of acute mesangial glomerulonephritis revealed that ω 3 PUFAs are readily incorporated into renal cells and result in decreased glomerular cell proliferation *in vitro* and *in vivo*. Also, DHA inhibits cultured rat mesangial cell proliferation, suggesting that this fatty acid regulates proliferation in the absence of cytokines, growth factors, or inflammatory mediators from other cell types.¹⁹⁷ In IgA nephropathy, studies of the efficacy of ω 3 PUFAs have led to varying results. However, the largest randomized clinical trial provided strong evidence that treatment for two years with 1.8 g of EPA and 1.2 g of DHA per day slowed the progression of renal disease in high-risk patients, with benefits persisting after 6.4 years of follow-up.¹⁹⁸

Animal studies and preliminary human studies have suggested a role for fish oil in the treatment of lupus nephritis. However, a double-blind, cross-over study in 26 patients with lupus nephritis followed for over two years indicated that fish oil dietary supplementation had no significant effect on proteinuria, glomerular filtration rate, disease activity index, or steroid consumption.¹⁹⁹ However, it did have a significant effect on lipid levels. There were methodologic difficulties in the study related to carryover effects and possible effects of the olive oil placebo.

In a double-blind clinical trial, 86 subjects randomly received either 6 g/d of fish oil or soy oil during the first three months after renal transplantation. Although lower lipid levels and a trend towards lower cytokine expression were found in the fish oil-treated group, treatment with fish oil did not influence acute rejection rate and had no beneficial effect on renal function or graft survival.²⁰⁰ In another study, the use of combined treatment with a low-dose statin along with fish oil (1 g/d) was more effective than the statin treatment alone for changing the lipid profile after renal transplantation.²⁰¹

Over 50% of all hemodialysis access grafts become thrombosed within a year after placement, and over 75% require a salvage procedure to maintain patency. The cost to maintain dialysis access for patients in the U.S. is over \$1 billion per year. Fish oil supplementation appears to significantly enhance graft survival. In a study of 24 subjects, given either 4 g of fish oil (1.76 g of EPA and 0.96 g of DHA) or a placebo (4 g of corn oil), 75.6% of the grafts in the fish oil group were patent at one year vs. only 14.9% for the control group ($P < .03$).²⁰²

Psoriasis. Elevated levels of AA and its proinflammatory metabolites such as LTB₄ are found in psoriatic skin lesions, suggesting a therapeutic role for fish oils in this condition. Six of seven open studies using 1.1–13.5 g EPA + 1.7–3.6 g DHA over 6–27 weeks reported improvements. However, results of five double-blind studies using 1.6–3.1 g EPA + 1.0–1.9 g DHA/d over 8–17 weeks were mixed. Two led to improvement and three to no benefit. In an attempt to overcome methodologic issues of oral supplementation, EPA + DHA in triglyceride form were administered IV and compared with ω 6 fatty acids given IV over 10–15 days in two studies. At ω 3 doses of 4.7–9.4 g/day (2.1–4.2 g EPA+DHA/d), there was a significantly larger decrease in clinical symptoms, although some regression of psoriatic lesions occurred with ω 6 fatty acids as well. In the larger (83 patients) of the two double-blind randomized trials, there was a higher response rate with ω 3s than ω 6s (37% vs. 23%).²⁰³

Bronchial asthma. Airway wall inflammation is present in mild asthma and is a prominent feature in fatal asthma attacks.²⁰⁴ LTs have been implicated in the pathogenesis of bronchial asthma, with cysteinyl LTs (CysLT) considered the most important class of such molecules. CysLTs are 100–1,000 times more potent bronchoconstrictors than histamine, and CysLT receptor antagonists such as montelukasts are used therapeutically in asthma management.²⁰⁵ LT production is increased with enhanced activity of key enzymes in CysLT synthesis, and markedly increased amounts of AA in eosinophils are recruited to areas of asthmatic inflammation. LTA₄ is the only LT synthesized and secreted by inflammatory cells. It is converted to LTC₄ in human mast cells, basophils, and eosinophils. LTC₄, in turn, is converted to LTD₄ and LTE₄ in the extracellular fluid. These latter three appear to be most important in asthma pathogenesis. Dysregulated production of CysLTs is often coupled with increased bronchial smooth muscle sensitivity to their bronchoconstrictor

activity. Calabrese et al.²⁰⁶ have found that the synthesis of CysLTs is increased in cells obtained by bronchial lavage from asthmatic patients. The expression of LTC₄ synthase is increased in eosinophils in these bronchial washings. Also, they report that these eosinophils from inflamed airways have increased AA content, some 4–10 times higher than that measured in peripheral blood cells. The elevated AA is related to high secretory phospholipase A₂ (sPLA₂), five times higher in patients with mild persistent asthma than in normal subjects. Secretory PLA₂ released in airways of asthmatics might function as a proinflammatory mediator. Thus, in asthmatics, large increases in the amount of AA occur in eosinophils recruited to an inflammatory area, and enhanced activity of key biosynthetic enzymes in CysLT synthesis leads to excessive CysLT production.²⁰⁷

In view of the effects of ω 3 fatty acids and of GLA (as precursor to DGLA) on LT formation, supplementation of these fatty acids has been studied in asthmatic patients. In a randomized, double-blind parallel group study in 23 atopic subjects with mild to moderate asthma, patients received placebo (olive oil) and low-dose and high-dose combinations of GLA and EPA for four weeks. Both combinations significantly suppressed *ex vivo* LTB₄ and TNF- α biosynthesis when compared with placebo.²⁰⁸ However, studies to date do not provide a definitive conclusion regarding the efficacy of ω 3 fatty acid supplementation as a treatment for asthma in children and adults.²⁰⁹ Omega-3 fatty acids have not consistently improved symptom severity, lung function, airway responsiveness, or medication use in asthmatic patients.²¹⁰ In a 12-month, double-blind, controlled trial of borage vs. corn oil in 54 subjects with stable asthma, increased generation of polymorphonuclear (PMN) 15-HETrE, decreased PMN AA, and decreased *ex vivo* LTB₄ generation by PMNs were seen.²¹¹ Again, the study did not reveal statistically significant suppression of asthma scores. A promising controlled study²¹² involved supplementation with ω 3 fatty acids in the first 18 months of life in infants at high risk of developing asthma. The treatment group had a 9.8% absolute reduction in parent-reported wheeze-ever ($P=0.02$) and a 7.8% lower prevalence of wheeze for more than 1 week ($P=0.04$). Wheeze-ever, doctor visits for wheeze, bronchodilator use, and nocturnal coughing were significantly reduced in children in higher plasma ω 3 fatty acid quintiles.²¹³ A five-year follow-up study is under way.

Coronary artery disease (CAD). It is now well accepted that coronary artery disease is an inflammatory condition (see discussion above by Libby). Myocardial infarction occurs most often as a result of rupture of a vulnerable plaque with subsequent acute thrombosis, despite lack of severe coronary artery narrowing. Vulnerable plaque is characterized by a large lipid core, rich in inflammatory cells, and a thin fibrous cap with compromise of its structural integrity by matrix-degrading enzymes, such as metalloproteinases.²¹⁴ Eicosanoids are involved in various aspects of the atherosclerotic process. Their critical importance is seen in their involvement in platelet function, and is underscored by the benefits of approaches to block their activity, as with aspirin. The pathophysiological role of TXA₂ via the COX pathway is well established in the thrombotic process of acute coronary syndromes. Platelet activation occurs in acute ischemic syndromes and in stable angina with greatly increased TX production.²¹⁵ TXA₂ from AA in platelets produces platelet aggregation and vasoconstriction, whereas TXA₃ from EPA is almost biologically inactive. TXA₂ is one of the most potent vasoconstricting and platelet-aggregating substances known.²¹⁶ Both prostacyclin I₂ from AA and prostacyclin I₃ from EPA via the same pathway in endothelial cells are anti-aggregatory and vasodilatory. The AA product in leukocytes, LTB₄, is proinflammatory, chemotactic, promotes cell adhesion, and can amplify the inflammatory response. The EPA product from leukocytes, LTB₅, is anti-inflammatory, non-adhesive, and non-chemotactic.

PGs are vasoactive lipid mediators formed in response to stimulation of vascular smooth muscle cells by a variety of chemical agonists. Different receptor subtypes mediate the contractile and relaxing effects of PGs and TXA₂ on coronary vascular smooth muscle.²¹⁷

Fish intake and CAD. Several studies have confirmed a relationship between fish intake and CAD mortality, including the Chicago Western Electric Study, which reported an inverse association between fish consumption and death from coronary heart disease, especially non-sudden death from myocardial infarction at year 30 in the follow-up of 1,822 men free of heart disease at the start of the study.²¹⁸ Many subsequent studies have found that the main cardiovascular benefit of fish intake was reduction in sudden cardiac deaths.

Fish intake does not have to be high to confer protection, according to several other studies. Ingestion of

as little as one to two fish dishes per week has been found to reduce the incidence of CAD. In the 20-year prospective Zutphen Study of middle-aged men in the Netherlands, the consumption of about two fish meals weekly was associated with a 50% reduction in CAD mortality compared with men who ate no fish at all.²¹⁹ Protective effects were not noted until the fifth year of the study. However, not all studies have confirmed an inverse relationship between fish intake and CAD mortality.²²⁰ A confounding factor in negative studies may have been smoking history. In the Honolulu Heart Program study of Japanese men, this was addressed. In the high-smoking group, the risk factor-adjusted relative risk for CAD mortality among those with intake of two or more servings of fish per week was half that of those with low fish consumption.²²¹ The Physicians Health Study of over 20,000 male physicians without evidence of prior cardiovascular disease found no association between dietary fish or ω 3 intake and risk of MI or death from cardiovascular disease over a four-year follow-up. However, it did find a relationship between fish intake and sudden cardiac death at the 11- and 17-year follow-ups. Their prospective data at year 11 suggested that consumption of fish at least once per week may reduce the risk of sudden cardiac death in men by about 50%.²²² There was also a significantly reduced risk of total mortality with fish consumption. At the 17-year follow-up, baseline blood levels of long-chain ω 3 fatty acids were inversely related to the risk of sudden death.²²³ Compared with men whose blood levels of long-chain ω 3 fatty acids were in the lowest quartile, the adjusted relative risk of sudden death was 0.28 among men with levels in the third quartile and 0.19 in the fourth quartile.

Not all studies confirm beneficial effects of fish oil in cardiovascular disease. The Diet and Reinfarction Trial (DART) included 2,033 men randomly assigned to receive or not receive advice to increase their intake of fatty fish. Those instructed to increase fish intake were told to consume 300 grams of fish (or equivalent fish oil capsules) per week (~ 3 fish meals/week). After two years, the group encouraged to eat fish had a 29% lower death rate than the control group.²²⁴ However, there was an increased risk in all-cause mortality and stroke death over the next three years in those given fish advice.²²⁵ In another study, 3,114 men under 70 with angina were randomly allocated to four groups, including one advised to eat two portions of oily fish each week or to

take three fish oil capsules daily, and another given no specific dietary advice. After 3–9 years, men advised to eat oily fish, and particularly those supplied with fish oil capsules, had a higher risk of cardiac death.²²⁶

However, the large GISSI-Prevenzione clinical trial of 11,323 men and women with myocardial infarction provides convincing evidence of the benefits of fish oil supplementation. Dietary supplementation with ω 3 PUFA (1 g/d), but not vitamin E, significantly lowered the risk of cardiovascular death by 17–30%, and the overall risk of death by 14–20%.²²⁷ All subjects received advice to increase their consumption of fish, fruit, raw and cooked vegetables, and olive oil. Compared with people in the worst dietary score quartile, the odds ratio for those in the best score quartile was 0.51.²²⁸ Total mortality was significantly lowered after three months of treatment (relative risk 0.59) and the reduction in risk of sudden death was statistically significant by four months (relative risk 0.47). The early effect of low-dose ω 3s on total mortality and sudden death supports the hypothesis of an antiarrhythmic effect.²²⁹

ALA and CAD. The two populations with the world's lowest CAD mortality are the Japanese and the Cretans. Both have high ALA intake, the Japanese from canola and soybean oils, and the Cretans from walnuts and possibly purslane.²³⁰ ALA supplementation was studied in the Lyon Heart Study, which compared the effects of a Mediterranean ALA-rich diet with a diet similar to the prudent American Heart Association guidelines. A total of 605 patients who survived a first MI were randomly assigned to an experimental or control group. In the experimental (Mediterranean diet) group, butter and cream were replaced by a canola oil-based margarine containing 5% ALA. They had significantly higher plasma ALA and EPA and lower LA and AA levels than controls. After 27 months of follow-up, there were 16 cardiac deaths in the controls and only three in the experimental group. There were 17 non-fatal MIs in controls and five in the treated group. Overall mortality was 20 in controls and eight in the experimental group. The study was terminated because the data were so compelling that it was deemed unethical to continue the investigation.²³¹ In an editorial, Alexander Leaf stated that "relatively simple dietary changes achieved greater reductions in risk of all-cause and coronary heart disease mortality in a secondary prevention trial than any of the cholesterol-lowering studies to date."²³²

Singh et al.²³³ studied 1,000 patients with CAD in a randomized, single-blind trial, half assigned to an Indo-Mediterranean diet rich in whole grains, fruits, vegetables, walnuts, and almonds and the remainder to a step I National Cholesterol Education Program prudent diet. The mean intake of ALA was twice as high in the intervention group (1.8 g vs. 0.8 g per day) related to intake of mustard or soybean oil. There were significantly fewer total cardiac end points in the intervention group than the controls (39 vs. 76 events, $p < 0.001$). Sudden cardiac deaths were also reduced (6 vs. 16, $p = 0.015$), as were non-fatal myocardial infarctions (21 vs. 43, $p < 0.001$).

Thus, the role of ω 3s in the secondary prevention of CAD is clearly supported by randomized clinical trials. However, their role in primary prevention will need to await future clinical trials.²³⁴

Mechanisms of Omega-3 Fatty Acid Effects on Cardiac Risk Factors

Several mechanisms may be involved in the apparent favorable effect of ω 3 fatty acids on risk and potential mortality from MI, in addition to the reduction in inflammation elucidated above. These mechanisms include:

- reduction in platelet clumping,
- reduction in triglyceride levels,
- reduction in arrhythmias, and
- reduction in blood pressure.

In addition, ω 3s may:

- increase LDL particle size, rendering them less likely to oxidize;
- retard growth of atherosclerotic plaque by inhibiting both cellular growth factors and the migration of monocytes;
- exert a direct cytoprotective effect against ischemia, free radical-induced damage, and lipid peroxidation;
- enhance insulin action;
- increase systemic arterial compliance; and
- help to reduce pulse pressure and total vascular resistance.²³⁵

Omega-3 fatty acids are incorporated into platelet membranes, leading to decreased platelet aggregation, probably due to inhibition of the synthesis of TXA_2 . Also, there may be a minor decrease in platelet number and a slight prolongation of the bleeding time, an effect similar to and synergistic with that of aspirin. An intake

of about 15 ml/d of marine oils causes anti-thrombotic changes in platelet membranes. Despite their effects on platelet function, standard doses of fish oil (3–4 g or 1.2 g of EPA + DHA) are unlikely to increase risk of hemorrhagic stroke.²³⁶ Bleeding times have remained in the upper limit of normal with fish oil intakes as high as 9 g/d (EPA+DHA 6 g/d). Fish oil retards the growth of the atherosclerotic plaque by inhibiting both cellular growth factors and the migration of monocytes.²³⁷

Triglycerides are consistently lowered by 30% or more with ω 3 fatty acid supplementation in subjects with elevated or normal triglyceride levels. Triglyceride synthesis may be inhibited, although enhanced breakdown may play a role.²³⁸ Reductions in triglycerides have been achieved with a fish oil dose equivalent to 200 g of fatty fish or in response to ingestion of about three fish meals per week (300 g of fatty fish per week). Hypertriglyceridemia may contribute to atherosclerosis by increasing the expression of cell adhesion molecules (CAMs).²³⁹ ICAMs mediate attachment of leukocytes and ICAM-1 is a predictor of risk for MI. Thus, fish oil may reduce high triglycerides and CAMs. HDL cholesterol does not change much in response to ω 3 fatty acid supplementation, but there is suggestive evidence that the cardioprotective HDL_2 subfraction does.

Fish oil has been shown to exert a mild blood pressure-lowering effect in both normal and mildly hypertensive individuals, possibly related to promotion of beneficial nitric oxide synthesis in the endothelium.²⁴⁰ As low a dose as 3 g of EPA and DHA was shown to be associated with a drop of 5 mm Hg systolic and 3 mm diastolic.²⁴¹ A 1% increase in blood ALA was associated with a 5 mm drop in blood pressure.²⁴² A meta-analysis of 1,356 subjects concluded that fish oils are associated with a small but significant lowering in blood pressure.²⁴³ This appears to occur in patients with preexisting heart disease, lipid abnormalities or hypertension, but not in healthy subjects with normal blood pressure.

There is considerable evidence that ω 3 fatty acids prevent cardiac arrhythmias, including inhibition of ventricular fibrillation and consequent cardiac arrest. Documentation comes from experiments in cultured myocytes, experiments in animals, epidemiologic correlations, and clinical trials.^{244,245} Within minutes of the addition of ω 3 fatty acids in tissue culture systems, susceptibility to arrhythmias is reduced. Also, heart rate variability, an independent risk factor of arrhythmic events and mortality, is increased by ω 3 fatty acids. A

significant increase in heart rate variability occurred when post-MI patients were given 5.2 g of ω 3 fatty acids daily for 12 weeks.²⁴⁶

Effects of fish oils on restenosis after angioplasty or coronary artery bypass graft have been variable. An effect, if present, is considered weak.²⁴⁷

Optimal Fat Intake

How much fat should be consumed? Ornish has recommended 10% of calories as fat in a vegetarian diet.²⁴⁸ Yet, the people of Crete eat a higher fat diet with 40% of calories as fat and have one-twentieth the mortality from CAD compared with Americans.²⁴⁹ Furthermore, the Greenland Inuit rarely develop CAD, despite a diet high in fat and cholesterol. It must be concluded that it is the type of fat that is most important, not the amount.

Summary

An understanding of the common threads in the pathogenesis of CAD, RA, IBD, psoriasis, and asthma allows the practitioner to utilize fatty acid supplementation in these and other disparate inflammatory conditions. Such conditions may be approached with a consistent strategy, manipulating diet, fatty acids, and other supplements to safely lower inflammatory mediators, while attention is given to treating underlying factors in disease etiology.

Digestion and Absorption

Thomas Sult, MD

Introduction

Functional medicine is a holographic approach to health care: the whole (the macrocosm) is contained within each of the parts (the microcosm). When any part is not functioning at an optimal level, the system as a whole is degraded. This is why we always address underlying functionality (the micro level)—there, we can see how system failure in one area affects the performance of other areas that may seem, at a macro level, to be unrelated. Using this approach, we often cross multiple conventional boundaries when discussing treatment. Here, we will explore digestion and absorption, what impairs the functionality of these vital processes, and what can be done to optimize them as part of an integrated approach to improving general physiologic function.

In this essay, we will briefly review some of the most important influences on digestion and absorption. Further on in the chapter, an in-depth discussion of microflora, mucosal integrity, and the gut-activated lymphoid tissue (GALT) will be provided. The chapter will close with a detailed presentation of the 4R program for gut restoration and repair. There will necessarily be some overlap as these topics are introduced and analyzed by different authors, but different perspectives help all of us to arrive at a comprehensive understanding of this complex system.

“As a group, functional gastrointestinal disorders are the most common gastrointestinal disorders seen by both generalists and specialists.”¹ They account for a very significant number of healthcare visits. Many of the so called “idiopathic GI syndromes” such as IBS have been found, in many cases, to have treatable causes.² Many of these idiopathic GI syndromes have been found to be postinfectious or autoimmune.³

The GI system is the primary gateway by which the external environment interacts with the body. It serves as both portal and obstruction to the entry of substances into the human body, working continuously to distinguish beneficial from harmful influences, allowing entry to the former and denying entry to the latter. An undamaged esophagus is a potent barrier, but the selectively permeable membrane that lines the GI tract from stomach to anus is critical to the homeodynamic function of the body. Even small aberrations in its function can have problematic results.

Function and Dysfunction in Digestion and Absorption

Digestion and absorption are under tight regulatory control. Both the neuronal and hormonal systems are involved with this regulation. Most of the moment-to-moment control is provided by the neuronal system, with feedback and amplification from the hormonal

system.⁴ Problems of digestion and absorption may occur mechanically, in functions such as mastication, motility, or permeability, and often originate from genetic polymorphisms, post-translational errors, or enzyme kinetic issues. Most often, GI complaints are caused by multiple interdependent dysfunctions.⁵

Loss of digestion and absorption efficiency and integrity may lead to cascading multisystem failure. Maldigestion can lead to symptoms of gas, bloating, diarrhea, pain, and/or constipation—that is, general irritability of the system. Gut irritability, left untreated, may lead to leaky gut and the development of food allergies, bacterial or yeast overgrowth, and the production of toxins. Toxins may accelerate the irritation and leakiness, resulting in toxic molecules entering the portal and then systemic circulation. This creates stress on systemic defenses, leading to immune, hormonal, or inflammatory imbalance. If systemic stress is left unchecked, and eventually outstrips the body's general adaptation response, adrenal insufficiency may occur.

Complex inflammatory interactions have been implicated in dysmotility disorders and autoimmune phenomena of the gut.⁶ Errors of enzymatic control or suboptimal genetic predisposition may lead to additional problems.⁷ The distribution of enzymes and transporters within the gut is clearly purposeful.^{8,9} Environmental changes¹⁰ as well as food availability changes have a great influence on enzyme and transporter expression and distribution.¹¹ Additionally, this distribution changes with age, again in a seemingly purposeful manner.¹²

Antigen load at the level of the lamina propria within the gut is another area of great concern.¹³ With increasing leakiness of the GI wall, more antigen/immune interactions occur.¹⁴ This results in increasing recruitment and production of inflammatory mediators. These mediators place the systemic immune system at a higher level of “irritability,” resulting in a lowered threshold for additional immune interactions.¹⁵

Symptoms and Conditions

Symptoms that may cause the clinician to suspect digestion and absorption as the focal problem include abdominal pain, gas, bloating, constipation, or diarrhea. GI disorders that should trigger the same suspicion include irritable bowel syndrome (IBS), infectious enterocolitis, celiac disease, Crohn's disease, and other irritable

bowel diseases. Systemic disorders that should also raise red flags concerning digestion and absorption include allergy, arthralgias, acne, autism, anxiety, depression, fatigue, myalgias, palpitations, neurologic disorders, immune deficiency disorders, and certain cancers.

Complex Interactions

If there are a finite number of basic imbalances that affect the GI system, assessing for each and treating appropriately should have profound impact on digestion and absorption. Indeed, clinically, this is the case, but the permutations are complex. Some imbalances can be both cause and effect. Inflammation, for example, may be caused by and may also contribute to leaky gut, comorbid conditions (such as infection or systemic disease), food allergy, aberrations of the enteric nervous system (ENS), autoimmunity, or molecular mimicry. In turn, any of these conditions could be an expression of others from the same list. To help explain this complex interacting model, I use the analogy of the bike wheel. A typical wheel has 36 spokes. With even one spoke broken, the whole wheel will be thrown out of balance, making it likely that other spokes will break under the additional stress. In a short time, the wheel will be so out of true that it will no longer fit between the forks. At that point, the entire bike is useless. Similarly, our patients experience cascading multisystem failure.

Enzymatic Function

Digestion is the mechanism for extracellular (and essentially extra-organism, as the gut lumen is technically external to the body) enzymatic breakdown of food. To accomplish this requires sufficient basic resources. Enzymes, HCl, soaps, bile salts, and transport proteins are needed. Where do the enzymes come from? Salivary enzymes are produced in the mouth; the stomach also produces enzymes; and a significant source of digestive enzymes comes from the pancreas. However, the majority of enzymes actually originate from the small intestine microvilli. When assessing digestive function, these key components must be considered.

Gastric acid secretion. Common symptoms of low gastric acidity include bloating, belching, burning, and flatulence, within moments of ingesting a meal. Nausea after taking supplements, post-adolescent acne, iron deficiency, chronic intestinal infection, and undigested food in the stool are also possible symptoms. Gastric

acidity is known to decrease with age; approximately 10% of people over 60 will have low levels.¹⁶

HCl has many functions within the gut, but two are of prime importance:

- HCl sterilizes the food bolus. The pH of the stomach can reach as low as 1. This level of acidity is capable of killing many hitchhiking microbes.
- The acid environment of the stomach favors the unfolding or denaturation of proteins. This opens sites of enzymatic action on the proteins and prepares them for degradation by gastric and pancreatic enzymes.

It is common in clinical practice to see patients on acid-suppression therapy. They frequently say they have not improved, despite taking their medication for long periods of time. The underlying mechanism of acid indigestion in the elderly is the loss of mucus-secreting protection out of proportion to the loss of acid-secreting parietal cell function. This results in a back-diffusion of activated HCL without sufficient mucous-barrier function to protect the lining cells of the stomach. In the absence of overt ulcer disease, it is reasonable to consider HCl repletion therapy with meals, but to continue acid suppressors until functional improvement of the mucous-secreting cells can be achieved. In many cases, symptoms will resolve and patients will feel better in a matter of days.

Gastric enzymes. The primary function of gastric pepsins is to degrade proteins into peptide fragments, preparing them for downstream enzymatic breakdown. Low gastric pepsin activity will delay protein breakdown and result in symptoms of protein maldigestion.

Small intestine phase. Pancreatic enzymes are released into the small intestine lumen by a complex regulatory mechanism. This mechanism involves elements of the ENS (enteric nervous system) and hormonal systems. Impaired regulation of these systems may result in poorly coordinated or insufficient release of enzymes. The result of either dysfunction may be complex protein, fat, and carbohydrate maldigestion, with symptoms of gas, bloating, abdominal pain, and diarrhea.

Under normal circumstances, the pancreatic enzymes break proteins into mono-, di-, and tri-peptides and oligopeptides. All but the oligopeptides are absorbed by specialized receptor/transporter sites within the gut. The oligopeptides must be further broken down at the level of the brush border of the small intestine. An insuffi-

ciency of brush-associated proteolytic enzymes will again result in protein maldigestion. This brush border enzyme concentration may be reduced due to polymorphic genetic inheritance, or by inflammatory or infectious causes. If there is a regulatory or polymorphic problem with the receptor/transporter sites within the gut, malabsorption will result. Therapeutic approaches to restoring enzymatic function include ensuring adequate provision of cofactors to improve “mass action,” and reducing inflammation and treating infections to minimize the presence of perturbing factors.

While some digestion of fats does occur in the stomach, most is accomplished in the small intestine. Bile salts “saponify” the fats (i.e., make them into a “soap”) and break them into smaller packets for enzymatic degradation; therefore, adequate bile acids are essential for fat digestion. Liver congestion or inflammation from toxic load or cholestasis may result in poor bile delivery. The common practice of cholecystectomy may also hinder fat digestion by leaving the patient with a constant trickle of bile rather than a bolus at appropriate times. This creates a relative bile insufficiency. Bile salt repletion may be very helpful in such patients. As with proteins, if the pancreas is unable to secrete sufficient enzymes, digestion will suffer. Fat maldigestion is an unpleasant syndrome characterized by gas, bloating, foul-smelling and floating stool. Digestive enzymes taken as supplements may be of benefit to patients with these problems. Enzymes are complex proteins and therefore are susceptible to the acidic and enzymatic breakdown that happens in the stomach. For that reason, one should consider enteric-coated or acid-resistant enzyme supplements.

Clinical Practice

Based on the fundamental mechanisms of pathogenesis outlined above and in prior sections of this book (see, for example, Chapters 17 and 24), the goals of treatment should be to place the patient on a therapeutic oligoantigenic elimination diet, reduce inflammation, improve gut permeability, improve digestive constituents, optimize absorption, modulate immune interactions, and improve GI microflora (discussed separately later in this chapter).

Foods as Triggers—Allergy and Sensitivity

The complex mechanisms of sorting out nutrients from non-nutrients at the level of the gut mucosa are not clearly understood. It is clear that many foods can become allergens. IgE-mediated food allergy is seen in about 5–7.5% of children and 1–2% of adults.¹⁷ Food intolerances appear to be considerably more common.¹⁸ Food intolerance has been linked to a number of conditions. While not an exhaustive list, we will discuss below a few examples of common food/illness interactions.

Asthma is a common medical problem responsible for many deaths and considerable disability, with a disproportionate impact on the inner-city poor.¹⁹ It has increased in prevalence and severity in recent years, with increasing levels of morbidity and mortality, thus driving the search for new treatment approaches.²⁰ Although most of the increase has been attributed to airborne, rather than food, allergens,²¹ and to our increasingly artificial habitats,²² the role of dietary factors has been investigated,²³ and several studies link foods to asthma. The mechanism underlying diet and asthma is not clear, but oligoantigenic diets help improve the condition.²⁴ In addition to the elimination of problem foods, the inclusion of certain beneficial foods has had favorable effects on the severity of asthma. Including more vegetables in the diet seems to reduce asthma,²⁵ and the incorporation of fish oils also reduces asthmatic symptoms.^{26,27} The mechanism of fish oils appears to involve the inhibition of leukotriene biosynthesis.²⁸

Atopic dermatitis is another common problem with abundant evidence that, at least in some individuals, the culprit is food intolerance. In one multicentered trial of 1,085 children with atopic dermatitis, an elimination diet was as effective as oral sodium cromoglycate in controlling symptoms.²⁹ A review of the literature on treatment of eczema/dermatitis syndrome (AEDS) with dietary approaches suggests that, for patients with IgE serum antibodies or multiple food sensitizations, food elimination is efficacious.³⁰ In fact, it is common for parents to use food elimination techniques on their children with dermatitis even before seeing a pediatric dermatologist. In one study, as many as 75% of children seen at a pediatric dermatology clinic had tried an elimination diet, and 39% of those reported a favorable response.³¹ Not all food intolerances are immediate. Prolonged observation may be needed to reveal food sensitivity. When workups that include common tests

such as skin prick or blood testing are not diagnostic, elimination-provocation food challenges with prolonged observation after re-introduction may be helpful.³² Once again, it is not just the elimination of problem foods but also the inclusion of beneficial foods that seems important. In a dog model of dermatitis, fish oils were able to reduce the need for steroids to suppress symptoms,³³ although orally-administered essential fatty acids alone have not always been shown effective in the treatment of dermatitis.³⁴

Childhood migraine,^{35,36} migraine with epilepsy,³⁷ and migraine with hyperkinetic behavior³⁸ have all been studied and shown to respond to an oligoantigenic diet. In all of these studies, a significant proportion of the children improved. In one study, as an incidental finding, several of the children had enuresis, which also improved for about half of them.

Gluten. Many studies have linked foods and food components to neurologic conditions, with gluten as one of the most frequently implicated substances. Gluten ataxia accounts for as much as 40% of sporadic ataxia and responds to gluten elimination even in the absence of gluten enteropathy.³⁹ In another study, the investigators suggest that “Antigliadin antibody testing is essential at first presentation of patients with sporadic ataxia.”⁴⁰

Gluten is clearly a common problem in human illness.⁴¹ In addition to ataxia, it has been implicated in neuropathy.⁴² MRI changes within the brain have been seen in gluten sensitivity, including white matter lesion similar to MS.⁴³ Skin conditions such as dermatitis herpetiformis⁴⁴ and lupus⁴⁵ have been reported. All have responded to the elimination of gluten.

Dairy. Cow’s milk proteins can cause allergic reactions in some people. In newborns, a syndrome similar to pyloric stenosis has been described.⁴⁶ In another study, cow’s milk proteins were able to induce a significant immune response with the production of several inflammatory cytokines.⁴⁷ Of interest is that probiotic bacterial species are able to mute at least some of these responses.⁴⁸

Elimination Diet

Clinically, the therapeutic importance of an adequate trial of an elimination diet cannot be overstated. With this one therapeutic modality, the practitioner can reduce food antigenicity and inflammatory reactions, improve gut permeability, rebalance Th1 and Th2

cytokines, rebuild the brush border, and improve digestion and absorption. This diet is designed to remove commonly offending foods, such as gluten, dairy, and other substances. Because reactions can be immediate or delayed, a careful observation period is essential. (More detailed discussions of the elimination diet can be found in Chapters 26 and 35 and the Appendix.) Implementation is simple but not necessarily easy for patients and their families. Patients are asked to eliminate a list of specific foods from their diets for a period of at least four weeks. This period of time is needed because some of the reactions are not due to simple allergy. Some improvements stem from the reduction of the antigenic load at the level of the gut, and the resultant T-helper cell Th1 vs. Th2 immune shifting. While the simple sensitivities may take hours to days to improve, the Th subtype rebalancing may take weeks to clear antigens from the gut and show improved symptoms on a clinical scale.

No one likes to change dietary habits, but it is an essential part of treating the chronically ill patient. It is imperative to stress the importance of complete adherence to the plan. When patients are prescribed an elimination diet, they will typically start “negotiating” the terms. They will want to have this food or that, or will want to eat “just a little” of another. I tell them a story about a friend of mine who is allergic to cats. He was having dinner in a home where there were cats. The cats had been removed the day before, and the house had been cleaned and dusted twice. Despite all of this effort, this person had watery eyes in five minutes, wheezes in 10, and a full-blown asthma attack in 20 minutes. He was forced to leave the dinner party. Food allergies and sensitivities can, of course, be more subtle and more distant from the trigger—thus decreasing that very obvious link between cause and effect that my friend experienced. But, as clinicians, we must remember, and we must teach our patients, that the allergy cascade is often an amplification process. The degree of allergic response is not always a result of total antigen load; exposure alone can trigger it. In the highly sensitized individual, very small quantities of an allergen will produce, in some cases, an anaphylactic reaction.

While we will not be able to remove every possible antigen from the diet, we should strive to reduce the total antigenic load as much as possible. Strict adherence to the elimination diet will help in this regard. After the exclusion period, foods should be reintro-

duced slowly and thoughtfully. The tendency of the patient is to jump back into a regular diet. The most important information-gathering part of the elimination diet is the reintroduction period. By introducing one new food every three or more days, patients can catalog any new or recurrent symptoms, whether they manifest immediately or over a period of several days. This systematic process allows the patient and the practitioner to build a list of problem foods. These should be avoided during the GI rebuilding period and, in some cases, permanently deleted from the diet.

Inflammation Reduction

Inflammation at the level of the gut mucosa plays a pivotal role in the development of GI diseases and other systemic diseases.^{49,50,51} Therefore, it is prudent to optimize inflammatory balance within the gut. The gut inflammation regulatory system is complex but approachable. As has been described by Plotkin,⁵² complex relationships often exist in nature; clinically, we can exploit them even without full understanding of their complex interdependence. Inflammation is regulated by multiple processes within the body. No single anti-inflammatory agent will suppress or inhibit the entire inflammatory spectrum. To that end, choosing complex food sources of anti-inflammatory agents often suits the functional practitioner best.

Many foods (and active constituents of foods) have been shown to have anti-inflammatory activity and, interestingly, many have a bi-functional role in the inflammatory cascade. That is, they are anti-inflammatory in one instance and proinflammatory in another. Such substances are called adaptogens. They may be advantageous to clinicians who are often working without full and accurate information at the level of the micro-milieu. Digestive enzymes can function in this manner. Several investigators have demonstrated anti-inflammatory effects of enzymes found in bromelain,^{53,54,55} but pancreatic enzymes in the face of intestinal ischemia will cause an inflammatory response⁵⁶ (probably to protect the organism from invasion). The biliary system tends to blunt this response with cholecystokinin, especially in the face of acute pancreatitis.⁵⁷

Other anti-inflammatory foods, herbs, and spices include:

- Essential fatty acids (thoroughly reviewed in Chapter 27) clearly play an important role in helping to reduce many forms of inflammation.

- Curcumin shows anti-inflammatory activities.⁵⁸
- Several Chinese herbal extracts have anti-inflammatory activity.^{59,60,61}
- Cat's claw appears to have anti-inflammatory activity.⁶²
- Many other Western herbal extracts have also shown anti-inflammatory activity.⁶³
- Green tea has also been studied extensively. Its anti-inflammatory activity appears robust.^{64,65,66}
- Cruciferous vegetables show not only anti-inflammatory effect but also anti-mutagenic effects.^{67,68}

Including foods and food substances rich in anti-inflammatory nutrients along with an elimination diet may help to create a synergistic response in controlling inflammation.

Gut Permeability

Leaky gut (LG), or intestinal hyperpermeability, is a common clinical syndrome, implicated in a wide array of conditions. Several lines of research suggest a significant role for LG in health and disease. One aspect is cytokine balance. Th1 vs. Th2 balance appears to be influenced by antigen presentation at the gut mucosal level.⁶⁹ While inflammation appears to play a role in the development of LG, NSAIDs have been shown to enhance rather than retard its development. Blockade of the COX-2 receptor has been associated with an upregulation of COX-2 receptor numbers and may be responsible for this. Complex nutraceutical approaches to inflammation reduction, as briefly mentioned above, may have the effect of reducing inflammation without upregulating COX receptors.

Arabinogalactans from a variety of sources, including kiwi and larch, have positive effects on cell growth and gut function. Kiwi has been shown to be a potent proliferant of epithelial cells and for that reason seems helpful in LG.⁷⁰ Larch has several important benefits to LG including immunologic, metabolic, and growth factors.⁷¹ Soluble and insoluble fibers also exert a positive effect on LG; insoluble fiber helps with bulk formation and waste elimination, and soluble fiber improves short-chain fatty acid production, a key nutrient for enterocytes and promotion of probiotic growth. Glutamine and bioactive peptides have also been shown to help ameliorate LG. See Chapter 31 for an extensive discussion on leaky gut.

Heavy Metals

Heavy metal accumulation may also play a part in poor digestion, due to its association with degraded enzyme function, dysbiosis, and bacterial or fungal overgrowth. The primary site of heavy metal poisoning is at the level of the metalloenzyme, the site of catalytic function within the enzyme. In simplest terms, the heavy metal displaces the mineral at the metallo-enzyme site, resulting in degraded or absent enzymatic function. These heavy metals also have antibiotic activity. (The historic use of mercury salts is an example of this.) The antibiotic function tends to alter the gut microflora and thus can lead to dysbiosis.
